INTRODUCTION

World Journal of Gastroenterology (WJG) is an international academic journal in digestology published in China. The WJG was established in 1995 under the name of *China National Journal of New Gastroenterology*, and adapted its present title in 1998. The WJG (ISSN 1007-9327), now published monthly by the WJG Press, is a 210×297 mm-sized journal with 256 pages in each issue. The Journal is distributed by the Beijing Newspaper and Periodical Subscription and Distribution Bureau (Postal Issuance Code 82-261). In response to continuing growth in both basic and clinical studies on digestive diseases and the increasing demands for the international exchange in science and technology, the WJG journal will be published twice monthly from January 2004, with 160 pages in each issue. The publication dates are on the 1st and 15th of each month.

MISSION

The WJG seeks to publish high-quality, original and innovative papers and short communications on basic and clinical studies in gastroenterology and hepatology. The editors accept manuscripts that report important findings in esophageal cancer, gastric cancer, liver cancer, intestinal cancer, viral hepatitis, *Helicobacter pylori* infection, as well as Chinese medicine and integrated Chinese and Western medicine in the treatment of digestive diseases. The Journal gives a higher priority to review articles that are based mainly on the own work of the authors. Thus, the WJG establishes itself as a window for the international academic exchange, and provides a bridge to the world for local medical researchers and professionals.

EDITORIAL BOARDS

The WJG Editorial Board consists of 179 members, representing a team of worldwide experts in gastroenterology and hepatology. They are from 53 countries including: Albania (1), Algeria (1), Argentina (2), Austria (1), Belarus (1), Belgium (1), Brazil (1), Bulgaria (1), Canada (1), China (41), Costa Rica (1), Croatia (1), Denmark (1), Egypt (1), Finland (1), France (2), Germany (7), Greece (1), Hungary (2), Iceland (1), India (2), Iran (1), Ireland (2), Israel (2), Italy (2), Japan (4), Latvia (1), Lithuania (1), Macedonia (1), Malaysia (2), Monaco (1), Netherlands (3), New Zealand (1), Pakistan (1), Philippines (1), Poland (2), Portugal (1), Romania (1), Russia (3), Singapore (1), Slovakia (1), Slovenia (2), South Africa (1), South Korea (2), Spain (1), Sri Lanka (1), Sweden (2), Switzerland (2), Thailand (1), Turkey (1), United Kingdom (6), United States (56), and Yugoslavia (1).

The WJG has a group of young and middle-aged experts who have made outstanding achievements in both medical research and clinical practice. The duties of WJG editorial members are to evaluate the originality, innovation, scientific standards and readability of the papers, provide constructive comments, suggestions and advice for further revision and improve English writing for papers written by non-English speaking authors. Acceptance of a submitted paper is based on the overall assessment of the title, introduction, materials and methods, findings, and discussion sections, and whether the paper reflects a high standard of clinical or basic study on digestive diseases. There has been a considerable variation in the quality of papers submitted to the journal over the past years. Major problems include the scientific standards and readability. To overcome these problems and improve the quality of the journal, the WJG has established its evaluation criteria.

EVALUATION

According to the evaluation of editorial members, submitted papers are classified as "high priority", "ready for publication", "publication after revision", "re-evaluation after revision" and "rejection". To ensure the academic standards of published papers, WJG defines the following evaluation criteria:
Title should accurately reflect the scientific nature of the study, and should be concise and innovative.
Abstract should clearly present the research background and objectives, the materials and methods, the findings (including important data) and the conclusion. The innovative and focal points of study should be consistent with the objectives, the materials and methods, the findings (including important data), and the conclusion.
Introduction should include research objectives and other study related matters.
Materials and methods should include material characteristics, e.g., randomization of large samples, safety and efficiency, double-blind and double-simulation, comparisons between multi-center parallel control groups in contrast to clinical experiments, special cases, and cell or tissue samples. Test methods and techniques should be standard, innovative, or systematic. Improved or innovative methods should be repeatable and verifiable by others. The design of comparative studies should be rational and reliable, and statistical methods should be appropriate.
Results should have a well-defined scientific conclusion based on the experimental evidence. Attention should be paid to the

sample size and statistical analysis when evaluating a clinical study.

Discussion should include logistic and systematic theoretical analyses and valuable scientific conclusions.

Bibliography Studies quoted should be proper and sufficient, especially for the latest literature.

General evaluation The originality, scientific standard, innovation and readability of the paper should reflect the advances in clinical and basic studies in gastroenterology and hepatology.

EDITING

Excellent papers as assessed by the editorial board may be published without revision. The authors will be advised to revise their papers according to the comments/suggestions made by the editorial members and in consistent with the journal format. The revised papers will be subjected to the first and second language processing. Format-revised papers will then be put into layout. Thereafter, laid out draft will be sent to the editor-in-charge for the proofreading and finally for printing once there are no grammatical and spelling mistakes. In order to ensure the editing quality of published papers, WJG defines the following editorial criteria.

Title should be concise and unique. The following words should be avoided: evaluation, study, analysis, observation, investigation, exploration, the article "the" and abbreviations that are not commonly used. For further information, please refer to "*Writing English Title for Scientific Papers*" http://www.wjgnet.com/1009-3079/new/26.asp.

Abstract should be in a structural format. Objectives should be directly pointed to the topic, e.g. "To investigate the..". A summary of the background or current development in the topic may be provided. Methods (including materials) and findings (including important data) should be stated in the past tense, and conclusion should be stated in the present tense. Personal address and voice should be natural, avoiding using "the dangling participles". First sentence of the abstract should not be a repetition of the title, it should be more specific. For further information, please see "*Writing English Abstract for Scientific Papers*" http://www.wjgnet.com/1009-3079/new/25.asp.

Text (1) *Short sentences*: Short sentences are preferred. As much as possible, multiple subordinate clauses should be avoided. The spelling and tenses should be correct, and tenses should be consistent. The past tense should be generally used in the Methods and Results sections. In the Discussion, the past tense should be used when a specific study is cited and present tense should be used when a conclusive statement is made based on previous studies. Tenses used in the main and subordinate clauses should be consistent with the tenses and implications of the paragraph. For Chinese authors, the Chinese version of the paper should be referred to in order to accurately express the original meanings. When using the participial phrases to express the adverb and attribute, attention should be paid to the proper voice usage for proper correspondence. Word comparisons should be consistent, and the same term should be used to refer to the same thing. Basic data and their percentages should be checked during editing. Editing checks should include accurate use of symbols and Latin terms (singular and plural forms). (2) *Numerals*: Numerals appearing at the beginning of the sentence should be stated in words, e.g. Sixteen cases...or A total number of 16 cases. No Arabic numerals, e.g. 16 cases, 100 patients, should be used to start a sentence. (3) *Abbreviations*: When an *abbreviation is used* for the first time in the text, the entire term should be spelt out, followed by the a*bbreviation* in parenthesis. (4) *Italics*: The following should be italicized: Latin terms of bacteria, virus, plants and animals, statistical symbols, genetic symbols, END for endonucleases (first three characters), measurement symbols, Latin terms, e.g. *in vivo, in situ, et al*, and titles of publications stated in the bibliography. (5) *Graphs*: The same graph should be used only once, data expressed in graphs should not be expressed in table again, or *vice versa*. Data shown in tables and graphs should be the same as those in the text. Annotation of the graph or table data should be stated in the present tense, e.g. the data are shown in Table 1. Graphs and tables should be included in the body text, first letter of the notation/definition should be capitalized, the rest should be in small letters.

References should be indicated in the order appeared in the text. Authors and titles should be consistent with those shown in the first page of the paper. The same is true for journals, year, volume number, pages (beginning and last pages), and PMID codes.

Others (1) The manuscript should be printed in double-space. (2) Formal language should be used. Informal and non-standard abbreviations or contractions, e.g., isn' t, aren' t, hasn' t, hadn' t, haven' t, don' t, can' t, wouldn' t, a lot of, a bit, too (also), thru (through), exam (examination), lab (laboratory), *etc*. should be avoided. (3) Methods and results should be objectively presented, statements should be simple and unexaggerated. Emotional or advertising promotional terms should be avoided. (4) The verb form is preferable, the gerund or noun form of verb should be avoided. (5) Proper use of articles is required, countable nouns should be expressed in the plural form as much as possible. (6) A prepositional phrase or a hyphen should be used to break off a noun phrase, and a long series of adjectives or nouns to modify nouns should be avoided. (7) As much as possible, sentences begin with important facts, not with phrases or subordinate clauses. (8) When referring to the work or research outcome of other investigators, the authors should state full name of the investigators, in the case of more than two investigators, the term "*et al*" should be used. For further information, please see "*Writing Scientific Paper in English*" http://www.wjgnet. com/1009-3079/new/31.asp.

COLUMNS

WJG consists of the following columns.

Review papers come from experts who are specialized in the fields.

Special topics include esophageal cancer, gastric cancer, liver cancer, viral hepatitis, Chinese medicine, integrated Chinese and Western medicine, and pioneering papers with Chinese characteristics or first-class international standards.

Basic research Studies should have complete experiment data, high academic values, and innovative and original findings.

Clinical research Studies should demonstrate randomization of large samples, safety and efficiency, double-blind and double-simulation, comparison between multi-center control groups and clinical experiments.

Brief reports should present innovative and original phase outcomes.

Case reports should have some instructional significance to clinical practitioners.

MANUSCRIPT MANAGEMENT

In an effort to speed up the computerization and electronization of WJG manuscript management, improve the journal quality, standardize editing procedures, and increase the work efficiency, the WJG Publishing Manuscript Management System was successfully established on April 15, 2003. It enables the automation and electronization of submission registration, submission acknowledgment, preliminary evaluation, second evaluation, evaluation results, final decision, acceptance/rejection notification, editing processing, data

exchange, and Internet submission inquiry. Authors can follow-up the status of their submitted papers at the WJG website, by typing in user name (first author's name) and password (manuscript number). Information regarding serial number, journal name, title, author, date of receipt, editing date, acceptance/rejection date, official invoice number, date of publication, issue (volume) and pages will be provided.

PUBLICATION FREQUENCY

From January 2004, the journal will be published twice monthly. Thus, the submission-publication lag period is expected to be controlled as short as between 1 to 4 months. This journal has been included in the famous international search systems such as the Science Citation Index –Expanded and *Index Medicus*/MEDLINE, in the hope of demonstrating the world leading position of Chinese researchers in gastroenterology. For instance, the paper "Different approaches to caudate lobectomy with "curettage and aspiration" technique using a special instrument PMOD: A report of 76 cases" written by Shu-You Peng, Jiang-Tao Li, Yi-Ping Mou, Ying-Bin Liu, Yu-Lian Wu, He-Qing Fang, Li-Ping Cao, Li Chen,Xiu-Jun Cai, Cheng-Hong Peng, Department of Surgery, 2nd Affiliated Hospital, School of Medicine, Zhejiang University and published in volume 10 of 2003 is of international standards. The submission-publication lag time of this paper was only 45 days.

TYPESETTING AND PRINTING

The WJG uses a uniform font and format from the top margin of book, column, title, author, position of authors, fund and grants, contact address, e-mail address, telephone numbers, fax numbers, date of receipt, acceptance date, abstract, reference format, class 1 heading font, class 2 heading font, graph, chart, to references. No subsequent papers are followed after the end of each paper, thus, papers can be used in the abstract database, ASP, SML, or PDF format. WJG uses the PageMaker publishing software, hence files can be automatically converted to ASP, XML or PDF format.

The printing films for WJG are imported films. Heildelberg color printing is used for the monochrome and color printing. In addition, the three-sided knife is used for trimming. Actual printing work is contracted by the Beijing KH Printing Company. The printing service covers the full-length production work from filming, design drafting, pre-binding sample, to full delivery to the magazine office for approval. Printing follows after every aspect has been approved.

ELECTRONIC VERSION

WJG website (http://www.wjgnet.com/1007-9327/index.asp) went online on April 15, 2003, and as of December 21, 2003, the site has been visited 678 857 times. The electronic version of the WJG has the following seven columns.
Journal introduces Editorial Board, Board member briefs, indexing services by which the WJG is abstracted, and current impact factor.
Published gives information about the publisher, copyright and subscription.
Submission includes instructions to authors and details for preparing review, original manuscript, brief report and case report.
News lists journals indexed in Index Medicus (IM) and impact factors by Journal Citation Reports (JCR).
Submission search allows authors to enter user name and password to obtain full information (up to 28 features) on their submissions.
E-journal allows search for current and previous issues (1995-2003). The WJG E-journal offers options such as HTM or PDF

files, abstracts, related studies, citation frequency, visiting times, download counts, and comments.
Reference links WJG proofreads the entire reference and first page to ensure accuracy of the author, title, year, volume, page number, and PMID. Reference is also linked with the PubMed and http://www.wjgnet.com/1007-9327/index.asp abstracts and documents for citation accuracy, thus providing readers with an access to the citation material and abstract.

CIRCULATION

In 2003, 973 WJG journals were circulated, that is 168 local post office subscriptions within 27 Chinese administrative regions, 105 international subscriptions from 56 countries and regions, and 700 complimentary issues mailed to the investigators in charge of National Project No. 973 and No. 863, as well as the project coordinators of China National Natural Science Fundation. We are providing with complimentary copies of the e-journal to the members of the American College of Gastroenterology, the American Association for the Study of Liver Diseases, and the American Association for Cancer Research, hoping that more international experts in gastroenterology read the papers published in the WJG. Currently, circulation volume of the e-journal has reached 21 200 copies.

SUBMISSION SOURCES AND GRANT STATUS FOR PUBLISHED PAPERS

The upgrade of our national scientific research standards has gradually increased the quality of scientific papers. A higher growth rate was noticed in the volume of papers coming from the famous universities, research facilities (especially laboratories with excellent scientific records), subject groups and scientists. During the period from April 01 to October 01, 2003, we received a total of 618 papers: 501 (81.06%) from China, and 117 (18.93%) from the overseas. A total of 521 papers (21 reviews, 27 esophageal cancer, 54 gastric cancer, 65 liver cancer, 39 intestinal cancer, 46 viral hepatitis, 20 *Helicobacter pylori*, 115 basic studies, 62 clinical studies, 62 brief reports, 8 case reports, and 2 letters from readers) were published in issues 1 to 10 in 2003, 450 (86.37%) were from Chinese institutions, and 71 (13.62%) from the overseas. There were 2 949 authors with 14.41% being from the overseas. The authors were from 34 nations and regions including Argentina, Australia, Pakistan, Brazil, Belgium, Poland, Denmark, Germany, France, Finland, Korea, the Netherlands, Canada, Croatia, United States, South Africa, Yugoslavia, Japan, Sweden, Switzerland, Saudi Arabia, Thailand, Turkey, Spain, Greece, Singapore, Hungary, Iran, Italy, India, United Kingdom, the Mainland of China, Taiwan and Hong Kong. Grant-funded papers accounted for 292 (56.04%) of the published papers. Grant-funded case study papers accounted for 440 (84.45%) papers, which were composed of 25 (4.79%) international grant-funded , 180 (34.54%) National Project No. 973 and No. 863, and National Science Council funded , and 235 (45.10%) government (ministry or provincial office) funded papers. In 2002, the WJG published 226 papers from 26 regions, 93.36% from China, and 6.63% from the overseas, and 60.61% were grant-funded papers. In 2001, the WJG published 173 papers from 20 regions and 112 institutions, 35% were from the overseas and 55% were grant-funded. In 2000, the WJG published 205 papers, and 50% were grant-funded. In 1999, the WJG published 144 papers from 20 regions and 100 institutions, 23% were from overseas and 50% were grant-funded. In 1998, the WJG published 183 papers from 11 regions, 9.84% were from the overseas and 59.56% were grant-funded.

VISITING NUMBER AND DOWNLOAD COUNT

The WJG started producing dynamic web pages from issues 4 to 9 in 2003 e-journal. Visiting number and download count of the papers were recorded. A total of 322 papers were published from issues 4 to 9, and 265 (82.29%) papers were visited and downloaded. During the period from April 13 to October 13, 2003, these 265 papers were visited 35 745 times, or an average of 134.89 times per paper. The highest visiting number was 1 918 and the lowest one was 11. Of these papers 131 (49.43%) had visiting times exceeding 100, 123 (46.41%) had 30-99 times and 11 (4.15%) had 11-29 times. The highest download count was 1 087 and the lowest was 10. For instance, in the review paper "RNA interference: Antiviral weapon and beyond. World J Gastroenterol 2003; 9(8): 1657-1661" written by Quan-Chu Wang, Qing-He Nie, Zhi-Hua Feng, The Center of Diagnosis and Treatment for Infectious Diseases of Chinese PLA, Tangdu Hospital, Fourth Military Medical University was visited 1 918 times and downloaded 1 087 times.

IMPACT FACTORS

Impact factor is an international journal evaluation index. It is a general quantification index reflecting the importance of a journal. Usually a greater impact factor would mean that a journal has a greater academic impact and effect. The total journal citation frequency refers to the total number that the entire paper content of a journal has been abstracted from the time the issue was published in the yearly statistics. It is a highly objective and practical evaluation index capable of showing the usage and degree of attention paid to the journal, as well as its effects and status in the science community. In the Journal Citation Reports (JCR) of the Institute for Scientific Information (ISI), the impact factor of the WJG in 2002 was rated 2.532 with a citation frequency of 1 535, which was ranked thirteenth among 45 journals in the international gastroenterology and liver disease fields, and ranked 797th among the 5 876 international science journals registered in the SCI. The impact factor of the WJG in 2001 and 2000 was 1.445 and 0.993, respectively, with a citation frequency of 722 and 327, respectively. The complete electronic version (ASP, PDF) of the papers published since 1998 has been linked to the PubMed digest, hence worldwide readers can have a free access to the papers published in the WJG using the PubMed search engine. Authors of the journal are thus given worldwide and immediate exposure. As a result, the impact factor of the journal has shown an annual growth, and more importantly, the international influence of the journal continues to expand.

AWARDS FOR PUBLISHED PAPERS

A total of 15 papers won the National, Ministerial, or Provincial Science and Technology Progress Awards during the 1998-2002 period. For example, the paper "Pharmacokinetics of traditional Chinese syndrome and recipe: A hypothesis and its verification (I). World J Gastroenterol 2000; 6(3): 384-391" written by Huang X, Ren P, Wen AD, Wang LL, Zhang L, Gao F, won the second prize of the National Science & Technology Progress Award.

COLLECTIONS OF INTERNATIONAL SEARCH SYSTEMS

Science Citation Index®-Expanded (SCI-E) of the ISI is a comprehensive search engine that collects over 5 876 authoritative scientific journals from different parts of the world. It has a stringent journal selection standard, and is an internationally recognized principal scientific statistics and evaluation engine, thus making it an important citation in the assessment of the value of a journal and the academic standards of its papers. The special citing and cited relations between the author-to-author and paper-to-paper for SCI-E make SCI-E become the most authoritative assessment system for scientific research results internationally. The frequency of scientific journals and papers that are collected or cited by SCI-E in one country or region, will be considered as an index of assessing the scientific research standards for that country or region. Since 1998, the WJG has been successively collected by (SCI-E, Research Alert®, Current Contents/Clinical Medicine®, Journal Citation Reports®, Clinical Medicine Citation Index®), *Index Medicus*/MEDLINE (US), Chemical Abstracts, CA (US), EMBASE/Excerpta Medica, EM (Netherlands), Abstract Journals, AJ (Russia).

HONORS

The WJG is nationally recognized as a core journal in national natural science and an outstanding journal in science and technology, with an honor of the 2nd National Journal Award, and was listed as one of the 100 most important journals in China. In 2001, it was selected into the China Journal Square consisting of "200" journals. It was awarded a specific project grant for the key academic journals by the National Natural Science Foundation in 2002 (project grant no.: 30224801).

Overall, the WJG has already developed to a value-oriented (quality and quantity) journal and functions pursuant to the international standard requirements. In addition, the journal has also completed the management marketation from manuscript submission to publication. Fair and scientific evaluation is applied to make acceptance/rejection decision for each paper submitted . In terms of academic standards and editorial quality, the WJG aims to become one of the best international journals. With the strong support of the authorities, authors, readers, the entire editorial board and the community, the WJG will become one of the most influential international academic journals of its field.

Abstract

AIM: The purpose of this review is to describe the various aspects of primary gastric lymphoma and the treatment options currently available.

METHODS: After a systematic search of Pubmed, Medscape and MDconsult, we reviewed and retrieved literature regarding gastric lymphoma.

RESULTS: Primary gastric lymphoma is rare however, the incidence of this malignancy is increasing. Chronic gastritis secondary to *Helicobacter pylori* (*H pylori*) infection has been considered a major predisposing factor for MALT lymphoma. Immune histochemical marker studies and molecular biology utilizing polymerase chain reaction have facilitated appropriate diagnosis and abolished the need for diagnostic surgical resection. Advances in imaging techniques including Magnetic Resonance Imaging (MRI) and Endoscopic Ultrasonography (EUS) have helped evaluation of tumor extension and invasion. The clinical course and prognosis of this disease is dependent on histopathological sub-type and stage at the time of diagnosis. Controversy remains regarding the best treatment for early stages of this disease. Chemotherapy, surgery and combination have been studied and shared almost comparable results with survival rate of 70-90%. However, chemotherapy possesses the advantage of preserving gastric anatomy. Radiotherapy alone has been tried and showed good results. Stage IIIE, IVE disease treatment is solely by chemotherapy and surgical resection has been a remote consideration.

CONCLUSION: We conclude that methods of diagnosis and staging of the primary gastric lymphoma have dramatically improved. The modalities of treatment are many and probably chemotherapy is superior because of high success rate, preservation of stomach and tolerable complications.

INTRODUCTION

Primary gastric lymphoma is a rare tumor, accounting for less than 5% of primary gastric neoplasms[1-5]. However it is the most common extranodal lymphoma, representing 4-20% of all extranodal lymphomas[6,7]. In the Middle East, stomach is the most common gastrointestinal site, with an incidence rate similar to that reported in the western literature[8-11]. However Turkish and Indian series suggested that intestinal lymphomas have been more predominant than gastric lymphoma in those regions[12,13].

Gastric lymphomas are prevalent in patients aged more than 50 years, however it still has been reported in the second decade of life[14,15]. Reported median age is 60-65 years and males are 2-3 times more affected than females[16-18]. Recently, several studies have shown an increase in the incidence among HIV infected and AIDS patients, affecting increasingly younger age groups[19-21].

PATHOLOGY

Malignant lymphomas affect the stomach as a primary tumor or as part of more wide spread disease process. Stomach is the most common site with secondary lymphoma[22,23]. Generally lymphomas are considered as "primary" in the gastrointestinal tract when the initial symptoms of the disease are in the abdomen indicating a disturbance of the gastrointestinal function, or when the bulk of the disease is in the stomach.

Most gastric lymphomas are thought to arise in the mucosa or submucosa from the so-called mucosa-associated lymphoid tissues (MALT), which usually develop after chronic inflammation induced by *H pylori* infection[23-26]. Histologically and immunohistochemically MALT lymphomas are of the B-cell non-Hodgkins type (NHLs) and share many features in common, therefore they are denoted as malignant lymphomas of MALT. The association between *H pylori* chronic gastritis and MALT lymphoma has been confirmed in large population based studies where immunological evidence of *H pylori* infection has been shown to be more in patients with gastric lymphomas than in matched controls[24-26]. Other forms of gastric lymphomas are non-MALT type, although many may be initially MALT tumors. Rare tumors may be T cell in origin[27-30].

The histological classification may vary from low to high grade. Grading has been classified into low, intermediate and high grade. Other terminology of primary and secondary high-grade lymphomas has been adopted[24]. In the histology of secondary high-grade lymphomas, there is evidence of low-grade component. Various systems (Rappaport, Working formulation and Modified Kiel) have frequently been utilized for histological classification, Combination of two or three classification systems have also been commonly used[17,23,30,31].

A majority of primary gastric lymphomas are histologically of the diffuse histiocytic or large cell type[15,32,33]. Reports from Saudi Arabia have shown a predominance of diffuse large B-cell type[14,33]. Gastric maltoma represents up to one half of primary gastric lymphoma. In the last few years, the Revised European American Lymphoma (REAL) classification of lymphoid neoplasms has been widely used with the advantage of high reproducibility and clinical relevance (Tables 1,2)[32,34].

Microscopically, low-grade lymphomas may not easily be distinguished from pseudolymphomas, a term used to describe the lymphocytic infiltration of the gastric mucosa, which may occur with chronic gastritis and peptic ulceration. Pseudolymphomas may mimic clinically and endoscopically gastric adenocarcinomas or lymphomas. Pathologists can differentiate between pseudolymphomas and lymphomas based on several histological characteristics which indicate malignant

changes, like prominent lymphoepithelial lesions (lymphoid infiltration of glands or crypts with partial destruction), Dutcher bodies and moderate cytologic atypia[35]. In cases which can not be diagnosed with histological differentiation, immunohistochemical marker studies or molecular biology utilizing polymerase chain reaction (PCR) may facilitate establishing an accurate diagnosis[36,37]. However, recent studies have indicated that the great majority of pseudolymphomas are in fact true lymphomas of low-grade malignancy using markers of clonality, and this term preferably has to be abandoned[37].

Table 1 The REAL classification of non-Hodgkin's Lymphomas

B-cell lymphomas
    Precursor B-cell lymphomas:
      B-lymphoblastic
    Mature B-cell lymphomas:
      B-cell CLL/small lymphocytic
      Follicular
      Marginal-zone-nodal
      Extranodal marginal-zone (MALT)
      Splenic marginal-zone
      Lymphoplasmacytic
      Mantle-cell
      Diffuse large B-cell
      Primary mediastinal large B-cell
      Burkitt's like
      Burkitt's
T-cell lymphomas
    Precursor T-cell lymphomas:
      T-lymphoblastic
    Mature T-cell lymphomas:
      Mycosis fungoides/sezary syndrome
      Peripheral T-cell (many subtypes)
      Anaplastic large T/null cell
      Adult T-cell leukemia/lymphoma

Table 2 Histologic classification of gastrointestinal lymphomas

B-cell
    Mucosa-associated lymphoid tissue (MALT)-type
    (extranodal marginal-zone lymphoma):
      Low-grade
      High-grade, with or without a low-grade component
    Immunoproliferative small intestinal disease (IPSID):
      Low-grade
      High-grade, with or without a low-grade component
    Lymphomatous polyposis (mantle-cell lymphoma)
    Burkitt's and Burkitt's-like
    Other types of low- or high-grade lymphoma corresponding
    to lymph node equivalents
T-cell

    Other types not associated with enteropathy

Macroscopically, gastric lymphomas may appear as ulcerated (single, multiple or diffuse), polypoid, granulonodular or infiltrative lesions[13,24,33]. Ulcerative type alone or combined with other lesions has been the most frequent endoscopic presentation of primary tumors. The lesion may vary from fine nodularity or normally looking mucosa to very advanced large fungating ulcerated mass[13]. Endoscopically, the differentiation between lymphomas and adenocarcinomas may not be easy, however early lymphomas tend to produce larger tumors than adenocarcinomas and may be multifocal as well[15]. Gastric lymphomas involve more frequently the antrum and corpus[33]. In a series, 46% of lesions are located at gastric body[24]. Entire gastric involvement has also been reported[18,24]. In advanced diseases tumors may spread to extraintestinal sites like central nervous system, bone, liver, kidneys, ovary and lungs[24].

CLINICAL PRESENTATION

The initial symptoms of upper abdominal pain and early satiety may be vague and nonspecific, leading to a delayed establishment of diagnosis up to several years[39]. Symptoms and signs may mimic that of other abdominal pathologies including peptic ulcer disease, gall bladder, pancreatic or functional disorders as well as other gastric neoplasms[15]. Other common symptoms included weight loss, nausea, vomiting, abdominal fullness and indigestion[30,31,33]. Weakness, night sweat, jaundice, fever and dysphagia occur less frequently[13,23,30]. Many patients came down late with advanced disease and complications may develop before diagnosis[38]. Twenty to thirty percent may present with bleeding in the form of hematemesis or melena while, gastric obstruction and perforation are less common[37,38]. Physical examination could be normal in 55%-60%[30]. Common signs include epigastric tenderness and palpable mass. The tenderness is encountered in 20%-35% and masses in 17%-25%[15,23,31]. Other uncommon findings included fever, hepatomegaly, splenomegaly, jaundice and lymphadenopathy. In one series, lymphadenopathy is found in 12%[24,30,31]. Signs of malnutrition may also appear in advanced disease[39].

DIAGNOSIS

Clinical presentation and radiological features are often nonspecific. Esophagogastroduodenoscopy (EGD) and biopsy are primary methods for diagnosis[15,40]. The diagnosis of low-grade MALT lymphoma by forceps biopsy is often difficult in early disease and reapeated endoscopies and biopsies may be required before final diagnosis is achieved[25].

Multiple and step biopsies are required because endoscopic findings may vary from subtle mucosal changes to gross lesions. These may include mucosal edema, friability, patchy redness, irregular patchy gray or whitish granularity, contact bleeding, superficial irregular erosions and ulcerations[33]. Repeated endoscopic biopsies are mandatory in case of clinical suspicion and negative or inconclusive histology. Furthermore, endoscopic mucosal resection enhances the histological yield[41]. Occasionally, rapid diagnosis by endoscopy can be made by detection of monoclonality in immunoglobulin heavy chain rearrangement of the lymphoproliferative disease by PCR[42]. It is reccommended that biopsy specimens should undergo histological, immunohistochemical and genotyping studies to make the diagnosis.

Radiological examinations can help establish diagnosis and determine the extent of the lesions. Gastric wall thickening, atypical ulcer deformities, obstruction and mass effect are enhanced features suggestive, but not specific for gastric lymphoma[30,31,38]. CT scan of the abdomen can identify the gastric wall thickening or mass lesions in 85% of cases. Sometimes it may show typical imaging features of more homogenous and pronounced mural thickening that can help differentiate lymphomas from adenocarcinomas[42,43]. On CT scan, three quarters of cases of low grade MALT lymphomas may present with infiltrative form and polyploid form in the remainder. Lymphadenopathy is detected in only 50%[43]. Conventional sonographic examination can be of value in identification of gastrointestinal involvement as well as abdominal lymph node enlargement in lymphoma staging. The MRI features include irregularly thickened mucosal folds, irregular submucosal infiltration, annular constricting lesion, exophytic tumor growth, mesenteric masses and mesenteric/retroperitoneal lymphadenopathy[44]. EUS is a valuable

technique in assessing the extent and invasion of the lesion. By EUS, infiltrative carcinomas tend to show a vertical growth in the gastric wall, while lymphomas tend to show mainly a horizontal extension[45,46]. It is highly accurate in determining the depth of lymphomatous infiltration and the presence of perigastric lymph nodes, thus providing additional information for therapeutic planning. It can differentiate between lymphomas and carcinomas in early stages, but in advanced stages both have similar appearances. With the development of the above diagnostic methods, open surgery is rarely needed to confirm the diagnosis.

STAGING

After establishing the diagnosis of primary gastric lymphoma, staging is essential for planning treatment. It is also important to rule out systemic lymphoma with secondary involvement of the stomach. The staging process starts with endoscopy and step biopsy to rule out microscopic infiltration of nearby structures like the duodenum. Chest radiography may show gross lesions in the lungs and mediastinum. CT scan of chest, abdomen and pelvis permits assessment of nodal involvement above and below the diaphragm, and extension of the tumor outside the stomach. EUS may be employed for accurate estimation of both the depth of invasion and involvement of regional lymphnodes[45,46]. It is superior to CT scan in false negative cases. Bone marrow examination helps determine presence or absence of tumor spread. Indirect laryngoscopy is also helpful for excluding Waldeyer's ring involvement, which is reported to be associated with gastric lymphoma[32].

Table 3 Staging classification according to Musshoff's criteria

Stage	Definition
IE	Lymphoma limited to the stomach
IIE_1	Involvement of stomach and contiguous lymph nodes
IIE_2	Involvement of stomach and noncontiguous subdiaphragmatic lymph nodes
III	Involvement of stomach and lymph nodes on both sides of diaphragm
IV	Hematogenous spread (stomach and one or more extralymphatic organs or tissues)

The Following subscripts may be added E=extranodal, S=splenic, A=asymptomatic, B=symptomatic.

Table 4 Modified Blackledge staging system for gastrointestinal lymphomas

Stage I	Tumor confined to gastrointestinal tract without serosal penetration: Single primary site Multiple, non-contiguous lesions
Stage II	Tumor extending into abdomen from primary site: Nodal involvement II_1 Local (gastric/mesenteric) II_2 Distant (paraaortic/paracaval)
Stage II_E	Penetration of serosa to involve adjacent 'structures': Enumerate actual site of involvement, e.g. stage II_E (pancreas), stage II_E (large intestine), stage II_E (post-abdominal wall) Perforation/peritonitis
Stage IV	Disseminated extranodal involvement or a gastrointestinal-tract lesion with supradiaphragmatic nodal involvement

Various staging systems have been used. The Ann Arbor staging for primary lymphomas has been modified by Musshoff, and utilized by several authors for staging gastric lymphomas (Table 3)[18,47,48]. Several alternative staging systems have been proposed, and the revised version of the Blackledge staging system has been recommended for general use (Table 4)[49,34]. Several authors have suggested that such staging modification may be of prognostic significance[50,51,53].

TREATMENT

The modalities of treatment for gastric lymphomas have been a controversial subject, and the best regimen has not been standardized. However, options of treatment depend on the histologic classification and stage of the disease. Some centers adopt surgery alone, while others advocate non-surgical treatment with radiation, chemotherapy or both.

SURGERY

Traditionally, aggressive surgical resection has been the main stay of treatment because it can collect definitive tissues for pathologic examination, allow exploration of the abdomen, reduce tumor burden and obviate the concern that gastric hemorrhage or perforation would complicate medical treatment of lymphomas. More recently, radical gastrectomy is disputed and considered unnecessary. Lesser procedures are now accepted where resection of the gross disease and involved lymphnodes will provide adequate results[39,52,53]. Several reports have shown a superior outcome when surgical resection is undertaken in the early stages of the disease with a 5-year survival rate of 80%-93%[54,55].

Kazaya *et al* advocated wide resection of early gastric tumor and extensive lymph node dissection[15]. Other authors also found surgery alone to be an adequate treatment for stage 1E or pure MALT lymphomas with a survival rate of >95%, provided staging is performed after radical gastrectomy[56]. In a large series of patients treated according to *H pylori* status, tumor grade and stage, surgical resection remained the treatment of choice in patients with stage IIE, low-grade lymphoma and non-responders of stage IE treated by eradication for *H pylori*, however the author advised further studies to compare surgical with conservative treatment[57].

A prospective study from France, has found that in stages I E and II E, the complete response, survival rate and disease free survival rates were similar to those who underwent complete resection, partial or no surgery prior to administration of chemotherapy. The survival rates of 60% with surgery alone compared to 85% if adjuvant chemotherapy was given, were reported[40]. In a retrospective study of 92 patients from Italy in different stages who underwent surgical resection when it was feasible, the ten-year actuarial survival rates were 100% and 80% for stage IE and IIE respectively compared with 21% and 0 for stage IIIE and IVE[58].

Surgical resection with clear margins is advised in order to maximize the chance of cure[39,55,59]. On the contrary, other reports have found no difference in survival, whether the margin of resection was clear or not, as long as post-operative chemotherapy had been given[60,61].

The mortality and morbidity related to surgery were similar if not more than those related to non-surgical treatment for stage I and II. Therefore, aggressive surgery is not indicated due to increased morbidity which is outweighing the benefit gained in terms of survival[60-62] and gastrointestinal organ preservation may provide substantial advantage for the quality of life in these patients[39]. Resectability rates ranged from 60%-88%, and the 5-year survival ranged from 50%-87%[55,60]. Debulking of advanced disease was associated with the high morbidity and mortality and low response rates of 6%-40%[63]. Operative mortality was between 3%-25% with higher rates

for palliative procedures which were performed for symptomatic relief, removal of tumor mass and avoidance of hemorrhage or perforation related to other mode of therapy[63]. In a prospective study of 208 patients, there was no difference in therapeutic outcome in surgically or conservatively treated patients, even after complete resection, the authors concluded that surgery favored by most authors in treatment of primary gastric lymphoma should be reassessed[64].

CHEMOTHERAPY

The effect of chemotherapy alone as a sole treatment for gastric lymphomas is still debatable. The needs behind trying chemotherapy were the considerable morbidity and mortality associated with resection[63]. Stomach conservation, and avoidance of postoperative complications such as myocardial infarction, gastrointestinal bleeding, enterocutaneous fistula and malabsorption syndrome were important factors that obviated the choice of chemotherapy. Initial trial in a small number of patients in stage I E and II E has shown excellent results by combination of chemotherapy and radiotherapy with a survival rate of 70% and few complications[52]. Salvgnol et al reported a survival rate of 71% in patients treated by chemotherapy[55]. Another recent study on aggressive gastrointestinal lymphoma found primary chemotherapy with or without radiotherapy useful and induced a complete response in 81% of patients, with fewer complications compared with surgery including less risk of perforation or bleeding[65]. Other reports showed no apparent difference in survival between patients treated by chemotherapy or surgery and chemotherapy with survival rates of 67% and 60%, respectively. There has been no report of serious adverse effects such as bleeding or perforation in chemotherapy-treated patients of intermediate and high grade non- Hodgkin lymphomas[60]. In a report from Italy, 17 patients with resectable large cell lymphoma treated primarily by chemotherapy with or without consolidation radiotherapy, only two failed in the first line therapy and 15 were free of disease at 6 years[66]. Consolidation radiotherapy might improve the efficacy of chemotherapy. None of the patients experienced acute treatment related morbidity or mortality from local complications[68]. In three recent trials with variable chemotherapy regimens, the survival rates of 82%-88% in stage IE and IIE, high grade lymphoma with only few and manageable complications were found[65,67,68].

In other series, chemotherapy alone compared with surgical resection alone, has shown no significant difference in the matter of survival. The overall 2-year survival was 67% and 81%[69-71].

In patients with comorbid factors and increased risk of surgery-related morbidity and mortality, chemotherapy offered an effective or equally effective mode of treatment to surgical resection 57% vs 58%[71].

The fear of chemotherapy-related complications, for instance, bleeding and perforation, has been disputed, and less significant compared with surgical resection[65,67-69]. Some authors reported the incidence of chemotherapy-related bleeding between zero and three percent and no perforation[60,72]. Therefore, chemotherapy has been suggested and adopted as a primary mode of treatment. Combined chemotherapy comprising cyclophosphamide, doxurubicin, vincristine and prednisolone (CHOP), has been the preferable and the most effective regimen for all tumor stages[31,65]. Several other regimens have also been used with almost similar efficacy and comparable toxicity[75]. While cyclophoshamide, vincristine and prednisolone (COP) were adopted for low grade lymphomas, high grade tumors were treated with doxurubicin, teniposide, cyclophosphamide and prednisolone (AVmCP). The latter two regimens combined with surgical resection have shown the survival rates of 80% and 100%, respectively[73].

COMBINED THERAPY

Multimodal therapy, combining resection with chemotherapy and occasionally radiotherapy have been commonly and widely accepted in many centers. It has significantly improved the 5-year survival[10,27,55,59,60,74]. Combination of radical surgery followed by chemotherapy has been associated with a significantly improved outcome in comparison with chemotherapy alone[73]. Lin et al have compared surgery, surgery with adjuvant chemotherapy and chemotherapy alone and found the 5-year survival rates of 57%, 76% and 58% compared with 0% in the untreated group. They recommended surgery when feasible with adjuvant chemotherapy as the mainstay of treatment for gastric lymphoma[71]. A Chinese study has suggested that chemotherapy plays a role in improving survival rates post-surgical resection[53]. A prospective study from France in 1990 reported a 100% survival in patients with high-grade tumors who underwent resection and adjuvant chemotherapy. A recent series has shown the superiority of combined surgery and chemotherapy to single mode with survival rates between 86%-94% for stages IE and IIE[53,59,66]. In these series the survival rates were higher for those who had complete resection, resection was the most important variable and major determinant of prolonged complete remission[59,60]. Survival was higher in low-grade lymphomas, although the initial response might be superior in high grade lymphomas[59]. Combined radical surgery and chemotherapy depending on the histologic grading were also associated with prolonged remission[73].

Resection of the tumor with clear margins is thought to have a better prognosis than with diseased margins[52,74,75]. However, other authors have found insignificant difference between the two procedures as long as post-operative chemotherapy was administered, and the extent of the disease at time of surgery, full thickness disease and lymph node involvement were important determining factors[39].

On the contrary, other studies reported no significant difference in outcome in groups treated with single or combined mode of treatment[57,62,70,72].

The stage and histologic grade of the disease play a role in the selection of the treatment modality, in addition to the comorbid disease and age of the patients.

Early stages of the disease regardless of the histological grade may be controlled by chemotherapy or chemotherapy and radiotherapy with the advantage of gastric conservation and avoidance of post-operative mortality and morbidity[54,62,65-67,69,74]. On the other hand, surgery is advocated as the first option with adequate control of the disease[57-59, 61], and occasionally with the necessity of wide resection and extensive lymph node dissection[15,78], however, adjuvant chemotherapy is indicated to control the local and distant disease if any[75,78].

In advanced stages of gastric lymphoma (stage IIIE, IVE) the behaviour of the tumor has the same manner as other advanced non-Hodgkin lymphomas, therefore combined chemotherapy is considered the treatment of choice for locally advanced or disseminated aggressive disease. In a prospective study of 700 patients with aggressive lymphoma treated with intensive chemotherapy, no difference in outcome was observed between patients with an advanced aggressive nodal lymphoma and the subset of patients (15%) in which the lymphoma was deemed to occur in the gastrointestinal tract[40].

MALT lymphomas have aroused special interest because regression of the tumor has been reported after H pylori eradication. Standardization of therapy is not yet available and is still a subject of controversies. The initial results were shown in five of six patients with low grade MALT lymphomas who had regression of the tumor after eradication of H pylori[77]. Thiede and associates studied a total of 120 patients with early gastric MALT lymphomas treated with amoxycillin and

omeprazole, a complete remission rate of 81% was achieved with partial response in 9%[78]. Zucca and colleagues, in a large multinational cooperative study, treated 233 patients with antibiotics and randomized them to observation alone or maintenance with chlorambucil. Complete remission was documented in 62% and partial response in 12% with a 6-month median time to lymphoma regression. At a 40-month follow-up, a total of 15 (13%) cases had relapse[79]. Manfred reported regression of reactive lymphoid infiltrates after *H pylori* eradication, without endoscopic or histolgical regression in MALT lymphomas[26]. It is not yet known which stages of MALT lymphomas respond to *H pylori* eradication. Although it seems that eradication therapy is an adequate option of treatment taking into consideration the utility of endosonography in determining the invasion of the disease[80].

Surgical resection, radiotherapy or chemotherapy and their combination have proven to be effective treatment modalities. Radiotherapy was tried as a local form of treatment in a small number of patients, resulting in a survival rate of 93%. Surgery, radiotherapy and antibiotics were compared and similar results were found[81].

Radiotherapy

In most instances, radiotherapy is used as an adjuvant to surgery, chemotherapy or both. It has rarely been tried as a single mode of therapy[31,81]. However, limited trials have suggested that radiotherapy can be utilized as a primary mode of treatment with reasonable outcome[78,81].

Radiotherapy has been studied in comparison with other treatment modalities for stage IE and IIE with comparable outcome of 80%-89% survival[13,31,68]. Higher survival rates (93%) have been reported in early stages of MALT lymphomas not responding to antibiotics[83]. Radiation was used post-operatively in high- and low-grade lymphomas, for any residual tumors in stages I and II to improve the disease free survival[9,57]. Combined chemotherapy might improve the chance of stomach conservation which may approach 100%[72]. Total gastrectomy has not improved the survival in patients in whom radiotherapy has been utilized as the primary mode of therapy with a survival rate of 84%. Contradictory studies have found the combined radiotherapy with either resection or chemotherapy to be of no significant difference in both modalities with a survival rate of 82%-88%[9,68,81].

PROGNOSIS

The prognostic factors in early stages were evaluated and defined in several studies. Good prognosis was associated with low grade disease, age below 65 years, free surgical margins in cases of resection, and achievement of initial complete remission[49,50,53]. In advanced diseases, good prognosis was found in low-grade histology, initial complete response, and in general the prognosis is the same as non-gastrointestinal lymphoma[50]. The grade of the disease also plays an important role in prognosis with better survival in low-grade disease rather than primary or secondary high-grade taking into consideration the stage[17]. Five-year survival rates were reported to be 91% for low-grade, 73% for secondary high-grade and 56% for primary high-grade tumors[17]. Debulking of the disease has not significantly altered the prognosis[50,53,61,64].

CONCLUSION

Due to the rarity of primary gastric lymphoma, many aspects of this neoplasm are still controversial. The incidence of the disease is increasing and HIV-infected people are more vulnerable. Universally, gastric lymphoma is the commonest gastrointestinal lymphoma except in a few countries where small intestinal lymphoma has been reported to be more common. On many occasions, patients present late, however with the availability of sophisticated diagnostic tools, the diagnosis can be made early and the classification and staging can be assessed accurately. The REAL classification despite being complex, has met a general agreement among pathologists and facilitated reproducibility. Most of the gastric lymphomas are primarily MALT type in origin. The best treatment for primary gastric lymphoma has not yet been exactly identified. It seems that for advanced disease, i.e., stage III and IV, combined chemotherapy and radiotherapy is superior since surgery is associated with failure of complete resection and significant morbidity and mortality. Most recent reports have advocated conservative treatment for early stages IE and IIE with the advantage of stomach conservation. On the other hand, many centers are still considering tumor resection as a better option. *H pylori* eradication with close observation has been considered adequate to treat early MALT lymphoma. Randomized trials are still needed to clarify whether conservative, surgical or combined treatment is more appropriate for treatment of localized gastric lymphoma.

Abstract

Hepatitis C is a major cause of liver-related morbidity and mortality worldwide. In fact, chronic hepatitis C is considered as one of the primary causes of chronic liver disease, cirrhosis and hepatocellular carcinoma, and is the most common reason for liver transplantation. The primary objectives for the treatment of HCV-related chronic hepatitis is to eradicate infection and prevent progression of the disease. The treatment has evolved from the use of α-interferon (IFNα) alone to the combination of IFNα plus ribavirin, with a significant improvement in the overall efficacy, and to the newer PEG-IFNs which have further increased the virological response, used either alone or in combination with ribavirin. Despite these positive results, in terms of efficacy, concerns are related to the safety and adverse events. Many patients must reduce the dose of PEG-IFN or ribavirin, others must stop the treatment and a variable percentage of subjects are not suitable owing to intolerance toward drugs. IFNβ represents a potential therapeutic alternative for the treatment of chronic viral hepatitis and in some countries it plays an important role in therapeutic protocols. Aim of the present paper was to review available data on the safety of IFNβ treatment in HCV-related chronic hepatitis.

The rates of treatment discontinuation and/or dose modification due to the appearance of severe side effects during IFNβ are generally low and in several clinical studies no requirements for treatment discontinuation and/or dose modifications have been reported. The most frequent side effects experienced during IFNβ treatment are flu-like syndromes, fever, fatigue and injection-site reactions. No differences in terms of side-effect frequency and severity between responders and non-responders have been reported. A more recent study, performed to compare IFNβ alone or in combination with ribavirin, confirmed the good safety profile of both treatments. Similar trends of adverse event frequency have been observed in subpopulations such as patients with genotype-1b HCV hepatitis unresponsive to IFNα treatment or with HCV-related cirrhosis and patients with acute viral hepatitis. If further studies will confirm the efficacy of combined IFNβ and ribavirin treatment, this regimen could represent a safe and alternative therapeutic option in selected patients.

INTRODUCTION

Hepatitis C is a major cause of liver-related morbidity and mortality worldwide and represents a significant public health problem[1]. In fact, chronic hepatitis C is considered as one of the primary causes of chronic liver disease, cirrhosis and hepatocellular carcinoma, and is the most common reason for liver transplantation[2]. Based on the increased knowledge surrounding the natural history of the disease, the primary objectives for the treatment of hepatitis C virus (HCV)-related chronic hepatitis are to eradicate infection and prevent progression to cirrhosis and thereby preventing complications associated with end-stage liver disease[3,4]. The treatment of HCV has evolved from the use of a single agent - mainly interferon alpha (IFNα) to the combination of IFNα and ribavirin treatment. Combination therapy can significantly improve the overall treatment efficacy compared to monotherapy (i.e., from 10%-15% of sustained viral clearance to 30%-40%) and now represents the standard treatment for chronic hepatitis.

Recently, new IFN preparations, such as pegylated IFNs (PEG-IFNs), have been introduced in clinical practice. Results obtained from large, multicenter studies of combined PEG-IFN and ribavirin treatment have shown a further increase in treatment efficacy. In fact, HCV infection was eradicated in 47%-54% of patients treated with PEG-IFNα-2b[5]. Similar results have been found with PEG-IFNα-2a treatment[6]. However, despite these positive results, several clinical problems remain. Of primary significance is the large number of patients treated with PEG-IFN (both α-2a and α-2b) and ribavirin who discontinue treatment due to the occurrence of adverse events associated with therapy. In fact, it has been reported that 34%-42% of patients treated with PEG-IFNα-2b (high and low doses, respectively) required dose reductions due to the appearance of adverse events and 13% stopped treatment for safety reasons[5]. In another trial concerning the efficacy of PEG-IFNα-2a, dose modifications due to adverse events were required in 8% of patients and treatment discontinuation was required in 19%[6]. In a pivotal trial of IFNα-2b and ribavirin performed by McHutchison *et al.*[7], dose reductions due to adverse events were needed in 13% and 17% of patients treated for 24 and 48 weeks, respectively. Treatment discontinuation rates were 8% and 21% in patients treated for 24 and 48 weeks, respectively. Furthermore, it has been recently documented that, due primarily to safety issues, the number of HCV patients eligible for current treatments and the rate of treatment completion were much lower in clinical practice than in clinical trials[8]. These concerns are particularly relevant considering that the primary goals of HCV treatment are viral eradication and the slowing of disease progression[9,10].

Since IFNs are a family of glycoproteins with a broad range of antiviral effects, IFN beta (IFNβ) represents a potential therapeutic alternative for the treatment of chronic viral hepatitis. In fact, in some countries, mainly in Japan, IFNβ already plays a central role in therapeutic protocols. Differences have been reported between the physicochemical, biological and pharmacological properties of IFNα and IFNβ[11,12]. Three forms of human IFNβ are available:[13] 1) Natural human IFNβ (nIFNβ) which is produced using human fibroblasts and is currently used in Japan for the treatment of chronic hepatitis C. 2) Recombinant human IFNβ-1a (rhIFNβ-1a), which is

procured from mammalian cells and is identical to IFNβ that occurs naturally in humans. 3) *Escherichia coli*-produced recombinant human IFNβ (IFNβ-1b) which contains an altered amino acid sequence with a serine substitution for the cysteine at position 17. rhIFNβ-1a appears to have advantages over the other two formulations and, in particular, is less immunogenic and more potent[14]. The aim of the present paper was to review available data on the safety of IFNβ for the treatment of chronic hepatitis C. Since IFNβ has been widely used for the treatment of multiple sclerosis (MS), studies referring to the safety of IFNβ in MS are reviewed briefly before discussing the results of this treatment in HCV-related chronic hepatitis.

IFN**b** in multiple sclerosis

Recombinant IFNβ is currently the gold standard for the treatment of relapsing-remitting MS (RRMS). In MS, IFNβ treatment lasts several years and regimens require high doses and frequent administration. Therefore, safety data on IFNβ therapy recorded in MS studies and clinical practice could be useful for providing an overview of the drug's safety characteristics.

In the PRISMS (prevention of relapses and disability by interferon beta-1a subcutaneously in multiple sclerosis) study[15], 560 patients with RRMS received 2.2 μg or 4.4 μg IFNβ or placebo subcutaneously (s c) thrice weekly (t.i.w.) for 2 years (PRISMS-2) and then, the subjects completing treatment (*n*=503) or study (*n*=533) were re-randomized to receive either 2.2 μg or 4.4 μg IFNβ s c, t.i.w., for an additional 2 years (PRISMS-4)[16]. The adverse events reported during the PRISMS-4 study were similar to those observed in the PRISMS-2 trial and, in general, most adverse events were mild. During the 4-year period of observation, the most frequent events reported were injection-site inflammation, flu-like symptoms, headache and fatigue, with similar rates in both active treatment groups. In the 2.2- and 4.4 μg groups, respectively, less frequent adverse events included laboratory abnormalities such as lymphopenia (27% and 35%), elevated ALT levels (24% and 30%), elevated AST levels (11% and 20%) and thrombocytopenia (3% and 8%). All cases of thrombocytopenia were mild and only one patient over the 4 years (in the 44 μg group) stopped treatment due to lymphopenia. In two other patients, treatment was discontinued as a result of elevated liver enzymes. In the SPECTRIMS (secondary progressive efficacy trial of rebif [interferon beta-1a] in multiple sclerosis) study[17] conducted in secondary progressive MS (SPMS) patients using a treatment schedule similar to that used in the PRISMS-2 study, the type, frequency and severity of adverse events with IFNβ-1a were similar to those reported in the PRISMS study. Overall, IFNβ-1a was well tolerated. Of the 618 patients enrolled, 3 receiving placebo, 8 receiving 2.2 μg IFNβ-1a and 7 receiving 4.4 μg IFNβ-1a discontinued treatment permanently. In general, liver function test abnormalities were mild or moderate and either resolved with treatment interruption or no treatment modification whatsoever. The recent EVIDENCE (The evidence for interferon dose-response: European North American comparative efficacy) study[18] compared the safety and efficacy of IFNβ-1a, 4.4 μg, s c , t.i.w., to IFNβ-1b, 3.0 μg, once weekly by intramuscular (i m) injection, in 677 patients with RRMS over 24 weeks. The most common adverse events recorded were injection-site disorders, flu-like symptoms, headaches, rhinitis and fatigue. The higher frequency of injection-site disorders in the IFNβ-1a group was related to the more frequent administration of this agent. However, injection-site disorders were mild and no skin necrosis was observed in over 20 000 s c injections. Hepatic and hematologic laboratory abnormalities were also more common on IFNβ-1a but again, these abnormalities were generally mild and responsive to dose

reductions (if required). In both treatment groups, severe laboratory abnormalities were rare (<1%).

IFN**b** pharmacokinetics

IFNβ can be administered intravenously (i v), intramuscularly (i m) and subcutaneously (s c). Pharmacokinetic and pharmacodynamic studies[19-21] have shown that the extent and duration of the clinical and biologic effects of IFNβ are independent of the route of administration. Furthermore, studies evaluating the most efficacious IFNβ dosing regimen[22-25] have shown that, in general, the highest doses have the greatest efficacy. However, these higher doses are also associated with a greater incidence of side effects (see below).

Evaluation of IFN**b** safety

Similar to the adverse events associated with IFNα therapy[26,27], the side effects of IFNβ can be separated into different categories, namely: a) common side effects (these range from mild-to-severe in nature and do not require dose modification), b) mild-to-moderate side effects which occur less frequently (i.e., less than 10% of treated patients) and may or may not require dose modification, and c) severe or life-threatening side effects. Thus far, no severe or life-threatening side effects have been reported with IFNβ use. Clinical IFNβ data are based on the results of clinical studies involving 1096 patients[23-25,28-52]. Studies have been performed on treatment-naïve patients as well as patients who did not respond to previous treatment (generally with IFNα), two other studies were performed in special populations (i.e., cirrhotic patients and patients with renal failure)[46,54].

Discontinuation and dose modification during IFN**b** treatment

The rates of treatment discontinuation and/or dose modification due to the appearance of severe side effects during IFNβ are generally low (Table 1). Furthermore, several clinical studies reported no requirements for treatment discontinuation and/or dose modifications. Kiyosawa *et al*[28] found that in naïve patients treated with i v IFNβ, dose modifications due to leukocyte counts below 1×10^9/L were required in only 4.2% of patients (1 of 12 patients). In a study by Villa *et al*[29] 5.3% of patients (1 of 19) did not complete the trial. Reasons for discontinuation were not specified. A comparison study of i v recombinant IFNβ and IFNα-2b plus ribavirin in patients who did not respond to previous IFNα treatment found that 12% of patients in the IFNα-2b plus ribavirin group (12 of 100) withdrew from treatment due to side effects such as flu-like symptoms. In the IFNβ group, the corresponding frequency was 9% (9 of 100 patients)[30].

Table 1 Frequency of treatment discontinuation and dose modifications during therapy with IFNβ

	Number of cases	References
Discontinuation		
Adverse events	14	25,28,29,30
Laboratory abnormalities	2	31
Dose modifications		
Adverse events	-	
Laboratory abnormalities	1	43

In a comparative study of two different doses (9 MU and 12 MU) of rhIFNβ produced using Chinese hamster ovaries, Habersetzer *et al*[25] observed a treatment discontinuation rate of 18.2% (2 of 11 patients in the lower dose group) in naïve patients due to the occurrence of side effects such as mild depression and cutaneous ulcers at the injection site. A treatment discontinuation rate of 18.2% (2 of 11 patients) was also found in a study[31] comparing the effects of different IFNβ

administration regimens (i v 6 MU once daily versus 3 MU twice daily), two patients who discontinued treatment were using IFNβ twice daily. Liver enzyme alterations (serum ALT/AST levels >700 IU/l) and severe proteinuria (urinary protein excretion >40 g/L and serum albumin level <30 g/L) were the causes of discontinuation. In conclusion, the frequency of treatment discontinuation and dose modifications that occur during IFNβ therapy is low.

Frequency of side effects during IFNβ treatment

The frequency of side effects experienced during IFNβ treatment is reported in Table 2.

Table 2 Frequency of side effects with IFNβ therapy

Side effects	Frequency (range) (%)	References
Flu-like syndrome	10-100	25,30,32,33,35, 36, 37, 39, 46
Fever	67-100	28,43,40
Fatigue	16-74	24, 33, 39,46
Local reactions (at the injection site)	43-76	25,34, 37
Headaches	8-47	33, 39, 46
Malaise	50	39
Arthro-myalgias	21-42	39,40,46
Weight loss	6-42	39,40
Gastrointestinal symptoms	20-26	25,37, 38
Anxiety, insomnia, irritability	10-25	32, 39, 38
Depression	10-21	25, 38,46
Alopecia	8-16	33, 39
Proteinuria	46-73	22, 51
Reduced platelet count	13-44	22, 32,51
Reduced white-cell count	13-20	32,38

Flu-like syndromes, fever, fatigue and injection-site reactions are the most frequently observed side effects of IFNβ therapy. No differences in terms of the frequency and severity of side effects between therapeutic responders and non-responders have been reported. In order to better evaluate the clinical significance of these side effects, results have been analysed with reference to the type of study.

Clinical studies evaluating the safety of IFNβ

In a study of 8 naï ve patients, Chemello et al[32] found that treatment with i v natural human fibroblast IFNβ was well tolerated, the predominant side effect was a mild form of a flu-like syndrome, which lasted between 3 and 23 days after the initiation of therapy. No hematologic toxicity was observed and reductions in white-blood-cell and platelet counts occurred in only one patient. A low side-effect rate was also observed in a study of 90 naï ve patients treated with i m IFNβ for 6 months[33]. In fact, mild flu-like syndromes appeared in less than 10% of treated patients and asthenia in 16% of patients. The frequency of other side effects was less than 10%. The same investigators[34] obtained similar results in another study of naï ve patients treated with s c IFNβ. A good safety profile with mild, transient flu-like syndromes as the predominant side effect was documented in two Italian studies[35,36] performed in patients previously unresponsive to IFNα and subsequently treated with i v IFNβ. Pellicano et al[37] treated 30 patients who did not respond to a standard course of IFNα therapy with rhIFNβ-1a (12 MU s.c., t.i.w.) for 3 months. The observed rate of flu-like symptoms, inflammation at the injection site, abdominal symptoms and psychiatric disturbances were 63%, 43%, 26% and 13%, respectively.

Clinical studies comparing different doses of IFNβ

In a study of 92 naï ve patients, Fesce et al[24] compared two

different doses of i m natural human fibroblast IFNβ: 3 MU and 6 MU t.i.w. for 12 months. Compared to the low-dose group, an increased frequency of flu-like syndromes (17% vs 9%), weakness (73% vs 57%), headache (48% vs 30%) and irritability (23% vs 11%) was documented in the high-dose group. However, these differences were not statistically significant. Habersetzer et al[25] compared two different doses of recombinant IFNβ-1a administered s c for 24 weeks in 21 naï ve patients: 9 MU t.i.w. and 12 MU t.i.w. No differences were found between the two groups with regards to individual side effects. In a study aimed at comparing i v IFNβ 3 MU twice daily vs 6 MU once daily in genotype-1b HCV-infected patients with high virus titres[23], side effects were found to be more prevalent in the 3-MU group, particularly proteinuria (56% vs 30%) and thrombocytopenia (44% vs 20%).

Clinical studies comparing the safety of IFNβ to IFNα

Several studies comparing the safety of IFNβ and IFNα have been performed[29,30,38-42].

Frosi et al[38] compared IFNα and IFNβ in 20 naï ve patients treated for 6 months and did not observe any significant differences between the two treatment groups in terms of the frequency of adverse events. In another study[39], flu-like syndromes and hair loss were less frequent in the IFNβ group (16% and 16%, respectively) compared to the IFNα group (86% and 57%, respectively), the frequency of other adverse events were similar between the two groups. Cecere et al[40] evaluated the efficacy and tolerability of the following types of IFN in 150 patients: lymphoblastoid IFNα, leukocytic IFNα and natural IFNβ. The frequency of side effects was lower in the IFNβ group than in the other treatment groups. In the IFNβ, the frequency of lymphoblastoid IFNα and leukocytic IFNα, respectively, fever was present in 66.8%, 83.9% and 73.4%, the frequency of bone and muscle pains in 33%, 72.5% and 46.3%, fatigue in 21%, 52% and 31%, and the frequency of weight loss in 6%, 21% and 15%. Barbaro et al[30] found no significant differences in the rates of side effects and treatment discontinuation between IFNβ-treated and recombinant IFNα-2b plus ribavirin-treated patients (n=200) who were non-responders to previous IFNα-2b therapy.

Clinical studies evaluating combination therapy (IFNβ plus ribavirin)

Kakumu et al[43] compared the efficacy of ribavirin alone, IFNβ alone and combined ribavirin/IFNβ therapy. The combined therapy was found to significantly reduce red-blood-cell count and hemoglobin concentrations. A significant reduction in white-blood-cell count was documented in the IFNβ and combined treatment groups. Despite these findings, all enrolled patients completed the study. More recently, a multicenter, randomised and controlled study has been performed[44] to compare rhIFNβ alone or in combination with ribavirin. One hundred and two naï ve patients with chronic hepatitis C were randomized to receive either rhIFNβ-1a alone (6 MU, s c, everyday) or in combination with ribavirin for 6 weeks. All patients in the IFNβ-alone group completed the study, while 3 of 51 patients in the combined treatment group stopped therapy due to adverse events. Overall, both treatment regimens were well tolerated, hematological and hematochemical parameters remained unchanged by the end of the study period (except for a significant decrease in hemoglobin levels in the combined treatment group).

Clinical studies in sub-populations of patients

Vezzoli et al[45] evaluated the efficacy and safety of IFNβ in 10 patients with genotype-1b HCV hepatitis who were

unresponsive to a previous cycle of IFNα treatment, no reference to side effects was reported. Bernardinello *et al*[46] examined the safety and tolerability of natural i m IFNβ in 61 patients with HCV-related cirrhosis and found that the treatment was well tolerated, the most frequent side effects were fatigue (24%), irritability or depression (21%), arthromyalgias (21%), headache (21%) and flu-like symptoms (16%). The frequency of these adverse events are similar to those found in chronic hepatitis patients without cirrhosis using IFNβ. Interestingly, in this study, the probability of developing clinically significant liver-related events during the follow-up period was not significantly different in untreated *versus* treated patients (the cumulative probability of decompensation at 60 months was 24% in treated patients and 35% in untreated ones). Although a recent Cochrane review[47] states that there is no definitive conclusion about the safety of IFNβ in acute hepatitis, IFNβ has been used in patients with acute hepatitis without causing significant side effects[48-50]. Takano *et al*[49] studied the effects of six different IFNβ treatment schedules in 97 patients with acute non-A, non-B hepatitis. The authors did not report data regarding the safety of IFNβ, however, all enrolled patients completed the study. A pharmacokinetic study[54] has been performed in patients with end-stage renal failure, i v infusion of natural human IFNβ was found to be safe.

CONCLUSION

HCV infection is a major health problem and efforts have been made to identify drugs able to eradicate the disease and, thereby reducing HCV-related morbidity and mortality. According to recent consensus conference reports[55,56], treatment of IFNα in combination with ribavirin represents the standard therapy for HCV-related chronic hepatitis. However, the use of high treatment doses for long periods, which is often required in subgroups of patients (i.e., those with genotype 1 disease) to reach acceptable levels of efficacy, increases the risk of side effects and as a result, can reduce patient compliance to treatment. In these cases, the search for further treatment strategies could be useful. IFNβ has been proposed as a possible therapy for chronic hepatitis. Studies examining the use of IFNβ in hepatitis originated in Japan[57] but, in recent years, studies have also been performed in Europe[25,29,30,32-38,40,44-46,53]. According to the available data, the treatment of chronic hepatitis C with IFNβ is associated with a good safety and tolerability profile. In fact, in most clinical studies, the frequency of side effects is lower, or at least similar, to that reported with IFNα therapy. Furthermore, the rate of dropouts in controlled clinical studies as well as the need for dose reductions or treatment discontinuation are very low. IFNβ has also been shown to be well tolerated and has an excellent safety profile in special patient populations, such as those with acute hepatitis[48-50], cirrhosis[46], and renal insufficiency[54].

The goals of treatment strategies for HCV-related chronic hepatitis are to eradicate HCV infection and to reduce disease progression. The availability of different therapeutic choices is critical in achieving these goals, particularly in patients unresponsive to a standard course of antiviral therapy. Due to its good safety profile, IFNβ may represent a possible second-line therapy if additional clinical studies can confirm this drug's efficacy, mainly in combination with ribavirin.

The eradication of HCV and the prevention or slowing of disease progression are clinical challenges that require a careful cost/benefit analysis. In order to expand the population of patients eligible for therapy and to treat subjects who cannot tolerate first-line treatments, new therapeutic options should be evaluated. If further studies will confirm the efficacy of combined IFNβ and ribavirin treatment, this regimen can represent a safe, alternative therapeutic option.

Abstract

AIM: Disruption of cell cycle regulation is a critical event in carcinogenesis, and alteration of the retinoblastoma (pRb) tumour suppressor pathway is frequent. The aim of this study was to compare alterations in this pathway in proximal and distal gastric carcinogenesis in an effort to explain the observed striking epidemiological differences.

METHODS: Immunohistochemistry was performed to investigate expression of p16 and pRb in the following groups of both proximal (cardia) and distal (antral) tissue samples: (a) biopsies showing normal mucosa, (b) biopsies showing intestinal metaplasia and, (c) gastric cancer resection specimens including uninvolved mucosa and tumour.

RESULTS: In the antrum there were highly significant trends for increased p16 expression with concomitant (and in the group of carcinomas inversely proportional) decreased pRb expression from normal mucosa to intestinal metaplasia to uninvolved mucosa (from cancer resections) to carcinoma. In the cardia, there were no differences in p16 expression between the various types of tissue samples whereas pRb expression was higher in normal mucosa compared with intestinal metaplasia and tissue from cancer resections.

CONCLUSION: Alterations in the pRb pathway appear to play a more significant role in distal gastric carcinogenesis. It may be an early event in the former location since the trend towards p16 overexpression with concomitant pRb underexpression was seen as early as between normal mucosa and intestinal metaplasia. Importantly, the marked differences in expression of pRb and p16 between the cardia and antrum strongly support the hypothesis that tumours of the two locations are genetically different which may account for some of the observed epidemiological differences.

INTRODUCTION

In the last decades the pattern of incidence of gastric cancer in the Western world has changed. Distal (corpus and antrum) cancers have decreased slightly whereas proximal (cardia/gastro-oesophageal) cancers have increased more than any other cancer[1,2]. The tumours are morphologically indistinguishable and intestinal metaplasia (IM) appears to be an important step in carcinogenesis in both sites[3,4]. The observed epidemiological differences are likely to be due to differences in the genetic pathways of carcinogenesis. However, so far they are poorly evaluated[4-6].

Abnormal regulation of the cell cycle is a feature of many neoplasms[7]. Regulation of the G1/S checkpoint is critical and is controlled by the retinoblastoma protein (pRb). Phosphorylated pRb releases E2F transcription factors which activate genes involved in DNA synthesis and cause G1/S transition. Phosphorylation of pRb is stimulated by the cyclin dependent kinase (CDK) 4-cyclin D complex. p16 specifically binds CDK4 which displaces it from cyclin D and thus acts to maintain pRb in an underphosphorylated state which causes G1 arrest[8]. Disruption of this so-called 'Rb pathway' is a critical event in many tumours. It is resulted from primary inactivation of Rb function, by overexpression of CDKs, or through loss of p16[7] which has a similar effect of G1/S progression. Several studies have shown a reciprocal expression of p16 and pRb[9,10]. The role of the pRb pathway in gastric carcinogenesis is the subject of many papers. In distal gastric cancers it may be that disruption of p16 is an early event[11] and a recent immunohistochemical study[12] has shown a progressive decrease in expression from gastritis to atrophy and dysplasia. Less information is available on the role of pRb expression.

The aim of the present study was to compare the role of the pRb pathway in proximal and distal gastric cancers. p16 and pRb immunoexpression was investigated in the following groups of both proximal (cardia) and distal (antral) tissue samples: (a) biopsies showing normal mucosa, (b) biopsies showing intestinal metaplasia and, (c) gastric cancer resection specimens including uninvolved mucosa and tumour.

MATERIALS AND METHODS

Patient and specimen data

Six groups were included in this cross sectional study on archival, paraffin embedded tissues. The material was retrieved from the files in Beaumont Hospital, Dublin, Ireland and the local ethics committee approved the study. Tissue samples from the gastric cardia included endoscopic biopsies showing histologically normal mucosa ($n=56$) or IM ($n=49$) and material from gastric cancer resection specimens ($n=39$). Non-involved mucosa as well as tumour were investigated in the latter specimens. Tissue samples from the gastric antrum included the same groups: Normal ($n=52$), IM ($n=50$) as well as non-involved mucosa and tumour from cancer resections ($n=78$). All patients were Caucasians. Clinical details are shown in Table 1.

Endoscopic biopsy material was obtained from patients who had presented to the endoscopy service with a variety of upper gastrointestinal symptoms. Biopsies of the cardia were

Table 1 Clinical data

	Proximal			Distal		
	Biopsies normal	Biopsies IM	Cancer resections	Biopsies normal	Biopsies IM	Cancer resections
Number of subjects	56	49	39	52	50	78
Gender{F/M}	28/28	22/27	13/26	30/22	29/21	34/44
Age, years Mean and (SD)	50 (16)	58 (16)$_A$	67 (11)$_B$	52 (18)	59 (14)$_C$	69 (10)$_D$
Tumour type			30 Intestinal 9 Diffuse			42 Intestinal 36 Diffuse
TNM-stage, mean and (SD)			T 3.1 (0.6) N 1.0 (0.8)			T 3.0 (1.1) N 1.0 (0.8)

There was a significant stepwise increase in patient age between patients with biopsies showing normal mucosa to patients with biopsies showing IM to patients with gastric cancer resections in both proximal and distal locations. A-D, $P<0.0001$. SD=Standard deviation.

only included when clearly labelled as such on the original request form without any endoscopic suspicion of Barrett's oesophagus or any prior or subsequent oesophageal biopsies showing Barrett's metaplasia. The distinction between proximal and distal gastric cancers was made on the basis of the clinical data as well as macroscopic description of the resection specimens on the pathology report. A case was labelled as proximal gastric cancer if it straddled the gastro-oesophageal junction with approximately equal amounts in the oesophagus and stomach and no histological evidence of Barrett's mucosa in the oesophagus. Distal gastric cancers were labelled as such when the tumour was clinically, macroscopically and histologically (i.e. at no point adjacent to squamous mucosa) confined to the more distal stomach. Tumours were classified according to the Lauren classification[13] as diffuse or intestinal.

Methods

Initially, 4 μm sections were cut from all blocks and stained with haematoxylin and eosin. Tissue microarrays (TMAs) were constructed[14]. The technique involves taking cylindrical core biopsies from 'donor' blocks with subsequent precise arraying into a new 'recipient' paraffin block using a precision instrument (Beecher Instruments, Silver Spring, MD, USA)[14,15]. Two different types of TMAs were constructed. Endoscopic biopsy fragments from wax blocks were arrayed using 2 mm punches. This size punch covers most endoscopic fragments in toto and *all* individual fragments from a donor wax block were sampled in separate cores (in this study 1-8 cores per donor block). Therefore, all the tissue from an original donor block containing endoscopic biopsy material was arrayed into the TMA block. Each 'biopsy-TMA' could hold up to 40 2 mm cores (i.e. up to 40 donor blocks depending on numbers of tissue fragments per original donor block). In the cancer resection specimens a different type of TMA was constructed due to the large size of tissue pieces in each block. The whole-section glass-slides were evaluated and areas of tumour as well as uninvolved mucosa were marked on the glass slides and identified in the corresponding wax blocks. Four 0.6 mm core biopsies were taken from each area. In 31 cases tumour and uninvolved mucosa were not present in the same wax block and two separate blocks were used. In this fashion, a total of 8 cores were taken per case (4 from tumour and 4 from uninvolved mucosa) with 35-40 cases (a total of 280-320 cores) fitted on to each TMA-block. Using TMAs the total number of TMA-blocks constructed was twenty-one.

Immunohistochemistry

Monoclonal mouse antibodies directed against p16 (1:100. Clone G175-405, PharMingen, USA) and pRb (1:300. Clone M7131, DAKO, Denmark) were used. Immunostaining was performed using standard procedures. Heat mediated antigen retrieval using a pressure cooker was required to unmask the antigen sites. Antibody binding was detected using the Vectastain universal elite ABC-peroxidase kit (Vector Laboratories Inc., Burlingame, CA, USA). The positive p16 control was a case of severe uterine cervical dysplasia which strongly expressed p16 in dysplastic foci. The positive control for pRb was a multi-tissue block including tonsil.

Immunohistochemical interpretation

p16 Positive staining was defined as nuclear staining whereas cytoplasmic staining was considered non-specific and ignored. Extent was scored semi-quantitatively as negative (0) if <5% of cells stained, 1 if 5-25% of cells stained, 2 if 26-50% of cells stained and 3 if >50% cells stained. In cancer resections the average score was calculated from each of the four 0.6 mm TMA cores of either carcinoma or non-involved mucosa. The average score of each of the four decided the overall positivity/negativity.

pRb Nuclear staining was considered positive. Extent was scored semi-quantitatively as negative (0) if <5% of cells stained, 1 if 5-25% of cells stained, 2 if 26-50% of cells stained and 3 if >50% cells stained. In cancer resections the average score was calculated from each of the four 0.6 mm TMA cores of either carcinoma or non-involved mucosa. The average score of each of the four decided the overall positivity/negativity.

Statistical analysis

Statistical significance was defined as $P<0.05$. Chi-square test was used for comparison between groups. Logistic regression analysis on the actual numbers of positive cases was used to test trends between tissue types within the proximal and distal groups.

RESULTS

Comparisons of p16 expression between different histological subsets within proximal and distal locations

In mucosa from biopsies (i.e. not associated with carcinoma) with and without intestinal metaplasia there was a low level of expression in both proximal and distal locations, mainly within the neck regions of the glands and absent in superficial epithelium. In distal tissue samples there was a statistically significant stepwise increase from normal mucosa to intestinal metaplasia to non-involved mucosa from cancer resections to carcinoma ($P<0.0001$, Table 2). In proximal tissue samples no such trend was noted and there were no differences between the different tissue samples (Figure 4). No differences in p16 expression were noted between tumour types in either of the two locations and there were no correlations between p16 expression and stage of tumour or any clinical parameters.
Figure 1 Antral biopsy showing focal intestinal metaplasia. This composite figure shows the H&E appearance, negative p16 staining (with some positive inflammatory cells in the background) and positive pRb staining limited to the neck region of the glands. Original magnification 200×.

Figure 2 Gastric antral carcinoma of intestinal type. The same 0.6 mm TMA core is shown stained with H&E, p16 and pRb. The latter is negative whereas p16 shows strong nuclear and cytoplasmic staining. The cytoplasmic staining was ignored for the scoring. Original magnification 200×.

Figure 3 Gastric antral carcinoma of intestinal type. The same 0.6 mm TMA core is shown stained with H&E, p16 and pRb. The latter shows strong and crisp nuclear staining whereas p16 is negative. Original magnification 200×.

Comparisons of pRb expression between different histological subsets within proximal and distal locations

pRb was highly expressed in normal epithelium and intestinal metaplasia, mainly in the more proliferative areas, i.e. the neck region within the glandular epithelium. In both proximal and distal stomach there was a statistically significant trend for decreased pRb expression from normal mucosa to intestinal metaplasia to non-involved mucosa from cancer resections to carcinoma. It was more pronounced in the distal tissue samples ($P<0.0001$) than in the proximal tissue samples ($P=0.035$) and in the latter location it was mainly a function of the high expression in normal mucosa compared with the other histological subsets which showed very similar expression rates (Figure 5). No differences in pRb expression were noted between tumour types in the two locations and there were no correlations between pRb expression and stage of tumour or any clinical parameters.

Figure 4 Graph showing percentage of p16 positive cases as pairs of proximal (empty columns, left hand sides) and distal (black columns, right hand sides) tissue samples. N: Biopsies showing normal mucosa, IM: Biopsies showing intestinal metaplasia, NT: Non-involved mucosa from gastric cancer resection specimens, T: Tumour from gastric cancer resection specimens. There was a significant stepwise increase in expression from normal mucosa→intestinal metaplasia→non-involved mucosa from cancer resections → carcinoma in the distal stomach only. [a]There was a significantly lower p16 expression in distal normal mucosa than in proximal normal mucosa, $P=0.0045$. [b] and [c]: There was a significantly higher p16 expression in both non-involved as well as carcinoma from cancer resections from distal compared with proximal stomach, [b]$P=0.0048$ and [c]$P=0.036$.

Figure 5 Graph showing percentage of pRb positive cases as pairs of proximal (empty columns, left hand side) and distal (black columns, right hand side) tissue samples. N: Biopsies showing normal mucosa, IM: Biopsies showing intestinal metaplasia, NT: Non-involved mucosa from gastric cancer resection specimens, T: Tumour from gastric cancer resection specimens. There was a significant stepwise decrease in expression from normal mucosa→intestinal metaplasia→non-involved mucosa from cancer resections→carcinoma in both the

distal and proximal stomach although in the latter location it was most likely due to the high expression in normal mucosa compared with the other types of tissues. [a]There was a significantly lower pRb expression in distal than in proximal carcinomas, $P=0.0047$.

Comparison of p16 and pRb expressions between similar histological subsets in proximal versus distal location

In cancer resection specimens there was a significantly lower expression of p16 in proximal than distal location, both in uninvolved mucosa ($P=0.0048$) and carcinoma ($P=0.0036$) whereas the opposite was seen in normal mucosa ($P=0.0045$) (Figure 4). pRb expression was significantly higher in proximal carcinomas ($P=0.0047$) (Figure 5).

Correlations between pRb and p16

In distal carcinomas there was a significantly negative association between expressions of the two molecules ($P=0.043$) (Table 3).

Table 3 p16 versus pRb staining in distal gastric carcinomas

		pRb	
		+	-
p16	+	16	26
	-	22	14

This distribution was significant, $P=0.043$.

DISCUSSION

Disruption of cell cycle regulation is a critical event in carcinogenesis. Alteration of the retinoblastoma (pRb) tumour suppressor pathway, which controls the G1/S checkpoint, is a common event in many neoplasms and typically implicates abnormal expression of both pRb and p16 although other molecules may be involved.

The current study aimed to compare alterations in this pathway in proximal and distal gastric carcinogenesis in an effort to explain the observed epidemiological differences between the two sites. Immunohistochemistry was performed to investigate expression of p16 and pRb in various histological stages from normal mucosa to carcinoma in both proximal (cardia) and distal (antral) tissue samples.

The results of this study showed highly significant trends for increase in p16 expression with a concomitant decrease in pRb expression in distal tissue samples from normal mucosa to intestinal metaplasia to uninvolved mucosa from cancer resections to carcinoma. This suggests that the pRb pathway plays a definite role in distal gastric carcinogenesis. It may be an early event since the trend towards p16 overexpression and pRb underexpression was seen even between normal mucosa and intestinal metaplasia. In the proximal stomach no differences in p16 expression were seen between the various stages whereas pRb expression decreased slightly from normal mucosa to carcinoma. This seemed to be mainly an effect of a higher expression of pRb in normal mucosa compared with any of the other tissue samples. Furthermore, the trend for decreasing pRb was not matched by an increase in p16 expression and there was no inverse relationship between the two molecules in the group of carcinomas. Taken together this argues against the pRb pathway as important in proximal gastric carcinogenesis.

Other studies on (distal) gastric carcinogenesis have shown a similar p16 'overexpression' in gastric carcinomas[16,17] with weak staining in non-involved mucosa. However, a recent immunohistochemical study found a progressive p16 decrease and a pRb increase from gastritis to dysplasia[12] in samples from the cardia. This is surprising in view of the *opposite* trend

in distal gastric samples seen here and also by others[17]. The reason for this discrepancy is uncertain. In the above-mentioned study patients were from an area in China with a high incidence of gastric carcinoma and compared with the current study, different entities (chronic gastritis, dysplasia) were investigated. Also, racial differences may play a role since all the patiens in this study were Caucasians.

A study on p16 expression in normal tissues[18] showed some staining in gastric antral glands. The following scenario is therefore likely: p16 is expressed with a low frequency in the normal state, which may be related to a relatively low proliferative status. In support of this is the limited expression in glandular (proliferative area) rather than surface epithelium (quiescent area) seen here and also noted by others[17,18]. In tumours there may be loss of negative feedback through decrease in pRb expression which causes p16 overexpression and other studies have also shown an inverse relationship between expression of the two molecules[9,10]. The current study showed mainly cases of distal gastric cancer resections with gain of p16 expression in cancers compared with non-involved mucosa. However, loss of p16 expression in cancers compared with uninvolved mucosa was also seen in some cases and it is entirely possible that, whereas most cancers lose pRb function/expression, some preferentially lose p16 expression.

This study did not entirely rule out a role for the pRb pathway in proximal gastric carcinogenesis since other molecules participate in this complex cell cycle control mechanism. It is unlikely, however, since altered expression of p16 and pRb would be expected if abnormal feedback from other molecules in this pathway existed.

In conclusion this study strongly suggests that alterations in the pRb pathway are significant in distal, but not proximal, gastric carcinogenesis. In the former location it may be an early event. Importantly, this study therefore supports the hypothesis that tumours of the two locations are genetically different which may account for some of the observed epidemiological differences.

Abstract

AIM: To study the effect of NF-κB, survivin, Bcl-2 and Caspase3 on tumor necrosis factors related apoptosis inducing ligand (TRAIL) induced apoptosis of gastric cancer cells.

METHODS: Gastric cancer cells of SGC-7901, MKN28, MKN45 and AGS lines were cultured in PRMI-1640 medium and the apoptosis rates of the cells of 4 lines were observed after treatment of tumor necrosis factors related apoptosis inducing ligand (TRAIL) with a flow cytometer. The expression of NF-κB, survivin, Bcl-2 and Caspase3 in gastric cancer cells of 4 lines was analyzed with Western blot.

RESULTS: After the gastric cancer cells were exposed to TRAIL 300 ng/ml for 24 hours, the apoptosis rate was 36.05%, 20.27%, 16.50% and 11.80% in MKN28, MKN45, AGS and SGC-7901cells respectively. Western blot revealed that the expressions of NF-κB and survivin were lower in MKN28 cells than in MKN45, AGS and SGC-7901 cells. In contrast, the expression of Caspase3 was higher in MKN28 cells than in MKN45, AGS and SGC-7901 cells.

CONCLUSION: There is a selectivity of TRAIL potency to induce apoptosis in gastric cancer cells of different cell lines. The anticancer potency of TRAIL is associated with the decreased expression of NF-κB and survivin and increased expression of Caspase3 of gastric cancer cells.

INTRODUCTION

Tumor necrosis factors related apoptosis inducing ligand (TRAIL) is one of the members of TNF family. TRAIL, also known as APO-2L[1,2], is highly homologous to FasL. TRAIL is capable of inducing apoptosis of many kinds of cancer cells but nontoxic to normal cells[3-13]. It has been found that cells of different cancers and even different types of cells of a cancer exhibit significantly different sensitivity to TRAIL[14-17].

Nuclear transcript factor (NF-κB), survivin and Bcl-2 are apoptosis inhibitors and play a key role in the mechanism of anti-apoptosis of tumors[18-29]. If the activity of these factors is suppressed, tumor cells can undergo apoptosis and stop growing[30,31]. Various modulation elements of cell apoptosis exert their action through Caspase enzyme system. Among them, Caspase 3 (also known as CPP32, YAMA, or apopain) is probably the one that so far best correlates with apoptosis[32,33]. Furthermore, Caspase 3 expression could be detected in several human malignancies such as non-small cell lung carcinoma[34], esophageal squamous cell carcinoma[35] and gastric cancer[36]. The inhibition of cell apoptosis is closely related to the onset, development and sensitivity to chemotherapy of malignant tumors. Consequently, we studied the relationship of the sensitivity of the cells of 4 gastric cancer cell lines to TRAIL with the expression of NF-κB, survivin, Bcl-2 and Caspase3 in order to clarify why and how gastric cancer cells were resistant to TRAIL.

MATERIALS AND METHODS

SGC-7901 line of gastric cancer cells was preserved in our laboratory. MKN28, MKN45 and AGS cell lines were donated by our colleagues of the Fourth Military Medical University. NC membrane and mouse antihuman survivin monoclonal antibody were bought from Santa Cruz Biotech Company. Mouse antihuman NF-κB (p65) monoclonal antibody, mouse antihuman Bcl-2 monoclonal antibody, mouse antihuman Caspase3 monoclonal antibody and peroxidase-conjugated rabbit anti-mouse IgG were from the Zhongshan Company in Beijing, and ECL chemofluerescent agent kit was from DingguoBiotech Center in Beijing. TRAIL protein was prepared by ourselves[37].

Gastric cancer cells of SGC-7901, MKN28, MKN45 and AGS lines were incubated in PRMI-1640 medium and 10% inactivated calf serum. Penicillin and streptomycin were added to a final concentration of 100 u/ml. Generation transition of the cells was achieved every 3 to 5 days through the adoption of 0.25% pancreatic enzyme and 0.02% EDTA.

Gastric cancer cells in the logarithmic proliferation stage were studied. The culture medium of every cell line was distubated into 5 bottles (100 ml in each). TRAIL was added to the 5 bottles of every cell line with a final concentration of 0 ng/ml, 50 ng/ml, 100 ng/ml, 200 ng/ml and 300 ng/ml respectively. All the bottles were incubated under 37 ℃, 5%CO_2 and saturated humidity for 24 hours.

The apoptosis rate of gastric cancer cells was determined with a flow cytometer. All the cells were collected, digested and washed twice in PBS, and the floating cells were precipitated with 0.1 ml PBS. After the cells were fixed in 70% precooled ethanol for 24 hours, they were stained with PI and examined.

Western blot was used to determine the expression of NF-κB, survivin, Bcl-2 and Caspase3. The gastric cancer cells were

ruptured with lysozyme and protein concentration of cells was measured with Lowry method. The protein concentration was unified with PBS. In order to denature the protein, the samples were heated with middle molecular weight protein Marker to 100 ℃ for 3 minutes. The protein, after being separated with SDS-PAGE electrophoresis, was transferred to a piece of nitrocellulose membrane with moisture transfer technique at 100v for 2 hours. The membrane was stained with ponceau-S to confirm whether the protein transfer was successful. Five percent of defat milk powder-PBS solution was used to block the unspecific antibody binding site for one hour. Then the membrane was washed 3 times in PBS-T solution, 15 minutes each time. Monoclonal antibody solution (1:1 000) of mouse antihuman NF-κB, survivin, Bcl-2 and Caspase3 was incubated with the membrane for 1 hour respectively. Again, each piece of membrane was washed 3 times in PBS-T solution, 15 minutes each time. Then, all the membranes were incubated with rabbit antimouse IgG solution (1:1 000) for one hour. The membranes were washed 3 times in PBS-T solution, 15 minutes each time. Eventually, the membranes were incubated with chemofluorescent agent for 5 minutes, and then were exposed to X-ray films in a dark room. The X-ray films were developed and examined.

SPSS statistic soft package was used to undergo single factor Chi square analysis and *t* test. $P<0.05$ was considered as significant.

RESULTS

TRAIL exerted a considerable apoptosis-inducing effect on the 4 line gastric cancer cells and the effect was in a dosage dependent manner. Figure 1 shows that the gastric cancer cells of the 4 lines had a different sensitivity to TRAIL. After the action of 300 ng/ml TRAIL for 24 hours, the apoptosis rate was 36.05% in MKN28, 20.27% in MKN45, 16.50% in AGS and 11.80% in SGC-7901 lines. The apoptosis rate was significantly higher in MKN28 than in other 3 kinds of cells ($P<0.05$), but there was no significant difference among the other 3 lines of gastric cancer cells. SGC-7901 cells were resistant to TRAIL.

Figure 1 Changes of apoptosis rate in 4 gastric cancer cell lines after 24 hours action of different dosage of TRAIL.

The expression of NF-κB (p65) in the 4 lines of gastric cancer cells is shown in Figure 2. NF-κB expression was lower in MKN28 than in SGC-7901 cells, but no significant difference was found between MKN45 and AGS cells.

Before administration of TRAIL, Western blot revealed that the expression of survivin was significantly lower in MKN28 than in SGC-7901 cells, and no significant difference was found between MKN45 and AGS cells (Figure 3).

Before administration of TRAIL, Western blot revealed that the expression of Bcl-2 had no significant difference in the 4 line gastric cancer cells (Figure 4).

Before administration of TRAIL, Western blot showed that the expression of Caspase 3 was lower in SGC-7901 and highest in MKN28 cells. The expression in AGS and MKN45 cells was in the middle range (Figure 5).

DISCUSSION

TRAIL is a recently discovered apoptosis inducing molecule. It has aroused great interest in the medical circle because it can selectively induce cancer cells, transform cells and virus-infected cells to undergo apoptosis with no toxicity to normal cells. In this study, anticancer effect of TRAIL on the 4 lines of gastric cancer cells was observed. We found that TRAIL exerted a certain degree of apoptosis inducing action on the gastric cancer cells and the action potency was dosage dependent. Twenty-four hours after administration of 300 ng/ml TRAIL, the apoptosis rate was 36.05% in MKN28, 20.27% in MKN45, 16.50% in AGS and 11.80% in SGC-7901 cells. This implies that the sensitivity to apoptosis inducing action of TRAIL varied among the 4 lines of gastric cancer cells.

Apoptosis is a cellular suicidal action. This process is under the combined modulation of apoptosis promoting factors including p53, Fas and others and apoptosis inhibiting factors including Bcl-2, CIAP, survivin and others. Survivin is an inhibitor of apoptosis protein (IAP), which has been found to be crucial for mitosis and cell cycle progression[38]. Survivin could act directly on Caspases and mainly suppress the activity of Caspase 3 and Caspase7[39]. Disruption of survivin-microtubule interactions could result in loss of survivin's anti-apoptosis function and increase caspase-3 activity, a mechanism involved in cell death during mitosis[40]. In addition, it has been found that deficiency of survivin in transgenic mice could exacerbate Fas-induced apoptosis via mitochondrial pathways[41]. In the present study, we found that the difference of sensitivity to TRAIL among the 4 lines of gastric cancer

cells was related to the expression of survivin and Caspase of the cells. SGC-7901 cells with high expression of survivin and low expression of Caspase 3 were resistant to TRAIL, but MKN28 cells with low expression of survivin and high expression of Caspase 3 were sensitive to TRAIL. So, the determination of the expression level of survivin and Caspase 3 in gastric cancer cells is helpful to determine whether the cells are sensitive to TRAIL. To suppress the expression of survivin and increase the expression of Caspase 3 could strengthen the sensitivity of gastric cancer cells to TRAIL[42].

The transcription factor NF-κB is a key regulator of immune responses and inflammation operating through the induction of numerous genes, including those coding for cytokines, chemokines and adhesion molecules[43-45]. NF-κB suppresses apoptosis by inducing expression of a number of genes whose products inhibit apoptosis, including inhibitors of apoptosis (IAPs), Caspase 8-FADD-like IL-1β-converting enzyme (Caspase 8-FLICE) inhibitory protein (cFLIP), A1 (also known as Bfl1), TNF receptor associated factor 1 (TRAF1) and TRAF2. These anti-apoptotic proteins have been found to work in a coordinated fashion to block apoptosis at multiple steps along the apoptotic cascade or to regulate other pro- or anti-apoptotic pathways[46]. NF-κB could also regulate the expression of several members of the Bcl-2 family[47]. In this study, we found that the sensitivity of the 4 line gastric cancer cells to TRAIL was related to the expression of NF-κB. SGC-7901 cells showed a relatively high expression of NF-κB and were resistant to TRAIL. On the contrary, MKN28 cells with a low expression of NF-κB were sensitive to TRAIL. It is considered that suppression of the expression of NF-κB in gastric cancer cells can increase their sensitivity to TRAIL.

Bcl-2 is a proto-oncogene and can suppress apoptosis. Bcl-2 has been found to be closely related to the onset and drug resistance of many kinds of malignant tumors[48-52]. Previous studies have confirmed that overexpression of Bcl-2 in the cells of various malignant tumors could result in resistance against cell apoptosis induced by chemotherapeutic agents such as cisplatin[53,54] and arsenic trioxide[55]. If Bcl-2 expression is suppressed, tumors are impelled to undergo apoptosis. We found that the sensitivity difference among the 4 lines of gastric cancer cells was not related with Bcl-2 expression, but the sensitivity difference to TRAIL did occur among them. This finding was in agreement with the recently published data on breast cancer[56].

To sum up, TRAIL possesses the characteristics of selectively inducing apoptosis of tumor cells. TRAIL-resistant tumor cells may be related to the expression of apoptosis-inhibitor survivin and NF-κB. Suppression of the expression of survivin and NF-κB, and reinforcement of Caspase 3 expression would increase the sensitivity of gastric cancer cells to TRAIL. Further study is imperative to clarify the mechanism of the apoptosis-inducing action of TRAIL.

Abstract

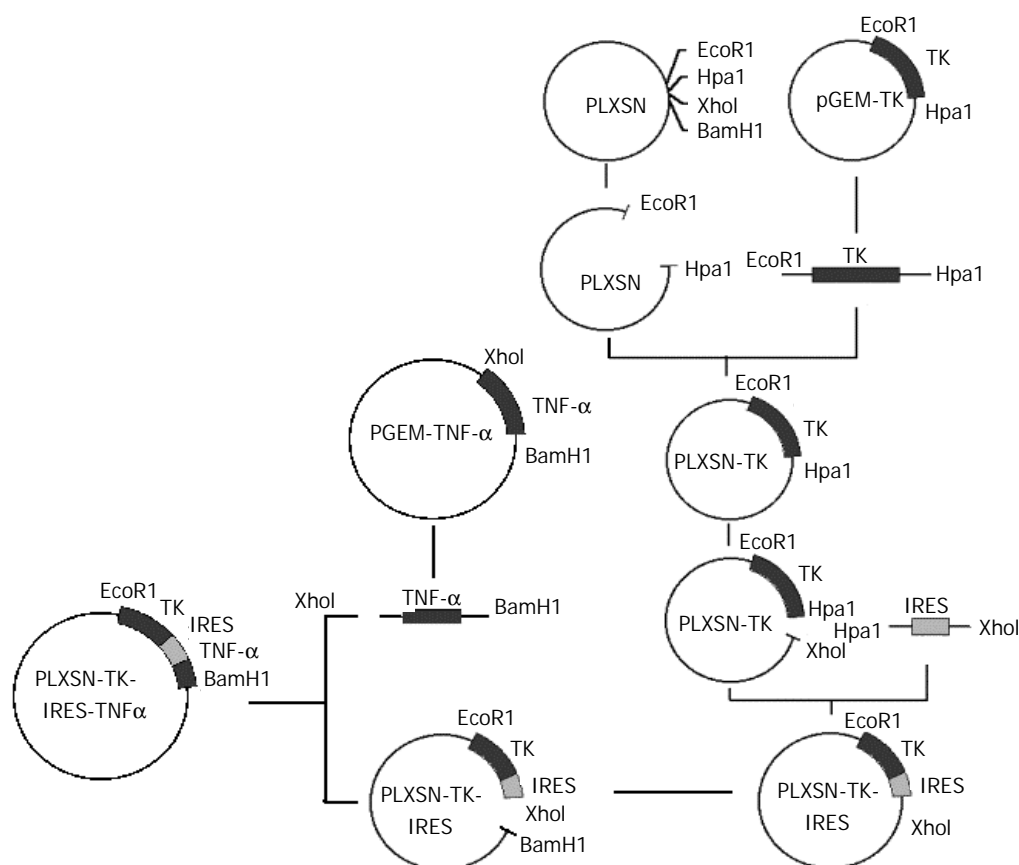
AIM: To construct and identify the recombinant vectors carrying herpes simplex virus thymidine kinase (HSV-TK) and tumor necrosis factor alpha (TNF-α) or interleukin-2 (IL-2) genes expressed in gastric carcinoma cell line SGC7901.

METHODS: The fragments of HSV-TK, internal ribosome entry sites (IRES) and TNF-α or IL-2 genes were inserted in a TK-IRES-TNF-α or TK-IRES-IL-2 order into pEGFP-N$_3$ and pLXSN to generate the therapeutic vectors pEGFP-TT, pEGFP-TI, pL(TT)SN and pL(TI)SN respectively, which were structurally confirmed by the digestion analysis of restriction endonuclease. The former two plasmids were used for the transient expression of recombinant proteins in the target cells while pL(TT)SN and pL(TI)SN were transfected into SGC7901 cells by lipofectamine for the stable expression of objective genes through G418 selection. The protein products expressed transiently and stably in SGC7901 cells by the constructed vectors were confirmed by fluorescent microscopy and Western blot respectively.

RESULTS: The inserted fragments in all constructed plasmids were structurally confirmed to be consistent with that of the published data. In the transient expression, both pEGFP-TT and pEGFP-TI were shown expressed in nearly 50% of the transfected SGC7901 cells. Similarly, the G418 selected vectors PL(TT)SN and PL(TI)SN were confirmed to be successful in the stable expression of the objective proteins in the target cells.

CONCLUSION: The constructed recombinant vectors in the present study that can express the suicide gene TK in combination with cytokines genes may serve as the potential tools to perform more effective investigations in future for the gene therapy of gastric carcinoma.

INTRODUCTION

Gastric cancer is one of the most common malignancies both in China and abroad[1-7]. Despite the improvements in surgical techniques, radiation and chemotherapeutic regimens, the disease remains a great challenge. Most patients still die finally of their disease, even after apparent "curative resection". In recent years, the promising conception of gene therapy has been advocated in a hope to deal with the malignant diseases more effectively. One of the landmark discoveries for this therapeutic strategy is the transfer of suicide genes, such as HSV-TK, into the tumor cells, which has been shown to exert antitumor efficacy on a variety of cancer cells[8-11]. The expressed HSV-TK/ganciclovir (GCV) system can not only inhibit the DNA synthesis of the target cells but also produce a bystander effect against tumors[12-16]. However, these effects have been found to be unstable in some of the transfected cells, which may result in a decreased efficiency in the treatment of malignancies. The use of tissue-specific vectors to deliver genes and combination of TK with cytokine genes may improve the efficacy of the antitumor effects[17-20]. In the present study, therefore, we tried to construct and identify the recombinant vectors containing HSV-TK, IRES in combination with cytokine genes, TNF-α or IL-2, in an attempt to establish more effective recombinants for the gene therapy of gastric malignances.


MATERIALS AND METHODS

Materials

Reagents Restriction enzymes (*EcoR* I, *Hpa* I, *Xho* I and *BamH*I), T$_4$ DNA ligase and *Taq* DNA polymerase were purchased from Gibco Co., USA. Lipofectamine was supplied by Boeringer Mannheim Co., Mannheim, Germany. Monoclonal antibodies of mouse anti-IL-2 and anti-TNF-α proteins and horseradish peroxidate-conjugated antimouse immunoglobulin were purchased from Zhongshan Co., Shanghai, China.
PCR primers The primer sequences used in the study were designed according to that of the individual genes (Table 1) with the modification of adding the recognition site sequences for the corresponding restriction enzymes (*Eco*R I, *Hpa* I, *Xho* I and *Bam*H I), and synthesized by Shanghai GeneCore Bio Technologies Co.
Plasmids and cell lines Plasmid pBluescript-TK was provided by Shanghai Institute of Biochemistry. pIRZA1neo with 585 bp IRES sequence[21,22] was purchased from Invitrogen Co., USA. The plasmid PT$_7$-TNF-α, pEGFP-N$_3$ carrying green fluorescent protein (GFP) gene, pGEM-T-Easy vector and *E.coli* JM109 were provided by Orthopedic Oncology Institute of PLA,

Figure 1 Diagram of the construction of the expression vector PL(TT)SN.

Xi' an, China. The retroviral expressing vector pLXSN was provided by Dr. Yu Bing from Fourth Military Medical University, Xi' an, China. IL-2 cDNA was made from human peripheral blood by RT-PCR.

The gastric carcinoma cell line SGC7901 was provided by Shanghai Institute of Biochemistry. Virus packaging cell PA317 and NIH3T3 cell lines were provided by Dr. Yu Bing. Cells were maintained in RPMI 1640 medium supplemented with 10% FBS (Hangzhou, Sijiqing Biotech Company), 2 mM L-glutamine, 100 units /ml penicillin and 100 μg/ml streptomycin. The PA317 was used as the packaging cell and the NIH 3T3 cells were used to assay the virus titre. The cell cultures were maintained at 37 ℃ in a humidified atmosphere with 5% CO_2.

Methods

Construction of the recombinant vectors The recombinant vectors were constructed with routine molecular cloning techniques[23-25]. The DNA fragments of HSV-TK, IRES, TNF-α and IL-2 were obtained by PCR amplification with specific primers from their corresponding templates. For the transient expression of the recombinant genes, the fragments of HSV-TK, IRES, TNF-α and the fragments of HSV-TK, IRES, IL-2 were cloned into pEGFP-N₃ to generate pEGFP-TT and pEGFP-TI respectively. Similarly, those fragments were separately inserted into pLXSN to generate plasmid PL (TT) SN and PL (TI) SN as shown in Figure 1 for the selection of the stable expression vectors. The structure of all these constructed vectors was confirmed by the digestion analysis of restriction endonuclease.

Transient expression The transient expression of recombinants was performed according to the literature[26]. The constructed vectors pEGFP-TT and pEGFP-TI, and the control plasmid were transfected into SGC7901 cells with a routine protocol by lipofectamine. Twenty hours after the transfection, cells were harvested and the expressed marker protein GFP fused with the objective genes were detected under a fluorescent microscope.

Stable expression The plasmids pL(TT)SN, pL(TI)SN and pL(TK)SN were transfected respectively into PA317 cells with lipofectamine (Gibco) according to the manufacturer' s

instruction. After 48 h of transfection, G418 (Promega) was added to the culture media at a concentration of 500 mg· L^{-1} to select G418-resistant colonies. After 2-weeks' culture with the changing of the G418-containing media every 3 days, the supernatant of G418-resistant colony was collected and diluted to different concentrations to infect NIH3T3 cells, which was further undergone the G418 selection for 2w when the G418-resistant NIH3T3 colonies were counted for the determination of viral titre. The viral titer of pL(TT)SN, pL(TI)SN, pL(TK)SN and empty plasmid pLXSN were 5×10^8 CFU/L, 6×10^8 CFU/L, 1×10^9 CFU/L and 1×10^9 CFU/L respectively.

For the stable expression of recombinants, a total number of 5×10^5 SGC7901 cells were incubated in a 6-well plate for 24 h, then rinsed with serum-free RPMI 1640 medium twice and incubated with 100 μl supermatant of G418-resistant PA317 colony for 3 h. After 4-weeks' cultivation, the G418-resistant colonies designated as SGC/TK-TNF-α, SGC/TK-IL-2, SGC/TK and SGC/0 respectively were used to confirm the objective gene expression by Western blot analysis.

Western blotting analysis The SGC/TT and SGC/TI cells were incubated respectively in the six-well plates at a density of 2.5×10^5 cells/well for 24 h, followed by a further cultivation of 48 h with the culture medium replaced with 1 ml of serum-free RPMI 1640. Then the serum-free medium was totally collected, concentrated in a microconcentrator to 20 μl and subjected to electrophoresis on a 120 g· L^{-1} SDS/PAGE gel. Proteins were transferred to a nitrocellulose membrane and incubated overnight in 50 ml· L^{-1} fat free milk in PBS at 4 ℃. After washed in 10 ml· L^{-1} fat free milk, the membrane was incubated with monoclonal antibody of mouse anti-rhIL-2 or anti-TNF-α, followed by incubation with horseradish peroxidate-conjugated antimouse immunoglobulin. Proteins were detected by using the ECL kit according to the manufacturer's protocol (Amersham).

RESULTS

Identification of constructed vectors
The segment analysis by restriction endonuclease digestion confirmed that the inserted gene sequences in all of the constructed plasmids were structurally consistent with that of the published data. The inserted fragments in pEGFP-TI and pEGFP-TT were identified as shown in Figure 2.

Figure 2 Segment analyses of pEGFP-TI and pEGFP-TT by restriction endonuclease digestion. Lane 1: DNA marker (from top to bottom: 1 543, 994, 697, 515 and 337 bp); Lane 2: pEGFP-TI/*Eco*R I and *Hpa* I (TK gene 1 128 bp); Lane 3: pEGFP-TI/*Eco*RI and *Xho*I (TK+IRES 1.71kb); Lane 4: pEGFP-TI/*Xho*I and *Bam*H I (IL-2 gene 456 bp); Lane 5: pEGFP-TT/*Eco*RI and *Hpa*I (TK gene 1 128 bp); Lane 6: pEGFP-TT/*Eco*RI and *Xho*I (TK+IRES 1.71 kb); Lane 7: pEGFP-TT/*Xho*I and *Bam*HI (TNF-α gene 474 bp).

Transient expressions of GFP-TT and GFP-TI protein
Twenty hours after the transfection, the GFP fluorescence was detected under fluorescent microscope in nearly 50% of the total cells transfected with pEGFP-TT or pEGFP-TI. The fluorescence was gradually increased with time and peaked at 72 h, which indicated that the TK-IRES-IL-2 and TK-IRES-TNF-α were transiently expressed in SGC7901 cells (Figure 3 A and B).

Figure 3 Transient expression of the recombinant genes in SGC7901 cells. A: Transient expression of pEGFP-TT in SGC7901 cells×100. B: Transient expression of pEGFP-TI in SGC7901 cells ×100.

Expressions of stable transfectants
The stable expression of recombinant proteins in SGC7901 cells was confirmed by Western blotting, in which two distinct bands of 15ku and 17ku were observed on the nitrocellulose membrane, corresponding to the fragment sizes of IL-2 and TNF-α respectively (Figure 4).

Figure 4 Stably expressed recombinant protein in transduced SGC7901 cells confirmed by Western blot. Lane 1: IL-2 (15ku) expressed in SGC/TI cells; Lane 2: TNF-α (17ku) expressed in SGC/TT cells.

DISCUSSION

Gene therapy has become a promising strategy for the treatment of gastric cancer[27-31], in which the transfer of suicide genes into tumor cells has emerged as an attractive modality for the selective elimination of cancer cells[14-16,30,31]. The suicide genes encode non-mammalian enzymes that can convert nontoxic prodrugs into cellular toxic metabolites. The most widely used suicide gene is the HSV-TK/ganciclovir (GCV) system that can convert prodrug GCV into GCV monophosphate. The latter is further phosphorated by cellular kinase to form GCV

triphosphate, a toxic substance that can inhibit cellular DNA synthesis and lead to cell death. Besides, the "bystander effect" induced by TK gene can also enhance the tumor-killing capacity of the HSV-TK/GCV system[16-20,32]. Because of the antitumor properties exerted by certain cytokines such as IL-2 and TNF-α, it is believed that the gene therapy combining cytokine with TK suicide gene would be more beneficial and effective for the treatment of cancers, which has been strongly supported by some of the recently published literatures[33]. However, there are fewer reports of this therapeutic strategy applied to the antitumor study of gastric malignancy.

Construction of a bicistronic retroviral vector with an internal ribosome entry site (IRES)[34,35] allows the simultaneous expression of two genes from a single transcript, which has been demonstrated to be efficient. However, the expressive levels of the objective protein are found lower in some circumstance. Five different genes, including human IL-2, IL-4, granulocyte macrophage stimulating factor, HSV-TK and hepatitis C virus core gene, have been tested using the modified vector for the gene transfer[36,37]. The new bicistronic vector, modified by abolishing the functional viral gag initiation codon and keeping it before the 5' end to the first initiation codon of the transduced gene, has made the protein expression greatly increased compared with the original vector. As the RNA levels and splicing patterns of these two vectors remain similar, the improvement was most likely at the translation level. Thus, the incorporation of the internal ribosome entry site sequence into a proper location of the retroviral vector for gene therapy represents a promising strategy to facilitate the simultaneous and efficient expression of several genes from the same promoter[21, 22].

In the present study, we employed the strategy to construct our expression vectors, in which the IRES gene was cloned in TK-IRES-TNF-α or TK-IRES-IL-2 order and the recombinants were constructed in combination with TK and cytokine genes. In the transient expression, the constructed vectors pEGFP-TT and pEGFP-TI were shown to be effectively expressed *in vitro* as demonstrated by the appearance of the fusing fluorescent protein GFP[26,38] in nearly 50% of the transfected SGC7901 cells. Similarly, in the experiment of stable expression, the G418 selected vectors PL(TT)SN and PL(TI)SN were also confirmed to be successful in both of the transfection into the target cells and the expression of the objective proteins. All of these results indicate that the expressive vectors constructed in the present study may serve as the potential tools to perform more effective investigations for the gene therapy of gastric carcinoma in future. Further studies are therefore needed to elucidate and characterize the antitumor effects of these constructed vectors on the transfected SGC7901 cells.

Abstract

AIM: This study was to investigate whether surgery could increase cancer dissemination and postoperative recurrence in patients with hepatocellular carcinoma (HCC) by detection of human α-fetoprotein messenger RNA (hAFP mRNA). hAFP mRNA in the peripheral blood of patients with HCC has been considered as a surrogate marker for circulating tumor cells.

METHODS: Eighty-one consecutive patients who underwent curative resection for HCC entered this prospective cohort study. We examined hAFP mRNA from the peripheral blood obtained preoperatively, perioperatively, and postoperatively to correlate the prognosis after curative resections from HCC patients and from the control subjects. Detection of hAFP mRNA by reverse transcriptase and polymerase chain reaction amplification (RT-PCR) was performed with primers specifically. The relations between the clinical variables (age, sex, associated liver cirrhosis, hepatitis B virus infection, hepatitis C virus infection, serum α-fetoprotein and Child-Pugh class), the histological variables (size, capsule, vascular permeation, grade of differentiation, and daughter nodules), hAFP mRNA in peripheral blood of 3 different sessions, and postoperative course (recurrence, and recurrence related death) were analysed.

RESULTS: No hAFP mRNA was detected in control group subjects. Twenty-two (27%), 24 (30%) and 19 (23%) of 81 HCC patients had hAFP mRNA positivity in the preoperative, perioperative and postoperative peripheral blood. The preoperative presence did not influence the risk of HCC recurrence (55% vs 41%, P=0.280). In contrast, patients with postoperative presence had a significantly higher recurrence (90% vs 31%, P<0.001; odds ratio 19.2; 95% confidence interval: 4.0-91.7). In the multivariate analysis by COX proportional hazards model, postoperative positivity

had a significant influence on recurrence (P=0.067) and recurrence related mortality (P=0.017). Whereas, the perioperative positivity of hAFP mRNA did not increase HCC recurrence (58% vs.39%, P=0.093). The correlation between perioperative hAFP mRNA positivity and recurrence related mortality had no statistical significance (P=0.836).

CONCLUSION: From our study, perioperative detection of hAFP mRNA in peripheral blood of patients has no clinical relevance and significant role in the prediction of HCC recurrence. Surgical resection itself may not accelerate cancer dissemination and does not increase postoperative recurrence significantly either.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the leading malignancy with a poor prognosis in areas of high hepatitis B and C prevalence[1-4]. After curative resections of HCC, a lage proportion of patients develop tumor recurrence within the first 3 years. Whether intraoperative manipulation contributes to cancer dissemination remains a debating subject.

How to detect these disseminated cancer cells in the perioperative period is a problem. The isolation and identification of tumor cells in a small blood sample by conventional methods is very difficult because the number of malignant cells in the circulation may be extremely small[5-8]. Recently, it has become possible and sensitive to identify tumor-specific gene transcripts (messenger RNA/circular DNA) by means of polymerase chain reaction (PCR). With the use of PCR-based method which permits detection of 1 tumor cell among 10^7 normal peripheral, mononuclear blood cells, the blood-borne dispersion of tumor cells during surgical manipulation has been reported in humans with prostatic carcinoma, melanoma, breast carcinoma and pancreatic carcinoma[9-12].

For detecting HCC cells in circulation, reverse transcriptase (RT) PCR targeting human alphafetoprotein (hAFP) messenger RNA (mRNA) or human albumin mRNA has been proposed[13-22]. Lack of the specificity of albumin mRNA has been emphasized[21,22]. Human AFP mRNA has been accepted as a liver specific and cancer-specific marker[23,24]. Many clinical studies have suggested that hAFP mRNA in peripheral blood can be used as a surrogate marker of circulating HCC cells and as a prognostic indicator in patients treated with ethanol injection and/or arterial embolization[18].

In an attempt to elucidate whether surgical resection of HCC accelerated cancer dissemination, we designed this prospective study.

MATERIALS AND METHODS

Study population

From August 1995 to July 1999, 81 consecutive patients [42 men and 39 women, with a mean age of 52±13 years (range: 16 to 79 years)] with HCC undergoing curative hepatic resection at Mackay Memorial Hospital, Taipei,Taiwan, China, were enrolled in this prospective study (Table 1). Patients who had previously or simultaneously other malignant disorders, and who had previously received hepatectomy, intraoperative blood transfusion, preoperative and postoperative hepatic arterial chemoembolization (TACE) or neoadjuvant ethanol injection were all excluded.

Table 1 Demographic data including clinical and tumor variables of patients with HCC undergoing curative resection (*n*=81)

Variables	No. of patients (%)
Age (mean, years)	52±13
Male	42 (52)
Cirrhosis	56 (69)
Child- Pugh' s class A	70 (86)
HBsAg (+)	62 (77)
Anti-HCV (+)	31 (38)
Serum AFP <20 ng/ml	29 (36)
$20-10^3$ ng/ml	29 (36)
$>10^3$ ng/ml	23 (28)
Size of HCC < 3 cm	25 (30)
3-10 cm	28 (35)
> 10 cm	28 (35)
Complete capsule	28 (35)
Daughter nodules	32 (40)
Vascular permeation	37 (46)
Edmondson-Steiner' s grade I	6 (7)
grade II	36 (44)
grade III	26 (32)
grade IV	13 (16)

AFP: serum alpha fetoprotein, HBsAg(+): positive hepatitis B surface antigen, Anti-HCV(+): positive hepatitis C virus antibody, Edmondson and Steiner grade: differentiation grades I, II, III, and IV.

The hepatectomy procedure was selected according to the patient' s liver function and cancer location. Prior to resection, intraoperative ultrasonography to scan the entire hepatic field was performed in every patient. Surgery was defined as curative when all gross lesions were removed with an over 1 cm free resection margin which was proven tumor-free histologically. The surgical procedures included 62 major resections (6 extended right lobectomies, 18 right lobectomies, 14 left lobectomies, and 24 double segmentectomies) and 19 minor resections (11 segmentectomies, 5 subsegmentectomies, and 3 wedge resections).

Peripheral blood samples for detection of hAFP mRNA were obtained from all study patients from forearm one day prior to surgery (preoperation), immediately (i.e., within 12 hours) after liver resection (perioperation), and 90 days after surgery (postoperation) from all 81 patients.

After discharge, all the patients were followed up at our outpatient clinic and received regular clinical assessments to detect tumor recurrence including periodic abdominal ultrasonography (every 2-3 months during the first 5 years, then every 4-6 months thereafter), and serum AFP and liver biochemistry (every 2 months during the first 2 years, then every 4 months during the following 3 years, and every 6 months thereafter). Abdominal computed tomography scans (CT) were also done (every 6 months during the first 5 years, then every year). Hepatic arteriography was obtained if there was a suspicion of cancer recurrence from ultrasonography or CT scan, or serum AFP. Chest X ray to detect pulmonary metastasis was done every 6 months. Bone scan to detect osseous metastasis was undertaken every 6 months. Detection of tumor on any imagimg studies was defined as "clinical recurrence".

Parameters analyzed for recurrence included sex (male *vs*. female), age, the presence of liver cirrhosis, Child-Pugh class of liver functional reserve (A *vs*. B), hepatitis B virus infection (hepatitis B surface antigen), hepatitis C virus infection (anti-hepatitis C virus antibody), serum AFP level (<20 ng/ml *vs*. 20-1 000 ng/ml *vs*. >1 000 ng/ml), tumor size (<3 cm *vs*. 3-10 cm *vs*. >10 cm), tumor encapsulation (complete *vs*. incomplete or absent), presence of daughter nodules, and vascular permeation (including vascular invasion and/or tumor thrombi, in either the portal vein or hepatic vein), and cell differentiation (Edmondson and Steiner grades I, II, III and IV)(Table1).

A control group included 30 healthy volunteers without liver disease and 20 patients with chronic liver disease without evidence of HCC. They also received hAFP mRNA detection from peripheral blood.

Detection of hAFP mRNA

We used human hepatocytes to determine the sensitivity of the assay. Using tetradecytrimethyl- ammonium bromide, nucleated cells were isolated from peripheral blood. Total RNA was extracted from cryopreserved liver tissues. The sequences of the sense primers were 5' -ACT GAA TCC AGA ACA CTG CAT AG-3' (external-sense) and 5' -TGC AGT CAA TGC ATC TTT CAC CA-3' (internal-sense) and those of the antisense primers 5' -TGG AAT AGC TTC CAT ATT GGA TTC- 3' (external-antisense) and 5' -AAG TGG CTT CTT GAA CAA ACT GG- 3' (internal-antisense). The sizes of the amplified products of hAFP mRNA were 176 and 101 base pairs by external and internal primer pairs, respectively.

A Hep G2 (hepatoblastoma) cell line served as positive control for hAFP mRNA expression. For negative controls, we used EDTA treated water (filtered and vaporized). With cDNA derived from Hep G2, specific bands for hAFP (101 bp) were observed. In contrast, the cell lines that served as negative controls did not yield these bands. It was also impossible to detect free RNA extracted from 5 ml aliquots of control blood, in which Hep G2 cells were suspended. The sensitivity of our assay, determined in a dilution experiment using freshly isolated human hepatocytes (10^5 to 10^1) in 1 ml whole blood before RNA extraction, was approximately 1 hepatocyte for every 10^5 peripheral mononuclear cells.

Ethylenediamine tetraacetic acid (EDTA)-treated whole blood was centrifuged and the plasma fraction was removed. The cellular fraction was enriched for mononuclear cells (MNC) or possible tumor cells according to the method described by Oppenheim. Total cellular RNA was then extracted with PUREscript RNA isolation kits TRI-Zol (Life Technologies Inc., Gaithersburg, USA), from 5 μg of which cDNA was synthesized. The reverse transcription reaction solution contained 6 μl of 5×first strand buffer, 10 mM dithiothreitol, 125 mM each of dCTP, dATP, dGTP and dTTP, 0.3 μg of random hexamers, and 200 units of superscriptase II moloney murine leukemia virus reverse transcriptase (Life Technologies Inc.). The RNA solution was incubated at 95 ℃ for 10 minutes, quickly chilled on ice, then mixed with the reverse transcription reaction solution (total volume 20 μl), and incubated at 37 ℃ for 60 minutes. The first PCR reaction solution contained 5 μl of the synthesized cDNA solution, 10 μl of 10X polymerase reaction buffer, 500 μM each of dCTP, dATP, dGTP and dTTP, 15 pmol of each external primer (EX-sense and EX-antisense), 4 units of Thermus Brockiamus Prozyme DNA polymerase (PROtech Technology Ent. Co., Ltd. Taipei, Taiwan, China), and water. The PCR cycles were: denaturing at 94 ℃ for 1 minute, annealing at 52 ℃ for 1 minute,

and primer extension at 72 ℃ for 1 minute. The cycles were repeated 40 times. The PCR product was reamplified with internal primers for nested PCR to obtain a higher sensitivity. The first and second PCR components were the same, but for the primer pairs (IN-sense and IN-antisense), the final product was electrophoresed on 2 % agarose gel and stained with ethidium bromide for the specific band of 101 base pairs.

Statistical analysis

A statistical software (SPSS for Windows, version 8.0, Chicago, Illinois) was used, with Student' s *t*-test for continuous variables, χ^2 test or Fisher' s exact test for categorical variables. Stepwised logistic regression and COX proportional hazards model were used for multivariate stepwise analysis to identify independently significant factors in predicting recurrence and mortality. A *P* value <0.05 was defined as significant.

RESULTS

No hAFP mRNA was detected in peripheral blood of all patients in control group

In patients with HCC, hAFP mRNA in peripheral blood was detected in 27% (22/81), 30% (24/81), and 23% (19/81) preoperatively, perioperatively and postoperatively, respectively. According to hAFP mRNA status, we classified patients into 8 groups. For example, in group 1, hAFP mRNA was consistently positive preoperatively, perioperatively,and postoperatively; in group 2, positive preoperatively and perioperatively but negative postoperatively; and in group 8, consistently negative preoperatively, perioperatively, and postoperatively, *etc* (Table 2).

Thirty-six patients (44.4%) had clinically detectable recurrence during the follow-up period (median 3 years, range 2-5 years), of whom 25 died. The presence of hAFP mRNA preoperatively did not correlate with the risk of recurrence (55% *vs.* 41%, *P*=0.280) and recurrence related mortality (*P*=0.7283) (Tables 3 and 4). In contrast, patients with postoperative hAFP mRNA had a significantly higher recurrence rate (90% *vs.* 31%, *P*<0.001), with an odds ratio of 19.2 (95% confidence interval [CI]: 4.0-91.7), which was also significantly associated with recurrence related mortality (*P*=0.017) (in the multivariate analysis by COX proportional hazards model) (Tables 3 and 4). The presence of hAFP mRNA perioperatively did not significantly correlate with the risk of recurrence (58% *vs.* 39%, *P*=0.093) and the recurrence related mortality (*P*=0.836) (Tables 3 and 4).

On multivariate analysis, the significant predictors of recurrence included vascular premeation (*P*=0.023), grade of cellular differentiation (*P*=0.007) and postoperative hAFP mRNA positivity (*P*<0.001 by univariate; *P*=0.067 by multivariate, weak significance) (Table 3). The significant parameters correlating with mortality after recurrence consisted of grade of cellular differentiation (*P*=0.057, weak significance) and postoperative hAFP mRNA (*P*=0.017) (Table 4).

DISCUSSION

Surgical dissemination of tumor cells has been observed in various solid cancers and manipulation *per se* has been regarded as the main cause. According to Nishizaki, using inoculation of VX2 carcinoma into rabbit liver, manual manipulation of a tumor might well enhance metastasis[25]. According to Liotta, tumor massage resulted in at least a 10-fold rise over the initial concentration of tumor cells, as well as a higher proportion of large clumps[26]. Yamanaka *et al*. demonstrated a large quantity of HCC cells in the portal vein during hepatic resection[27]. In our series, 30% of patients had the presence of hAFP mRNA perioperatively. The detection rate seemed higher than that of preoperation (27%), and postoperation (23%), but the difference had no statistical significance among them. In addition, this increase did not correlate with postresection recurrence. Further more, from individual group point of view, we found the alteration from preoperative negativity to perioperative positivity in groups 5 and 6 (Table 2). Whereas the postoperative recurrence varied greatly (80% *vs* 0%) between them. Statistically, perioperative detection did not contribute to cancer dissemination (Table 3).

The interpretation of detection of hAFP mRNA remains controversial. From our study, among 3 different sessions of blood sampling, only postoperative detection of hAFP mRNA correlated significantly with postresection recurrence related mortality. We proposed that some possible factors contributed to the different significance among the three different blood sampling times.

The detection before surgery may be attributed to the cells released spontaneously from primary tumor *in situ*. HCC tissue is surrounded by a vascular space analogous to the hepatic sinusoids. Because of this anatomic structure, tumor cells might easily be released into the sinusoids spontaneously. Thereafter, they might migrate into the portal or hepatic vein and finally enter the systemic circulation. However, from our study, these preoperative circulating HCC cells had no prognostic significance.

Molecular methods now permit us to detect a small number of cancer cells in the blood by use of RT-PCR targeting a cell-specific gene. Studies in animal models have indicated that at least 10^4 circulating tumor cells are required for metastasis to develop. To date, however, the absolute number of cells required for metastasis in the human circulation is unclear and even if cancer cells are detected in the circulation, their potential to develop metastatic foci is unknown. When malignant cells were released into the circulation, a variety of host and tumor cell factors could determine their distribution and fate[28-33]. Most circulating HCC cells may rapidly die in the blood by various host immune and non-immune defenses, and are destroyed by mechanical forces, including turbulence and the trauma associated with vascular adhesion and transcapillary passage, or lysed by lymphocytes, monocytes, and natural killer (NK) cells. Some tumor cells are nonspecifically trapped or specifically arrested in the first capillary bed encountered. Circulating tumor cells trapped in a given location could then recirculate and arrest at other locations, then grow into tumor colonies[29-33].

Okuda *et al*[34] and Komeda *et al*[14] could not detect any hAFP gene transcripts in patients with liver metastases or in healthy persons. Ijichi *et al* considered this RT-PCR assay targeting hAFP mRNA as a sensitive and specific method for detecting HCC cells in the circulation *in vivo* and *in vitro* experiments, and no positivity was found in any healthy controls[35]. From our study, hAFP mRNA could not be detected from all the 50 controls. However, some authors suggested that AFP gene wass not hepatoma-specific, but rather a liver-specific marker[13,15,17,18,36,37].

Surgery itself may increase the release of liver cells, not only HCC cells but also normal hepatocytes. Both kinds of cells may contribute to the positivity of hAFP mRNA. According to Louha M, not only liver surgery but also nonsurgical invasive managements such as needle liver biopsy or intervention therapies such as TACE, chemotherapy and ethanol ablation therapy, the increased shedding of either HCC cells or normal hepatocytes into circulation might contribute to the increase of detection rate of hAFP mRNA[38]. This was also the reason why we excluded those who had received these intervention therapies from the current study.

It has become a fact that RT-PCR based tests lose its specificity for HCC cell detection when they are performed on samples obtained immediately after surgical or nonsurgical invasive procedures. This pitfall may also account for the gap between the frequency of cell detection after surgery and the expected tumor recurrence rate. A consensus existed that hAFP mRNA might not be regarded as specific markers of HCC cells if blood samples were taken during liver surgery[39].

Secondly, the different site of blood sampling might contribute to the discrepancy. Central venous blood in Kienle' s study was drawn before it passed through any capillary bed, with only a short distance after leaving the liver, the cells expressing hAFP might not undergo apoptosis or were not filtered out in capillary beds, therefore possibly accounting for the high detection rate (46%) during surgery[37]. Another factor influencing the detection of hAFP mRNA in intraoperative central venous blood samples might be by a "dilution effect" following intraoperative blood transfusion[37]. This was the reason why we excluded those receiving transfusion from our study.

Thirdly, the different blood sampling time might contribute to the discrepancy. Similarly, from the literature, in intraoperative detection of other tumors, this factor also existed. Brown *et al* sampled blood at the time of maximum tumor manipulation and postoperative 24 hours in those with breast cancer[11]. Eschwege P obtained blood samples 5 minutes after prostate carcinoma removal[9]. Warr RP obtained blood samples at 2 different sessions and 24 hours postoperatively in those with malignant melanoma[10]. According to Hayashi N, the blood samples were obtained through a catheter in the portal vein before, during, and after manipulation of colorectal cancer[40].

Lemonie obtained peripheral blood samples at two different intervals: the first, during the exploratory phase and the second, after hepatectomy was completed[41]. Witzigmarn obtained blood samples before and during the operation (after mobilization of the liver), and on the second postoperative day[39]. Louha obtained peripheral blood samples before treatment, 1 hour and 24 hours after percutaneous ethanol injection or TACE treatment[38]. Witzigmann obtained blood samples on the second day after TACE[39].

Louha found unexpectedly that liver cells began spreading at an early stage during surgery, i.e., after liver mobilization and rotation, before liver parenchyma transection. This was probably related to the sponge-like structure of the liver and to the stretching and compression of the organ during liver mobilization[42]. Surgery-related liver cell spreading also occurred more frequently, compared with that induced by needle liver biopsy. This difference of cell number was probably related to the different degree of manipulation on the liver between resection and biopsy.

In the present study, we selected the sampling time within the first 12 hours after hepatectomy because of two reasons. First, the so-called "maximal manipulation" during surgery was usually difficult to define. The degrees of manipulation among the mobilization of the liver, or the division of important vessels and ducts of the segment or lobe, and the dissection of

hepatic parenchyma, were difficult to quantitate. In addition, the detailed procedure among individual patients varied. Second, we believed that within 12 hours after resection, the released cells, if present, might still remain. Funaki, Okuda, and Ijichi thought destruction of circulating HCC cells transiently liberated during surgery needed 7 days[15,34,35].

From prognostic point of view, in literature, whether the shedding of cancer cells during intraoperative manipulation contributed to cancer dissemination and postoperative recurrence has remained debatabe[33].

Witzigmann[39] and Lemonie[41] did not find any correlation between postresection recurrence of HCC and the presence of hAFP mRNA irrespective of whether it was measured before, during, or after surgery. Lemonie mentioned that his result concurred with other experimental and clinical data, suggesting that release of abnormal cells in the circulation, either spontaneously or secondary to surgical manipulation, was an intermittent and transient phenomenon[41]. Okuda found that most patients whose hAFP mRNA was not detected in peripheral blood perioperatively were diagnosed as free of intrahepatic recurrence or distant metastasis within 9 months after the operation[34].

In contrast, Ijichi *et al*. suggested that surgical dissemination might actually cause HCC recurrence within a short period[35]. The fact that alteration from negative to positive hAFP mRNA throughout the perioperative time might indicate a high risk of recurrence has been emphasized by Okuda[34]. Funaki *et al* reported that hAFP mRNA positive 2-3 days after the operation might be thought of as a high risk indicator of recurrence[15]. Ferris found HCC recurred in 28% of patients with HCC after orthotopic liver transplantation[43]. Ferris inferred that circulating HCC cells were present in the peripheral blood even after removal of the diseased liver, and that these residual tumor cells formed intra-and extra-hepatic metastatic foci after transplantation. To decrease cancer dissemination, we suggest that forceful mobilization or manipulation of the liver has to be avoided.

In addition, some studies have proposed anesthesia and unrelated surgery promote the spread of malignant disease[44]. It is another challenging issue whether surgery per se, or general anesthesia *per se*, or both, may change the immune system of the host perioperatively and increase the opportunity of postoperative cancer spread.

Based on Salo' s animal studies, during an operation, operative trauma was generally considered to have a greater role than anaesthesia in altering immune responses. The immune responses to major surgery, and operative complications resulting in massive mediator release might place the patient at risk[44].

Recent investigations have suggested that general anesthesia may cause an unregulated activation of the process of apoptosis leading to lymphocytopenia and immune suppression resulting in different response in B-lymphocytes (but not in T-lymphocytes), natural killer cell activity or antibody-dependent cellular cytotoxicity 3-4 days after surgery[44,45]. The true trigger mechanisms are still unclear. However, lymphocytopenia was not found in our patients, and it might not have significant contribution to recurrence. The association between transfusion-induced immunosuppression and poorer prognosis in patients with cancer has also been mentioned[46]. It was also the reason why we excluded those receiving intraoperative transfusion from this study.

The postoperative presence of circulating HCC cells may therefore represent surviving malignancy that can continue the metastatic process. The possible explanations are as follows. A proportion of cancer cells released from the resected tumor (s) survive in the circulation for a long time without being destroyed, or the presence of unresected occult metastases are undetectable at the time of surgery, or a newly developing

malignant focus is too small to be detected by conventional follow-up studies.

Perioperative detection of hAFP mRNA has no relevant and significant role in the prediction of prognosis. We suggest surgical resection itself accelerate cancer dissemination and does not increase postoperative recurrence significantly either.

Abstract

AIM: To study the effect of *Ginkgo biloba* extract (EGb 761) containing 22-27% flavonoids (ginkgo-flavone glycosides) and 5-7% terpenoids (ginkgolides and bilobalides) on cell proliferation and cytotoxicity in human hepatocellular carcinoma (HCC) cells.

METHODS: Human HCC cell lines (HepG2 and Hep3B) were incubated with various concentrations (0-1 000 mg/L) of EGb 761 solution. After 24 h incubation, cell proliferation and cytotoxicity were determined by 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium (MTS) assay and lactate dehydrogenase (LDH) release, respectively. After 48 h incubation, the expression of proliferating cell nuclear antigen (PCNA) and p53 protein was measured by Western blotting.

RESULTS: The results showed that EGb 761 (50-1 000 mg/L) significantly suppressed cell proliferation and increased LDH release ($P<0.05$) in HepG2 and Hep3B cells compared with the control group. The cell proliferation of HepG2 and Hep3B cells treated with EGb 761 (1 000 mg/L) was 45% and 39% of the control group ($P<0.05$), respectively. LDH release of HepG2 cells without and with EGb 761 (1 000 mg/L) treatment was 6.7% and 37.7%, respectively, and that of Hep3B cells without and with EGb 761 (1 000 mg/L) treatment was 7.2% and 40.3%, respectively. The expression of PCNA and p53 protein in HepG2 cells treated with EGb 761 (1 000 mg/L) was 85% and 174% of the control group, respectively.

CONCLUSION: *Ginkgo biloba* extract significantly can suppress proliferation and increase cytotoxicity in HepG2 and Hep3B cells. Additionally, *Ginkgo biloba* extract can decrease PCNA and increase p53 expression in HepG2 cells.

INTRODUCTION

Extract from the leaves of *Ginkgo biloba* (maidenhair tree) has been used therapeutically in China and Western countries for centuries. The liquid extract was made from dried leaves with an extraction ratio of 1:50[1]. Standard *Ginkgo biloba* extract, EGb 761 (commercial name), contains 22-27% flavonoids (ginkgo-flavone glycosides) and 5-7% terpenoids (ginkgolides and bilobalides), which are the most important active substances in the extract. The most important flavonoids are glycosides of kaempferol, quercetin, and isorhamnetin with glucose or rhamnose. Ginkgolides, not found in any other living species and only present in *Ginkgo biloba* extract, can be divided into types A, B, C, and a very small quantity of J, which are only different in the number and position of hydroxyl groups.

Ginkgo biloba extract has been mentioned in the traditional Chinese pharmacopoeia, and used for the treatment of asthma and bronchitis[1]. *Ginkgo biloba* extract is well known for its antioxidant property, which may result from its ability to scavenge free radicals[2], and to neutralize ferryl ion-induced peroxidation[3]. Several studies have reported that the antioxidant activity of *Ginkgo biloba* extract could be helpful in the prevention and therapy of diseases and degenerative processes associated with oxidative stress[4-8]. However, there have been very limited studies on the anti-proliferative activity of *Ginkgo biloba* extract. Ginkgetin or isoginkgetin, a biflavonoid from *Ginkgo biloba* extract, at 10 μmol/L showed a suppressive activity against lymphocyte proliferation induced by concanavalin A (ConA) or lipopolysaccharides (LPS)[9]. Additionally, Su *et al.*[10] found that ginkgetin selectively inhibited the proliferation of human ovarian carcinoma OVCAR-3 cells via the induction of apoptosis in a dose-dependent manner. So far, no study has investigated the effect of *Ginkgo biloba* extract on hepatocellular carcinoma (HCC), which is the most common malignant tumor occurred in men in Taiwan. It is reasonably hypothesized that *Ginkgo biloba* extract may be helpful for the therapy of HCC through regulating cell proliferation and/or cell death. Therefore, the purpose of this study was to investigate the cytotoxic effect of *Ginkgo biloba* extract on HCC.

MATERIALS AND METHODS

Cell culture and treatments

Human hepatocellular carcinoma cell lines, HepG2 (BCRC No. 60025) and Hep3B2.1-7 (Hep3B, BCRC No. 60434) were purchased from the Bioresources Collection and Research Center (BCRC) of the Food Industry Research and Development Institute (Hsinchu, Taiwan). Cells were grown in 900 mL/L minimum essential medium (MEM, GIBCO™, Invitrogen Corp., Carlsbad, CA) containing 100 mL/L fetal bovine serum (GIBCO™) at 37 ℃ in a humidified atmosphere of 950 mL/L air and 50 mL/L CO_2. Prior to addition of the treatment, the cells were grown to 80-90% confluency and synchronized by incubating in the basal medium (100% MEM) for 24 h. The cells were then incubated with various concentrations (0-1 000 mg/L) of standard *Ginkgo biloba* extract solution (EGb 761, Cerenin®, Dr. Willmar Schwabe GmbH and Co., Karlsruhe, Germany) for 24 or 48 h. *Ginkgo biloba* extract contained 22-27% flavonoids and 5-7% terpenoids in 10 mL/L ethanol and 10 mL/L sorbitol solution. Cells without addition of *Ginkgo biloba* extract as the control group were incubated with 10 mL/L ethanol and 10 mL/L sorbitol solution. The cells and medium were collected. Protein contents in cells and medium were

measured by the modified method of Lowry *et al.*[11] using a Bio-Rad DC protein kit (Bio-Rad Laboratories, Hercules, CA).

Cell proliferation assay

Cell viability was colorimetrically determined at 490 nm using a commercial proliferation assay kit (CellTiter 96® AQ$_{ueous}$, Promega Corp., Madison, WI). After incubation with various concentrations of EGb 761 for 24 h, the cells (*n*=8) in a 96-well plate were incubated with 333 mg/L 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium (MTS) and 25 μmol/L phenazine methosulfate solution for 3 h at 37 ℃ in a humidified, 50 mL/L CO$_2$ atmosphere[12]. The absorbance of soluble formazan produced by cellular reduction of MTS was measured at 490 nm using an ELISA reader (Multiskan RC, Labsystems, Helsinki, Finland).

Cell cytotoxicity assay

Lactate dehydrogenase (LDH) release from cells was determined as an index of cytotoxicity or necrosis. The quantity of LDH released by the cells into the medium was measured by the decrease in the absorbance at 340 nm for NADH disappearance within 5 min[13]. After incubation with various concentrations of EGb 761 for 24 h, the cell culture supernatant and medium (100 μL) were mixed with 900 μL of modified Krebs-Henseleit buffer (118 mmol/L NaCl, 4.8 mmol/L KCl, 1 mmol/L KH$_2$PO$_4$, 24 mmol/L NaHCO$_3$, 3 mmol/L CaCl$_2$, 0.8 mmol/L MgPO$_4$, pH 7.4), 0.2 mmol/L NADH, 1.36 mmol/L sodium pyruvate, and 20 mg/L bovine serum albumin (BSA). Percentage of LDH release (*n*=3) was equal to LDH activity in medium divided by that in both cell culture supernatant and medium ×100%.

Analysis of proliferating cell nuclear antigen (PCNA) and p53 protein

After incubation with various concentrations of EGb 761 for 48 h, cell suspension (15 μg and 50 μg protein for PCNA and p53) pooled from 6 independent experiments (*n*=6) was mixed with an equal volume of 2×SDS-PAGE sample buffer (0.125 mol/L Tris-HCl, pH 6.8/40 mg/L SDS/200 mL/L glycerol/100 mL/L 2-mercaptoethanol)[14], denatured at 100 ℃ for 3 min, and applied to SDS-PAGE (Bio-Rad Mini-PROTEAN 3 Cell, Bio-Rad Laboratories). Proteins were separated by 12.5% resolving gel, with 4% stacking gel in the running buffer (25 mmol/L Tris, pH 8.3/192 mmol/L glycine/ 1 mg/L SDS) at 100 V for 1.5 h. After that, the proteins were transferred onto nitrocellulose membrane (0.45 μm) using a semi-dry transfer unit (Hoefer Semiphor TE 70, Amersham Biosciences Corp., San Francisco, CA) in Towbin buffer (25 mmol/L Tris/192 mmol/L glycine/1.3 mmol/L SDS/100 mL/L methanol) at 200 mA for 1.5 h[15]. The membrane was washed briefly with PBS, and incubated with a blocking buffer (50 mg/L skim milk/1 mL/L Tween-20 in PBS) for 1 h. Then the membrane was incubated with 0.4 mg/L mouse anti-human PCNA (PC-10, 0.2 mg/L), p53 (DO-1, 0.4 mg/L), or α-tubulin (TU-02, 1 mg/L) mAb (Santa Cruz Biotechnology, Inc., Santa Cruz, CA) at room temperature for 1 h. Alpha-tubulin was as an internal control. The membrane was washed 3 times with the wash buffer (1 mL/L Tween-20 in PBS), and incubated with 0.2 mg/L goat anti-mouse IgG-horseradish peroxide conjugate (Santa Cruz Biotechnology, Inc.) for 1.5 h. The blot was washed 3 times again with the wash buffer, incubated with luminol reagent (Santa Cruz Biotechnology, Inc.) for 1 min, and exposed to an X-ray film (Eastman Kodak Co., Rochester, NY) for 5-10 s. The bands were quantitated by an image analysis system (Gel analysis system, EverGene Biotechnology, Taipei, Taiwan) and Phoretix 1D Lite software (version 4.0, Phoretix International Ltd., Newcastle upon Tyne, UK).

Statistical analysis

Data are expressed as $\bar{x} \pm s$. Data were analyzed by one-way ANOVA to determine the treatment effect using SAS (version 8.2, SAS Institute Inc., Cary, NC). Fisher' s least significant difference test was used to make *post-hoc* comparisons if the treatment effect was demonstrated. Differences were considered significant when *P*<0.05.

RESULTS

Cell proliferation assay

After 24 h incubation, EGb 761 (25-1 000 mg/L) significantly inhibited cell growth (*P*<0.05) in HepG2 cells compared with the control group in a dose-dependent manner determined by MTS assay (Figure 1). EGb 761 at 750 and 1 000 mg/L inhibited cell growth to 50% and 45% of the control, respectively, in HepG2 cells. Similarly, EGb 761 (50-1 000 mg/L) dose-dependently inhibited cell growth (*P*<0.05) in Hep3B cells compared with the control group. EGb 761 at 750 and 1 000 mg/L inhibited cell growth to 48% and 39% of the control, respectively, in Hep3B cells.

Figure 1 Effects of EGb 761 on cell growth in HepG2 and Hep3B cells measured by MTS assay. Data are expressed as $\bar{x} \pm s$ (*n*=8). Values not sharing the same letter differed significantly (*P*<0.05) in the same cell line by Fisher' s least significant difference test.

Figure 2 Effects of EGb 761 on cell cytotoxicity in HepG2 and Hep3B cells determined by lactate dehydrogenase (LDH) release. Data are expressed as $\bar{x} \pm s$ (*n*=3). Values not sharing the same letter differed significantly (*P*<0.05) in the same cell line by Fisher' s least significant difference test.

Cell cytotoxicity assay

Cell cytotoxicity was directly measured by LDH release. After 24 h incubation, EGb 761 (50-1 000 mg/L) significantly increased cell cytotoxicity (*P*<0.05) in both HepG2 and Hep3B cells compared with the control group (6.7% and 7.2% in HepG2 and Hep3B cells) (Figure 2). EGb 761 at a dose of 250 mg/L significantly increased LDH release to 36.6% and 31.2% (*P*<0.05), respectively, in HepG2 and Hep3B cells compared with EGb 761 at a dose of 50 mg/L (18.9% and

17.5% in HepG2 and Hep3B cells). However, EGb 761 at the dose of 250-1 000 mg/L did not dose-dependently increase cell cytotoxicity in both HepG2 (35.2-41.3% LDH release) and Hep3B (31.2-40.3% LDH release) cells.

Analysis of proliferating cell nuclear antigen (PCNA) and p53 protein

After 48 h incubation with EGb 761, the expression of PCNA and p53 protein in HepG2 cells was analyzed by SDS-PAGE and Western blotting. EGb 761 at the dose of 500, 750, and 1 000 mg/L decreased PCNA expression to 90%, 84%, and 85% of the control, respectively (Figure 3). However, EGb 761 at the dose of 500, 750, and 1 000 mg/L increased p53 expression to 135%, 152%, and 174% of the control, respectively (Figure 4).

Figure 3 Expression of proliferating cell nuclear antigen (PCNA) with the molecular weight of 36 kDa which was visualized by Western blotting (A) and quantitated by an image analysis system (B) after HepG2 cells were incubated with 0-1 000 mg/L EGb 761 for 48 h. Samples were pooled from 6 independent experiments (n = 6). Alpha-tubulin (55 kDa) was as an internal control.

Figure 4 Expression of p53 protein with the molecular weight of 53 kDa which was visualized by Western blotting (A) and quantitated by an image analysis system (B) after HepG2 cells were incubated with 0-1 000 mg/L EGb 761 for 48 h. Samples were pooled from 6 independent experiments (n=6). Alpha-tubulin (55 kDa) was as an internal control.

DISCUSSION

Ginkgo biloba extract (EGb 761) at the dose of 50-1 000 mg/L significantly decreased cell proliferation measured by MTS assay in a dose-dependent manner in both HepG2 and Hep3B cells with 50% inhibition at approximately 750 mg/L. Similarly, EGb 761 and ginkgolide B were found to inhibit cell proliferation in highly aggressive human breast cancer MDA-231 cells in a dose-dependent manner[16]. Another *Ginkgo biloba* extract, IPS200 devoid of proanthocyanidins, at 200 mg/L decreased cell proliferation of Hep3B cells[17]. EGb 761 also showed an inhibitory effect on cell proliferation of cultured vascular smooth muscle cells in a dose-dependent pattern *in vitro* and significantly decreased the percentage of proliferating cells in the balloon-injured abdominal aorta of cholesterol-fed rabbits *in vivo*[18]. Additionally, EGb 761 given orally at 50 or 100 mg/kg· d or superoxide dismutase injected intravenously at 15 000 U/kg· d inhibited preretinal proliferation in pigmented rabbits, suggesting that antioxidants might efficiently prevent preretinal proliferation[19]. The biflavonoids of *Ginkgo biloba* extract, ginkgetin and isoginkgetin at 10 µmol/L, inhibited lymphocyte proliferation induced by Con A or LPS[9]. Ginkgetin was also found to dose-dependently inhibit the growth of human ovarian adenocarcinoma OVCAR-3 cells with 50% inhibition at 1.8 mg/L[20]. Quercetin, an important flavonoid of *Ginkgo biloba* extract, significantly inhibited cell proliferation of HCC cell lines BEL-7402, HuH-7, and HLE with a peak inhibition at 50 µmol/L[21]. The inhibitory effect of EGb 761 on cell proliferation may be attributed to its antioxidation capacity, however, other constituents of EGb 761 may contribute to its cytotoxic action. Recently, *Ginkgo biloba* extract has been reported to affect gene expression related to cell growth[17]. EGb 761 dramatically reduced, in a consistent manner, the expression of α-fetoprotein in Hep3B cells using fluorescence and membrane DNA microarrays, in which protein is present at very low concentration in adults but is increased in hepatoma patients. Moreover, IPS200 inhibited 40-50% mRNA levels of peripheral-type benzodiazepine receptor, positively correlated with cell proliferation and metastasis in MDA-231, Hep3B, and U87 (human glioblastoma) cells using quantitative RT-PCR and Northern blot analysis. In contrast to our study, a previous study demonstrated that the components of *Ginkgo biloba* extract, such as quercetin, kaempferol, sciadopitysin, ginkgetin, and isoginkgetin, enhanced cell proliferation of normal human skin fibroblasts *in vitro*[22]. The various effects of *Ginkgo biloba* extract on cell proliferation may result from different cell lines, cell morphology (normal *vs* malignant), and the dosage of *Ginkgo biloba* extract or the individual constituents.

Besides the inhibitory effect of EGb 761 on cell proliferation, EGb 761 at higher doses (50-1 000 mg/L) significantly increased cytotoxicity determined by LDH release in both HepG2 and Hep3B cells. However, the cytotoxic effect of EGb 761 reached the plateau at the dose over 250 mg/L. The cytotoxic effect of EGb 761 could be attributed to necrosis and/or apoptosis. Our result revealed increased LDH release as an index of necrosis in EGb 761-treated cells, indicating that EGb 761 could enhance necrosis. Although we did not directly measure apoptosis, the expression of p53 protein, as an inducer of apoptosis in human HCC cells[23], was increased in EGb 761-treated groups. There may exist the possibility that apoptosis contributes to the cytotoxic effect of EGb 761. The cytotoxic activity of EGb 761 has been suspected to derive from ginkgolic acids[24,25] and ginkgetin[10] through their induction of apoptosis. Ginkgolic acids restricted in EGb 761 at less than 5 µg/g have been recognized as hazardous compounds with suspected cytotoxic, allergenic, mutagenic, and carcinogenic properties[24,25]. Ginkgolic acids caused death

of cultured chick embryonic neurons in a dose-dependent manner, and ginkgolic acid-induced death showed both signs of apoptosis and necrosis possibly via the mediation of protein phosphatase 2C[24]. Additionally, increased apoptotic cells from 6% (control) to nearly 80% were found in human keratinocyte cell line HaCaT incubated with ginkgolic acids at the concentration of more than 30 mg/L, which was primarily regulated by transformation of mitochondria probably induced by uncoupling of oxidative phosphorylation[25]. Ginkgetin (5 mg/L) increased intracellular levels of hydrogen peroxide and induced apoptosis in OVCAR-3 cells, which was mediated mainly through the activation of caspase (s) by the generation of hydrogen peroxide perhaps through autooxidation of ginkgetin[10]. However, some constituents of EGb 761 have been reported to possess anti-apoptotic capacity[26,27]. EGb 761 (100 mg/L), ginkgolide J (100 μmol/L), and ginkgolide B (10 μmol/L) reduced apoptosis from 74% in staurosporine-induced apoptotic chick embryonic neurons to 24%, 62%, and 31%, respectively[26]. Furthermore, EGb 761 (100 mg/L) and bilobalide (100 μmol/L) rescued rat neurons from apoptosis induced by serum deprivation. A previous study also found that the total flavonoids of EGb 761, two pure flavonoid components (rutin and quercetin), and a mixture of flavonoids and terpenes protected cerebellar granule cells from oxidative stress and apoptosis induced by hydroxyl radicals[27]. However, total terpenes of EGb 761 neither protected against apoptosis nor had a synergistic effect, suggesting that terpenes did not scavenge hydroxyl radicals directly to suppress apoptosis. The apoptosis-stimulatory and anti-apoptotic properties of EGb 761 might depend on the target cells, the dosage, and its constituents.

Both cell proliferation and apoptosis were involved in HCC[27]. The expression of PCNA and p53 proteins has been regarded as cell proliferation and apoptosis biomarkers, respectively, for the malignant phenotype of HCC, and was associated with prognosis and therapeutic outcome[28-31]. Cell proliferation was increased as HCC progressed to become more poorly differentiated[29,30]. Apoptotic HCC cancer cells were consistently negative for PCNA, and p53-positive cancer cells showed apoptosis[28]. Consistent with the result of MTS assay that EGb 761 suppressed cell proliferation of HCC cells, EGb 761 at the dose of 500-1 000 mg/L decreased the expression of PCNA by 10-16%. Additionally, the expression of p53 protein, measured in HepG2 cells expressing endogenous p53, while not in Hep3B cells lacking endogenous p53 expression[32], was increased by 35-74% in EGb 761-treated groups (500-1 000 mg/L). It suggested that EGb 761 might be potentially useful for the prevention of HCC progression. *Ginkgo biloba* extract or its constituent has been considered as an anti-cancer agent. A previous study showed that EGb 761 ameliorated the deleterious effects on the forestomach and liver in mice with benzo(a)pyrene-induced gastric carcinoma[33]. Furthermore, combined quercetin and a recombinant adenovirus vector expressing human p53, granulocyte-macrophage colony-stimulating factor (GM-CSF), and B7-1 (CD80) genes, as a combined anti-cancer agent, synergetically inhibited cell proliferation and induced apoptosis of HCC cells[21].

In conclusion, *Ginkgo biloba* extract at the concentration above 50 mg/L can significantly suppress cell proliferation and increase cell cytotoxicity in human hepatocellular carcinoma cell lines. Additionally, *Ginkgo biloba* extract can decrease PCNA and increase p53 protein expression in HepG2 cells, suggesting that *Ginkgo biloba* extract may regulate not only cell proliferation but also apoptosis of HCC cells. Therefore, *Ginkgo biloba* extract may have therapeutic potential for HCC.

Abstract

AIM: The heptadecapeptide nociceptin alias orphanin FQ is the endogenous agonist of opioid receptor-like1 receptor. It is involved in modulation of pain and cognition. High blood level was reported in patients with acute and chronic pain, and in Wilson disease. An accidental observation led us to investigate nociceptin in hepatocellular carcinoma.

METHODS: Plasma nociceptin level was measured by radioimmunoassay, aprotinin was used as protease inhibitor. Hepatocellular carcinoma was diagnosed by laboratory, ultrasound, other imaging, and confirmed by fine needle biopsy. Results were compared to healthy controls and patients with other chronic liver diseases.

RESULTS: Although nociceptin levels were elevated in patients with Wilson disease (14.0±2.7 pg/mL, n=26), primary biliary cirrhosis (12.1±3.2 pg/mL, n=21) and liver cirrhosis (12.8±4.0 pg/mL, n=15) compared to the healthy controls (9.2±1.8 pg/mL, n=29, P<0.001 for each), in patients with hepatocellular carcinoma a ten-fold increase was found (105.9±14.4 pg/mL, n=29, P<0.0001). High plasma levels were found in each hepatocellular carcinoma patient including those with normal alpha fetoprotein and those with pain (104.9±14.9 pg/mL, n=12) and without (107.7±14.5 pg/mL, n=6).

CONCLUSION: A very high nociceptin plasma level seems to be an indicator for hepatocellular carcinoma. Further research is needed to clarify the mechanism and clinical significance of this novel finding.

INTRODUCTION

The heptadecapeptide nociceptin (N/OFQ), alias orphanin FQ, is the endogenous agonist ligand of a G-protein-coupled, naloxon insensitive opioid receptor-like 1 receptor (ORL1), recently named as NOP[1]. Although N/OFQ is structurally related to opioid peptides, especially to dynorphin A, it does not interact with μ, δ and κ receptors. The nociceptin/NOP system represents a new peptide-based signalling pathway. Nociceptin is involved in a number of pharmacological actions in the central nervous system (CNS), including modulation of pain and cognition. However, numerous studies investigating the functional role of nociceptin in physiology have failed to provide coherent view, and its exact physiological role remains to be determined[2,3]. Although N/OFQ is produced by some brain structure and peripheral neurons, it is present in the liquor and blood[4], and recent data prove that nociceptin transcripts are expressed in human immune cells as well[5]. NOP mRNA is expressed not only in nervous system, but in immune cells and other organs including the liver[6-8]. High nociceptin blood level was shown in patients with acute and chronic pains[9], and Wilson disease[10].

An accidental observation led us to investigate plasma nociceptin level in patients with hepatocellular carcinoma (HCC). While measuring plasma nociceptin in patients with Wilson disease, we noticed that in one patient the nociceptin level was extremely high compared both with the controls and other Wilson patients. This patient had liver cirrhosis and primary hepatocellular carcinoma without any pain. This observation prompted us to study N/OFQ in patients with hepatocellular carcinoma and other liver diseases. Striking differences were found.

MATERIALS AND METHODS

Patients

Plasma nociceptin level was measured in 26 patients with Wilson disease (aged from 14-55 years, 11 with hepatic, and 15 with neurological symptoms, each D-penicillamine treated), 21 patients with primary biliary cirrhosis (age ranged from 36-72 years; each woman with AMA M2 positive, histologically proven and treated with ursodeoxycholic acid; mean disease duration: 9.4 years), 18 patients with chronic hepatitis (14 HCV positive, 1 HBV positive and 3 autoimmune, each proved by liver biopsy), 15 patients with liver cirrhosis (9 alcoholic, 6 HCV positive), and 18 patients with primary hepatocellular carcinoma (8 with alcoholic cirrhosis, 6 HCV cirrhosis, 1 HBV cirrhosis, 1 Wilson disease, 1 PBC, and 1 patient without any underlying liver disease) from the Hepatological Unit, the 1st Department of Medicine, the Semmelweis University, Budapest. The diagnosis of HCC was based on clinical laboratory tests, US, CT, MRI findings and was confirmed by fine needle aspiration cytology, and histology, in which 3 cases underwent surgery, and one case by autopsy. Serum alpha fetoprotein (AFP) was elevated in 11 out of 18 HCC patients. The size of the tumour ranged from 2.5 cm to 12 cm in diameter. It was smaller than 5 cm in 5 patients, and larger than 5 cm in 13 patients. No metastasis was found outside the liver. In the HCC group 12 patients had temporary pain treated with non-opioid analgetics and 6

patients were without any pain.

Two scoring systems were used for characterisation of patients with HCC. The distribution of patients according to the Barcelona Clinic Liver Cancer (BCLC) classification[11], which includes the performance status, single or multifocal appearance of the tumor, vascular invasion, portal hypertension, Okuda stage and Child-Pugh classification: Stage A1 (*n*=5), stage A4 (*n*=6), stage B (*n*=3) and stage D (*n*=4). Ranking of patients according to the Cancer of the Liver Italian Program group (CLIP) criteria[12,13], which includes Child-Pugh stage, tumor morphology and extent, presence of portal vein thrombosis and serum level of alpha fetoprotein: CLIP 0 (*n*=2), CLIP 1 (*n*=5), CLIP 2 (*n*=5), CLIP 3 (*n*=4), CLIP 4 (*n*=1), CLIP 5 (*n*=1). Demographics, clinical data and ranking of HCC patients according to the BCLC and CLIP classification are shown in Table 1.

Twenty-nine healthy persons including blood donors and members of the medical staff served as control group. The study was approved by the Local Regional Committee of Science and Research Ethics. Written informed consent was obtained.

Methods

Blood drawn from fasting subjects between 08:00 and 10:00 AM was collected in vacutainer tubes containing K-EDTA as anticoagulant. Aprotinin was added immediately as protease inhibitor. Plasma samples were stored at minus 80 ℃. Nociceptin was measured by radioimmunoassay (^{125}I-Nociceptin kit, Phoenix Pharmaceuticals, Phoenix, CA, USA) with minimum sensitivity of 1 pg/mL, as described before[9]. Comparison of the plasma N/OFQ concentration in groups was made using Mann-Whitney U Test. Correlation between N/OFQ level and liver function test results was evaluated by Spearmann RO correlation.

RESULTS

Results are shown in Figure 1. Although nociceptin levels were elevated in patients with Wilson disease (14.0±2.7 pg/mL), in patients with PBC (12.1±3.2 pg/mL) and liver cirrhosis (12.8±4.0 pg/mL) compared to the healthy controls (9.2±1.8

pg/mL, *P*<0.001 for each), more than ten-fold higher values were found (105.9±14.4 pg/mL, *P*<0.0001) in patients with HCC. In patients with chronic hepatitis the N/OFQ level was 10.2±3.6, but the difference was not significant compared to the healthy controls. The clinical data, chemical laboratory findings, AFP and N/OFQ levels of patients with HCC are individually indicated in Table 1.

Figure 1 Plasma nociceptin level (pg/mL±SD) in healthy controls (Control) and in patients with Wilson disease (Wilson), primary biliary cirrhosis (PBC), chronic hepatitis (CH), cirrhosis and hepatocellular carcinoma (HCC). [a]*P*<0.001 *vs* control, [b]*P*<0.0001 *vs* control and each other group.

We did not find any correlation between nociceptin level and liver chemical laboratory tests including AFP in any group of patients with liver disease. Nociceptin was elevated in each HCC patient including those with normal AFP. The N/OFQ level did not show correlation with the presence and severity of the pain. High levels were found in subgroups of patients with pain (104.9±14.9 pg/mL, *n*=12) and without pain (107.7±14.5 pg/mL, *n*=6). There was no difference in nociceptin level between groups with tumor size smaller than 5 cm and larger than 5 cm (109.4±16.5, *n*=5 and 115.2±12.7, *n*=13,

AFP=alpha fetoprotein, BCLC st. cl.=Barcelona Clinic Liver Cancer (BCLC) staging classification, CLIP cl.=Cancer of the Liver Italian Program Group (CLIP) scoring system, Bi=Serum total bilirubin, ALP=alkaline phosphatase, GGT=gamma glutamyl transferase, C-P=Child-Pugh score, N/OFQ=nociceptin/orphanin FQ.

respectively) or between single nodular and multinodular HCC groups, and even symptomatic or asymptomatic tumors. No difference was found in the N/OFQ level between any subgroup of patients with different BCLC and CLIP score values.

Repeated nociceptin measurements were done in one patient before and after non-surgical ablation treatment of HCC. The high nociceptin level did not decrease significantly at least within 10 days following ethanol injection treatment of the tumor, since values were 116 pg/mL before, and 110, 108, 112, 103 pg/mL after treatment at 1, 3, 7, and 10 days, respectively.

However, progressive and significant elevation in plasma nociceptin level parallel with the increase of AFP was observed in a PBC patient with HCC during the follow up. This 67 year old patient was monitored and treated with ursodeoxycholic acid throughout 18 years when her liver tumor was detected by yearly regular ultrasound check up. Fine needle aspiration cytology proved HCC, and she died within two years. Nociceptin was measured in blood samples collected from other reason. The AFP level was normal throughout the years, but elevated at the time of the diagnosis of HCC (426 ng/mL) and rose up to 3 480 ng/ml. The plasma nociceptin (10.6 pg/mL) was within the normal range (9.2±1.8 pg/mL) in the tumor free stage, ten-fold higher (103.7 pg/mL) when the tumor was diagnosed and reached 172.2 pg/mL before the death. Sixteen-fold higher nociceptin content was measured in the tumor tissue (0.16 pg/mg) compared to the tumor-free liver tissue sample (0.01 pg/mg) taken during the autopsy. Detailed presentation of this case is published in this issue of World Journal of Gastroenterology (Horvath et al World J Gastroenterol 2004; 10: 152-154)

DISCUSSION

Shortly after cloning of the three known opioid receptors a fourth member of the subfamily of G protein-coupled receptors was identified. In a search for additional opioid receptor subtypes, a sequence of an opioid-like receptor, termed ORL1 was found, which, however, did not bind any of the known natural opioid ligands. Therefore ORL1 represented an "orphan" receptor. Later two working groups simultaneously reported the isolation of the natural ligand for ORL1, a 17 aminoacid polypeptide and named it orphanin FQ or nociceptin[14,15].

Anatomic studies have revealed high levels of expression of N/OFQ messenger RNS in brain structures involved in sensory, emotional and cognitive processing. Like all other neuropeptides, the heptadecapeptid N/OFQ is synthesized as a part of a larger precursor named prepro-nociceptin, a 176 aminoacid polypeptide in human, from which N/OFQ and nocistatin are cleaved in brain cells and peripheral neurons[16,17]. Although nociceptin is present in the brain, the liquor and blood, human immune cells and polymorphonuclear cells, the gastrointestinal tract and other organs, there are no data on N/OFQ or its receptor in malignant diseases with exception of human neuroblastoma cell lines[18,19]. This is the first report focusing on nociceptin in hepatocellular carcinoma and other liver diseases.

The novel finding of this study is the striking elevation in plasma N/OFQ level in patients with hepatocellular carcinoma. Although nociceptin was elevated in patients with Wilson disease, primary biliary cirrhosis and liver cirrhosis, very high levels over ten-fold increase compared with healthy controls was found in HCC. Since nociceptin level was extremely high in each patient with HCC, and the difference among HCC patients and groups of patients with other liver diseases was highly significant ($P < 0.0001$), the very high plasma level of nociceptin seems to be an indicator for HCC. It is remarkable that nociceptin level was very high in even those patients with normal level of alpha-fetoprotein[20]. The size of HCC is an

important element of prognostic assessment[21]. However, nociceptin level was equally very high in patients with tumor size smaller and larger than 5 cm in diameter.

Further research is needed to clarify the mechanism and clinical significance of the highly elevated nociceptin level in HCC. Increased production or decreased catabolism of nociceptin may be the cause of elevation in plasma level. It is to be determined whether the tumor produces nociceptin or it gives signal for brain cells or peripheral neurons to increase the secretion of N/OFQ. We had the opportunity to determine the tissue nociceptin content in one PBC patient with HCC. Although more than 15-fold higher nociceptin content was measured in the carcinoma tissue than in the tumor-free liver tissue samples taken during autopsy, it did not necessarily mean that nociceptin was produced by the tumor. It is also possible that the tumor simply accumulates nociceptin via binding it by NOP receptors. This possibility could be supported by the fact that ORL1/NOP receptor mRNA has been detected in the liver[22], although no study is yet available on nociceptin or its receptor mRNA expression in hepatocellular carcinoma tissue.

Nociceptin is involved in the processing of pain signals, and it modulates the pain perception[23,24]. However, we did not find difference in N/OFQ level between patients with pain and without. There was no correlation between the plasma N/OFQ level and the severity of pain.

Whether a very high plasma N/OFQ level is a specific marker of HCC should be investigated and subjected to further study. Since nociceptin transcripts are expressed in immune cells[5], it has also been shown that polymorphonuclear cells express nociceptin receptors and N/OFQ stimulates neutrophil chemotaxis and recruitment[25]. The high nociceptin level could also be an indicator of altered reaction of the body including immunological, cytokine and other mechanisms. The bacterial endotoxin (LPS) and proinflammatory cytokines including TNF-alpha, commonly increased in malignancies, induce N/OFQ mRNS in astrocytes. It may suggest a role for nociceptin in neural-glial communication and in inflammatory responses[26].

In humans, the N/OFQ gene has been mapped to the chromosomal location 8p21[27]. Transcription of this gene was shown to be enhanced by cytokines, neurotrophic factors[26], also by estrogen[28]. This cAMP-dependent transcription could be blocked by glucocorticoids[19]. Our patients in this study have not received glucocorticoid treatment, and only one PBC patient used transdermal estrogen hormone replacement for osteoporosis prevention.

Elevated N/OFQ level might partly represent a compensatory mechanism in the nociceptin/NOP system to modulate pain perception in the central nervous system. That mechanism might explain why some patients with a very high plasma N/OFQ level did not have any pain despite advanced stage of the malignant liver tumor. It is remarkable that nociceptin in HCC patients was 3-fold higher than the highest values reported in patients with chronic pain without malignant diseases[9]. We believe that our results could stimulate further investigation.

Abstract

AIM: Inactivation of p53 gene is one of the most frequent genetic alterations in carcinogenesis. The mutation status of p53 gene was analyzed, in order to understand the effect of p53 mutation on chemical hepatocarcinogenesis of rats.

METHODS: During hepatocarcinogenesis of rats induced by 3'-methyl-4- dimethylaminoazobenzene (3'-Me-DAB), prehepatocarcinoma and hepatocarcinoma foci were collected by laser capture microdissection (LCM), and quantitatively analyzed for levels of p53 mRNA by LightCycler™ real-time RT-PCR and for mutations in p53 gene exons 5-8 by direct sequencing.

RESULTS: Samples consisting of 44 precancerous foci and 24 cancerous foci were collected by LCM. A quantitative analysis of p53 mRNA showed that p53 mRNA peaked at an early stage (week 6) in the prehepatocarcinoma lesion, more than ten times that of adjacent normal tissue, and gradually decreased from week 6 to week 24. The expression of p53 mRNA in adjacent normal tissue was significantly lower than that in prehepatocarcinoma. Similar to prehepatocarcinoma, p53 mRNA in cancer was markedly higher than that in adjacent normal tissue at week 12, and was closer to normal at week 24. Direct p53 gene sequencing showed that 35.3% (24/68) (9 precancer, 15 cancer) LCM samples exhibited point mutations, 20.5% of prehepatocarcinoma LCM samples presented missense mutations at exon 6/7 or/and 8, and was markedly lower than 62.5% of hepatocarcinoma ones ($P<0.01$). Mutation of p53 gene formed the mutant hot spots at 5 codons. Positive immunostaining for p53 protein could be seen in prehepatocarcinoma and hepatocarcinoma foci at 24 weeks.

CONCLUSION: p53 gene mutation is present in initial chemical hepatocarcinogenesis, and the mutation of p53 gene induced by 3'-Me-DAB is an important factor of hepatocarcinogenesis.

INTRODUCTION

Abnormalities of some tumor suppressor genes and oncogenes play important roles in the development and progression of hepatoma[1,2]. Gene abnormalities in precancerous liver lesions (adenomatous hyperplasia and atypical adenomatous hyperplasia) and early hepatocellular carcinoma have been reported[3-5]. p53 tumor suppressor protein plays an important role in preventing malignant development, and p53 function is lost or compromised in most human cancers[6-8]. One of the principal functions of p53 is to inhibit cell growth, and p53 shows a strong cell cycle arrest and apoptotic activities[9,10]. As a result, cell proliferation is suppressed and/or programmed cell death is induced[11,12]. In cells with DNA injury, p53 can stop the cell cycle through p21 protein and then promote DNA repair. When DNA is seriously damaged, p53 can induce the cell to undergo programmed cell death to maintain the stability of genome and cells. Loss of p53 function activates oncogenes and inactivates cancer suppressor genes, playing an essential role in multistage carcinogenesis[13,14]. Some study has shown that mutation and loss of p53 gene are closely related to the conversion of adenoma to early colorectal cancer, and so are those in liver[15]. When cancer cell differentiation is low and the tumor becomes large, p53 gene mutation frequently arises in hepatocarcinoma, making p53 gene most closely concerned with the progress of hepatocarcinoma[16]. It is not yet clear which of these gene alterations is responsible for hepatocarcinogenesis, especially in a prehepatocarcinoma lesion.

3'-methyl-4-dimethylaminoazobenzene (3'-Me-DAB) could produce prehepato- carcinomatous lesions (altered focus and neoplastic nodules) in rats. Our study showed that mutation of p53 gene, in precancerous and cancerous foci of the F344 rat liver induced by 3'-Me-DAB, was successfully detected by integrating LCM, LightCycler RT-PCR with direct sequencing.

MATERIALS AND METHODS

Animals

Thirty-nine male F344 rats at 10 weeks of age were kept in a room with a 12h light and dark cycle and maintained at 22 ℃. They were provided with a diet containing 0.06% 3'-Me-DAB[17] and tap water *ad libitum* for 6 weeks, 12 weeks, and 24 weeks, respectively. After the last day of each experimental period, the animals were anesthetized with ether and hepatectomized. The cavum thoracis and abdominal cavity were opened immediately with a sterilized scalpel, and part of the liver was quickly dissected out, placed in a cryomold, covered with Tissue-Tek O. C. T compound before being frozen in liquid nitrogen, and preserved at -80 ℃ until use. The remaining liver was perfused with 30% PBS-buffered sucrose before being removed and fixed in 10% neutral formalin, and then embedded in paraffin.

LCM of sample

The liver preserved at -80 ℃ was sequentially sliced into twenty 10 μm thick sections, in a cryostat, which were mounted on clean microscope slides. The sections were stored at -80 ℃. Of the 10 successive slide sections, three were stained chemically with H&E and immunohistochemically with glutathione *S* transferase placenta (GST-P) and AFP polyclonal antibody using Elite ABC kit (Funakoshi Co. Ltd., Tokyo, Japan). Prehepatocarcinoma and hepatocarcinoma foci were diagnosed by Pathologists and their positions were identified on the slides. Other slide sections underwent quick H&E staining based on the LCM manufacturer's protocols, and were then cleaned in xylene for over 1 min. Once air-dried, slides were ready for LCM. Based on the position of GST-P (+) or AFP (+) foci from immunostained slide sections and the cancer pathology on the H&E section, a LCM cap was placed over the target area of the slide section[18,19]. Target foci in the same position as GST-P (+) or AFP (+) foci were then microdissected.

Extraction of DNA of LCM samples

After microdissection, the LCM cap was inserted into an Eppendorf tube containing 50 μl of digestion buffer of 0.04% proteinase K, 10 mM Tris-HCl pH 8.0, 1 mM EDTA, and 1% Tween-20. The tube was then placed upside down overnight at 37 ℃. Following ethanol precipitation, DNA was extracted by the phenol/chloroform/isopropanol method and used directly as a template for PCR.

Extraction of total RNA of LCM samples

After laser transfer, the LCM cap was gently placed on the Eppendorf tube containing 200 μl of reaction mixture. The tube was inverted back and shaken several times for over two minutes to digest the tissue on the cap. The digestive solution was removed from the Eppendorf tube and placed into a 1.5 ml sturdy tube, extraction and purification of total RNA were conducted according to conventional methods. The pellet of total RNA was then resuspended in H_2O, and stored at -80 ℃.

Primers for RT-PCR, direct sequencing of p53

We designed upstream PCR primers P1, P2, and P3 in the region corresponding to introns 4, 5, and 7 (Figure 1 and Table 1). They were used in combination with downstream primers P4, P5, and P6 within the region corresponding to introns 5, 7 and 8 of p53 gene (Figure 1 and Table 1), to specifically amplify exons 5, 6/7, and 8 of the functional p53 gene without p53 pseudo-gene. The primers Pmu and Pmd for RT-PCR were located on exons 7 and 8 (Figure 1 and Table 1).

Quantitative analysis of mRNA

RNAs extracted from prehepatocarcinoma and hepatocarcinoma foci captured by LCM were reverse-transcribed into first strand cDNA at 42 ℃ for 50 min and at 99 ℃ for 5 min using Olig-dT-adaptor-primer of an RNA PCR kit (Takara, Co. Ltd., Japan) as the primer. A 1 μl aliquot of first-strand cDNA or H_2O (as a negative control) was put into LightCycler capillary, together with 1 μl of 20 pM primer (Table 1) for target DNA and 18 μl of mixture of LightCycler-DNA Master SYBR Green I mixture. Various concentrations of standard sample cDNA were also used to construct a standard curve. After instantaneous centrifugation, capillaries were loaded onto a LightCycler instrument. Quantitative analysis of mRNA was conducted under PCR conditions in Table 1. The standard curve was shown as a straight line of linear regression with cycle number *versus* log-concentration of standard samples. This standard curve, in turn, was used to estimate the concentration of each sample. Since the expression of β-actin mRNA is constant in all types of cells, it was used to calibrate the original concentration of mRNA, i.e., the concentration unit of mRNA in tissue was defined as the ratio of target mRNA copies *versus* β-actin mRNA copies[20].

Mutation screening of p53 exons 5, 6/7, and 8

DNAs from the same LCM samples were amplified by PCR under the conditions in Table 1. PCR products were refined by a Microcon-100 kit (Takara, Co. Ltd., Japan). The sense strand

Figure 1 Strategy of primers. To avoid p53 pseudogene co-amplification, the upstream PCR primers P1, P2, and P3 in the region corresponding to introns 4, 5, and 7 were used in combination with downstream primers P4, P5, and P6 within the region corresponding to introns 5, 7, and 8 of p53 gene. Primers Pmu and Pmd for RT-PCR located in exons 7 and 8, respectively.

of PCR products was sequenced using a cycler sequencing ready reaction kit (ABI, Perkin-Elmer Corp., USA) and analyzed on an ABI Prism™ 310 genetic analyzer (ABI, Perkin-Elmer Corp., USA).

Immunohistochemical staining

Immunohistochemical staining was conducted using the avidin-biotin-peroxidase complex technique (Vectastain Elite ABC Kit, Funakoshi Co. Ltd., Tokyo, Japan)[21]. Paraffin-embedded or frozen rat liver specimens were sectioned at 5 µm and placed on a precleaned glass microscope slide. After deparaffination and blocking of endogenous biotin activity, the sections were incubated with primary antibodies (anti-GST-P IgG diluted at 1:500, anti-AFP IgG diluted at 1:200 (polyclonal antibody) and anti-p53 monoclonal antibody Ab1 (Oncogene Science, Inc., USA) diluted at 1:100) for 90 min at 30 ℃, then incubated with biotinylated anti-rabbit (for polyclonal antibody) or anti-mouse (for monoclonal antibody) secondary antibody for 30 min at 30 ℃. The slides were incubated for 30 min with avidin-peroxidase conjugates. Finally, the sections were reacted with 3' 3-diaminobenzidine tetrahydrochloride and hydrogen peroxide for 3 min followed by counter-staining with hematoxylin. For a negative control, pre-immune serum instead of primary antibody was used.

Statistical methods

Student-t test was used to identify the differences of mRNA concentration in normal tissue, precancerous and cancerous foci.

RESULTS

Hepatocarcinogenesis

Prehepatocarcinoma foci could be found in all (13) the livers of rats treated with 3'-Me-DAB for 12 weeks, which were intensely stained by GST-P (Figure 2, B). By H&E staining, the size of prehepatocarcinoma cells was similar to that of normal hepatocytes, but the cytoplasm of precancer cells was clearer. Under low power magnification, the edge of prehepatocarcinoma focus was distinct and bright (Figure 2, A). Hepatocarcinoma foci were seen in 6 liver sections. By H&E staining, the sizes of nuclei were different, the cytoplasm was a little basophilic and a lot of fat vescles were present in cytoplasm of hepatocarcinoma cells (Figure 2, C). Immunohistochemically staining for AFP was intensive in hepatocarcinoma foci. At week 24 (Figure 2, D), all (13) the livers exhibited hepatocarcinoma foci and some showed prehepatocarcinoma foci simultaneously. The diameter of precancerous foci was 0.5 mm-1.0 mm at week 6, 1.2 mm-1.5 mm at week 12 and >2.5 mm at week 23. Forty-four precancerous and 24 cancerous samples were obtained for DNA sequencing analysis and quantitative analysis of p53 mRNA.

Expression of p53 and GST-P mRNA

The time course of p53 gene expression showed that the mRNA levels peaked at week 6 in prehepatocarcinoma foci and at week 12 in hepatocarcinoma foci, although they declined significantly by week 24 ($P<0.01$, Figure 3). The relative concentration of p53 mRNA in adjacent normal tissue remained significantly lower than in prehepatocarcinoma and hepatocarcinoma foci. In hepatocarcinoma foci, the relative concentration of p53 mRNA was 10 *odd* times higher than in adjacent normal tissue at week 6 of the experiment ($P=5.6\times10^{-9}$) and 4 times as high at week 12 ($P=4.8\times10^{-9}$). p53 mRNA concentration was also significantly higher in cancer than in adjacent normal tissue at week 12 ($P=0.028$). However, at week 24, p53 mRNA of both prehepatocarcinoma and hepatocarcinoma foci was obviously elevated. Relative p53 mRNA concentration was the highest in prehepatocarcinoma foci and the lowest in adjacent normal tissue among the three tissues examined (Figure 3).

Moreover, the expression of GST-P mRNA was low in adjacent normal tissue from week 6 to week 24, and was significantly higher in prehepatocarcinoma foci than in adjacent normal tissue and hepatocarcinoma foci ($P<0.001$),

Figure 2 Hepatocarcinogenesis. A: Prehepatocarcinoma foci were stained by H&E, morphology of prehepatocarcinoma cells was similar to that of normal hepatocytes, and the edge of prehepatocarcinoma focus was distinct and bright. B: Prehepatocarcinoma focus was as intensely stained by GST-P as A. C: Hepatocarcinoma foci by H&E staining showed a lot of foam cells. D: Immuno-histochemical staining for AFP was intense in hepatocarcinoma foci.

and higher in hepatocarcinoma foci than in adjacent normal tissue (Figure 4).

Figure 3 Quantitative analysis of p53 mRNA. After rats were treated with 3'-Me-DAB for 6, 12 and 24 weeks, the expressions of p53 mRNA were markedly higher in prehepatocarcinoma than in hepatocarcinoma and adjacent normal tissue, $P<0.001$. The time course of p53 mRNA showed that mRNA levels peaked at week 6, and gradually decreased to minimum at week 24. Normal=adjacent normal tissue, Precar=prehepatocarcinoma, Car=hepatocarcinoma.

Figure 4 Quantitative analysis of GST-P mRNA. After rats were treated with 3'-Me-DAB for 6, 12 and 24 weeks, the expressions of GST-P mRNA were markedly higher in prehepatocarcinoma than that in hepatocarcinoma and adjacent normal tissue, $P<0.001$, and also higher in hepatocarcinoma than that in adjacent normal tissue, $P<0.001$. GST-P mRNA levels were expressed on a logarithmic scale. Normal=adjacent normal tissue, Precar=prehepatocarcinoma, Car=hepatocarcinoma.

Direct sequencing analysis of p53 mutation

Direct sequencing analysis of genomic DNA from 24 LCM samples showed 39 mutations at 18 codons of exons 6/7 and 8 in p53 gene (Figure 5, A, C, E). Of these 39 mutations, 10 transition mutations (1 A:T→G:C, 9 G:C→A:T) (Figure 5, A,C) and 29 transversion mutations (9 G:C→C:G, 9 G:C→T:A , 5 C:G→A:T, 2 C:G→G:C, 2 A:T→C:G, 1 T:A→A:T and 1 A:T→T:A) (Figure 5, E) were identified. A base inserting mutation following the first base substitution, G→TA, in codon 283 of exon 7 resulted in a putative substitution "end" for glutamic acid in p53 protein. Interestingly, four LCM samples had triple mutations and eight LCM samples had double mutations in exons 6/7 or/and 8 simultaneously. One LCM sample with triple mutations and 3 with double mutations were prehepatocarcinoma foci, and 3 other samples with triple mutations and 5 with double mutations were hepatocarcinoma foci.

In brief, 24/68 (35.3%) of LCM samples had mutations of p53 gene. No mutation in exon 5 was found by direct sequencing.

Incidence of p53 gene mutation in hepatocarcinogenesis

20.5% precancerous foci samples expressed point mutation or inserting mutation in exons 6/7 and 8, and the incidence of mutation was markedly higher than that of cancerous samples ($\chi^2=12.02$, $P<0.01$). At 12 weeks, the incidence of mutation was significantly higher in hepatocarcinoma samples than in prehepatocarcinoma samples, $P=0.034$ by Fisher's exact probabilities (Figure 6). At 24 weeks, the incidence of mutation was not different between prehepatocarcinoma and hepatocarcinoma foci samples.

Figure 5 Direct sequencing of p53 exons 6/7 and 8. A: GAG to AAG transition mutation (red box) at codon 202 of exon 6/7 was seen in prehepatocarcinoma foci at 6 weeks. C: Four hepatocarcinoma foci with GAC to AAC transition mutation (red box) at codon 206 formed one of the mutation hot spots. E: GGG to TGG transversion mutation (red box) at codon 300 of exon 8 in hepatocarcinoma foci. B, D and F were normal sequence.

Figure 6 Mutation ratio of p53 exons 6/7 and 8 in prehepatocarcinoma (precar) and hepatocarcinoma foci (car).

Hot spot of mutation

Among the 34 mutation codons of p53 exons 6/7 and 8, 9 were at codon 233, 5 at codons 278 and 279, respectively, 4 at codon 206 (Figure 5,C), and 3 mutations were at codon 212. These mutational codons formed the mutational hot spots of precancerous and cancerous foci in this study, and were located in highly conservative DNA binding domain of p53 protein.
Figure 7 Mutant p53 protein expressions in prehepatocancer and hepatocancer. A: Normal tissue. B: Nuclei of prehepatocarcinoma cells immunostained by anti-p53 Ab1. C: Nuclei of hepatocellular carcinoma cells stained by anti-p53 Ab1. D: Nuclei of adenohepatoma cells stained by anti-p53 Ab1. Enlarged nuclei intensely stained for Ab1 were seen in cells. Original magnification 400×.

Expression of p53 protein in cells

As shown in Figure 7, paraffin-embedded or frozen liver sections from rats treated with 3'-Me-DAB for 24 weeks exhibited intensive immunostaining of p53 protein in at least 30% cells of prehepatocarcinoma (Figure 7B) and hepatocarcinoma foci (Figure 7, C, D). Staining was predominantly limited to enlarged nuclei with intensive staining for the anti-p53 antibody. In contrast, no liver sections from rats treated with 3'-Me-DAB for 6 or 12 weeks demonstrated immunostaining for p53 protein (Figure 7, A).

DISCUSSION

Researchers are used to studying human tumors by obtaining human hepatocarcinoma tissue after hepatectomy, but it is difficult to obtain pre-hepatocarcinoma foci in cases without clinical symptoms. We and other investigators were therefore constrained to using rats as the animal model for assessing the effects of p53 gene mutations on hepatocarcinogenesis[22,23]. It has been found that rat p53 gene differs from human p53 gene, in that it processes pseudogenes in its genome[24,25]. Pitfalls associated with p53 pseudogene co-amplification from genomic DNA could be avoided, however, by designing PCR primers based on the intron sequence[24,26].

Carcinogenesis is a complex process characterized by the cumulative activation of various oncogenes and the inactivation of suppressor genes. About 30-40% of human hepatocarcinomas and 20-60% of rat experimental tumors demonstrated mutations of p53 gene[2,27-30]. Chemically induced rat liver cancer proceeds through multiple, distinct initiation-promotion-progression stages and mutation of the suppressor p53 gene has been found in relatively early preneoplastic lesions in the rat liver.

We used quantification of p53 mRNA expression to detect genetic alterations at RNA level in the present study. The results showed that in precancerous foci of the rat liver, p53 mRNA rose quickly and peaked at week 6 of 3'-Me-DAB treatment. It then gradually decreased from week 12 and fell to a minimum at week 24 of the experiment. Similar results were also seen in cancer foci. The time course of mRNA expression differed from that of p53 protein accumulation in nuclei. GST-P is one of the detoxification enzymes involved in the metabolism of 3'-Me-DAB as well as other carcinogens and plays a protective role during chemical hepatocarcinogenesis. It is considered as an early marker of preneoplastic lesion. When GST-P played a protective role, mRNA transcript increased coincidentally with positive GST-P immunostaining in prehepatocancerous foci of the rats at all experimental time points tested (data not shown). GST-P overexpression was not consistent with an aberration in p53 protein expression[31].

In this paper, 20.5% of precancerous foci occurring after week 6, week 12, and week 24 exhibited missense mutations of p53 exons 6/7 or/and 8, with double or triple codon mutations found in the same sample by direct sequencing. Of the hepatocancerous foci, 58.3% and 66.7% had mutations in p53 gene at week 12 and week 24 of 3'-Me-DAB treatment, respectively. Mutations were distributed widely throughout exons 6/7 and 8, but not in exon 5. p53 mutation rate increased from week 6 to week 24, suggesting that p53 gene mutation is closely associated with hepatocarcinoma development and progression. It is possible that p53 mutation ran through the initiative, intermediate, and late stages of hepatocarcinogenesis, and was not an event occurring only at the advanced stage of liver cancer. Therefore, mutant p53 molecules have been thought to have some unique properties that are important in carcinogenesis in rats[32].

A tetramer of p53 molecules has been assembled through carboxyterminal oligomerization domains. This allows the central domains to interact directly with a consensus DNA element. As a consequence, aminoterminal transactivation domains could interact with basal transcription factors, resulting in increased gene expression[33,34]. Among the 39 mutation codons of p53 exons 6/7 and 8, 9 were at codon 233, 5 at codons 278 and 279, respectively, 4 at codon 206, and 3 mutations were at codon 212. These mutational codons formed

mutational hot spots of precancerous and cancerous foci in this study, and were located in the highly conservative DNA binding domain of p53 protein[35].

Over 90% of mutations are missensed, causing the substitution of amino acids. It has been found that mutation hot spots were dispersed in three exons of p53 gene, and three hotspots fell within two evolutionarily highly conserved regions[35,36], suggesting no single spot is responsible for maintaining p53 tumor suppressor function. In fact, a certain oncogenic agent could act on only one or more spots of the p53 gene DNA sequence. The effect of the hotspots is yet uncertain, because a certain oncogenic agent has made different mutational hotspots of p53 gene in different species[37-40] and tissues[28,39,40].

Amino acid residues 278 and 279 of the p53 protein have been found to be located in helix H_2 of loop-sheet-helix fitting in the major groove of DNA, allowing them to contact edges of the bases, and to play a central role in DNA recognition[41], so mutation occurring in this area may cause p53 to lose its growth regulation.

Positive immunostaining of p53 was only found in sections of LCM samples treated with 3'-Me-DAB for 24 weeks, not in those treated for 6 or 12 weeks, demonstrating that p53 protein accumulates relatively late during hepatocarcinogenesis. Positive immunostaining of p53 was consistent with the increased half-life of mutant p53 protein compared to wild-type p53[35,42,43]. As the half-life of wild-type p53 protein is short, it is usually too difficult to detect it in normal tissue with Western blotting or immunohistochemical staining. Mutant p53 protein could competitively inhibit the function of wild p53 protein, promoting hyperplasia of cells and leading to tumor development[44,45]. A few studies have reported that accumulation of p53 protein in nuclei in late chemical hepatocarcinogenesis was not synchronized with the increased expression of p53 mRNA[28,46,47]. The rise of p53 mRNA markedly preceded the rise of the expression quantity of p53 protein[19,48].

We showed that mutation of p53 gene occurred in early precancerous and cancerous foci of F344 rats treated with 3'-Me-DAB and mutation increased progressively from week 6 to week 24, but the expression of p53 mRNA decreased progressively from week 6 to week 24. The detection of p53 gene mutation may benefit the early diagnosis of tumors[49], and also may aid in understanding the mechanism behind hepatocarcinogenesis.

Abstract

AIM: To construct an eukaryotic superantigen gene expression vector containing the recombinant gene of SEA and CD80 molecule transmembrane region (CD80TM), and to express staphylococcus enterotoxin A (SEA) on the membrane of hepatocellular carcinoma (HCC) cell to form a superantigen gene modified tumor vaccine for HCC.

METHODS: SEA and linker-CD80TM gene were amplified through PCR from plasmid containing cDNA of SEA and CD80. Gene fragments were then subcloned into the multiple cloning sites of retroviral vector pLXSN. Recombinant plasmid was transferred into HepG2 cells mediated with lipofectamine, positive clones were selected in culture medium containing G418. RT-PCR and indirect immunofluorescence studies confirmed that SEA was expressed specifically on HCC cell membrane. INFγ-ELISPOT study demonstrated that SEA protein was expressed on the membrane of HCC cells. Cytotoxicity of HepG2-SEA primed CTLs (SEA-T) was analyzed by ^{51}Cr release assay. T cells cultured with rhIL-2 (IL-2-T) were used as control.

RESULTS: Restriction digestion and sequence analyses confirmed the correctness of length, position and orientation of inserted fusion genes. SEA was expressed on the surface of HepG2 cells, HepG2-SEA had strong stimulating effect on production of HepG2 specific CTL ($P<0.001$). SEA-T had enhanced cytotoxicity to HepG2 cells ($P<0.05$).

CONCLUSION: Tumor cell membrane expressed superantigen can be used to reinforce the immune effect of tumor cell vaccine for HCC, which provides a new method of the enhanced active immunotherapy for HCC.

INTRODUCTION

Autologous and allogeneic tumor cells have been used as tumor vaccines in clinic for a long time[1,2]. The tumor cell-based vaccines possess the entire relevant tumor antigens recognized by the immune system and can be produced even without knowing the gene sequence of specific antigens. To identify the tumor specific antigen is time consuming, only few tumor specific antigens have been identified until now. But tumor cell-based immunization could not always elicit anti-tumor responses in sufficient magnitude to cause regression of established tumors due to scarcity of stimulatory surface molecules such as MHC-I, MHC-II or CD80[3].

Superantigens are a family of bacterial and viral proteins that bind to MHC class II molecules as unprocessed proteins and activate a large number of T cells bearing T cell receptor variable region beta chain (TCR Vβ)[4,5]. These T cells proliferate, and secrete cytokines (e.g. IFN-γ, TNF-α, IL-2, and IL-12), induce strong cytolytic activity, and mediate tumor regression[6-12]. SEA is an important member of superantigen family. Anchoring SEA onto MHC-II negative tumor cells through monoclonal antibody has been demonstrated to direct T cell-mediated cytotoxicity against these tumors[13,14]. Other studies suggested that artificially anchoring a recombinant superantigen-transmembrane region chimera (SAg-TM) onto a tumor cell surface could substitute for the effect of MHC-II presentation[15].

In the present study we sought to construct an eukaryotic expression vector containing recombinant gene of SEA and transmembrane region sequence of CD80 molecule (CD80TM). Recombinant gene was transfected into HCC cells, chimera protein (SEA-CD80TM) was expressed on the membrane of living cells. SEA gene modified cells were irradiated and used as a superantigen enhanced tumor cell-based vaccine for HCC, which was capable of inducing antitumor immunity *in vitro*.

MATERIALS AND METHODS

Reagents
EX Taq DNA polymerase, T4 DNA ligation kit Ver.2.0, and restriction endonuclease were obtained from TakaRa Biotechnology (Dalian). DNA isolation and purification kit was purchased from Shanghai ShunHua Biotechnology. Lipofectamine™ 2000 were from Invitrogen. IPTG, X-gal, DNA maker and FITC labeled sheep anti mouse IgG were from Sino-American Biotechnology. Dulbecco' s modified Eagle media, Trizol and G418 were from GibcoBRL. Access RT-PCR system was from Promega. Human INF-γ ELISPOT assay kit was from Diaclone, Recombinant human interleukin-2 (rhIL-2) and BD TriTEST™antibody CD4 FITC/ CD8 PE/ CD3 PerCP were from BD Biosciences. Mouse anti-SEA monoclonal antibody was provided by the Department of Immunology, Fourth Military Medical University, P. R. China.

Plasmids
PBluescript II KS (+) plasmids containing cDNA of SEA and CD80 were constructed by Li *et al*[16]. Retroviral vector pLXSN was preserved in our laboratory.

Cell culture
Human HCC cell lines HepG2 and SMMC-7721 were cultured

in DMEM containing 10% heat-inactivated fetal calf serum, 100 units/ml penicillin, 100 μg/ml streptomycin, 0.292 mg/ml glutamine. The cell lines were incubated in a humidified 5% CO_2 incubator at 37 ℃.

Polymerase chain reaction (PCR) and vector construction

The primers used for cloning SEA (774 bp) and CD80TM (147 bp) were as follows. SEA, forward: GCGAATTCGCAT GAAAAAAACAGCATTTAC, reverse: CGGGATCCACTT GTATATAAATATATATCAAT. CD80TM, forward1: GGT GGCTCTGGCGGTGGCGGATCGGATAACCTGCTCCCATCC, forward2: CGGGATCCGGTGGAGGCGGTTCAGGCGG AGGTGGCTCTGGCGGT, reverse: CCGCTCGAGTTATAC AGGGCGTACACT. Linker (GGGGSGGGGSGGGGS) was introduced into the upstream of CD80TM using two forward primers. PCR was performed in a 50 μl reaction system consisting of 1 μM each primer, 200 μM each dNTP, 5 μL 10×polymerase reaction buffer, and 1.25U EX Taq DNA polymerase with 1 μL SEA or CD80 gene vector. Samples were heated to 94 ℃ for 5 min followed by 30 cycles at 94 ℃ for 30 s, at 50 ℃ for 50 s, and at 68 ℃ for 1 min. The final extension was done at 72 ℃ for 7 min. Then 10 μl of each PCR product was electrophoresed on 1 % agarose gel containing 0.5 μg/mL EB, and PCR products were then purified from agarose gel according to the protocol of DNA purification kit. DNA fragments of SEA (S) and linker-CD80TM (LC) were subcloned into pBluescript II ks(+). The positive clones were selected from the transfected DH5α by the method described by Sambrook et al[17]. The constructed plasmids (designated as ks-S, ks-LC) were identified by restriction enzyme analysis. DNA sequences were verified in DNA sequencing core facility in Bioasia Biotechnology (Shanghai, China). Gene fragments were cut with EcoRI-BamHI, BamHI-XhoI, and inserted into the EcoRI-XhoI site of pLXSN to construct SAg gene expression vector pLXSN-SLC. The recombinant gene was verified by digestion with restriction endonuclease (Figure 1).

Figure 1 Gene map of expression vector.

In vitro transfection of pLXSN-SLC

pLXSN-SLC was transfected into HepG2 cells using Lipofectamine™ 2000 reagent according to the manufacturer's instructions. Briefly, 2×10⁵ HepG2 cells were seeded into 12-well culture plates and cultured for 18 hours until 90% to 95% confluence of the cells, transfection was performed with 1 μg of DNA per dish. Forty eight h after transfection, cells were passaged at 1:4 dilution into a fresh medium. The next day, G418 400 μg/mL was added into culture medium for the screening of stably transfected cells. The cells were then grown in G418 culture medium for 4 weeks and cloned by limiting dilution. Mock cell line transfected with empty pLXSN vector was selected in G418, and used as control (HepG2-pLXSN).

Detection of SEA expression in transfected cells

Expression of SEA in screened monoclones was detected by RT-PCR. Total RNA was extracted from the tumor cells (HepG2 cells and SEA gene transfected or mock transfected HepG2 cells) using Trizol reagent. RNA (1.5 μg) was used to synthesize cDNA in 20 μl reaction mixtures following standard protocol of Access RT-PCR system. PCR was carried out with 5 μl of RT products in 50 μl PCR reaction buffer containing Tfl polymerase, 1 mM $MgCl_2$, annealing temperature was 50 ℃. SEA cDNA was used as positive control in PCR. Indirect immunofluorescence was performed to locate the expressed SEA. Briefly, 2×10⁵ SEA transfected HepG2 cells (HepG2-SEA) were plated into 12-well culture plates. At the bottom of each well a sterilized coverslip was placed in advance. HepG2 cells were plated as control. When the plated cells were 95-100% confluence, the coverslips were washed twice in cold PBS (0.01M) and fixed with 4% paraformaldehyde for 30 min at room temperature. Cells were stained following the standard protocol of indirect immunofluorescence. First antibody was 1:100 diluted mouse anti-SEA monoclonal antibody in PBS, irrelevant sheep anti-mouse IgG was used as control. Second antibody was 1:500 diluted FITC labeled sheep anti-mouse IgG in 0.1% evan blue. Coverslips were then mounted directly onto a glass slide with a tiny drop of 50% glycerol in PBS (9.1 mM Na_2HPO_4/1.7 mM NaH_2PO_4/50 mM NaCl, pH 7.4). Fluorescent images were captured at 490 nm using a Nikon Eclipse E1000 microscope attached to a MicroMax camera (Princeton Instruments, Trenton, NJ).

Preparation of T cell lines

Human peripheral blood mononuclear cells (PBMC) were isolated from healthy volunteers by routine density centrifugation, and stimulated with HepG2-SEA to establish SEA-reactive T-cell line (SEA-T). The T cell line was stimulated repeatedly by exposure to irradiated (4 000 rad) HepG2-SEA and rhIL-2 (200 U/mL) in complete medium for 2 weeks, and then stored in frozen. These cells were thawed 1 week before use. T-cell lines stimulated by HepG2-pLXSN (pLXSN-T), HepG2 (HepG2-T) or just maintained with rhIL-2 (IL-2-T) were also prepared and used as control. Cell phenotypes of T cell lines were analyzed using BD TriTEST™ antibody by FACS.

Elispot assay

PVDF 96-well plates were incubated with 100 μl of 70% ethanol for 10 min at room temperature, and washed three times in 100 μl of PBS. Capture antibody was added and incubated at 4 ℃ overnight. After washed in 100 μl of PBS, each well was added 100 μl of 2% skimmed dry milk in PBS, and incubated for 2 hours at room temperature. Wells were emptied and tapped on absorbent paper, 5×10⁴ effector cells (including SEA-T, pLXSN-T, HepG2-T, IL-2-T) and 1×10⁴ target cells (irradiated HepG2) were seeded to each well and incubated for 20 h in RPMI-1640 medium without IL-2 and serum. Plates were then washed and incubated with detection antibody in PBS-1% BSA for 1 hour and 30 min at 37 ℃, and with streptavidin-alkaline phosphatase for 1 h at 37 ℃. After washed, substrate (5-bromo-4-chloro-3-indolyl phosphate/nitroblue tetrazolium) was added and incubated for 5-20 min. After the final washing, dark-violet spots on plate membranes were counted under microscope.

Cytotoxicity of HepG2-SEA stimulated T cell line

Cytotoxicity was measured in a standard 4-hour ⁵¹Cr-release assay and expressed in formula: (%)specific lysis=100× (experimental - background cpm/maximal background cpm). Target cells (HepG2, SMMC-7721) were labeled for 2 hours with $Na_2{}^{51}CrO_4$ (⁵¹Cr, New England Nuclear, Boston, MA), 250 μCi/1×10⁶ cells. The cells were then washed twice and 5×10³ cells per well were seeded in triplicate in v-bottomed microtiter plates. Effector cells (SEA-T, HepG2-T and IL-2-T) were added at an effector-to-target (E:T) cell ratio of 40:1, 25:1, 10:1, 5:1 and 3:1, respectively. The plates were incubated

at 37 ℃ and 5% CO_2 for 4 h, supernatants were collected, and the released ^{51}Cr was measured with a gamma counter (LKB-Wallac 1 282; Stockholm, Sweden). Spontaneous release was estimated by incubation of target cells in medium alone, and maximum release by resuspending the wells with 0.1% Tween 20. Spontaneous release was typically less than 30% of maximum release.

Statistical analysis

All experiments were performed in triplicate, data were presented as the mean ± SD and analyzed using Student's *t* test.

RESULTS

Insertion of SEA and linker-CD80TM into MCS of pLXSN

PCR products were subcloned into a pBluescript II ks (+) vector. DNA sequencing confirmed the correct sequence of both fragments. SEA gene was cloned into the *Eco*R I/*Xho* I site of pLXSN with linker-CD80TM. Recombinant gene SEA-linker-CD80TM was 1.0 kb with *Eco*R I and *Xho* I restriction site on each side, the size of pLXSN was 5.9 kb. Expressing vector pLXSN-SLC was digested by *Eco*R I/*Xho* I, 1.0 kb and 5.9 kb DNA fragments were appeared as expected (Figure 2).

Figure 2 Enzyme digestion analysis of expression vector. A. Lambda DNA (EcoRI, HindIII); B. pLXSN (EcoRI, xhoI); C. pLXSN-SLC (EcoRI, xhoI).

Figure 3 RT-PCR detected the transcription of SEA gene. A. 200 bp DNA marker; B. HepG2; C. HepG2 transfected with pLXSN-SLC; D. HepG2 transfected with pLXSN; E. Positive control; F. β-actin (RNA of C).

SEA expressed on the membrane of HepG2

HepG2 was transfected with plasmid pLXSN-SLC and empty pLXSN vector, respectively. The expression of SEA was detected in HepG2 cells transfected with pLXSN-SLC only by RT-PCR (Figure 3). Indirect immunofluorescence test confirmed that most of the expressed SEA appeared to be located on the HepG2 cells membrane (Figure4). SEA expression was detected in 5-10 percent of cells screened with G418. Irradiated HepG2-SEA cells were used as T cell stimulator in following experiments.

Increased HepG2 reactive T cells with HepG2-SEA

Interferon-γ (IFN-γ) ELISPOT assay was used to detect the specificity of HepG2 CD8+ T cells quantitatively. Cells tested included unstimulated PBMC (IL-2-T) and polyclonal T-lymphocyte lines stimulated by HepG2-SEA, HepG2-pLXSN or HepG2. After a short term of culture *in vitro*, the percentage of positive cells was more than 90% for CD3+, 80% to 90% for CD8+, and 5% to 10% for CD4+ (Figure 5). The number of HepG2 reactive CTL in the SEA-T cell line was much higher than that of HepG2-T (155.67±7.22 *vs* 38.03±8.18, *t*=18.67, *P*<0.0001), pLXSN-T (39.50±6.26, *t*=21.06, *P*<0.0001) or IL-2-T (32.00±4.26, *t*=25.56, *P*<0.0001) (Figure 6). Both the size and density of spots in SEA-T group were greater than those of controls (data not shown). The difference of spot number between HepG2-T and IL-2-T cell lines was not significant (*t*=-1.13, *P*=0.321).

Figure 4 SEA expressed on the membrane of HepG2 (indirect immunofluorescence). HepG2-SEA cells were stained according to the standard protocol of indirect immunofluorescence. First antibody is mouse anti-SEA IgG and second antibody is FITC labeled sheep anti-mouse IgG diluted in 0.1‰ evan blue. Positive signal is green while the background is red. SEA was located on the membrane of HepG2. Untransfected HepG2 cells did not express SEA (data not show).

Figure 5 Lymphocyte phenotype analysis. 1×10⁵ SEA-T cells were stained with BD TriTEST™ antibody CD4 FITC/CD8 PE/CD3 PerCP, and assayed by FACS. CD3+90.75%, CD8+84.46%, CD4+6.29%.

Figure 6 HepG2-SEA increased the number of hepG2 specific CTL in T lymphocyte line. Each bar represents average of spots in triplicate wells.

Enhanced cytotoxicity elicited by membrane expressed SEA
Cytotoxicity of the SEA-T effector cell line against HepG2, and SMMC-7721 target cells was measured (Figure 7). HepG2-T and IL-2-T cells were used as control. In contrast, SEA-T was highly efficient in directing specific lysis of HepG2 cells when compared with HepG2-T (51.55±5 051% *vs* 33.16±4.54, $t=4.47$, $P=0.011$). The two T cell lines had effective cytotoxicity to SMMC-7721 cells.

**Figure 7** [1] Membrane expressed SEA enhanced specific lysis on autologous tumor cells. Cytotoxicity was measured in a standard 4-hour ^{51}Cr-release assay. Target cells (HepG2, SMMC-7721) were seeded in triplicate in v-bottomed microtiter plates at a concentration of $5×10^3$ cells per well. Effector cells were added at an effector-to-target (E:T) cell ratio of 40:1, 25:1, 10:1, 5:1 and 3:1 respectively. A: SEA-T was highly efficient in directing specific lysis of HepG2 cells (*squares*), HepG2-T has moderate cytotoxicity on HepG2 (*cross*) cells (*P<0.001*). B: None of T cell line has killing effect on SMMC-7721 cells.

DISCUSSION

T cells have been found to possess various potent antitumor effects through releasing cytotoxic effector molecules such as perforin or growth-suppressive cytokines IFN-γ and TNF-α[18-21]. However, the frequency of tumor-specific T cells could is generally too low and insufficient to interfere with progressive tumor growth. The goal of this experiment was to examine the possibility of developing a new experimental vaccine from irradiated HepG2 cells that were transfected to express superantigen-SEA on membrane (designed as HepG2-SEA) to augment cellular and humoral anti-tumor immune responses. Superantigen is the most effective T cell activator. Upon stimulation by superantigens, naïve T cells could respond and then become quickly anergized and/or deleted, while mature T cells could not become anergized[22-24]. Characteristis of superantigens can thus be exploited to enhance specific antigen responses. Because superantigens can cause anergy and/or deletion of potentially competing naïve T cells bearing the same Vβ element (s), thus there is less "competition" for cytokines and the desired specific immune response can be amplified.

HCC cells do not induce an effective immunological rejection process because of their weak antigenicity, the abnormal expression of MHC molecules as well as the deletion or deficiency of costimulatory molecules. In the present study, the expressed superantigen-SEA on the membrane of HepG2 cells was confirmed by RT-PCR and indirect immunofluorescence assays. When HepG2-SEA cells were used as a vaccine, two stimulating signals would present to T cells simultaneously, one was SEA, the other was tumor-associated antigens expressed on the surface of HepG2 cells, which facilitated the occurrence of specific anti-tumor immune reaction.

IFN-γ ELISPOT (enzyme-linked immunospot) assay was used for the quantitative detection of HepG2-specific CD8$^+$ T cells. This technique could detect T cells that secrete a given cytokine (e.g., IFN-γ) in response to an antigenic stimulation[25]. The size and density of spots represented the quantity of IFN-γ secreted by single CTL[18]. The results showed that the number of HepG2 cell specific CTLs in repeatedly stimulated T cell line (SEA-T) with new vaccines was significantly increased than that of HepG2 cell-based vaccines (P<0.001). Cytotoxic assay demonstrated that SEA-T was highly efficient in directing specific lysis of HepG2 cells other than SMMC-7721 cells. When compared with HepG2-T, the difference induced by new vaccines had statistical significance (P=0.011). So we conclude that tumor cell membrane expressed SEA can stimulate the proliferation of tumor specific CTL and enhance the specific lysis on autologous tumor cells.

This superantigen modified tumor cell-based vaccine has an advantage over ordinary tumor cell-based vaccines in three aspects. First, this vaccine could make up for the disadvantage of low-level expression of class II MHC molecule on the surface of most tumor cells[26]. It has been found that T cell activation by SEA superantigen could occurr in the absence or presence of MHC class II[14,27-29], and artificially anchoring a superantigen onto a cell surface through transmembrane protein could substitute for MHC-II presentation[15]. Second, although most immunotherapeutic strategies have focused on activating tumor-specific CD8$^+$ T cells, optimal antitumor activity could be achieved if both CD4$^+$ and CD8$^+$ tumor specific T cells were induced[30,31]. Likewise, if tumor immunity plays a role in limiting the recurrence of primary tumor or the future onset of metastatic diseases, then CD4$^+$ and CD8$^+$ immunological memory should be optimized. Both CD4$^+$ and CD8$^+$ T cells can be activated by bacterial superantigens. Third, superantigens could preferentially direct cytotoxicity against MHC-II-positive cells[32-34], *in vivo* administration of intact superantigens in sufficiently therapeutic amount could produce unwanted cytotoxicity to normal cells. Anchoring of superantigen and other TM fusion proteins on the surface of tumor cells would offer a novel strategy for the use of superantigens as immunostimulatory molecules. This method can confine the effect of SEA within the tumor, thus decreasing the side effects of treatment.

As presented above, irradiated HepG2-SEA cells could be used as an effective tumor cell-based vaccine *in vitro*. The superantigen enhanced vaccine is superior to tumor cell alone on the prime of tumor cell specific T cells, which provides a new strategy for the addition of superantigen as immunostimulatory molecules in tumor therapy. *In vivo* studies are currently under way to evaluate the effectiveness of these superantigen based vaccines for cancer therapy.

Abstract

AIM: To explore the feasibility of computed tomography (CT)-guided percutaneous ethanol injection (PEI) using a disposable curved needle for treatment of malignant liver neoplasms and their metastases in retroperitoneal lymph nodes.

METHODS: CT-guided PEI was conducted using a disposable curved needle in 26 malignant liver tumors smaller than 5 cm in diameter and 5 lymph node metastases of liver cancer in the retroperitoneal space. The disposable curved needle was composed of a straight trocar (21G) and stylet, a disposable curved tip (25 G) and a fine stylet. For the tumors found in deep sites and difficult to reach, or for hepatic masses inaccessible to the injection using a straight needle because of portal vein and bile ducts, the straight trocar was used at first to reach the side of the tumor. Then, the disposable curved needle was used via the trocar. When the needle reached the tumor center, appropriate amount of ethanol was injected. For relatively large malignant liver tumors, multi-point injection was carried out for a better distribution of the ethanol injected throughout the masses. The curved needle was also used for treatment of the metastasis in retroperitoneal lymph nodes blocked by blood vessels and inaccessible by the straight needle.

RESULTS: All of the 26 liver tumors received 2 or more times of successful PEI, through which ethanol was distributed throughout the whole tumor mass. Effect of the treatment was monitored by contrast-enhanced multi-phase CT and magnetic resonance imaging (MRI) examinations three months later. Of the 18 lesions whose diameters were smaller than 3 cm, the necrotic change across the whole mass and that in most areas were observed in 15 and 3 tumors, respectively. Among the 8 tumors sizing up to 5 cm, 5 were completely necrotic and 3 largely necrotic. Levels of tumor seromarkers were significantly reduced in some of the cases. In 5 patients with metastases of liver cancer in retroperitoneal lymph nodes who received 1 to 3 times of PEI, all the foci treated were completely necrotic and smaller demonstrated by dynamic contrast-enhanced CT or MRI 3 months later.

CONCLUSION: CT-guided PEI using a disposable curved needle is effective, time-saving and convenient, providing an alternative therapy for the treatment of malignant liver tumors and their retroperitoneal lymph node metastases.

INTRODUCTION

Percutaneous ethanol injection (PEI) is a common procedure for the treatment of malignant liver neoplasms. But in the treatment of small or deep foci with CT-guided PEI, repeated punctures are necessary for the needle tip to reach an appropriate position. This may result in prolongation of the operation time and an increase of the risk for complications. This article reported our recent experience in PEI treatment of liver tumors using a disposable curved needle.

MATERIALS AND METHODS

Clinical data

Thirty-one patients (22 males, 9 females; 37 to 72 years old, mean 48.9 years) were included in this study. Of them, 19 had primary liver cancer and 7 had metastatic liver tumors, including a single focus in 15 patients and multiple foci ($\geqslant$ two tumors) in 11 patients. Twenty-six foci in 26 patients were treated by PEI using a disposable curved needle, including 18 smaller than 3 cm in diameter and 8 sizing from 3 cm to 5 cm. Metastases in retroperitoneal lymph nodes were found in 5 patients, with a single node involved in 3, 2 nodes in one and 3 nodes in the other. All of the five patients received PEI treatment, one lesion for each. Every patient was informed of possible complications and the consent was obtained before operation. The procedure was approved by the Ethics Commission of the hospital.

Instruments

PQ 5000 V helical CT machine (Picker International INC, Cleveland, Ohio, USA) was used to guide the puncture. The disposable curved needle set (DCHNS, COOK, Bloomington, USA) is composed of a tip (25 G), a fine stylet, a straight trocar (21 G) and a trocar stylet. Volume Zoom multi-slice helical CT scanner (Siemens AG, Forchheim,Germany) and Symphony 1.5T MRI machine (Siemens AG, Munchen, Germany) were used to evaluate the post-operative lesions.

Procedures

The location, morphology and size of the focus were determined by enhanced CT or MRI. Prothrombin time, blood

routine, liver function and tumor markers were evaluated. The patients were fasted for four hours and notified of precautions before the procedure. Sedatives were administered for patients with mental stress.

An appropriate posture was selected and the skin surface was marked. The focal area was scanned by 5-10 mm thickness to determine the optimal puncture point, angle and depth. Local sterilization, draping and local anesthesia with 2% lidocaine were conducted. The patients were advised to hold breath at rest, when the needle was inserted into the focus according to the preplanned angle. The needle was adjusted under CT guidance in case of any deviation. The disposable curved needle was used in the following cases: 1) foci too small in size or too deep in location for the straight needle, 2) the way to the tumor center blocked by the portal vessel or bile dust, 3) large foci with multiple-site injections of ethanol by one puncture. When the straight trocar of the disposable curved needle reached the proximity of the tumor, stylet was withdrawn and the 25 G curved needle was inserted. The needle tip was 90° to the needle body in a natural state. When the tip traveled out of the trocar, it was bent by its own elasticity. The next step was to direct the tip to the focus and insert into it the tumor. Then, the stylet was removed and ethanol was injected. For the larger foci, the trocar was inserted, through which ethanol was injected from superficial to deeper areas. After that, the flexible needle was inserted, through which ethanol was injected into the areas around the trocar. Before injecting ethanol, a test withdrawal was done to make sure that the needle was not misled to the blood vessel or biliary duct. Ethanol injection should be sufficient to diffuse to all or most parts of the tumor. The total volume of ethanol injected each time should not exceed 40 ml. As absolute alcohol is of low density, it could be mixed with a small amount of contrast medium to increase its density so that the diffusion of ethanol could be more visible. A small amount of the anesthetic was administered while the needle was being withdrawn. When the needle was removed, a check-up was necessary to see whether the ethanol was well distributed within the tumor, whether there was ethanol reflex, or whether passage of the needle through the pulmonary region caused pneumothorax.

Postoperative treatment included fluid replacement, analgesic and liver protection therapies, and re-examination of liver function and tumor markers. A second treatment was given at an interval of 5 to 7 days.

Outcome evaluation

Multi-slice helical CT scan or contrast-enhanced MRI was done three months after PEI to evaluate the outcome by the necrotic area of the foci, changes of the tumor marker level and clinical manifestations.

RESULTS

All of the 26 tumors received 2 or more times of CT-guided PEI. Single-point or multi-point injections were performed for foci smaller than 3 cm, and multi-point injections for all of the foci larger than 3 cm in diameter. The ethanol distribution was found to cover the whole tumor areas in all these 26 cases (Figures 1-4). CT or MRI images showed that, of the 18 foci smaller than 3 cm, 15 were completely necrotic (Figure 5) and the remaining three were mostly necrotic. Of the 8 foci larger than 3 cm, 5 were completely necrotic and the other three were mostly necrotic. In four patients who were found to have residue nodules, CT-guided PEI was performed again, and AFP level declined markedly and the symptoms improved in some of these patients. Apart from abdominal pain of varying degrees during the procedure, no other severe complication was observed.

Figure 1 A tumor in the right lobe of liver (2.2 cm×2.0 cm). A small amount of high-density iodipin could be seen in some areas of the tumor receiving TACE.

Figure 2 When a deeply embedded tumor is difficult for a straight needle to reach the appropriate point within it, a straight trocar (21G) is used to reach the tumor side.

Figure 3 Insertion of the 25-G disposable curved needle into the tumor through the straight trocar. The tip position is adjusted to the target by changing the direction of the curved needle. Ethanol can be injected at multiple points within the tumor by changing the direction of the curved needle.

Figure 5 A complete necrotic change of the tumor found at enhanced MRI check-up three months after the PEI.

DISCUSSION

The common treatments for malignant liver tumors include surgery, transcatheter arterial chemoembolization (TACE), PEI, radiofrequency thermal ablation, microwave coagulation, laser thermal ablation therapy[1-4]. Although surgery is the most radical treatment, it is not indicative for patients with severe cirrhosis or in cases where tumors are very close to the major vessels. Surgery was not usually preferable if there were multiple foci within the liver[5]. TACE is a good alternative, but it causes severe damage to the liver. The outcome of TACE is usually poor for tumors with insufficient blood supply. PEI is a better alternative approach for treatment of malignant liver tumors, as it has proved to be effective and to cause minimal trauma[6-10]. According to Ryu et al., PEI was the choice of treatment for clinical stage II patients with tumors smaller than 3 cm. For clinical stage I patients with such small tumors, selective PEI or surgical resection should be considered[11]. In these cases, the outcomes of PEI and surgery were similar but better than TACE. Therefore, PEI should be selected according to the conditions of individual patients[12]. Combination of PEI and TACE and other treatment was sometimes used to achieve optimal outcomes[13-18]. Moreover, PEI is more convenient and safer than radiofrequency thermal ablation and microwave coagulation therapy. PEI has become a preferable approach for lesions adjacent to main biliary ducts or to intestinal loops and for well-differentiated hepatocellular carcinoma[19-21].

Chemotherapy, radiotherapy and surgery have become the routine treatments for retroperitoneal metastases of liver cancer and other malignant tumors[22-28], but some of the lesions are not sensitive to radiotherapy and chemotherapy. In addition, radiotherapy and chemotherapy are more traumatic and expensive. Dissection of metastatic lymph nodes usually results in more traumas and complications. Some patients whose general conditions are poor can not tolerate chemotherapy, radiotherapy or surgery. While CT-guided PEI is more effective for the treatment of lymph node metastases in the retroperitoneal space and abdominal cavity with less trauma and lower cost. Following CT-guided PEI, appropriate chemotherapy and radiotherapy still can be considered.

Clear visualization of tumor location and ethanol distribution during CT-guided PEI for malignant liver tumors makes it possible to inject sufficient ethanol for a better outcome. It is especially suitable for foci that could be clearly detected on ultrasound[29]. For the CT-guided PEI, it is a key step to insert the needle accurately into the target. Using the needle with a disposable curved tip, it is convenient to reach the foci and to avoid disadvantages of routine PEI procedure. What you need to do is to insert the trocar to the edge of the tumor and the disposable curved needle tip into the tumor through the trocar. It saves time and reduces complications. The disposable curved

tip can easily reach a deeply embedded tumor and avoid possible damages to the surrounding vessels or bile ducts. For tumors larger than 3 cm, multiple injections are necessary. By the procedure described here, a straight trocar is used at first to inject ethanol, and then the disposable curved needle tip is inserted through the trocar to inject ethanol into areas that the straight trocar cannot reach, so that ethanol can diffuse to the whole tumor. Retroperitoneal lymph nodes are usually deep and adjacent to abdominal aorta and inferior vena cava, PEI is usually done under CT guidance because CT guidance is accurate and the distribution of ethanol within the metastatic lymph node can be clearly visualized. The disposable curved needle can be used for metastatic lymph nodes in way to which is blocked by vessels. For larger metastatic lymph nodes, multiple-site injections of ethanol by one puncture can be done using a disposable curved needle and the procedure is more convenient than that using a routine straight needle.

As we know, this is the first report describing the use of a disposable curved puncture needle in CT-guided PEI for malignant liver tumors and retroperitoneal lymph node metastases. This procedure could also be used in CT-guided acetic acid injection for liver tumors[30,31], ethanol injection for adrenal tumors[32], and thymus ethanol injection for myasthenia gravis[33].

Abstract

AIM: To explore the cooperative effects of antisense oligonucleotide (ASON) of cell adhesion molecules and cimetidine on the expression of E-selectin and ICAM-1 in endothelial cells and their adhesion to tumor cells.

METHODS: After treatment of endothelial cells with ASON and/or cimetidine and induction with TNF-α, the protein and mRNA changes of E-selectin and ICAM-1 in endothelial cells were examined by flow cytometry and RT-PCR, respectively. The adhesion rates of endothelial cells to tumor cells were measured by cell adhesion experiment.

RESULTS: In comparison with TNF-α inducing group, lipo-ASON and lipo-ASON/cimetidine could significantly decrease the protein and mRNA levels of E-selectin and ICAM-1 in endothelial cells, and lipo-ASON/cimetidine had most significant inhibitory effect on E-selectin expression (from 36.37±1.56% to 14.23±1.07%, $P<0.001$). Meanwhile, cimetidine alone could inhibit the expression of E-selectin (36.37±1.56% *vs* 27.2±1.31%, $P<0.001$), but not ICAM-1 (69.34±2.50% *vs* 68.07±2.10%, $P>0.05$)and the two kinds of mRNA, either. Compared with TNF-α inducing group, the rate of adhesion was markedly decreased in lipo-E-selectin ASON and lipo-E-selectin ASON/cimetidine treated groups($P<0.05$), and lipo-E-selectin ASON/cimetidine worked better than lipo-E-selectin ASON alone except for HepG2/ECV304 group ($P<0.05$). However, the decrease of adhesion was not significant in lipo-ICAM-1 ASON and lipo-ICAM-1 ASON/cimetidine treated groups except for HepG2/ECV304 group ($P >0.05$).

CONCLUSION: These data demonstrate that ASON in combination with cimetidine *in vitro* can significantly reduce the adhesion between endothelial cells and hepatic or colorectal cancer cells, which is stronger than ASON or cimetidine alone. This study provides some useful proofs for gene therapy of antiadhesion.

INTRODUCTION

Previous researches have shown that recurrence and metastasis of cancer are closely related to the adhesion between tumor cells and endothelial cells. A variety of cell adhesion molecules (CAM) induced by cytokines such as IL-β and TNF-α released by tumor cells, promote the adhesion. Therefore, how to inhibit the adhesion is worth of study.

Antisense oligonucleotide (ASON) technique is a new alternative of gene therapy. ASONs are short synthetic oligonucleotides (10 to 25 bases in length) designed to hybridize to RNA (sense strand) that encodes the protein of interest. On binding to an mRNA, the oligonucleotide may inhibit the expression of target protein by multiple mechanisms[1,2], exhibiting an important significance in antivirus and cancer treatment researches[3,4]. Phosphorothioate oligonucleotides have a sulfur substituting for one of the nonbridging oxygens in the phosphate backbone, markedly enhancing the stability against cellular and serum nucleases[5,6]. E-selectin, an early expressed CAM, and intercellular adhesion molecule-1 (ICAM-1), a late expressed CAM, are important proteins that mediate cell adhesion. Relevant studies on antiinflammation or antiadhesion using ASON have aroused increasing attention[7-9].

Cimetidine, a kind of H2R antagonist, has been shown to improve the survival of patients with colorectal cancer, melanoma, and renal cell cancer. Other H2R antagonists including ranitidine and famotidine did not have such an effect[10,11], indicating that cimetidine may exert its effect by enhancing the host immune response against tumor cells[12] or by blocking the cell growth-promoting activity of histamine[13], but not directly via histamine antagonism.

The key of anti-metastatic therapy lies in the complete inhibition of metastasis, because even if one metastatic colony is formed in an organ, it may result in death of the host eventually. Combined treatment may be an effective way to reach the goal. On the basis of previous work, we investigated the combined inhibitory effects of E-selectin or ICAM-1 ASON and cimetidine on tumor cell adhesion to provide data for further animal experiment and potential clinical application.

MATERIALS AND METHODS

Materials
Human endothelial cell line ECV304, hepatic cancer cell lines HepG2 and BEL7404 and colorectal cancer cell line Ls-174-t were purchased from the Cellular Biology Institute of Chinese Academy of Sciences and grown in DF medium (DMEM: Ham's F12=3:1) containing 100 mL· L^{-1} fetal calf serum, penicillin 1×10^5U· L^{-1} and streptomycin 100 mg· L^{-1}. Transfection kit TransFast^{TM} liposome, Taq enzyme, RT-PCR kit and marker were from Promega. Mouse anti-human ICAM-1 mAb and E-selectin mAb were from Lab Vision. RNA extract (Trizol) was purchased from GIBCO BRL. Human recombinant TNF-α was purchased from Jingmei Biological Engineering Co., Shenzhen. ^{3}H-TdR was purchased from the Atomic Energy Institute of Shanghai. Cimetidine was the product of Smithkline d Beecham Pharmaceutical Co., Germany.

ASON and primers

As previously described[14,15], phosphorothioate oligoribonucleotides of ICAM-1, E-selectin and control ASON were synthesized by Shenggong Bio-Engineering Company, Shanghai. The sequences of ICAM-1, E-selectin and control ASON, and the primers for ICAM-1, E-selectin and β-actin are shown in Table 1.

Table 1 Sequences of ASON and primers

Name		Sequence	Length
ASON			
E-selectin		5'-TTCCCCAGATGCACCTGTTT-3'	
ICAM-1		5'-CCCCCACCACTTCCCCTCTC-3'	
Control primer		5'-GCCGAGGTCCATGTCGTACGC-3'	
E-selectin	Forward:	5'-AAAATGTTCAAGCCTGGCAGTTCC-3'	
	Reverse:	5'-GTGGTGATGGGTGTTGCGGTTTCA-3'	509 bp
ICAM-1	Forward:	5'-CACAAGCCACGCCTCCCTGAACCTA-3'	
	Reverse:	5'-TGTGGGCCTTTGTGTTTTGATGCTA-3'	458 bp
β-actin	Forward:	5'-CTGTCTGGCGGCACCACCAT-3'	
	Reverse:	5'-GCAACTAAGTCATAGTCCGC-3'	250 bp

Methods

Preparation of lipo-ASON In order to improve the efficiency of ASON uptake of cells and prevent degradation in cultured cells and human serum, we used a commercial liposome that was comprised of synthetic cationic lipid and neutral lipid. It enhanced ASON's biofunction by improving its merging with cell membrane of eukaryotic cells and entering cell plasma to combine with mRNA[16]. At a lower final concentration of 1/10 the nude ASON, lipo-ASON worked more effectively on inhibition in our previous report. According to the manufacturer's protocol of TransFast™ liposome, 200 μl of serum-free medium per well should contain 3.6 μl(1.5 μg) ASON and 4.4 μl liposome. So 10 minutes before the experiment, ASON was first mixed with serum-free medium, then liposome was added to make lipo-ASON medium (1 μmol/L) at room temperature.

Treatment of endothelial cells A total of 5×10^4 ECV304 endothelial cells (3 to 6 generations) per well were put into a 24-well plate and incubated at 37 ℃ in 5 mL/L CO_2 humidified atmosphere for 48 hours, when cells grew to a confluence of 80%. E-selectin and ICAM-1 were divided into 5 groups according to the following different treatments, respectively. GroupI (Basal): Treatment with TNF-α without lipo-ASON or cimetidine, and the cultivation time was identical to the other groups. Group II (TNF-α): After cultivation for 48 hours, the supernatants were discarded, endothelial cells were washed with PBS and replaced with 200 μl of serum-free medium. Group III (cimetidine): After cultivation for 24 hours, 200 μl of serum-free medium containing cimetidine (10^{-8}M) was added and cultured for another 24 hours, then the supernatants were discarded, cells were washed with PBS and replaced with 200 μl of serum-free medium. Group IV (lipo-ASON): After cultivation for 48 hours, the supernatants were discarded, cells were washed with PBS and replaced with 200 μl of serum-free medium containing lipo-ASON. Group V (lipo-ASON/cimetidine): After cultivation for 24 hours, 200 μl of serum-free medium containing cimetidine (10^{-8}M) was added and cultured for another 24 hours, then the supernatants were discarded, cells were washed with PBS and replaced with 200 μl of serum-free medium containing lipo-ASON.

Groups II to V were cultured for 4 hours at 37 ℃. For E-selectin expression groups, the supernatants were discarded, 200 μl medium containing 5 ng TNF-α was added and continuously cultured for 4 hours at 37 ℃. For ICAM-1 expression groups, the supernatants were discarded, 200 μl

medium was added and continuously cultured for 4 hours at 37 ℃, then 5 ng TNF-α was added and cultured for 16 hours.
Flow cytometry Endothelial cells, treated with ASON or cimetidine and TNF-α as described above, were removed from the plate by brief trypsinization with 0.25% trypsin. Cells were washed with DEME plus 10% FCS, stained with primary mAb (2 μg/μl) diluted in D-PBS containing 2% BSA and 0.2% sodium azide, followed by fluorescein-conjugated goat anti-mouse IgG. Each step was performed at 4 ℃. Cells were analyzed by flow cytometry using a Bryte HSFACScan (BID-RAD, US).
RT-PCR 2.5×10^5 of ECV304 endothelial cells per well were placed into a 6-well plate and then performed as described above. Total cellular RNAs were extracted and quantitated by a spectrophotometer. 2 μg of RNA was used to perform reverse transcription as recommended by the supplier. E-selectin gene was amplified 30 cycles by half-quantitation under the following conditions: denaturation at 94 ℃ for 5 min followed by at 94 ℃ for 30 s, at 64 ℃ for 45 s and at 72 ℃ for 45 s, then extension at 72 ℃ for 7 min. ICAM-1 gene was amplified 30 cycles by half-quantitation under the following conditions: denaturation at 94 ℃ for 5 min followed by at 94 ℃ for 30 s, at 60 ℃ for 45 s and at 72 ℃ for 45 s, then extension at 72 ℃ for 7 minutes. For analysis, 10 μL of the amplified product was tested in 20 g/L agarose gel with ethidium bromide staining, then photographed and scan-analysed. The ratio of average integrated density value (IDV) of E-selectin and ICAM-1 to IDV of β-actin was expressed as the relative intensity of E-selectin and ICAM-1, respectively.
Monolayer cell adhesion assays 1×10^4 ECV304 endothelial cells per well were placed into a 96-well plate and then performed as described above. Human hepatic cancer cell lines HepG2 and BEL7404 and colorectal cancer cell line Ls-174-t were subcultured for 24 hours, then incubated with medium containing ^{3}H-TdR(9 μCi/ml)for 12 hours at 37 ℃. The three kinds of cells (2.5×10^5) were added to ECV304 monolayer in a final volume of 0.1 ml respectively, and incubated for 1 h at 37 ℃. Nonadherent cells were removed from the plate by gentle washing with warm PBS. By brief trypsinization with 0.25% trypsin, the adherent cells were removed onto a piece of fiberglass paper (49#), washed with 5% trichorolacetic acid and dried at 80 ℃. The number of adherent cells was determined by measuring flash value using a flash-detecting device (Tri-Carb 2300TR, Packard Co Lit).

Statistics analysis

Data were presented with $\bar{x} \pm s$, statistical analysis was performed using ANOVA. Differences were judged to be statistically significant when the *P* value was less than 0.05.

RESULTS

Effect of ASON and/or cimetidine on expression of E-selectin and ICAM-1

Using cytofluorometry, we examined the effect of lipo-ASON or cimetidine on the level of E-selectin and ICAM-1 protein in ECV304 cells stimulated by TNF-α (Figure 1). Maximum expression of E-selectin or ICAM-1 was observed in TNF-α inducing group with no other treatments. Compared with TNF-α inducing group, the expression of E-selectin in all treated groups was differently decreased (*P*<0.001), most markedly in lipo-ASON/cimetidine treated group (*P*<0.001, *vs* lipo-ASON alone group), showing that lipo-ASON in combination with cimetidine had a better inhibitory effect. Similarly, the expression of ICAM-1 in lipo-ASON and lipo-ASON/cimetidine treated groups decreased significantly (*P*<0.001), but the change of ICAM-1 expression in cimetidine treated group was not significant (*P*=0.296), suggesting that cimetidine did not affect ICAM-1 expression in endothelial cells.

Figure 1 Effect of ASON on expression of E-selectin and ICAM-1 in endothelial cells ([a]P<0.01, *vs* group II, *n*=5). I: Basal, II: TNF-α, III: cimetidine, IV: lipo-ASON, V: lipo-ASON/cimetidine.

Figure 2 Agarose gel electrophoresis of RT-PCR products. M:Marker, 1: E/basal, 2: E/TNF-α, 3: E/cimetidine, 4: E/lipo-ASON, 5: E/lipo-ASON/cimetidine, 6: I/basal, 7: I/TNF-α, 8: I/cimetidine, 9: I/lipo-ASON, 10: I/cimetidine.

Agarose gel electrophoresis of RT-PCR products

To investigate the effects of lipo-ASON and/or cimetidine on the level of E-selectin and ICAM-1 mRNA, RT-PCR analysis was carried out. As shown in Figures 2 and 3, TNF-α could induce E-selectin and ICAM-1 gene expression. Lipo-ASON or lipo-ASON/cimetidine could significantly reduce the level of E-selectin and ICAM-1 mRNA, but cimetidine did not.
Figure 3 Relative expression value of ICAM-1 and E-selectin to β-actin by RT-PCR. I: Basal, II: TNF-α, III: Cimetidine, IV: Lipo-ASON, V: Lipo-ASON/Cimetidine.

Effect of ASON and/or cimetidine on adhesion

To examine the effects of lipo-ASON and/or cimetidine on the adhesion between tumor cells and ECV304 cells, a monolayer cell adhesion assay was carried out. As shown in Table 2, the adhesions of HepG2, BEL7404 and Ls-174-t cells to ECV304 cells were strongly induced by stimulation with TNF-α. Compared with TNF-α inducing group, the rate of adhesion was markedly decreased in lipo-E-selectin ASON and lipo-E-selectin ASON/cimetidine treated groups (*P*<0.05), and lipo-E-selectin ASON/cimetidine worked better than lipo-E-selectin ASON alone except for HepG2/ECV304 group (*P*<0.05). However, the decrease of adhesion was not significant in lipo-ICAM-1 ASON and lipo-ICAM-1 ASON/cimetidine treated groups except for HepG2/ECV304 group (*P*>0.05).

DISCUSSION

ICAM-1 cDNA with 2.98 Kb in length consists of 5'-untranslated region, 57 bp, a continuous open reading frame, 1 598 bp, and 3'-untranslated region, 1 330 bp. E-selectin cDNA with 3.85 Kb in length consists of 5'-untranslated region, 116 bp, a continuous open reading frame, 1 830 bp, and 3'-untranslated region, 1 898 bp. Bennett's research[14] showed that among all the designed ASONs, ASONs hybridized to 3'-untranslated region were more potent than those hybridized to AUG transcription-initiation site or 5'-untranslated region. In our previous experiment, we found that each selected ASON of ICAM-1 and E-selectin hybridized to 3'-untranslated region

could reduce the expression of objective gene by nearly 40% respectively, demonstrating that their effects were sequence specific. This loss in mRNA might be due to the ASON targeted objective pre-mRNA in the nucleus, which resulted in activation of endogenous RNase H or a related enzyme and mediated hydrolysis of mRNA-ODN at the hybridization site[17,18].

With the presence of cytokines such as IL-1β and TNF-α secreted by tumor cells, vascular endothelial cells can produce different adhesive molecules at different times. After stimulation of cytokines, E-selectin shows its features in 4 to 5 hours, which mediate the early adhesion, and ICAM-1 shows its features in 12 to 48 hours, which mediate the late adhesion. In this article, through the treatment with E-selectin or ICAM-1 ASON before the induction by TNF-α, the expressions of objective molecules were blocked, but the adhesion between endothelial cells and tumor cells was only significantly inhibited by E-selectin ASON. The reasons were as follows: 1) Hepatic and colorectal cancer cells could highly express sle[x] Ag[19], the ligand of E-selectin. It is the major molecule that mediates the adhesion to endothelial cells directly. 2) ICAM-1 also appeared in the membrane of hepatic or colorectal cancer cells. The adhesion between cancer cells and vascular endothelial cells *in vitro* resorted to LFA-1[20], the ligand of ICAM-1, which expresses on the membrane of white blood cells. However, there were no white blood cells to bridge *in vivo*. 3) Hepatic or colorectal cancer cells like HepG2 could also express affluent integrin $\alpha_2\beta_1$, which directly mediated the adhesion between tumor cells and endothelial cells[19]. It is this kind of molecules that work in ICAM-1 ASON treated group.

Cimetidine, a kind of H2 receptor antagonist, has been used to inhibit the secretion of gastric acid in clinic. It has also been used to prolong the survival of patients with various forms of cancer in recent years[21,22]. Even at the highest noncytotoxic concentration (10^{-4}M), cimetidine has been shown not to influence the expression of ICAM-1 protein, ICAM-1 mRNA and E-selectin mRNA, but could obviously reduce the expression of E-selectin protein[22,23]. We proposed that cimetidine's inhibitory action on metastasis was due to blocking the adhesion between endothelial cells and tumor cells, especially colorectal cells with higher expression of sle[x] Ag[24]. Since other H2 receptor antagonists, such as ranitidine and famotidine, did not play the same role under the same experimental conditions[22], it has become obvious that the mechanism of cimetidine's inhibiting function is involved in a step after transcription. p38 MAPK[25], for instance, might be the regulatory molecule that activates the expression, of a number of genes at the level of posttranscription[26-28].

Our research demonstrated that E-selectin played a primary role in initiating the adhesion of cancer cells to vascular endothelial cells through its interaction with its specific ligand, sialyl Lewis antigens[29,30]. Lipo-E-selectin ASON in combination with cimetidine could inhibit the expression of E-selectin more effectively and reduce the adhesive rate of endothelial cells to tumor cells in early stage, reaching the goal of double benefits from outside and inside of cells. It not only guarantees the major aim of inhibiting adhesion, but also lowers the negative influence of cells subjected to drug *ab extra*. In short, this study provides some useful proofs for gene therapy of antiadhesion, which would become a new therapeutic alternative to inhibit high recurrence and metastasis of hepatic or colorectal cancer.

Abstract

AIM: To investigate the correlation of enhancement features of hepatocellular carcinoma (HCC) revealed by single-level dynamic spiral CT scanning (DSCT) with tumor microvessel density (MVD), and to determine the validity of DSCT in assessing *in vivo* tumor angiogenic activity of HCC.

METHODS: Twenty six HCC patients were diagnosed histopathologically. DSCT was performed for all patients according to standard scanning protocol. Time-density curves were generated, relevant curve parameters were measured, and gross enhancement morphology was analyzed. Operation was performed to remove HCC lesions 1 to 2 weeks following CT scan. Histopathological slides were carefully prepared for the standard F_8RA immunohistochemical staining and tumor microvessel counting. Enhancement imaging features of HCC lesions were correlatively studied with tumor MVD and its intra-tumor distribution characteristics.

RESULTS: On DSCT images of HCC lesions, three patterns of time-density curve and three types of gross enhancement morphology were recognized. Histomorphologically, the distribution of positively stained tumor endothelial cells within tumor was categorized into 3 types. Curve parameters such as peak enhancement value and contrast enhancement ratio were significantly correlated with tumor tissue MVD ($r=0.508$ and $r=0.423$, $P<0.01$ and $P<0.05$ respectively). Both the pattern of time-density curve and the gross enhancement morphology of HCC lesions were also correlated with tumor MVD, and reflected the distributive features of tumor microvessels within HCC lesions. Correlation between the likelihood of intrahepatic metastasis of HCC lesions with densely enhanced pseudocapsules and rich pseudocapsular tumor MVD was found.

CONCLUSION: Enhancement imaging features of HCC lesions on DSCT scanning are correlated with tumor MVD, and reflect the intra-tumor distribution characteristics of

tumor microvessels. DSCT is valuable in assessing the angiogenic activity and tumor neovascularity of HCC patients *in vivo*.

INTRODUCTION

Tumor angiogenesis plays a fundamental role in the pathogenesis of tumor growth and metastasis[1-3], and significantly influences the biological behaviors of tumor and prognosis of patients[3-6]. The inhibition or blockade of this angiogenic activity, on the other hand, can slow down the tumor growth rate and positively affect the outcome of patients[7-9]. Although a single standardized and thoroughly validated method to evaluate the structure and function of tumor angiogenesis is not available, some histomorphological markers, such as microvessel density (MVD) and vascular endothelial growth factor, have been used as indicators of tumor angiogenic activity currently[3,10-12]. However, these markers were studied immunohistochemically *in vitro* on biopsy or surgical tissues, and could not provide information of functional status of tumor angiogenesis, and were hardly to repeat for patients in follow-up. An ideal test should be non-invasive, fast, easy to perform, repeatable and reproducible, and most importantly, it should provide accurate and comprehensive information on the structure and biological characteristics of tumors *in vivo*.

Modern medical imaging modalities can depict the blood flow or reflect the hemodynamic changes. Recent studies using Doppler Sonography[13-16] or MR[17-28] or CT[29,30] to assess tumor angiogenesis and neovascularity have yielded encouraging results in differential diagnosis and the correlation of aggressiveness and metastasis of tumor with the prognosis of patients. Correlation of enhanced imaging features of hepatocellular carcinoma (HCC) with tumor MVD was investigated to determine the validity of single-level dynamic spiral CT scanning (DSCT) *in vivo* for assessment of tumor angiogenic activity and neovascularity.

MATERIALS AND METHODS

Study subjects
From June 1997 to January 1999, 26 HCC patients were histopathologically proved and used for the study, and all the patients met the criteria for DSCT scanning and for histopathological specimen sampling and slides preparation. There were 23 males and 3 females with a mean age of 43.5 years (27 to 72 years). None of them had anti-tumor therapies prior to CT examination, and 1-2 weeks after CT, surgery was performed on all HCC patients to remove the lesions.

DSCT protocol

A Somatom Plus 4 VA spiral CT scanner (Siemens, Erlangen, Germany) was used for the study, 2 ml/kg of 65% angiografin or ultravist-300 (Schering, Germany) was used as intravenous contrast agent and injected via the antecubital route on the constant rate of 3 ml/sec. Before the start of CT scanning, the patients were educated and trained on how to cooperate for CT examination. The whole scanning procedure included 3 steps. First, all the liver was scanned without enhancement, then dynamic scanning at the selected target slice level (single-slice dynamic scanning) was followed, and finally the portal venous phase spiral CT acquisition of the entire liver was obtained. The target slice was selected based on the abnormal findings on the initial scanning. Only the central slice with the smallest area of tumor necrosis was chosen as the target for dynamic scanning. The dynamic scanning was performed 18 seconds after intravenous administration of contrast agent. For the dynamic scanning the sequence scan mode was employed with the cycle time of 2.3 seconds. A total of 18 slices were generated. The spiral scan mode was used for the initial scan and acquisition data on the final portal venous phase. Seven mm was used for calibration, table feed and slice thickness (pitch=1/1), and the scan delay time for the portal venous phase was 65 seconds.

Image data processing

Generation of time-density (T-D) curve Any visible blood vessel, necrotic foci and hypodense septum were avoided in selection of the region of interest (ROI) for HCC lesions. For the abdominal aorta, ROI was placed in its cross sectional center. The size of ROI was restricted to around 1 cm in diameter. With the built-in software program, the T-D curves of both HCC lesions and abdominal aorta were generated on the basis of the selected ROIs.

T-D curve parameters Several curve parameters were defined for the T-D curve of HCC lesions. (a) The peak enhancement value (PV) of the abdominal aorta was defined as the CT attenuation number at the junction between the up-slope portion with the steepest rise and the portion with gradual or flat rise. The corresponding time was referred to as the peak enhancement time (PT). (b) The PV for HCC lesion was the result of maximum enhancement CT attenuation number minus the baseline CT attenuation number on plain CT scan, and the time to reach the maximum CT attenuation number after enhancement was the PT. (c) The contrast enhancement ratio (CER) was defined as the percentage of the PV of HCC lesion divided by the PV of the abdominal aorta. Patterns of T-D curves were analyzed and the related curve parameters (PV, PT, and CER) were calculated.

Image interpretation All the CT images were jointly analyzed with standardized criteria by two senior radiologists experienced in liver imaging. Special attention was paid to the morphological enhancement patterns of HCC lesions and other associated imaging findings, such as pseudocapsules, daughter foci, and invasion of the portal venous system.

Histomorphological analysis of tissue specimen

Great care was taken to ensure that the matching of tissue sampling sites of surgically resected gross HCC tumor specimen with the correspondingly selected ROIs on DSCT images was on one-to-one basis. The obtained tissue specimens were processed by standard macro- and micro-slide techniques to verify the histomorphological tumor extension. Then slides of 5 μm thickness were stained with the standard immunoperoxidase method using factor VIII-related antigen (F_8RA stain)[2]. Criteria for positive stain and microvessel counting were those established by Weidner et al[2-3]. Two

independent experienced pathologists counted each ROI separately, and consensus counting was done for dispute. The counting was first proceeded at 100 x magnification for "hot spot" representing the area of the highest microvessel density (MVD), then switched to 200 x magnification for clear depiction and better counting. For each slide three "hot spots" were counted, and the mean count represented the final MVD. The distribution of "hot spots" within tumor lesions was also recorded.

Statistical analysis

Pearson's correlation analysis and variance analysis were performed to test the strength of association between CT imaging features and the histomorphological marker, $P<0.05$ was considered statistically significant.

RESULTS

Dynamic CT scan

Patterns of T-D curve Some distinctively different patterns of T-D curves of HCC lesions were observed and categorized into three types. Type I, the initial rise of T-D curve was very fast and steep, then abruptly changed to a more flat and steady gradual rise till the plateau phase. This curve pattern occurred in 7 patients. In type II curve, the up-rise of the curve slope was obvious, yet relatively smooth, no abrupt turn in the configuration of the curve up-slope. Thirteen patients demonstrated T-D curve pattern of type II. Type III curve in 6 patients was characterized by slow and flat rise of the initial curve up-slope with low amplitude. These three patterns of T-D curves of HCC lesions are depicted in Figure 1, and the calculated curve parameters are summarized in Table 1. PV and CER of type III patients were obviously lower than those of type I and type II patients, and the differences were statistically significant ($P<0.05$). On the other hand, the differences of PV and CER between type I and type II patients were not statistically significant. There was a trend for PT to increase gradually from type I to type III, but the differences among the three types were not statistically significant.

Figure 1 Three patterns (I, II, III) of time-density curve observed in HCC patients. The transverse axis represents the time and the Y-axis represents the peak enhancement value in Hounsfield units.

Table 1 HCC time-density curve patterns

Curve parameters	Type I	Type II	Type III
Number of patients	7	13	6
PV (Hu)	53.6±7.8	47.9±12.6	20.6±7.2[a]
PT (Sec)	43.8±9.5	52.2±7.7	57.9±8.3
CER (%)	25.0± 7.2	22.5±6.5	8.2±3.4[a]

[a]The differences of PV and CER between type III and those of type I and II were statistically significant ($P<0.05$).

Figure 2 Three types of enhancement morphology depicted in HCC patients. A: Type A. Marked and homogeneous enhancement of the entire HCC lesion in the posterosuperior segment of right hepatic lobe (black arrow). B: Type B. Bright peripheral ring-like enhancement of HCC lesion on arterial phase image in the right posterosuperior segment (black arrow), and the dilated right hepatic artery (black arrow). C: Portal venous image at the same slice level as in (B). HCC lesion remained hypodense despite obvious enhancement of normal liver parenchyma elsewhere. D: Type C. Inhomogeneous patchy enhancement of HCC lesion in right lower hepatic lobe from arterial phase image. Bright dots and linear shadows represent enhanced tumor vessels within the lesion.

Morphological enhancement patterns of HCC The gross morphological enhancement manifestations of HCC lesions could also be grouped into 3 types (Figure 2). Type A was seen in 7 patients, the HCC lesions were densely enhanced in a homogeneous pattern (Figure 2A). The mean transverse diameter of lesions was 3.1 cm. Type B was in 5 patients, the

lesions demonstrated complete or partial rim-like peripheral enhancement, without or with only few dots of enhanced tumor vessels within the lesion center (Figure 2B, 2C). Mean diameter was 5.7 cm. Type C was seen in 14 patients, HCC lesions were inhomogeneously enhanced in a patchy fashion. Many small round-shaped, linear or reticular shadows representing enhanced tumor vessels were clearly visible, along with many hypodense necrotic foci and fibrous septa within the lesions (Figure 2D). The mean transverse diameter in this group of patients was 8.5 cm. The differences in the transverse diameter of tumor lesions among the three groups were statistically significant.

Immunohistochemical findings

F_8RA staining revealed a great variation in the distribution of positively stained tumor vascular endothelial cells within HCC lesions. Such a distribution variability in our patient could be roughly grouped into three patterns (Figure 3). (1) Twelve patients exhibited very rich blood sinusoids but scanty tumor microvessels in the interstitium. In 9 patients, positively stained sinusoidal endothelial cells were abundant and distributed inhomogeneously in a patchy fashion (Figure 3A). But in the rest 3 patients, sinusoidal endothelial cells had no positive staining. (2) Eleven patients had both rich sinusoids and interstitial microvessels, a large number of positively stained endothelial cells were distributed in both sinusoids and interstitium (Figure 3B). (3) Three patients had rich interstitium, with few interstitial microvessels and scanty sinusoids, and positively stained endothelial cells were very scarce (Figure 3C).

The MVD of HCC tumor tissue varied greatly from 6 to 91 among patients.

Correlation of DSCT features and tumor MVD

(1) T-D curve parameters and MVD A statistically significant positive correlation was demonstrated between tumor MVD and both PV and CER of corresponding HCC lesions. The correlation coefficients (*r*) were 0.508 (*P*<0.01) and 0.423 (*P*<0.05) respectively. However, MVD had no positive correlation with PT.

(2) Curve patterns, enhancement morphology and MVD The relationships between tumor MVD and T-D curve patterns and the three gross enhancement morphological types of HCC lesions are summarized in Table 2. The tumor MVDs of T-D curve type III and the gross enhancement morphology type B were significantly lower than those of curve type I and II (*P*<0.05), and gross morphology type A and C (*P*<0.05), respectively. The differences of MVDs between types I, II of T-D curve and the enhancement morphological patterns (type A, C) were not statistically significant.

Table 2 HCC time-density curve patterns, types of gross enhancement morphology and tumor MVD

	Type I	Type II	Type III	Type A	Type B	Type C
Patient No	7	13	6	7	5	14
MVD	41.8±16.7	48.0±18.2	23.0±7.4ᵃ	49.7±14.2	15.6±5.7ᵇ	44.0±19.7

ᵃThe differences of MVDs between type III and type I, type II were statistically significant (*P*<0.05). ᵇThe differences of MVDs between types B, A, C were statistically significant (*P*<0.05).
(3) Curve patterns, enhancement morphology and distribution of MVD The intratumoral distribution characteristics of tumor MVD and their relationships with T-D curve patterns and gross morphological enhancement types of HCC lesions are listed in Table 3.

Table 3 HCC time-density curve patterns, types of gross enhancement morphology and intratumoral MVD distribution
	Type I	Type II	Type III	Type A	Type B	Type C
Rich S	0	10	2	4	2	6
Rich S & I MVD	7	3	1	3	0	8
Scanty S & I MVD	0	0	3	0	3	0

S-tumor blood sinusoids, I-tumor interstitium.

(4) Other DSCT signs and related histomorphological changes Eleven patients demonstrated intrahepatic metastatic foci or daughter lesions. 7 of the 11 patients had prominent pseudocapsules that were hyperdense on DSCT images (Figure 4). In 1 patient the pseudocapsule remained to be hypodense throughout the entire scanning period, and no discrete pseudocapsule was discernible in the other 3 patients. Immunohistochemical F_8RA stain revealed abundant positively stained tumor endothelial cells in connective tissue of the tumor pseudocapsule in 8 patients. In the remaining 3 patients, judgement could not be made as whether or not the tumor pseudocapsule was present on the histopathological slides, due to improper tissue sampling, which missed the border region between HCC lesion and the neighboring normal liver tissue.

Figure 3 Three patterns of intratumoral MVD distribution revealed by F_8RA immunohistochemical staining. A: Pattern I. Markedly dilated and abundant blood sinusoids with very rich positively stained sinusoidal endothelial cells and scanty tumor interstitium. B: Pattern II. Sinusoids and interstitium abundant and rich in positively stained endothelial cells (black arrow). C: Pattern III. Rich tumor interstitium with few positively stained endothelial cells (white arrow) and scanty blood sinusoids.

Figure 4 Enhancement of HCC pseudocapsules and pseudocapsular MVD. A: Marked enhancement of HCC pseudocapsule (hyperdensity) in the medial segment of left hepatic lobe shown by DSCT. Note the similar enhancement pattern of the satellite or daughter lesion in the anterior segment of right hepatic lobe. B: F_8RA staining Rich positively stained endothelial cells within tumor pseudocapsule (black arrow) revealed by F_8RA staining.

DISCUSSION

MVD, one of the histomorphological markers, is currently regarded as the best available means to represent tumor angiogenesis, and has been widely used to characterize tumor angiogenic activity *in vitro*. However, it may not be an ideal method for clinical purposes, as it is invasive and hard to perform and to repeat. Clearly, from the clinical perspective, it is of great clinical importance to look for a noninvasive method, which can provide *in vivo* overall functional information about tumor angiogenesis, besides accurate morphological information. We designed this dynamic spiral CT study to investigate the correlation of enhancement patterns of HCC lesions with the histomorphological marker of tumor angiogenesis – tumor MVD, and to determine the validity of DSCT in assessing angiogenic activity and neovascularity of HCC lesions.

Our study showed that the curve parameters generated from T-D curves of HCC lesions, such as PV and CER, were positively correlated to tumor MVD with statistical significance. As T-D curve parameters were representative of the hemodynamic characteristics of tumor microvasculature, this observation indicated that the degree of tumor enhancement on DSCT was affected by tumor MVD. The tumor enhancement degree could also truly reflect the distribution characteristics of tumor microvessels within a tumor mass, as the area with the greatest enhancement was often associated with the highest MVD. Higher tumor MVD was shown to be associated with worse degree of

malignancy and more potential of metastases[4,10], thus it is possible to estimate the biological behaviors of HCC in terms of aggressiveness and metastasis by calculating the parameters of HCC T-D curve through dynamic spiral CT scanning.

The patterns of T-D curves of HCC lesions also provided *in vivo* clues to the histomorphological distribution characteristics of tumor microvessels within a tumor mass. Type I curve was often histologically associated with rich blood sinusoids and microvessels in the interstitium, both demonstrating abundant positively stained tumor vascular endothelial cells. Such a histomorphological feature of microvessel-rich tumor interstitium might well explain the early rapid rise of the up-slope and the high amplitude of this type of T-D curves observed in this subset of HCC patients. As more and more contrast agents reached the sinusoids where the rate of blood flow was sluggish, alteration of the rise pace resulted in an abrupt turn of the curve up-slope configuration. Abundant, often dilated and tortuous sinusoids with positively stained tumor endothelial cells resulted in type II curve. Sluggish blood flow with prolonged accumulation of contrast agent in sinusoids might cause the slow and steady rise of the up-slope of T-D curve in this group of HCC patients. However, in 3 patients with type II curve, both sinusoids and interstitium showed rich positively stained endothelial cells. Two reasons might be implicated for this discrepancy between T-D curve pattern and histomorphological marker. First, the hemodynamic effect of rich blood sinusoids might overrun that of microvessel-rich interstitium in these 3 HCC patients, causing the distribution of contrast-containing blood within the tumor mass to be relatively slower. Misrepresentation due to sampling error was another possible reason. As the selected area of ROI was 1 cm, much larger than what could be represented on a histological slide, it was possible that the selected ROIs might actually contain many more sinusoids than what was shown on the corresponding histological slides in these 3 HCC patients. Type III curve was histologically characterized either by rich interstitium but with scanty interstitial microvessels and scanty blood sinusoids, or by rich sinusoids which were devoid of positively stained endothelial cells. These tumor sinusoids had structural and functional resemblance to those of normal liver sinusoids, therefore, the rise of the up-slope in this type of T-D curve was quite slow and flat in the hepatic arterial phase. In the patient with type III curve, both rich sinusoids and interstitial microvessels with positively stained endothelial cells were observed. We speculated that the cause might be the mismatch of selected ROI with the sampling site for histomorphological measurement, and the variation in tumor angiogenic activity within a tumor lesion, which could lead to the misrepresentation by MVD.

The study also found that the gross enhancement morphology of HCC lesions was related to the distribution of tumor microvessels within a tumor mass. As shown in Table 3, type A enhancement morphology was mainly seen in relatively small HCC lesions, while type C enhancement morphology was found in larger lesions. However, both types were histomorphologically characterized by rich blood sinusoids or coexistence of microvessel-rich interstitium, both of witch had abundant positively stained endothelial cells. Such findings might suggest that when a hypervascular HCC lesion was small, the distribution of tumor microvessels within it tended to be homogeneous, giving rise to the homogeneous enhancement appearance on DSCT scan. With the tumor became larger, intratumoral necrosis, fibrous septation and granulation formation occurred. The original homogeneity of tumor microvessels distribution was altered and distorted, so did the gross morphological enhancement patterns on CT images. Type B enhancement morphology showed that tumor interstitium was abundant in quantity, but either with scanty

interstitial microvessels and few sinusoids, or with rich sinusoids that were devoid of positively stained endothelial cells. In sharp contrast, tumor microvessels with positively stained endothelial cells were rich in pseudocapsules of this type of HCC patients. Thus the gross morphological enhancement pattern could well reflect the underlying histomorphological characteristics of tumor microvessels in this group of HCC patients. Therefore, by analyzing the enhancement morphology of HCC lesions on dynamic spiral CT scan, it was possible to estimate both the *in vivo* tumor angiogenic activity and the distribution characteristics of tumor neovascularity. Compared to the measurement of histomorphological markers, dynamic spiral CT was able to maximally avoid the possibility of sampling errors and offered a comprehensive overview of the gross enhancement morphology of HCC lesions.

Our another interesting finding was that most of HCC lesions with intrahepatic metastases or daughter foci demonstrated characteristic hyperdense pseudocapsules on dynamic CT images corresponding to hepatic arterial phase. These pseudocapsules were histomorphologically characterized by very rich positively stained endothelial cells diffusely distributed in the connective tissues of pseudocapsules. Such an association indicated that hypervascularized tumor pseudocapsules with abundant interstitial structurally defective tumor microvessels[31] might facilitate intrahepatic metastasis or homogeneous spreading of HCC.

Though the close positive correlation of enhancement imaging features of HCC lesions revealed by DSCT with tumor MVD was demonstrated, several other factors, such as perfusion rate, microvessel permeability, and size or volume of extracellular space, might also influence the uptake rate of contrast agent by tumor tissue, thus affecting the configurations of T-D curve. Little has been known about major contributors for the difference in the contrast agent uptake rate[11,32]. We suspect that the differences might depend on the type or even subtype of tumors, and further studies are required to clarify this issue.

In conclusion, the characteristics of T-D curve of HCC revealed by DSCT scanning are closely related to tumor MVD. The grass enhancement morphology of HCC lesions on DSCT images can reflect the features of histomorphological distribution of tumor microvessels within a tumor. DSCT is valid for the *in vivo* assessment of tumor angiogenic activity and neovascularity of HCC lesions, which is very important in making differential diagnosis, evaluating tumor malignancy and aggressiveness, monitoring therapeutic effects, and determining the final outcome of HCC patients.

Abstract

AIM: Ischemic preconditioning (IP) is a brief ischemic episode, which confers a state of protection against the subsequent long-term ischemia-reperfusion injuries. However, little is known regarding the use of IP before the sustained cold storage and liver transplantation. The present study was designed to evaluate the protective effect of IP on the long-term preservation of liver graft and the prolonged anhepatic-phase injury.

METHODS: Male Sprague-Dawley rats were used as donors and recipients of orthotopic liver transplantation. All livers underwent 10 min of ischemia followed by 10 min of reperfusion before harvest. Rat liver transplantation was performed with the portal vein clamped for 25 min. Tolerance of transplanted liver to the reperfusion injury and liver damage were investigated. The changes in adenosine concentration in hepatic tissue and those of nitric oxide (NO) and tumor necrosis factor (TNF) in serum were also assessed.

RESULTS: Recipients with IP significantly improved their one-week survival rate and liver function, they had increased levels of circulating NO and hepatic adenosine, and a reduced level of serum TNF, as compared to controls. Histological changes indicating hepatic injuries appeared improved in the IP group compared with those in control group. The protective effect of IP was also obtained by administration of adenosine, while blockage of the NO pathway using Nω-nitro-L-arginine methyl ester abolished the protective effect of IP.

CONCLUSION: IP appears to have a protective effect on the long-term preservation of liver graft and the prolonged anhepatic-phase injuries. NO may be involved in this process.

INTRODUCTION

Liver transplantation is an accepted therapy for patients with end-stage liver diseases[1]. Hepatic ischemia-reperfusion (I/R) injury associated with liver transplantation is an unresolved problem in the clinical practice. Primary non-function of liver graft remains one of the most severe complications of liver transplantation, and poor initial graft function also occurs in one third of cases after liver transplantation. To deal with these complications, no effective treatment can be used but retransplantation[2,3]. Evidently, approaches need to be established to handle or even to avoid these complications.

The underlying mechanisms of cold I/R injuries are still poorly understood. Long-term ischemia of liver graft leads to impairment of liver function and reduction in survival rate of the recipients[4]. On the other hand, anhepatic phase is the most important parameter for orthotopic rat liver transplantation (ORLT), because prolonged anhepatic phase can be associated with an endotoxin-like syndrome caused by the warm intestinal ischemia and is not related to the cold ischemia injuries of the liver[5]. The hepatic reticulo-endothelial system plays a key role in the elimination of endotoxins. The detoxification system is usually deficient in recipients due to liver failure and is completely absent during the anhepatic phase of transplantation. The endotoxin content has been proven to increase markedly in the portal circulation of cirrhotic patients compared to that in the peripheral blood[6]. The hypothermia may affect the ability of Kupffer cells to eliminate endotoxins and to release cytokines, such as tumor-necrosis factor (TNF). It has been shown that TNF is partly responsible for initiation of the lethal toxicity of endotoxins[7].

Ischemic preconditioning (IP) is a process by which a brief ischemic episode confers a state of protection against the subsequent more sustained ischemic insult[8]. Recent studies have demonstrated that a brief ischemia treatment, followed by an episode of reperfusion, can reduce the sustained I/R injury[9,10]. These observations suggest a potential application of IP in liver transplantation. In this study, the protective effect of IP on the long-term preservation of liver grafts and the prolonged anhepatic phase was observed.

MATERIALS AND METHODS

Materials
Male *Sprague-Dawley* rats weighing 200 to 230 g supplied by the Center of Experimental Animal in Sichuan University, were used as donors and recipients. Animals were bred in a controlled environment with a 12 hour light/dark cycle. Donor rats were fasted for 12 hours with free access to water before surgery, while the recipients had free access to normal rat chow and water before surgery. This study was approved by Sichuan Bioethics Committee, and the procedures were carried out according to the routine animal-care guidelines.

ORLT
Liver transplantation was performed according to Kamada's cuff-technique[11] under anesthesia with ether inhalation. Briefly, the abdomen was opened through a midline incision and the liver was freed from its ligaments with minimal manipulation. The donor bile duct was transected, and a 0.4 cm

length of tube was insert into the lumen of the bile duct and secured with a circumferential 5-0 silk suture. The animal was injected intravenously with 50 U of heparin. The liver was perfused through portal vein with an intravenous cannula connected with a syringe with 36 U of heparin in 6 ml of cold saline. The donor liver was placed in the saline bath at 4 ℃ for 100 min. The cuff preparation of portal vein and infrahepatic vena cava was performed also in the saline-ice bath. After the recipient liver was removed, the donor liver was implanted in the orthotopic position by connecting the suprahepatic vena cava with a running suture, inserting cuffs into the infrahepatic vena cava and the portal vein, and splint tube into the bile duct. The anhepatic phase was estimated to be 25 min for all recipients. ORLT was performed without artery reconstruction.

Experimental design

A total number of 128 rats were randomly divided into 4 groups, 32 for each. 1) Control group, the donor livers were flushed through the portal veins with physiological saline containing heparin only before harvested. 2) IP group, before the donor livers were harvested, the portal vein and hepatic artery were interrupted for 10 min, and the blood flow was restored for 10 min, then the liver was treated as control group. 3) Adenosine group, the donor livers were flushed through the portal vein with physiological saline containing heparin and adenosine (10 mmol/L) only before harvested. 4) Nω-nitro-L-arginine methyl ester (NAME) group, the donor livers were treated as IP group, but NAME (10 mmol/L), an NO synthesis inhibitor, was included in flushing solution. For each group, half of animals were used to investigate the one-week survival rate of recipients, and the remaining animals were for sample collection of blood from infrahepatic vena cava and hepatic tissue after 2 hours of reperfusion.

Determination of liver function and survival

Serum alanine transaminase (ALT) was measured using an automated analyzer (BECKMAN CX7, Beckman Instruments, Fullerton, CA). Survival of recipients was observed for 7 days after operation.

Determination of serum NO

Values of circulating nitrate and nitrite were determined to reflect serum NO level. Serum was separated by centrifugation and stored at -70 ℃ before use. Nitrite was measured after enzymatic conversion by nitrate reductase using the Griess reaction, as described by Schmidt[12]. Values obtained represented the sum of serum nitrite and nitrate.

Determination of serum TNF

Serum was separated by centrifugation, and concentration of serum TNF was measured by radioimmunoassay. The TNF standard (100 μl, Sigma, ST. Louis, MO. USA) and the serum samples (100 μl) were added separately to appropriate tubes. Two hundred μl of the 0 ng/ml TNF standard was added to each non-specific binding tube. All tubes were added 100 μl of ¹²⁵I-TNF reagent (Sigma, ST. Louis, MO. USA). TNF antiserum (100 μl) was also added to each tube, except the nonspecific binding tubes. Incubation was done at 4 ℃ for 24 hours following gentle agitation for 2-3 seconds. With 500 μl of precipitating reagent added, the tubes were vortexed immediately, and incubated for 20 minutes at room temperature (-25 ℃). All the tubes were centrifuged at 1500×g for 25 min, the suspension was dropped out. Radioactivity was read using a gamma counter (262 Factory, Xi' an, Shaanxi, China).

Assay for adenosine from hepatic tissue

Adenosine standard was purchased from Sigma (St. Louis, MO,

USA). High-performance liquid chromatography (HPLC) was performed using a Beckman Gold Nouveau system equipped with a 168 photo-diode-array detector (210 nm; 262 Factory, Xi' an, Shaanxi, China). Satisfactory separation of the marker substances was obtained with a reversed-phase column and eluted at a flow rate of 1 ml/min. Adenosine separation was allowed to precede in a phosphate-buffer solution (331 mmol/L KH_2PO_4, pH 6.24) containing 3.5% CH_3CN and 2.3 mmol/L t-butylamine (TBA). Lyophilized liver tissue was homogenized in 0.5 ml of 0.42 mol/L perchloric acid and incubated for 20 min at 4 ℃. The supernatant was separated by centrifugation at 3 000 rpm for 10 min at 0.5 ℃, and neutralized with 85 μl/200 μl NaOH. After 5 min of centrifugation at 3 000 rpm, 20 μl of the supernatant was subjected to HPLC.

Histopathologic examination

Liver samples were fixed in 10% neutral buffered formalin, embedded in paraffin. Sections of 5 μm in thickness were prepared, stained with hematoxylin and eosin, and observed under a light microscope.

Statistics

All statistical computations were performed using SPSS software (version 10.0 for Windows 98; SPSS, Inc., Chicago, Illinois). The P values less than 0.05 were considered statistically significant.

RESULTS

Animal survival

The survival rates of these four groups are shown in Figure 1. Most of the recipients died within 3 days after liver transplantation. The survival rate at day 7 was higher in IP group (87.5%, 7 of 8) and adenosine group (87.5%, 7 of 8) than that in control group (37.5%, 3 of 8) and NAME group (25%, 2 of 8, $P<0.05$, Figure1).

Figure 1 Survival of recipients in different groups. The donor livers were treated respectively as described in Materials and Methods, and the recipients were divided into control (Contr group), IP-(IP group), adenosine-(Ade group), and NAME-treated groups. The 7-day survival rate was 37.5% (3/8) and 25% (2/8), respectively, in the control group and NAME group, compared with 87.5% (7/8) in both the IP group and adenosine group ($P<0.05$). The survival curves were calculated using Kaplan-meier' s methods.

Liver function

The serum ALT values in control group (588±58 U/L) were significantly higher as compared to those in IP group (287±82 U/L) ($P<0.001$). Meanwhile, administration of adenosine also reduced the level of serum ALT (357±93 U/L) as compared to that in control group ($P<0.001$). However, with administration of NAME, the response in ALT level to IP was abrogated (634±65 U/L, $P>0.05$, Figure 2).

Figure 2 Values of serum ALT in different groups of recipients at 2 hours after ORLT. The ALT levels in control group and NAME group increased significantly compared with IP group and adenosine group. [a]*P* and [b]*P*<0.001, [c]*P*>0.05 *vs.* control group. The values were expressed as means ± SD.

Serum TNF and NO level

TNF concentration in serum was measured 2 hours after ORLT as described previously[5,6]. In IP group (1.15±0.23 ng/ml) and adenosine group (1.14±0.27 ng/ml), it was significantly lower compared to that in control group (1.59±0.35 ng/ml, *P*<0.01). The level in NAME group (1.71±0.23 ng/ml) was as high as that in control group (*P*>0.05, Figure 3).

Concentrations of NO were shown to be 32.96±6.10 μmol/L, 29.14±6.49 μmol/L in IP and adenosine groups, respectively, which were significantly higher than that in control group (15.44±2.99 μmol/L, *P*<0.001). The value of the recipients in NAME group was 13.74±3.11 μmol/L, which was similar to that in control group (*P*>0.05, Figure 4).

**Figure 3** Serum TNF levels measured at 2 hours after ORLT in different recipient groups. In control and NAME groups, the concentrations of serum TNF were elevated significantly as compared to those in IP and adenosine groups. [a]*P* and [b]*P*<0.01, [c]*P*>0.05 *vs.* control group. Values were expressed as means ± SD.

Figure 4 NO levels in serum at 2 hours after ORLT. When the donor livers were pretreated with IP or adenosine, the serum NO levels were elevated significantly. When IP-treatment followed by administration with NAME, the serum NO concentration was as low as that in control group. [a]*P* and [b]*P*<0.001, [c]*P*>0.05 *vs.* control group. Values were expressed as means ± SD.

Adenosine in hepatic tissue

Figure 5 shows the levels of hepatic adenosine at 2 hours after ORLT in liver grafts. Concentrations of tissue adenosine were 7.22±1.83 mol/g, 5.68±1.32 mol/g, and 5.56±1.19 mol/g in liver grafts pretreated with IP, adenosine and IP+NAME, respectively, which were higher than that in the reference liver grafts (3.69±0.54 μmol per gram of dry liver tissue, *P*<0.05). Animal survival and liver function were improved after adenosine administration. The protective effect of IP was abrogated in NAME group, though the content of adenosine in the tissue also increased.

Figure 5 Adenosine concentrations in liver tissues at 2 hours after ORLT. When the donor livers were pretreated with IP or adenosine, or even the IP-treatment followed NAME, the adenosine levels in dry hepatic tissue were elevated as compared to that in control group. [a]*P,* [b]*P* and [c]*P*<0.05 *vs.* control group. Results were expressed as means ± SD.

Histopathologic examination

Hepatocyte swelling and ballooning were observed in tissues from the control and NAME groups. No identifiable morphological alterations or only minor changes were found in IP and adenosine groups (data not shown).

DISCUSSION

The ORLT model, established in 1973 by Lee *et al*.[13], has received wide acceptance in the study of liver transplantation. IP is a procedure originally described during heart transplantation. A brief ischemia treatment followed by reperfusion has been shown to be able to decrease infarct size after subsequent prolonged I/R[8,14,15]. IP has been found to be protective during transplantation of several organs including brain, intestine and skeletal muscle[16-18]. In liver, IP was found to reduce tissue damages and mortality after warm ischemia and cold ischemic storage[5, 19].

In the present study, The harvested livers were preserved in saline for 100 min at 4 ℃ and the anhepatic phase was selected for 25 minutes, poor outcomes of recipients in control group were observed, and the survival rate 7 days after operation was 37.5% (3/8). In IP group, ALT level was reduced markedly and the survival rate was significantly elevated (87.5%, 7 of 8). The protective effect of IP was further indicated by the morphologic parameters presented.

The effects of a long anhepatic phase on the graft were associated with an endotoxin-like syndrome induced by the prolonged congestion of internal organs. Endotoxemia has been shown to be one of the processes causative for early graft dysfunction[20,21]. This was most probably associated with Kupffer cell activation by splanchnic endotoxin accumulation and release during intestinal congestion/reperfusion[22,23]. During the ORLT with a long anhepatic phase, Kupffer cells were shown to be directly responsible for overproduction of TNF, causing endotoxicosis-like syndrome[24]. The cytotoxic effects of TNF are associated with activation of phospholipase

A_2, release of ceramide, formation of reactive oxygen intermediate (ROI) and promotion of cell apoptosis. However, it is not known whether the protective effect of IP in this study was associated with TNF.

The definite mechanism underlying IP is not clear, and there are several explanations about its protective effects. According to some authors, the protective effects were not attributed to blood flow alterations[25,26]. However, the IP protective effect was associated to certain substances produced by ischemic tissue against injury[4]. On the contrary, another study indicated that IP could improve blood flow, and decrease hepatic vascular resistance of liver grafts preserved in cold storage[10], and this was probably related to some potential mediators such as NO and adenosine.

NO was reported to exert a protective effect through inhibiting endothelin synthesis[27], and the upregulating effect of adenosine NO release in endothelial cells was also documented[28]. During ischemia, adenosine is rapidly formed from adenosine triphosphate and reaches high concentrations. Enhanced adenosine level might in turn induce NO synthesis through the activation of adenosine A_2 receptors[27]. The functions of the two mediators might lead to an improvement in graft blood flow and accordingly improve liver function. Since the ROIs are known to cause cell injury by promoting the peroxidation of lipids and proteins in cell membranes, it is possible that the antioxidant action of NO might also be involved in the protective effect of IP.

In the present study, the concentrations of NO in serum and adenosine in hepatic tissues of IP group were significantly higher than those in control group. In contrast, the level of serum TNF was greatly reduced after IP treatment. Furthermore, the protective effect of IP was also achieved by administration of adenosine before the donor livers were harvested. Our results showed NAME had negative effects on the protective effect of IP and suppressed NO synthesis, indicating that, in the absence of NO, adenosine was unable to develop protective effects. IP might exert its protective role by inducing the production of NO.

In summary, the data presented suggest that an elevated adenosine level can induce the generation of NO under IP, conferring protection to liver grafts and recipients. IP may be an important approach to reduce the transplantation risk resulted from preservation/reperfusion injuries. Further studies are needed for further understanding of the underlying mechanisms.

Abstract

AIM: To observe the possible effects of transforming growth factor (TGF) β_1, interleukin (IL)-6, tumor-necrosis factor (TNF) α and IL-10 on experimental rat hepatic fibrosis.

METHODS: One hundred SD rats were divided randomly into the three groups. Control group received intraperitoneal injection of saline (2 ml· kg^{-1}), twice a week. Fibrogenesis group was injected intraperitoneally with 50% carbon tetrachloride (CCl$_4$) (2 ml· kg^{-1}) twice a week. Fibrosis-intervention group was given IL-10 at a dose of 4 μg· kg^{-1} 20 minutes before CCl$_4$ administration from the third week. At the fifth, seventh, and ninth weeks, 7 to 10 rats in each group were sacrificed to collect serum. Levels of TGF-β_1, TNF-α, IL-6 and IL-10 were determined by enzyme-linked immunosorbent assay (ELISA). The liver tissues were taken for routine histological examination.

RESULTS: Hepatic fibrosis was developed with the injection of CCl$_4$. Values of the circulating TGFβ_1, TNFα, IL-6 and IL-10 in the control group were 25.49±5.56 ng· L^{-1}, 15.18±3.83 ng· L^{-1}, 63.64±13.03 ng· L^{-1} and 132.90±12.13 ng· L^{-1}, respectively. Their levels in the CCl$_4$-intoxication group were 31.13±6.41 ng· L^{-1}, 18.91±5.31 ng· L^{-1}, 89.08±25.39 ng· L^{-1} and 57.63±18.88 ng· L^{-1}, respectively, and those in the IL-10-intervention group were 26.11±5.32 ng· L^{-1},13.99±1.86 ng· L^{-1}, 74.71±21.15 ng· L^{-1} and 88.19±20.81 ng· L^{-1}, respectively. A gradual increase was observed in the levels of TGFβ_1, TNFα and IL-6 during hepatic fibrogenesis. These changes were partially reversed by simultaneous administration of IL-10. The histological parameters, characterized by CCl$_4$-intoxification, also seemed to be improved with IL-10 treatment, the collagen production was reduced at the ninth week and the histological activity index was decreased from 7.9±1.2 to 4.7±0.9.

CONCLUSION: TGFβ_1, TNFα and IL-6 may play important roles during CCl$_4$-induced hepatic fibrogenesis, and IL-10 may counterbalance their effects.

INTRODUCTION

Hepatic fibrosis is a common process of chronic liver injuries, characterized by increased deposition and altered composition of extracellular matrix (ECM)[1-3]. Its final stage is cirrhosis, with the liver architecture distorted by collagen bands and formation of islands of regenerating parenchymal cells[4,5]. Advanced fibrosis and cirrhosis are generally considered irreversible conditions. Many of the cellular mechanisms have been associated to hepatic fibrosis. Cytokines are soluble autocrine and paracrine mediators[6]. Expression of several cytokines has been described in human liver diseases and experimental liver injuries. Carbon tetrachloride (CCl$_4$) is a hepatotoxin, causing liver necrosis, fibrosis and cirrhosis when administered sequentially. Hepatotoxicity is thought to involve two phases[7]. First, CCl$_4$ is metabolized by cytochrome P450 in hepatocytes, giving rise to highly reactive trichloromethyl radicals. Second, inflammatory responses caused by CCl$_4$ play an important role. In the latter process, some hepatic cells, including Kupffer cells (KCs), hepatic stellate cells (HSCs) and sinusoidal endothelial cells (SECs), are activated to secrete cytokines which mediate the liver fibrogenesis. Several functions have been attributed to cytokines, including activation of HSCs, modulating expression and deposition of matrix proteins and regulating the regeneration of hepatocytes. Therefore, resolution of liver fibrosis could be associated with the downregulation of inflammatory responses mediated by cytokines[8,9]. Among the cytokines, transforming growth factor (TGF) β_1 is associated to the activation of HSC and the following production of ECM[10]. Tumor-necrosis factor (TNF) α and interleukin (IL)-6 are considered major hepatotoxicity mediators in several experimental models of liver injuries[11]. IL-10 can modulate the inflammatory response and alleviate hepatotoxicity[12]. In the present study, levels of circulating TGFβ_1, TNF-α, IL-6 and IL-10 were measured to investigate their possible roles during CCl$_4$-induced hepatic fibrogenesis in rats.

MATERIALS AND METHODS

Animals

One hundred SD rats, weighing 140 to 180 g, were divided randomly into control (*n*=24), fibrogenesis (*n*=40) and fibrosis-intervention groups (*n*=36). All rats were bred under routine conditions (room temperature, 22 ℃±2 ℃; humidity, 55%±5%; light, 12 hrs per day; drinking tap water and eating in any time; animal feed was provided by BK Company in Shanghai, China). The control rats were injected intraperitoneally with saline at a dose of 2 ml· kg^{-1}, twice a week. The rats in the other groups received intraperitoneal injection of 50% CCl$_4$ (2 ml· kg^{-1}), twice a week, as described previously[13]. From the third week, the rats in intervention group were given intraperitoneally IL-10 (4 μg· kg^{-1}, dissolved in saline) 20 minutes before CCl$_4$ administration, as proposed by Nelson *et al*[14]. All injections were performed at Monday and Thursday, with their body weights determined before each injection. In the fifth week, 3 rats in the fibrogenesis group and 2 in the intervention group died. In the seventh week, 8 and 4 animals

in these two groups died. In the ninth week, 10 and 6 died. At this time point, 3 rats in the control group also died. In the fifth, seventh and ninth weeks, 7 to 10 rats in each group were sacrificed to collect plasma from the common carotid artery and their liver samples.

Histological examination

The formalin-fixed liver tissues were embedded in paraffin. Sections were stained with hemotoxylin and eosin (HE) and examined under a light microscope independently by two pathologists. Stages of fibrosis were assessed using a semi-quantitative score method as described previously. Histological activity index (HAI) was evaluated using a numerical system proposed by Knodell et al[15].

Enzyme-linked immunosorbent assay (ELISA)

Serum was collected by centrifugation at 4 ℃ and frozen till use. The levels of TGF-β_1, TNF-α, IL-6 and IL-10 were measured by ELISA using the kits following the manufacture' s instructions (Endogen Company, USA). Briefly, diluted serum samples were added in duplicate to 96-well plates coated with antibody and incubated at 37 ℃ for 2 hours. After each well was washed five times with washing buffer, peroxidase-labeled secondary antibody was added to each well and the plate was incubated at 37 ℃ for 1 hour. After each well was washed in a similar manner, the plate was incubated with tetramethylbenzine at room temperature for 20 minutes. The reaction was stopped by adding 1 N sulfuric acid. Optical density was measured at 450 nm using a spectrophotometric reader. Sample concentration was accessed by a standard curve.

Statistical analysis

All data were expressed as $\bar{x}\pm s$, t test was used for comparison between groups. P values less than 0.05 were regarded as statistically significance.

RESULTS

Animal model

Liver fibrosis, as shown histologically, became remarkable during the treatment with CCl$_4$. In the fifth week, steatosis and ballooning degeneration were obvious. In the seventh week, the collagen fibers increased and began to extend to the parenchyma. In the ninth week, complete fibrous septa were seen and psedolobular structures were also present occasionally. In the IL-10-intervention group, the CCl$_4$-caused alterations as described above seemed to be markedly alleviated, with no evident changes observed in the fifth week, less profound steatosis and necrosis noted in the seventh week, and only early-stage fibrosis found in the ninth week. HAI decreased from 7.9±1.2 in the fibrogenesis group to 4.7±0.9 in the IL-10-intervention group (P<0.05) (Figures 1-5).

**Figure 4** Liver of rats in group C (the ninth week, H-E staining, ×100).

Figure 5 Liver of rats in group E (the ninth week, H-E staining, ×100).

Serum levels of TGFb$_1$, TNF-a, IL-6 and IL-10

As shown in Figure 6, the level of circulating IL-10 was lower in fibrogenesis group than in the control group (P<0.05). The levels of TGF-β_1, TNF-α and IL-6 in were higher in

fibrogenesis group than in the control group ($P<0.05$). However, values of these three cytokines were significantly reduced after the intervention treatment with IL-10 ($P<0.05$), being similar to the levels in the control group ($P>0.05$). Therefor, serum concentrations of TGF-β_1, IL-6 and TNF-α were increased during CCl$_4$-caused hepatic fibrogenesis.

Table 1 Concentrations of TGF-β_1, TNF-α, IL-6 and IL-10 in sera from different groups (ng·L^{-1})

Groups	Numbers of rats	TGF-β_1	TNF-α	IL-6	IL-10
Control (N)	21	25.49±5.56	15.18±3.83	63.64±13.03	132.90±12.13[a,b]
Fibrogenesis (C)	30	31.13±6.41	18.91±5.31	89.08±25.39	57.63±18.88
IL-10-intervention (E)	30	26.11±5.32	13.99±1.86	74.71±21.15	88.19±20.81[c]

[a]$P<0.05$ *vs.* C, [b]$P<0.05$ *vs.* E, [c]$P>0.05$ *vs.* C.

Figure 6 Levels of TGF-β_1, TNF-α, IL-6 and IL-10 in serum from control, fibrogenesis and IL-10-intervention groups.

As shown in Figures 7-10, concentrations of TGF-β_1, TNF-α and IL-6 were gradually increased along with CCl$_4$-intoxication ($P<0.05$). These changes were partially reversed by the treatment with IL-10, particularly in the ninth week ($P<0.05$).

DISCUSSION

Previous data have shown that rats chronically exposed to CCl$_4$ were resistant to cirrhosis. In rats, exposed to CCl$_4$ for 8 to 12 weeks could result in localized fibrosis[16]. In the present study, fully developed hepatic fibrosis was observed in the rats after 9 weeks of CCl$_4$ intoxication. The contents of cytokines in serum were found to vary during the process. Cytokines constitute a complex network involved in the regulation of inflammatory responses and homeostasis of organ functions. Following liver injury, a wound healing process evolves, including proliferation of surrounding hepatocytes, proliferation and differentiation of stem cells, and conversion of parasinusoidal cells into activated HSCs capable of driving the accumulation of ECM. If the injuries were persistent or the wound healing process was aberrant, the final phenotype might be a fibrotic, dysfunctional liver[8]. A number of cytokines and growth factors could augment or inhibit the fibrotic response to injuries[18]. Accumulating data indicate that HSCs are the major source of fibrillar and non-fibrillar matrix proteins during hepatic fibrogenesis. When activated, HSCs could proliferate and transform to a myofibroblast-like phenotype, expressing α-smooth muscle actin (α-SMA) and collagen types I, III and IV, fibronectin and proteoglycan[19]. It has been found several cytokines play roles by acting on HSC, and among them, TGF-β_1 is one of the most important cytokines involved in the fibrotic and cirrhotic transformation of the liver[20-23]. After a fibrogenic injury, expression of three forms of TGF-β is greatly upregulated in HSCs. It was reported that administration of TGF-β_1 *in vivo* induced an inflammatory reaction, and knock-out of TGF-β_1 gene resulted in widespread inflammatory diseases. Therefore, TGF-β_1 may have a pro-inflammatory effect.

TNF-α was originally identified as a circulating factor that resulted in remarkable hemorrhage and necrosis of tumors when administered to tumor-bearing mice. It has been implicated in a number of liver diseases and is an important mediator of

many physiological conditions. Several evidences suggest that TNF-α is among the most crucial components in the early signaling pathways leading to regeneration. However, there has been evidence that TNF-α is a primary endogenous factor mediating acute inflammatory conditions such as endotoxic shock. It appears that inhibition of the TNF-α effect might have a broader clinical application value than expected previously[26]. In several animal models of immune-mediated liver injury or hepatotoxin sensitization, TNF-α administration could lead to hepatocyte apoptosis and liver failure[27]. Besides its modulation effect on ECM production, TNF-α has been considered a mediator of cell injuries in liver caused by alcoholism, reperfusion, primary graft nonfunctional, graft rejection and endotoxic insult[28,29]. TNF-α is expressed by both infiltrating inflammatory cells and hepatocytes in chronic liver injuries, and it has been proposed to play an important role during tissue damage[30]. Our data provide a further evidence for the role during hepatic fibrosis.

The role of IL-6 during chronic liver injuries and fibrogenesis remains to be clarified. Some reports provided evidences for an important role of IL-6 in reducing CCl$_4$-induced acute and chronic liver injury and fibrosis[31-33]. However, some other data showed that the serum level of IL-6 was associated with hepatic necroinflammatory activity in patients with chronic hepatitis and cirrhosis[34,35]. Our results support the latter view. Animal experiments showed that IL-6 was associated to activated HSCs during acute and chronic injuries, indicating that IL-6 is a responsive element to liver injuries. Moreover, CCl$_4$-induced expression of TGF-β$_1$ and hepatocyte growth factor in liver was shown to be associated with the serum level of IL-6. Thus, IL-6 might be vitally involved in fibrotic changes, partly by modulating intrahepatic expression of other cytokines[36,37].

Recent studies have suggested a protective role of IL-10 during liver transplantation and experimental liver injuries induced by galactosamine and lipopolysaccharide[38]. However, the mechanism of the protective effects is not fully understood. IL-10 is a potent anti-inflammatory cytokine that inhibits the synthesis of pro-inflammatory cytokines by T helper type 1 cells. It is produced locally in the liver and acts in an autocrine or a paracrine manner. Previous reports indicated that IL-10 had some role in remodeling ECM[39,40]. IL-10 was shown to downregulate the synthesis of collagen type I and to upregulate expression of metalloproteinase. It could also play an antifibrogenic role by downregulating the profibrogenic cytokines including TGF-β$_1$ and TNF-α[11,41]. Nelson *et al* treated 24 patients with chronic hepatitis C using IL-10, and found that IL-10 administration resulted in reduction of the serum ALT level, partial resolution of the hepatic inflammation and alleviation of the fibrosis[14]. IL-10 may be useful in the treatment of chronic liver diseases regarding the prevention of advanced fibrosis and cirrhosis[42].

Abstract

AIM: To evaluate the covalently closed circle DNA (cccDNA) level of hepatitis B virus (HBV) in patients' liver and sera.

METHODS: HBV DNA was isolated from patients' liver biopsies and sera. A sensitive real-time PCR method, which is capable of differentiation of HBV viral genomic DNA and cccDNA, was used to quantify the total HBV cccDNA. The total HBV viral DNA was quantitated by real-time PCR using a HBV diagnostic kit (PG Biotech, LTD, Shenzhen, China) described previously.

RESULTS: For the first time, we measured the level of HBV DNA and cccDNA isolated from ten HBV patients' liver biopsies and sera. In the liver biopsies, cccDNA was detected from all the biopsy samples. The copy number of cccDNA ranged from from 0.03 to 173.1 per cell, the copy number of total HBV DNA ranged from 0.08 to 3 717 per cell. The ratio of total HBV DNA to cccDNA ranged from 1 to 3 406. In the sera, cccDNA was only detected from six samples whereas HBV viral DNA was detected from all ten samples. The ratio of cccDNA to total HBV DNA ranged from 0 to 1.77%. To further investigate the reason why cccDNA could only be detected in some patients' sera, we performed longitudinal studies. The cccDNA was detected from the patients' sera with HBV reactivation but not from the patients' sera without HBV reactivation. The level of cccDNA in the sera was correlated with ALT and viral load in the HBV reactivation patients.

CONCLUSION: HBV cccDNA is actively transcribed and replicated in some patients' hepatocytes, which is reflected by a high ratio of HBV total DNA vs cccDNA. Detection of cccDNA in the liver biopsy will provide an end-point for the anti-HBV therapy. The occurrence of cccDNA in the sera is an early signal of liver damage, which may be another important clinical parameter.

INTRODUCTION

Chronic hepatitis B Virus (HBV) infection is one of the most common diseases leading to a high morbidity and mortality due to the development of liver failure, liver cirrhosis (LC) and hepatocellular carcinomas (HCC)[3-28]. There are over 300 million people suffering from HBV infection worldwide, and more than 10% of Chinese are HBV carriers[3,5,14]. Infection by hepatitis B virus causes complicated biochemical, immunological and histological changes in host[7-9,11,16,18,23,24,27]. Viral kinetic studies have shown that the viral load goes through a complex series of stages during anti-HBV chemotherapy[21,22,29-31]. The HBV reactivation often occurs after cessation of anti-HBV treatment[22,24,32], which is reflected by the increases of hepatitis B e antigen (HBeAg) and DNA levels in serum. Clinically, this may manifest as hepatitis, hepatic failure, and even death. Despite its clinical importance, there are few data on the incidence and risk factors of hepatitis due to HBV reactivation after chemotherapy. In particular, the relationship of various HBV virological parameters and HBV reactivation is unclear.

HBV covalently closed circular (ccc) DNA is a critical intracellular replicative intermediate, which acts as the template for transcription of viral RNAs serving either as viral pregenome RNAs, or as mRNAs coding for the multifunctional polymerase, core, X and envelope (S) proteins[25,26]. All the HBV proteins play crucial roles in HBV gene transcription, replication, viral packaging and recycling. Due to lack of proofreading functions of polymerase, HBV goes through a fast mutagenesis and creates drug resistant strains[13,17,19,24,26,29,32], which contributes to the viral cccDNA pool. Because cccDNA of HBV is resource of new HBV viruses and resistance to drug treatment, it is believed that cccDNA is the major reason for HBV reactivation after stopping the anti-HBV therapy[21,24,25]. Monitoring of HBV viral load, antigenes, mutations and cccDNA levels will therefore provide a direct indication of HBV activity in the body[12,13,15,17-21, 28-32].

We previously developed a sensitive method to quantify HBV cccDNA, which has been successfully used to determine the amount of HBV cccDNA isolated from liver biopsy[1]. Here we report that HBV cccDNA can be detected both in liver biopsy and in patients' sera. The sera cccDNA level is correlated with ALT and viral load in HBV reactivation patients, but cannot be detected in patients' sera without HBV reactivation. Our results indicate that the occurrence of cccDNA is an early signal of liver damage, which may be another important clinical parameter.

MATERIALS AND METHODS

cccDNA standard[1, 2]

A plasmid containing Chinese HBV genome (pHBV-adr) was a gift from Professor Yuan Wang. The supercoid plasmid (cccDNA) was isolated by CsCl purification. The cccDNA concentration was determined by measurement of OD260 and verified by agarose gel electrophoresis. The copy number was determined by its molecular weight.

HBV viral DNA preparation[1]

HBV viral DNA was extracted from either 200 ul of patients' sera or weighed liver biopsies using a QIAamp DNA blood or

tissue mini kit (QIAGEN, Hilden, Germany) according to the manufacturer's instructions.

Quantification of HBV cccDNA using real-time PCR

HBV cccDNA quantification was performed as described previously[1,2], with minor modifications. Briefly, a pair of primers (forward primer: 5'-ACTCTTGGACTCBCAGCAATG-3', reverse primer: 5'-CTTTATACGGGTCAATGTCCA-3'), which can specifically amplify a DNA fragment from HBV cccDNA but not viral genomic DNA by PCR, were used for real-time PCR. In a typical real-time PCR reaction, 250 nM of the probe (5'-FAM-CTTTTTCACCTCTGCCTAATCAT CTCWTGTTCA-TAMRA-3') and 900 nM of the two PCR primers were used. For total HBV quantification, PCR amplification was performed with an HBV DNA diagnostic kit (PG Biotech. Ltd, China) using ABI 7900HT sequence detection system. The PCR program consisted of an initial denaturing step at 95 ℃ for 10 min, followed by 40 amplification cycles at 95 ℃ for 15 sec and at 61.5 ℃ for 1 min.

Patient samples

The patients were treated with chemotherapy at Queen Mary Hospital, Hong Kong, from January 2000 to May 2002. In accordance with the standard protocols, all the patients who received chemotherapy were screened for HBsAg, HBsAb, human immunodeficiency virus antibody (HIV Ab), and HBV DNA by PCR and hepatitis C antibody (anti-HCV), with commercially-available enzyme immunoassays (Abbott Laboratories, Chicago, IL, USA). HBcAb was tested by RIA (Corab; Abbott). For all HBsAg positive patients, further serological testing for hepatitis B e antigen (HBeAg), hepatitis B e antibody (HBeAb) and serum HBV DNA was performed by PCR, and chemotherapy was administered with lamivudine. All HbsAg-positive recipients were tested at 2-week intervals for liver function (including serum alanine aminotransferase, serum albumin and bilirubin) and serum HBV DNA during chemotherapy. Hepatitis serology (HBsAg, HBeAg, HBeAb, HBV DNA by PCR, and HCV RNA by RT-PCR) was performed on the serum collected preceding and during the events whenever there was any clinical suspicion of liver damage due to hepatitis B infection. The occurrences of hepatic events (acute hepatitis, chronic hepatitis, anicteric and icteric hepatitis, hepatic failure) were recorded. Hepatitis was defined as a more than three-fold elevation of serum aminotransferase above the upper limit of normal, on two consecutive determinations at least five days apart. HBV reactivation was defined to occur when preceded or accompanied by an elevation of serum HBV DNA to more than ten times that of the pre-exacerbation baseline, or when the serum HBV DNA turned from negative to positive, or when the HBsAg became positive and remained so for two consecutive readings five days apart.

All serum and biopsy samples were stored at -70 ℃. All patients who developed post-chemotherapy hepatitis due to HBV reactivation were treated with lamivudine 100 mg once daily.

RESULTS

HBV cccDNA existed in all patients' hepatocytes but only in a subset of patients' sera

To elucidate the cccDNA status in HBV patients, we quantified the cccDNA and total HBV DNA level in the liver biopsies. The total DNA was isolated from weighed liver biopsies and quantified with an HBV diagnostic kit by real-time PCR. The HBV cccDNA was also measured by real-time PCR. HBV cccDNA was detected in all the HBV patients' liver biopsies. The copy number of cccDNA in patients' hepatocytes ranged from 0.05 to 168 copies per cell, which is consistent with the estimates from Southern blot data[10]. The copy number of total HBV DNA in patients' hepatocytes ranged from 0.08 to over 3 000 copies per cell. The ratio of cccDNA to total HBV DNA ranged from 1 to 3 406 (Table 1), indicating that cccDNA in patients' hepatocytes had active replication and relative silent status.

To investigate whether cccDNA could be released into sera due to liver inflammation and necrosis, viral DNA was isolated from patients' sera and quantified by real-time PCR. Interestingly, cccDNA could only be detected in a subset of patients' sera, while HBV DNA was detected in all the patients' sera. The copy number of viral load ranged from 5.4×10^5 to 1.8×10^{11} per ml while the copy number of cccDNA ranged from undetectable level (less than 1 000 copies/ml[11]) to 3.1×10^7 per ml. The ratio of cccDNA to total viral DNA ranged from 0 to 1.77%. There was no correlation between the copy number of cccDNA and total viral DNA in the randomized patients (Table 1).

cccDNA is an early signal of liver damage

To investigate the medical significance of cccDNA in sera, longitudinal studies were performed. Patients with or without HBV reactivation during lamivudine treatment were chosen for this study. The patients' sera were collected every two weeks and HBV DNA was isolated for quantification of HBV cccDNA and total HBV DNA. According to our results, HBV cccDNA was not detectable by sensitive real-time PCR in patients without HBV reactivation (data not shown), but was detectable in patients with HBV reactivation (Figures

[a]The total HBV copies per cell in the patients' liver biopsies; [b]The ratio of total HBV DNA to cccDNA in the patients' liver biopsy; [c]The total HBV copies per ml of the patients' sera; [d]The ratio of cccDNA to total HBV DNA in the patients' sera. UN, untedectable.

1A and 1B). The cccDNA level was correlated with viral load (Figures 1A and 1B), which occurred earlier than ALT. Before the ALT value increased, both the cccDNA level and viral load rose to a high level. Once the ALT value increased, the cccDNA level dropped rapidly. These results suggest that patients whose sera contain cccDNA are at a high risk of HBV reactivation, and that HBV cccDNA develops in the sera earlier than ALT elevation.

Our results suggest that serum cccDNA level may be an important parameter for anti-HBV treatment, and that a low level of cccDNA in hepatocytes should be an end point of anti-HBV treatment.

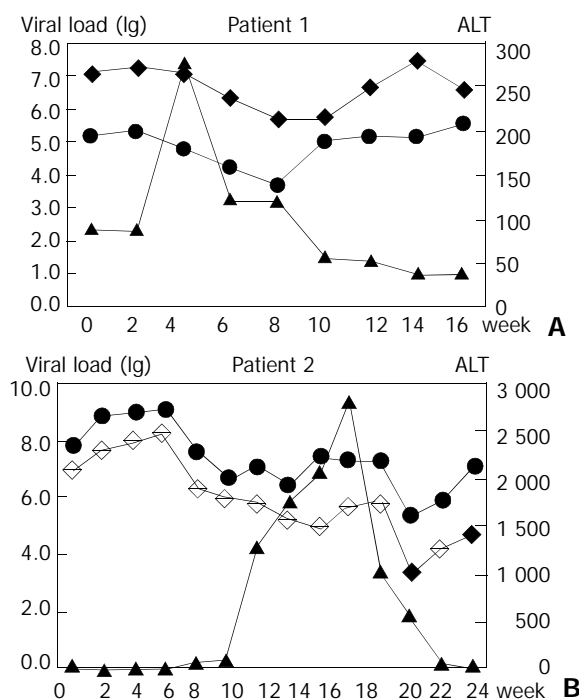

Figure 1 Kinetics of cccDNA in HBV reactivation patients. The copy numbers of total HBV and cccDNA were determined by real-time PCR. The cccDNA level was parallel to the total viral load both in the patients 1 and 2; the cccDNA level increased before ALT rose. Diamond: HBV viral load, dot: cccDNA, triangle: ALT.

DISCUSSION

Little information is available about HBV cccDNA and its activities *in vivo* due to the difficulty of differentiation of HBV cccDNA and viral genomic DNA, although a lot of work has been done on the HBV viral kinetics[21,22,29-31]. In the hepatitis B virus life cycle, cccDNA serves as templates for viral gene transcription and replication in hepatocytes[25,26]. It has been shown that cccDNA is the major reason for HBV reactivation after cessation of anti-HBV treatment[24,25]. Therefore, quantification of HBV cccDNA will provide useful information for the end-point of anti-HBV therapy.

In this paper, we first report the quantitative data on HBV cccDNA in patients' liver biopsy and sera. We previously established a quantitative real-time PCR method which can specifically differentiate HBV viral genomic DNA and cccDNA[1]. This sensitive method provided us an opportunity to investigate HBV cccDNA status in the liver biopsy and patients' sera. Our data indicated that cccDNA in the patients' liver might have two status: active and relative silent status. This was reflected by the ratio of viral total DNA to cccDNA. To our surprising, HBV cccDNA was also detected in a part of patients' sera. The release of cccDNA of hepatitis B virus to the sera might be the consequence of liver damages, such as

liver inflammation, necrosis. Longitudinal studies revealed that the release of cccDNA to the sera was an early signal of liver damage, which is correlated with ALT and viral load in HBV reactivated patients. Therefore, measurement of the cccDNA level in the liver may provide an end-point of anti-HBV therapy, and detection of the cccDNA level in the sera may provide a better guidance to protect patients from HBV reactivation.

Because this is the first time to provide the quantitative data on HBV cccDNA status, and the limitation of patient samples, more clinic studies on the cccDNA kinetics are required to better understand HBV biology and provide a better guidance for the anti-HBV treatment.

Abstract

AIM: To investigate the location and expression of TIMP-1 and TIMP-2 in the liver of normal and experimental hepatic fibrosis in rats.

METHODS: The rat models of experimental immunity hepatic fibrosis ($n=20$) were prepared by the means of immunologic attacking with human serum albumin (HSA), and normal rats ($n=10$) served as control group. Both immunohistochemistry and *in situ* hybridization methods were respectively used to detect the TIMP-1 and TIMP-2 mRNA and related antigens in liver. The liver tissue was detected to find out the gene expression of TIMP-1 and TIMP-2 with RT-PCR.

RESULTS: The TIMP-1 and TIMP-2 related antigens in livers of experimental group were expressed in myofibroblasts and fibroblasts (TIMP-1: 482±65 *vs* 60±20; TIMP-2: 336±48 *vs* 50±19, *P*<0.001). This was the most obvious in portal area and fibrous septum. The positive signals were located in cytoplasm, not in nucleus. Such distribution and location were confirmed *by situ* hybridization (TIMP-1/*b*-actin: 1.86±0.47 *vs* 0.36±0.08; TIMP-2/*b*-actin: 1.06±0.22 *vs* 0.36±0.08, *P*<0.001). The expression of TIMP-1 and TIMP-2 was seen in the liver of normal rats, but the expression level was very low. However, the expression of TIMP-1 and TIMP-2 in the liver of experimental group was obviously high.

CONCLUSION: In the process of hepatic fibrosis, fibroblasts and myofibroblasts are the major cells that express TIMPs. The more serious the hepatic fibrosis is in the injured liver, the higher the level of TIMP-1 and TIMP-2 gene expression.

INTRODUCTION

Chronic viral hepatitis, alcoholism and schistosomiasis are the most common diseases in China[1-9]. At present, two main strategies for the treatment of chronic liver diseases are anti-viral therapies and anti-fibrotic therapies[10-14]. Hepatic fibrosis is a main pathologic basis of chronic liver diseases, particularly caused by viral hepatitis, and cirrhosis as a severe outcome is the end stage of various chronic liver diseases with increased synthesis and/or inhibition of matrix degradation. Although important progress in hepatic fibrosis has been achieved in the last decades, its mechanism is still debated at present. The formation of hepatic fibrosis is a response to inflammation, but it is interesting that hepatic fibrosis is not found in acute liver injury. It has been proved by the experiment *in vitro* that apoptosis could not be found in inactive hepatic stellate cells (HSC). This may imply that the mechanism of hepatic fibrosis is complicated, and many questions are being explored[15-23].

Hepatic fibrosis is a pathological process with the overlapped extracellular matrix (ECM) protein. The latest evidence suggests that the change of ECM mainly is regulated by metalloproteinases (MMPs). Hepatic fibrosis is formed because the specific tissue inhibitors of metalloproteinases (TIMPs) inhibit ECM degradation[24-28]. Which cells can express and produce TIMPs? Until now, there still are different views on the involvement of TIMPs in normal liver tissue and experimental hepatic fibrosis rats. The expression and location of TIMPs antigens and TIMP mRNA are measured in rat livers with mAb and cDNA probes of TIMP-1 and TIMP-2 by immunohistochemical staining, and gene expression of TIMP-1 and TIMP-2 is observed by PCR technique.

MATERIALS AND METHODS

Animal experiments

Forty adult female Wistar rats, weighing 120-150 g (provided by Experimental Animal Centre of Fourth Military Medical University) were employed in the study. The rats were randomly divided into 2 groups. A rat model of hepatic fibrosis was produced by immunological attacking with human serum albumin (HSA), using the method introduced by Wang *et al*[29]. Anti-mouse monoclonal antibody IgG was purchased from Coulter Co.(France). Twenty healthy female Wistar rats were regarded as control group. Animals survived from the experimental attack were randomly allocated as follows. All rats were injected with 0.5 mL HSA diluted with normal saline (0.5 mL equals to 4 mg HSA) and same quantity of an incomplete Freund' s adjuvant (Sigma), once every 14 days for the first two times, then once every 10 days, 2 times. Ten days after the last injection, serum antibody was measured. Positive rats were chosen for experiment through coccygeal vein injection of HSA, twice a week, 2.5 mg for each at the first week, and then gradually 0.5 mg- increase once for each to 4.5 mg, and this dose was maintained for 2 months. All animals were sacrificed under narcosis, and their livers were immediately excised. Part of liver specimen was frozen in liquid nitrogen, part fixed in 40 g/L formaldehyde, the rest was fixed with glutaraldehyde, and investigated with electron microscope.

Immunohistochemical staining of TIMP-1 and TIMP-2

According to the methods previously described[30-33], the serial paraffin sections of liver samples at 4 μm thickness were performed for SP immune staining described by streptomycin

Table 1 Sequences of TIMP-1, TIMP-2 and β-actin primers

	Primer	Nucleic acid sections	Position (bp)
TIMP-1	Positive strand	5'-TTCGTGGGGACACCAGAAGTC-3'	
	Antisence strand	5'-TATCTGGGACCGCAGGGACTG-3'	482
β-actin	Positive strand	5'-GGAGAAGATGACCCAGATCA-3'	
	Antisence strand	5'-GATCTTCATGAGGTAGTCAG-3'	234
TIMP-2	Positive strand	5'-GTTTTGCAATGCAGATGTAG-3'	
	Antisence strand	5'-ATGTCGAGAAACTCCTGCTT-3'	540
β-actin	Positive strand	5'-ACCCCCACTGAAAAA-3'	
	Antisence strand	5'-ATCTTCAAACCTCCATGATG-3'	120

avidin-peroxidase immunohistochemistcal kit (Maxim Biological Technology Company, USA). Anti-mouse monoclonal antibodies of TIMP-1 and TIMP-2 were also obtained from Maxim.The sections were deparaffinizd and rehydrated. After retrieval of the antigens, nonspecific binding sites were blocked with 100 mL/L normal serum for 20 min.The sections were incubated with monoclonal antibody against TIMP-1 or TIMP-2 at 4 ℃ overnight, and then with secondary antibody at 37 ℃ for 30-40 min, avidin-peroxidase at 37 ℃ for 20 min, and finally with DAB to be colorated for 10 min, and counterstained with hematoxylin, dehydrated with ethanol, rinsed in xylene, and mounted with gum for microscopic examination and photography. To ensure the reliability of the experiment, rabbit serum and phosphate buffer were used instead of monoclonal antibody and secondary antibody, respectively. In addition, 10 healthy liver tissues were selected for control group. The background density of positive cells from 5 microscopic fields at random was measured, and its mean value was used for statistical analysis with *SPSS* 10.0

In situ hybridization
The experiment was performed as previously described[33,34] using *in situ* hybridization kit (Boshide Biological Technology Limited Company, Wuhan, China, *No* MK1549). Briefly, the serial paraffin sections (thickness 4 μm) were dried at 80 ℃, then deparaffinizd by xylene and rehydrated in graded ethanol, acidified in 1 mol/L HCl for 30 min, and blocked in 30 ml/L H_2O_2 3 mL for 10 min before digestion with proteinase K for 30 min, and then dehydrated with graded ethanol. After prehybridization at 37-40 ℃ for 2 h, the labeled cDNA probes were denatured at 95 ℃ for 10 min, then at -20℃ for 10 min, added onto liver tissue sections which had been prehybridized at 37 ℃ overnight. The sections were washed with 2×SSC, 1×SSC, and 0.2×SSC respectively. Buffer I was added, and then blocking solution was added at room temperature for 20 min, and then rabbit anti-digoxin at 37 ℃ for 60 min, biotinylated goat anti-rabbit at 37 ℃ for 30 min, SABC at 37 ℃ for 30 min, finally DAB was added to develop color. After several washings, the sections were counter-stained with hematoxylin, dehydrated with ethanol, rinsed in xylene, and mounted with gum for microscopic examination and photography. Blank control: TIMP-1 and TIMP-2 cDNA probes for positive hepatic tissues were replaced by pre-hybridization solution. Negative control: *in situ* hybridization was performed in 10 normal liver tissues. Semi-quantitative results were determined by *in situ* hybridization. (-) as no positive cells, (+) as positive cells <1/3 of all hepatic cells, (++) as positive cells between 1/3-2/3 of all hepatic cells, (+++) as positive cells >2/3 of all hepatic cells in a lobule.

PCR amplification
PCR primers of TIMP-1 were designed according to the whole TIMP-1 cDNA sequence of rats[35]. The PCR primers of TIMP-1 and TIMP-2 are listed in Table 1.

Total RNA of the liver was extracted with an isolation system (Promega). PCR was performed in 20 μL reaction volume containing 2 μL cDNA, 2 μL 10×buffer, 2 μL (2 mmol/L) 4×dNTP, 10 mmol/L primer (2 μL TIMP-1, 2 μL β-*actin* and 2 μL TIMP-1, 2 μL β-*actin*, respectively) and 1U *Taq* DNA polymerase. The samples were subjected to 30 thermal cycles, each consisting of 2 min at 97 ℃ for predenaturation, 30 s at 94 ℃ for denaturing, 30 s at 56 ℃ for annealing, 50 s at 72 ℃ for extension and 7 min at 72 ℃ for final extension after the last cycle. Ten μL sample of PCR product was subjected to electrophoresis in 20 g/L agarose gel with TAE buffer at 50 V for 1 h. After stained with ethidium bromide, quantitative analysis was performed. The ratios of TIMP-1/*b*-*actin* and TIMP-2/*b*-*actin* were regarded as the expression levels of TIMP-1 and TIMP-2.

Pathologic observation
Some liver sections were stained with hematoxylin and eosin, while other sections for Von Gieson and Masson special staining. The liver samples were also fixed with glutaraldehyde, and examined with electron microscope.

Statistical analysis
Was performed with *SPSS* 10.0.

RESULTS
Pathologic findings
In liver tissues from rats with hepatic fibrosis, hyperplasia of the lattice fibers and collagenous fibers was observed in portal area and extended outwards. Hyperplasia surrounding the central vein observed was distributed along hepatic sinus and connected each other. The hepatic lobules were encysted and separated by collagen bundles. The normal structure of lobules was destroyed, and pseudolobules formed. Infiltration of inflammatory cells was found around the portal area and central vein. The structure of liver tissues was normal in control.

Under electron microscopy, proliferation of activated hepatic stellate cells (HSC) surrounded by collagen fibers was found in early stage, in which abundant rough endoplamic reticulum and lipids were present. Eventually, with the deposition of collagen bundles, myofibroblasts formed in portal area, and the deposition of collagens produced a wide compartment. Lots of collagen fibrils resided within the space of Disse. A vast amount of swelling mitochondria and some lipids were detectable in degenerative hepatocytes.

TIMP-1 and TIMP-2 expression and localization
TIMP-1 and TIMP-2 antigens in the liver from experimental rats were detected in myofibroblasts, fibroblasts and vascular endothelial cells predominantly in the portal area and fibrous septum. Expression of TIMP-1 and TIMP-2 exhibited as brown particles in cytoplasm. No positive expression was found in nucleus. There was only a mild positive expression in vascular

endothelial cells of the normal rat liver. Image pattern analysis showed that the expression in the experimental group was much stronger than that in the control group (Table 2, Figure 1), so did the *in situ* hybridization (Figure 2). In order to confirm the specificity of immunohistochemical experiment, the first antibody and second antibody were replaced by at serum and buffer, respectively. Negative results were found in controls, with specific confirming experiment *for in situ* hybridization, and no positive result was found.

Table 2 Expression of TIMP-1 and TIMP-2 related antigens in rat liver

| Group	n	TIMP-1	TIMP-2
Experimental group	20	482.50±65.00	336.50±48.32
Normal group	10	59.8±20.31	49.86±18.54

$P<0.001$.

Figure 2 Expression of TIMP-1 mRNA in liver tissue from rats with experimental fibrosis (*in situ* hybridization ×400).

TIMP-1 and TIMP-2 gene expression

The expression of TIMP-1 in the liver of normal rats was strikingly low, while its expression in experimental group was significantly higher than that in the normal group (Table 3).

Table 3 Gene expression of TIMP-1 and TIMP-2 in rat liver

Group	n	TIMP-1/β-*actin*	TIMP-2/β-*actin*
Experimental group	20	1.86±0.47	1.06±0.22
Normal group	10	0.36±0.08	0.36±0.08

$P<0.001$.

DISCUSSION

It is necessary to establish and develop an ideal animal model of hepatic fibrosis, so as to investigate the etiology or pathogensis, to explore the effective diagnosis or treatment and to select or evaluate anti-fibrotic medicines. An ideal animal model should be very similar to the characteristics of human disease, with distinct stages of disease and a low mortality. The model should be economically and easily established without difficulty to get the animals.

Researchers began to establish the hepatic fibrosis model of rats with carbon tetrachloride (CCL₄) in 1936, which was an early study on animal model of hepatic fibrosis and cirrhosis. Since it was repeatedly improved, the experimental model has been widely employed. People gradually established various models, such as rat model by bile duct ligation (Zimmermann, 1992), rabbit model with schistosomiasis (Dunn, 1994), rat model by thioacetamide (Okanoue, 1954), *etc*. However, these models with various characteristics are not very ideal to the animal experiment because of their common shortcomings that the hepatic fibrosis lasted shortly and was absorbed spontaneously soon.

In 1966, Paronetto and Popper[36] have proved that an immune response could induce liver injury. The animals injected repeatedly with the globulin or swine albumin or the serum from swine, bovine or horse developed hepatic fibrosis after 5 weeks, and cirrhosis after 10 weeks. However, the model had a high mortality because of allergic reaction. We studied various models and improved the model developed by Wang *et al*[29]. The survival rate of rats obviously increased and the fibrosis lasted for more than 363 days when the rats were injected with a small quantity of dexamethasone through its caudal vein soon after the first or secondary attack. The fibrosis was proved pathologically and the formation of fibrosis belonged to the type III allergic reaction induced by the immunocomplex of albumin. Under electron microscopy it was proved that the pathological process stimulated the proliferation of hepatic stellate cells (HSC), which would transform to the myofibroblasts and secrete a large amount of collagens.

At present, it was found that TIMP-1 in the injured liver increased early and obviously, and many researchers thought that TIMP-1 was a very important promoting factor in the process of hepatic fibrosis[27,32,37], and that it could inhibit MMPs (such as MMP-1) to deposit ECM. Up to now, only TIMP-1 and TIMP-2 were found in liver and TIMP-1 increased more obviously than TIMP-2, and strong expression of TIMP-1 reflected the severity of hepatic fibrosis. With the method of immunohistochemistry, we found that TIMP-1 and TIMP-2 were expressed obviously only in myofibroblasts or fibroblasts of livers from experimental group, mostly in portal area and fibrous septum, while very mildly in vascular endothelial cells of livers from control group. Such a distribution was also shown in the results of *in situ* hybridization.

The results of *in situ* hybridization demonstrated that TIMP-1 mRNA was expressed in hepatocytes and in almost all mesenchymal cells, especially strong in lipocytes of inflammation area of the liver induced by CCL₄ or bile duct ligation model[38]. Our results indicated that it was strongly expressed only in myofibroblasts, fibroblasts and vascular endothelial cells, mainly in portal area and fibrous septum. The results of immunohistochemistry were similar. Whether the expression difference is due to various models or other causes is still unknown.

From the gene expression levels of TIMP-1 and TIMP-2 we suggested that the more severe the hepatic fibrosis was, the higher the gene expression levels of TIMP-1 and TIMP-2 were, and that the strong expression of TIMP-1 inhibited the degeneration of collagen by MMP-1 and pro MMP-9, and that the expression of TIMP-2 inhibited MMP-2, MMP-9, *etc*. to promote the deposition of ECM. The continuous deposition of collagen fibers in the liver finally resulted in hepatic fibrosis.

The concentrations of TIMP-1 and TIMP-2 in peripheral blood indicated their gene expression levels. Iredale *et al*[39] isolated hepatocytes, HSC and Kupffer cells from the liver of experimental hepatic fibrosis model, but failed to find TIMP-1 mRNA in hepatocytes with Northern hybridization in 1997. We detected the expression of TIMP-1 in hepatocytes, HSC and Kupffer cells with PCR technique, and the expression of TIMP-1 was mild in normal rat liver, but strong in fibrotic rat liver. Therefore, further experiments might prove no expression of TIMP-1 in hepatocytes. The strong expression of TIMP-1 in fibroblasts and myofibroblasts of fibrotic liver probably resulted from the activation of HSC. In fact, hepatic fibrosis was essentially a "repair" reaction to chronic liver damage because of the cell-cell interaction mediated by cytokines and the activation of HSC induced by the interaction of mesenchymal cells. The persistence of HSC activation was induced by repeated liver damage. Thus, the activation of HSC was mainly in the pathologic process of hepatic fibrosis[19,21].

Although TIMP-1 and TIMP-2 were closely related to hepatic fibrosis, study on TIMPs has just begun. Thus far, the mechanism of strong expression of TIMP-1 and TIMP-2 in fibrotic liver is still unknown, and other characteristics of TIMPs are being studied[40-43]. To enhance the study on TIMPs has become very important for the diagnosis, treatment and pathogensis of hepatic fibrosis[44-47].

Abstract

AIM: To better clarify the main target organs of dimethylarsinic acid toxicity and the role of metallothionein (MTs) in modifying dimethylarsinic acid (DMAA) toxicity.

METHODS: MT-I/II null (MT$^{-/-}$) mice and the corresponding wild-type mice (MT$^{+/+}$), six in each group, were exposed to DMAA (0-750 mg/kg body weight) by a single oral injection. Twenty four hours later, the lungs, livers and kidneys were collected and undergone pathological analysis, induction of apoptotic cells as determined by TUNEL and MT concentration was detected by radio-immunoassay.

RESULTS: Remarkable pathological lesions were observed at the doses ranging from 350 to 750 mg/kg body weight in the lungs, livers and kidneys and MT$^{+/+}$ mice exhibited a relatively slight destruction when compared with that in dose matched MT$^{-/-}$ mice. The number of apoptotic cells was increased in a dose dependent manner in the lungs and livers in both types of mice. DMAA produced more necrotic cells rather than apoptotic cells at the highest dose of 750 mg/kg, however, no significant increase was observed in the kidney. Hepatic MT level in MT$^{+/+}$ mice was significantly increased by DMAA in a dose-dependent manner and there was no detectable amount of hepatic MT in untreated MT$^{-/-}$ mice.

CONCLUSION: DMAA treatment can lead to the induction of apoptosis and pathological damage in both types of mice. MT exhibits a protective effect against DMAA toxicity.

INTRODUCTION

Arsenic is a metalloid that naturally occurs in soil, water, and air. Arsenicals are also non-biodegradable by-products during production of copper, lead, and other ores and coal consumption. Exposure to arsenic by food, drinking water, soil and air containing arsenic is widely existed in the world. Inorganic arsenicals are well known human carcinogens, specifically for the lung, liver, kidney, skin, bladder and other internal organs[1,2]. Dimethylarsinic acid (DMAA) is a major form of organic arsenic in the environment and the main metabolite of ingested inorganic arsenicals in most mammals, including humans[2-4]. DMAA itself can be used as herbicide and pesticide and also naturally exists in some seafood. Recent studies have revealed that DMAA is a genotoxic, multi-site promoter of carcinogenesis as well as a complete carcinogen in rodents[5-7], which provides a novel clue to investigate the mechanism of arsenicals in carcinogenesis.

Arsenicals, including DMAA, are moderately effective inducers of MT in mice and rats[8,9]. MTs, thiol-rich metal binding proteins, have been shown to be easily induced by oxidative stress and heavy metals and play an important role in homeostasis of essential metals, detoxication of heavy metals, scavenging reactive oxygen intermediates and preventing carcinogenesis as an endogenous defensive factor[10-15]. Especially to be mentioned, its capacity of scavenging hydroxyl and superoxide radicals is much more efficient than GSH, an established antioxidant[15]. Among the four major isoforms of identified MTs, MT-I and MT-II existing in all tissues examined, are the predominant forms in the livers. Recently Liu et al[16] reported that MT-I/II null mice were more sensitive than wild type mice to hepatotoxic and nephrotoxic effects of oral or injected inorganic arsenicals. Sakurai et al[17] reported that DMAA could induce apoptosis by reducing glutathione (GSH) in vitro. However, the effect of MT on induction of apoptosis and the main organic toxicity by DMAA in vivo remain elusive.

MT-I/II null (MT$^{-/-}$) mice have been proved to be a good tool for studying MT's normal function and the consequences of its deficiency[18]. In the present study, MT-I/II null (MT$^{-/-}$) mice and the corresponding wild-type mice (MT$^{+/+}$) were exposed to DMAA by oral injection, we investigated the pathological lesions and apoptosis in main target organs including the liver, lung and kidney of the mice, to elucidate the toxicity of DMAA and the ability of MT to modify DMAA toxicity.

MATERIALS AND METHODS

Chemicals
Dimethylarsinic acid (purity 100 %) was purchased from Wako Pure Chemical Co. (Osaka, Japan). An *in situ* apoptosis detection kit (ApopTag^{TM}) was purchased from Intergen Co. NY, USA.

Animals and treatment
MT null (MT$^{-/-}$) mice whose MT-I and II genes had null mutation and wild type (MT$^{+/+}$) mice provided kindly by Dr. A. Choo (Murdoch Institute for Research into Birth Defects, Royal Children's Hospital, Australia), were of a mixed genetic background of 129 Ola and C57BL/6 strains. F1

hybrid mice were mated with C57BL/6 mice, and their offsprings were back-crossed to C57BL/6 for six generations. $MT^{-/-}$ and $MT^{+/+}$ mice were obtained by mating of those heterozygous ($MT^{-/+}$) mice.

$MT^{-/-}$ and $MT^{+/+}$ mice were routinely bred in the vivarium of the National Institute for Environmental Studies (NIES, Japan). Microbiological and viral examinations were performed with regular quarantine procedures for more than one year, and we did not find either pathogenic infections or significant phenotypical abnormalities. Both strains of mice were housed in cages in ventilated animal rooms with a controlled temperature of 23±1 ℃, a relative humidity of 55±10%, and a 12 h light/dark cycle. They were maintained on standard laboratory chow and tap water *ad lib*, and received humane care throughout the experiment according to the guidelines of the NIES. Eight-week-old female $MT^{-/-}$ and $MT^{+/+}$ mice were assigned randomly in equal numbers to all groups (six mice for each treatment group). Fresh DMAA solution was prepared by dissolving it in sterilized water. The mice were administered DMAA (0-750 mg/kg) by oral gavage.

Sample collection

At 24 h after administration of DMAA, the lung, liver and kidney were collected from each mouse under diethyl ether anesthesia. Portions of tissues were fixed in 10% neutral formalin, processed by the standard histological techniques, and stained with hematoxylin and eosin for light microscopic examination. For TUNEL staining, sections (5 μm) were placed on poly-L-lysine precoated slides.

TUNEL for apoptosis

Apoptotic cells were detected with an apoptosis detection kit according to the manufacturer's instructions. Briefly, the samples were incubated with digoxigenin-labeled dNTP in the presence of terminal deoxynucleotidyl transferase followed by peroxidase-conjugated anti-digoxigenin antibody. Nuclear staining of apoptotic cells was detected with 3', 3' -diaminobenzidine followed by counterstaining of nuclei with methyl green. An apoptosis index (AI) was obtained by dividing the number of positive cells in the area observed[19].

MT Concentration

MT (MT-I and MT-II isoforms) concentration in the liver was measured by radioimmunoassay using sheep anti-rat MT-I antiserum[20]. The detection limit of this method was 0.2 μg MT/g of tissue.

Statistical analysis

ANOVA with subsequent *post hoc's* test was used as appropriate. All values were expressed as $\bar{x}\pm s$. Differences were considered significant at $P<0.05$.

RESULTS

Histopathological observation

In untreated $MT^{-/-}$ mice and the corresponding $MT^{+/+}$ mice, the lung, liver and kidney showed normal morphology. Significant lesions were observed at doses of DMAA ranging from 375 to 750 mg/kg body weight in both types of mice. However, the pathological lesions in $MT^{-/-}$ mice were more severely widespread when compared to that in dose matched $MT^{+/+}$ mice.

Changes including congestion, atelectasis and mild to moderate hemorrhages in the alveoli of the lungs were observed in $MT^{-/-}$ mice. Adequate air space in the alveoli was observed more frequent in $MT^{+/+}$ mice compared to that of $MT^{-/-}$ mice. Pulmonary capillary congestion could affect alveolar space, resulting in severe acute impairment of respiratory function.

Capillary rupture led to leakage of red blood cells into the interstitium, as well as into the alveoli (Figure 1).

Figure 1 Typical HE staining. The bar is 100 μm. A, B: the lungs from control of $MT^{-/-}$ and $MT^{+/+}$ mice; C, D: the lungs from 750 mg/kg DMAA group of $MT^{-/-}$ and $MT^{+/+}$ mice. Arrows indicate atelectasis and hemorrhage.

At 24 h after DMAA treatment, severe liver damages characterized by cellular cloudy swelling, paleness of cell cytoplasm, vacuolization of hepatocytes and a few areas of focal necrosis were found in $MT^{-/-}$ mice while a limited degree of changes was observed in dose matched $MT^{+/+}$ mice livers (Figure 2).

Figure 2 Typical HE staining. The bar is 100 μm. A, B: the livers from control of $MT^{-/-}$ and $MT^{+/+}$ mice; C, D: the livers from 750 mg/kg DMAA group of $MT^{-/-}$ and $MT^{+/+}$ mice. The arrows indicate necrosis.

Histological changes in the kidney are shown in Figure 3. Treatment with DMAA produced swelling of glomerulus and its surrounding tubular tissue and urinary space compression in both types of mice.

Figure 3 Typical HE staining. The bar is 100 μm. A, B: the kidneys from control of MT$^{-/-}$and MT$^{+/+}$ mice; C, D: the kidneys from 750 mg/kg DMAA group of MT$^{-/-}$and MT$^{+/+}$ mice. The arrows indicate the swelling of glomerulus and the surrounding tubular tissue and urinary space compression.

A: Typical apoptotic cells in alveolar area of MT$^{-/-}$ mice at a dose of 188 mg/kg body weight. Brown staining indicates the apoptotic cells. The bar is 20 μm. B: Typical apoptotic cells in bronchial area of MT$^{-/-}$ mice at a dose of 188 mg/kg body weight. Brown staining indicates apoptotic cells. The bar is 20 μm. C: AI in alveolar area. D: AI in bronchial area. All the values were expressed as $\bar{x}\pm s$. ANOVA with subsequent *post hoc's* test was performed for comparison of AI. [a,b]Significant difference at $P<0.05$, $P<0.01$ when compared with the corresponding control group. [c,d]Significant difference at $P<0.05$, $P<0.01$ when compared with the dose-matched MT$^{-/-}$ mice group.

Induction of apoptotic cells detected in lungs, livers and kidneys of MT$^{-/-}$ and MT$^{+/+}$ mice

High induction of apoptotic cells in bronchial epithelial cells was observed in MT$^{-/-}$ mice treated with DMAA at 375 mg/kg body weight, however, the same changes were not observed in dose matched MT$^{+/+}$ mice. At a high dose of 750 mg/kg body weight, the coincident increase of apoptotic cells was observed in both types of mice and no significant difference was observed between them.

In control group, the incidence of apoptotic cells in alveolar epithelial cells in MT$^{+/+}$ mice was significantly higher than that in MT$^{-/-}$ mice, implying that MT$^{+/+}$ mice might have a stronger ability to induce apoptosis than MT$^{-/-}$ mice. A significant increase of apoptotic cells occurred in MT$^{-/-}$ mice treated by 188 mg/kg DMAA, a relative low dose when compared with that in bronchial epithelial cells. However, no significant increase was observed in MT$^{+/+}$ mice at the same dose of 188 mg/kg DMAA. With the increase of dose, high induction of apoptotic cells was observed in both types of mice (Figure 4).

Figure 5 shows that in control group, the incidence of apoptotic cells in MT$^{+/+}$ mice was $156.33 \pm 41.041/cm^2$, significantly higher than that in MT$^{-/-}$ mice. The incidence of apoptotic cells in the livers rose with the increase of dose in both types of mice. However, at the highest dose of 750 mg/kg, DMAA produced more necrotic cells rather than apoptotic cells observed by HE staining (Figure 2).

DMAA failed to induce remarkable apoptotic cells in the kidneys from both types of mice (data not shown).

MT concentration in liver of MT$^{+/+}$ mice

MT concentration was determined in the liver of MT$^{+/+}$ mice and MT$^{-/-}$ mice treated with DMAA (Figure 6). Hepatic MT level in MT$^{+/+}$ mice was significantly increased by DMAA in a dose-dependent manner. However, there was no detectable amount of hepatic MT in untreated MT$^{-/-}$ mice, and it could not be induced by DMAA.

Figure 6 MT concentration in livers of MT$^{+/+}$ mice detected by radio-immunoassay. All the values were expressed as $\bar{x} \pm s$. ANOVA with subsequent *post hoc's* test was performed for comparison of AI. [b]Significant difference at $P<0.01$ when compared with the corresponding control group.

DISCUSSION

The present study demonstrated that DMAA could produce pathological lesions in the lungs, livers and kidneys, and induce apoptosis in the lungs and livers. Most importantly, it is the first report to show that inability to produce MT-I/II in MT$^{-/-}$ mice caused an increased sensitivity to toxicity induced by DMAA.

Treatment with DMAA caused severe and wide spread lesions in MT$^{-/-}$ mice, whereas, these changes were much less severe in MT$^{+/+}$ mice. It indicates that MT$^{-/-}$ mice were more

sensitive to DMAA and MT played a protective role against the toxicities to main organs. Yamanaka[7] reported that DMAA in mice could be further metabolized and converted into dimethylarsine radicals and dimethyl arsenic peroxy radicals. Marked formation of 8-oxod G was observed in the lung and liver, which are the target organs for arsenic carcinogenesis. No increase in 8-oxod G levels was observed in the kidney. Meanwhile, MT was capable of scavenging hydroxyl and superoxide radicals and its capability of scavenging them was much more efficient[11,12,15]. In our study, the expression of MT (I/II) was induced by DMAA in a dose dependent manner in the livers of MT$^{+/+}$ mice, no MT(I/II) was observed in MT$^{-/-}$ mice. Thus the reduction of lesions induced by DMAA in the main target organs of MT$^{+/+}$ mice could be explained at least partly by MT reduction induced by DMAA, and the toxicity induced by DMAA could be explained partly by way of oxidative stress participation.

After a lethal damaging stimulation, two main structural routes of cell death might occur: apoptosis and necrosis. It has become apparent that the magnitude and type of injurious stimuli could determine whether a cell underwent death through apoptosis or necrosis. Severe damaging stimuli tended to result in necrosis, and lower grade damaged stimuli tended to cause apoptosis[21-30].

Recently, Sakurai *et al* reported that DMAA could induce apoptosis by reducing glutathione (GSH) *in vitro*[17]. However, the effect of MT on the induction of apoptosis by DMAA *in vivo* remains elusive. Furthermore, the perturbation of apoptosis has been thought to contribute to carcinogenesis either through enhanced initiation or progression[29-38]. In this study, the induction of apoptosis was detected by TUNEL in the lungs, livers and kidneys from both types of mice. In the lungs, a significant increase of apoptosis was observed in alveolar cells of MT$^{-/-}$ mice at a relative low level compared with that in bronchial cells, suggesting that alveolar cells were more sensitive than bronchial cells and MT had some protective role against the induction of apoptosis induced by DMAA at a relative low level. With the increase of dose, DMAA induced high levels of apoptosis in both types of mice and at the highest dose of 750 mg/kg, necrotic cells predominated over apoptosis in the livers, revealing the serious toxicity of DMAA at this dose. Since the kidney is the major organ for arsenic elimination and most of arsenicals could be rapidly eliminated through the kidney[1-3], renal cells are thus exposed to a major portion of the absorbed arsenical dose. However, the induction of apoptosis was not affected by DMAA, the underlying mechanism needs further investigations.

In conclusion, the present studies demonstrate that oral administration of DMAA can produce toxic response of the respiratory system, liver and kidney in both MT$^{-/-}$ and MT$^{+/+}$ mice. The pathological effects are clearly pronounced in MT$^{-/-}$ mice. Intracellular MT appears to play an important role in preventing the toxic effects of DMAA.

Abstract

AIM: To study the change of intracellular calcium-magnesium ATPase (Ca²⁺-Mg²⁺-ATPase) activity in pancreas, liver and kidney tissues of rats with acute pancreatitis (AP), and to investigate the effects of Qingyitang (QYT) (Decoction for clearing the pancreas) and tetrandrine (Tet) and vitamin E (VitE) on the activity of Ca²⁺-Mg²⁺-ATPase.

METHODS: One hundred and five Sprague-Dawley rats were randomly divided into: normal control group, AP group, treatment group with QYT (1 ml/100 g) or Tet (0.4 ml/100 g) or VitE (100 mg/kg). AP model was prepared by a retrograde injection of sodium taurocholate into the pancreatic duct. Tissues of pancreas, liver and kidney of the animals were taken at 1 h, 5 h, 10 h respectively after AP induction, and the activity of Ca²⁺-Mg²⁺-ATPase was studied using enzyme-histochemistry staining. Meanwhile, the expression of Ca²⁺-Mg²⁺-ATPase of the tissues was studied by RT-PCR.

RESULTS: The results showed that the positive rate of Ca²⁺-Mg²⁺-ATPase in AP group (8.3%, 25%, 29.2%) was lower than that in normal control group (100%) in all tissues ($P<0.01$), the positive rate of Ca²⁺-Mg²⁺-ATPase in treatment group with QYT (58.3%, 83.3%, 83.3%), Tet (50.0%, 70.8%, 75.0%) and VitE (54.2%, 75.0%, 79.2%) was higher than that in AP group (8.3%, 25.0%, 29.2%) in all tissues ($P<0.01$). RT-PCR results demonstrated that in treatment groups Ca²⁺-Mg²⁺-ATPase gene expression in pancreas tissue was higher than that in AP group at the observing time points, and the expression at 5 h was higher than that at 1 h. The expression of Ca²⁺-Mg²⁺-ATPase in liver tissue was positive, but without significant difference between different groups.

CONCLUSION: The activity and expression of intracellular Ca²⁺-Mg²⁺-ATPase decreased in rats with AP, suggesting that Ca²⁺-Mg²⁺-ATPase may contribute to the occurrence and development of cellular calcium overload in AP. QYT, Tet and VitE can increase the activity and expression of Ca²⁺-Mg²⁺-ATPase and may relieve intracellular calcium overload to protect the tissue and cells from injuries.

INTRODUCTION

The pathogenesis of acute pancreatitis (AP) is complicated. A number of theories have been proposed. It is generally accepted that "calcium overload" plays a key role in the occurrence and progression of AP[1-3]. However, the exact mechanism of intracellular calcium overload in acute pancreatitis is not clear yet. This study was designed to explore the mechanism of intracellular calcium overload by determining the activity of intracellular Ca²⁺-Mg²⁺ ATPase in AP rats. The experiment also investigated the therapeutic mechanisms of some medicines, such as Chinese medicines Qingyitang (QYT) and tetrandrine (Tet), and Vitamin E (VitE) on AP in rats.

MATERIALS AND METHODS

Animals
One hundred and five Sprague-Dowley (SD) rats including male and female (1:1) were used. The animals, weighing 220-250 g, were provided by the Animal Center of Chinese Academy of Sciences, Shanghai, China.

Reagents
Sodium taurocholate from Sigma Co. was diluted with distilled water to make a 4% solution for use. QYT was from Zunyi Medical College, Tet from the Pharmaceutical Institute of the Second Military Medical University, VitE (emulsion, 2 ml/kg) from Xinan Pharmaceutical Factory, ATP disodium salt from Shanghai Institute of Biochemistry, Chinese Academy of Sciences. Trizol, reverse transcriptase Superscript II RNase H- were from Gib Co. (USA), hexamer from Promega (USA), and Taq DNA polymerase, dNTP, RNAase inhibitor from Takara Co. (Japan), diethyl pyrocarbonate (DEPC) from Serva Co. (USA). Primers for Ca²⁺-Mg²⁺-ATPase (upstream primer -5' GAACATCCTGCAGACGGACA-3', downstream primer -5' CAAAGCTATGGGAGTGGTGG-3') (790-1 241 bp) and primers for GAPDH (upper - 5' ACCACAGTCCATGCCAT CAC-3', lower - 5' TCCACCACCCTGTTGCTGTA-3') were purchased from Takara Co. (Japan).

Animal model preparation and grouping
The rats were randomly divided into normal control group ($n=9$), AP+ normal saline (NS) group ($n=24$), AP+QYT group($n=24$), AP+Tet group ($n=24$), AP+VitE group ($n=24$). In normal control group the pancreas of rats were exposed. In the other groups, the pancreas of rats was exposed and sodium taurocholate was injected into the pancreatic duct to induce AP[4]. In AP+NS group, rats were injected with NS (0.4 ml/100 g, ip) after AP induction. In AP+QYT group, rats were infused with QYT (1 ml/100 g) by a nose-gastric catheter, in AP+Tet group, rats were injected peritoneally

with Tet (0.4 ml/100 g), and in AP+VitE group, rats were given VitE (100 mg/kg) intravenously through mesenteric vein.

HE staining
At 1 h, 5 h or 10 h after operation, the tissue samples of pancreas, liver and kidney were taken and fixed with formalin solution. Some sections of the specimens were stained with HE, and then observed under a light microscope.

Enzyme histochemistry
Some of the tissue blocks were used for enzyme histochemistry staining. Four µm thick tissue slices were mounted to polylysine-coated slides with a cryotome. Wachstein-Meisd lead nitrate method[5] was used to conduct enzyme histochemistry stain for intracellular Ca^{2+}-Mg^{2+}-ATPase. The slides were examined under a light microscope.

RT-PCR
Primers for Ca^{2+}-Mg^{2+}-ATPase gene were designed based on mRNA sequence of intracellular Ca^{2+}-Mg^{2+}-ATPase[6]. GAPDH gene was used as internal housekeeping gene. Total RNA of pancreas and liver were taken for RT-PCR at 1 h and 5 h after AP was induced. Total RNA was extracted with Trizol reagents. Quantity and purity of RNA were determined with an ultraviolet spectrophotometer. RNA integrity was confirmed by agar gel electrophoresis. The reverse transcription system was 20 µl in volume, containg 2 µg total RNA, 1 µl reverse transcriptase, 1 µl dNTP (10 mmol/L), 2 µl (100 ng/1 µl) hexamer, 4 µl 5×buffer, 2 µl 0.1M DTT, 8 µl water. The mixture was incubated at 37 ℃ for 1 hour and then at 70 ℃ for 15 minutes to inactivate reverse transcriptase. cDNA was used as a template for subsequent PCR. PCR reaction was performed in a thermal cycler (PE480). PCR reaction solution contained 1 µl cDNA, 2 µl dNTP (2 mmol/L), 1 µl primers, 2.5 µl 10×buffer, 2U Taq polymerase, 18 µl water. PCR process was at 94 ℃ for 5 minutes, followed by 35 cycles at 94 ℃ for 1 min, at 57 ℃ for 1 min, and at 72 ℃ for 1 min. Final extension was at 72 ℃ for 10 minutes, 8 µl of PCR products was examined on 1% agar gel electrophoresis. The bands were observed and photographed under Ultraviolet light.

Statistical analysis
Data were analyzed by χ^2 test and $P<0.01$ was considered significant.

RESULTS
Pathological findings in pancreas, liver and kidney tissues of AP rats
Pancreas Large areas of hemorrhage were found in pancreatic tissue of AP+NS group. Acinar structure was obscure. There were large areas of necrosis. Some nuclei were lysed and disappeared. Apparently saponified spots were seen. A number of inflammatory cell infiltrations were observed in the peri-necrotic tissues. In AP+QYT, AP+Tet or AP+VitE groups, the pancreas only slightly swelled with sporadic bleeding and necrosis, and mild inflammatory infiltration in the pancreatic tissue.

Liver In AP+NS group, degeneration and necrosis of the liver cells were found, and hepatocytes were disordered and some hepatic cords disappeared. In AP+QYT, AP+Tet or AP+VitE groups, hepatocytes were only degenerated and swelled with slight focal hemorrhagic necrosis.

Kidney In AP+NS group, epithelial cells in the proximal convoluted renal tubule were observed with degeneration and necrosis. Hyperemia, swelling and inflammatory cell infiltration were seen in renal glomeruli. Only edema was found in proximal convoluted renal tubular epithelial cells in AP+QYT, AP+Tet and AP+VitE groups (Figure 1).

Activity of intracellular Ca²⁺-Mg²⁺-ATPase in pancreas, liver and kidney tissues of AP rats
Positive stains were diffusely distributed in cellular membrane and cytoplasm of pancreatic acinar cells, hepatocytes, and proximal renal tubule epithelial cells. Positive rate of Ca^{2+}-Mg^{2+}-ATPase stain in tissues of normal group was significantly higher than that of other groups. The lowest positive rate was found in AP+NS group ($P<0.01$). There was no significant difference between groups of AP+QYT, AP+Tet, and AP+VitE ($P>0.05$) (Table 1, Figure 2).

Positive cells were defined as cells with uneven chocolate brown particles in cytoplasm under light microscope. The darker the staining color was, the higher the activity was. The cells were classified into 4 levels based on color intensity and number of positive cells. No staining or only a small number of light brown particles in cellular membrane and cytoplasm, and more than 25% of stained cells were negative (-); with a medium number of brown particles, and 25%-50% of stained cells were positive (+); with a large number of brown particles and more than 50% of stained cells were positive (++); more than 75% of stained cells were positive (+++).

Expression of Ca²⁺-Mg²⁺-ATPase in pancreas and liver tissues of AP rats
By RT-PCR technique, the expression of Ca^{2+}-Mg^{2+}-ATPase in pancreas and liver of all groups was measured respectively. The gene fragment of Ca^{2+}-Mg^{2+}-ATPase was 451 bp. The amplified fragment of internal housekeeping gene GAPDH was 450 bp. The results showed that the highest expression of Ca^{2+}-Mg^{2+}-ATPase was in normal group, the lowest was in AP+NS group, and moderate in AP+QYT, AP+Tet and AP+VitE groups. The expression decreased with time in AP+NS group, While in AP+QYT, AP+Tet and AP+VitE groups, the expression increased with time. The expression of Ca^{2+}-Mg^{2+}-ATPase in liver had no significant difference between groups (Figure 3).

Table 1 Positive rate of activity of intracellular Ca^{2+}-Mg^{2+}-ATPase in tissues of AP rats

Group	n	Pancreatic acinar cells				Hepatocytes				Renal epithelial cells

DISCUSSION

The level of intracellular free calcium (Ca^{2+}) is not only dependent on the inflow of extracellular calcium through cell membrane and release from calcium reservoir inside the cell, but also on the function of Ca^{2+}-Mg^{2+}-ATPase on cell membrane and membrane of endoplasmic reticulum and mitochondria. By Ca^{2+}-Mg^{2+}-ATPase, Ca^{2+} could be pumped out of cell or into calcium reservoir. Thus Ca^{2+}-Mg^{2+}-ATPase could play an important role in intracellular calcium homeostasis[7-9].

Activity and expression of intracellular Ca²⁺-Mg²⁺-ATPase in AP and its implication

Our experimental results showed that, in AP rats, the activity of Ca^{2+}-Mg^{2+}-ATPase in pancreatic, hepatic and renal tissues was decreased in AP rats. At the same time the pathological findings were aggravated. These results suggested that alteration of Ca^{2+}-Mg^{2+}-ATPase activity in AP might take part in the occurrence and progression of AP. It was reported that permeability of cell membrane was increased in AP. Ca^{2+} inflow might increase and lead to intracellular calcium overload. In the meantime, some stimulating factors could activate corresponding receptors on the surface of membrane to activate guanylate cyclation (GC). As a result, energy was released to cascade effector phospholipase C intracellular phosphatidylinositol diphosphate (PIP_2) into inositol triphosphate (IP_3) and diacylglycerol (DG). The IP_3 subsequently activated IP_3 receptors on endoplasmic reticulum to stimulate Ca^{2+} release from calcium reservoir. Consequently intracellular Ca^{2+} level increased abruptly. If the intracellular Ca^{2+}-Mg^{2+}-ATPase activity was decreased, Ca^{2+} could not be effectively pumped back into the reservoir or out of cells, which further aggravated intracellular calcium overload[10,11]. Intracellular calcium overload further facilitated the release of pro-inflammatory mediators, which would cause strong contraction and thrombosis of microcirculation. Thus energy metabolism in tissues was disordered and ATP production was reduced[12-16]. In addition, large quantities of free radicals produced during acute pancreatitis would cause phospholipids re-distribution in cell membrane. All of these factors might contribute to the inhibition of ATPase activity, which in turn would aggravate intracellular calcium overload. The vicious cycle occurred. Therefore, decrease of intracellular Ca^{2+}-Mg^{2+}-ATPase activity plays a key role in the development and aggravation of calcium overload.

In the present study, we found that activity of intracellular Ca^{2+}-Mg^{2+}-ATPase was decreased in hepatocyte of AP rat, but the expression of Ca^{2+}-Mg^{2+}-ATPase in the tissues did not change greatly. This finding suggested that intracellular Ca^{2+}-Mg^{2+}-ATPase activity was not only dependent on the level of its gene expression but also was affected by many other factors[17-19].

Therapeutic effect and mechanism of QYT, Tet and VitE

Chinese medicine QYT is an effective compound in the treatment of AP. It has been proved to have bacteriostatic and anti-inflammatory effects, and to promote intestinal movement[20,21]. Tet is a kind of bisbenzylisoquinoline alkaloid extracted from root tuber of Stephania tetrandran, a Chinese herbal medicine. It has been proved to be a natural non-selective calcium channel blocker[22,23], and VitE has also been proved to be a scavenging agent of free radicals and blocker for lipid peroxidation[24-27]. The present study found that in AP rats, intracellular Ca^{2+}-Mg^{2+}-ATPase activity in pancreatic, hepatic and renal tissues was increased after treatment with the above three medicines, and in pancreas the expression of Ca^{2+}-Mg^{2+}-ATPase was enhanced. Furthermore, pathological changes of hemorrhage and necrosis in the tissues were relieved. The complicating ascites and pleural effusion were improved[28-34].

In summary, QYT, Tet and VitE have certain protecting effects on tissues and cells in AP, and the mechanisms are related with improved blood supply, increased intracellular Ca^{2+}-Mg^{2+}-ATPase activity and reduced intracellular calcium overload.

Abstract

AIM: To study the effect of red oil A5 on pancreatic cancer cells and its possible mechanisms.

METHODS: Effect of different concentrations of red oil A5 on proliferation of three pancreatic cancer cell lines, AsPC-1, MiaPaCa-2 and S2013, was measured by ^{3}H-methyl thymidine incorporation. Time-dependent effects of 1:32 000 red oil A5 on proliferation of three pancreatic cancer cell lines, were also measured by ^{3}H-methyl thymidine incorporation, and Time-course effects of 1:32 000 red oil A5 on cell number. The cells were counted by Z1-Coulter Counter. Flow-cytometric analysis of cellular DNA content in the control and red oil A5 treated AsPC-1, MiaPaCa-2 and S2013 cells, were stained with propidium iodide. TUNEL assay of red oil A5-induced pancreatic cancer cell apoptosis was performed. Western blotting of the cytochrome c protein in AsPC-1, MiaPaCa-2 and S2013 cells treated 24 hours with 1:32 000 red oil A5 was performed. Proteins in cytosolic fraction and in mitochondria fraction were extracted. Proteins extracted from each sample were electrophoresed on SDS-PAGE gels and then were transferred to nitrocellulose membranes. Cytochrome c was identified using a monoclonal cytochrome c antibody. Western blotting of the caspase-3 protein in AsPC-1, MiaPaCa-2 and S2013 cells treated with 1:32 000 red oil A5 for 24 hours was carried out. Proteins in whole cellular lysates were electrophoresed on SDS-PAGE gels and then transferred to nitrocellulose membranes. Caspase-3 was identified using a specific antibody. Western blotting of poly-ADP ribose polymerase (PARP) protein in AsPC-1, MiaPaCa-2 and S2013 cells treated with 1:32 000 red oil A5 for 24 hours was performed. Proteins in whole cellular lysates were separated by electrophoresis on SDS-PAGE gels and then transferred to nitrocellulose membranes. PARP was identified by using a monoclonal antibody.

RESULTS: Red oil A5 caused dose- and time-dependent inhibition of pancreatic cancer cell proliferation. Propidium iodide DNA staining showed an increase of the sub-G0/G1 cell population. The DNA fragmentation induced by red oil A5 in these three cell lines was confirmed by the TUNEL assay. Furthermore, Western blotting analysis indicated that cytochrome c was released from mitochondria to cytosol during apoptosis, and caspase-3 was activated following red oil A5 treatment which was measured by procaspase-3 cleavage and PARP cleavage.

CONCLUSION: These findings show that red oil A5 has potent anti-proliferative effects on human pancreatic cancer cells with induction of apoptosis *in vitro*.

INTRODUCTION

Pancreatic cancer is one of the most enigmatic and aggressive malignant diseases[1-4]. It is now the fourth leading cause of cancer death in both men and women in the USA and the incidence of this disease shows no sign of decline[1-3,5]. Pancreatic cancer is characterized by a poor prognosis and lack of effective response to conventional therapy[6]. The 5-year survival rate is less than 4% and the median survival period after diagnosis is less than 6 months[7,8]. At present, surgical resection is still the only effective treatment option, but only about 15% of carcinomas of the head of pancreas are resectable and there are few long-term survivors even after apparent curative resection[7,8]. On the other hand, chemotherapy or radiation therapy provide only limited palliation, without meaningful improvement of survival in patients with non-resectable pancreatic cancer[7-9]. Only new therapeutic strategies can improve this dismal situation[10,11].

A series of prospective and case-control studies have shown an association between higher fish intake and reduced cancer incidence, and other benefits including inhibition of cancer cell proliferation, induction of apoptosis[12-22]. Recent studies indicate that diets containing a high proportion of long-chain n-3 polyunsaturated fatty acids was associated with inhibition of growth and metastasis of human cancer including pancreatic cancer[12,14,23,24]. Diets rich in linoleic acid (LA), an n-6 fatty acid, stimulate the progression of human cancer cell in athymic nude mice, whereas supplement of fish oil components, docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) exerts suppressive effects. Fish oil has been shown to reduce the induction of different cancer in animal models by a mechanism which may involve suppression of mitosis, increase apoptosis through long-chain n-3 polyunsaturated fatty acid EPA[12,14,25-27]. In parallel, dietary supplementation with DHA is accompanied by reduced levels of 12- and 15-hydroxyeicosatetraenoic acids (12- and 15-HETE), suggesting that changes in eicosanoid biosynthesis may have been responsible for the observed decrease in tumor growth[14,16,28,29]. Previous studies also have shown that the anti-cancer effect of fish oil is accompanied by a decreased production of cyclooxygenase and lipoxygenase metabolites[10,30,31]. The efficacy of fish oil which we have found exhibits particularly potent anticancer effects that appear to be related to its content of lipoxygenase inhibitors rather than its EPA or DHA contents. Red oil A5 is lipid isolates from the epithelial layer of the echinoderm. This oil is non-toxic and exerts a marked anti-inflammatory effect in laboratory animals. Red oil A5 almost totally inhibits pancreatic cancer cell proliferation at dilutions

of up to 1:32 000. The inhibition of proliferation induced by this fish oil is accompanied by marked induction of apoptosis. To date, no information is available regarding the effects of red oil A5 in pancreatic cancer. In the present study, the effects of red oil A5 on proliferation, apoptosis and cell cycle distribution were investigated in pancreatic cancer cells.

MATERIALS AND METHODS

Pancreatic cancer cell lines

The human pancreatic cancer cell lines (AsPC-1, MiaPaCa-2 and S2013) were purchased from the American Type Culture Collection (Rockville, MD, USA). These cell lines span the types of differentiation in human pancreatic adenocarcinomas. AsPC-1 and MiaPaCa-2 are poorly- differentiated, whereas S2013 is well-differentiated but heterogenous.

The cells were cultured in Dulbecco's Modified Eagle's Medium (DMEM) (obtained from Sigma, St. Louis, MO) supplemented with penicillin G (100 U/mL), streptomycin (100 U/mL) and 10% Fetal Bovine Serum (FBS) (purchased from Atlanta Biologicals, Atlanta, GA) in humidified air with 5% CO_2 at 37 ℃. The cells were harvested by incubation in trypsin-EDTA (obtained from Sigma, St. Louis, MO) solution for 10-15 minutes. Then the cells were centrifuged at $\times 300$ g for 5 minutes and the cell pellets suspended in fresh culture medium prior to seeding into culture flasks or plates.

Red oil A5

Red oil A5 (Coastside Research Chemical Co.) was dissolved in 1:2 DMEM as a stock solution. The stock solution was diluted to the appropriate concentrations with serum-free medium prior to the experiments.

Cell proliferation assay

Cell proliferation was analyzed by the ^{3}H-methyl thymidine (from Amersham Inc., Arlington Heights, IL) incorporation and cell counting. Following treatment of pancreatic cancer cells with a series of concentrations of red oil A5 from 1:64 000 to 1:4 000 for 24 hours, and following treatment of pancreatic cancer cells with 1:32 000 red oil A5 for 6, 12 and 24 hours, cellular DNA synthesis was assayed by adding ^{3}H-methyl thymidine 0.5 μCi/well. After a 2 hour incubation, the cells were washed twice with PBS, precipitated with 10% TCA for two hours and solublized from each well with 0.5 ml of 0.4 N sodium hydroxide. Incorporation of ^{3}H-methyl thymidine into DNA was measured by adding scintillation cocktail and counting in a scintillation counter (LSC1414 WinSpectral, Wallac, Turku, Finland). For cell counting, the cells were seeded in 12-well plates and cultured in serum-free medium for 24 hours prior to red oil A5 treatment and then switched to serum-free medium with or without 1:32 000 red oil A5 for the respective treatment times (24, 48, 72 and 96 hours). The cells were removed from the plates by trypsinization to produce a single cell suspension for cell counting. The cells were counted using Z1-Coulter Counter (Luton, UK).

Analysis of cellular DNA content by flow cytometry

The cells were grown at 50%-60% confluence in T75 flasks, serum-starved for 24 hours and then treated with 1:32 000 red oil A5 for 24 hours. At the end of the treatment, the cells were harvested with trypsin-EDTA solution to produce a single cell suspension. The cells were then pelleted by centrifugation and washed twice with PBS. Then the cell pellets were suspended in 0.5 ml PBS and fixed in 5 mL ice-cold 70 % ethanol at 4 ℃. The fixed cells were centrifuged at 300×g for 10 minutes and the pellets were washed with PBS. After resuspension with 1 ml PBS, the cells were incubated with 10 μL of RNase I (10 mg/mL) and 100 μL of propidium iodide (400 μg/mL; Sigma) and

shaken for 1 hour at 37 ℃ in the dark. Samples were analyzed by flow cytometry. The red fluorescence of single events was recorded using a laser beam at 488 nm excitation λ with 610 nm as emission λ, to measure the DNA index.

Terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate nick-end labeling (TUNEL) assay

TUNEL assay kits were purchased from Pharmingen and PARP antibody from BioMol. The assay was carried out for terminal incorporation of fluorescein 12-dUTP by terminal deoxynucleotidyl transferase into fragmented DNA, in pancreatic cells. Cells grown in T75 flasks were cultured in serum-free conditions for 24 hours and then treated with or without 1:32 000 red oil A5 for 24 hours. The cells were then trypsinized and fixed in 1% ethanol-free formaldehyde-PBS for 15 minutes. The cells were incubated with the enzyme substrate mixture with the addition of 20 mM EDTA and then counterstained with 5 μg/mL propidium iodide in PBS containing 0.5 mg/mL DNase-free RNase A, in the dark for 30 minutes. Laser flow cytometry was used to quantify the green fluorescence of fluorescein-12-dUDP incorporated against the red fluorescence of propidium iodide.

Preparation of cytosolic and mitochondrial extraction

Mitochondria/Cytosol Fractionation Kit was purchased from BioVision (Mountain View, CA94043, USA). Cells (5×10^7) were collected by centrifugation at 600×g for 5 minutes at 4 ℃ from control and red oil A5-treated AsPC-1, MiaPaCa-2 and S2013 cells. Wash the cells with ice-cold PBS twice. Centrifuge at 600×g for 5 minutes at 4 ℃. Remove the supernatant and resuspend the cells with 1.0 mL of 1×Cytosol Extraction Buffer Mix containing DTT and Protease Inhibitors. Incubate on ice for 10 minutes. Homogenize the cells in an ice-cold dounce tissue grinder (45 strokes) until 70-80% of the nuclei do not have the shiny ring. Transfer the homogenate to a 1.5 mL microcentrifuge tube, and centrifuge at 700×g for 10 minutes at 4 ℃. Transfer the supernatant to a fresh 1.5 mL tube, and centrifuge at 10 000×g for 30 minutes at 4 ℃. Collect the supernatant as cytosolic fraction. Resuspend the pellet in 0.1 mL Mitochondrial Extraction Buffer Mix containing DTT and Protease inhibitors, vertex for 10 seconds and save as Mitochondrial Fraction. Both cytosolic fraction and mitochondrial fraction were stored at -80 ℃ until ready for Western blot.

Western blot

Cells were seeded into flasks and grown to 50% to 60% confluence for 24 hours. The cells were then placed in serum-free medium with or without 1:32 000 red oil A5 for a period of 24 hours. In the end, the attached cells and floating cells were extracted in lysis buffer [20 mM Tris-HCl (pH 7.4), 2 mM sodium vanadate, 1.0 mM sodium fluoride, 100 mM NaCl, 2.0 mM phosphate substrate, 1% NP40, 0.5% sodium deoxycholate, 20 μg/mL each aprotinin and leupeptin, 25.0 μg/mL pepstatin, and 2.0 mM each EDTA and EGTA] for further analysis. Protein concentrations were determined using the bicinchoninic acid assay with BSA as standard. Western blot was carried out using standard techniques. Briefly, equal amounts of proteins in each sample were resolved in 10% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and the proteins transferred onto nitrocellulose membranes. After blocking with non-fat dried milk, the membranes were incubated with the appropriate dilution of primary antibody (Santa Cruz Biotech, Santa Cruz, CA, USA). The membranes were then incubated with a horseradish peroxidase-conjugated secondary antibody. The proteins were detected by an enhanced chemiluminescence detection system (Santa Cruz Biotech), and light emission was captured on

Kodak X-ray films (Eastman Kodak Company, Rochester, NY). The rabbit polyclonal antibody against cytochrome c and caspase-3, and the mouse monoclonal antibody against PARP were also purchased from Santa Cruz Biotech.

Statistical analysis

The data was analyzed by analysis of variance (ANOVA) with Bonferonni's or Dunnet's multiple comparison post-test for significance between each two groups. This analysis was performed with the Prism software package (GraphPad, San Giego, CA, USA). The data were expressed as mean ±SEM and represented at least 3 different experiments.

RESULTS

Effect of red oil A5 on thymidine incorporation in pancreatic cancer cells

Red oil A5 caused marked, concentration-dependent inhibition of thymidine incorporation in AsPC-1, MiaPaCa-2 and S2013 cells, at concentrations ranging from 1:64 000 to 1:4 000 (ANVOA, AsPC-1: $F_{(5,23)}$=86.99, $P<0.0001$; MiaPaCa-2: $F_{(5,23)}$=92.63, $P<0.0001$; S2013: $F_{(5, 23)}$=94.94, $P<0.0001$ (Figure 1). The red oil A5-induced inhibition of proliferation was also time-dependent (ANOVA, AsPC-1: $F_{(3,11)}$=89.88, $P<0.0001$; MiaPaCa-2: $F_{(3,11)}$=53.64, $P<0.0001$; S2013: $F_{(3,11)}$=80.06, $P<0.0001$ (Figure 2).

Figure 1 (A,B,C) Effect of different concentrations of red oil A5 on proliferation of three pancreatic cancer cell lines, AsPC-1, MiaPaCa-2 and S2013, as measured by ^{3}H-methyl thymidine incorporation. Results are expressed as % of control from three separate experiments. [a]$P<0.05$, [b]$P<0.01$, [c]$P<0.001$ *vs* control.

Figure 2 (A,B,C) Time-dependent effects of 1:32 000 red oil A5 on proliferation of three pancreatic cancer cell lines, AsPC-1, MiaPaCa-2 and S2013, as measured by ^{3}H-methyl thymidine incorporation at 6, 12 and 24 hours. The results are expressed as % of control from three separate experiments. [a]$P<0.05$, [b]$P<0.01$, [c]$P<0.001$ *vs* control.

Effect of red oil A5 on pancreatic cancer cell proliferation measured by cell counting

Red oil A5 induced significant time dependent inhibition of pancreatic cancer cell growth, as measured by the cell number in AsPC-1, MiaPaCa-2 and S2013 cells (two-way ANOVA, AsPC-1: $F_{(4,29)}$=49.54, $P<0.0001$; MiaPaCa-2: $F_{(4,29)}$=43.48, $P<0.0001$; S2013: $F_{(4,29)}$=39.25, $P<0.0001$. During the first 24 hours, no obvious effects were seen compared to controls. At 48, 72, and 96 hours, red oil A5 resulted in a marked and progressive decrease in cell number compared to control (Figure 3).

Effect of red oil A5 on cell cycle phase distribution

To understand the mechanism of inhibition of cell proliferation, the distribution of cell cycle phases was analyzed following treatment with 1:32 000 red oil A5 for 24 hours. The cells were accumulated in the G2/M-phase in AsPC-1, MiaPaCa-2 and S2013 cell lines. The number of the cells in S-phase was increased also in all three cell lines when compared to control. A peak of the sub-G0/G1 cell population, a hallmark of apoptosis, was seen following 24 hours, exposure in all three cell lines (Figure 4).

Apoptosis of pancreatic cancer cells induced by red oil A5

To characterize the observed apoptosis, analysis of DNA fragmentation was carried out using the TUNEL assay. TUNEL staining of pancreatic cancer cells was markedly increased by 1:32 000 red oil A5 treatment for 24 hours (Figure 5).

Figure 3 (A,B,C) Time-course effects of 1:32 000 red oil A5 on cell number in AsPC-1, MiaPaCa-2 and S2013 cells from 24 to 96 hours. The data represent mean ± SEM of three separate experiments. [a]$P<0.05$, [b]$P<0.01$, [c]$P<0.001$ *vs* control.

Figure 4 (A,B,C) Flow-cytometric analysis of cellular DNA content in control and red oil A5 treated AsPC-1, MiaPaCa-2 and S2013 cells, stained with propidium iodide. The cells were treated with 1:32000 red oil A5 in serum-free conditions for 24 hours. The distribution of cell cycle phases is expressed as % of total cells. Results were representative of three separate experiments.

Red oil A5 induced cytochrome C release

Cytochrome c is a mitochondrial protein that is released from the mitochondria to cytosol during apoptosis when mitochondrial membrane permeability is disrupted. An increase in the amount of cytochrome c in the cytosolic fraction was seen in all three cell lines, AsPC-1, MiaPaCa-2 and S2013 after red oil A5 treatment. Meanwhile, a decrease in the amount of cytochrome c in the mitochondrial fraction was seen in all three cell lines after red oil A5 treatment (Figure 6).

Effect of red oil A5 on activation of caspase-3 and cleavage of PARP

The expression and activation of caspase-3 by cleavage as well as the specific cleavage of its downstream substrate, PARP during apoptosis were observed by Western blotting. The 32 kDa procaspase-3 was cleaved into products of lower molecular weight, including a band corresponding to the 17 kDa active form. The uncleaved 116 kDa proform of PARP and its active 85 kDa cleaved fragment were detected. Both caspase-3

Figure 5 (A,B,C) TUNEL assay of red oil A5-induced pancreatic cancer cell apoptosis. Dot plot shows TdT-mediated dUTP nick-end labeling of control cells and cells treated with 1:32 000 red oil A5 which is expressed as % of total cells. The increases in fluorescence events in the upper panels are due to UTP labeling of fragmented DNA. The results are representative of three different experiments.

activation and PARP cleavage were induced and coincident with the induction of apoptosis (Figures 7, 8).

Figure 6 Western blot of the cytochrome c protein in AsPC-1, MiaPaCa-2 and S2013 cells treated with 1:32 000 red oil A5 for 24 hours. Proteins in cytosolic fraction and in mitochondrial fraction are extracted. Proteins extracted from each sample are electrophoresed on an SDS-PAGE gel and then are transferred to nitrocellulose membranes. Cytochrome c is identified using a monoclonal cytochrome c antibody. The results are representative of three different experiments.

for 24 hours. Proteins in the whole cellular lysates are electrophoresed on an SDS-PAGE gel and then transferred to nitrocellulose membranes. Caspase-3 is identified using a specific antibody. The results are representative of three different experiments.

Figure 8 Western blot of poly-ADP ribose polymerase (PARP) protein in AsPC-1, MiaPaCa-2 and S2013 cells are treated with 1:32 000 red oil A5 for 24 hours. Proteins in whole cellular lysates are separated by electrophoresis on SDS-PAGE gels and then are transferred to nitrocellulose membranes. PARP is identified using a monoclonal antibody. The results are representative of three different experiments.

DISCUSSION

Because of its significant medical properties, fish oil has been used for many years. The experimental results in the present study indicate that red oil A5 inhibits proliferation and induces apoptosis in pancreatic cancer cells.

In preliminary experiments, we tested a series of concentrations of red oil A5 ranging from 1:64 000 to 1:4 000. At low concentrations, red oil A5 inhibited growth and induced apoptosis in a concentration-dependent and time-dependent manner in all three cell lines tested. Because 1:32 000 red oil

A5 inhibited ^{3}H-methyl thymidine incorporation into DNA by about 30%-50% in 24 hours, we tested this concentration on cell proliferation by cell counting over a longer time period (24 to 96 hours). The results revealed profound inhibition that was time-dependent.

To better understand the effect of red oil A5 on the proliferation of pancreatic cancer cells, flow cytometric analysis of propidium iodide-stained cells and TUNEL assay were carried out. Cytometric analysis showed that cells were accumulated in the G2/M-phase and S-phase in all three cell lines at 24 hours, compared to control. These cell cycle changes suggested that pancreatic cancer cells underwent an oxidative stress response to red oil A5, with DNA damage leading to apoptosis. Because the effects of red oil A5 persisted throughout the course of cell proliferation, cells with DNA damage increased progressively and developed apoptosis successively. Therefore, the sub-G0/G1 cell population typical of apoptosis was observed after 24-hour treatment with red oil A5. At the late stages of apoptosis, genomic DNA was cleaved in fragments following activation of endonucleases. The TUNEL assay used attachment of a fluorescent indicator to identify DNA fragments in apoptotic cells. The TUNEL assay results showed marked apoptosis in all the cell lines tested.

Red oil A5 induces cytochrome c release from the mitochondria to cytosol. Caspases are cysteine proteases produced as inactive forms and activated during apoptosis. Apoptosis in pancreatic cancer cells is mitochondria dependent as evidenced by release of cytochrome c into the cytosol[32]. Caspases induce cytochrome c release from mitochondria by activating cytosolic factors[33]. Once cytochrome c is released from the mitochondria, it complexes with apoptosis, apoptotic protease-activating factor 1 to activate caspase-3[34-37]. Casepase-3 is the most important executer in the apoptotic process. Caspase-3 plays an important role in the apoptotic program of cells[38-44]. The present experiment shows that caspase-3 is activated by cleavage of procaspase during apoptosis of pancrestic cancer cells induced by red oil A5. Furthermore red oil A5 also causes specific activation by cleavage of the caspase-3 substrate, PARP provides further evidence of apoptosis. PARP, a nuclear protein implicated in DNA repair, is one of the earliest proteins targeted for a specific cleavage to the signature 85-kDa fragment during apoptosis. PARP cleavage can serve as a sensitive parameter for identification of early apoptosis[45,46].

Induction of cancer cell apoptosis, without affecting healthy cells or producing side-effects, is a major goal for development of new therapeutic agents. Our findings indicate that red oil A5 has a potent anti-proliferative effect on human pancreatic cancer cells with induction of apoptosis.

Abstract

AIM: To prepare the chitosan-pmEpo nanoparticles and to study their ability for transcellular and paracellular transport across intestinal epithelia by oral administration.

METHODS: ICR mice were fed with recombinant plasmid AAV-tetO-CMV-mEpo (containing mEpo gene) or pCMVβ (containing LacZ gene), whether it was wrapped by chitosan or no. Its size and shape were observed by transmission electron microscopy. Agarose gel electrophoresis was used to assess the efficiency of encapsulation and stability against nuclease digestion. Before and after oral treatmant, blood samples were collected by retro-orbital puncture, and hematocrits were used to show the physiological effect of mEpo.

RESULTS: Chitosan was able to successfully wrap the plasmid and to protect it from DNase degradation. Transmission electron microscopy showed that freshly prepared particles were approximately 70-150 nm in size and fairly spherical. Three days after fed the chitosan-pCMVβ complex was fed, the mice were killed and most of the stomach and 30% of the small intestine were stained. Hematocrit was not modified in naive and 'naked' mEpo-fed mice, a rapid increase of hematocrit was observed during the first 4 days of treatment in chitosan-mEpo-fed animals, reaching 60.9±1.2% (*P*<0.01), and sustained for a week. The second feed (6 days after the first feed) was still able to promote a second hematocrit increase in chitosan-mEpo-fed animals, reaching 65.9±1.4% (*P*<0.01), while the second hematocrit increase did not appear in the 'naked' mEpo-second-fed mice.

CONCLUSION: Oral chitosan-DNA nanoparticles can efficiently deliver genes to enterocytes, and may be used as a useful tool for gene transfer.

INTRODUCTION

The oral delivery of peptide, protein, vaccine and nucleic acid-based biotechnology products is the greatest challenge facing the drug delivery industry. Oral delivery is most attractive due to easy administration, leading to improved convenience and compliance to patients, thereby reducing the overall healthcare cost. Gene therapy will provide a huge new therapeutic opportunity, and has stimulated an interest in oral gene delivery. To date, various methods have been used for oral gene therapy, such as cationic lipids, recombinant viruses, recombinant live bacteria, polymers, and particle bombardment to buccal mucosa[1-3].

Chitosan is a natural biodegradable mucoadhesive polysaccharide derived from crustacean shells, and a biocompatible polymer that has been widely used in controlled drug delivery[4-9], and it may provide a less immunogenic and non-toxic carrier for successful oral delivery of plasmid DNA. Complex coacervates of DNA and chitosan could be used as a delivery vehicle in gene therapy and vaccine design[10-12], and have been shown to increase transcellular and paracellular transport of macromolecules across intestinal epithelial monolayers[13-15], further indicative of its potential in oral gene delivery.

Erythropoietin is a glycoprotein, which stimulates red blood cell production. It is produced in the kidney and stimulates the division and differentiation of committed erythroid progenitors in the bone marrow. When the kidney function decreases, anemia or low red blood cells are developed. Erythropoietin is used in patients with anemia associated with chronic renal failure, and in cancer patients for stimulation of erythropoiesis during autologous transfusion. Erythropoietin is also a good reporter gene in gene therapy study *in vivo*, because obvious biological effect can be observed even in a low dose of it. Hormones of therapeutic interest like growth hormone and erythropoietin require a tight adjustment of dose delivery to prevent adverse effects. Since most of the physiological regulatory processes are difficult to transfer to engineered cells, transgene expression must rely on artificial regulatory systems. Artificial inducible expression systems use transcriptional stimulation by chimeric transactivating factors, the activity of which can be controlled by drugs such as tetracycline derivatives[16], mifepristone[17], ecdysone[18], or rapamycine[19]. Heard observed that retrovirus-engineered myoblasts expressing rtTA and the chimeric transactivator conferring doxycycline-inducible gene expression, could be stably engrafted in mice, thus allowing the long-term control of Epo secretion *in vivo*[20]. Here we reported the oral gene therapy using chitosan–DNA nanoparticles carrying murine Epo (mEpo driven by tetO-CMV and rtTA) and LacZ, and demonstrated their efficacy in delivering genes to enterocytes.

MATERIALS AND METHODS

Materials

Chitosan (molecular weight, about 300 000Da) was supplied by Shandong Luneng Chemical Company. Plasmid pCMVβ was purchased from Clontech. mEpo was a gift from Jean

Michel Heard (MD, Laboratoire Ré́trovirus et Transfert Gé́ne´tique, Institut Pasteur, Paris, France). A 630 bp DNA fragment containing the murine Epo coding sequence was inserted between tetO-CMV promoter and 5' end of the SV40 polyadenylation signal puHD10.3[21]. An expression cassette for the reverse transactivator (rtTA) chimeric protein[16] was inserted into the SV40 polyadenylation signal in reverse orientation. This cassette contains a 1 858 bp fragment of the MFG retroviral vector[22] encompassing the 5' LTR and *gag* intronic sequences, followed by an 1 020 bp of the rtTA coding sequence.

Figure 1 Structure of rAAV-ET vector. ITR: AAV-2 inverted terminal repeats, tetO-CMV: tetracycline-inducible promoter including seven repeats of the tetracycline operator inserted upstream of the CMV minimal promoter, mEpo: murine erythropoietin cDNA, (A)n: SV4O bidirectional polyadenylation signal, rtTA: coding sequences for the tetracycline reverse transactivator, LTR: long terminal repeat of the MFG retrovirus construct. The BamHI fragment used as an Epo-specific probe is indicated.

The construction was then constructed into the pSUB-201 AAV vector plasmid, giving rise to pAAV-ET, with a total length of 5 017 bp (Figure 1). Plasmid was purified by CsCl super centrifugation.

Nanoparticle formulation
Nanoparticles were made by complex coacervation of chitosan and DNA as reported[12]. Plasmid (10 μg) was added to 100 μl of 50 mM sodium sulfate and heated to 55 ℃. Chitosan (pH 5.7, 0.02% in a 25 mM sodium acetate-acetic acid buffer) was also heated to 55 ℃ and 100 μl of chitosan was added to the DNA–sodium sulfate solution while samples were vortexed at a high speed for 20 s. Complex particles were examined immediately and stored at room temperature.

Measurement of nanoparticle size and morphology
Transmission electron microscopy (TEM, Hitachi HU-11B) was used to determine the particle size and morphology. A drop of particle dispersion was placed on a carbon- coated copper grid, and the particle size was determined from the micrographs.

DNase degradation test
Agarose gel electrophoresis was performed in a 1% (w:v) gel, ethidium bromide included for visualization, for 2 h at 60V. To assess the efficiency of encapsulation and stability against nuclease digestion, uncomplexed plasmid DNA (1 μg) and chitosan-DNA complex (containing 1 μg plasmid) were incubated with 1 mU DNaseI per mg of DNA for 1 h at 37 ℃. Adding EDTA stopped the reaction. Then the undegraded (1 μg) and degraded plasmid, undegraded and degraded chitosan-DNA complex, were subjected to agarose gel electrophoresis as described above.

Gene expression and animal experiments
ICR mice (4-week-old, purchased from BK Company, Shanghai) were fed with either chitosan–DNA nanoparticles containing the LacZ gene (pCMVβ, 50 μg/mice) or ' naked' plasmid DNA (pCMVβ), using animal feeding needles. Three

days later, the mice were killed, with their stomachs and small intestines surgically removed. The whole tissues were stained with 4-chloro-5-bromo-3-indolyl-β-galactoside (X-Gal) according to standard protocols. After stained overnight in a humidified chamber, the tissues were photographed by a digital camera (Nikon CoolPIX995). The pictures were transferred into a computer and adjusted for equal brightness and contrast using Adobe Photoshop.

ICR mice were fed every week with either chitosan–DNA nanoparticles containing the mEpo gene (50 μg/mice) or ' naked' plasmid DNA using animal feeding needles. Doxycycline-HCl (Sigma, Saint-Quentin Fallavier, France) was dissolved in drinking water to a final concentration of 200 μg/mL with 5% sucrose. No obvious side effect was observed in animals. Hematocrit was measured every two days by collecting 40 μL of blood via retro-orbital puncture before and after feeding.

Figure 2 Measurement of microsphere size and morphology. Transmission electron micrographs of chitosan–DNA nanoparticles, and scale bar represents 100 nm.

Statistical analysis
Results of quantitative data in hematocrit analysis were expressed as mean ±SD, statistical differences between groups were tested with F-test, and the significant level was defined as a $P < 0.01$. The data were analyzed by SPSS statistical software.

RESULTS

Nanoparticle synthesis and characterization
We synthesized nanoparticles by complexing high-molecular-weight (about 300 000Da) chitosan with plasmid DNA, and obtained the particles by adding 0.02% chitosan, pH 5.7, at 55 ℃ to plasmid DNA (50 μg/ml in 50 mM sodium sulfate) during high-speed vortexing. Transmission electron microscopy showed that freshly prepared particles were approximately 70-150 nm in size and fairly spherical (Figure 2). The encapsulation coefficiency was higher than 98 %, and the complex could efficiently protect the plasmid from DNase degradation (Figure 3).

Figure 3 Determination of encapsulation coefficiency, and DNase degradation test. Line 1. DNA ladder, Line2. undegraded pCMVβ (1 μg), Line 3. undegraded chitosan-DNA complex (containing plasmid 1 μg), Line 4. degraded chitosan-DNA complex (containing plasmid 1 μg), Line 5. degraded plasmid (1 μg).

Figure 4 β-galactosidase expression in mouse stomach and small intestine 3 days after oral delivery of DNA nanoparticles. A-D: Whole tissue staining for LacZ, only stained sections are shown. The mice were fed with high-molecular-weight chitosan-pCMVβ nanospheres at a dose of 50 μg (A) or 100 μg (B) per mouse, PBS (C) or 'naked' DNA (pCMVβ, D).

Gene expression studies

To assess the expression and distribution of transduced genes after oral DNA delivery, we fed ICR mice with either chitosan–DNA nanoparticles containing the LacZ gene (pCMVβ) or 'naked' plasmid DNA (pCMVβ), and then determined the expression of bacterial β-galacotosidase (LacZ) in the stomach and small intestine 3 days after oral administration of DNA (Figures 4A-D). Most of the whole small intestines and stomachs were stained. Although naive mice and those fed with 'naked' DNA showed some background staining, mice fed nanoparticles showed a higher level of gene expression both in stomachs and in small intestines.

Figure 5 mEpo expression and its physiological effect test. Hematocrit was measured every two days in mice fed with (●) chitosan-mEpo and doxycycline (200 μg/mL), n=9; (▲) chitosan-mEpo alone, n=3; (◆) doxycycline (200 μg/mL) alone, n=4; (■) naked mEpo and doxycycline (200 μg/mL), n=5. ↓ indicating the mice fed with 'naked' mEpo DNA or chitosan-Epo.

mEpo expression and its physiological effect

Hematocrit was measured every two days in mice that were fed with 'naked' mEpo DNA, chitosan-mEpo and doxycycline-HCl or not (Figure 5). To assess the basal Epo secretion level, three animals were fed with chitosan-mEpo and not treated

with doxycycline, and their hematocrit remained 45%-48%. Doxycycline (200 μg/mL) was added to drinking water for naive (n=4), 'naked' mEpo-fed mice (n=5), and chitosan-mEpo-fed mice (n=9). Though hematocrit was not modified in naive and 'naked' mEpo-fed mice, a rapid increase was observed during the first 4 days of treatment in chitosan-mEpo-dox-fed animals, reaching 60.9±1.2%, and sustained for a week. The second feed (6 days after the first feed) seemed to promote a second hematocrit increase in chitosan-mEpo-dox-fed animals, reaching 65.9±1.4%, while the second hematocrit increase did not appear in the 'naked' mEpo-second-fed mice (Figure 5). Statistical analysis showed the hematocrit level in chitosan-mEpo-dox-fed group was significantly higher than that in other groups (F=184.1, P<0.01), while there were no significant difference between the 'naked' mEpo-fed group and naïve group (F=0.3, P>0.01). These results indicated that oral administration of chitosan-mEpo induced repetitively robust Epo secretion in doxycycline- treated mice.

DISCUSSION

In 1998, Heard *et al* transfected erythropoietin in mice by intramuscular injection of an adeno-associated vector, and they observed the long-term, high-level and controlled expression of erythropoietin in mice[23]. Although viral gene delivery vectors yielded a high transfection efficiency over a wide range of cell targets[24-26], they presented major drawbacks, such as virally induced inflammatory responses and oncogenic effects. To circumvent these obstacles, gene delivery research also aimed at the development of non-viral gene delivery vectors. To date, there have been many available methods that are able to deliver plasmids to cells *in vitro* and *in vivo*, such as liposomes[27], cationic polymers[28], electro-gene-transfer[29], ultrasound[30] and hydrodynamic[31], but they have also many disadvantages, such as toxicity, relatively low transfection efficiency as compared to viral gene delivery vectors, tissue damage and difficulties of application in humans.

However, chitosan is a useful oral gene carrier because of its adhesive and transport properties in the gut, and has already

been available in a pill form as an alternative therapy to reduce dietary fat and cholesterol absorption[32]. Recently, chitosan has been successfully used to deliver a reporter gene (encoding chloram-phenicol acetyl transferase) orally to enterocytes, Peyer's patches and mesenteric lymph nodes[33]. Chitosan, when complexed with plasmid DNA, can form stable nanoparticles that are endocytosed by cells in the gastrointestinal tract. Further more, its safety and non-toxicity have been shown in animal models and humans[12,34,35], indication that chitosan-DNA nanoparticles may be a useful tool for gene therapy by oral administration.

Ion concentration, temperature, pH and the ratio of chitosan to DNA (or N/P) were the four main factors that influenced the formulation of chitosan-DNA complex[36]. The conditions we used above, could make the complex smaller, more stable, and easier to be absorbed. The zeta potential was approximately +10 mV at pH 5.7 and close to neutral at pH 7. Thus, the particles might be positively charged at gastric and early duodenal pH but neutral thereafter at more physiological or alkaline pH. Since pH influences the formulation and stability of the complex, the buffer that dilutes the complex is crucial in the test. The 25 mM sodium acetate-acetic acid buffer (pH 5.7) is able to partially neutralize the alkaline condition in small intestine, makeing the complex infect more enterocytes than other buffers (PBS, Ringer's, buffer saline). The long-term expression and the expression level still need to be improved, such as to increase the complex's absorptivity and to resist expression silence *etc*.

Further more, as chitosan is a mucoadhesive polymer[37-39], such DNA nanoparticles might adhere to gastrointestinal epithelia, be transported across the mucosal boundary by M cells and transfect epithelial and/or immune cells in the gut associated lymphoid tissues either directly or through 'antigen transfer', indicating that it may generate protective mucosal immune responses.

Abstract

AIM: To determine the ultrastructure of junction areas between neurons and astrocytes of supraoptic nuclei in rats orally administered 30 g/L NaCl solution for 5 days.

METHODS: The anti-connexin (CX) 43 and anti-CX32 double immunoelectromicroscopic labeled method, and anti-Fos or anti-glial fibrillary acidic protein (GFAP) immunohistochemistry were used to detect changes in the junctional area between neurons and astrocytes in supraoptic nuclei of 5 rats after 30 g/L NaCL solution was given for 5days.

RESULTS: A heterotypic connexin32/connexin43 gap junction (HGJ) between neurons and astrocytes (AS) in rat supraoptic nuclei was observed, which was characterized by the thickening and dark staining of cytomembranes with a narrow cleft between them. The number of HGJs and Fos like immunoreactive (-LI) cells was significantly increased following hyperosmotic stimuli, that is, the rats were administered 30 g/L NaCl solution orally or 90 g/L NaCl solution intravenously. HGJs could be blocked with carbenoxolone (CBX), a gap junction blocker, and the number of Fos-LI neurons was significantly decreased compared with that in rats without CBX injection, while Fos-LI ASs were not affected.

CONCLUSION: HGJ may be a rapid adaptive signal structure between neurons and ASs in response to stimulation.

INTRODUCTION

Human and animals normally maintain homeostasis of ion concentration, pH, body fluid and osmotic pressure. Homeostasis would markedly change, if human and animals drink excessive hypernatric fluids. Variations in osmotic pressure of extracellular fluid induce changes in cell volume that result in profound alteration of cell function and signal transduction between cells by modifying both extracellular and interacellular spatial arrangement and solute concentrations. Osmotic stimuli are resulted from the integration of multiple sensory inputs including peripheral and central osmoreceptors[1,2]. Peripheral osmoreceptors are mainly localized in mesenteric vasculature of the upper small intestine and hepatic portal vein[3]. The osmotic, immune, and noxious information from these peripheral receptors would transmit to medullary nuclei (the medullary visceral zone-MVZ that includes nucleus of the tractus solitarius and ventrolateral medulla) via vagus[4-8]. The effects of infusions of salt and water on the stomach can be mostly prevented by damage of the splanchnic or hepatic vagal nerves[3]. The neurons in medullary nucleus relay information and reach the supraoptic nucleus (SON) and paraventricullar nucleus (PVN) of hypothalamic neurosecretory cells[4-6].

It is well known that the supraoptic nucleus (SON) plays a key role in regulation of osmotic pressure regulation. Increased Cx32 mRNA levels in rat supraoptic nuclei have been found in late pregnancy and during lactation[2]. But the ultrastructural characteristics of the gap junctions (GJs) between neurons and astrocytes in SON following osmotic stimulation are unknown. In the present study, the characteristics of ultrastructure at junction areas between the neurons and astrocytes were examined in rat SON following hyperosmotic stimulation by using an immuno-electron-microscopic technique, and a heterotypic Cx32/Cx43 GJs at junction areas between neurons and astrocytes was observed.

It is well known that carbenoxolone (CBX), a drug to treat gastric ulcer, could block information transmitting *via* GJs, but whether CBX affects action of GJs between the neurons and astrocytes in SON is not clear. Thus, we studied the effect of CBX on GJs and found that CBX inhibited the activity of neurons in SON rather than the activity of astrocytes.

MATERIALS AND METHODS

Animal model

Ten adult male Sprague-Dawley rats (250-300 g) were provided by the Laboratory Animal Center, Fourth Military Medical University (FMMU, Xi' an, China) and divided into experimental group and control group. The protocols used in animal study were approved by the FMMU Committee of Animal Use for Research and Education. Adequate measures were taken to minimize pains or discomforts for all experimental animals. The experimental animals were fed with 30 g/L NaCl solution, the control animals with fresh water. After 5 days, the animals were anesthetized (ip) and transcardially perfused with 500 mL solution of 0.1 mol/L PB (pH 7.4) containing 40 g/L paraformaldehyde and 2 g/L saturated picric acid for 0.5 hour. Hypothalamus including SON was then removed immediately and placed in 0.05 mol/L PB containing 200 g/L sucrose at 4 ℃ overnight.

Tissue preparation

Hypothalamus including SON was cut into 50 μm thick frontal sections on a vibratome (Microslicer DTK-100; Dosaka, Kyoto, Japan) and placed into 0.01 mol/L KPBS for 60 minutes. Subsequently, the sections were frozen in liquid nitrogen for enhancement of penetration of antibody. Then the sections were placed in 0.01 mol/L KPBS and divided randomly into three groups.

The sections in the first group were incubated in rabbit polyclonal antibody against GFAP (1:3 000, Dako) for 48 hours at 4 ℃, and then in secondary goat anti-rabbit IgG (1:500, Sigma) and in ABC complex (1:500, Sigma) at room temperature for 2 hours. Finally, the sections were visualized with glucose oxidase-DAB-nikel as a chromogen.

The sections in the second group were incubated in rabbit anti-Cx43 antibody (Chemicon, CA) for 48 hours at 4 ℃, and then processed according to the methods mentioned above. After washed, the sections were again incubated with monoclonal antibody against Cx32 (Chemicon, CA) and labeled with 5nm gold particles.

The sections in the third group were used as control.

After washed with 0.01 mol/L PBS, the sections were post-fixed with 10 g/L OsO_4 in PB for 45 minutes, dehydrated through a graded ethanol and propylene oxide, flat-embedded with Epon 812. The sections were examined with a light microscope and the regions containing GFAP-like immunoreactive (-LI) cells or Cx-32- and Cx43- LI cells were investigated under an electron microscope. Small pieces from tissue were sampled from SON and re-embedded in beam capsules. Tissue samples from the selected regions were cut into sections on an ultramicrotome (Reichert – Nissei S; Leica, Vienna, Austria), and prepared for the study with electron microscope (H-7100; Hitachi, Tokyo, Japan).

CBX blockade

Twenty-one adult male SD rats were divided into three groups. The rats in control group (n=5) were intravenously injected with 9 g/L NaCl (1 mL). The rats in hyperosmotic group (n=10) were intraveneously injected with 90 g/L NaCl (1 mL). The rats in the third group rats (n=6) were pre-injected with CBX (1.5 µg/g, 10 g/L) into the lateral ventricle and 2 hours latter, injected with 90g /L NaCl (1 mL) into the femoral vein. One hour after NaCl injection, all the rats in three groups were transcardially perfused. The brains were removed with the methods mentioned above. Then the hypothalamus including SON was cut into 30 µm thick frontal sections on a cryostat (Cryostal; Leitz, Wetzal, Germany).

The sections from each rat were randomly divided into three sets. Two sets were processed for anti-Fos and anti-glial fibrillary acidic protein (GFAP) immunohistochemical staining respectively. Briefly, the sections were incubated with rabbit polyclonal antibodies anti-Fos (1:3 000; Santa Cruz), and GFAP (1:3 000; Dako) at 4 ℃ for 48 hours, and then in goat anti-rabbit IgG (1:500, Sigma) and ABC complex (1:500, Sigma) at room temperature for 2 hours. Nickel-intensified DAB reaction was used to detect peroxidase. The other set group of sections was treated as control, and processed without primary antibodies and therefore no immunoreactivity was found.

RESULTS

The behaviors of control animals were normal, while experimental animals looked languid and emaciated.

Puncta electron dense areas at the membrane of junction areas between neurons and astrocytes within SON were found on control sections. This structure consisted of astrocytic process on one side and neurons (cell body or dendrite) on the other side. It was characterized by thickened and dark stained membrane with a 2nm-cleft between them (Figure1A).

We also observed anti-GFAP-like immunoreactive (-LI) processes located within astrocyte side of the junction area between neurons and astrocytes (Figure1B).

The results of anti-Cx32 and anti-Cx43 double immuno-electron-microscopic reaction indicated that Cx32-LI and Cx43-LI appeared in the neuron side and astrocyte side of the junction areas respectively (Figure1C). We concluded that

puncta electron dense areas at the junction areas might be the heterotypic Cx32/Cx43 gap junction that was called heterotypic gap junction (HGJ) in our study.

Figure 1 Electron microscopic observation of HGJ. A: A dendrite (D) contacts with the process of ASs (G), the arrow indicates the thickened and dark stained cell membrane, and there is a narrow cleft between them. B: Peroxidase labeling shows a dendrite (D) and a process of astrocyte (G). C: Located between the Cx32-LI dendrites (D) (5 nm black gold particles labeling, black arrow) and astrocytic process (G) (peroxidase labeling).

Figure 2 Histogram comparison between hyperosmotic group (H) and control group (C) demonstrating percentages of HGJ formed by processes of astrocytes with neuronal dendrites (LD: large dendrites, SD: small dendrites). The percentage indicated the ratio of positive LD or SD bearing HGJ in the total number of LD or SD, respectively. Significant difference was seen between the experimental group and control group (P<0.001).

Figure 3 A,B: Expression of Fos-LI neurons and GFAP-LI ASs in SON of control group rats. C, D: Number of Fos-LI neurons and GFAP-LI ASs in hyperosmotic stimulation group compared to that of control group. E, F: Inhibited expression of Fos-LI neurons in CBX-injected rats, and uninhited GFAP-LI ASs.

It is of interest to note that the number of HGJ in SON of the experimental group rats was significantly increased compared with that in control. We found that 17.43 per 100 large dendrites ($\geq$1 μm) and 7.43 per 100 smaller dendrites (<1 μm) had specialized areas in SON of normal control rats, while in SON of experimental group rats, 66.75 per 100 large dendrites ($\geq$1 μm) and 24.35 per 100 smaller dendrites (<1 μm) were found to bear HGJs. Statistical analysis suggested that there was a significant difference in the number of dendrites and axons bearing specialized areas between the control and experimental rats (Figure 2). It indicated that HGJs could sensitively respond to stimulation.

CBX inhibited expression of Fos-LI neurons. In control group, Fos-LI neurons in SON were not found and a few GFAP-LI astrocytes were observed. In hyperosmotic group, the number of Fos-LI neurons was significantly increased compared with that in control group. The number of GFAP-LI astrocytes was also slightly increased, and activated GFAP-LI astrocytes became hypertrophied and their processes became thickened. In the third group, the number of Fos-LI neurons in SON was decreased more significantly than that in hyperosmotic group, while GFAP-LI ASs did not differ remarkably (Figure 3).

DISCUSSION

It is well known that peripheral osmoreceptors are mainly localized in the mesenteric vasculature of the upper small intestine and the hepatic portal vein[3]. The osmotic, immune, and noxious information from these peripheral receptors could transmit to medullary nuclei (medullary visceral zone-MVZ that include nucleus of the tractus solitarius and ventrolateral medulla) *via* vagal nerve[4-8]. The neurons in medullary nuclei could relay information and reach hypothalamic neurosecretory cells of the supraoptic nucleus (SON) and paraventricullar nucleus (PVN)[4-6].

Our study indicated that astrocytes, as well as neurons, could sensitively respond to hyperosmotic stimuli induced by administration of 30 g/L NaCl solution orally or 90 g/L NaCl solution intravenously. Activated astrocytes appeared to be GFAP-LI positive, and activated neurons exhibited Fos-LI nuclei. The activated astrocytes have been found to be generally marked with GFAP, and neurons with Fos[9-12].

The discovery of intercommunication between neurons and astrocytes was an important advance in neurobiology in recent twenty years[13]. It has been that gap junction is an important channel of intercellular communication and also a direct link of the interiors of cells[14-16], and consists of connexins of the protein family[17, 18]. However, about 15 types of Cx (followed by molecular mass designation) have been identified in mammals including the nervous and non-nervous systems[19,20]. At least 9 of the 15 types of Cx identified so far were expressed in CNS[21]. The same Cx types could be expressed in different cells and more than one Cx type could be expressed by the same cell. Nagy and Rash[18] reported that Cx30 was labeled by 5nm

gold particles and Cx43 was labeled with immunoperoxidase, which was observed at the same astrocytic GJ in rat brain. Neurons and oligodendrocytes expressed Cx32, astrocytes expressed Cx43, and ependyma and leptomeningeal cells expressed both Cx26 and Cx43.

It is well known that GJs may occur between the same cell types such as neurons and glias, they may also occur between different cell types such as neuron and astrocyte, neuron and oligodendrocyte, and astrocyte and oligodendrocyte. GJs consisting of the same Cx protein have been termed as homotypic GJs[14-16], while that consisting of different Cxs at two sides of GJs in culture as heterotypic Cxs GJ[17, 21]. It was reported that heterotypic Cx45/Cx43 GJs were observed in culture HeLa cells[11,22,23] and the oligo-astrocyte GJs in white matter arose by pairing astrocytic Cx43 with oligodendrocyttic Cx45[24]. Whether there were GJs between the neurons and astrocytes, some studies suggested that astrocytes might play a direct role in neuromodulation through GJs-mediated interaction between astrocytes and neurons[15,17]; Meanwhile, on the basis of fracture replica immunogold labeling, no evidence has been found for GJs between glial cells and neurons in the adult brain[19].

This study demonstrated that Cx32 and Cx43 appeared simultaneously at the neuronal side and astrocyte side, respectively, and formed the heterotypic Cx32/Cx43 gap junction. The special heterotypic Cx32/Cx43 gap junctions observed in this study had a narrow cleft (diameter: 2nm) between the neuronal and astrocytic membranes. This structure differed from the conventional gap junction, which has a seven-layer structure. It is of interest to note that the number of HGJs in SON of experimental group rats was significantly increased compared with that in control rats. In this study we also observed other types of ultrastructures, for example, synapses between neurons and astrocytes, tripartite synaptic structures and the gap junction between glial cells, but their number and structure did not show any significant change following stimulation (data not shown). It indicated that HGJs might be involved in signal communication of osmotic pressure regulation.

Results from this study indicated that the expression of Fos-LI neurons in experimental animals, which were injected CBX into the lateral ventricular, was markedly decreased compared with control animals. CBX, a glycyrrhetinic acid, is used to treat gastric ulcer by blocking information transmitting *via* gap junction. It was reported that CX cloud block GJs between neurons, and delay induction of epileptiform activity and reduces established epileptiform activity[25-27], and significantly decrease the spread of cell death induced by ischemia[28]. CX could also blocks GJs between glias[29,30] or between neurons and glias[15,31].

There has been debate on direction of intercommunication between the neurons and astrocytes coupling. Nedergaard[32] and Robinson *et al.*[33] described that unidirectional dye coupling from astrocytes to neurons and from astrocytes to oligodendrocytes occurred in intact neural tissues. Alvarez-Maubecin *et al.*[15] also suggested the existence of functional coupling between brainstem glia and noradrenergic neurons in slices taken from postnatal animals. But Rozental *et al.* and Carmignoto[15,34] considered that there was bidirectional signaling through gap junction between neurons and astrocytes. The results from the present research indicated that the expression of Fos-LI SON neurons induced by hyperosmotic stimulation could be inhibited with CBX, while the response of astrocytes to stimulation was not affected. It is suggested that the signaling *via* HGJs is unidirectional from astrocytes to neurons.

Abstract

AIM: This study investigated the effects of intense training on lipid metabolism, bone metabolism and bone mineral density (BMD) in female athletes.

METHODS: Sixty-six female subjects participated in this study, age ranging from 18 to 55 years. The sample group included thirty-six athletic subjects and the control group comprised thirty non-athletic individuals. Five athletes competed with national level (5/36) and nine non-athletic subjects (9/30) were postmenopausal women. The assessment items included body composition, radius BMD, calcaneus BMD, lung function, muscular endurance, renal and liver function, bone marker assay and hormone status. All data were analysed, using SPSS 10.0 software, and were presented as mean rank statistical difference, using the Kurskal-Wallis (K-W) test. After that the non-parameter statistics were used. Either K value or P value below 0.05 was considered significant.

RESULTS: Urine deoxypyridinoline/creatinine (Dpd/Cre) levels increased significantly (5.93±2.31 vs 6.85±1.43, $K<0.01$), sit-reach (29.30±9.48 cm vs 41.31±9.43 cm, $K<0.001$, $P<0.001$), 1 minute sit-ups with bended knees (1 min sit-ups) (17.60±9.34 count vs 30.00±10.38 count, $K<0.001$, $P<0.001$), and vertical jump (25.27±6.63 cm vs 34.69±7.99 cm, $K<0.001$, $P<0.001$) improved significantly in the athletes group. The athletes group also had a significantly increased level of estriol (E_3) (0.14±0.13 pg/mL vs 0.07±0.04 pg/mL, $K<0.01$, $P<0.01$), radius BMD (1.37±0.49 gm/cm^2 vs 1.19±0.40 gm/cm^2, $K<0.05$) and calcaneus BMD (0.57±0.17 gm/cm^2 vs -0.20±0.17 gm/cm^2, $K<0.01$, $P<0.05$) compared with those of the controls. The high density lipoprotein (HDL) (65.00±14.02 mg/dL vs 52.26±4.84 mg/dL, $K<0.05$, $P<0.05$) was significantly lower in postmenopausal inactive athletes (5/36) than premenopausal active athletes (31/36). On the other hand, low-density lipoprotein (LDL) (98.35±23.84 mg/dL vs 131.00±21.63 mg/dL, $K<0.05$, $P<0.01$), cholesterol (CHO) (164.03±27.01 mg/dL vs 193.00±23.48 mg/dL, $K<0.05$, $P<0.05$), triglyceride (TG) (63.00±26.39 mg/dL vs 147.00±87.21 mg/dL, $K<0.01$), body fat % (BF%) (28.16±4.90% vs 34.84±4.44%, $K<0.05$, $P<0.001$) and body mass index (BMI) (21.98±2.98 kg/m^2 vs 26.42±5.01 kg/m^2, $K<0.05$, $P<0.001$) were significantly higher in postmenopausal inactive athletes (5/36) than premenopausal active athletes (31/36). TG (90.22±39.82 mg/dL vs 147.00±87.21 mg/dL), CHO (186.44±24.90 mg/dL vs 193.00±23.48 mg/dL) were higher, but the HDL was significantly lower (62.18±10.68 mg/dL vs 52.26±4.84 mg/dL, $P<0.05$) in postmenopausal athletes (5/36) group than in postmenopausal control group (9/30).

CONCLUSION: Postmenopausal athletes (5/36) who no longer took competing exercises had reduced levels of physical activity, faced increased risk of cardiovascular disease compared to active athletes (31/36) and the postmenopausal controls (9/30). We may thus concluded that long term exercise effectively improves musculoskeletal fitness and prevents BMD loss in female athletes.

INTRODUCTION

Weightlessness or immobilization, as experienced by astronauts in space, is a well known cause of significant and rapid bone mineral loss[1-24]. Furthermore sedentary individuals generally have a lower bone mass than physically active individuals, moderate exercise is known to increase skeletal mass[3]. The above effect is most obvious in sports that place a significant stress on the skeleton. Investigations of athletes have identified physical activity as a major determinant of bone mass in the general population.

Physical fitness significantly influences quality of life. In Taiwan, medical care quality and public health environment have improved markedly over recent decades. The incidence of fatal infectious diseases thus has reduced significantly and the life span of Taiwanese has enlongated. Simultaneously, the incidence of chronic diseases has increased, yet people remain ignorant of the importance of exercise[1-5].

Exercising for 20-60 min per day, three days per week, at moderate intensity level of 3-6 Metabolic Equivalent units (METs) for most individuals derives at least some health-related benefits, including improved cardiorespiratory fitness, muscle strength and endurance, flexibility and body composition, as well as associated psychological benefits. Consequently, lifelong physical exercise is recommended to optimize health-related benefits[2-8]. And the influence of physical activity and exercise training on BMD in females previously has been assessed in cross-sectional, retrospective longitudinal and controlled trial studies[3-13].

Even though no relationship about growth hormone and BMD was found. But the effect of E_3 significantly improved BMD by inhibiting bone resorption, female athletes with low estradiol (E_2) level take a risk for increased lipid peroxidation following exercise[11-15]. Thus hormone status and lipid metabolism may play an important role in the protection against cardiovascular disease, this physiological response has implications for risks of heart disease. Longitudinal information on associations between life style factors and age-related bone loss remains quite controversial. Some studies have found no relationship between bone loss and body composition or body weight, while others

have shown them to predict bone mass changes[3-16].

Therefore, the purpose of this study was to explore the physiological function of female athletes, including BMD, renal function, liver function, hormone status, bone marker assay, lipid metabolism and muscle biology related to the effectiveness of exercise intervention for the health status of female athletes compared with controls.

MATERIALS AND METHODS

Subjects

Sixty-six female subjects participated in this investigation, with ages ranging between 18 and 55 yrs. The sample group was the athlete group (n=36), while the control group comprised non-athletic individuals (n=30). Inclusion criteria were that the female athletes had participated in high-intensity resistance or impact activities (e.g., basketball, dancing). Exclusion criteria for both the subjects and the controls were that the subjects had no major medical illnesses, including coronary artery disease which could influence lipid metabolism, and were free of other risk factors that are associated with influencing lipid metabolism, such as smoking or ethanol intake or treatment within the last two years with systemic gluco-mineralocorticoids, anticonvulsants, bisphosphonates, oestrogen, or raloxifene. Five athletes competed with national level (5/36) and nine non-athletic subjects (9/30) were included in the analysis of postmenopausal women. The parameters to be measured included body composition, radius BMD and calcaneus BMD, lung function, muscular endurance, renal function, liver function and hormone status.

Anthropometric measurement of body composition

Anthropometric measurements were taken based on conventional criteria. The measurement procedures of body weight (Wt) and body height (Ht) were estimated to the nearest 0.1 kg and 0.5 cm, respectively. Finally BMI was calculated using the formula: BMI (kg/m^2)=Wt (kg)/Ht (m^2).

Health related fitness

They were tested using a modified Guthrie R test[6]. Health related fitness tests included vertical jump, 3 min steps, sit-reach, hand grip and 1 min sit-ups items.

Lung function

Respiratory muscle strength and pulmonary function were assessed by spirometry. The flow volume and respiratory muscle forces were measured using a Fukuda, microspiro HI-501 model spirometer.

Renal and liver function

Sixty-six blood samples per subject were drawn from an antecubital vein with the subjects in the seated position. Routine complete blood counts (CBC) were taken using a Sysmex-E9000 (TOA Electronic, Inc., Tokyo, Japan) and renal and liver function tests were performed using a Hitachi 7170 instrument (Hitachi Electronic, Inc., Tokyo, Japan) by clinical chemistry laboratory staff at Li-Shin Hospital, Taoyuan County, Taiwan.

Hormone status

E_2, E_3, triiodothyronine (T_3), thyroxine (T_4), thyroid stimulating hormone (TSH), parathyroid hormone (PTH), cortisol and human growth hormone (HGH) were assayed in basal conditions, using commercial radioimmunoassay (RIA) and enzymeimmunoassay (EIA) Kits.

Bone marker assay

Serum bone specific alkaline phosphatase (BAP) activity was measured using an EIA kit obtained from Metra Biosystems (Monutain View, CA, USA). Urine Dpd level was measured using enzyme immunoassay (Ciba-Corning ACS-180) kits purchased from Bayer international (Bayer Diagnostics, Tarrytown, NY, USA).

BMD determination

Calcaneus site BMD was measured via speed of sound (SOS) equipped for a bone mineral densitometry (Aloka Medical Ltd, modelAOS-100, Tokyo, Japan) and all BMD values were also expressed as a T-score, accurately reflecting the BMD. Distal site BMD was measured using the osmometer DTX-100 (SPA, Single Photon Absorptiometry, Osmometer, Rodovre, Denmark). The scanners were calibrated daily against the standard calibration block supplied by the manufacturer to control baseline drift.

Statistical analysis

All data were analysed, using SPSS 10.0 software, and were presented as mean rank statistical difference, using the Kurskal-Wallis (K-W) test. After that the non-parameter statistics were be used. The confidence interval was set at 95% and the significance level used was K<0.05 (two sides). All statistical analyses were carried out with SPSS statistical package. The Kruskal-Wallis test does not use any information on the relative magnitude of each observation when compared with every other observation in the combined sample. This comparison is replaced in each observation by its rank in the pool sample. The smallest observation is replaced by its rank 1, the next smallest by rank 2, and so on, the largest by its rank n. Since the test is an extension of the Mann-Whitney-Wilcoxon (M-W-W) test. Either K value or P value below 0.05 is considered significant.

RESULTS

No difference in body composition

The thirty-six female athletes enrolled in this cross- sectional study did not differ significantly in terms of BF, BF%, BMI and resistance compared with the control group (Table 1).

Table 1 Body composition of two groups

Variables	66 females		K-Value
	Control group n=30	Athlete group n=36	
	mean rank		
Body fat	31.68	35.01	0.483
BF%	33.83	33.22	0.898
BMI	32.45	34.38	0.685
Resistance	34.95	32.29	0.575

Exercise improvements muscular endurance in female athletes

These two different groups did not differ significantly in muscular endurance. The hand grip (28.06±6.14 kg *vs* 26.85±5.73 kg), 3 min steps (55.32±6.90 count/min *vs* 57.82±7.21 count/min) and vital capacity (86.86±15.98 L *vs* 88.23±12.05 L) in athlete group were better than those in control group, but did differ significantly in terms of sit- reach (29.3±9.48 cm *vs* 41.31±9.43 cm, K<0.001, P<0.001), 1 min sit-ups (17.60±9.34 count *vs* 30.00±10.38 count, K<0.001, P<0.001) and vertical jump (25.27±6.63 cm *vs* 34.69±7.99 cm, K<0.001, P<0.001) as listed in Table 2.

Lipid metabolism

Table 3 shows that the results were not significantly different between both groups. But lipid metabolism including HDL (59.36±12.23 mg/dL *vs* 63.23±13.83 mg/dL) and Hb (12.95±1.22 g/dL *vs* 13.43±1.09 g/dL) in the athlete group was higher than

in the control group. However, LDL (105.93±30.76 mg/dL vs 102.89±25.92 mg/dL), TG (81.53±49.53 mg/dL vs 74.60±48.31 mg/dL) and CHO (170.20±32.20 mg/dL vs 168.06±28.13 mg/dL) were lower in the athlete group than those of the control group. Thus exercise could improve the lipid metabolism, and it is good for health.

Table 3 No significant differences in blood CHO and lipid variables between both groups

Group	n	HDL	LDL	CHO	TG	Hb

Table 8 Postmenopausal female athlete lipid metabolism compared to premenopausal active athletes

Athletes group	n	BF%	BMI	HDL	LDL	CHO	TG	Hb
Premenopausal (mean rank)	31	16.84	17.08	20.15	16.74	16.98	16.55	18.79
Postmenopausal (mean rank)	5	28.60[ac]	27.30[be]	8.30[ac]	29.40[ad]	27.90[ac]	30.60[b]	16.70

[a]$K<0.05$ vs statistically significant when compared with premenopausal group. [b]$K<0.01$ vs statistically significant when compared with premenopausal group. [c]$P<0.05$ vs statistically significant when compared with premenopausal group. [d]$P<0.01$ vs statistically significant when compared with premenopausal group. [e]$P<0.001$ vs statistically significant when compared with premenopausal group.

as glutamic oxalocetic transminase (GOT), glutamic pyruvic transminase (GPT), blood urea nitrogen (BUN), uric acid (UA), total protein (TP), globulin (GLO) and bilirubin (BIL). But the control group displayed significantly lower alkaline phosphatase (ALP) (61.03±13.99 U/L *vs* 70.81±15.23 U/L, $K<0.05$, $P<0.01$), ALB (4.52±0.18 g/dL *vs* 4.62±0.27 g/dL, $K<0.05$), Cre (0.75±0.09 mg/dL *vs* 0.81±0.10 mg/dL, $P<0.05$, $K<0.05$) and direct bilirubin (DBIL) (0.25±1.11 mg/dL *vs* 0.29±0.8 mg/dL, $K<0.05$) than the athlete group.

Electrolytes and BMD

According to non-parameter statistical tests, both the radius BMD (1.37±0.49 gm/cm^2 *vs* 1.19±0.40 gm/cm^2, $K<0.05$) and calcaneus BMD (0.57±0.17 gm/cm^2 *vs* -0.20±0.17 gm/cm^2, $K<0.01$, $P<0.05$), increased significantly in the athlete group compared with those of the control group. Moreover, the athlete group's body electrolytes such as urine-Cre (132.22±72.30 mg/dL *vs* 166.83±62.52 mg/dL, $K<0.05$, $P<0.05$), blood calcium (Ca) (8.76±0.32 mg/dL *vs* 8.43±0.37 mg/dL, $K<0.01$) and chloride (Cl) (99.94±2.41 meq/L *vs* 102.83±1.97 meq/L, $K<0.001$) significantly decreased compared to the control group.

Hormone status

HGH and T$_4$ were lower in the athlete group than in the control group (8.95±1.51 µg/dL *vs* 9.38±1.51 µg/dL), but cortisol (11.39±4.03 µg/dL *vs* 10.75±3.42 µg/dL), E$_2$ (88.82±66.42 pg/mL *vs* 80.56±63.10 pg/mL), T$_3$ (112.07±13.52 ng/dL *vs* 114.78±17.16 ng/dL) and PTH (39.07±16.97 pg/mL *vs* 34.70±11.66 pg/mL) levels were higher. Notably, E$_3$ level (0.14±0.13 pg/mL *vs* 0.07±0.04 pg/mL, $K<0.01$, $P<0.01$) significantly increased in the athlete group compared to those of the control group.

Bone marker assay and BMD

All biochemical and bone turnover markers, for example, (67.97±39.67 nmol/mmol *vs* 102.63±46.97 nmol/mmol, $K<0.01$, $P<0.01$), Dpd/Cre ratio (5.93±2.31 *vs* 6.85±1.43, $K<0.01$), and BAP (14.04±3.31 µg/L *vs* 20.93±6.17 µg/L, $K<0.001$, $P<0.001$) significantly increased in the female athlete group compared to those of the control group. The athletes displayed positive correlation of regional radius BMD ($K<0.05$) and calcaneus BMD ($K<0.01$, $P<0.05$) with these results (Table 7).

Lipid metabolism in postmenopausal athletes

Table 8 displays levels of LDL (98.35±23.84 mg/dL *vs* 131.00±21.63 mg/dL, $K<0.05$, $P<0.01$), CHO (164.03±27.01 mg/dL *vs* 193.00±23.48 mg/dL, $K<0.05$, $P<0.05$), TG (63.00 ±26.39 mg/dL *vs* 147.00±87.21 mg/dL, $K<0.01$), BF% (28.16±4.90% *vs* 34.84±4.44%, $K<0.05$, $P<0.001$) and BMI (21.98±2.98 kg/m^2 *vs* 26.42±5.01 kg/m^2, $K<0.05$, $P<0.001$) increased in the postmenopausal (5/36) inactive athletes group compared to the premenopausal (31/36) active athletes. Then the level of HDL (65.00±14.02 mg/dL *vs* 52.26±4.84 mg/dL, $K<0.05$, $P<0.05$) markedly decreased in the postmenopausal (5/36) inactive athletes.

Table 9 Lipid metabolism of postmenopausal female athletes

Postmenopausal group	n	BMI	HDL	LDL	CHO	TG	Hb
Control group (mean rank)	9	6.56	9.00	7.11	7.06	6.44	7.61
Athletes group (mean rank)	5	9.20	4.80[a]	8.20	8.30	9.40	7.30

[a]$P<0.05$ *vs* statistically significant when compared with post-menopausal control group.

Lipid metabolism in postmenopausal females

Results from this study show higher levels of TG (90.22±39.82 mg/dL *vs* 147.00±87.21 mg/dL), CHO (186.44±24.90 mg/dL *vs* 193.00±23.48 mg/dL), but lower levels of HDL (62.18±10.68 mg/dL *vs* 52.26±4.84 mg/dL, $P<0.05$), Hb (13.82±0.88 g/dL *vs* 13.52±0.21 g/dL) in postmenopausal athletes (5/36) group compared with the postmenopausal control group (9/30). This implies that the effect is a cardiovascular disease risk for postmenopausal retired female athletes (Table 9).

DISCUSSION

The data in this study were expressed as mean $\bar{x}\pm s$. Statistical significance in the mean values was evaluated by the Student's t test. But in our study, only sixty-six female subjects participated in this investigation. Therefore, we use K-W test to analyze the results of all tests. The Kruskal-Wallis test does not use any information on the relative magnitude of each observation when compared with every other observation in the combined sample. This comparison is replaced in observation by its rank in the pool sample. The smallest observation is replaced by its rank 1, the next smallest by rank 2, and so on, the largest by its rank n. Since the test is an extension of the M-W-W test. Either K value or P value below 0.05 was considered significant.

Exercise is important for maintaining skeletal health. However, the ability of exercise to influence bone might not be entirely related to hormone status. This study has shown that hormones and exercise interact to influence bone adaptations, and thus raise E$_3$ level related to increased BMD following exercise in female athletes. For example, serum E$_2$, cortisol, PTH and T$_3$ levels in the athlete group were higher than those of the controls, and the major finding of this study was that increased radius BMD ($K<0.05$) and calcaneus BMD ($K<0.01$, $P<0.05$) were significantly and positively related to serum E$_3$ ($K<0.01$, $P<0.01$) concentrations[10-12]. Therefore, a clear understanding the interaction suggested by the present data between E$_3$ concentration and the adaptation of bone to exercise is important, and provides an interaction through which the estrogen receptors involved in the early response of bone cells might increase their responsiveness to loading[11,12].

These results indicate that physical exercise positively affects the maintenance of radius BMD ($K<0.05$), calcaneus BMD ($K<0.01$, $P<0.05$) in female athletes, thus increased E$_3$ level can prevent BMD loss and possible risk of osteoporosis[12]. The athletes have higher levels of all the biomarkers than the controls, including Dpd ($K<0.01$, $P<0.01$), urine-Cre ($K<0.05$, $P<0.05$), Dpd/Cre ratio ($K<0.005$), BAP ($K<0.001$, $P<0.001$) and lower levels of blood-Ca ($K<0.01$), blood-Cl ($K<0.001$) these results were associated with markedly increased radius BMD and calcaneus BMD[13-22].

Further studies are required to examine a larger population, and also to consider the effects of BMD marker assay (for example insulin-like growth factors).

Physical inactivity has been designated by the American Heart Association as a major modifiable risk factor for cardiovascular disease. Numerous studies have examined individual morbidity and mortality from cardiovascular disease. The results presented here indicate that exercise can improve physiological characteristics, such the lowering levels of serum CHO and TG in female athletes, all of which may improve cardiovascular fitness and reduce morbidity and mortality from cardiovascular disease[12-16,23-26].

But the findings regarding the renal function, liver function and lipid metabolism of retired female athletes were surprising. Enzyme activity indicates that this group (5/36) may not have the same health benefits from physical exercise as the control subjects. Specifically, this group displayed decreased HDL ($K<0.05$, $P<0.05$), Hb and increased LDL ($K<0.05$, $P<0.01$),

CHO ($K<0.05$, $P<0.05$), TG ($K<0.01$) compared to the premenopausal active athletes (31/36). Postmenopausal retired female athletes (5/36) engaged in less physical activity than previously, displayed increase rates of liver and renal dysfunction, which require further investigation[17,23-28].

An understanding of the dyslipidemia and ensuing atherosclerosis has implications for the pathophysiology of coronary heart disease (CHD). Risk of cardiac morbidity and mortality is directly related to concentration of plasma total CHO or LDL. Lipid lowering therapy has been shown to reduce the risk of cardiovascular events in both high risk individuals and patients with manifest CHD[17-22,24-28]. The present study has found that postmenopausal retired female athletes (5/36) who were no longer engaged in strenuous physical activity, they had a significantly higher BF% ($K<0.05$, $P<0.001$) and BMI ($K<0.05$, $P<0.001$) compared to the active female athletes (31/36) group, specifically, in lipid dysfunction marker with the postmenopausal retired female athletes. Results from this study show higher levels of TG, CHO, but lower levels of HDL, Hb in athletes (5/36) group compared with the control group (9/30). Then, five postmenopausal athletes (5/36), who had retired from competition, and were engaged in less physical activity than previously, had significantly higher BF%, BMI and lipid dysfunction markers had a significantly decreased level of HDL ($P<0.05$) compared to the controls (9/30). This suggest that the effect is a cardiovascular disease risk for postmenopausal retired female athletes.

Future studies should recruit more numbers of female athletes, who have retired from competition but still maintained high levels of physical activity, and then compare this group with the low physical activity group that serves as the control group. Lipid metabolism related apolipoprotein E (*ApoE*) genotypes with an allele specific oligonucleotide (ASO) based microarray system may interact with exercise training to affect their plasma lipid profiles. To clarify the atherogenic risk of different lipoprotein phenotypes, the relations among total CHO, LDL, HDL and CHD risk in older female athletes should be investigated.

Abstract

AIM: During emergency period, infectious diseases can be a major threat to military forces. During field training in southern China, diarrhea is the main cause of nonbattle injury. To evaluate the causes of and risk factors for diarrhea in emergency period, we collected clinical and epidemiological data from the People's Liberation Army (PLA) during field training in southern China.

METHODS: From September 25 to October 2 1997, 2636 military personnel were investigated. Fecal sample cultures for lapactic pathogens were obtained from 103 military personnel with diarrhea. In addition, a questionnaire was administered to 103 cases and 206 controls to evaluate the association between illness and potential risk factors. At the same time, another questionnaire of 1:4 case-case control was administered to 22 severe cases (each severe case paired 4 mild cases).

RESULTS: The training troop's diarrhea incidence rate was significantly higher than that of garrison. The diarrhea incidence rate of officers was significantly lower than that of soldiers. A lapactic pathogen was identified in 63.1% (65/103) of the troops with diarrhea. *Enterotoxigenic Escherichia coli* (35.0%) and *plesiomona shigelloides* (16.5%) were the most common bacterial pathogens. All bacterial isolates were sensitive to norfloxacin and ceftazidine. However, almost all of them were resistant to sulfamethoxazole, trimethoprim-sulfamethoxazole, oxytetracycline, doxycycline, furazolidone, ampicillin and cloromycetin to a different degree. Risk factors associated with diarrhea included drinking raw water, eating outside, contacting diarrhea patients, lacking sanitation, depression, lacking sleep, which were established by multiple-factor logistic regression analysis. In addition, the unit incidence rate was associated with the density of flies and the average daily boiled water available by regression and discriminate analysis.

CONCLUSION: A series of risk factors are associated with the incidence rate of diarrhea. Our results may provide a useful basis for prevention and cure of diarrhea in emergency period of PLA.

INTRODUCTION

Acute diarrhea (abbreviated diarrhea) is a common disease during peace and war period in the army[1-4]. It has been shown that the year incidence rate of diarrhea varied from 49.5% to 64.0% in the stationed army in southern China and the main pathogens were e*nterotoxigenic Escherichia coli* (ETEC) and *enteropathogenic Escherichia coli* (EPEC)[5]. Diarrhea is also a serious problem for military forces during an emergency period usually including war, military maneuver, dealing with emergency and providing disaster relief, field training, *etc*. In addition, diarrhea is the major cause of nonbattle injury[6,7]. The life style, sanitary system, and appliance of foreign armies are quite different from our army, therefore, the results from their study cannot be applied to our army[8-13]. To probe into the epidemic features, pathogen spectrum and the main risk factors of diarrhea during an emergency period and to provide the basis for taking preventive and therapeutic measures, we carried out an initial study during an army exercising in a coastal training field in southern China.

At the training base in the west of Leizhou Peninsula, weeds and bushes are overgrown and tall trees are rare. There is no other inhabitant except the garrison. The weather is harsh, with constant high temperature, high humidity, and plenty of rain. Insects, such as flies and midges, are present everywhere. Along the coastline, camps, kitchens, reservoirs, simple toilets, garbage disposal facilities, and other life support facilities have been established. At the base, the whole sanitary standard is low and the living condition is hard. During exercises, villagers nearby provide fried dishes, cold dishes, fruits, and other seafood products. None of the food has hygiene certificates. The source of drinking water is from the wells with self-prepared covers. The water supply is limited, and no laboratory test has been carried out to check the quality of the water.

MATERIALS AND METHODS

Concerned definition

As was recommended by WHO, the definition of diarrhea is attacking acutely, having three or more motions with properties changed. Those whose interval between two diarrheas exceeded 7 days were recorded twice. According to the clinical manifestations, cases were divided into group of severe cases and group of mild cases. Severe cases were defined as those with diarrhea of more than 5 stools or accompanied by fever (>=38 ℃).

Surveillance of disease

Our study lasted for 20 days, and was divided into transporting and assembling stage (8 days) and field training stage (12 days). At the first stage, diarrhea patients were investigated retrospectively by battalion medical officers because the army was on the move. We began formal surveillance at the second stage. Battalion medical officers and investigators registered all training soldiers and collected information about diarrhea attack twice a day (morning and evening). They also delivered fecal samples to laboratory for detection of pathogens before antibiotics were used.

Pathogen detection

The samples on LB were incubated in alkaline peptone solution

for 24 hours at 37 ℃. Next day 1 ml of culture medium was taken out and put into glycerin and paraffin oil separately. Detection of pathogens was based on the diarrhea detection rules of WHO[14]. ETEC was detected by a DNA probe, which was prepared by our department. The micro-biochemical tubes used to detect the germs of enterabacteriaceae, vibrio and serum of Shigella, Salmonella, EPEC and EIEC were bought from Lanzhou Institute of Biological Products.

The antibiotic susceptibility was performed by K-B method recommended by WHO[15]. The antibiotics included norfloxacin, ceftazidine sulfamethoxazole, trimethoprim-sulfamethoxazole, oxytetracycline, doxycycline, furazolidone, ampicillin and cloromycetin. Standard strain coliform bacillus ATCC25923 and staphulococcus aureus ATCC25923 and pseudomonas ATCC27853 were used for quality control.

Epidemiologic survey

The diarrhea patients identified by surveillance were investigated using "The army acute diarrhea epidemiological case survey form" and "System distress checklist (SCL-90)" in 48 hours by 1:2 case-control study. Controls were chosen from soldiers without diarrhea within 7 days in the same company, with the same sex, the same rank. The differences of age and time of military service were within 1 year. The 129 investigated factors in 15 categories in these two survey forms were analyzed with conditional one-way and multiple logistic regression analysis. To explore the relationship between environmental hygiene and the unit diarrhea incidence, unit environmental hygiene questionnaire of field training troop was filled by surveillance group. In addition, 1:4 case-case control was administered to 22 severe cases (each severe case paired 4 mild cases) to study the main factors of severe clinical manifestations.

Quality control

(1) In order to reduce the failure of report and to increase the collection rate of specimens, we strengthened propaganda and organization and tried to make officers and soldiers fully understand the meaning and purpose of our study. (2) All investigators were trained. (3) To ensure the quality of survey, the screening results from one or two companies were checked randomly and about 10% of the forms in the same day were reinvestigated to identify potential mistakes. (4) The collected fecal specimens were sent in iceboxes and examined by a full-time laboratory technician.

Statistic methods

The data were recorded and checked using SPSS10.0/PC statistical package (SPSS, Chicago). Proportions were compared using the chi-square test with Fisher's exact test. Conditional multiple logistic regression analysis was performed using SAS. Logistic models were established by the maximum-likelihood method. Confidence intervals were calculated by the method of Woolf for univariate analysis and logistic-regression parameter estimates and their standard errors were used for multivariate analysis[16]. A two-tailed P value of 0.05 was considered as statistically significant.

RESULTS

Diarrhea incidence rate

The personnel investigated consisted of 320 officers and 2 316 soldiers in the training troop, and 24 officers and 180 soldiers in the garrison. They were all males, with a mean age of 22 years (SD of 4 years, ranging from 18 to 48 years). There was no difference in constituent ratio in these two troops by statistic analysis (χ^2=0.025, P=0.874). During the whole training period, the diarrhea incidence rate was 7.32% (193/2 636). The diarrhea incidence rate at the second training stage was 4.10% (108/2 636), which was significantly higher than that of the permanent garrison in corresponding time (0.98%, 2/204). The incidence rate of each training company varied from 0.84% to 12.38%. There was also a significant difference among different companies in the same battalion (χ^2=11.105, P<0.001), but no difference was found in the same company. The severe cases who could not work due to diarrhea accounted for 20.4% of the patients with diarrhea.

Pathogen detection

We surveyed 108 diarrhea patients and collected 103 samples (including 37 cotton swabs of anus). The collection rate was 95.4%. Most of the samples were watery and loose stools; few were mucus or pus and bloody stool.

The pathogens found in our study included 72 strains of 6 types of lapactic bacteria (Table 1). The positive detection rate was 63.1% (65/103). The most common pathogen was ETEC, followed by plesiomonas shigelloides. The rate of Shigella and Samonella infection was relatively high. There were 7 samples in which two types of pathogens were detected at the same time. Campylobacter and Yersinia were not found because of the limited conditions on the spot.

Table 1 Pathogen detection rate

Pathogen	Number of patients	Detection rate (%)
ETEC	36	35%
Plesiomonas shigelloides	17	16.5%
Salmonella	6	5.8%
Shigella	5	4.9%
EIEC	3	2.9%
Aeromonas schubertii	2	1.9%
Aeromonas hydrophila	1	1%
Vibrio metschnikovi	1	1%
Vibrio vulnificus	1	1%

The susceptibility of seventy-two strains of lapactic bacteria to nine types of antibiotics was examined. It showed that all these bacteria were sensitive to norfloxacin (95.8%) and ceftazidine (100%). All the lapactic bacteria were resistant to sulfamethoxazole, trimethoprim-sulfamethoxazole, oxytetracycline, doxycycline, furazolidone, ampicillin and cloromycetin to a different degree (Table 2)[17,18].

Table 2 Resistance rate of pathogens to antibiotics

Antibiotics	ETEC n^*=36	Vibrio n=22	Salmonnlla n=6	Shigella n=5	EIEC n=3	Overall n=72
Sulfamethoxazole	91.7	68.2	83.3	100.0	66.7	83.3
Trimethoprim-Sulfamethoxazole	91.7	59.1	83.3	80.0	66.7	79.2
Oxytetracycline	69.4	77.3	100.0	100.0	100.0	75.0
Doxycycline	61.1	72.7	100.0	100.0	100.0	69.4
Furazolidone	16.7	90.9	50.5	100.0	33.3	52.0
Ampicillin	30.6	36.4	50.0	40.0	33.3	34.7
Cloromycetin	25.0	4.5	0.0	40.0	33.3	18.1
Norfloxacin	5.6	0.0	0.0	20.0	0.0	4.2
Ceftazidine	0.0	0.0	0.0	0.0	0.0	0.0

*n was the number of strains.

Sixty-eight environmental specimens (drinking water, flies, seafood, cooking utensils of the training troops and local vendors) were examined for lapactic pathogens[19-22]. Forty-two strains of 10 types of lapactic pathogens were detected, including 14 strains of lapactic vibrio, 12 strains of aerobacter

cloacae, 8 strains of plesiomonas shigelloides, 8 strains of aeromonas, 7 strains of ETEC, 3 strains of shigella, 2 strains of salmonella and 1 strain of EIEC (Table 3). All the environmental specimens had lapactic pathogens to some extent, especially flies, seafood, and cooking utensils of the local vendors, which reached 87.5%, 80.0%, and 73.3%, respectively[23].

Table 3 Detection rate of lapactic pathogens from environmental specimens

Source of specimen	Number	Detection rate (%)
Flies	8	87.5
Seafood	10	80.0
Cooking utensils of vendors	15	73.3
Drinking water	15	66.7
Cooking utensils of troops	10	40.0
Camping appliances	10	20.0
Total	68	61.8

Risk factors analysis

Analysis of individual risk factors of diarrhea Unconditional single factor logistic regression analysis was performed, and the result showed that 25 factors were in association with individual diarrhea. In order to control interactions and confounding factors, and to make the studied factors more actually significant in theory, the above-mentioned 25 factors were entered to the equation of conditional multivariate logistic regression following the significant level <0.05, seven statistical significant variables were screened in the end (Table 4).

Analysis of unit risk factors of diarrhea Thirty-seven environmental sanitary questionnaires, which were checked to satisfy statistic requirements, were analyzed. Linear stepping regression was performed to determine the relationship between the 23 environmental factors with the incidence of field training troops. The result indicated that the density of flies in toilets, garbage disposal methods and daily average boiled water supply per person were the main factors. The regression equation was incidence=-3.107+2.051*density of flies in toilets + 1.601* garbage disposal methods - 0.743* daily average boiled water supply per person. The standard regression coefficient was 0.544, 0.264, and 0.201, respectively. The R square was 0.784. The variance analysis showed that F value of the regression equation was 40.34 ($P<0.001$).

To simplify the equation and improve the goodness of fit, ten curves estimation (quadratic, compound, growth, logarithmic, cubic, s, exponential, power, inverse and logistic) was used to fit the relation between the density of flies in toilets

and the diarrhea incidence. R square of 5 curves estimation (power, compound, growth, exponential and logistic) was larger than that of linear regression equation, of which power's R square reached 0.816 and the left four's R square was 0.798.

The diarrhea incidence rates were further divided into 3 groups: ≤3%, 3-6%, ≥6%. According to the field environmental sanitary questionnaire and the incidence, stepping discriminate function was used to establish the discriminate function. The discriminate function was composed of six variables (density of flies in toilets, toilet disinfection, density of flies in garbage dump, disposal method of garbage, density of flies near waste water and use of anti-fly cover) (Table 5). The false discriminate rate was 0%, 13.3% and 11.1%, respectively. The total false discriminate rate was 91.9%.

Table 5 Linear discriminant function coefficients

Factor	Linear discriminant	Function coefficient	
	<3%	3%-6%	≥6%
Disinfection of toilets	29.354	46.645	45.882
Garbage disposal methods	-14.564	-34.839	-25.324
Density of flies in toilets	9.127	7.143	19.911
Density of flies in garbage dumps	8.753	16.595	16.056
Density of flies near waste-water	15.855	38.361	27.858
Use of anti-fly cover	21.243	34.128	32.386
Constant	-46.378	-117.197	-133.264

Analysis of case-case control study Twenty-two case-case control study questionnaires were collected, 20 of them had no missing data and were analyzed by single factor conditional logistic regression. The result showed that 30 possible risk factors had a relationship with severe symptoms. Drinking raw water within seven days, eating outside, not washing hand before eating, were then analyzed by conditional logistic multiple-regression (Table 6).

DISCUSSION

The diarrhea incidence rate during the training stage was 4.10%, which was significantly higher than that of the garrison at the corresponding time (0.98%) and much higher than the 10 day incidence rate (1.35%) of an stationed army in the same season[5]. Because of the differences in duration, location and diagnostic standard in an emergency period, the rates could not be directly compared, however, the increase of diarrhea incidence rate was a common phenomenon during emergency. There must be some factors that contribute to the increased diarrhea incidence, and

Table 4 Multiple-factor conditional logistic- regression results of case-control study

Factor	Regression coefficient	Standard error	Odds ratio	95%Confidence interval	*P* value
Drinking raw water	3.1460	0.4638	23.2148	9.3641-57.6862	0.0000
Eating outside	3.1365	0.6055	23.0229	7.0273-75.4280	0.0000
Contacting with patients	2.9447	0.5707	19.0055	6.2104-58.1625	0.0000

Not washing hand before eating	1.3445	0.6142	2.7487	1.1519-12.7877	0.0286

if we can find these factors and control them, we should be able to strengthen the fighting capacity of the army.

The incidence rate of officers was clearly lower than that of soldiers, which was not in accordance with the results from stationed army and other related researches[24]. For example, a research of Hyams in "desert shield action" suggested the incidence rate was not affected by age and rank, while another study showed that the risk of officers was a little higher than that of soldiers. More data are still needed to confirm the real features of our army[25]. According to our study, the possible explanation was that the training and working of soldiers were more intensive, meanwhile their hygiene habits were worse than officers. In addition, they drank raw water and eating outside more often than officers[26].

From our research, the time distribution of diarrhea can be concluded as follow. The number of patients increased obviously in the early days of an action, then became stable after three or four days, and sustained at a certain rate[27]. During this period the incidence rate in each unit of the army was different and small outbreak could be seen occasionally, which was similar to some conclusions from foreign armies. The possible reasons of the increased rate during the early time were as follows. Normal living pattern of soldiers was disrupted and physically weakened. During training, soldiers increased significantly their contact with environments and the chances of infection were also increased. Failure to adapt to a new environment and lack of immunity, and no sanitary and anti-epidemic measures were taken. These possible reasons still need to be further explored. To control the incidence peak at early stages, we should strengthen propaganda on hygiene and enhance soldiers' abilities to self-guard against diarrhea. In addition, antibiotics should be used to prevent special diarrheas (such as tourist diarrhea, soldier diarrhea with special task_), but attention should be paid to selection and time limit of antibiotics[28,29]. With the army's adapting to the environment and the perfection of preventive measures, the incidence rate maintained at a lower degree. However, because of the existence of many unhygienic temporary food stalls outside the camps and soldiers often eating outside, outbreak of different scales did take place[30,31]. Apart from propaganda, we should strengthen the discipline and forbid soldiers to eat outside the camps.

In spite of the failure to detect Campylobacter and Yersinia due to limited condition on spot, 61.3% detection rate indicated that bacterial diarrhea was a main cause in Summer and Autumn during field training in coastal area in southern China. It was reported ETEC was the most common pathogen in stationed army[32] and so was in our study, which was in accordance with some reports from American army[8]. It suggested that ETEC was one of the focal points in diarrhea prevention in army, no matter Chinese or foreign[8,33-35], stationed or training in field. We should enhance the basic clinical and preventive researches on diarrhea to guarantee fighting capacity. Moreover, we detected a relatively high rate of vibrio, especially that of plesiomonas shigelloides which was 16.5%, at the second place[36]. This may be correlated with training at coastal area as water, food, and articles for daily use contain high counts of such pathogens (results not shown). Many studies showed that this germ had a relatively high detection rate in southeast coastal area.

It is important to evaluate hygiene standards of our army and develop related education to analyze individual risk factors of diarrhea. The incidence rate will decrease markedly if we can efficiently control these risk factors. As shown in Table 4, after multi variable analysis seven variables emerged as significant risk factors, which were drinking raw water, eating outside, lack of hygiene knowledge, not frequently trimming nails, contacting with diarrhea patients, having no enough sleep

and depression. Of these factors the first two were consistent with the results from stationed army, which indicates that the two risk factors are common in our military officers and soldiers. So it is necessary to strengthen sanitary education, to enforce administration, and to change unhealthy habits. During the survey, we found that none of the patients was separated from others and all the patients ate, slept and trained with the healthy personnel, which made contact transmission more easily.

For a long time, mental factors of diarrhea in an emergency period have been ignored. To explore the relationship between mental factors and diarrhea in an emergency period, we used "SCL-90" widely used in foreign countries, especially in mental health field. In a study, the mental condition of new recruits and the influence of each mental factor on injury in military training were analyzed by "SCL-90" in our army, and evaluation of the results was excellent. It indicated that using "SCL-90" to analyze the mental factors was feasible[37-40]. In an emergency period, especially in modern warfare, intense danger and cruelty would cause a great pressure on serviceman's mentality. Therefore, mental factor may be a risk factor of diarrhea in an emergency period. In our study, 1:2 case-control study was performed to evaluate the relation between mental factor and diarrhea. The result of single-factor analysis suggested that the gross score and 9 factors (except paranoiac factor) were associated with diarrhea. In addition, the result of multiple-factor analysis suggested that depression was a risk factor of diarrhea, as only depression was entered to the aggressive equation. Whether this relation exists or not is still a problem worth further studying. The possible explanation is that mental factor, acting through the neuroendocrinic system, can lead to enterocinesia and gastroenteric secretion disorder or weaken the immune functions, so the body is more susceptible to pathogens, resulting in diarrhea[41,42].

Case-case control study has been used to analyze the risk factors of chronic infant diarrhea[40] but not used to analyze that of diarrhea in a military emergency period. For the first time, we used it to analyze the risk factors of diarrhea in an emergency period. During the emergency period, it was critical to deal with the problems which influenced the fighting capacity due to limited human and material resources. Our study demonstrated that 20.4% of diarrhea patients could not work, because of the severe clinical manifestations. If these patients can be prevented from diarrhea, the fighting capacity will be greatly increased. In our study, the result indicated that three risk factors (drinking raw water 7 days before diarrhea, eating outside, not washing hand before eating) had a relation with severe clinical manifestations. Overall, the result indicated that preventive measures should be taken to control the three risk factors.

No report has been published on using unit incidence as risk factors to prevent diarrhea. In our study, the unit diarrhea incidence rate was different. To maintain the fighting capacity, decreasing the unit incidence rate is important. If we can find out the unit risk factors, measures can be taken to control them. The result of linear stepping regression showed that three (density of flies in toilets, garbage disposal methods and daily average boiled-water supply) out of 23 potential factors might be the cause of the increased unit incidence. From the standard regression coefficient, the density of flies in toilets had the major influence on diarrhea incidence rate. The higher the density of flies in toilets, the higher the diarrhea incidence rate. Fly is an important route of transmission, which has been confirmed before. The study of the Gulf War also demonstrated that persistent existence of flies was an important reason of low-epidemic diarrhea. Meanwhile, we thought the garbage disposal methods have a relation with the density of flies. Some troops buried garbage by the sanitary unit strictly, thus preventing the reproduction of flies.

Abstract

AIM: To explore the difference of somatostatin receptor subtype 2 (SST2R) gene expression in pancreatic cancerous tissue and its adjacent tissue, and the relationship between the change of SST2R gene expression and pancreatic tumor angiogenesis related genes.

METHODS: The expressions of SST2R, DPC4, p53 and ras genes in cancer tissues of 40 patients with primary pancreatic cancer, and the expression of SST2R gene in its adjacent tissue were determined by immunohistochemiscal LSAB method and EnVision™ method. Chi-square test was used to analyze the difference in expression of SST2R in pancreatic cancer tissue and its adjacent tissue, and the correlation of SST2R gene expression with the expression of p53, ras and DPC4 genes.

RESULTS: Of the tissue specimens from 40 patients with primary pancreatic cancer, 35 (87.5%) cancer tissues showed a negative expression of SST2R gene, whereas 34 (85%) a positive expression of SST2R gene in its adjacent tissues. Five (12.5%) cancer tissues and its adjacent tissues simultaneously expressed SST2R. The expression of SST2R gene was markedly higher in pancreatic tissues adjacent to cancer than in pancreatic cancer tissues ($P<0.05$). The expression rates of p53, ras and DPC4 genes were 50%, 60% and 72.5%, respectively. There was a significant negative correlation of SST2R with p53 and ras genes ($\chi_1^2=9.33$, $\chi_2^2=15.43$, $P<0.01$), but no significant correlation with DPC4 gene ($\chi^2=2.08$, $P>0.05$).

CONCLUSION: There was a significant difference of SST2R gene expression in pancreatic cancer tissues and its adjacent tissues, which might be one cause for the different therapeutic effects of somatostatin and its analogs on pancreatic cancer patients. There were abnormal expressions of SST2R, DPC4, p53 and ras genes in pancreatic carcinogenesis, and moreover, the loss or decrease of SST2R gene expression was significantly negatively correlated with the overexpression of tumor angiogenesis correlated p53 and ras genes, suggesting that SST2R gene together with p53 and ras genes may participate in pancreatic cancerous angiogenesis.

INTRODUCTION

Recent studies have indicated that somatostatin and its analogs have obviously antiproliferative effects on various solid tumors, such as colon cancer, liver cancer, which are mediated through somatostatin receptors[1-7], but a large number of clinical researches indicate that the therapeutic effects of somatostatin and its analogs on pancreatic cancer are different, the reason is not known[8,9]. Moreover, studies have already reported that the change of SST2R gene expression in human pancreatic cancerous cells is related with tumor angiogenesis factors such as transforming growth factor beta (TGF-β), but the relationship between SST2R and tumor angiogenesis related genes such as DPC4, ras and p53 is still not clear[10]. Our study aimed at exploring the cause for the different therapeutic effects of somatostatin and its analogs on human pancreatic cancer, and the relationship between the changes of SST2R gene expression and pancreatic tumor angiogenesis correlated genes.

MATERIALS AND METHODS

Tissue specimens

Tissue samples from 40 primary pancreatic cancer patients were obtained from the Department of Pathology in Tongji Hospital. The patients consisted of 26 males and 14 females aged from 33 to 71 years (means: 55.65 years). All lesions were diagnosed pathologically as pancreatic ductal adenocarcinoma, consisting of 23 pancreatic cancers in the head, and 17 pancreatic cancers in the body and tail of pancreas. All patients were staged according to UICC TNM classification, I-II in 14 patients, and III-IV in 26 patients. All the specimens of pancreatic cancer tissues and its adjacent tissues were fixed and dehydrated in 10% formalin, embedded in paraffin and cut into 4 μm serial sections.

Reagents

Goat SST2R and DPC4 polyclonal antibodies were from Santa Cruz (USA). p53, ras monoclonal antibody and mouse anti-human ras monoclonal antibody were from Maixin Biotech Kaifa Company (Fuzhou, China). Secondary biotinylated rabbit anti-sheep IgG (ZB-2050) was from ZYMED (USA). EnVision™ mouse-anti reagent kit, EnVision™ rabbit-anti reagent kit and peroxidase conjugated streptavidin were from DAKO (Denmark).

Immunohistochemical staining

Three-step methods (LSAB) were used for DPC4 and SST2R staining, and two-step methods (EnVision™ system) were used for p53 and ras genes. Formalin-fixed, paraffin-embedded sections were dewaxed, rehydrated, and boiled in 0.01M-citrate buffer, pH 6.0 in a microwave oven for 10 minutes. Then primary antibody was added and incubated at 4 ℃ overnight. Biotinylated rabbit anti-sheep IgG (1:300 dilution) was added

and incubated at 37 ℃ for 1 hour, followed by incubation with peroxidase conjugated streptavidin (1:400 dilution) at 37 ℃ for 30 minutes. For p53 and ras staining, peroxidase conjugated streptavidin was replaced by EnVision. DAB chromogen was applied for 10 to 20 minutes and rinsed for visualization under microscope, followed by slight counterstaining with haematoxylin, dehydration, and finally cover slips were sealed with permount. Negative control was obtained by replacing the primary antibody with PBS.

Evaluation of immunohistochemical staining

Positive staining was located in cell membrane/cytoplasm for SST2R, and the cytoplasm for DPC4 and ras, and the nucleus for p53. At least 1000 cells were counted per 40 X 10 field. The expressions were graded, as follows. Negative (-) if <10% of the cancerous cells in a given specimen were positively stained. Weak positive (+) if 10% to 20% of the cancerous cells in a given specimen were positively stained. Positive (++) if 20% to 50% of the cancer cells in a given specimen were positively stained, and strongly positive (+++) if 75% of the cancer cells in a given specimen were positively stained.

Statistical analysis

Chi-square test was used to analyze the results. *P*<0.05 was considered statistically significant.

RESULTS

Expression of SST2R gene in pancreatic cancer tissue and its adjacent tissue

The expression rate of SST2R gene was markedly higher in the adjacent non-cancerous tissue (85%) than in cancer tissue (12.5%) (*P*<0.05). Twenty-nine patients (72.5%) expressed SST2R gene only in the adjacent non-cancerous tissue. For SST2R gene expression in pancreatic cancer tissue, strong positive was only 10%, weak positive 2.5%, and negative 87.5%, 12.5% pancreatic cancer tissue and its adjacent non-cancerous tissue expressed SST2R simultaneously (Table 1 and Figures 1, 2).

Figure 1 Ductal adenocarcinoma in pancreatic head (Immunohisto-chemistry LSAB method, ×400). Brown yellow staining of SST2R gene expression in cell membrane/cytoplasm.

Expression of p53 gene in pancreatic cancer tissue

For p53 gene in pancreatic cancerous tissue, 19 patients (47.5%) had strong positive expression, 20 patients (50%) negative expression, and 1 patient (2.5%) weak positive expression. The SST2R gene expression in 17 patients with strong positive expression of p53 was negative. Three patients with strong positive expression of SST2R were negative for p53 gene expression. The SST2R and p53 gene expressions in 1 patient were strong positive. One patient with weak positive expression of p53 gene was negative for SST2R gene expression. The SST2R gene expression of 1 patient with strong positive expression of p53 gene was weak positive (Table 1 and Figure 3).

Figure 2 Pancreatic ductal adenocarcinoma in pancreatic body and tail (Immunohistochemistry LSAB method, ×400). Brown yellow staining of SST2R gene expression in cell membrane/cytoplasm.

Figure 3 Ductal adenocarcinoma in pancreatic head (EnVision™ method, ×400). Brown yellow staining of p53 gene expression in cell nucleus.

Figure 4 Ductal adenocarcinoma in pancreatic body and tail (EnVision™ method, ×400). Brown yellow staining of ras gene expression located in cytoplasm.

**Figure 5** Ductal adenocarcinoma in pancreatic body and tail (EnVision™ method, ×400). Brown yellow staining of DPC4 gene expression located in cytoplasm.

Expression of ras gene in pancreatic cancer tissue

For expression of ras gene, 14 patients (35%) were strong positive, 10 patients (25%) weak positive, and 16 patients (40%) negative. Eleven patients with strong positive expression of ras gene showed negative expression of SST2R gene, 1 patient with negative expression of ras gene showed strong positive expression of SST2R gene. The SST2R and ras genes in 4 patients showed positive expression of different grades correspondingly. The SST2R and ras gene expressions in 15 patients were negative. Nine patients with weak positive expression of ras gene were negative for SST2R gene expression (Table 1 and Figure 4).

Expression of DPC4 gene in pancreatic cancer tissue

Seven patients (17.5%) were positive, 4 patients (10%) weak positive, and 29 patients (72.5%) negative for DPC4 gene expression. Twenty-six patients (65%) had negative expression of both DPC4 and SST2R gene. Of the 9 patients with negative expression of SST2R gene, 5 patients were strong positive, and 4 patients weak positive for DPC4 gene expression. Both SST2R and DPC4 genes expression of 2 patients were strong positive. One patient with negative expression of DPC4 gene was weak positive for SST2R gene expression (Table 1 and Figure 5).

Statistical analysis indicated that SST2R was significantly negatively correlated with the expression of p53 or ras genes ($P<0.01$), whereas not distinctly correlated with DPC4 gene ($P>0.05$).

Table 1 Expressions of SST2R and ras, DPC4 and p53 genes in 40 primary pancreatic cancerous tissues

	Strong positive (++-+++) n (%)	Weak positive (+) n (%)	Negative (-) n (%)
SST2R	4.0 (10)	1.0 (2.5)	35.0 (87.5)
ras	14.0 (35)	10.0 (25)	16.0 (4)
DPC4	7.0 (17.5)	4.0 (10)	19.0 (47.5)
P53	19.0 (47.5)	1.0 (2.5)	20.0 (50)
Cancer adjacent SST2R	34.0 (85)	0.0	6.0 (15)

DISCUSSION

Somatostatin and its analogs can inhibit the growth of benign and malignant tumors, and it has been found that the inhibitory effects are directly correlated with the expression of SST2R on tumor tissues[11-15]. The mechanisms of the inhibition are the combined interaction of somatostatin and its analogs with SST2R in tumor tissues, either directly inhibiting division and proliferation of tumor cells or inhibiting the activities of growth factors such as vascular endothelial growth factor (VEGF), insulin-like growth factor (IGF)[16-21], and moreover, counteracting tumorigenesis and tissue proliferation[22,23]. In addition, somatostatin and its analogs could arrest pancreatic cancer cell cycle at G_0-S_1 phase by up-regulating p27, and thus induced apoptosis[24,25].

The expression of SST2R was decreased or lost in primary pancreatic cancerous tissue[26-29], but there is no report on the expression of SST2R in pancreatic cancerous adjacent tissue. Our study showed that 5 of 40 primary pancreatic cancer tissues showed positive expression of SST2R gene, suggesting that most of pancreatic cancerous tissues lack the expression of SST2R, which may be the major reason why somatostatin and its analogs had no marked therapeutic effects on pancreatic cancer. Interestingly, expression of SST2R was higher in most of the pancreatic cancerous adjacent tissues, which may be beneficial for somatostatin and its analogs to inhibit fast outward infiltration and growth of tumor cells. Our study

indicated that if SST2R decreased in pancreatic cancerous tissue and its adjacent tissue, somatostatin and its analogs might not have therapeutic effect on pancreatic cancer. But when pancreatic cancerous tissue and its adjacent tissue obviously expressed SST2R, they had a definite therapeutic effect on patients with pancreatic cancer. Hence the differences in the expression of SST2R in pancreatic cancerous tissue and its adjacent tissue would certainly lead to different therapeutic effects. At present, this is the main possible cause for the different therapeutic effects of somatostatin and its analogs on pancreatic cancer. We consider that it is important to define the expression of SST2R in pancreatic cancerous tissue and its adjacent tissue before using somatostatin and its analogs. This will be beneficial to the ultimate definition of the exact therapeutic effects of somatostatin and its analogs on pancreatic cancer.

Mutations of DPC4, ras and p53 genes have been found to play crucial roles in tumor angiogenesis[30-32]. The mutation rates of these genes are higher in pancreatic cancerous tissue, indicating that the similar mechanism of pancreatic tumorigenesis with other tumorigenesis involving mutation and abnormal expression of multiple genes. Our study indicated that the expression of SST2R gene was significantly negatively correlated with p53 and ras genes, suggesting that the decrease or loss of SST2R gene expression in pancreatic cancerous tissue participates in tumor angiogenesis through certain pathway, further investigation is required to probe into its the mechanism.

Abstract

AIM: To study the effects of perioperative administration of cimetidine (CIM) on peripheral blood lymphocytes, natural killer (NK) cells and tumor infiltrating lymphocytes (TIL) in patients with gastrointestinal (GI) cancer.

METHODS: Forty-nine GI cancer patients were randomized into treatment group, who took CIM in perioperative period, and control group, who did not take the drug. The treatment was initiated 7 days before operation and continued for 10 days after surgery. At baseline examination before operation, on the 2nd and 10th postoperative days, total T lymphocytes, T helper cells, T suppressor cells, and NK cells in peripheral blood were measured respectively by immunocytochemical method using mouse-anti human CD_3, CD_4, CD_8 and CD_{57} monoclonal antibodies. Blood samples from 20 healthy volunteers were treated in the same way as normal controls. Surgical specimens were examined during routine histopathological evaluation for the presence of TIL in tumor margin. Immunohistochemical study was performed to measure the proportion of T and B lymphocytes in TIL population. T and B lymphocytes were detected respectively using mouse-anti-human CD_3 and CD_{20} monoclonal antibodies.

RESULTS: In comparison with normal controls, both the treatment and control groups had decreased T cells, T helper cells and NK cells at baseline. In control group, total T cells, T helper cells and NK cells declined continuously with the disease progression and the decrease became more obvious after operation. From baseline to the 2nd postoperative day, the proportion of total T cells, T helper cells, and NK cells went down from 60.5±4.6% to 56.2±3.8%, 33.4±3.7% to 28.1±3.4%, and 15.0±2.8% to 14.2±2.2%, respectively. On the other hand, there were significant improvements in these parameters after CIM treatment. On the 10th postoperative day, the treatment group had significantly higher percentages of total T cells, T helper cells and NK cells than control group. Moreover, CIM treatment also boosted TIL response, as was reflected by findings that 68%

(17/25) of the patients in treatment group had significant TIL responses and only 25% (6/24) of the cases had discernible TIL responses (*P*<0.01).

CONCLUSION: Perioperative application of CIM to GI cancer patients could help restore the diminished cellular immunity induced by tumor burden and surgical maneuver. The drug could also boost TIL responses to tumor. These effects suggest that the drug be used as an immunomodulator for GI cancer patients.

INTRODUCTION

Gastric and colorectal cancers are the most common cancers in China, with their incidence ranking number one and number four respectively. Although surgery, chemotherapy and radiotherapy are major treatment options for GI cancer, the long-term survival is low. Treatment failure is mainly due to recurrence and metastasis. One major cause for such an adverse outcome is the patients' diminished immunity against residual tumor cells after surgery. Therefore, how to restore and improve the patients' immunity against cancer has been an area of active study.

There has been much progress in understanding the relationship between the immune system and GI cancer, which has led to the use of immunomodulatory therapy as an adjuvant and palliative treatment. Many non-specific immunomodulatory agents such as levamisole, CIM, alpha interferon, *n*-3 fatty acids, polysaccharide K (PSK), supplementary diet with glutamine, arginine and omega-3-fatty acids, and Bacillus Calmette-Guerin (BCG) have been tried[1-4]. CIM is a type 2 histamine receptor antagonist widely used for the treatment of peptic ulcers. It also has important effects on immune system. Administration of CIM has been found to preserve, to some degree, the patients' perioperative immunity[5,6], to improve the survival of patients with colorectal cancer, melanoma, and renal cell cancer[7-15]. Although it is not clear whether this effect of CIM on cancer is direct or indirect, it has been proposed that CIM may act by enhancing the host immune response to tumor cells[16,17] or by blocking the cell growth-promoting activity of histamine in cancer cell lines[14,16-20].

In this study, we used CIM in the perioperative period as an adjuvant immunomodulatory agent, and studied its effects on peripheral blood lymphocytes, NK cells and TIL in a randomized controlled clinical trial in patients with GI cancer.

MATERIALS AND METHODS

Study design

This was a prospective, randomized clinical trial. The subjects included in this study were selected from patients with pathologically confirmed GI cancer who were admitted to the Department of Oncology, Zhongnan Hospital of Wuhan University, from Sept.1997 to May 1998. The entry criteria were: primary GI cancers indicative of surgery, no preoperative evidence of distant metastasis, no history of previous immunity-impairing chronic diseases such as diabetes mellitus, and no history of preoperative chemotherapy, radiotherapy or immunotherapy. From a total of 125 patients admitted during this period, 49 eligible patients were recruited and staged according to the International Union against Cancer Classification. After signing informed consent forms, the patients were randomized into treatment group (n=25) and control group (n=24). The clinico-pathological characteristics of the two groups were comparable and balanced. The patients in treatment group started oral CIM treatment (Tagamet, Tianjin Smith Kline and French Laboratories Ltd.) at the dose of 400 mg, tid, 7 days before operation until the operation day. During and after operation, they were given CIM at 600 mg, i.v. drip, bid, until the 10th postoperative day. The patients in control group received similar routine treatment except for perioperative CIM intervention. All the patients in both groups underwent curative resection of cancer.

Separation of peripheral blood mononuclear cells (PBMCs) and immunocytochemical staining

From all the patients in both groups, 2 ml of venous blood was taken and heparinized at admission, before operation, on the 2nd and the 10th postoperative days, respectively. PBMCs were obtained immediately by standard Ficoll-Hypague gradient centrifugation at 2 000 rpm for 20 min at 4 ℃ and smeared onto slides, dried and fixed for immunocytochemical staining. The primary antibodies were mouse-anti-human CD_3, CD_4, CD_8 and CD_{57} monoclonal antibodies (Sigma Chemical Company, St Louis, MO, USA) for the detection of total T lymphocytes, helper T lymphocytes, inhibitor T lymphocytes and natural killer (NK) cells, respectively. The primary antibody was visualized with avidin-biotin-peroxidase supersensitive kit (Wuhan Boster Bioengineering Co. Ltd., Wuhan, China). The slides were counterstained with methyl green. PBMCs from 20 healthy controls were processed in the same way as normal controls.

The slides were mounted and viewed under binocular microscope (Olympus, Japan) by an independent viewer. Positive cells were stained green in nuclei and yellow-brown in cytoplasm and cell membrane (Figure 1). A total of 200 cells were counted on each slide and positive cells were recorded. The immunocytochemical staining procedure was repeated 3 times and the percentage of each cell subpopulation was calculated and expressed as mean ± standard deviation ($\bar{x}\pm s$).

Immunohistochemical study on TIL in surgical specimens

Immediately after resection, the specimens were cut open and washed clean. For each patient, three pieces of tumor samples were taken at different sites from the peripheral margin of the tumor, fixed in 10% neutral formalin and processed in standard histopathology procedure. For observation of TIL responses, conventional HE staining was performed on the 4 μm thick tissue sections. Immunohistochemical staining on the sections was conducted for subpopulation study of TIL, with anti-CD_3 monoclonal antibody to recognize T lymphocytes and anti-CD_{20} monoclonal antibody to recognize B lymphocytes (both from Sigma). The immunohistochemical staining procedure followed a standard protocol. The sections were counterstained by hemotoxylin, mounted and interpreted under microscope. The number of TIL was recorded in five high power (HP, 200×) view fields randomly chosen at the tumor border. The degree of TIL response was determined based on a modified grading system by Jass[21]. Grade I (±): no TIL response, in which there were less than 10 infiltrating lymphocytes per HP view field; grade II (+): mild TIL response, in which there were 10-100 infiltrating lymphocytes per HP view field; grade III (++): intermediate TIL response, in which there were 101-200 infiltrating lymphocytes per HP view field; and grade IV (+++): prominent TIL response in which there were over 201 infiltrating lymphocytes per HP view field. Grades I and II TIL responses were defined as poor responses and grades III and IV lymphocyte responses as significant responses.

Figure 1 Immunocytochemical staining of PBMCs with monoclonal antibodies to CD_3, CD_4, CD_8 and CD_{57}. Positive cells were stained green in the nuclei and yellow-brown in cytoplasm and cell membrane. The microphoto showed CD_3 positive cells.

Statistical analysis

All data were expressed as mean ± standard deviation ($\bar{x}\pm s$). Analysis of variance (ANOVA) was used to process the data within groups. Student's *t* test and *chi*-square test were used to evaluate the differences between groups. For the comparison in TIL response among different tumor TNM stages, Fisher's exact test was used. All the tests were two-tailed with a level of significance P=0.05.

RESULTS

Clinico-pathological characteristics of patients

A total of 49 eligible patients were enrolled in this study, 25 of whom were randomized into treatment group and 24 into control group. Their clinico-pathological characteristics are detailed in Table 1. There were no statistically significant differences in demographic and histopathologic variables between the two groups (P>0.05) (Table 1).

Percentages of lymphocyte subpopulations at baseline

At randomization, the percentages of CD_3^+, CD_4^+, CD_{57}^+ cells and the CD_4^+/CD_8^+ ratio in both treatment and control groups were lower than those in normal control (P<0.001), and the percentage of CD_8^+ cells was higher in treatment and control groups than in normal control (P<0.05) (Table 2). There were no statistically significant differences between the treatment and control groups in the percentages of the above parameters, implying that the patients were well balanced with regard to peripheral lymphocyte subpopulations at randomization. The results indicated that the cellular immunity was significantly decreased in patients with GI cancer in this study population.

Table 1 Clinico-pathological characteristics of 49 GI cancer patients

Parameters	Treatment group (n=25)	Control group (n=24)
Age (y)		
Mean (range)	50 (25-73)	53 (27-78)
Gender		
Male	13	16
Female	12	8
Tumor sites		
Stomach	6	5
Colon	3	3
Rectum	16	16
Pathological types		
Tubular adenocarcinoma	14	12
Papillary adenocarcinoma	3	3
Villous adenocarcinoma	2	1
Signet-ring-cell carcinoma	2	3
Mucous adenocarcinoma	4	5
TNM stages		
I	3	5
II	7	9
III	9	6
IV	6	4
Tumor differentiation		
Well differentiated	5	6
Moderately differentiated	8	7
Poorly differentiated	12	11

All the variables showed no statistically significant differences between the two groups ($P>0.05$).

Table 2 Baseline values of lymphocyte subpopulations in peripheral blood mononuclear cells of normal control, treatment and control groups (%, $\bar{x}\pm s$)

Groups	n	CD_3^+	CD_4^+	CD_8^+	CD_{57}^+	CD_4^+/CD_8^+
Normal control	20	67.1±6.3	40.2±5.1	27.7±5.0	18.5±2.31	1.49/0.24
Treatment	25	60.8±6.3[b]	33.6±4.2[b]	30.6±5.2	14.8±4.4[a]	1.15±0.34[b]
Control	24	60.5±4.6[b]	33.4±3.7[b]	31.0±3.9[a]	15.0±2.8[a]	1.11±0.25[b]

[a]$P<0.05$ vs normal control, [b]$P<0.01$ vs normal control.

Changes in lymphocyte subpopulations in PBMCs during CIM treatment

During the perioperative period, dynamic changes in the percentages of peripheral blood lymphocyte subpopulations were observed in both treatment and control groups. Preoperative treatment with CIM for 1 wk had positive effects on the percentages of CD_3^+, CD_4^+ lymphocytes, and CD_4^+/CD_8^+ ratio. CD_3^+ cells were increased from 60.8±6.3% at randomization to 63.0±4.9% after CIM treatment for 1 wk. After operation, CD_3^+ cells were decreased to 60.3±5.4% on the 2nd postoperative day, and recovered gradually thereafter until it reached 64.2±3.9% on the 10th postoperative day, which was higher than the pretreatment level. In contrast, the percentage of CD_3^+ cells in control group continued declining during the perioperative period, and became significantly lower than that in the treatment group on both the 2nd and 10th postoperative days. The changes in CD_4^+ and CD_{57}^+ cells followed a similar pattern (Table 3, Figures 2, 3, 4).

Effects of CIM treatment on TIL

In addition to routine histopathological examinations of resected specimens, all the tumor sections were reviewed for the presence of peritumor lymphocytes and TIL responses. Six out of 24 patients (25%) in control group had discernible lymphocyte infiltration in the peritumor area, whereas 17 out of 25 cases (68%) in CIM treatment group had obvious TIL responses ($P<0.01$) (Table 4).

Table 3 Changes of lymphocytes and NK cells in perioperative period (%, $\bar{x}\pm s$)

Items	Groups	Perioperative period			
		A	B	C	D
CD_3^+	Treatment	60.8±6.3	63.0±4.9[d]	60.3±5.4[a]	64.2±3.9[d]

$/CD_8^+$	Control	1.11±0.25	1.08±0.22[b]	0.87±0.17[bd]	0.98±0.24[ab]

A: at admission, B: before operation, C: on the 2nd postoperative day, D: on the 10th postoperative day. [a]$P<0.05$, [d]$P<0.01$, B vs A, C vs B, D vs C; [b]$P<0.01$ vs treatment group.

Figure 2 Changes in CD_3^+ cell percentages in perioperative period. A: at randomization; B: before operation; C: on the 2nd postoperative day; and D: on the 10th postoperative day. The difference in CD_3^+ percentages between treatment and control groups at time points C and D was statistically significant, [b]$P<0.01$. The difference in CD_3^+ percentages on the 10th postoperative day and the randomization day was statistically significant for both treatment and control groups, [d]$P<0.01$.

Figure 3 Changes in CD_4^+ cell percentages in perioperative period. A: at randomization; B: before operation; C: on the 2nd postoperative day; and D: on the 10th postoperative day. The difference in CD_4^+ percentages between treatment and control

groups at time points C and D was statistically significant, [b]$P<0.01$. The differences in CD_4^+ percentages on the 10th postoperative day and the randomization day was statistically significant for both treatment and control groups, [d]$P<0.01$.

Figure 4 Changes in CD_{57}^+ cell percentages in perioperative period. A: at randomization; B: before operation; C: on the 2nd postoperative day; and D: on the 10th postoperative day. The difference in CD_{57}^+ percentages between treatment and control groups at time points C and D was statistically significant, [b]$P<0.01$. The differences in CD_{57}^+ percentages between treatment group and normal control on the 10th postoperative day was statistically significant, [d]$P<0.01$.

Table 4 TIL responses in treatment and control groups

Groups	SR		PR		Total	Rate (%)
	+++	++	+	+		
Treatment	9	8	6	2	25	68[b]
Control	2	4	9	9	24	25
Total	23		26		49	

SR=significant response, PR=poor response. [b]$P<0.01$ *vs* control group, *chi*-square test.

There was a negative correlation between TIL response and the clinico-pathological stages of the tumor (Table 5). In control group, TIL responses were mainly observed in TNM stages I and II cases, and there were very few peritumor lymphocyte responses in stages III and IV cases. In contrast, there were obvious TIL responses in 78% (7/9) of TNM stage III cases and 83% (5/6) of stage IV cases in CIM treatment group, both of which were significantly higher than those in control group ($P<0.05$ and $P<0.01$, respectively, Fisher's exact test) (Figure 4). Immunohistochemical studies of the specimens revealed that most of the TILs were CD_3^+ T lymphocytes clustered around tumor tissues. There were few CD_{20}^+ cells in TIL population.

Table 5 Comparison in TIL responses by TNM stages between control and treatment groups

TNM stages	Groups	Poor response	Significant response	Response rate (%)
I	Treatment	2	1	33
	Control	3	2	40
II	Treatment	3	4	57
	Control	6	3	33
III	Treatment	2	7	78[a]
	Control	5	1	17
IV	Treatment	1	5	83[b]
	Control	4	0	0

[a]$P<0.05$, [b]$P<0.01$, *vs* control (Fisher's exact test).

Figure 5 TIL responses in surgical specimens in treatment and control groups. In control group, there was a progressive decrease in TIL responses with increase of TNM staging. On the other hand, the treatment group showed a steady increase in TIL responses after CIM treatment for 1 wk. The differences in TIL response rates were statistically significant between treatment and control groups for TNM stages III and IV diseases ([a]$P<0.05$ and [b]$P<0.01$, respectively, Fisher's exact test).

DISCUSSION

To date, surgical resection remains the only approach that can offer possible cure for GI cancer patients. However, operation itself is a double-edged sword to cancer patients in terms of tumor immunology. On the one hand, a successful operation can remove tumor burden which is immuno-suppressive. This will help bring about an improved clinical outcome for most patients. On the other hand, the operation itself is a major blow to the immune system. Lines of evidence suggest that surgical patients undergo a period of immunodepression immediately after operation, the length of which depends on many factors such as the general status of the patients, extent of the operation itself, pre-operative treatment. Previous studies demonstrated that T helper cells decreased and T suppressor cells increased significantly as early as 1 day after surgery[22-24]. Many subsequent studies also confirmed that surgery for patients with lung cancer[25], esophageal cancer[26], gastric cancer[27,28] and colorectal cancer[29,30] induced immediate severe immunosuppression. For cancer patients, an important function adversely affected by this immunosuppression is the anti-tumor response itself. This immunosuppression might increase the chance of accelerated growth of residual tumors or micro-metastases already present at the time of surgical resection. As a result, postoperative immunosuppression maybe one of the major contributing factors for post-operative recurrence and metastases. Indeed our previous study found a local recurrent rate as high as 34.27% for rectal cancer 5 years after curative resection, most of which (89.04%) occurred 3 years after operation[31]. Other studies also revealed that 7% to 65% of rectal cancer patients would develop local recurrence after curative surgery[32-34]. Therefore, how to effectively improve peri-operative immunity of GI cancer patients remains a major challenge of significant clinical importance.

Many researches have been conducted to tackle this problem, and one approach is to use small molecular immunomodulator drugs such as CIM, a histamine H_2 receptor antagonist. It has long been observed that histamine was a growth factor for certain cancers and could, by itself, stimulate tumor cell proliferation[18-20]. As one of the many important chemo-mediators involved in immune responses, histamine had inhibitory effects on immune response[35-38] via its H_2 receptors[39]. It was discovered that T suppressor cells, which are part of the regulatory arm of the immune system, could express histamine receptors on their surface[40-42], and histamine was capable of suppressing the immune response by activating

these T suppressor cells[43]. Many tumors, particularly colorectal cancer, secrete histamine resulting in elevated histamine levels within the tumor. Histamine is also often secreted in response to surgical resection of colorectal cancers. All these factors working together will create an immuno-suppressive environment both in the area of tumor growth and in the whole body, facilitating tumor growth.

Several clinical studies have shown that administration of CIM could help reduce the immuno-suppression due to increased histamine level in the tumor environment[15,16,44-46]. *In vitro* studies also demonstrated that CIM could inhibit the adhesion of some breast cancer cells[47], and the adhesion of human colon cancer cells to human umbilical cord cells[48], a very important step in tumor growth and progression. *In vivo* experimental studies also showed that daily administration of CIM to a mouse model of colon cancer significantly retarded tumor growth by up-regulating the expression of tumor-suppressive cytokines[49], and the use of CIM also retarded the growth of human melanoma in a nude mouse model and prolonged the survival of tumor bearing SCID mice by directly inhibiting the proliferation of tumor cells and indirectly promoting the infiltration of activated macrophages to tumor site[50,51].

In line with previous findings, our study discovered the diminished cellular immunity in GI cancer patients. Compared with normal controls, the total T lymphocytes (CD3+), T helper lymphocytes (CD4+), and NK cells (CD57+) were significantly decreased in GI cancer patients. This reflects the nature that GI tumor burden exerts inhibitory effects on immune system. Moreover, the percentages of these immune cells showed a continuously declining trend with the progression of the disease, as reflected by the finding that patients with advanced TNM stage tumors had a more profound decrease in these immune cells than those with early stage tumors. Surgery itself, while removing the tumor burden, did have a temporary negative impact on host cellular immunity, as reflected by the marked decline in total T lymphocytes, T helper cells and NK cells in the immediate post-operative period. This decline continued with a downhill course in control group, in which no immunity-boosting therapies were given besides conventional surgical treatment. It is noteworthy that total T cells, T helper cells and NK cells did not return to baseline level 10 days after curative resection. This again highlighted the fact that while most patients in control group were physically recovered from operation at this time, they were far from immunologically recovered, and some interventional measures should be warranted to facilitate the recovery of cellular immune functions.

In contrast to control group, patients in treatment group showed favorable responses to CIM therapy in terms of cellular immunity parameters. After CIM treatment for 1 wk, total T cells, T helper cells and NK cells showed a slow but steady increase, although the increments did not reach statistical significance for NK cells, they did reach statistical significance for both total T cells and T helper cells. However, their levels were still lower than those found in normal controls, implying that while GI cancer patients have reduced their cellular immunity, they were nevertheless responsive to immunity-boosting measures, although such measures alone could not efficiently restore the hosts' cellular immunity to the level of normal controls. The data demonstrated again that surgery itself reduced cellular immunity, but to a much less degree, as a result of CIM treatment. Moreover, such reductions were quickly addressed and a positive balance was reached 10 days after CIM treatment, as reflected by the fact that the total T cells, T helper cells and NK cells on the 10th postoperative day were significantly higher than the baseline level (at randomization). Although total T cells, T helper cells were not up to the level of normal controls, NK cells did exceed the level of normal controls. If the cellular immunity parameters for both treatment and control groups on the 10th postoperative day were analyzed, it would be obvious that CIM treatment did exert remarkable boosting effects on cellular immunity parameters.

The current study also demonstrated that immunity-enhancing effects of CIM treatment were not limited to peripheral blood immune cells alone, it also enhanced TIL response at the tumor site, as was revealed by the findings that while 25% of the patients in the control group had discernible TIL responses in the peri-tumor area, as high as 68% of cases in the treatment group showed obvious TIL responses. As demonstrated by immunohistochemical studies, most of the TILs were T lymphocytes. TILs have been found to be the highly effective tumoricidal lymphocytes[52-54], and TIL treatment could decrease the relapse rate and prolong the survival of stage III melanoma patients with one positive lymph node[55,56], and the overall survival of stage IV gastric and colorectal cancers[57,58], and induce regression of metastatic tumors in the lung, liver and lymph nodes in patients with advanced melanoma after lymphodepletion[59]. The enhanced TIL response at the tumor site induced by CIM treatment, therefore, might help reduce tumor aggressiveness and promote local control.

In summary, the current randomized clinical trial demonstrated that perioperative administration of CIM to GI cancer patients helped accelerate the recovery of cellular immunity and boost TIL responses at the tumor sites. This has potential therapeutic implications. Since circulating T lymphocytes and NK cells are major defense mechanisms against tumor cells released into the circulation, and TIL is one of the most crucial factors restricting local tumor growth and progression, it is desirable to use it as an immunomodulator in the perioperative period. Moreover, since CIM has many other favorable effects besides immunomodulation on lymphocytes, such as activating macrophages, increasing tumor inhibitory cytokines[49], enhancing the antigen presenting capacity of dendritic cells[60], reducing tumor cell proliferation, inhibiting tumor cell metastasis via anti-adhesion mechanisms[49] and increasing the overall survival of colorectal cancer patients with high levels of sialyl Lewis-X and sialyl Lewis-A epitope expression on tumor cells[61], it is therefore advisable to use this low cost, convenient and almost nontoxic drug as a practical immunity-enhancing measure for GI cancer patients.

Abstract

AIM: TT virus (TTV) is a newly described DNA virus related to postransfusion hepatitis that produces persistent viremia in the absence of clinical manifestations. PEG-IFN plus ribavirin have been useful in the treatment of chronic hepatitis C infection. This study investigated the responses of TT virus (TTV) and hepatitis C virus (HCV) to PEG-IFN plus ribavirin therapy.

METHODS: Fifteen patients infected with HCV were treated with PEG-IFN(0.5 μg/body weight/week) and ribavirin (1 000 mg-1 200 mg/daily) for 48 weeks. Blood samples were drawn at the beginning and the end of the therapy. Serum TTV DNA and HCV RNA were quantified by real time PCR.

RESULTS: At the beginning of treatment, TTV infection was detected in 10/15 (66.6%) of HCV-infected patients. Loss of serum TTV DNA at the end of therapy occurred in 6/10 (60%) patients. Out of these 6 patients, 4 (67%) became positive for TTV DNA after 6 months of therapy. Regarding HCV viremia, 11/15 (73%) patients were negative for serum HCV RNA after 48 weeks of therapy, 7/11 (64%) of these cases also became negative for TTV DNA following the combined treatment. In the 3/4 (75%) patients who were positive for HCV RNA at the end of therapy, TTV DNA was detected as well. Sustained HCV response at 6 months after treatment was 53% (8/15).

CONCLUSION: No TTV sustained response can be achieved in any patient after PEG-IFN plus ribavirin administration.

INTRODUCTION

TT virus (TTV) has been recently identified in patients with elevated alanine aminotransferase (ALT) levels following transfusions[1]. TTV presents an extreme diffusion of active infection throughout the world[2]. It is known that TTV may be highly contagious although its way of spread is poorly understood. However, its high prevalence rate among the people receiving or being in contact with blood products could indicate that TTV can be parenterally transmitted[3]. Although it has been proposed that TT virus be responsible for the small proportion of acute and chronic forms of hepatitis that still remain unsolved, no other illness has yet been attributed to the virus. The TTV genome is a circular, single-stranded DNA of negative polarity, which shares similarities with members of the Circoviridae family and, in contrast to DNA viruses, TTV isolates exhibit a high level of genetic heterogeneity[4,5].

Hepatitis C virus (HCV) is the major cause of chronic liver infection which may progress to cirrhosis and eventually to hepatocellular carcinoma (HCC)[6]. Recently, pegylated interferon (PEG-IFN), initially alone and later in combination with ribavirin, a nucleoside analogue with a broad antiviral activity against a variety of DNA and RNA viruses, has provided new perspectives for the treatment of most patients with chronic HCV infection[7,8]. Co-infection of TTV and HCV is commonly seen maybe because both viruses share the same transmission routes such as blood transfusion[9]. In previous studies, IFN therapy was reported to be effective against TTV[10,11], but the possible susceptibility of the virus to the combination of PEG-IFN plus ribavirin treatment has not yet been investigated. Thus, we investigated the response of TTV infection to PEG-IFN plus ribavirin therapy in patients with chronic hepatitis C and evaluated whether PEG-IFN plus ribavirin combined therapy on chronic hepatitis C was influenced by a TTV co-infection.

MATERIALS AND METHODS

Patients

We enrolled randomly in the study 15 patients (11 males and 4 females, mean age: 41.6 years, range: 30 to 57 years) with chronic HCV infection who had undergone PEG-IFN plus ribavirin therapy. The diagnosis of chronic hepatitis was made on histological (stage of fibrosis and grade of activity) and biochemical liver function tests. Five patients had a history of blood transfusion, 6 acquired HCV infection by parenteral route (intravenous drug abusers, tattoos...) and in 4 patients the transmission route was unknown. Biochemical and virological features of the patients are shown in Table 1.

PEG-IFN was administered intramuscularly at a dose of 0.5 μg/body weight/week, ribavirin was given orally at a dose of 1 000-1 200 mg/daily (weight adjusted) for 48 weeks. Blood samples were taken at the baseline time and when therapy was stopped. To evaluate the effects of PEG-IFN plus ribavirin, levels of ALT, TTV DNA and HCV RNA were evaluated at each time. TTV and HCV clearance was defined as the disappearance of serum TTV DNA and HCV RNA after 48 weeks of combined treatment. All patients gave written informed consent before enrollment in the study, which was approved by the Ethics Committee of the hospital.

Detection and quantification of TTV DNA

Total DNA was purified from 200 μl of serum using the high

pure viral nucleic acid kit (Roche Diagnostic, Mannheim, Germany) and eluted in 50 µl distilled water. TTV DNA was subjected to nested PCR for qualitative analysis. First PCR was performed with primer pair NG054/NG132[12] and nested PCR with primer pair T801/T935[13]. In those positive samples for viral DNA, TTV DNA quantification was carried out with real time PCR by the SYBR Green approach using primers targeting a fragment of the untranslated region (UTR) of the viral genome as previously described by Garcia *et al*[14].

HCV markers

HCV antibodies (anti-HCV) were determined by immunoassay (Ortho Diagnostic System, Raritan, NJ). Serum HCV RNA levels were measured using the Amplicor HCV monitor test (Roche). HCV genotyping was carried out using the Inno-Lipa HCV test (Innogenetics).

Statistical analysis

Statistical analyses were performed using Student's *t* test. Data were analyzed with the computer program SPSS (SPSS Inc., Chicago, IL, USA). A probability (*P*) value less than 0.05 was considered statistically significant.

RESULTS

Detection and response of TTV to PEG-IFN plus ribavirin therapy

Fifteen patients infected with HCV were monitored randomly for levels of TTV and HCV in serum, at the beginning and end of PEG-IFN plus ribavirin combined treatment. Of the 15 patients, serum TTV DNA could be detected in 10/15 (67%) by real time PCR at the beginning of therapy, with a TTV value that ranged from 1.3×10^3 to 1.7×10^5 genomes/ml of serum (mean: 3.4×10^4 genomes/ml). After 48 weeks of PEG-

IFN plus ribavirin therapy, 6/10 patients (60%) lost serum TTV DNA. Regarding the 4 patients who still had detectable serum TTV DNA, TTV value ranged from 10^3 to 4×10^4 genomes/ml of serum (mean: 1.4×10^4 genomes/ml). In 3/4 patients (75%) positive for TTV, circulating HCV RNA was detected simultaneously after completion of the combined therapy. With respect to these 4 positive TTV DNA patients, at the end of treatment and relative to baseline levels, 3 patients (75%) had a reduction of serum TTV load and 1 case (25%) presented an increase in the levels of serum TTV DNA. The latter patient presented a grade III fibrosis while the remaining 3 individuals presented a grade I fibrosis (Table 1).

When TTV DNA was analyzed at 6 months after stopping PEG-IFN plus ribavirin administration, four responders (67%) had a relapse of TTV viremia, in the 2 remaining cases no serum samples were available (Table 1). The 4 patients, who did not eliminate TTV DNA at the end of treatment, still maintained DNA during the follow-up period. With respect to the 5 TTV DNA negative patients at the beginning of therapy, 1 (20%) became positive for TTV after stopping combined therapy, 2 (40%) cases remained negative for TTV and in 2 individuals viral marker was not determined (Table 1).

Serum TTV DNA level with respect to HCV in non-responder and responder patients to PEG-IGN plus ribavirin treatment was also analyzed and no statistically significant differences were found when pretreatment serum samples were compared between both groups (*P*=0.281). However, we observed that those patients eliminating TTV at the end of therapy presented a lower basal HCV load when compared with the non-responder TTV patients (1.1×10^6 *vs* 2.1×10^6 genomes/ml, respectively *P*=0.03). Regarding the changes of ALT levels, no statistical differences were observed when they were analyzed between TTV responder and non-responder (Table 2). In contrast, serum ALT level was persistently maintained

Table 1 Features of patients in the study

Patient No.	HCV Genotype	Fibrosis	Before treatment			End of treatment			6 months after treatment

ALT level was expressed as IU/L. TTV and HCV loads were expressed as viral genomes/ml of serum.

Table 2 Changes of ALT levels in TTV and HCV responder and non-responder patients to PEG-IFN plus ribavirin therapy

	TTV		*P*[a]	HCV		*P*[a]
	Responders (*n*=6)	Non-responders (*n*=4)		Responders (*n*=11)	Non-responders (*n*=4)	
Before therapy	97.16±30.18	103.0±84.87	0.09	112.54±51.90	72.00±31.01	0.33
End of therapy	28.66±11.09	27.00±9.83	0.92	30.09±12.96	31.50±14.20	0.76

ALT level was expressed as IU/L. [a]Student´s *t*-test.

in the normal range before and after the combined therapy in one patient who did not eliminate TTV and HCV (Table 2, patient No. 15).

HCV response to PEG-IFN plus ribavirin treatment

Pretreatment serum HCV RNA values ranged between 9×10^4 and 6.3×10^6 genomes/ml of serum (mean: 1.36×10^6 genomes/ml). The decline of HCV viremia was clearly evident after therapy and the response rate was 73% (11/15). When serum HCV RNA pretreatment levels were compared between non-responder and responder patients, the difference was statistically significant (1.85×10^6 *vs* 1.15×10^6 genomes/ml, respectively; $P=0.005$). Sustained HCV response after 6 months of treatment was found in 8/15 (53%) patients, 2 patients (13%) became HCV RNA positive during the follow-up period and in one case no serum sample was available for the detection of HCV RNA (Table 1). Following combined therapy, baseline and final ALT levels between responder and non-responder patients were compared but the differences between both groups were not statistically significant (Table 2).

DISCUSSION

Many studies have been done trying to assess whether TTV could cause liver disease, but its molecular properties and its pathogenic potential are still poorly understood. Different epidemiological studies have clearly indicated that TTV is a transmissible blood-borne virus sharing common transmission routes with hepatitis viruses. Then, coinfection of TTV was frequently observed in patients with chronic hepatitis C[9]. We found that 66.6% of our patients infected with HCV were TTV DNA-positive, which confirms previous studies showing that the prevalence of TTV infection varied between 30%-88%[15,16].

It has been reported that TTV infection treated with IFN alone had a response rate of 62%-83% after monotherapy[11,17]. Our data showed that 60% of the TTV-infected patients could eliminate TT virus at the end of PEG-IFN plus ribavirin combination treatment. By comparing our results with earlier published studies, the novel and interesting information obtained from our work is that the treatment of TTV infection with PEG-IFN plus ribavirin, for a period of 48 weeks, did not promote an additional and increased response to therapy. Then, ribavirin did not produce any effect on TTV replication because of the similar sensitivity of TTV to combined treatment or to standard IFN monotherapy. Moreover, in these published studies the sustained TTV response after 6 months of therapy was decreased to 32%-50%[18]. In contrast, in our series no sustained clearance of TTV was achieved in any patient after 6 months of combined therapy. It is well known that TTV tended to last many years[19] although spontaneously resolved viremias after short periods of time were described in the literature[20]. That the majority of our TTV responder patients relapsed during the follow-up period could suggest the possibility that TTV could become temporarily latent, as a result of the sensitivity of TTV to PEG-IFN during its administration, and that a new reinfection of the virus occurred. In other words, it was possible that TTV could persist in other type cells such as peripheral blood mononuclear cells where TTV persistence could occur[10]. Among other explanations, it could be possible that because of TTV high level of genetic diversity, viral genomes with different PEG-IFN sensitivities could arise over time. Finally, we suggest that TTV response to PEG-IFN may be affected by a combination of virus and host factors as observed in other viruses[21].

With respect to the effect of PEG-IFN plus ribavirin administration for the treatment of chronic hepatitis C, this study confirms earlier reports in which HCV infection responded positively to the combined therapy with a high rate of viral clearance and normalization of ALT levels during the treatment period. Both factors occurred in HCV/TTV-coinfected patients as well as in non-coinfected ones, so it could be suggested that the response of HCV to IFN-PEG plus ribavirin treatment was not affected by TTV coinfection. Moreover, in those patients without sustained TTV response ALT levels were normal in contrast with those who had a HCV relapse. Then, in agreement with other published studies, TTV might not have any clinical association with producing HCV hepatitis[16,22]. Furthermore, another interesting result from our study was that PEG-IFN plus ribavirin therapy seemed to be specially efficacious in patients with more advanced liver diseases such as grade III fibrosis. Thus, in 45.5% of HCV responder patients with advanced fibrosis, only 25% of non-responder ones presented a minor grade fibrosis, which supported the beneficial effect of PEG-IFN on patients with difficult-to-treat diseases reported in previous studies[23,24].

In conclusion, TTV has a similar response rate to PEG-IFN plus ribavirin combined treatment or to IFN monotherapy, suggesting that neither PEG-IFN nor ribavirin has any additional effect on TTV replication. Furthermore, TTV relapse was found in most of the responder patients after the combined therapy was stopped for 6 months, so it seems likely that TTV is not as sensitive to PEG-IFN as HCV.

Abstract

AIM: To evaluate the synergistic antitumor effects of herpes simplex virus thymidine kinase (HSV-TK) together with tumor necrosis factor alpha (TNF-α) or interleukin-2 (IL-2) gene expression on gastric cancer cell line SGC7901.

METHODS: Recombinant vectors pL(TT)SN and pL(TI)SN, which express TK-IRES-TNF-α and TK-IRES-IL-2 genes separately, as well as the control plasmids pL(TK)SN and pLXSN were employed to transfect PA317 cells respectively to generate the viruses that can stably express the objective genes through G418 selection. The gastric cancer cells were then transfected by the retroviral serum from the package cells and maintained in culture to determine the cell growth and apoptosis. The cytotoxic effects of HSV-TK together with TNF-α or IL-2 gene expression on the transfected cancer cells were evaluated by the cell viability and bystander effects in the presence of GCV supplemented in the cultural medium.

RESULTS: Expression of recombinant proteins including TNF-α and IL-2 by stable transfectants was confirmed by Western blotting. The percentage of cell apoptosis in the SGC/0, SGC/TK-TNF-α, SGC/TK-IL-2 and SGC/TK clone was 2.3%, 12.3%, 11.1% and 10.9% respectively at 24 h post-transfection. Cell growth status among all the experimental groups as judged by cell absorbance (A) at 570nm did not exhibit any significant difference ($P>0.05$); although it was noted to be slightly lower in the SGC/TT group. Cell survival rate in SGC/TI, SGC/TT and SGC/TK group was significantly decreased in a dose-dependent manner of GCV compared with that of the SGC/0 group ($P<0.05$-0.01). Among all studied cells, the SGC/TT was shown most sensitive to GCV with a half lethal dose of 0.5 mg· L^{-1}. In contrast, the survival rate of SGC/0 cells was not affected by the presence of GCV with the doses less than 10 mg· L^{-1}. The half lethal dose of GCV for SGC/0 cells was more than 100 mg· L^{-1}. Marked bystander effect induced by SGC/TI, SGC/TT and SGC/TK cells was confirmed by the fact that 20% of these stable transfectants could kill 50% of the co-cultured cells, in which the most prominent bystander effect was found in the circumstance of SGC/TT presence. However, no significant difference of these variables was found among SGC/TI, SGC/TT and SGC/TK cells ($P>0.05$).

CONCLUSION: The synergistic antitumor effects produced by the co-expression of HSV-TK with TNF-α or IL-2 genes were not present in the transfected SGC7901 cells. The mechanism underlying these phenomena was not known.

INTRODUCTION

Gastric cancer is one of the most prevalent malignancies in China[1]. Despite the recent progress in early diagnosis and treatment of the disease, aggressive surgical or chemotherapeutic interventions have not sufficiently prolonged the survival time of patients with distant metastases[2]. Thus, searching for more effective therapeutic modalities, especially for the stage IV gastric cancer patients, has become an urgent task in our daily medical practice.

The transfer of suicide genes into tumor cells that is currently being studied as a method of treatment for various cancers has made the target cells become sensitive to the pharmacological agents. Suicide gene therapy with the herpes simplex virus thymidine kinase (HSV-TK) fragment, the most widely used strategy for the cancer therapeutic study[3], has been shown to exert antitumor efficacy in various cancer models[4-7]. However, its efficacy seems not to be fully developed to eliminate tumor cells in some of the investigations[8-12]. Gene therapy with HSV-TK and cytokine genes together may produce a complementary effect, and has become a new insight for the treatment of malignancies[13, 14].

Previously, we constructed two retroviral vectors, pL(TT)SN and pL(TI)SN, which have been confirmed to express TK-IRES-TNF-α and TK-IRES-IL-2 genes respectively in the gastric cancer cell line SGC7901[15]. In the present study, the synergistic antitumor effects of these vectors on human gastric cancer cells were investigated in the presence of GCV to confirm their efficiency.

MATERIALS AND METHODS

Cell lines and vectors
The mouse fibroblast cell line NIH3T3 and the amphotropic retroviral packaging cells PA317 were the generous gifts from

Dr. Yu Bing (Fourth Military Medical University, Xi' an, China). The human gastric carcinoma cell lines SGC7901 were obtained from Shanghai Institute of Biochemistry. All of the cells were maintained in RPMI 1640 medium, supplemented with 10% FBS (Hangzhou, Sijiqing Biotech Company), 2 mM L-glutamine, 100 units/ml penicillin and 100 μg/ml streptomycin. The PA317 was used as the packaging cell and the NIH 3T3 cells were employed to assay the virus titre. The cell cultures were maintained at 37 ℃ in a humidified atmosphere with 5% CO_2.

The recombinant vectors pL(TT)SN and pL(TI)SN, which express TK-IRES-TNF-α and TK-IRES-IL-2 genes respectively, as well as the control plasmid pL(TK)SN carrying only TK fragment were constructed and identified in our previous study[15]. The empty plasmid PLXSN used as another control vector was provided by Dr. Yu Bing (Fourth Military Medical University, Xi' an, China).

Establishment of stable transfectants

The retrovirus plasmids pL(TT)SN, pL(TI)SN, pL(TK)SN and pLXSN were transferred into PA317 cells respectively by lipofectamine (Gibco) according to the manual instructions[16, 17]. After 48 h of transfection, G418 (Promega) was added to the culture medium at a concentration of 500 mg· L^{-1} to select G418-resistant colonies. After 2-weeks' culture with the changing of the G418-containing medium every 3 days, the supernatant of G418-resistant colonies was collected and diluted to different concentrations to infect NIH3T3 cells, which were further undergone the G418 selection for 2w, then the G418-resistant NIH3T3 colonies were counted for the determination of viral titre[18]. The viral titers of pL(TT)SN, pL(TI)SN, pL(TK)SN and empty plasmid pLXSN were 5×10^8 CFU/L, 6×10^8 CFU/L, 1×10^9 CFU/L and 1×10^9 CFU/L respectively.

A total number of 5×10^5 SGC7901 cells were incubated in a 6-well plate for 24 h, then rinsed with serum-free RPMI 1640 medium twice and incubated with 100 μl supernatant of G418-resistant PA317 colony for 3 h. After 4-weeks' cultivation, the G418-resistant colonies designated as SGC/TK-TNF-α, SGC/TK-IL-2, SGC/TK and SGC/0 respectively according to the transfected vectors were collected and used both to confirm the objective gene expression by Western blot and to perform other determinations.

For Western blotting, the SGC/TT and SGC/TI cells were incubated respectively in the six-well plates at a density of 2.5×10^5 cells/well for 24 h, followed by a further cultivation of 48 h with the culture medium replaced with 1 ml of serum-free RPMI 1640. Then the serum-free medium was totally collected, concentrated in a microconcentrator to 20 μl and subjected to electrophoresis on a 120 g· L^{-1} SDS/PAGE gel. Proteins were transferred to a nitrocellulose membrane and incubated overnight in 50 ml· L^{-1} fat free milk in PBS at 4 ℃. After washed in 10 ml· L^{-1} fat free milk, the membrane was incubated with monoclonal antibody of mouse anti-rhIL-2 or anti-TNF-α, followed by incubatino with horseradish peroxidate-conjugated antimouse immunoglobulin. Proteins were detected by using the ECL kit according to the manufacturer' s instruction (Amersham)[19].

Determination of cell apoptosis

Cell apoptosis was quantitated by the protocol of flow cytometry. Briefly, 100 μl of the observed cells (2×10^5) in binding buffer and 5 μl of FITC-conjugated annexin V/PI dual staining reagents (Annexin V-FITC kit, Pharmingen, USA) were transferred in turn into a 5 ml culture tube and incubated for 15 min at room temperature in the dark. After 400 μl of binding buffer was added into the culture tube, the flow cytometric analysis for apoptosis was performed as soon as possible within 12 h (FACScaliber; Becton. Dickinson, USA).

Cell growth assay

Cell growth was scaled in SGC/TI, SGC/TT, SGC/TK and SGC/0 cells as described in the references[20,21]. Cells were cultured in 24-well plate (Nuc, Co) at 37 ℃ in a humidified atmosphere with 5% CO_2 and adjusted to a density of 1.5×10^4 cells/well at the time of determination. Cell absorbance (A) at 570nm was determined each day for 6 days. The figures obtained were used to draw a cell growth curve.

MTT assay

An MTT assay was conducted to determine the cell survival rate[22,23]. Following 24 h incubation, cells cultured in 96-well plates were treated with different concentrations of GCV (Roche Co.) and continued to be cultured for 6 d, when the MTT mixture was added to medium and the cells were incubated further for another 4 h. The absorbance of the cells was measured at a wavelength of 525nm with a microtiter plate reader. The survival rate was expressed as A/B×100%, where A was the absorbance value from the experimental cells and B was that from the control by SGC7901 cells.

Bystander effect observation

Twenty-four hours after tumor cells were infected with recombinant retrovirus, different proportions of transfected and untransfected cells that were adjusted to a density of 1×10^5 cells/well were co-cultured on 4-well flat-bottom plates at 37 ℃ for 5 d in the presence of 5 mg· L^{-1} GCV. The cell survival rate was measured by MTT method[24].

Statistical analysis

Quantitative variables are described as mean ± standard error of the mean. Categorical variables are expressed as percentages. Comparisons between means were done with the Student' s t-test. Comparison between percentages was performed with the χ^2 test. A P value <0.05 was taken as the criterion of statistical significance.

RESULTS

Expressions of stable transfectants

The stable expression of recombinant proteins in target cells was confirmed by Western blot, in which two distinct bands of 15ku and 17ku were observed on the nitrocellulose membrane, corresponding to the fragment sizes of IL-2 and TNF-α respectively (Figure 1).

Figure 1 Stably expressed recombinant protein in transduced SGC7901 cells confirmed by Western blot. Lane 1: IL-2 (15ku) expressed in SGC/TI cells; Lane 2: TNF-α (17ku) expressed in SGC/TT cells.

Cell apoptosis

Cells in the early phase of apoptosis were labeled by single annexin V fluorescence. The percentage of cell apoptosis in the SGC/0, SGC/TK-TNF-α, SGC/TK-IL-2 and SGC/TK clone was 2.3%, 12.3%, 11.1% and 10.9% respectively at 24 h post-transfection, indicating a slightly higher percentage of apoptosis appeared in the SGC/TK-TNF-α, SGC/TNF-α

and SGC/TK clones compared with that in the SGC/0 clone ($P>0.05$, Figure 2).

Figure 2 Percentage of early apoptotic cells in different groups of transfectants.

Cell growth status

The A value of cells among all experimental groups did not exhibit any significant difference ($P>0.05$), although it was slightly lower in the SGC/TT group (Figure 3). The result showed that the cell growth status was not severely influenced by the vector's variety used for the transfection in the present study.

Figure 3 Cell growth status of the different transfectants.

Cell viability

Cell survival rate in SGC/TI, SGC/TT and SGC/TK group was significantly decreased in a dose-dependent manner of GCV compared with that of the SGC/0 group ($P<0.05$-0.01). Among all studied cells, the SGC/TT was shown most sensitive to GCV with a half lethal dose of 0.5 mg· L^{-1}. In contrast, the survival rate of SGC/0 cells was not affected by the presence of GCV with the doses less than 10 mg· L^{-1}. The half lethal dose of GCV for SGC/0 cells was more than 100 mg· L^{-1} (Figure 4).

Bystander effect

Marked bystander effect was shown by SGC/TI, SGC/TT and SGC/TT cells as manifested by the fact that 20% of these stable transfectants could kill 50% of the co-cultured cells (Figure 5). However, the most prominent bystander effect was found in the circumstance of SGC/TT presence.

Figure 4 Cell survival rate in different experimental group treated with 5 mg· L^{-1} GCV for 6 d.

Figure 5 Bystander effect of different transfectants.

DISCUSSION

Transfer of suicide gene into tumor cells has emerged as an attractive strategy of gene therapy for the selective elimination of cancer cells, in which the suicide gene system alone or in combination with other immunological genes have been considered to be the favorable modalities for the treatment of malignancies[25-27]. The suicide genes encode non-mammalian enzymes that can convert nontoxic prodrugs into cellular toxic metabolites. The most widely used suicide gene is the HSV-TK/GCV system that can convert prodrug GCV into phosphorated GCV. The latter is further phosphorated by the cellular kinase to form GCV triphosphate, a toxic substance that can inhibit cellular DNA synthesis and lead cell to death. Besides, the "bystander effect" induced by TK gene can also enhance the tumor-killing capacity of the HSV-TK/GCV system[28-30]. However, it was found in some investigations that the antitumor efficiency of this system was limited by the lower rate of gene transfection and their insufficient induction of host immunity[31-33].

Cytokine therapy is another strategy for the treatment of malignancies. It can not only directly kill tumor cells, inhibit tumorigenesis and tumor metastasis, but can also enhance these effects by the induction of antitumor immunity. Based on the antitumor properties of certain cytokines such as IL-2 and TNF-α, it is believed that the gene therapy combining cytokine with TK suicide gene would produce more beneficial and effective effects for the treatment of cancers, which has received strong supports from some of the recently published literatures. Majumdar and his associates[33] have compared the therapeutic effect of IL-2 expression alone with that by the co-expression of IL-2 and TK genes on squamous cell carcinoma in nude mice, and found that the combined gene expression was most efficient for the gene therapy. In another study, Chen *et al*[34]

reported that cytokine gene IL-2 could act synergistically with the suicide gene to induce a systemic antitumor immunity. Unfortunately, there have been few reports up to the present about this therapeutic strategy in the antitumor study of gastric malignancy.

In the present study, we tried to observe the antitumor effects by the co-expression of suicide gene HSV-TK and cytokine gene TNF-α or IL-2 on gastric carcinoma cell lines SGC7901. It was found that the percentage of cell apoptosis in the SGC/0, SGC/TK-TNF-α, SGC/TK-IL-2 and SGC/TK clone was 2.3%, 12.3%, 11.1% and 10.9% respectively at 24 h post-transfection, and the cell growth status as judged by cell absorbance (A) at 570nm among all the experimental groups did not exhibit any significant difference ($P>0.05$), although they were noted to be slightly varied in the SGC/TT group. This indicated that the apoptosis and growth status of SGC7901 cells were not severely influenced by the vector's variety used in the study. Whereas the cell survival rate in SGC/TI, SGC/TT and SGC/TK group was significantly decreased in a dose-dependent manner of GCV compared with that of the SGC/0 group ($P<0.05$-0.01) in the presence of GCV, in which the SGC/TT cells were shown to be most sensitive to GCV with a half lethal dose of 0.5 mg·L^{-1}. In contrast, the survival rate of SGC/0 cells was not affected by the presence of GCV with the doses less than 10 mg·L^{-1}. The half lethal dose of GCV for SGC/0 cells was more than 100 mg·L^{-1}. Marked bystander effect induced by SGC/TI, SGC/TT and SGC/TK cells was also confirmed by the fact that 20% of these stable transfectants could kill 50% of the co-cultured cells and the most prominent bystander effect was found in the presence of SGC/TT. However, no significant difference of these variables was found among SGC/TI, SGC/TT and SGC/TK cells, which meant that the synergistic antitumor effects produced by the co-expression of HSV-TK and TNF-α or IL-2 genes were not present in the transfected SGC7901 cells. Whether this was due to the speciality of the gastric cancer cell line is unknown. Further studies, therefore, are needed to elucidate the mechanisms underlying these phenomena in order to search for more efficient therapeutic modalities for the treatment of gastric malignancies.

Abstract

AIM: Although liver cirrhosis is a predisposing factor for hepatocellular carcinoma (HCC), relatively few reports are available on HCC in primary biliary cirrhosis. High plasma nociceptin (N/OFQ) level has been shown in Wilson disease and in patients with acute and chronic pain.

METHODS: We report a follow-up case of HCC, which developed in a patient with primary biliary cirrhosis. The tumor appeared 18 years after the diagnosis of PBC and led to death within two years. Alfa fetoprotein and serum nociceptin levels were monitored before and during the development of HCC. Nociceptin content was also measured in the tumor tissue.

RESULTS: The importance and the curiosity of the presented case was the novel finding of the progressive elevation of plasma nociceptin level up to 17-fold (172 pg/mL) above the baseline (9.2±1.8 pg/mL), parallel with the elevation of alpha fetoprotein (from 13 ng/mL up to 3 480 ng/mL) during tumor development. Nociceptin content was more than 15-fold higher in the neoplastic tissue (0.16 pg/mg) than that in the tumor-free liver tissue samples (0.01 pg/mg) taken during the autopsy.

CONCLUSION: Results are in concordance with our previous observation that a very high plasma nociceptin level may be considered as an indicator for hepatocellular carcinoma.

INTRODUCTION

The incidence of hepatocellular carcinoma (HCC) in primary biliary cirrhosis (PBC) is reported to range from 0.5% to 4.2%, which is somewhat less frequent than that in liver cirrhosis from other etiologies[1,2]. However, recent reports have shown an increasing trend. The incidence of HCC was found higher in stage III/IV than in stage I/II patients[1,3,4].

Relatively few prospective and comprehensive studies are available on HCC in PBC, and the number of case reports is also limited. Summarizing the data of the literature, 126 of 6 188 PBC patients (2.0%) were found to have HCC. Since HCC usually develops many years after the diagnosis of PBC, screening of HCC has clinical importance and offers best with hope for early detection. Serum AFP is a widely accepted marker of HCC[5]; however, using the conventional cut-off value of 500 ng/mL, it has a sensitivity of about 50% and a specificity of more than 90% in detecting HCC in a patient with coexisting liver disease[6]. The average survival of patients with HCC improved in the last decades[7]. Female HCC patients often have a better prognosis than male patients[8]. Because of the lack of sensitive markers of malignant hepatic tumors, HCC is usually recognized in the advanced stage.

We reported a follow-up case of HCC in a PBC patient. The importance of this case is the novel finding of progressive elevation in plasma nociceptin (N/OFQ, formerly named as orphanin FQ) up to 17-fold above the baseline, parallel with the elevation of alpha fetoprotein (AFP) during tumor development. Moreover, high nociceptin content was found in the tumor tissue as well.

Nociceptin, a newly discovered neuropeptide of 17 aminoacids, is the natural agonist of NOP receptor, earlier named opioid receptor-like 1 (ORL1) receptor. N/OFQ is a neuropeptide that is endowed with pronociceptive activity *in vivo*. Both the long and the short splice variants of the OP4 receptor mRNA were isolated in rat liver[9]; however, there are no data about its physiological or pathophysiological role in liver function. To date only few clinical studies on nociceptin were reported, and only one of them dealt with liver disease.

Findings of the presented case are in concordance with our previous observation that a high plasma NC level may be an indicator of HCC.

CASE REPORT

A 47-year-old woman was admitted for fatigue, itching, hepatomegaly, high alkaline phophatase and gamma-GT levels. Primary biliary cirrhosis was diagnosed based on the clinical symptoms, laboratory findings, AMA M2 positivity, normal US and ERCP pictures. Liver biopsy revealed stage II/III. There was no family history of liver disease or autoimmune disease, and all other confounding risk factors including alcohol, HBV and HCV infections were excluded. The patient was a heavy smoker. The past surgical history was significant only for an appendectomy and two caesarean sections. Her menopause started at the age of 38. Bone mineral density was slightly below the normal range at the time of diagnosis of PBC. Ursodeoxycholic acid (Ursofalk) treatment, calcium and vitamin D supplementation were introduced.

Severe progression of osteoporosis was observed during the following years. Five years after the diagnosis of PBC significantly decreased bone mineral density was shown both on the femoral neck (T-score: -5.12, Z score: -3.38) and on the lumbar vertebrae (T-score: -5.44, Z-score: -3.9). At the age of

57 despite the calcium, vitamin-D supplementation, calcitonin and bisphophonate (Fosamax) treatment, the severe osteoporosis led to hip fracture and multiple vertebral collapses, which made the patient lifelong disabled.

Progression of PBC to stage IV occured. She was monitored by yearly US, by regular laboratory tests and AFP every 3-4 months. For different reasons we collected blood samples for plasma nociceptin level determination as well. Sampling was done in conformity to accepted ethical standards and was approved by the regional ethical committee.

Hepatocellular carcinoma developed 18 years after the diagnosis of PBC. Regular follow-up US investigations revealed a focal lesion of 2.5 cm in diameter, which increased rapidly in segment V of the liver. Fine needle biopsy findings proved hepatocellular carcinoma. After the HCC diagnosis a continuous and rapid increase in the size of the tumor, an elevation of ALP, GGT, plasma nociceptin and AFP levels and clinical deterioration were observed.

Figure 1 Serum alpha fetoprotein and plasma nociceptin levels before and during the development of hepatocellular carcinoma in the presented patient with primary biliary cirrhosis.

Figure 2 Hepatocellular carcinoma in the presented patient with primary biliary cirrhosis. A: Gross view of liver at autopsy. Grayish nodules of carcinoma protrude on the surface of the cirrhotic liver. Bar=1 cm. B: The focal red staining on the histologic picture of the hepatocellular carcinoma shows the immunohistochemical reaction of AFP. Original magnification 400×.

The AFP value had been within the normal range one year before the tumor was detected (13 ng/mL), but it was elevated at the time of the diagnosis of HCC (426 ng/mL) and rose up to 3 480 ng/ml. The plasma nociceptin measured by radioimmunoassay ^{125}I-Nociceptin-kit, Phoenix Pharmaceuticals, Phoenix, CA, USA (10.6 pg/mL) was within the normal range (9.2±1.8 pg/mL) in the tumor-free stage, while progressive elevation was detected during the tumor development (15.8, 65.8, 103.7, 128.0, 172.2 pg/mL), reaching the highest value before death (Figure 1). Higher nociceptin content was measured in the tumor tissue (0.16 pg/mg) compared to the tumor-free liver tissue sample (0.01 pg/mg) taken during the autopsy. The patient refused any surgical or other systemic or local tumor treatment. The size of the tumor increased up to 12 cm in diameter and involved segments V, VII, VIII and partly IV. No metastasis was detected, but necrosis developed in the central region of the tumor. The patient received supportive treatment, analgetics, and died of tumorous cachexia 19 months after the discovery of HCC. The autopsy confirmed both PBC stage IV and HCC. Focal presence of AFP was shown in the tumor by immunohistochemistry (Figures 2 A and B).

A nociceptin content in the HCC tissue (0.16 pg/mg) was 15-fold higher than that in the tumor free liver tissue sample (0.01 pg/mg) taken during the autopsy.

DISCUSSION

The presented case is a further example of the occurrence of HCC in PBC, and it supports previous observations that HCC usually develops in stage III/IV patients[3]. The tumor developed 18 years after the diagnosis of PBC and led to the death of the patient within two years. Furthermore, severe osteoporosis is a common disorder in PBC, although recently it is considered as a non-specific complication[10,11]. In our patient the early menopause together with PBC resulted in many bone fractures causing lifelong disability. The low serum osteocalcin level indicated a low turnover osteoporosis. High serum osteoprotegerin and low RANKL have been reported in PBC[12], and we found the same alteration in this patient. Progression of bone loss was detected despite the serum osteoprotegerin was two-fold higher than normal, which suggested that inflammatory process in the liver could also contribute to the elevation of osteoprotegerin.

This is the first follow-up case in which progressive elevation of plasma nociceptin level was detected in parallel with the elevation of AFP during tumor development, and high N/OFQ content was found in the tumor tissue.

Nociceptin is the endogenous agonist of a G-protein coupled, naloxon insensitive opioid-like 1 receptor (ORL1) recently named as OP4. Although nociceptin is structurally related to opioid peptides, especially to dynorphin A, it does not interact with μ, δ and κ receptors. N/OFQ/OP4 system is a newly discovered peptide-based signalling pathway, involved in the modulation of pain and cognition. Opioid antagonists were successfully used for the treatment of pruritus in patients with PBC[13]. These results together with the data that high plasma N/OFQ level has been reported in Wilson disease and in patients with chronic pain, led us to measure plasma nociceptin level in primary biliary cirrhosis[14]. Our motivation was reinforced by an accidental observation that we found extremely high N/OFQ in a Wilson patient with advanced HCC.

The nociceptin levels in blood samples collected in the pre-tumor stage and during the tumor development period clearly showed that the elevation of N/OFQ was parallel with that of AFP and the clinical deterioration. When the tumor was first detected the N/OFQ level was 6-fold higher than that in healthy controls (65.8 versus 9.2±1.8 pg/mL, *n*=29) and in other PBC patients without HCC (12.1±3.2pg/mL, *n*=21). When the tumor reached 11 cm the N/OFQ level was 17-fold

higher than normal. Since N/OFQ content was 15-fold higher in tumor tissue than in tumor free parts of the liver, the question arose whether nociceptin was produced by HCC tissue or it accumulated in the tumor by passive binding or via increased nociceptin receptor expression.

Further research is needed to clarify the mechanism and clinical significance of the highly elevated N/OFQ level in HCC. Since N/OFQ transcripts are expressed in immune cells[15], the high N/OFQ level may also be an indicator of altered reaction of the body including immunological, cytokine and other mechanisms.

Elevated N/OFQ level might represent a compensatory mechanism in the N/OFQ/OP4 system to modulate pain perception in the central nervous system. This mechanism could explain why some patients with a very high plasma N/OFQ level did not have pain despite advanced stage of malignant liver tumor. It is remarkable that the N/OFQ was 3-fold higher in our patient than the highest values reported in patients with chronic pain without malignant disease[16].

In conclusion, the novel finding of this study is that progressive elevation of plasma nociceptin was detected in parallel with the elevation of AFP during tumor development, as well as high N/OFQ content was found in the tumor tissue in a PBC patient with hepatocellular carcinoma. This is in concordance with our previous observation that high plasma N/OFQ level might be considered as an indicator of HCC.

Abstract

Cellular response to genotoxic stress is a very complex process, and it usually starts with the "sensing" or "detection" of the DNA damage, followed by a series of events that include signal transduction and activation of transcription factors. The activated transcription factors induce expressions of many genes which are involved in cellular functions such as DNA repair, cell cycle arrest, and cell death. There have been extensive studies from multiple disciplines exploring the mechanisms of cellular genotoxic responses, which have resulted in the identification of many cellular components involved in this process, including the mitogen-activated protein kinases (MAPKs) cascade. Although the initial activation of protein kinase cascade is not fully understood, human protein kinases ATM (ataxia-telangiectasia, mutated) and ATR (ATM and Rad3-related) are emerging as potential sensors of DNA damage. Current progresses in ATM/ATR research and related signaling pathways are discussed in this review, in an effort to facilitate a better understanding of genotoxic stress response.

INTRODUCTION

Cellular response to genotoxic stress is a very complex process. However, it can be "simply" envisioned as a signal transduction cascade in which DNA lesions act as the initial signal that is detected by sensors and passed down through transducers. Eventually the effectors receive the signal and execute various cellular functions (Figure 1). Much knowledge has been gained over the years concerning the signal transducers, and a large group of serine-threonine protein kinases, namely the mitogen-activated protein kinases (MAPKs), along with their upstream kinases, have been shown to play prominent roles in cellular

genotoxic responses[1]. Three major classes of MAPKs, i.e., extracellular signal-regulated kinase (ERK), c-Jun N-terminal kinase/stress-activated protein kinase (JNK/SAPK), and p38 (also known as SAPK2, RK, CSBP, or Mxi2), could all be activated by various genotoxic stresses[1-7]. Although the precise mechanism has not been fully understood, it is known that damage to cellular DNA somehow leads to the activation of a group of serine-threonine kinases called MAPK kinase kinases (MAPKKK, or MEKK, MEK kinase), which phosphorylate the downstream dual-specificity kinases called MAPK kinases (MAPKK, or MEK, MAPK/ERK kinase). These MAPKKs then phosphorylate the threonine and tyrosine residues in MAPKs. This three-component module could be assembled together by scaffold proteins that ensure the efficiency and specificity of each individual MAPK pathway[8-10]. The activated MAPKs then translocate to the nucleus and phosphorylate scores of target proteins, including many transcription factors. Among these transcription factors is the tumor suppressor p53 protein, which plays such an important role in the genotoxic stress response that has earned the reputation as the "universal sensor for genotoxic stress"[2,11,12].

Figure 1 A general schematic representation of cellular responses to genotoxic stress. Ultraviolet (UV), ionizing radiation (IR), and various chemicals can induce DNA damage, such as double strand breaks (DSBs), which can be detected by "sensors". This generates some signal that can be transduced by the transducers to effector molecules. Finally, there is the presence of an attenuation mechanism to control the cellular response to genotoxic stress.

Although studies on MAPKs have provided a lot useful information about signal transducers, the initial sensors for DNA damage remain to be identified. Recently, it has been proposed that some multi-protein complexes that are involved in DNA maintenance or repair, such as the Rad family member Rad1, 9, 17, 26, and Hus1, might function as DNA damage sensors[13-18]. Members of the phosphatidylinositol 3-kinase (PI-3) superfamily, which are activated at the very early stages of DNA damage response, could also serve as sensors, as

well as initiators, of the ensuing cellular genotoxic stress response, including ATM and ATR in humans[19]. Although these proteins share the PI-3-like kinase domain, they could not function as lipid kinases, but rather as serine-threonine protein kinases[14,20-25].

ATM AND ATR

Biochemistry of ATM and ATR
One distinguishing characteristic of the PI-3 family members is their unusually large size, which ranges from around 300 kDa to over 500 kDa. ATM is a 3 056 amino acid (aa) protein while ATR is a 2 644 aa protein, and both have a C-terminal catalytic domain (-300 aa) which is flanked by two loosely conserved domains. Although it has not been known how exactly these two kinases sense the DNA damage, it is clear that both kinases can be activated by DNA damage. However, it has been found that ATM responds primarily to double-strand breaks induced by ionizing irradiation (IR), while ATR also reacts to UV or stalled replication forks[13,14,26-29].

Activation of ATM and ATR
Several mechanisms have been proposed for the activation of ATM and ATR by DNA damage: a) direct activation through interaction with damaged DNA, b) indirect activation through interaction with DNA repair or maintenance proteins, or c) a combination of both[30]. Existing experimental data support the third mechanism, that they are activated both through interactions with DNA and members of the repair complexes. For example, ATM could bind directly to DNA. Furthermore, pre-treatment of DNA-cellulose matrix with IR or restriction enzymes could stimulate ATM binding, suggesting that ATM binds to DNA ends[31,32]. ATR could also bind to DNA, with a higher affinity to UV-damaged than undamaged DNA. In addition, damaged DNA could stimulate the kinase activity of ATR to a significantly higher level than undamaged DNA[33,34]. ATM and ATR also interact with many proteins that co-localize at the site of DNA damage. For example, ATM as a part of a super protein complex called BRCA1-associated genome surveillance complex (BASC), is involved in the recognition and repair of aberrant DNA structures. It has been found this complex contains several other proteins such as breast cancer gene 1 (BRCA1), mismatch-repair protein hRad50, and BLM helicase[35]. ATM could bind to histone deacetylase HDAC1 both *in vitro* and *in vivo*, and the extent of this association was increased after exposure of MRC5CV1 human fibroblasts to IR[36]. ATR was also able to bind to Rad17[37] and BRCA1[38], and associated with components of the nucleosome remodeling and deacetylating (NRD) complex such as chromodomain-helicase-DNA-binding protein 4 (CHD4) and histone-deacetylase-2 (HDAC2)[39]. All these data support the model that multiple checkpoint protein complexes localize at the sites of DNA damage independently and interact to trigger the checkpoint-signaling cascade.

Interaction with c-Abl
c-Abl, a non-receptor tyrosine kinase that is ubiquitously expressed and localized in both nucleus and cytoplasm, could be up-regulated following exposure to IR or genotoxic chemicals such as cisplatin, methyl methane sulfonate (MMS), mitomycin-C, hydrogen peroxide, but not UV[3,40-42]. IR-induced activation of c-Abl has been shown to require the involvement of ATM in some cases, with ATM phosphorylating serine residue 465 located within the kinase domain of c-Abl[43-45]. However, other studies found that c-Abl was not essential for ATM function in chromosomal maintenance, suggesting that c-Abl and ATM are at least partially independent[46].

An important effect which has been found following the activation of c-Abl, is the induction of cell cycle arrest in a p53-dependent manner, with the possible involvement of Rb, but not p21[Cip[47,48]. c-Abl could directly interact with and phosphorylate p53, and regulate the level of p53 by preventing its nuclear export and ubiquitination-dependent degradation[49,50]. It could also induce apoptosis in response to DNA damage[51,52], although this activity involved collaboration with p73 more than p53[53-55]. c-Abl binds to p73 through its Src-homology (SH3) domain to phosphorylate p73 at tyrosine residues, which in turn activates p73-dependent apoptosis pathway.

Regulation of the tumor suppressor p53 protein
Since p53 is such an important mediator in cellular response to genotoxic stress, it is no wonder that ATM/ATR can regulate p53 activity at multiple levels (Figure 2). The most straightforward way to manage p53 is through direct interaction, e.g., phosphorylation of p53. Both ATM and ATR have been shown to phosphorylate p53 protein at serine 15 to enhance its transactivating activity[56-59]. ATM is also required for dephosphorylation of Ser 376, which can create a binding site for 14-3-3 protein. The association of p53 and 14-3-3 could increase the affinity of p53 for its specific DNA sequence, therefore enhancing its transcriptional activity[60]. Other sites that could be phosphorylated by ATM on p53 include Ser 6, 9, 46, and Thr 18, which may be important for the apoptotic activity of p53 (Ser 46) or may enhance the acetylation of p53 (Ser 6, 9, Thr18)[61]. In addition, ATM/ATR could regulate p53 through the action of other kinases. For example, ATM-activated c-Abl could phosphorylate p53 at Ser 20, which is important for the stabilization of p53 since this modification interferes with the binding between p53 and its regulator murine double minute 2 (Mdm2)[49,62]. ATM-activated Chk2 could also phosphorylate p53 protein at Ser 20 and possibly at other sites, leading to the activation of p53[63-65]. Furthermore, ATM has been found able to bind and phosphorylate Mdm2 and HDM2 (the human homologue of Mdm2), thus inhibiting p53 degradation and promoting its accumulation in cells[66-68].

Figure 2 Regulation of p53 protein by ATM and ATR. ATM and ATR can influence the activity of p53 directly through phosphorylation or indirectly through the action of other kinases. Furthermore, ATM can regulate p53 through phosphorylation of Mdm2 molecule, the negative regulator of p53, which can be up-regulated by p53.

Activation of MAPKs
Accumulative data support the notion that the activation of MAPKs in response to genotoxic stress is ATM/ATR dependent. For example, DNA damaging stimuli, including etoposide (ETOP), adriamycin (ADR), IR, and UV could activate ERK1/2 in primary (MEF and IMR90), immortalized (NIH3T3) and transformed (MCF-7) cells. It has further been shown that ERK activation in response to ETOP could be

Figure 3 The relationship between ATM and carcinogenesis.

abolished in ATM-/- fibroblasts (GM05823) independently of p53[69]. UVA (320-400 nm) triggered ATM-dependent p53 phosphorylation and JNK activation that resulted in apoptosis, while ATR was required for UVC (200-290 nm)-mediated p53 phosphorylation and JNK activation[70]. In addition, activation of ATM by gamma irradiation could lead to the activation of MKK6 and p38γ isoform, and that activation of both MKK6 and p38γ was essential for the proper regulation of G2 checkpoint in mammalian cells[71].

Although the link between ATM/ATR and MAPKs has been established, it is still not clear how ATM/ATR activates MAPKs. In general, MAPK pathways are activated by extracellular signals or signals generated in the cytoplasm, and then the activated MAPKs transduce the specific "messages" to the nucleus. However, in response to genotoxic stress, the signal seems to flow from the nucleus to the cytoplasm to activate MAPKs. In this case, c-Abl kinase may provide an explanation. It has been found that c-Abl can activate p38 through MKK6[72-74], and JNK by translocating from nucleus to cytoplasm to phosphorylate hematopoietic progenitor kinase (HPK1), an upstream kinase of JNK[75]. Therefore, c-Abl may fulfill a role as the message carrier to transduce signals between subcellular locations. This may further explain why in response to genotoxic stress the activation of p38 was rather late (- 1 h) and prolonged[71], while the cytokine activation of p38 was rapid and transient (maximum around 30-60 min)[76].

In addition to their ability to activate MAPKs, ATM/ATR may also regulate these kinases through their negative regulators, the dual specificity of phosphatase MAPK and phosphatase family (MKP). One member of the MKP family, MKP-5, is known to dephosphorylate and inactivate the stress-activated JNK and p38. The phosphorylation-dephosphorylation cycle of JNK and p38 stimulated by radiomimetic chemical neocarzinostatin (NCS), which can induce double strand breaks (DSBs), could be attenuated in A-T cells[77], further emphasizing the role of ATM as a master regulator in the cellular response to genotoxic stress.

Mutations in ATM in association with cancer

Homozygous mutations in the ATM gene can cause human genetic disorder ataxia-telangiectasia (A-T), which is characterized by cerebellar degeneration, immunodeficiency, cancer predisposition, and acute sensitivity to IR. The affected individual has been found to be prone to develop T cell pro-lymphocytic leukemia, B cell chronic lymphocytic leukemia, as well as sporadic colon cancer with microsatellite instability[78]. *Atm*-deficient mice also showed a striking predisposition to lymphoid malignancies, particularly thymic lymphomas, to which they succumbed before the age of 1 year. However, much of the literature on *ATM* mutations and cancer was not about A-T patients, but was, instead, on heterozygous carriers of A-T mutations. For example, recent studies have found an unusually high occurrence of breast cancer in the relatives of A-T patients, and that loss of heterozygosity of ATM occurred frequently during the early stages of breast cancer development[79].

Furthermore, heterozygous mice were more sensitive to radiation-induced cataracts than their wild-type counterparts[80]. Spring *et al*, established a knock-in mouse mutant in which an inframe deletion was previously found to cause A-T in humans was induced. Mice homozygous for this mutation could produce small amounts of inactive ATM and usually showed the hallmarks of the *Atm*-knockout phenotype. Notably, mice heterozygous for this mutation were predisposed to various cancers, unlike the animals that carry a single knockout allele that does not produce any protein[81]. Therefore, ATM heterozygotes in human population might also be more radiosensitive, and have a higher risk for cancer[82](Figure 3).

No human disease has been found to link to defects in ATR, although it was found that defects in ATR led to embryonic lethality in mice, suggesting that ATR is essential for of development of ATR[83,84]. Nonetheless, it is known that over-expressing the inactive form of ATR had a dominant negative effect, causing increased sensitivity to DNA damaging stimuli and failure to activate cell cycle checkpoints in response to IR[28,85]. Finally, over-expressing active ATR could restore S phase checkpoint defect in A-T cells, suggesting that ATM and ATR may complement each other in the cellular genotoxic stress response[85].

Down-regulation of ATM and ATR

Once the sensors detect DNA damage and initiate the signaling pathway, and the biological consequences (including DNA repair, cell cycle arrest, and apoptosis) take effect, the signals need to be inactivated or attenuated. The regulation of some downstream components in the cellular genotoxic stress response has been rather clearly defined, and usually involves a negative feedback mechanism. One such example is the p53-Mdm2 regulation loop. In this loop p53 could activate the expression of Mdm2, and Mdm2 could mediate the rapid degradation of p53 through the ubiquitin pathway[62]. MAPKs have a similar feedback regulation mechanism with MKPs. MAPKs could induce the expression of MKPs, and MKPs then could interact with specific MAPKs to deactivate them through dephosphorylation[1]. On the other hand, the mechanisms for the regulation of ATM and ATR, remain obscure, although some recent studies have significantly advanced our understanding.

In contrast to the vast volume of reports about the activation of ATM under genotoxic stress, very few studies have been conducted to evaluate how ATM was inactivated. The results from these studies so far all pointed toward inactivation of ATM through Caspase-mediated cleavage during apoptosis[86-88]. This same mechanism has also been shown to regulate many other proteins involved in apoptosis, including serine/threonine protein kinase Cδ (PKCδ), Mdm2, PARP, replication factor C, 70 kDa U1snRNP, fodrin and lamins[87]. It was reported that during apoptosis induced by c-Myc or DNA-damaging agents (such as etoposide or IR), ATM but not ATR, was specifically cleaved by members of the Caspase family. Detailed studies revealed that the Caspase responsible for this

cleavage was either Caspase-3 or -7, but not Caspase-6. This cleavage abrogated the kinase activity of ATM to phosphorylate p53, although the resulting two fragments retained their DNA binding ability and interacted with each other. This finding led to the hypothesis that cleaved ATM protein, without its kinase activity, might act in a trans-dominant-negative fashion to compete with the intact ATM, thus preventing DNA repair and DNA damage signaling through its binding to DNA[86-88].

Even less information is available regarding the inactivation of ATR. However, the recent identification of an ATR-interacting protein (ATRIP) might provide a lead for future studies[89]. ATRIP is an 86-kDa protein with a coiled-coil domain near its N-terminal and its expression is regulated by ATR. The deletion of ATR mediated by Cre recombinase could cause the loss of both ATR and ATRIP expression, along with the loss of DNA damage checkpoint responses and cell death. ATRIP could be phosphorylated by ATR and co-localized at intranuclear foci with ATR after DNA damage caused by hydroxyurea (HU), IR, or UV, or inhibition of DNA replication. Conversely, ATRIP could also regulate the expression of ATR, as inhibition of ATRIP expression with small interference RNA (siRNA) would result in decreased ATR protein expression, while ATR mRNA levels would not be affected. Interference with ATRIP function could cause the same loss of G2-M response to DNA damage as that seen in the case of ATR deletion, suggesting that these two proteins work as mutually dependent partners in cell cycle checkpoint pathways[89].

CONCLUSION

Human cancer is a major health issue for society, causing millions of deaths each year and huge economical losses. Since most of human carcinogens are genotoxins[90,91], considerable resources have been and are being expended in efforts to understand the mechanism of genotoxin-induced carcinogenesis, thus leading to a better prevention or even the treatment of cancer. Since the sensing of DNA damage is one of the earliest steps in the cellular response to gentoxic stress, identification of these "sensors" is the most prominent challenge. As discussed in this review, ATM and ATR are showing their promise as potential candidates. However, what we should keep in mind is that detection of DNA damage may not be such a simple process, and may require more than just one or two proteins to fulfill this role. Supporting this idea is the finding of "foci" at damaged DNA sites, where many proteins involved in DNA repair and maintenance aggregate. It is more likely that interactions of these proteins, combined with some unidentified factors might function as DNA damage sensors[92]. Further elucidation of these "foci" will be an exciting area for future research.

Abstract

AIM: To study the effect of staurosporine (ST) on the cell
cycle of human gastric cancer cell lines MGC803 and
SGC7901.

METHODS: Cell proliferation was evaluated by trypan blue
dye exclusion method. Apoptotic morphology was observed
under a transmission electron microscope. Changes of cell
cycle and apoptotic peaks of cells were determined by flow
cytometry. Expression of $p21^{WAF1}$ gene was examined using
immunohistochemistry and RT-PCR.

RESULTS: The growth of MGC803 and SGC7901 cells was
inhibited by ST. The inhibitory concentrations against 50%
cells (IC_{50}) at 24 h and 48 h were 54 ng/ml and 23 ng/ml for
MGC803, and 61 ng/ml and 37 ng/ml for SGC7901. Typical
apoptotic bodies and apoptotic peaks were observed 24 h
after cells were treated wth ST at a concentration of 200
ng/ml. The percentage of cells at G_0/G_1 phase was decreased
and that of cells at G_2/M was increased significantly in the
group treated wth ST at the concentrations of 40 ng/ml,
60 ng/ml, 100 ng/ml for 24 h, compared with the control
group ($P<0.01$). The expression levels of $p21^{WAF1}$ gene in
both MGC803 and SGC7901 cells were markedly up-regulated
after treatment with ST.

CONCLUSION: ST can cause arrest of gastric cancer cells
at G_2/M phase, which may be one of the mechanisms that
inhibit cell proliferation and cause apoptosis in these cells.
Effect of ST on cells at G_2/M phase may be attributed to the
up-regulattion of $p21^{WAF1}$ gene.

INTRODUCTION

Protein kinase C (PKC) isoforms are serine/threonine kinases
involved in signal transduction pathways that govern a wide
range of physiological processes including differentiation,
proliferation, gene expression, membrane transport and
organization of cytoskeletal and extracellular matrix proteins[1].
PKC isoforms are often overexpressed in disease states such
as cancer. The important role they play in the processes relevant
to neoplastic transformation, carcinogenesis and tumor cell
invasion renders PKC a potentially suitable target for anticancer
therapy[2].

Staurosporine (ST), a microbial alkaloid (indolocarbazole
produced by *Streptomyces sp.*), has been shown to be a potent
inhibitor of a wide range of protein kinases, including different
serine/threonine and tyrosine protein kinases, which acts by
competing with the ATP-binding region of the kinase catalytic
domain[3]. Staurosporine has been reported to exert various
pharmacological actions involving protein kinase C both *in vivo*
and *in vitro*, such as diminishing thrombin enhanced procoagulant
activity, reducing carbachol-induced insulin secretion[4-7]. PKC
function is altered in some neoplasias, and this dysfunction
has been related to uncontrolled proliferation[8,9].

Completion of the cell cycle requires the coordination of
a variety of macromolecular syntheses, assemblies, and
movements[10]. Coordination of the timing and order of these
processes are achieved by a regulatory system that responds
to checkpoints at major transitions in the cycle. Two key
checkpoints are at the G_1/S and G_2/M phase transitions. G_1 and
G_2 cyclins, the cyclin-dependent kinases and cycle kinase
inhibitors (CKI) are responsible for controlling the transitions.
Here, we investigated the effect of the potent phospholipid/
Ca^{2+}-dependent kinase (PKC) inhibitor, ST, on cell cycle of
human gastric cancer cell lines, MGC803 and SGC7901.

MATERIALS AND METHODS

Cell lines and cell culture
Human gastric mucinous adenocarcinoma cell line, MGC803,
was obtained from Department of Immunity, China Medical
University and human gastric carcinoma metastatic lymph node
cell line, SGC7901, was obtained from Laboratory of
Oncology, the First Affiliated Hospital of China Medical
University. The derived cell lines were grown in RPMI 1640
medium supplemented with 10% heat-inactivated fetal calf
serum, 50 U/ml penicillin and 50 µg/ml streptomycin. The
cells were maintained at 37 ℃ in a humidified atmosphere
containing 5% CO_2. Viability of the cells used in these
experiments was consistently more than 95% when evaluated
by the trypan blue exclusion method. Staurosporine was
purchased from Sigma Company (St. Louis, USA).

Analysis of cell viability
Effect of ST on cell growth and viability was measured by
directly counting the number of cells by means of trypan blue
dye exclusion. Cells at a density of $2.5×10^5$/ml were seeded
onto 24-well plates, and then treated with ST at different
concentrations for 24 and 48 h. Control cells were also cultured
at the same time. Cell proliferation and inhibition curves were
drawn, and the inhibitory concentration against 50% cells (IC_{50})
was determined.

Cell morphological analysis with transmission electron microscope
Transmission electronic microscope was employed to observe

the effect of ST on cell apoptosis. Cells (1×10^6) were collected after being treated with ST at 200 ng/ml for 24 h, washed twice with PBS solution, centrifuged for 5 min at 1 500 rpm, then fixed in 2% glutaraldehyde at 4 ℃ for 72 h, then placed in 1% phosphotungstic acid. The cells were desiccated with gradients, and embedded with EPON-812. Ultrathin sections were prepared and observed after double staining with uranium and plumbum under a transmission electron microscope. Each experiment was repeated four times. At the same time, the cells without treatment with ST were used as a control group.

Cell cycle analysis

Flow cytometry was employed to determine the DNA content and the apoptotic peaks of the cells. The cells were seeded on 100 mm-dishes and grown in RPMI-1640 supplemented with 10% FCS. After treated with ST at the concentrations of 40 ng/ml, 60 ng/ml, 100 ng/ml, 200 ng/ml, 500 ng/ml for 24 h respectively, the cells were harvested, trypsinized, washed with D-PBS, fixed by adding slowly 2 ml of cold 70% ethanol into the tube and then stored at 4 ℃. After fixation, the cells were washed, centrifuged, and resuspended in 0.05 mg/ml propidium iodide (Fluka Co, MILWAUKEE, USA), 100 units/ml RNase (Fluka Co, MILWAUKEE, USA) in PBS. The sample was incubated at room temperature for 30 min, and analyzed on a FACSCalibur (BD PharMingen, FRANKLIN Lakes, USA). Cell cycle data originally obtained with Cell Quest software (BD PharMingen, FRANKLIN Lakes, USA) were re-analyzed using MODFIT software (Verity Software House, Topsham, USA). At the same time negative controls were constructed.

Immunohistochemistry

p21 protein was detected by immunohistochemistry using specific monoclonal antibody (Maxin Co, Fuzhou, China). After treated with ST at the concentrations 40 ng/ml, 60 ng/ml, 100 ng/ml for 24 h, respectively, the cells were harvested. At the same time the negative controls were constructed. The cells were smeared on a slide with cell smear centrifugal apparatus, and stained using conventional S-P immunohistochemical method. Color was developed with DAB reagent and counterstained with hematoxylin. The cells were observed under a light microscope. The cells clearly showing brown color in their nuclei and plasma were considered to be positive for p21 protein.

Semiquantitative reverse transcription-PCR

The expression of p21 mRNA was determined by RT-PCR. After treated with ST at the concentration of 60 ng/ml, the cells were harvested. At the same time the negative controls were constructed. The cells were washed, and total RNA was extracted with the Qiagen RNA isolation kit (GIBCO Co., New York, USA). Aliquots containing 5 μg/ml of RNA from each treatment were used for the first-strand cDNA synthesis (TaKaRa Co., Dalian, China). In each reaction, 100 μl solution containing 3 μM of random hexamers, 25 mM Tris-HCl, 37 mM KCl, 1.5 mM MgCl$_2$, 10 mM DTT, 0.25 mM dNTP, 40 units of RNAsin,an RNase inhibitor, 50 U/ml Super Taq DNA polymerase, and 200 units of reverse transcriptase was used. The annealing mixture was incubated at room temperature for 15 min, and then incubated in a water bath at 41 ℃ for 60 min. The reverse transcriptase enzyme was inactivated by heating the solution to 95 ℃ for 5 min. PCR was then carried out using the Perkin-Elmer PCR reaction kit and primers. The PCR was performed using a thermocycler for 30 cycles consisting of denaturation at 94 ℃ for 1 min, annealing at 57 ℃ for 1 min, and extension at 72 ℃ for 2 min. The PCR products were separated on 2% agarose gel. The primers used for PCR were as follow: p21 sense (5'-GGG GAC AGC AGA GGA AGA C-3'), p21 antisense (5'-CGG CGT TTG GAG TGG TAG A-3'); β-actin sense (5'-GAT TGC CTC AGG ACA TTT CTG-3'), β-actin antisense (5'-GAT TGC TCA GGA CAT TTC TG-3'). Gene primers were synthesized by Beijing Oake Company (Beijing, China).

Statistical analysis

Student's t-test was used to compare the difference between control and ST treated groups. Data of cell growth were presented as $\bar{x}\pm s$. A P value less than 0.05 was considered statistically significant.

RESULTS

ST inhibited proliferation of MGC803 and SGC7901 cells in a time-dependent and concentration-dependent manner

In this study, the exponentially grown MGC803 and SGC7901 cells were treated with 40 ng/ml, 60 ng/ml, 100 ng/ml ST, respectively, and the cell proliferation was measured 24 and 48 h after ST addition. Figures 1 and 2 show the cell proliferation curves at various ST concentrations. The inhibition of proliferation of MGC803 and SGC7901 cells by ST was clearly observed in a time-dependent and concentration-dependent manner. The IC$_{50}$ was 54 ng/ml and 23 ng/ml for MGC803 and 61 ng/ml and 37 ng/ml for SGC7901 at 24 and 48 h.

Figure 2 Inhibition of staurosporine on SGC-7901 cell proliferation.

Morphological observation of ST treatment effects

Cell morphological changes were observed under a transmission electron microscope after treatment with ST at the concentration of 200 ng/ml for 24 h. The ultrastructural appearances showed the typical changes in the cell morphology, including blebbing of the plasma membrane, chromatin condensation and formation of apoptotic bodies. Figure 3 shows the morphological changes of MGC803 and SGC7901 cells under a electron microscope after treatment with ST.

Figure 5 Expression of p21 protein in MGC803 and SGC7901 cells after ST-treatment as determined by immunohistochemistry (SP×400). A: MGC803 control cells, B: MGC803 cells treated with 60 ng/ml ST, C: SGC7901 control cells, D: SGC7901 cells treated with 60 ng/ml ST.

ST induced MGC803 and SGC7901 cells G_2/M phase arrest

The effects of ST on cell cycle progression, population distribution and apoptotic incidence in` MGC803 and SGC7901 cells were determined using flow cytometry. ST-induced effects were detected by comparing the cell cycle profiles between ST treated and untreated cells. Notably, the cells demonstrated significant G_2/M arrest 24 h after ST treatment ($P<0.01$), in comparison to untreated cells. Interestingly, the S phase population was also increased, but to a lesser extent as compared with untreated cells. The percentage of cells in the S, G_1, and G_2/M phases are shown in Table 1. Apoptotic peaks were observed and cell apoptotic incidence was determined 24 h after treatment with ST at the concentrations of 200 ng/ml and 500 ng/ml. The apoptotic incidence increased to 50.2% and 89.6% in MGC803 cells, and 34.6% and 80.7% in SGC7901 cells after ST treatment. Figure 4 shows ST-induced apoptosis in MGC803 and SGC7901 cells.

ST resulted in an increase of p21 expression

The effect of ST on p21 protein levels was determined by immunohistochemistry analysis. Normally, p21 was not expressed in MGC803 and SGC7901 cells. However, p21 was significantly expressed, the positive rates were 19.3%, 26.6%, 31.8% in MGC803 cells, and 20.5%, 24.2%, 30.3% in SGC7901 cells after treatment with ST at the concentration 40 ng/ml, 60 ng/ml, 100 ng/ml for 24 h. Figure 5 shows the

levels of p21 expression in MGC803 and SGC7901 cells by immunohistochemistry.

Figure 6 Effect of ST treatment on p21[WAF1] mRNA expression in MGC803 cells. M: DNA Marks, 1: control cells, 2: cells treated with 60 ng/ml ST.

ST upregulated p21[WAF1] expression

Normally, *p21[WAF1]* mRNA was almost not expressed in MGC803 and SGC7901 cells when detected by RT-PCR. However, treatment with ST at the concentration of 60 ng /ml induced the upregulation of *p21[WAF1]* mRNA in MGC803 and SGC7901 cells. Figures 6 and 7 show that *p21[WAF1]* mRNA expression was upregulated in MGC803 and SGC7901 cells after treatment with ST.

Figure 7 Effect of ST treatment on p21^{WAF1} mRNA expression in SGC7901 cells. M: DNA Marks, 1: control cells, 2: cells treated with 60 ng/ml ST.

DISCUSSION

Cancer cells have been found to be different from normal cells in many important characteristics, including loss of differentiation and decrease of apoptosis[11,12]. These differences did not arise simply from uncontrolled cellular growth but rather from a process of cellular evolution[13-15]. Cell cycle plays an important role in the modulation of tumor cell growth, and attention has been paid to preventing unlimited proliferation of tumor cells by cell cycle control[16].

Twenty years ago, staurosporine (ST) was isolated from bacteria and identified as a potent inhibitor of PKC activity[17-19]. In this study, the proliferation of human gastric cell lines, MGC803 and SGC7901, was significantly inhibited in a time- and concentration-dependent manner and classical apoptosis (sub-diploid peak on flow cytometry, and typical morphological changes) was observed after treated with ST. ST also blocked the G$_2$/M phase of the cell cycle. In order to examine the distribution of DNA content, the cells treated with ST were detected using flow cytometry. The first peak (2C C=haploid DNA content) was produced by the cell population in G$_1$ phase, the second (4C) was produced by the cells in G$_2$/M phase with or without cells in G$_1$ phase at a higher DNA ploidy (tetraploidy, G$_{1t}$), and the third (8C) was produced by cells in G$_2$ phase at a higher DNA ploidy (tetraploidy, G$_{2t}$). The results presented in this study indicated that the cells were blocked in G$_2$/M phase. These results lead to the suggestion that, ST can make damaged cells stagnate at G$_2$/M phase of cell cycle, and inhibit proliferation of cells, allowing them to repair the damage. If this happens, cells will reenter the cycle, otherwise, they will undergo apoptosis or death. More importantly, ST affects the selectively on G$_2$/M phase of these cells and participates in the regulation of the cell cycle, and thus the blocking effect of ST on cells in G$_2$/M phase might be the mechanism of its antitumor effect. These observations may provide some useful information that ST can be used as an antitumor agent.

The present study was undertaken to delineate the mechanism of ST effect on the G$_2$/M phase arrest of cells, and techniques including inmmunohistochemistry and RT-PCR were used to detect the expression of *p21^{WAF1}* protein and gene. Our results revealed that *p21^{WAF1}* expression was low in MGC803 and SGC7901 cells. However, ST significantly increased the expression of p21 in MGC803 and SGC7901 cells. Cell cycle events, including microtubule dynamics, membrane organization and DNA synthesis, were tightly controlled, and specific changes were induced at particular points in the eukaryotic cell cycle during cell proliferation[20,21]. Negative controls on cell cycle progression were exerted during development, differentiation, senescence, and cell death. These negative controls might play an important role in preventing tumorigenesis. *p21^{WAF1}*, the pioneer member of p21 family of cyclin-CDK inhibitor class of proteins, has been implicated as a growth arrest mediator in cell terminal differentiation and

apoptosis[22]. Regulation of cell cycle progression is orchestrated by a family of CDKs, which can be negatively regulated by CDK inhibitors, such as *p21^{WAF1}*. *p21^{WAF1}* is a downstream effector of p53 that mediates both G$_1$ and G$_2$/M phase arrest. Mechanistically, the *p21^{WAF1}*-mediated arrest of the G$_2$/M cell cycle transition has been suggested to include a *p21^{WAF1}*-CDK2 and *p21^{WAF1}*-PCNA protein interaction[23,24]. p21 is the strongest kinase inhibitor, and has been found to inhibit the CDK4/6-cyclinD complex when overexpressed, leading to growth arrest and, under some conditions, to apoptosis[25-27]. Although our knowledge on cell cycle checkpoints is still limited, it is clear that many such control points existed within the cell cycle and that they played a major role in maintaining the integrity of the genome[28,29]. At least two checkpoints could detect DNA damage, one at the G$_1$-S transition and another at the G$_2$-M transition[30-32]. ST up-regulates *p21^{WAF1}*, which then affects cell growth by repressing G$_2$/M phase, probably through interaction with cyclin-CDK complex. However, this hypothesis needs to be further investigated.

In conclusion, the present study demonstrates that ST can effectively inhibit the proliferation of human gastric cancer MGC803 and SGC7901 cells, induces apoptosis, blocks these cells in G$_2$/M phase, and up-regulates the *p21^{WAF1}* expression. This study provides some experimental data for the use of ST in the treatment of gastric carcinoma.

Abstract

AIM: To observe the effect of β-ionone on the proliferation of human gastric adenocarcinoma cell line SGC-7901 and the inhibition of metalloproteinase.

METHODS: Using growth inhibition, Zymograms assays and reverse transcription-polymerase-chain reaction (RT-PCR), we examined cell growth rates, activities of matrix metalloproteinases-2 (MMP-2) and -9 (MMP-9), and expression of metalloproteinases-1 (TIMP-1) and -2 (TIMP-2) in SGC-7901 cells after the treatment with β-ionone for 24 h and 48 h, respectively.

RESULTS: β-ionone had an inhibitory effect on the growth of SGC-7901 cells. Eight days after the treatment with β-ionone at concentrations of 25, 50, 100 and 200 μmol/L, the inhibition rates were 25.9%, 28.2%, 74.4% and 90.1%, respectively. The IC_{50} value of β-ionone for SGC-7901 cells was estimated to be 89 μmol/L. The effects of β-ionone on MMP-2 and MMP-9 activities in SGC-7901 cells were not observed. However, the levels of TIMP-1 and TIMP-2 transcripts were elevated in cells treated with β-ionone in a dose-dependent manner.

CONCLUSION: β-ionone can inhibit the proliferation of SGC-7901 cells, upregulate the expression of TIMP-1 and TIMP-2 expression, and may influence metastasis of cancer.

INTRODUCTION

Epidemiological data showed that regular consumption of fruits and vegetables was associated with a reduced risk of chronic diseases such as cancer and cardiovascular diseases[1-4]. Isoprenoid is an important group of nutritious elements found in fruits, vegetables and cereal grains, giving rise to about 22 000 secondary products during its metabolism in these plants. It has been found that these compounds shared a common precursor, mevalonic acid[14]. Isoprenoids have been shown to suppress chemically-induced carcinogenesis[5-10] and the growth of cancer cells[11-13]. β-ionone, an end-ring analog of β-carotenoid, represents a subclass of cyclic isoprenoids and has been demonstrated to have an anticancer effect[15]. β-ionone was effective in chemoprevention of 7,12-dimethylben[a] anthracene-induced mammary carcinogenesis in SD rats, with its tumor multiplicity reduced by 45%[16]. It has also been found to be associated with growth inhibition of melanoma and breast cancer cells as well as metastasis of tumor cells[17-20]. However, the exact mechanisms remain to be clarified, and the effect of β-ionone on gastric cancer cells is unknown.

Chemoprevention has been an approach to treat advanced cancers[21-25]. Gastric cancer is one of the most common malignancies in China and in other parts of the world[26-34]. Understanding the mechanisms of the possible inhibitory effect of β-ionone on proliferation of gastric adenocarcinoma cells could provide a way to prevent this disease. Therefore, in this study, we studied the effect of β-ionone on the proliferation of human gastric adenocarcinoma cell line SGC-7901 and on the regulative factors of tissue metalloproteinases and investigated the underlying mechanism.

MATERIALS AND METHODS

Cell culture

Human gastric adenocarcinoma cell line SGC-7901, provided by Beijing Cancer Research Institute, was grown in RPMI 1640 medium (Gibco BRL, Life Technologies Inc, Gaithersburg, MD, USA), supplemented with 100 ml/L calf serum, 100×10^3 U/L penicillin and 100 mg/L streptomycin at 37 ℃ in a humidified atmosphere containing 5% CO_2.

IC50 and cell growth assessment

β-ionone (purity>95%) (Sigma, USA) was dissolved in absolute ethanol and further diluted to the concentrations of 25, 50, 100 and 200 μmol/L, respectively.

The SGC-7901 cells were seeded into six 24-well plates (Nuc, Denmark) with 2×10^4 cells/well after 24 h culture. Twenty-four hour later, the medium was replaced with the media supplemented with at different concentrations of β-ionone. In the next 8 days, the cells were treated with a trysin-EDTA solution at 37 ℃ for 2 minutes and harvested from 3 wells per day for each plate. The cells were pelleted by a short spin at 1 000 g and resuspended in phosphate-buffered saline (PBS). Typan blue exclusion test was used to count viable cells by a hemocytometer. The number of cells at 24 h was deducted from the final cell counts to provide an estimate of the net increase. The β-ionone concentration required to inhibit the net increase in the 48 h cell count by 50% (IC_{50}) was measured by plotting data obtained from three or more times. The means were obtained on each of the eight days and used to draw a cell growth curve. The inhibitory rate (IR) was calculated according to the formula: IR (%) = (total number of cells in

negative control - number of cells in test group)/total number of cells in negative control ×100%.

Zymograms assay for activities of gelatinase

Although many kinds of proteinase are involved in tumor metastasis, members of the matrix metalloproteinase (MMPs, gelatinase) and TIMP families, play a pivotal role in these events. MMPs are a group of zinc-dependent endopeptidase molecules that have the potential to degrade proteins of the extracellular matrix. MMP activity was under regulation at several levels, including activation of the MMP zymogens and specific inhibition by the tissue inhibitors of metalloproteinase (TIMPs)[54]. We determined the activities of gelatinase in SGC-7901 cells treated with β-ionone.

The SGC-7901 cells were seeded in 100 ml bottles, each containing 5×10^6 cells. After incubation for 24 h, the medium was replaced with 400 μL of serum-free medium supplemented with β-ionone at different concentrations for 24 h and 48 h. The serum-free media were loaded onto a 100 g/L SDS-polyacrylamide gel co-polymerized with 1 g/L gelatin (Amresco Corp, USA) and separated under a non-denaturing condition for 3-4 h. Then, the gels were incubated in 25 g/L Triton X-100 (Sigma, USA) for 1 h and subsequently in a substrate buffer (50 μmol/L Tris, pH 7.5, containing 10 mmol/L $CaCl_2$, 200 mmol/L NaCl and 1 μmol/L $ZnCl_2$) for 12 to 16 h at 37 ℃. Finally, the gels were stained in a solution containing 1 g/L Commassie blue R250, 450 g/L methanol and 100 g/L acetic acid, and the gelatinolytic activity was indicated by bands in a blue background.

RT-PCR

Tissue inhibitor of TIMP-1 and TIMP-2 were related to several tumorigenic processes in lung, stomach, and mammary gland[56]. We examined the expression of TIMP-1 and TIMP-2 in SGC-7901 cells exposed to different concentrations of β-ionone.

SGC-7901 cells (5×10^6) were incubated at different concentrations of β-ionone for 24 h and 48 h, the total cellular RNA was isolated. Concentrations and purity of total RNA were determined. RT-PCR was performed following the manufacturer's instructions (Takara Biotech, Dalian, China). Total RNA (5 μg) and AMV reverse transcriptase XL were used to synthesize cDNA. Twenty-five μL PCR mixture containing 4 μL of RT reaction product, 2.5 U *Taq* DNA polymerase and 20 pmol primers, was heated for 5 min at 94 ℃ for pre-denaturation, and then subjected to 35 PCR cycles, denaturation at 94 ℃ for 30 s, annealing at 60 ℃ for 30 s for and extension at 72 ℃ for 45 s, in a PTC-100 thermocycler (MJ Research, USA). TIMP-1 and TIMP-2 genes were amplified with specific primers, with the gene for β-actin as an internal control (Table 1). The amplified products were resolved in a 20 g/L agarose gel containing ethidium bromide, and visualized under ultraviolet light. The density and area of each band were analyzed using the ChemiImager™ 4 000 digital system (Alpha Innotech Corp, USA).

Table 1 Primer sequences and size of TIMP-1 and TIMP-2 in expected PCR products for RT-PCR

Genes	Primer sequences	Product size (bp)
TIMP-1	Sense: 5'-CTGTTGGCTGTGAGGAATGCACAG-3'	106
	Antisense: 5'-TTCAGAGCCTTGGAGGAGCTGGTC-3'	
TIMP-2	Sense: 5'-AGACGTAGTGATCGGGCCA-3'	490
	Antisense: 5'-GTACCACGCGCAAGAACCT-3'	
β-actin	Sense: 5'-AAGGATTCCTATGTGGGC-3'	532
	Antisense: 5'-CATCTCTTGCTCGAAGTC-3'	

Statistical analysis

Student' *t* test was used for analysis of data. *P*<0.05 was considered statistically significant.

RESULTS

Cell growth inhibition of b-ionone

The inhibitory effect of β-ionone on the growth of SGC-7901 cells was shown in Figure 1. Growth of the cells in the media containing 200 μmol/L and 100 μmol/L β-ionone was markedly slower than that of the negative control within 8 d (*P*<0.01). The change was less obvious the cells treated with 50 μmol/L and 25 μmol/L of β-ionone. The inhibitory rates were 25.9%, 28.2%, 74.4% and 90.1%, respectively. The IC$_{50}$ of β-ionone was 89 μmol/L.

Figure 1 Proliferation kinetics of SGC-7901 cells treated at various concentrations of β-ionone.

Expression of type IV collagenases

The effects of β-ionone on type IV collagenase activities (97kD for MMP-9 and 72kD for MMP-2) in SGC-7901 cells were presented in Figure 2. In the serum-free supernatants of SGC-7901 cells preincubated in the media supplemented with various concentrations of β-ionone, the activities of type IV collagenases (both MMP-9 and MMP-2) were not different in comparison with the negative control. No effect of β-ionone on the activities of type IV collagenases in SGC-7901 cells was shown.

Figure 2 Effect of β-ionone on gelatinase/type IV collagenase secretion (97kD for MMP-9 and 72kD for MMP-2) in SGC-7901 cells.

Levels of TIMP-1 and TIMP-2 mRNA in SGC-7901 cells

As shown in Figures 3 and 4, the levels of TIMP-1 and TIMP-2 transcripts in SGC-7901 cells were gradually elevated with increase of the β-ionone concentration, indicating a upregulation effect of β-ionone on the expression of TIMP-1 and TIMP-2 in SGC-7901 cells.

Figure 3 RT-PCR result: expression of TIMP-1 mRNA in SGC-7901 cells treated by β-ionone for 24 h (A) and 48 h (B). C: area of peaks; Lanes 1-5: 0, 25, 50, 100 and 200 μmol/L of β-ionone; M: molecular weight markers.

Figure 4 RT-PCR results showing expression of TIMP-2 mRNA in SGC-7901 cells treated by β-ionone for 24 h (A) and 48 h (B). C: chart of area of peaks; Lanes 1-5: 0, 25, 50, 100 and 200 μmol/L of β-ionone; M: molecular weight markers.

DISCUSSION

Interactions between cells and extracellular matrix (ECM) were critical for many cellular functions including division, migration, differentiation, and apoptosis[35]. In different mature normal tissues, ECM is specified by its structures and compositions to maintain tissue homeostasis and cellular quiescence. It have been found that remodeling of the ECM occurred during embryonic development and certain normal pathological processes such as wound-healing[36,37]. However, restructuring of the ECM has also been implicated in the pathogenesis of various human diseases including impaired wound-healing and fibrosis[38], rheumatoid arthritis[39], restenosis following balloon angioplasty[40], atherosclerosis[41], tumor development, invasion and metastasis[35,42].

Tumor invasion is a complex biological process, during which tumor cells detach from the primary tumor and infiltrate the surrounding tissues. This process has been found to require loss of cell contacts between tumor cells, active cell migration, adhesion to ECM and proteolytic degradation of the ECM[43,44]. Different molecules including cadherins, integrins, proteases, and growth factors were implicated in the regulation of invasion of tumor cells[44].

A major group of enzymes responsible for ECM degradation in cancer tissue has been found to be the MMP family, including collagenases, gelatinase, and stromelysins[45-49]. Collagenases can cleave fibrillar collagens at neutral conditions and play an important role in matrix remodeling. The largest sub-family of the MMPs is membrane-type (MT). MT-MMPs play a dual role in cell surface proteolysis. They can cleave a variety of extracellular components, and activate some secreted MMPs. Evidence has suggested that proteolytic activities at cell surface could promote cell invasion[50]. MMP-2, a 72-kDa type IV collagenase, is a cell surface-associated type I collagen-degrading MMP, which was found to designate gelatinase A[51]. Its overexpression has been observed in different types of tumors, and it was believed to be involved in tumor metastasis, primary tumor growth and angiogenesis[52]. MMP-2 is also regarded as a type IV collagenase involved in cell invasion across basement membrane. Thus, serum and tissue MMP profiles have been used as prognostic factors in certain types of malignant tumors including gastric and breast cancers[53]. MMP-9, a 97-kDa type IV collagenase also designating gelatinase B, was found to be associated with tumor invasion as well, its expression has been proven to be correlated with the differentiation grade of some malignancies[54]. In the present study, we did not find any effect of β-ionone on MMP-9 and MMP-2 activities in SGC-7901 cells. The growth inhibition on SGC-7901 cells appeared to be independence of the type IV collagenase activity.

TIMPs (TIMP-1, -2, -3 and -4) have been found to be the key regulators of MMP activity and ECM degradation[60]. The MMP inhibitors, TIMP-1 and TIMP-2 have been associated to several tumorigenic processes including development, invasion and metastasis of bronchial cancer[55-59]. Recent transgenic animal studies have demonstrated that alteration of the MMP/TIMP balance *in vivo* in favor of TIMP-1 activity could block neoplastic proliferation in the SV40 T antigen-induced murine hepatocellular carcinoma[61]. Active MT1-MMP was found to bind to amino-terminal domain of TIMP-2[62], whereas an interaction between the carboxyl-terminal domains of TIMP-2 and pro-MMP-2 was also described[63]. TIMP-2 might prevent SH2-protein-tyrosine phosphatase-1 (SHP-1) dissociation from immunoprecipitable epidermal growth factor receptor complex and a selective increase in total SHP-1 activity[64]. Our results showed that β-ionone might increase the expression of TIMP-1 and TIMP-2 in SGC-7901 cells. Clearly, further studies are needed to elucidate whether β-ionone inhibits metastasis of the cancer cells.

In summary, β-ionone can inhibit SGC-7901 cell growth

and proliferation and has an effect on upregulating TIMP-1 and TIMP-2 expression in SGC-7901 cells. It seems to be related to potential tumor metastasis in SGC-7901 cells induced by β-ionone. However, the mechanism of the inhibitory effect of β-ionone inhibits cell proliferation remains to be clarified.

Abstract

AIM: To determine the expression levels of three metabolic enzymes of fluoropyrimidines: thymidylate synthase (TS), thymidine phosphorylase (TP) and dihydropyrimidine dehydrogenase (DPD) in seven human gastrointestinal cancer cell lines, and to compare the enzyme levels with the sensitivity to 5-fluorouracil (5-FU) and 5-fluoro-2'-deoxyuridine (FdUrd).

METHODS: TS, TP and DPD mRNA levels were assessed by semi-quantitative RT-PCR, TP and DPD protein contents were measured by ELISA. Fifty percent inhibitory concentrations of growth (IC50), representing the sensitivity to drugs, were determined by MTT assay.

RESULTS: IC50 values ranged from 1.28 to 12.26 uM for 5-FU, and from 5.02 to 24.21 uM for FdUrd, respectively. Cell lines with lower DPD mRNA and protein levels tended to be more sensitive to 5-FU ($P<0.05$), but neither TS nor TP correlated with 5-FU IC50 ($P>0.05$). Only TS mRNA level was sharply related with FdUrd sensitivity ($P<0.05$), but TP and DPD were not ($P>0.05$). A correlation was found between mRNA and protein levels of DPD ($P<0.05$), but not TP ($P<0.05$).

CONCLUSION: DPD and TS enzyme levels may be useful indicators in predicting the antitumor activity of 5-FU or FdUrd, respectively.

INTRODUCTION

The antimetabolite, 5-fluorouracil (5-FU), remains to be widely prescribed in the treatment of gastrointestinal carcinoma. Although it was originally synthesized 46 years ago, and the deoxyribonucleoside derivative of 5-FU, 5-fluoro-2'-deoxyuridine (FdUrd) is also applied in clinics through regional administration[1-3].

The response rate of gastrointestinal carcinoma to 5-FU as a single agent, however, is only 10%-30%, and differs greatly among patients[1,4]. So it is imperative to identify some indexes which could be applied to predict the efficacy of 5-FU in clinical settings. As a pyrimidine analog, 5-FU is metabolized *in vivo* similarly to uracil, and exerts its antitumor effects through anabolism, which is determined by the rate of catabolism. Thus, the expression level of genes coding for key enzymes in the metabolism within tumor cells may play a pivotal role in the sensitivity and efficacy of 5-FU[1,4,5].

The primary biochemical mechanism responsible for cytotoxicity of 5-FU and FdUrd is the formation of 5-fluorouridine monophosphate (FdUMP), which can bind tightly to and inhibit thymidylate synthase (TS) in the presence of 5, 10-methylene tetrahydrofolate (CH$_2$FH$_4$). TS catalyzes the reductive methylation of deoxyuridine-5'-monophosphate (dUMP) to deoxythymidine-5'-monophosphate (dTMP), which is the only pathway for *de novo* synthesis of dTMP, so the inibition of TS by FdUMP disrupts intracellular nucleotide pools necessary for DNA synthesis[1,3]. As the main target of fluoropyrimidines, the expression level of TS is assumed to influence the response of chemotherapy, although the amount of TS is not unanimously recognized as a determinant factor of 5-FU sensitivity[6-8].

Thymidine phosphorylase (TP) is known to be elevated in tumors compared with surrounding normal tissue. When 5-FU is administered, it is anabolized to FdUMP by TP present in the tumor, and FdUrd can be converted to 5-FU by TP[9-11]. TP levels might affect the sensitivity of 5-FU, the transfection of TP cDNA into cancer cells increased their sensitivity to 5-FU[12]. The expression of TP was reported to be useful for predicting the efficacy and survival of fluoropyrimidine chemotherapy[13,14], but this tendency was not confirmed in a recent clinical trial of colorectal carcinoma[15]. The relationship between TP and the sensitivity of fluoropyrimidines needs to be further explored.

In contrast to anabolism of 5-FU, much less attention has been focused on its catabolism. In human, dihydropyrimidine dehydrogenase (DPD) is the initial and rate-limiting enzyme of 5-FU catabolism, 85% of an administered dose of 5-FU is degraded to inactive metabolites by DPD, with only 1-3% of the drug anabolized. While anabolism is essential for the antitumor activity of 5-FU, catabolism by indirectly controlling the availability of 5-FU for anabolism is a critical determinant of 5-FU cytotoxicity[4,5,16,17]. Several studies have shown a great interindividual difference in DPD activity, and suggested that DPD activity could be used as a predictive marker of 5-FU response[18-20].

We measured the expression levels of TS, DPD and TP on a panel of seven gastrointestinal cancer cell lines to probe the correlation between TS/DPD/TP and 5-FU or FdUrd sensitivity.

MATERIALS AND METHODS

Chemicals

5-FU was kindly provided by Faulding Pharmaceuticals Co,

FdUrd and MTT were obtained from Sigma-Aldrich Chemicals Co.

Cell culture

Seven cancer cell lines of human origin were adopted, including four gastric carcinoma cells (MKN45, SGC7901, MKN28 and AGS) and three colorectal carcinoma cells (SW1116, Lovo and HCT-8). Cells were routinely cultured in RPMI-1640 media (Gibco BRL), supplemented with 10% heat-inactivated fetal bovine serum (Gibco BRL), 100 u/ml penicillin and 100 ug/ml streptomycin in a humidified incubator at 37 ℃ with an atmosphere containing 5% CO_2.

Evaluation of 5-FU and FdUrd-induced cytoxicity by MTT assay

Cells were dispersed into 96-well microtitration plates, and the initial cell density was 5 000-10 000 cells per well, so that the cells were in a Log growth phase. Twenty-four hours after plating, the cells were exposed to a series of 10-fold dilutions of 5-FU or FdUrd (10^{-2}-10^{-9}M) for 72 hours. Each concentration was performed in quadruplicate, the percentage of growth inhibition was assessed by MTT assay, and determined according to the following equation: $[1-(T-T_0)/(C-T_0)]\times100\%$, where T is the absorbance of the experimental wells after 72 h of 5-FU or FdUrd exposure, and T_0 is that of background control with the same drug concentrations, C is that of cell control wells (without drug) after 72 h incubation. The 5-FU or FdUrd concentrations causing a 50% growth inhibition as compared to cell controls (IC50) were calculated by modified Kärbers method[21]: IC50=l g^{-1}[X_k-i(ΣP-0.5)], in which X_k represents logarithm of the highest drug concentration, i is that of ratio of adjacent concentration, ΣP equals the sum of the percentage of growth inhibition at various concentrations, and 0.5 is a constant of experience. All experiments were repeated 4 times, from which we reported the mean and standard deviation of IC50.

Semi-quantification of TS/DPD/TP mRNA by RT-PCR

Total RNA from seven gastrointestinal cancer cell lines was extracted using TRIzol (Gibco BRL) and quantified by UV spectrophotometry. First-strand cDNA was synthesized from 1 μg of total RNA with oligo (dT)$_{15}$ primer and avian myeloblastosis virus reverse transcriptase using an RT-PCR kit (Promega) following the conditions of the manufacturer. PCR primers were designed based on the sequences of human TS/DPD/TP and GAPDH mRNA (internal standard), and the specificity of all primers was confirmed by DNA sequencing of the PCR products amplified with them (Table 1).

Table 1 Primers for TS, DPD, TP and GAPDH amplification

mRNA	Bases	Sequences (5' →3')	Product size (bp)
TS	613-632	accaaccctgacgacagaag	405
	998-1017	atgcggattgtacccttcaa	
DPD	1325-1344	tgttcggacagagcaagatg	400
	1705-1724	cttcaatccggccatttcta	
TP	390-408	aggagacctcggtgctgac	402
	772-791	tgagaatggaggctgtgatg	
GAPDH	109-127	gaaggtgaaggtcggagtc	226
	315-334	gaagatggtgatgggatttc	

TS/DPD/TS was co-amplified with GAPDH in 50 μl of PCR mixture containing 4 μg of cDNA template, 2.5 mM $MgCl_2$, 5 μl 10×buffer, 0.4 mM dNTP, 2.5 u Taq polymerase (Promega), 12.5pmol of each sense and anti-sense primer. The PCR profile of TS consisted of an initial 4 min denaturation at

95 ℃, followed by 25 PCR cycles (at 94 ℃ for 1 min, at 60 ℃ for 30 s, and at 72 ℃ for 1 min) and a final 7 min extension (33 cycles of amplification for DPD and 35 cycles for TP). The PCR products were separated by ethidium bromide-stained 2% agarose gel electrophoresis, the images were scanned and analyzed by densitometry using Fluro-s™ image software (Bio-Rad). The relative amount of mRNA was calculated by determining the product intensity ratio of TS/DPD/TP to GAPDH within the linear amplification range of PCR, and four separate experiments were repeated.

Protein contents of TP and DPD

Cell lines in a Log growth phase were harvested and washed twice by phosphate buffered saline (PBS, pH 7.4). After the last wash, cell pellets were resuspended in 500 μl PBS and lysed by a sonifier (pulses, 10 min), then the lysates were centrifuged at 13 000×g for 15 min, and the supernatants were carefully collected, the protein concentration of which were determined using a BCA protein assay reagent kit (Pierce).

The protein contents of DPD and TP in cell lines were determined by sandwich ELISA (Roche), according to the manufacturer' s instructions. Enzyme levels were expressed as U/mg protein, where one U of TP is an amount equivalent to 1 μg 5-FU generated in an hour, and one U of DPD is an amount equivalent to catabolizing 1pmol of 5-FU per minute.

Determination of population doubling time

As described before[22], 1-2×10^5 cells were cultured in a 25 ml flask containing 2.5 ml of RPMI-1640, and the number of cells per flask was counted every 24 hours for 7 days. When the cells were in a Log growth phase, the population doubling time (dt) was determined by the following formula: dt=l g2/l g (C_t/C_0)×t, where t means the time between cell counts C_t and C_0, C_0 is the initial count, and C_t is the count after time *t*.

Statistics

Linear regression analysis and paired *t*-test were performed by SPSS software, $P<0.05$ was regarded as statistically significant.

RESULTS

Sensitivity of cell lines to 5-FU and FdUrd

Table 2 shows the parameters of interest for the whole cell line panel. After 72-hour drug exposure, the chemosensitivity of cell lines presented a marked difference, with IC50 values ranged from 1.28 to 12.26uM for 5-FU (9.57-fold), and from 5.02 to 24.21uM (4.83-fold) for FdUrd, respectively. The IC50 value of 5-FU was 2.8-fold lower than that of FdUrd ($P<0.01$), and there was no significant correlation between IC50 values of these two drugs among seven gastrointestinal cancer cell lines ($P>0.05$).

TS mRNA levels

TS mRNA was highly expressed in the seven cell lines, and the TS:GAPDH product intensity ratio varied from 0.84 to 2.69 (Figure 1A, Table 2). TS mRNA expression was significantly correlated with the sensitivity of cell lines to FdUrd ($r=0.81$, $P=0.028$), where low TS mRNA levels were associated with the high sensitivity to FdUrd (Figure 2), but the sensitivity to 5-FU was not influenced by TS mRNA levels.

DPD mRNA and protein levels

DPD mRNA expression was measurable in all cell lines but HCT-8 (Figure 1B). Although cDNA of DPD was amplified by PCR with 8 more cycles, DPD mRNA expression was much lower than TS expression, as shown in Table 2. DPD protein content, representing enzyme activity, ranged from 1.16 to

Table 2 Sensitivity to 5-FU or FdUrd and enzyme levels for cell lines

Cell line	IC50[a]		TS mRNA[b]	DPD		TP		Doubling time (hours)
	5-FU	FdUrd		mRNA[b]	protein[c]	mRNA[b]	protein[c]	
MKN45	12.26±2.13	16.85±2.28	1.13±0.22	0.57±0.17	10.13	0.72±0.13	5.11	22.9
SGC7901	8.97±1.55	12.45±1.46	1.04±0.17	0.50±0.09	9.13	0.59±0.06	1.78	25.8
MKN28	3.44±0.36	5.02±1.32	0.84±0.21	0.36±0.12	4.57	0.70±0.12	0.55	20.5
AGS	2.77±0.58	19.31±1.85	1.27±0.23	0.35±0.08	4.95	0.67±0.20	3.835	29.5
SW1116	5.45±0.47	24.21±3.26	2.69±0.36	0.47±0.11	5.99	0.57±0.11	2.60	22.2
Lovo	4.86±0.92	14.41±0.96	1.19±0.12	0.31±0.05	1.83	0.70±0.08	0.04	33.9
HCT-8	1.28±0.43	17.62±1.84	1.54±0.31	ND[d]	1.16	0.10±0.06	0.67	28.1

a: values of IC50 ($\bar{x}±s$), b: TS/DPD/TP mRNA levels, expressed as TS/DPD/TP:GAPDH product intensity ratio ($\bar{x}±s$), c: DPD/TP protein levels, in U/mg protein, d: not detectable.

10.13 U/mg protein (8.73-fold), and there was a statistically significant correlation between mRNA and protein level of DPD ($r=0.88$, $P=0.009$, Figure 3A).

Linear regression analysis showed that both mRNA ($r=0.82$, $P=0.025$) and protein level of DPD ($r=0.88$, $P=0.009$) were significantly correlated to the sensitivity to 5-FU (Figure 4). The greater the enzyme level was, the higher the IC50 of 5-FU. The most sensitive cell line (HCT-8) exhibited the lowest DPD mRNA and protein level, and the most resistant cell line (MKN45) had the greatest DPD mRNA and protein level. But the correlation between mRNA or protein level of DPD and the IC50 of FdUrd was not found ($P>0.05$).

Figure 1 mRNA expression of seven gastrointestinal cancer cell lines by RT-PCR. (A) the bands of TS and GAPDH; (B) the bands of DPD and GAPDH; (C) the bands of TP and GAPDH (1-MKN45; 2-SGC7901; 3-MKN28; 4-AGS; 5-SW1116; 6-Lovo; 7-HCT-8). The relative amount of mRNA was expressed as the intensity ratio of TS/DPD/TP to GAPDH RT-PCR products, as showed in Table 2.

Figure 2 Linear regression for the sensitivity to FdUrd as a function of TS mRNA level (FdUrd-IC50=7.89TS mRNA+4.77, $r=0.81$, $P=0.028$). Scatter plot shows the corrlation between TS mRNA levels and IC50 of FdUrd.

Figure 3 (A) Correlation between mRNA and protein level of DPD ($r=0.88$, $P=0.009$); (B) Correlation between mRNA and protein level of TP ($r=0.33$, $P=0.466$).

Figure 4 (A) Linear regression for the sensitivity to 5-FU as a function of DPD mRNA level (5-FU-IC50=16.77DPD mRNA-0.54, $r=0.82$, $P=0.025$). (B) Linear regression for the sensitivity to

5-FU as a function of of DPD protein level (5-FU-IC50=1.00DPD protein+0.20, r=0.88, P=0.009). Scatter plot shows the corrlation between DPD mRNA or protein levels and IC50 of 5-FU.

TP mRNA and protein levels

Both mRNA and protein of TP had lower expression levels compared to TS or DPD (Figrure 1C, Table 2). Figure 3B shows no correlation between TP/GAPDH RT-PCR product intensity ratio and TP protein level (r=0.33, P=0.466). Although it was expected that mRNA and protein level of TP would predict the sensitivity to 5-FU or FdUrd, no significant correlation was shown (P>0.05).

Doubling time of cell lines

The cell doubling time ranged from 20.5 (MKN28) to 33.9 hours (Lovo), and no correlation was demonstrated between the doubling time and IC50 of 5-FU or FdUrd. Cell doubling time did not correlate with either TS/DPD/TP mRNA or protein levels (P>0.05).

DISCUSSION

There is a high prevalence of gastrointestinal cancer, including gastric and colorectal cancer in China, but most of the diagnoses are established at advanced stages, when chemotherapy is regarded as one of the main treatments. At present, 5-FU has been considered as the principal component of chemotherapy regimen for gastrointestinal cancer in both advanced disease and the adjuvant setting[2,23], and FdUrd is also available commercially for chemotherapy, especially for intraarterial and intracavitary infusion. But the response of gastrointestinal cancer to fluoropyrimidines was still unsatisfactory and their efficacy varied greatly among individuals, so how to enhance the chemotherapeutic response of 5-FU has become a very interesting subject[24,25]. The identification of predicative markers of chemosensitivity through pharmacogenomics means could clarify which subset of patients might benefit, and enable clinicians to design individualized chemotherapy regimens[26].

It has been demonstrated in our study that the sensitivity of seven gastrointestinal cancer cell lines to 5-FU corresponded to DPD mRNA or DPD protein levels linearly. The cancer cells with lower DPD levels were more sensitive to 5-FU, and DPD mRNA was even undetectable in the most sensitive cell line HCT-8. But no correlation between TS or TP levels and sensitivity to 5-FU was found in the present study, in view of the known relevance of TS or TP as a determinant of response of 5-FU in some preclinical and clinical studies[6,7,27], therefore the results obtained from the study of seven cancer cell lines must be interpreted scrupulously.

The low expression levels of TP could partly explain our finding, besides inhibition of TS activity through anabolism to FdUMP by TP catalyzation. 5-FU exerted its antitumor activity by converting to FdUTP and FUTP for incorporating into DNA and RNA, respectively[1], thereby interfering with their normal structure and function, so there was no correlation between TS or TP levels and 5-FU sensitivity. On the other hand, Nita *et al*[28] also observed DPD expression and predicted 5-FU sensitivity in colorectal cancer cell lines. Etienne *et al*[29] confirmed this association in tumor biopsy tissues from the patients of head and neck cancers, but no relationship was demonstrated between TS activity and 5-FU response, either. Our findings, similar to these results, suggested that most of 5-FU within insensitive tumor cells was quickly catabolized by a higher DPD level, which regulated the amount of 5-FU available for anabolism, thereby affecting its cytotoxicity. In addition, these results suggested that DPD inhibitors, such as eniluracil[30], uracil[31], 5-chloro-2,4-dihydroxypyrimidine (CDHP)[32], and BOF-A2[33], might be used as a novel type of biochemical

modulators for elevating the antitumor activity of 5-FU.

It has been indicated in our work that TS may contribute greatly to the sensitivity of FdUrd, and the higher the TS mRNA levels, the higher the IC50 of FdUrd. Because both TP mRNA and protein levels of this panel of cell lines were rather low, and only little amount of FdUrd could be converted to 5-FU, the suppression of TS through conversion to FdUMP was the principal mechanism of action of FdUrd[1,10,11]. Therefore TS may serve as a predictive marker of FdUrd. Given the metabolic characteristics of FdUrd, it is comprehensible that there was no correlation between TP or DPD levels and FdUrd sensitivity.

Grem *et al*[8] found cell doubling time was a potentially important variable in drug sensitivity, and cell lines with faster doubling times tended to have higher TS activities, but we did not observe the similar trend. In their study, the cytotoxicity was determined by MTT assay after 48 hours of drug exposure, whilst we did it after 72 hours by the same protocol. Since the cell doubling time, ranging from 20.5 to 33.9 hours, was relatively shorter in our study than Grem' s, the influence of doubling time on fluoropyrimidines seemed to be much weaker.

We used semi-quantitative RT-PCR and ELISA to determine DPD/TP mRNA and protein level, respectively, and found a statistically significant correlation between mRNA level and protein content of DPD. Compared to traditional radioisotopic enzyme acitivity assay[34], RT-PCR and ELISA were less laborious, less expensive, and more feasible in most laboratories. In general, even small amounts ($\leqslant$100 mg) of tissues were enough for them, and the correlation between DPD activity and mRNA or protein levels has been already confirmed in several preclinical and clinical trials[18,35-38]. But there was no such a correlation in TP, a close look showed three cell lines had extremely low TP protein contents, and even TP enzyme level of MKN45, the highest one, was only 5.11 U/mg protein. A recent clinical trial disclosed that the range of TP level in primary colorectal cancer was 13.8-196.0 U/mg protein[36], which might explain this apparent discrepancy between mRNA and protein level. Griffiths also pointed out by immunohistochemistry that the predominant cells positive for TP were macrophages and other stroma cells within tumor tissues, and the activation of fluoropyrimidines in human might rely on the paracrine of TP by these stroma cells, but not tumor cells[10]. As the low expression of TP could directly influence the sensitivity of these seven cell lines to fluoropyrimidines, the role of TP in gastrointestinal cancer cells sensitive to 5-FU and FdUrd needs to be more deeply explored.

In summary, we found that DPD and TS were potential indicators in predicting tumor sensitivity to 5-FU and FdUrd. However, the conclusions were drawn from the limited *in vitro* experiment. This study was merely a first step toward the goal of individualized fluoropyrimidine chemotherapy for gastrointestinal cancers. Controlled, prospective clinical trials are required to confirm our results and to establish the advantage of pre-treatment tumor biopsy for TS/DPD screening, which permits a more rational decision on whether to proceed a fluoropyrimidine-based therapy as first-line treatment. So patients who are unlikely to respond may spare unnecessary toxicity and can be treated with alternative drugs such as CPT-11, oxaliplatin, or with potent biochemical modulators of fluopyrimidine.

Abstract

AIM: To investigate the expression of NF-κBp65 protein and human telomerase reverse transcriptase (hTERT) and their correlation in gastric cancer and precancerous lesions.

METHODS: Forty-one patients with primary gastric cancer, 15 with dysplasia, 23 intestinal metaplasia and 10 with normal gastric mucosa were included in this study. Expression of NF-κBp65 protein, hTERT mRNA and protein were determined by immunohistochemistry and *in situ* hybridization.

RESULTS: The rate of p65 expression in normal gastric mucosa, intestinal metaplasia, dysplasia and carcinoma was 0%, 34.78%, 53.33% and 60.98%, respectively, while the rate of hTERT mRNA expression was 10.00%, 39.13%, 66.67% and 85.37% and the rate of hTERT protein expression was 0%, 30.43%, 60.00% and 78.05%, respectively. All the three parameters were significantly increased in dysplasia and carcinoma compared to normal mucosa, while the expression levels were also significantly higher in carcinoma than in intestinal metaplasia ($P<0.05$). In gastric cancer tissues, nuclear staining rates of p65 and hTERT protein were both significantly associated with the degree of differentiation, lymph node metastasis, clinical stage and invasion depth ($P<0.05$). However, hTERT mRNA expression was only significantly associated with clinical stage. There was a positive correlation between p65 and hTERT mRNA ($r_s=0.661\text{-}0.752$, $P<0.01$), and between hTERT protein and hTERT mRNA ($r_s=0.609\text{-}0.750$, $P<0.01$).

CONCLUSION: NF-κBp65 and hTERT expressions are upregulated at the early stage of gastric carcinogenesis. NF-κB activation may contribute to hTERT expression and thereby enhance telomerase activity, which represents an important step in carcinogenesis progress.

INTRODUCTION

NF-κB is a family of dimeric transcription factors that play a critical role in host defense by regulating the expression of immune and inflammatory genes[1-3]. The most common dimer is RelA (p65)/NF-κB1 (p50) heterodimer. In resting cells, NF-κB is localized in the cytoplasm, which is noncovalently associated with the cytoplasmic inhibitory protein IκB. Upon stimulation with a variety of pathogenic inducers such as viruses, mitogens, bacteria, agents providing oxygen radicals, and inflammatory cytokines, IκB is phosphorylated, ubiquitinated, and degraded in the cytoplasm, and the NF-κB complex migrates into the nucleus and binds to DNA recognition sites in the regulatory regions of target genes[4]. Recently, there were several reports on the role of NF-κB gene products in cell proliferation, transformation, and tumor development[5-9]. Recent studies have also indicated that NF-κB is constitutively activated in several tumors[10-13]. However, the biological significance of NF-κB activation remains unclear in gastric carcinogenesis although gastric cancer is one of the most aggressive forms of cancer.

Telomerase is a key enzyme that catalyzes the synthesis of telomere DNA participating in cell immortalization through stabilization of chromosomal structure[14]. Telomerase is expressed in germ tissues as well as in majority of human tumors, including gastrointestinal carcinomas, but is low and difficult to detect in somatic cells generally[15-19]. So it may be a useful molecular marker for cancer diagnosis and therapeutic strategies. Human telomerase reverse transcriptase (hTERT) has been identified as a putative catalytic subunit of human telomerase[20]. Recent reconstitution experiments, both *in vitro* and *in vivo*, also strongly suggest that hTERT is the major determinant of human telomerase activity[21,22]. Overexpression of hTERT in cancer cells is thought to contribute to tumor development and angiogenesis[23-25]. However, the mechanism by which hTERT is overexpressed in cancer cells remains unclear. There are evidences that hTERT expression may be regulated by the highly inducible NF-κB transcription factor[26]. So it is interesting to investigate the relation between NF-κB and hTERT at cellular level.

We undertook the present study to determine whether NF-κB was constitutively activated in precancerous and cancerous tissues of the stomach, to examine whether expression of hTERT gene correlated with NF-κB activation, and to evaluate the relationship between clinicopathological features and NF-κB activation as well as hTERT gene expression.

MATERIALS AND METHODS

Tissue samples

Gastric tissues were obtained by surgical resection from 89 patients: 10 with normal gastric mucosa, 23 with intestinal metaplasia, 15 with dysplasia and 41 with gastric cancer. Patients with gastric cancer were admitted to Renmin Hospital of Wuhan University from February to December in 2000, and had not been treated with chemotherapy or radiation therapy before operation. Histological examinations were performed, according to the criteria of the Japanese Gastric Cancer Association[27]. All specimens were fixed in 10 % buffered neutral formalin and embedded in paraffin. Serial tissue sections (4.5 μm thick) were placed on glass slides coated with 3-aminopropyltriethoxysilane (Sigma, USA), and then used in the following experiments.

Immunohistochemistry for NF-*k*B p65 and hTERT proteins

Immunostaining was performed as described previously with slight modification[28]. Briefly, slides were treated overnight at 4 ℃ with either anti-p65 mAb (4 µg/ml) or anti-hTERT polyclonal antibody (3 µg/ml). Both antibodies were from Santa Cruz Biotechnology (USA). Then, slides were incubated with secondary antibody by using a streptavidin-peroxidase kit (Maixin-Bio, Fujian). Finally, the antigen sites were visualized by incubating with diaminobendizine (DAB) solution (Zhongshan Biotechnical Co, Beijing), and the nuclei were weakly counterstained with Mayer's hematoxylin (Maixin-Bio, Fujian). The specificity of immunostaining was determined by replacement of the primary antibody with PBS. Positive reaction was detected as nuclear stain presenting in brown-yellow color. Slides positively stained were further stratified from 1+ to 3+ based on the overall intensity and percentage of the stained tumor cells, with an estimated scale of <25% cell positive =1+, 25% to 50% =2+, and >50% =3+. Staining was defined as negative if positive cells were <5%.

In situ hybridization for hTERT mRNA

hTERT mRNA ISH detection kit and antisense polyoligonucleotide probe (digoxin-labeled) were purchased from Boster Biological Technology Ltd. (Wuhan). In brief, deparaffinized sections were incubated with 3% hydrogen peroxide for 30 min and then with 1 µg/ml pepsin for 15 min. The prehybridization was performed at 37 ℃ for 2 h, and the hybridization was conducted in a 42 ℃ water bath for 18 h with each section covered with a soil coverslip. After thorough washing, tissue sections were preblocked for 20 min with blocking solution. Then, rabbit anti-digoxin antibody was added for 60 min at 37 ℃. After washed in PBS, the sections were visualized according to the manufacturer's instructions. A negative control was prepared by using a hybridization solution without the probe. A positive reaction was detected as plasmatic stain presenting in brown-yellow color. Slides positively stained were further stratified from 1+ to 3+ as described above.

Statistics

Statistical analysis was performed using chi-squared test, Fisher's exact test, and spearman rank test. A *P* value <0.05 (one-sided) was accepted as statistically significant.

RESULTS

Staining of NF-*k*Bp65 protein, hTERT mRNA and protein

P65 immunostaining was significantly enhanced both in cytoplasm and in nuclei of the tumor cells in comparison to that in normal epithelial cells (Figure 1). Since nuclear staining, which indicated nuclear transportation of p65, was considered as a marker of NF-κB activation, we only counted the number of nuclear stained cells and took them into calculation of the percentage of positively stained cells. Similarly, hTERT protein was mainly localized in the nuclei of tumor cells, and only a small number of cells showed a positive reaction in the cytoplasm (Figure 2). Stromal cells such as endothelial cells and smooth muscle cells (except lymphocytes) showed no reaction for hTERT. Weak staining of p65 and hTERT proteins was observed in some epithelial cells in the lower two-thirds of the glands of nonneoplastic mucosa.

In situ hybridization

Revealed that hTERT mRNA was significantly enhanced in the cytoplasm of tumor cells (Figure 3). Only a few signals were seen in nonneoplastic cells, which were slightly increased in the replicating basal layer, and in intestinal metaplastic cells as well as in activated lymphocytes, while the surface epithelia were negative (Figure 4).

Figure 1 Immunohistochemical detection of NF-κBp65 protein in gastric carcinoma showing cytoplasmic and nuclear staining SP×400.

Figure 2 Immunohistochemical detection of hTERT protein in poorly differentiated gastric carcinoma. A positive reaction was shown in the nuclei of cancer cells. SP×400.

Figure 3 Detection of hTERT mRNA in a mucinous adenocarcinoma. Most tumor cells displayed strong signals that were localized in the cytoplasm. ISH×400.

Figure 4 Detection of hTERT mRNA in intestinal metaplasia. The reaction was localized in the cytoplasm of intestinal meta-plastic cells, activated lymphocytes, as well as replicating cells in basal layer, while the surface epithelia were negative. ISH×100.

Table 1 Expression of NF-κBp65 protein, hTERT mRNA and protein in precancerous lesions and gastric cancer

Lesion	Cases	NF-κBp65				hTERT mRNA				hTERT protein			
		+	++	+++	Total (%)	+	++	+++	Total (%)	+	++	+++	Total (%)

[a]$P<0.05$, *vs* normal mucosa group; [b]$P<0.01$, *vs* cancer group.

Expression of NF-*k*Bp65 protein, hTERT mRNA and protein

Expression of p65 protein, hTERT mRNA and protein in gastric precancerous and cancerous tissues was increased compared with normal mucosa (Table 1). The nuclear staining rates of p65 (active form) were higher in gastric cancer than in intestinal metaplasia ($P<0.05$), or normal mucosa ($P<0.05$). The rates were also significantly higher in dysplasia than in normal mucosa. Similarly, expression of hTERT mRNA and protein was increased in precancerous and cancerous tissues (Table 1).

The relations between clinicopathological features and expression of p65 and hTERT in the 41 patients with gastric carcinoma were further analyzed (Table 2). Nuclear staining rates of p65 and hTERT proteins were both significantly associated with the degree of differentiation, lymph node metastasis, clinical stage and the depth of invasion ($P<0.01$-0.05). Furthermore, the nuclear staining of p65 was significantly higher in tumors $\geqslant 5$ cm than in those <5 cm. With respect to expression of hTERT mRNA, we found that carcinomas at advanced stage showed a significantly higher level than those at early stage. However, there was no significant association between expression of hTERT mRNA and other clinicopathological features.

[a]$P<0.05$, [b]$P<0.01$, From comparison in each group of clinicopathologic feature by chi-square test or Fisher's exact test. m: mucosa, sm: submucosa, mp: muscularis propria, ss: subserosa, se: invasion to serosa, si: invasion to other organ. Tumor size was defined as the largest size in extension on the gastric mucosa.

Correlation between NF-*k*B activation and expression of hTERT

There was a positive correlation between NF-κB activation and hTERT mRNA expression in patients with intestinal metaplasia ($r_s=0.665$), dysplasia ($r_s=0.661$) and gastric cancer ($r_s=0.752$). Similarly, hTERT mRNA expression was also positively correlated with hTERT protein in these three groups ($P<0.05$), with the r_s values of 0.609, 0.750 and 0.730, respectively.

DISCUSSION

The present study reported the detection of NF-κB activation and hTERT gene expression, as well as their correlation, in cancerous and precancerous tissues of stomach.

NF-κB, an important transcription factor, consists of dimeric complexes. We used immunohistochemistry to detect NF-κB activation. The polyclonal antibody we used, could bind to the active and inactive forms of p65, one of NF-κB subunits, as shown in a previous study[29]. We only quantified the nuclear staining (active form) to evaluate NF-κB activation. With such an analysis, nuclear translocation of p65 could be estimated at single-cell level. We found that active NF-κB was not only in the nuclei of tumor cells but also in the nuclei of infiltrating inflammatory cells, especially lymphocytes, which was accordant with the role of NF-κB involved in immune and inflammatory responses[30,31]. Isomoto *et al*[32] also reported that in *Helicobacter pylori*-associated gastritis, activated NF-κB was expressed in macrophages, vascular endothelial cells and B lymphocytes in addition to epithelial cells, which might be involved in the inflammation process.

Using *in situ* hybridization and immunohistochemistry methods, we detected the expression of hTERT at both RNA and protein levels. Importantly, the *in situ* detection enabled us to differentiate whether telomerase activity was due to proliferative normal cells or lymphocytes. Therefore immunohistochemical detection of hTERT might be a novel tool for the diagnosis of gastric cancer[33]. In this study, we demonstrated that, besides tumor cells, hTERT mRNA and protein were also expressed, albeit weakly in normal gastric fundic mucosa. These epithelial cells were terminally differentiated. It is possible that low levels of hTERT expression might be the characteristics of physically regenerating tissues containing stem cells, and hTERT-positive cells might be competent for regeneration if severe mucosal damage occurred[28]. Although the level of hTERT mRNA correlated significantly with that of hTERT protein in our study, their expression levels were not always coincident in precancerous and cancerous lesions. It is likely that post-translational modifications, such as phosphorylation by akt kinase, might be involved in hTERT expression[28,34].

The present study revealed that NF-κBp65 nuclear staining rates were higher in cancer tissues, followed by dysplasia,

intestinal metaplasia and normal mucosa. This is the first report on NF-κBp65 detection in gastric precancerous tissues. As to the expression of hTERT gene, previous studies revealed that carcinomas could express hTERT more frequently than noncancerous tissues[25,35-38]. Our findings support these results. The present study indicated that NF-κB and telomerase were both activated in precancerous lesions, suggesting that NF-κB activation and increased hTERT gene expression emerge at the early stage of gastric carcinogenesis, and that they may be the prerequisites for malignant transformation. Therefore, NF-κB and telomerase might be potentially important targets for the development of anti-tumor therapies for gastric carcinoma[15,39,40].

Sasaki et al[29] reported that NF-κB activation was positively correlated with tumor size, lymphatic invasion, depth of invasion and peritoneal metastasis. Besides that, our study also revealed significantly positive correlations between nuclear staining of NF-κB p65 and differentiation degree and clinical stage. Therefore, NF-κB activation might be associated with tumor growth, invasion and metastasis.

It has been reported that hTERT expression might be downstream of NF-κB activation[26,41]. Yin et al[26] found a potential NF-κB binding site at 350 base pairs upstream from the translational start site of mouse TERT promoters and NF-κB was found to contribute to the activation of TERT expression. In addition, Akiyama et al[41] showed that NF-κB interacted directly with hTERT protein in multiple myeloma cells. In the present study we examined the relationship between nuclear staining of NF-κBp65 and hTERT mRNA at the cellular level by immunohistochemistry and in situ hybridization. We observed that both p65 and hTERT mRNA were overexpressed in gastric cancer with the positive staining rates of 60.98% and 85.37%, respectively. In fact, most specimens showing a high p65 level also showed high hTERT mRNA expression and vice versa. Furthermore, the expression of p65 and hTERT mRNA showed a significant correlation in cancerous and precancerous tissues (intestinal metaplasia and dysplasia). And in nonneoplastic mucosa, the positive staining of p65 and hTERT mRNA were detected simultaneously in proliferative glands and activated lymphocytes. All of these suggested that NF-κBp65 cooperated with hTERT in gastric carcinogenesis. We speculate that NF-κBp65 may induce hTERT promoter activity and upregulate telomerase activity and contribute to the aggressiveness of gastric carcinoma.

However, our study was limited by the high specificity of p65 mAb for the p65 subunit, and thus we could not evaluate other NF-κB dimers. The relationship between other NF-κB subunits and gastric cancer needs further studies.

In conclusion, we demonstrated the presence of activated NF-κBp65 and increased hTERT expression in gastric cancerous and precancerous tissues. The levels of p65 and hTERT expression were higher in gastric cancer than in normal mucosa, and NF-κB activation was associated with tumor growth, invasion and metastasis. Our findings suggest that NF-κBp65 cooperates with hTERT in gastric carcinogenesis.

Abstract

AIM: To evaluate the tumor-positive ratio and number of perigastric lymph nodes as prognostic factors of gastric carcinoma in surgically-treated patients.

METHODS: The postoperative survival of 169 patients with gastric cancer who were performed D_2 curative gastrectomy was analyzed with regard to its lymph node metastasis ratio and number. Meanwhile correlation of tumor-positive ratio and number of perigastric lymph nodes with pathological parameters of these patients was studied.

RESULTS: The overall 5-year survival rate of all the patients studied was 29.6%. The 5-year cumulative survival rate in patients with 1%-20% and more than 20% of tumor-positive lymph nodes was 70.6% and 12.0% respectively, and 46.6% and 17.4% in those with 1-5 and more than 5 of tumor-positive lymph nodes respectively, which were significantly decreased with the increment of involved lymph nodes assessed by either numbers or ratio ($P<0.05$). Multiple stepwise regression analysis showed that both the positive ratio and number of tumor-involved lymph nodes were sensitive prognostic factors in these surgically-treated patients, which were also significantly correlated with tumor size and depth of submucosal invasion ($P<0.05$).

CONCLUSION: Tumor-positive ratio and number of perigastric lymph nodes are associated with cancer progression and five-year survival rate, and may serve as valuable prognostic factors of gastric cancer in surgically-treated patients.

INTRODUCTION

It has been well recognized that lymph node metastasis in patients with gastric cancer is one of the important prognostic factors[1-4]. In 1997, the International Union Contrele Cancer (UICC) and American Joint Commission for Cancer (AJCC) redefined metastatic status of lymph node on the basis of the involved node number rather than its location, in which pN1 was defined as 1-6 local lymph nodes being involved, pN2 as 7-15 local lymph nodes being involved and pN3 as more than 15 local lymph nodes being involved[5-7]. Some reports strongly suggested that this classification was more sensitive with a higher reproducibility in the prognostic evaluation of gastric cancer patients than that assessed by the metastatic locations of lymph node[8,9]. However, In China there are few reports concerning the correlation of local lymph node metastatic ratio and number with the prognosis of gastric cancer patients, which was the motivation for us to initiate the present study of such cases in the Chinese population.

MATERIALS AND METHODS

Patients and materials

Between January 1995 and November 1997, 304 patients with primary gastric cancer were performed D_2 radical gastrectomy in the Department of General Surgery, First Affiliated Hospital of Nanjing Medical University. Of them, 121 male and 48 female cases aging from 32 to 78 years (mean, 58.4 years) were found to have lymph node metastasis, and analyzed in the present study, with a following-up time from 0 to 61 months postoperation.

Methods

The status of lymph nodes was assessed according to the staging system formulated by UICC/AJCC in 1997. Of the 169 patients with positive lymph nodes, 32 were found to have remote lymphatic metastasis such as that in the retropancreatic, mesenteric and paraortic regions. The total number of resected lymph nodes was 10 223 (mean: 34.1, range: 11-122), the median number of examined lymph nodes was 26 (mean: 31.1, range: 12 to 91) for all 304 patients, the median number of involved regional lymph nodes was 5.0 (mean: 7.1, range: 1 to 42). Lymph node metastasis ratio was defined as the number of metastatic lymph nodes to the total number of resected ones.

To elucidate the prognostic significance of metastatic lymph nodes, the clinical and histopathological records of these 169 patients were analyzed. The relationships of 5-year survival rate with sex, age, tumor location, histopathological grading, macroscopic type, lymph node resection and depth of tumor invasion were determined. Tumor location, macroscopic type, and lymph node resection were graded according to the Japanese classification of gastric carcinoma proposed by Japanese Gastric Carcinoma Association (JGCA).Histopathological grading was defined according to the fifth edition of TNM classification. Following-up information was obtained from routine clinical examinations.

Statistical analysis

Statistical analysis was carried out using SPSS 10.0 for Windows. The 5-year survival rate of those performed using D_2 radical gastrectomy was analyzed by cox's proportional

hazard models. The log rank test was used to compare the survival data between groups. Comparison between qualitative results for the PN categories and clinical or histopathological parameters was performed using the χ^2 test. Independent predictors of postoperation survival were identified by logistic regression analysis. Kaplan-Meier curves were used to demonstrate survival distribution.

RESULTS

Among the 304 patients, 169(55.6%) had lymph node metastasis. The 5-year survival rate was 29.6% for the node-positive patients, and was 91.2% for the node-negative patients. The cancer -specific 5-year survival rate of patients with lymph node metastasis was significantly lower than that of those without lymph node metastasis ($P<0.05$).

Correlation between lymph node metastatic ratio and 5-year survival rate

The patients were divided into two groups by the ratio of metastatic lymph node number to the total number of resected lymph nodes. The 5-year survival rate of 51 patients with metastatic lymph nodes less than 20% was 70.6% (36 cases), while that of 118 patients with 21% or more was 12% (14 cases). A significant difference was noted between the two groups ($P<0.05$, Table 1). As the ratio of lymph node metastatasis increased, the 5-year survival rate decreased (Figure 1).

Table 1 Correlation between lymph node metastatic ratio and survival years

| Ratio of positive lymph nodes | *n* | Survival years | | | | | *P* |
		1	2	3	4	5	
<20%	51	51	49	45	39	36	<0.05
>21%	118	104	87	66	43	14[a]	

[a]$P<0.05$ *vs* the group with lymph node metastatic ratio less than 20%.

Figure 1 Negative correlation between survival years and ratio of metastatic lymph nodes in patients with gastric cancer. +: patients with metastatic ratio of lymph node less than 20%: -: patients with metastatic ratio of lymph node more than 21%.

Relation between lymph node metastasis number and 5-year survival rate

There was no significant difference in the outcome of patients with 1, 2, 3, 4 or 5 positive nodes, but there was a sharp decrease in survival rate when the sixth node was involved (Table 1), So the patients were divided into two groups according to the lymph node metastatic number. Group A having less than 5 and group B having more than 6. The 5-year survival rate of 71 patients with less than 5 metastatic lymph nodes was 46.6% (33 cases), and the 5-year survival rate of 98 patients with more than 6 metastatic lymph nodes was 17.4% (17 cases).

A sharp decrease in survival was seen between two groups ($P<0.05$, Table 2). The 5-year survival rate decreased as the number of lymph node metastatases increased (Figure 2).

Table 2 Correlation between lymph node metastatic number and survival years

| Number of positive lymph node | *n* | Survival years | | | | | *P* |
		1	2	3	4	5	
1	9	9	9	8	6	5	
2	20	20	19	18	15	10	0.908
3	12	12	12	10	9	5	1.0

>5	98	86	70	53	35	17	0.00072[a]

[a]$P<0.05$, *vs* the group with lymph node metastatic number more than 5.

Figure 2 Negative correlations between survival years and number of metastatic lymph nodes in patients with gastric cancer. +: patients with metastatic number of lymph nodes less than 5: -: patients with metastatic number of lymph nodes more than 6.

Correlation between positive ratio of lymph node metastasis and tumor characteristics

As shown in Table 3, lymph node metastatic ratio was positively correlated to tumor size, depth of invasion. No significant difference was found between lymph node metastatic ratio and tumor location.

Table 3 Correlation between lymph node metastatic ratio and tumor characteristics

Pathological characteristics	Lymph node <20% metastatic ratio	>21%	*P*
Size of tumor			
<4 cm	42	43	
≥4 cm	9	74[a]	0.48
location			
Lower third	5	8	
Middle third	22	47	
Upper third	24	63	<0.001
Depth of invasion			
Mucosa and submucosa	12	9	
Muscle and subserosa	16	6	
Serosa	23	103[b]	<0.001

[a]$P<0.05$, [b]$P<0.05$ *vs* the group with lymph node metastatic ratio less than 20%.

Correlation between number of positive lymph nodes and tumor characteristics

As shown in Table 4, tumors with one to five involved lymph nodes compared with those with six or more involved lymph nodes were significantly characterized by size, depth of invasion, there was no significant difference between the number of involved lymph nodes and tumor location.

Table 4 Correlation between number of involved lymph nodes and tumor characteristics

Pathological characteristics	Number of positive lymph nodes 1-5	>5	P
Size of tumor			
<4 cm	51	34	
≥4 cm	20	64[a]	0.48
location			
Lower third	7	6	
Middle third	31	38	
Upper third	33	54	<0.05
Depth of invasion

Muscle and subserosa	18	4	
Serosa	33	93[b]	<0.05

[a]$P<0.05$, [b]$P<0.05$ *vs* the group with lymph node metastatic number more than 5.

DISCUSSION

Gastric carcinoma, one of the most common human malignant tumors, is as the first leading cause of gastrointestinal cancer-related mortality. Over 50% of patients with gastric cancer operated in China had lymph node metastasis, which resulted in poor prognosis of these patients[10-13]. As yet, lymph node status has been considered as the major determinant of gastric cancer recurrence for patients undergoing a curative gastrectomy[14-16]. However, some authors suggested that the prognostic assessment of these patients by counting the number of positive lymph nodes related to tumor locations was too complicated to be used in routine practice. A simple and easy system for lymph node staging has been considered to be urgently needed[14-16].

In the present study, we observed the effect of metastatic lymph node number on the survival years of gastric cancer patients. The result showed that the five–year survival rate in patients with 0, 1-5 and more than 5 tumor-positive lymph nodes was 91.2%, 46.6% and 17.4% respectively, indicating that considerable differences in the five-year survival rate existed between the patients. However, There was no significant difference observed between the outcomes of patients with 1, 2, 3, 4 and 5 tumor-positive lymph nodes. Thus it is more reasonable to classify gastric cancer patients with criteria of tumor-positive node numbers rather than tumor-positive nodes. Similar results have been revealed in a previous report by Wu *et al*. They divided the gastric cancer patients into two groups according to the number of involved lymph nodes, and found that the number of positive nodes rather than lymph node involvement was suitable for the classification of nodal stages in gastric cancer[8,17,18].

Lymph node metastatic ratio, namely the number of metastatic lymph nodes to the total number of resected lymph nodes, has also been found to be an important prognostic factor[19-22]. We observed that the 5-year survival rate in patients with the metastatic lymph node ratio of 0, 1-20% and more than 21%, was 91.2%, 70.6% and 12% respectively. Similar results have been shown by Kwon and his colleagues that the metastatic ratio of lymph nodes was one of the main factors in determining the five-year survival rate of gastric cancer patients. Furthermore, the lymph node metastatic ratio has also been found to be more objective and reliable than the metastatic number in the prognosticating outcomes of these patients, because the former could effectively eliminate the influence of variance in resected lymph number on the prognosis of gastric cancer patients[23-27].

It is generally accepted the depth of cancer invasion is an other important prognostic indicator in gastric cancer. Yasuda *et al* showed that the metastatic rate of lymph nodes was correlated with the depth of submucosal invasion in early stage of gastric carcinoma[28,29], which was in accordance with our present results. We found that the number and ratio of metastatic lymph nodes were positively related with the depth of cancer invasion and tumor size in gastric cancer cases.

In conclusion, gastric cancer patients with 5 or more positive lymph nodes and 20% or more of positive lymph node metastasis associated with a poor prognosis. The positive number and ratio of lymph node metastasis are simple and useful indictors in evaluating the surgical results of patients with gastric cancer[19,30,31].

Abstract

AIM: To construct a recombinant adenoviral vector carrying *AFP* promoter and *EGFP* gene for specific expression of *EGFP* gene in AFP producing hepatocellular carcinoma (HCC) HepG2 cells.

METHODS: Based on the Adeno-X™ expression system, the human immediate early cytomegalovirus promoter ($P_{CMV\ IE}$) was removed from the plasmid, *pshuttle*, and replaced by a 0.3 kb α-fetoprotein (*AFP*) promoter that was synthesized by polymerase chain reaction (PCR). The enhanced green fluorescent protein (*EGFP*) gene was inserted into the multi-clone site (MCS), and then the recombinant adenovirus vector carrying the 0.3 kb *AFP* promoter and *EGFP* gene was constructed. Cells of a normal liver cell line (LO2), a hepatocarcinoma cell line (HepG2) and a cervical cancer cell line (HeLa) were transfected with the adenovirus. Northern blot and fluorescence microscopy were used to detect the expression of the *EGFP* gene at mRNA or protein level in three different cell lines.

RESULTS: The 0.3 kb *AFP* promoter was synthesized through PCR from the human genome. The *AFP* promoter and *EGFP* gene were directly inserted into the plasmid *pshuttle* as confirmed by restriction digestion and DNA sequencing. Northern blot showed that *EGFP* gene was markedly transcribed in HepG2 cells, but only slightly in LO2 and HeLa cells. In addition, strong green fluorescence was observed in HepG2 cells under a fluorescence microscopy, but fluorescence was very weak LO2 and HeLa cells.

CONCLUSION: Under control of the 0.3 kb human *AFP* promoter, the recombinant adenovirus vector carrying *EGFP* gene can be specially expressed in AFP-producing HepG2 cells. Therefore, this adenovirus system can be used as a novel, potent and specific tool for gene-targeting therapy for the AFP positive primary hepatocellular carcinoma.

INTRODUCTION

In recent years, research in tumor gene therapy has made great progress in laboratory, However, there is an urgent need for gene therapy in clinical practice. Recombinant adenovirus is one of the most popular and promising tools for gene therapy[1,2]. But how to construct a proper recombinant adenovirus vector carrying the interested gene that is specifically expressed only in target tumor cells has become the bottle neck which restricts the application of the vector in clinical gene therapy for tumors[3,4]. The aim of this study was to construct a recombinant adenovirus vector carrying a 0.3 kb *AFP* promoter, and to investigate the expression of enhanced green fluorescent protein (*EGFP*) gene that was inserted into the vector in AFP positive hepatocarcinoma cells.

MATERIALS AND METHODS

Reagents
EX Taq DNA polymerase, T4 ligase, DNA isolation and purification kit were purchased from Promega (USA), restriction endonucleases and the DNA marker from Takara Biotechnology, Dalian (China), Lipofectamin™ 2000 from Invitrogen (USA), and RPMI 1640 medium and fetal calf serum from Hyclone (USA).

Cell lines
Hepatocarcinoma cell line, HepG2, was a gift from Professor Wei-Xue Tang, Department of Pathophysiology, Chongqing University of Medical Sciences. A normal hepatocyte cell line, LO2, and human cervical cancer cell line, HeLa, were preserved in our laboratory. Low-passage HEK 293 cells were obtained from the Institute for Cytobiology, Chinese Academy of Sciences, Shanghai. All cells were cultured in RPMI-1640 medium containing 10% fetal calf serum at 37 ℃ in saturated humidified air with 5% CO_2. The cells were subcultured once every three days.

Vectors
Adenovirus vector Adeno-X™ expression system and *pEGFP-C1* were purchased from Clontech Corporation (USA).

Polymerase chain reaction (PCR)
PCR was employed to amplify human *AFP* promoter and *EGFP* gene from HepG2 cell genomic DNA and *pEGFP-C1*, respectively. Specific primers for AFP promoter were as follows: 5'-GCG CTA GCA TTC TGT AGT TTG AGG AG-3' (sense), 5'-ATG GGC CCA TTG GCA GTG GTG GAA-3' (antisense). *Nhe*I and *Apa*I sites were introduced into the sense and antisense primer, respectively, as underlined. Specific primers for *EGFP* gene were as follows: 5'-AAG GGC CCT TTA GTG AAC CGT CAG AT-3' (sense), 5'-GCC TTA AGT

TAT CTA GAT CCG GTG GAT-3' (antisense). *Apa*I and *Afl*II sites were introduced into the sense and antisense primer, respectively.

To remove the p$_{CMV IE}$ from the *pshuttle*, PCR was used to amplify the 99-744 region of *pshuttle*, and specific primers were as follows: 5'-AGC CAG TAT CTG CTC CCT GCT TGT G-3' (sense), 5'-ATG CTA GCG GTG CCA AAA CAA ACT CCC A-3' (antisense). *Nhe*I site was introduced into the antisense primer.

PCR was performed in a total volume of 50 µl consisting of 1 µM each primer, 200 µM each dNTP, 5 µl 10×polymerase reaction buffer, 1.25U EX taq DNA polymerase and 1 µl DNA template. The samples were heated to 94 ℃ for 5 min followed by amplification for 30 cycles at 94 ℃ for 30 s, 55 ℃ for 30 s, and 72 ℃ for 50 s. After the last cycle, a final extension step was at 72 ℃ for 7 min. Then 5 µl of each product was analyzed by 1% agarose gel (containing 0.5 µg/ml EB) electrophoresis. PCR products were purified from the agarose gel using DNA purification kit.

Construction of the adenoviral vector

pshuttle and the PCR products of 99-744 region were both doubly digested with *Mlu*I and *Nhe*I, and the digested products were ligated with T4 ligase. *Mlu*I site was 256, and the *Nhe*I was 921 in *pshuttle*. The 256-921 region of the *pshuttle* was removed from the plasmid, and replaced by the region of 256-744, then the 744-921 region containing the p$_{CMV IE}$ was removed from *pshuttle*. Thus, a new plasmid *pCMV*$^{(-)}$ was constructed.

Subsequently, the *pCMV*$^{(-)}$ and *AFP* PCR products were doubly digested with *Nhe*I and *Apa*I. The 0.3 kb AFP promoter was inserted into the *pCMV*$^{(-)}$, which was called *pAFP*. Then the p$_{CMV IE}$ was replaced by the AFP promoter.

To insert the *EGFP* gene into the *pAFP*, both the *pAFP* and *EGFP* PCR products were doubly digested with *Apa*I and *Afl*II. The digested products were Ligated to construct *pAFP-EGFP*.

The newly constructed plasmid *pAFP-EGFP* was then doubly digested with *PI-Sce/I-Ceu I* (New England Biolabs. UK), and the purified product was ligated with Adeno-X genome DNA. It was amplified in *E.coli DH5a*. The HEK293 cells were transfected with recombinant adenovirus which was linearized with *Pac*I, as described in the manual. In brief, the HEK293 cells were cultured in a 60 mm plate, and 10 µl *Pac* I-digested Adeno-X DNA was added in the culture medium when the cells were 50-70% confluent, then the cells were transfected with Lipofectamin and incubated for another week. For virus collection, the cells were lysed with three consecutive freeze-thaw cycles, and the virus was collected from supernatant. The titer of the virus was about 1×10^7 pfu/ml, which was determined with end-point dilution assay.

Northern blot analysis

HepG2, LO2 and HeLa cells were cultured in 6-well plates, and the medium was removed after 24 h, followed by addition of adenovirus at multiplicity of infection (M.O.I) of 100 plaque-forming units (pfu)/cell, and fresh culture medium was added 4 h later. After 48 h of normal culture, total RNA was extracted from the cells for Northern blot. In brief, 10 µg total RNA of each sample was added to 10 g·L^{-1} formaldehyde denatured agarose gel, and electrophoresis was performed. mRNA was transferred onto the nitrocellular (NC) membranes by capillary blot, and exposed to 254 nm ultraviolet for 1 min (600×100 µJ·cm^{-1}) to fix mRNA. The NC membranes were pre-hybridized for 3 h at 42 ℃. The cDNA probes were labeled by a random primer method. The probes were added and hybridized at 42 ℃ for 20 h. Then the membranes were washed,

dried and used for X-ray film autoradiography at -70 ℃ in a black box for 48 h. The relative amount of *EGFP* cDNA was semi-quantified from relative optical density of the band, using a Bio-image analysis system (Bio-Rad Doc Gel 2000, USA).

Fluorescence microscopy

The cells were cultured and transfected with the recombinant adenovirus as described above. Fluorescent images were captured at 490 nm using a Nikon Eclipse E1000 microscope.

RESULTS

PCR amplification and DNA sequencing of AFP promoter

Electrophoretic results of PCR product of the human 0.3 kb *AFP* promoter are shown in Figure 1. The sequence of the promoter was described as below:

*gcg**ctagc**at tctgtagttt gaggagaata tttgttatat ttgcaaaata aaataagttt*
          *Nhe*I -229

*gcaagttttt tttttctgcc ccaaa**gagct ctgtgtcct**t gaacataaaa tacaaataac*
                              GRE

*cgctctg**ctg ttaattattg gca**aatgtcc catttttcaac ctaaggaaat accataaagt*
        HNF-1

*aacagatata ccaacaaa**ag gttactagtt aacagg**catt gcctgaaaag ag**tata**aaag*
                     HNF-1

*aatttcagca tgattttcca tattgtgcttc caccactgcc aatg**ggccc**a t*
                                      +25 *Apa I*

The AFP promoter region of -229 to 25 was indicated with italics;
GRE: glucocorticoid response element;
HNF-1: hepatocyte nuclear factor;
tata: TATA Box.

Figure 1 Human 0.3 kb *AFP* promoter.

Enzyme digestion analysis of the recombinant pshuttle

The plasmid *pshuttle* and the 99-744 region of the PCR product were both doubly digested with *Mlu*I and *Nhe*I (Figure 2). A 670 bp fragment was released from *pshuttle*, and replaced by a 490 bp fragment that was digested from the PCR product. The p$_{CMV IE}$ was removed from the *pshuttle*.

Figure 2 Plasmid *pshuttle* and PCR product doubly-digested with *Mlu*I / *Nhe*I. M: marker, 1: the PCR product of 99-744 region of *pshuttle*, 2: the product of PCR doubly digested with *Mlu*I / *Nhe*I, 3: *pshuttle*, 4: doubly-digested *pshuttle* with *Mlu*I / *Nhe*I, a 670 bp fragment was released from *pshuttle*.

Specific expression of EGFP gene in HepG2 cells

As shown in Figure 3, strong expression of *EGFP* mRNA was observed in HepG2 cells but was weak in AFP negative LO2 and HeLa cells, only 38% and 17% of that in HepG2 cells, respectively.

Under fluorescence microscopy, green fluorescence indicating expression of EGFP was strong in HepG2 cells (Figure 4A) but very weak in LO2 (Figure 4B) and invisible in HeLa cells.

Figure 3 A: Transcription levels of *EGFP* shown by Northern blot in three different cell lines, B: Transcription levels of *EGFP* gene detected by semi-quantity analysis in three cell lines. Lane 1, HeLa cell; lane 2, HepG2 cell; lane 3, LO2 cell.

Figure 4 Expression of *EGFP* mRNA in HepG2 cells (A) and LO2 cells (B) ×200.

DISCUSSION

Hepatocellular carcinoma (HCC) is one of the most common malignancies worldwide. All the treatment strategies used today had a poor outcome[5-7]. Gene therapy might be a promising way[8,9]. Gene transfer into specific tissues or cell types is a key technique in the development of gene therapy. A tissue-specific promoter has been found to be potentially valuable for the study of specific gene function and for gene therapy[10-14], as it permitted a linked cytotoxic or any other gene to be expressed specifically in target cells[15-17]. The AFP could be re-expressed in the majority of hepatocellular carcinomas[18,19], and thus utility of the *AFP* promoter for gene therapy against HCC might be a rational approach[20-22].

Adenoviral gene transfer is one of the most reliable methods for introducing genes into almost all types of mammalian cells and for expressing the genes at high levels since many cells receive multiple copies of the recombinant genome. Gene therapy using replication-competent adenovirus that selectively propagates in tumor cells might be an effective treatment for cancer[23,24]. We developed an adenovirus carrying an *AFP* promoter, thus the replication of the target gene was restricted specifically in AFP-producing HCC[25]. The full length *AFP* promoter was 5.1 kb[26,27], previous studies have shown that the 0.3 kb of the *AFP* promoter had an enough activity to stimulate *AFP* transcription containing a glucocorticoid response element and two binding sites of hepatocyte nuclear factor (HNF)-1, a hepatocyte-specific transcriptional factor, and a TATA box, but no typical CCAAT sequence[28,29].

In this study, primers containing specific enzyme-cutting sites were designed to amplify the 0.3 kb *AFP* promoter from human genome, and the 0.3 kb sequence was cloned into the plasmid *pshuttle* to replace the primary *CMV* promoter. *EGFP* gene as a target gene was inserted into the downstream of *AFP* promoter. Then AFP expressing hepatocarcinoma cells (HepG2), AFP negative normal hepatocytes (LO2) and HeLa cells were transfected with the recombinant adenovirus. Northern blot showed that *EGFP* gene was dramatically transcribed in HepG2 cells, however, in LO2 and HeLa cells, the transcription was very weak. Under fluorescent microscopy, green fluorescence was strong in HepG2 cells, but very weak in the other two cell lines. Therefore, this recombinant adenovirus carrying the 0.3 kb *AFP* promoter can be used as a proper vector to express the interested gene in AFP expressing hepatocarcinoma cells or tissues.

It has been reported that the promoter activity of 0.3 kb *AFP* promoter was limited for transcription of downstream genes[30,31]. For this reason, several enhancers have been inserted into the upstream of the promoter in order to upgrade its activity[32-35]. In our study, the original enhancer in *pshuttle* was reserved, which might contribute to the satisfactory transcription of the downstream gene using the 0.3 kb promoter.

Abstract

AIM: To evaluate the effects of p53 on apoptosis and proliferation of hepatocellular carcinoma (HCC) cells treated with transcatheter arterial chemoembolization (TACE).

METHODS: A total of 136 patients with HCC received TACE and other management before surgery were divided into TACE group and non-TACE group. TACE group included 79 patients who had 1-5 courses of TACE before surgery, of them, 11 patients had 1-4 courses of chemotherapy (group A), 33 patients had 1-5 courses of chemotherapy combined with iodized oil (group B), 23 patients had 1-3 courses of chemotherapy, iodized oil and gelatin sponge (group C), 12 patients had 1-3 courses of chemotherapy combined with iodized oil, ethanol and gelatin sponge (group D). Non-TACE group included the remaining 57 patients who had surgery only. The extent of apoptosis was analyzed by transferase mediated dUTP nick end labeling (TUNEL) staining. The expressions of p53, Bcl-2, Bax, Ki-67 and PCNA protein were detected by immunohistochemical method.

RESULTS: P53 protein expressions in trabecular and clear cells in HCC specimens were significantly lower than that in pseudoglandar, solid, poorly differentiated or undifferentiated and sclerosis HCC ($P<0.05$). Expression of p53 protein in HCC cells increased with the increase of pathological grades ($P<0.05$), and correlated positively with expressions of Ki-67 and PCNA protein, and negatively with Bcl-2 to Bax protein expression rate and AI ($P<0.05$). Expression of p53 protein was significantly higher in group A than in groups B, C, D and the non-TACE group, and was higher in group B than in groups C and D, and lower in group D than in the non-TACE group ($P<0.05$).

CONCLUSION: Expression of p53 protein can enhance proliferation of HCC cells and suppress apoptosis of HCC cells after TACE.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignancies. Surgical resection has been recognized as the most effective method for the treatment of HCC[1,2], but it is only indicated for small number of HCC patients. Transcatheter arterial chemoembolization (TACE) has become one of the most popular and effective palliative methods for HCC. Various mixtures of anticancer drugs, Lipiodol and gelatin sponge have been used as TACE agents. There have been a few reports on comparison of the efficacy of different TACE regimens on HCC patients[3].

Cellular homeostasis in tissue depends on the balance between apoptosis and cell proliferation. Wild-type p53 protein inhibits the growth of tumor by arrest of cell proliferation and induction of apoptosis[4]. Bcl-2 and Bax protein are important regulators of apoptosis[5]. Bcl-2 proteins can prolong cell survival by suppressing apoptosis, and Bax proteins can enhance apoptosis[6]. PCNA and Ki-67 protein are useful markers for proliferative activity[7]. PCNA functions as a cofactor of DNA-polymerase and an important mark for evaluating the proliferation of colon cancer[8], gastric adenocarcinoma[9], *H pylori* associated gastric epithelial lesions[10], lung cancer[11], ovarian cancer[12],large intestine polyps[13] and HCC[14,15] .

As far as we know, the effect of p53 on apoptosis and proliferation of HCC cells treated with different TACE regimens has not been investigated yet. In particular, it is unclear whether p53 can affect apoptosis and proliferation of HCC cells treated with TACE by modulating the expressions of Bcl-2, Bax, PCNA and Ki-67 proteins. In the present study, we examined the effects of p53 on apoptosis and proliferation of HCC cells treated with TACE alone or in combination with others.

MATERIALS AND METHODS

Patients
From February 1992 to February 2001, 136 patients with HCC were referred to our hospital for surgery, including 122 men and 14 women with a mean age of 45 years (range 20 to 70 years). Preoperative ultrasound (US), computed tomography (CT), magnetic resonance (MRI), digital subtraction angiography (DSA) and plasma AFP levels were used to diagnose the conditions and the diagnosis was finally confirmed with pathological biopsy.

Surgical procedure
The patients were divided into TACE or non-TACE group. In TACE group, 79 patients underwent 1-5 courses chemoembolization prior to liver resection. Of them, 11 patients had 1-4 courses of chemotherapy only (group A), 33 patients had 1-5 courses of chemotherapy combined with iodized oil (group B), 23 patients had 1-3 courses of chemotherapy, iodized oil and gelatin sponge (group C), 12 patients had 1-3 courses of chemotherapy combined with iodized oil, ethanol and gelatin - sponge (group D). Considering the course of TACE, 50 patients underwent one course, 19 patients underwent two courses, 10 patients underwent three or more courses. The interval from the last TACE to the surgery was 52.8 ± 12.2 days ($\bar{x}\pm s$), 25 patients had

1 month or less, 29 patients had 2 months or less, 16 patients had 3 months or less, 9 patients had over 3 months. In non-TACE group, 57 patients had surgery without preoperative TACE. The types of hepatectomy were dependent on the location of tumor, the severity of concomitant hepatic cirrhosis and preoperative hepatic function.

TUNNEL staining
Transferase-mediated dUTP nick end labeling (TUNEL) staining was used to examine apoptosis. Positive control slides were treated with DNAse-1 and negative controls were stained in the absence of terminal deoxynucleotidyl transferase enzyme. Dark brown nuclei with nuclear condensation in stained cells were considered as TUNEL positive. Apoptotic index was the ratio of the number of positively stained tumor cells to the total number of tumor cells.

Immunohistochemical method
The formalin-fixed, paraffin-embedded specimens were examined immunohistochemically using respective antibodies to p53 M7001 (dilution:1:100), Bcl-2 MO887(dilution:1:60), Bax A3533 (dilution:1:200), Ki-67 M7187(dilution:1:50) and PCNA M0879 (dilution:1:200) (LSAB kit Dako). Positive controls were selected cases known to be positive for the primary antibody, such as laryngeal carcinoma or normal lymph nodes. Negative controls were stained with a nonspecific Ig G (normal rabbit Ig G) and Tris-buffered saline. Brown-yellow staining in nuclei of cancer was found in p53, Ki-67 and PCNA positive cells, while brown-yellow staining in cytoplasm and/or cell membrane was observed in Bcl-2 and Bax positive cells. All slides were reviewed and scored by two independent observers in blind. A few cases with discrepant scoring were reevaluated to reach a final agreement.

Statistical analysis
Data were expressed as $\bar{x}\pm s$ and analyzed by means of SPSS 10.0 software package (SPSS, Chicago, IL, USA, 1999). The Student *t* test, the Crosstabs (chi-square and Fisher's exact probability test), K independent samples and Pearson rank correlation coefficient test were used to test the correlation between parameters. A *P* value <0.05 was considered statistically significant.

RESULTS

P53 expression in different histopathologic types
P53 protein expression in trabecular and clear cells of HCC was significantly lower than that in pseudoglandar, solid, poorly differentiated or undifferentiated and sclerosis HCC (*P*<0.05, Table 1).

P53 expression in different pathological grades
Pathological grades were divided into four groups. Expression of p53 protein in HCC cells increased as the increase of pathological grade in non-TACE or TACE group (*P*<0.05). P53 protein expression in grade II specimens in TACE group was significantly lower than that in non-TACE group (*P*<0.05, Table 2).

Table 2 Expressions of proteins in different grades of HCC

Treat groups	I	II	III	IV
Non-TACE	60.99±30.58	67.22±15.53	72.98±20.60	93.47±0.00
TACE	32.59±11.68	60.02±14.67	74.69±8.65	82.64±1.11
P	>0.05	<0.05	>0.05	>0.05

P53 expression in HCC cells
Expression of p53 protein in HCC cells was 69.37±18.81% in the non-TACE group, 65.09±15.71% in TACE group, 75.34±5.36% in group A, 69.34±12.59% in group B, 60.94±17.24% in group C, and was 53.41±18.13% in group D. Expression of p53 protein was significantly higher in group A than in groups B, C, D and non-TACE group, and was higher in group B than in groups C and D, and lower in group D than in non-TACE group (*P*<0.05, Figures 1-4).

Correlation between courses of TACE and p53 protein expression
Expression of p53 protein in HCC cells was 69.37±18.81% in non-TACE group, 65.76±13.96% in one-course of TACE group, 64.09±19.81% in two-courses of TACE group, and 65.19±17.80% in three or more courses of TACE group. No statistical difference was found among groups (*P*>0.05).

Correlation between interval of TACE and p53 protein expression
Considering the interval from the last TACE to the operation, expression of p53 protein was 69.37±18.81% in non-TACE group, 63.54±13.72% in TACE group with an interval ⩽1 month, 61.17±18.32% in TACE group with a 1-2 months interval, 70.87±15.06% in TACE group with a 2-3 months interval, and 73.67±5.87% in TACE group with an interval >3 months. P53 protein expression was significantly lower in patients with an interval ⩽2 months than that in patients with an interval >3 months (*P*<0.05).

Correlation of p53 expression with Ki-67, PCNA, Bax, Bcl-2 protein expressions and AI
In non-TCAE group, p53 expression (69.37±18.81%) had a positive correlation with expressions of Ki-67 protein

Table 1 P53 protein expression of different types of HCC

Groups	Histological types					
	Trabecular	Pseudoglandar	Solid	Clear cell	Poorly differentiated	Sclerosis
Non-TACE	63.66±19.96	72.29±12.47	70.83±24.45	68.27±19.22	74.79±16.18	72.11±0.00
TACE	56.90±17.12	72.35±13.70	74.93±8.76	62.15±11.78	73.66±8.54	
P	>0.05	>0.05	>0.05	>0.05	>0.05	

Table 3 Correlation p53 expression with Ki-67, PCNA, Bax, Bcl-2 and AI

			Ki-67	PCNA	bcl-2	bax	bcl-2/bax	AI
Non-TCAE group	P53	PC	0.454[a]	0.331[a]	-0.141	0.054	-0.375[a]	-0.198

DISCUSSION

HCC is one of the most common malignant neoplasms. Most HCC patients are treated palliatively to improve the resectable rate and prolong survival. The best therapeutic method for HCC with tumor thrombi in portal vein (PVTT) has been regional hepatic TACE treatment after hepatic resection with removal of tumor thrombi[16]. TACE has become one of the most common and effective palliative approaches. The prognosis of patients treated with TACE was dependent on both the effect of TACE and tumor factors[17].

To our knowledge, few data regarding the molecular mechanism of TACE treatment for HCC are available, the current study is the first report to describe the correlations between p53 expression and different TACE regimens.

Our study showed that the frequency of p53 expression was higher in group A than in group B, non-TACE group and TACE group, the lowest in group C and D (*P*<0.05). Our previous study showed that multidrug resistant gene product-Pgp protein was significantly increased in chemotherapy group alone[18], suggesting that p53 expression increased after chemotherapy with the development of chemoresistance. p53 status might be an important determinant of tumor response to

Figure 3 P53 staining cells in HCC in group D (Dako Envision, peroxidase method ×200).

Figure 4 P53 expressions in different groups.

chemotherapy. Tumors with P53 (-) expression might respond to chemotherapy. Inversely, chemotherapy was not effective in patients with P53 (+) expression[19]. This study demonstrated that p53 protein expression had no significant difference between the TACE and non-TACE groups[20].

The reverse correlation between AI and p53 protein expression of HCC cells was found in both TACE and non-TACE groups in this study. Most p53 protein measured was the mutant-type. AI was significantly positively correlated with wild-type p53 which enhanced apoptosis by activating proapoptotic Bax and by down-regulating antiapoptotic Bcl-2[21].

The current study demonstrated that p53 expression was positively related to Ki-67 and PCNA protein expression in the non-TACE and TACE groups, suggesting that the mutated p53 protein could enhance the growth of HCC. Our previous study showed both PCNA and p53 expressions had a significantly parallel correlation, the overexpression of mutated p53 resulted in cancer immortalization, high tumor recurrence risk, more aggressive growth and poor survival[22] and Kieser *et al* found that a mutated p53 gene could provide an advantage for tumor proliferation[23]. Igarashi *et al* reported that expression of p53 protein like Ki-67 labeling index was a useful indicator for high proliferative activity[24]. A mutated p53 gene provided an advantage for tumor proliferation not only by allowing escape from apoptosis, but also by leading to formation of a vascular-rich microenvironment[25]. However, it has been known that wild-type p53 could inhibit the expression of PCNA[26].

Wild-type p53 is a positive transcriptional activator for human Bax gene and a negative transcriptional activator for human Bcl-2 gene. The activation of p53 pathway could lead to the down-regulation of Bcl-2 and up-regulation of Bax[27]. The current study demonstrated that p53 protein expression was positively related to Bax expression, and negatively to Bcl-2 expression in the non-TACE group. Bcl-2 expression had an inverse correlation with mutant p53, and wild-type p53

and majority of mutant p53 proteins could down-regulate Bcl-2 expression and up-regulate Bax expression *in vitro* and *in vivo*[28]. Moreover, Bcl-2 and p53 could cooperate in regulating pathogenetic pathways in the processes of tumor invasion and metastasis[29].

The current study demonstrated that p53 protein expression was negatively related to Bax expression, and positively to Bcl-2 expression in the TACE group, which was in accordance with the previous report that Bax expression was significantly increased in tumors with wild-type p53 gene after chemotherapy but did not increase in tumors with mutatant p53 gene[21].

This study demonstrated that discrepancy of P53 existed in different types of HCC. P53 protein expression was significantly lower in trabecular and clear cells of HCC than that in solid and poorly differentiated or undifferentiated HCC, in both non-TACE and TACE groups, Zhao *et al* reported that p53 gene mutation varied in histological types and the mutated rate was 10.5% in trabecular cells, 37.5% in pseudoglandar cells, 60.0% in solid cells and 33.3% in sclerosis ($P<0.05$)[30]. Our previous study showed that trabecular and clear cells were more sensitive to TACE than solid, poorly or undifferentiated, and small cells of HCC[31]. Wang *et al* also found that the clear cells of HCC were more sensitive to TAE than small cells of HCC and poorly differentiated or undifferentiated HCCs[32]. Yamashita *et al* found that most HCCs responded to TACE well[33]. These suggest that p53 protein expression would influence the effects of TACE on HCC. Further study is needed to clarify the correlation between p53 protein expression and tumor necrosis and patient survival.

This study also demonstrated that P53 protein expression increased as grades increased in both non-TACE and TACE groups ($P<0.05$), which was inconsistent with the study of Zhao *et al*[30].

P53 protein expression of grade II HCC was significantly lower in TACE group than in non-TACE group, suggesting that influences of the molecular markers were very complicated and discrepancy in therapeutic effect of TACE on different histopathological types of HCC was existed. It would be the best choice to use TACE in an individualized mode.

The best interval of treatment for repeated TACE or second stage resection is controversial. In this study, we found that p53 protein expression of HCC cells was significantly lower in the group with a 2 months or less interval than in the group with an over 3 month treatment interval ($P<0.05$). We found that the best interval between treatment with TACE or second stage resection was 2-3 months.

In conclusion, discrepancy of histological types and pathological grades in p53 protein expression is existed in HCC. P53 protein expression can enhance proliferation of HCC cells and suppress apoptosis of HCC cells after TACE. P53 protein expression would influence effects of TACE on HCC. We need further study to clarify the correlation between p53 protein expression, tumor necrosis and patient survival.

Abstract

AIM: To investigate the expression of 4-1BB molecule in hepatocellular carcinoma (HCC) and its adjacent tissues.

METHODS: Reverse transcription–polymerase chain reaction (RT-PCR) was used to determine the gene expression of 4-1BB in hepatocarcinoma and its adjacent tissues, and peripheral blood mononuclear cells (PBMCs) from both HCC and health control groups. Flow cytometry was used to analyse the phenotypes of T cell subsets from the blood of HCC patients and healthy volunteers, and further to determine whether 4-1BB molecules were also expressed on the surface of CD4+ and CD8+ T cells. The localization of 4-1BB proteins on tumor infiltrating T cells was determined by direct immunofluorescence cytochemical staining and detected by confocal microscopy.

RESULTS: 4-1BB mRNA, which was not detectable in normal liver, was found in 19 liver tissues adjacent to tumor edge (<1.0 cm). Low expression of 4-1BB mRNA was shown in 8 tumor tissues and 6 liver tissues located within 1 to 5 cm away from tumor edge. In PBMCs, 4-1BB mRNA was almost not detected. Percentage of CD4[+], CD8[+] and CD3[+]/CD25[+] T cells, as well as ratio of CD4 to CD8 revealed no difference between groups (*P*>0.05, respectively), while a significant lower percentage of CD3[+] T cell was found in HCC group as compared to healthy control group (*P*<0.05). However, 4-1BB molecules were almost not found on the surface of CD4+ and CD8+ T cells in HCC and healthy control group. Double-staining of 4-1BB[+]/CD4[+] and 4-1BB[+]/CD8[+] immunofluorescence on tumor infiltrating T cells was detected in 13 liver tissues adjacent to tumor edge (<1.0 cm) by confocal microscopy.

CONCLUSION: Although HCC may escape from immune attack by weak immunogenicity or downregulated expression of MHC-1 molecules on the tumor cell surface, tumor infiltrating T cells can be activated via other costimulatory signal pathways to exert a limited antitumor effect on local microenvironment. The present study also implicates that modulating 4-1BB/4-1BBL costimulatory pathway may be an effective immunotherapy strateg to augment the host response.

INTRODUCTION

Hepatocellular carcinoma (HCC) has a very poor prognosis owing to its high malignancy, and it ranks second cause of cancer death in China[1]. Curative tumour resection or orthotopic liver transplantation (LTx) seems to be an optimal treatment. Nevertheless, the recurrence rate remains high both after tumour resection and LTx[2-10]. Chemotherapy and embolisation are at best palliative with few impacts on survival[3]. Recently, immunotherapy has been used with some success for such tumours as melanoma[11-14] and renal-cell carcinoma[15,16] that are associated with an inflammatory or immune response. However, like most solid tumours, HCC has long been considered poorly immunogenic and substantially refractory to immunotherapy. Since a better prognosis of HCC attributes to the anti-tumor effect induced by cellular immunity of infiltrating CD8[+] and CD4[+] T lymphocytes[17], these tumor infiltrating lymphocytes (TILs) might be in an activated status and play a limited immune protection in microenvironment.

The 4-1BB receptor, a recently identified molecule of tumor necrosis factor- receptor (TNFR) superfamily, is a type I membrane protein expressed on activated cytolytic and helper T cells[18,19], as well as NK cells[20]. The ligand for 4-1BB receptor is a 4-1BB ligand (4-1BBL), which is expressed on APCs including B cells, macrophages, and dendritic cells[21,22]. Ligation of 4-1BB with 4-1BB ligand plays an important role in sustaining T cells activation, amplifying cytotoxic T lymphocyte (CTL) response, as well as inducing IL-2 production in the complete absence of a signal through CD28 molecule[22,23]. A recent research demonstrated that immunomodulatory gene therapy with 4-1BB ligand could induce long-term remission of liver metastases in a mouse model and augment CTL response against tumor[24]. The present study was to detect whether 4-1BB molecules were expressed on infiltrating CD4+ and CD8+ T cells in HCC and its adjacent tissues, and to illustrate the role of 4-1BB/4-1BBL pathway in tumor immunity.

MATERIALS AND METHODS

Patients

Nineteen patients with HCC confirmed by histopathologic examination were selected. Among them, 14 were male and 5 female aged from 28 to 68 years (average, 49.67±13.04 years). Three liver specimens from mismatched cadaver donor and 22 healthy peripheral blood specimens from Blood Center of Zhejiang Province were served as controls.

Reagents

Fluorescein isothiocyanate (FITC) -conjugated mouse

monoclonal antibodies (mAbs) specific for human surface antigens including anti-CD4 (IgG1k clone RPA-T4), anti-CD8 (IgG1k clone RPA-T8), anti-CD3 (IgG1k clone UCHT1), phycoerythrin (PE)-conjugated anti- CD25 (IgG1k clone M-A251), anti-4-1BB (IgG1k clone 4B4-1), and FITL or PE-conjugated mouse IgG1k (clone MOPC-21) as isotype controls were purchased from Becton Dickinson, San Jose, CA. RevertAid™ M-MuLV reverse transcriptase and Taq DNA polymerase were obtained from Promega, USA.

Peripheral blood mononuclear cell preparation

In order to isolate PBMCs, 5 ml heparinized blood was diluted 1:1 with PBS containing 0.6% Na3-citrate and layered over a 5 ml Ficoll cushion. After centrifugation (20 min, 700×g), the interface containing PBMCs was collected and washed twice with PBS. This precipitate contained approximately 25% monocytes and 75% lymphocytes.

Reverse transcriptase-polymerase chain reaction (RT-PCR)

Semi-quantitative assessment of 4-1BB mRNA expression was performed using RT-PCR on a PTC-200 DNA engine (MJ Research, USA). Briefly, total RNA was prepared from PBMCs and liver tissues using TRIZOL (Gibco BRL Life Technologies, Breda, the Netherlands). cDNA was synthesized with 2 μg of total RNA template using the superscript pre-amplification system (Promega, USA) and random primers in a final volume of 20 μl. The cDNA used as template was checked in respect to human β_2-MG amplification. The following primers (Shanghai Sangon, China) were used: β2-MG sense primer: 5' -CCAGCAGAGAATGGAAAGTC-3' , β2-MG antisense primer: 5' - GATGCTGCTTACATGTCTCG-3' , 4-1BB sense primer: 5' -TCAGGACCAGGAAGGAGTGT-3' , 4-1BB antisense primer: 5' -AACGGAGCGTGAGGAAGAAC-3' . Using these primers, fragments of 240 bp, and 414 bp were expected to result from amplification of β_2-MG and 4-1BB cDNAs, respectively. PCR reactions contained 20 pmol of each primer for 4-1BB, 2.5 u of Taq polymerase, 1 μ1 of 25 mM dNTPs, 1.2 μl of 25 mM MgCl2 and 10×PCR buffer in a final volume of 25 μl. For β_2-MG amplification, 1 μl of each primer at a 1:8 diluted concentration to 4-1BB primers was used for the reaction. PCR products (8 μl) were analyzed on 1.5% agarose gel containing ethidium bromide using Kodak DNA analyser (Gibco BRL) with Kodak digital science 1S 2.0 software. The expression level of 4-1BB mRNA was described as the ratio of 4-1BB/β_2-MG×100.

Flow cytometric analysis

One hundred microliters of heparinized peripheral blood were incubated with monoclonal antibody at room temperature in dark for 15 min to 30 min according to the manufacturer' s instructions. Another 100 μl of heparinized peripheral blood incubated with FITL or PE- conjugated mouse IgG1k (clone MOPC-21) was used as negative isotype control. Erythrocytes were lysed in turn with ImmunoPrep A, B, and C haemolytic solution on Coulter Q-Prep (Beckman-coulter). Alignment was checked using immunocheck beads (Beckman-coulter). All results were obtained using EPICS® XL FACScan (Beckman-coulter) with system[III] software.

Direct immunofluorescence histochemical staining protocol

Tissues were stored at -70 ℃ until use. Four μm-thick frozen sections (on poly-L-lysine coated slides) were fixed in acetone for 10 min at 4 ℃. The sections were blocked in phosphate buffered saline (PBS) and 1% bovine serum albumin (BSA) for 1 h, followed by incubation with FITC and PE labeled antibodies or conjugated isotype matched control antibodies for 16 h at 4 ℃. After extensively washed (overnight), stained sections were covered in PBS and kept in dark at 4 ℃.

Confocal microscopy

LEICA TCS-SP confocal microscope (Germany) was equipped with argon lasers and Leica inverted research biological microscope with an oil immersion objective lens of ×40 (NA1.30). The sections processed for immunocytochemistry were viewed under LEICA TCS-SP confocal microscope. After standard fluorescence observations, 4-1BB and CD4 or CD8 localization on TIL was automatically scanned by laser emitted at 488 nm and imaged by using PowerScanner physiology software. FITC and PE fluorescence emissions were captured through grating at 530/30-nm and 605/30-nm respectively.

Statistical analysis

Data were expressed as mean±SD. Statistical analysis was performed using one-way ANOVA with SPSS 10.0 software. Kruskal-Wallis H test and Student' s t test were also used for the nonparametric and parametric data analysis between two groups, respectively. A P value ≤ 0.05 was considered significant.

RESULTS

Expression of 4-1BB mRNA in tumor tissues but almost not in PBMCs

4-1BB mRNA was not detectable in normal liver, but was detected in all 19 liver tissues adjacent to tumor edge (<1.0 cm). Low expression of 4-1BB mRNA was shown in 8 tumor tissues and 6 liver tissues located within 1 to 5 cm away from tumor edge. However, in PBMCs, 4-1BB mRNA expression was not detected in samples from 18 healthy controls (81.82%, 18/22) and 13 patients with HCC (68.42%, 13/19). Very low expression of 4-1BB mRNA was detected in another 4 healthy volunteers and 6 patients with HCC. However, the median level of 4-1BB mRNA expression from PBMCs in each group was 0 (P>0.05) (Figures 1, 2).

Figure 1 Representative RT-PCR results of 4-1BB mRNA expression in normal liver, and HCC tissues as well as its adjacent tissues. (M, GeneRulerTM 100 bp DNA Ladder Plus; N, normal liver; H, HCC tissues; P, adjacent tissues to HCC (<1 cm), P' : liver tissues located within 1 to 5 cm away from tumor edge)

Figure 3 Comparison of 4-1BB molecules on CD4[+] or CD8[+] PBMCs between healthy controls and HCC patients.

Figure 4 Confocal laser micrographs of TILs in HCC adjacent tissues processed for the immunocytochemical detection of 4-1BB and CD4 or CD8 molecules. (A and D, FITC immunofluorescence for CD4 and CD8 molecules respectively; B and E, PE immunofluorescence for 4-1BB molecules; C and F, automatically synthetic micrographs by computer soft for A and B, and D and E, respectively).

cytometric analysis was used. The results are shown in Table 1. Percentages of CD4[+], CD8[+] T cells and CD3[+]CD25[+] T cells, as well as the ratio of CD4 to CD8 had no significant differences between the groups (*P*>0.05). However, a significantly higher percentage of CD3[+] T cells was found in healthy control group as compared to HCC group (*P*<0.05). 4-1BB molecules were almost not found on the surface of CD4[+] and CD8[+] T cells in HCC and healthy control group. The percentage of 4-1BB[+]/CD4[+] or CD8[+] T cells in two groups was not more than 0.1%, and the median value in each group was 0 (*P*= 0.406 for 4-1BB[+]/CD4[+], *P*=0.209 for 4-1BB[+]/CD8[+], respectively). (Table1, Figure 3).

Co-localization of 4-1BB and CD4 or CD8 on TILs
To determine whether TILs were the same clones as T lymphocytes from peripheral blood, confocal laser microscopy was used to detect 4-1BB expressions on TILs. As expected, we did not find any PE conjugated 4-1BB and FITC conjugated CD4 or CD8 fluorescence located within 3 normal liver tissues. However, co-localization of 4-1BB[+]/CD4[+] or CD8[+] on TIL was visualized by confocal laser microscopy in 3 tumor tissues and

1 liver tissue located within 1 to 5 cm away from tumor edge, as well as 13 tumor adjacent tissues within 1 cm. (Figure 4).

DISCUSSION

It seems that a better prognosis of HCC could attribute to the anti-tumor effect induced by cellular immunity of infiltrating CD8[+] and CD4[+] T lymphocytes[17]. However, like most solid tumours, HCC has long been considered poorly immunogenic. Tumor cells were capable of delivering antigen-specific signals to T cells clone, but could not deliver costimulatory signals, e.g., a B7/CD28 interaction[25-27], necessary for full T cell activation, could lead to the evasion of immune surveillance by malignant cells[28]. Moreover, evidences have demonstrated that TILs can down-regulate the expression of CD28 molecules, but still could retain a limited immune protection in local tumor microenviroment[27]. Therefore, other molecules may involve in sustaining T cells activation and amplifying cytotoxic T lymphocytes response.

In this study, we found that 4-1BB mRNA transcripts were

not detectable in normal liver, but were detected in all 19 liver tissues adjacent to tumor edge (<1.0 cm). In some tumor and liver tissues located within 1 to 5 cm away from tumor edge, low expression of 4-1BB mRNA was also detected. Since 4-1BB molecules were mainly expressed on activated T lymphocytes[18,19], 4-1BB transcripts might derive from TILs. To identify this hypothesis, direct immunofluorescence staining of 4-1BB and CD4 or CD8 on TILs was examined by confocal microscope. Co-localization of 4-1BB+/CD4+ or CD8+ fluorescence located on TILs was visualized by confocal microscopy in tumor and liver tissue within 1 to 5 cm away from tumor edge, as well as tumor adjacent tissues within 1 cm. Previous researches reported that interaction of 4-1BB with 4-1BB ligand played an important role in sustaining T cells activation, amplifying cytotoxic T lymphocyte (CTL) response, as well as inducing IL-2 production in the complete absence of a signal through CD28 molecule[22,23]. A recent report indicated that under the condition of repeated Ag-stimulation, down-regulated expression of CD28 molecule on activated T cells could lead to activation-induced cell death (AICD)[29], while very few 4-1BB molecules might supply sufficient costimulatory signals to sustain T cells activation, and inhibit AICD[30,31]. In fact, accumulative evidence has confirmed that 4-1BB/4-1BB ligand pathway plays a role in transplant immunity[32-34] and autoimmune disease[35-37]. Therefore, the present study may provide an important clue that 4-1BB molecules are also involved in the process of infiltrating CD4+ and CD8+ T cells activation, at least partly, and that modulating 4-1BB/4-1BB ligand pathway might augment CTL response against tumor[24,38-40].

However, even if these infiltrating lymphocytes are functionally activated via 4-1BB signals or the others, and are truly specific for tumor cells, why they could not inhibit the tumour growth? This phenomenon was inexplicable. Cytotoxic T cells propagated from biopsies showed a specific killing of the tumor cells *in vitro*, confirming that the complex microenvironment inside the tumor tissue was not able to provide the optimal condition for TILs to fully exert their functions in inhibiting tumor growth, or even to induce apoptosis of TILs through Fas/Fas ligand system[41,42].

To explore if the TILs were the same clones as T lymphocytes from peripheral blood, we analyzed the phenotypes of peripheral blood lymphocytes, and examined 4-1BB molecules and its mRNA transcripts by flow cytometry and RT-PCR respectively. To our surprise, we failed to detect 4-1BB mRNA in peripheral blood lymphocytes and 4-1BB molecules on peripheral CD4+ or CD8+ T cells from HCC patients. But our results confirmed that a significantly lower percentage of CD3+ T cells was found in HCC group as compared to healthy control group, which was coincided with other research data[43]. Since the phenotype and function of lymphocytes collected from the peripheral blood were not the same as those of lymphocytes from tumor draining regional lymph nodes and tumor tissues, we found that 4-1BB molecules were existed in infiltrating CD4+ and CD8+ T cells but not in peripheral blood lymphocytes. Therefore, we may conclude that TILs and peripheral blood lymphocytes are not the same clones[43-45].

In summary, we examined 4-1BB molecules expression in infiltrating T cells in HCC specimens, indicating that tumor infiltrating T cells can be activated via other costimulatory signals, e.g., 4-1BB, and exert a limited antitumor protection in local microenvironment. The present study also implicates that modulating 4-1BB/4-1BBL costimulatory pathway may be an effective immunotherapy strategy to augment the host response.

Abstract

AIM: To develop a tumor DNA vaccine encoding a fusion protein of murine AFP and CTLA4, and to study its ability to induce specific CTL response and its protective effect against AFP-producing tumor.

METHODS: Murine α-fetoprotein (mAFP) gene was cloned from total RNA of Hepa1-6 cells by RT-PCR. A DNA vaccine was constructed by fusion murine α-fetoprotein gene and extramembrane domain of murine CTLA4 gene. The DNA vaccine was identified by restriction enzyme analysis, sequencing and expression. EL-4 (mAFP) was developed by stable transfection of EL-4 cells with pmAFP. The frequency of cells producing IFN-γ in splenocytes harvested from the immunized mice was measured by ELISPOT. Mice immunized with DNA vaccine were inoculated with EL-4 (mAFP) cells in back to observe the protective effect of immunization on tumor. On the other hand, blood samples were collected from the immunized mice to check the functions of liver and kidney.

RESULTS: 1.8 kb mAFP cDNA was cloned from total RNA of Hepa1-6 cells by RT-PCR. The DNA vaccine encoding a fusion protein of mAFP-CTLA4 was constructed and confirmed by restriction enzyme analysis, sequencing and expression. The expression of mAFP mRNA in EL-4 (mAFP) was confirmed by RT-PCR. The ELISPOT results showed that the number of IFN-γ-producing cells in pmAFP-CTLA4 group was significantly higher than that in pmAFP, pcDNA3.1 and PBS group. The tumor volume in pmAFP-CTLA4 group was significantly smaller than that in pmAFP, pcDNA3.1 and PBS group, respectively. The hepatic and kidney functions in each group were not altered.

CONCLUSION: AFP-CTLA4 DNA vaccine can stimulate potent specific CTL responses and has distinctive antitumor effect on AFP-producing tumor. The vaccine has no impact on the function of mouse liver and kidney.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a major cause of cancer death with more than 1.2 million global annual incidences. The incidence of HCC has been increasing rapidly in both Asian and Western countries because of the global pandemic of hepatitis B and C infections[1]. Surgery and liver transplantation are the only effective treatments, but most HCC patients are not eligible due to the advanced stage of disease or poor hepatic function concomitant with cirrhosis[2-8]. It is important to develop novel therapies for HCC, and some genes and immunotherapeutic strategies for HCC are under investigation.

Understanding of antigen processing and presentation by antigen-presenting cells, as well as the conditions of induction of T-cell immunity, has spawned the discipline of genetic immunotherapy. DNA-based immunization can induce strong cellular immune responses to a variety of antigens, including tumor antigens, such as antigens associated with malignant melanoma[9-11], ovarian carcinoma[12], breast cancer[13,14], small-cell lung cancer[15], neuroblastoma[16] and prostate carcinoma[17].

Two major obstacles in developing rational strategies in tumor immunotherapy are identification of suitable target tumor antigens and effective process and presentation by professional antigen-presenting cells to induce T cell immunity.

Recent studies on the immunodominant epitopes of AFP have provided a solution to the obstacle of HCC immunotherapy. The majority of human HCCs overexpress the oncofetal antigen AFP, M_r 70 000 glycoprotein. AFP is produced at fetal liver at high levels, and transcriptionally repressed at birth and is present thereafter at low serum levels throughout life[18]. Butterfield *et al*[19-21] found recently that 4 peptides of human AFP processed and presented in the context of HLA-A0201, could be recognized by the human T cell repertoire, and could be used to generate AFP-specific CTL in human T cell cultures and HLA-A0201/K^b-trangenic mice. It was also found that the murine immune system could generate T-cell responses to this oncofetal antigen[22-24]. AFP can serve as an effective tumor-specific antigen but its immunogenicity is weak[19-25].

Cytotoxic T-lymphocyte antigen 4 (CTLA4) is a glycoprotein expressed on activated T cells. It has a strong binding affinity to both B7-1 (CD80) and B7-2 (CD86) molecules[26], which are primarily expressed on APCs. CTLA4 is a homodimer, but dimerization of CTLA4 is not required for B7 binding[27]. CTLA4-Ig has been used as an immunosuppressive drug in animal models of transplantation and autoimmune diseases[28,29].

In the present study, we investigated whether the immunogenicity of mouse AFP could be improved by targeting to APCs through B7-1 and B7-2 molecules. We constructed a plasmid DNA encoding mAFP and the extramembrane domain of mouse CTLA4 and found this DNA vaccine could stimulate potent specific CTL responses and had distinctive antitumor effect on AFP-producing tumor.

MATERIALS AND METHODS

Cell lines and plasmids

Hepa 1-6 (murine HCC) and EL-4 (murine lymphoma) cell lines were gifts from Dr Wang Hao (The Second Military

Medical University, Shanghai, China). CHO cells were provided by China Center for Type Culture Collection (Wuhan, China). The plasmid pmCTLA4-Ig encoding murine CTLA4-Ig was kindly provided by Professor Wang DW (Tongji Medical College, Huazhong University of Science and Technology, Hubei, China). Eukaryotic expression vector pcDNA3.1/myc-His was from Invitrogen Company.

Main reagents

TRIzol was a product of Gibco Company. RT-PCR kit was purchased from TaKaRa Biotechnology Company. Lipofectamine 2000 was a product of Invitrogen Company. Goat anti-AFP polyclonal antibody was purchased from Sant Cruz Company. Biotinylated rabbit anti-CTLA4 polyclonal antibody was purchased from PepraTech Company. Primers were synthesized by the Shanghai Bioasia Biocompany. ECL Western blotting detection reagents were products of Pharmacia Company. Murine IFN-γ ELISPOT kit was a product of Diaclone Company.

Construction of Plasmids

The 1.8 kb mAFP cDNA was cloned from total RNA of Hepa1-6 cells by RT-PCR. Total RNA was isolated from Hepa1-6 cells by the TRIzol method. RT-PCR primers were designed to include the entire mAFP coding region, including the signal sequence. The primers used were 5' -CTCAGGAATTCGCC ATGAAGTGGATCACA-3' and 5' -CTCTGCTCTAGATT ACTCGAGAACGCCCAAAGCATCACG-3' . The 1.8 kb mAFP cDNA PCR product was cloned into pcDNA3.1/myc-His to construct the plasmid pmAFP. The plasmid pmCTLA4-Ig was used as a temple to get the extramembrane domain of CTLA4 through PCR. To construct the mAFP-mCTLA4 fusion protein expression vector, we used overlap PCR to add a GGGGSGGGGS peptide linker upstream of the extramembrane domain of mouse CTLA4 gene. The forward primer 5' -TATGGCGGGGGCTCGATGGAAGCCATAC AGGTG-3' and the reverse primer 5' -CTCTCTCTCTAGATC AAGAATCCGGGCATGGT-3' were used in the first round PCR on the mouse CTLA4-Ig gene. The PCR product was used as a template to perform a second round PCR using the same reverse primer and a second forward primer 5' -TTATATTCTC GAGGGAGGCGGGGGCTCGGGAGGCGGGGGCTCGATGG-3' . The 5' side of the first forward primer and the 3' side of the second forward primer were overlapped for 17 nucleotides. The N terminal of extramembrane domain of CTLA4 with linker was fused in frame with the C terminal of mAFP in pmAFP to construct the mAFP-mCTLA4 fusion protein expression plasmid pmAFP-CTLA4. The recombinant vector was identified by restriction enzyme analysis and sequencing.

Western blot

Lipofectamine 2000 was used for transient transfection of CHO cells according to the manufacturer' s instructions. Proteins were separated on SDS-PAGE, and transferred onto a nitrocellulose membrane by semidry electrobloting. Proteins were stained with goat anti-AFP polyclonal antibody or biotinylated rabbit anti-CTLA4 polyclonal antibody, followed by anti-goat IgG-HRP or HRP-avidin. The blot was developed with ECL Western blotting detection reagents.

Stable transfection of EL-4 cells with plasmids pmAFP

EL-4 (mAFP) was developed by stable transfection of EL-4 cells with pmAFP by Lipofectamine 2000 according to the manufacturer' s instructions. Transfectants were selected and maintained with G418 (0.3 mg/ml) in RPMI1640 complete media. The expression of mAFP mRNA in EL-4(mAFP) was assessed by RT-PCR.

Immunization and ELISPOT assay

Twenty-four female C57BL/6 mice were divided into pmAFP-CTLA4 group, pmAFP group, pcDNA3.1 group and PBS group, each group had 6 mice. For each mouse, 100 μg plasmid was administered in the left anterior tibialis muscle on day 0 and day 14, respectively. On day 28 of study, all mice were killed. The splenic lymphocytes were separated for ELISPOT and the blood was drawn for examination of the functions of liver and kidney. The splenocytes were restimulated *in vitro* by EL-4(mAFP) as reported[22]. In brief, splenocytes were cultured with irradiated EL-4 (mAFP) cells containing 10 unit/ml human IL-2 for 48 h at 37 ℃. The anti-IFN-γ antibody coated ELISPOT plate was incubated with restimulated cells at 37 ℃ for 24 h.

Protective effect of DNA vaccine against tumor

Another 24 C57BL female mice were grouped and immunized as above. Two weeks after the last immunization, all mice were injected by 2×10^5 EL-4 (mAFP) on the back subcutaneously. Tumor mass was assessed two times weekly as the follow formula: $4/3 \pi r^3$ (r = radius).

Examination of functions of liver and kidney

The serum ALT and creatinine were measured with ALT assay kit and creatinine assay kit, respectively.

Statistical analysis

Software SPSS 10.0 was employed to process the data. The *t* test was used for statistical analysis. $P < 0.05$ was considered significant.

RESULTS

Plasmids construction

The 1.8 kb mAFP cDNA was isolated from murine HCC cell line Hepa1-6 by RT-PCR and subcloned into pcDNA3.1 to construct plasmid pmAFP. We cloned the extracellular domain of mouse CTLA4 from plasmid pmCTLA4-Ig, and added a flexible linker (GGGGSGGGGS) before CTLA4 by overlap PCR. The N terminal of extramembrane domain of CTLA4 with linker was fused in frame with the C terminal of mAFP in pmAFP to construct the mAFP-mCTLA4 fusion protein expression plasmid pmAFP-CTLA4. Correct orientation of the ligations was determined by restriction enzyme analysis (Figure 1). Sequencing analysis showed that the reading frame was correct.

Figure 1 Identification of pmAFP and pmAFP-CTLA4 with restriction enzyme analysis. M: DNA marker, Lane 1: pcDNA3.1/ EcoRI, Lane 2: pmAFP-CTLA4/EcoRI+XbaI, Lane 3: pmAFP-CTLA4/EcoRI, Lane 4: pmAFP-CTLA4/EcoRI+XhoI, Lane 5: pmAFP-CTLA4/XhoI+XbaI, Lane 6: pmAFP/EcoRI+XbaI, Lane 7: pcDNA3.1/EcoRI, Lane 8: pmAFP/EcoRI.

Western blot

Expression of plasmids pmAFP and pmAFP-CTLA4 in transient transfection of CHO cells was analyzed with Western blotting, the expected two protein bands (-70 and -84 kDa)

were shown (Figure 2). The expression of mAFP mRNA in EL-4(mAFP) was confirmed by RT-PCR(data not shown).

Figure 2 Detection of protein expression of plasmids by Western blotting. A: the blot was probed with anti-AFP. Lane 1: CHO/pmAFP-CTLA, Lane 2: CHO/pmAFP, Lane 3: Hepa 1-6, Lane 4: CHO/pcDNA3.1, B: the blot was probed with anti-CTLA4. Lane 1: CHO/pmAFP-CTLA, Lane 2: CHO/pmAFP, Lane 3: CHO/pcDNA3.1.

ELISPOT assay

ELISPOT results showed the number of IFN-γ-producing cells in pmAFP-CTLA4 group was significantly higher than that in pmAFP group ($P<0.01$), pcDNA3.1 group ($P<0.01$) and PBS group ($P<0.01$) (Figure 3).

Figure 3 Number of IFN-γ-producing cells in 4 different groups.

Protective effect of DNA vaccine against tumor

The tumor growth in pmAFP-CTLA4 group was slower than that in other groups. Twenty two days after tumor challenge, the tumor volume of pmAFP-CTLA4 group was significantly smaller than that in pmAFP group ($P<0.01$), pcDNA3.1 group ($P<0.01$) and PBS group ($P<0.01$) (Figure 4).

Figure 4 Comparison of tumor masses in 4 groups on 22 days following tumor challenge.

Functions of liver and kidney

The serum level of ALT and creatinine in each group was unchanged (Table 1), suggesting that the immunization had no impact on the function of liver and kidney.

Table 1 Serum level of ALT and creatinine after immunization with DNA vaccine

Groups	n	ALT/U· mL^{-1} ($\bar{x}\pm s$)	Creatinine/μmol· L^{-1} ($\bar{x}\pm s$)
PBS	6	51.1±1.7	119.4±6.9
pcDNA3.1	6	50.9±1.5	116.6±9.7
pmAFP	6	51.6±2.5	116.4±6.0
pmAFP-CTLA4	6	52.5±3.2	118.6±11.5

DISCUSSION

Many tumors express tumor-associated or tumor-specific antigens but do not elicit an efficient immune response. Various experimental strategies have been explored to enhance the immunogenicity of tumor vaccines. Targeting immunogens to APCs with Abs against class MHC[30,31], FcγR[30], 33D1[31], or surface Ig[32] could substantially increase Ab responses. Antigens could be presented to APCs more efficiently by conjugating with FcγR[33], IP10[34], MCP-3[34], L-selectin[35] and CTLA4[35,36], and lead to significant antitumor immunity[34,36]. A DNA vaccine that can express carcinoembryonic Ag (CEA), AFP, and CD40 ligand trimer fusion protein, could break peripheral T cell tolerance against CEA and achieve effective tumor-protective immunity against murine colon carcinoma in CEA-transgenic mice[37].

HCC is a highly malignant tumor with a poor prognosis and few therapeutic options. AFP is a HCC-associated Ag but can not elicit efficient immune response. Some experimental strategies have been explored to enhance the immunogenicity of HCC vaccines based on AFP. Previous experiments of AFP-specific genetic immunotherapy for HCC included AFP plasmid immunization, AFP-transduced DCs immunization and AFP plasmid prime-AFP adenovirus boost immunization. Plasmid AFP immunization resulted in detectable but low levels of AFP-specific T-cell responses and poorly reproducible protective immunity[22-25]. DCs engineered to express murine AFP demonstrated a powerful ability to generate AFP-specific T-cell responses and protective immunity in mice[22,23]. However, the need for costly cell culture procedures precluded their wide availability for clinical use, and minor variation in the culture technique or antigen loading might yield sub optimal, even tolerating vaccines[38,39]. AFP plasmid prime-AFP adenovirus boost immunization could generate significant AFP-specific T-cell responses and protective immunity in mice[23]. But this method at least has two steps. In the present study, we tested a novel strategy for inducing anti-HCC immunity by specifically targeting APCs with a DNA vaccine encoding both AFP and CTLA4 in mice. We found that the vaccine elicited strong AFP-specific T-cell responses and had distinctive preventive effect on AFP-producing tumor.

We attributed the successful α-fetoprotein specific T cell responses in mice to the CTLA4 moiety targets APCs for efficient receptor-mediated uptake and processing of mAFP. CTLA4 could likely provide such a strong adjuvant activity due to its strong binding affinity to B7 molecules on APCs. CTLA4 could bind to both B7-1 and B7-2 with a 20- to 50-fold higher affinity than CD28[40]. A CTLA4-Ig fusion protein composed of CTLA4 and IgG Fc was 4-fold high of that in draining lymph nodes, levels of nontargeted protein within 2-24 hours administration[41]. Monomeric CTLA4 also has binding activity for B7-1 and B7-2, though its binding activity is low when compared with dimeric CTLA4.

CTLA4-Ig has been used as an immunosuppressive drug in animal models of transplantation and autoimmune

diseases[28,29]. Our current study showed the enhanced immunogenicity of mAFP-CTLA4. CTLA4 had 20 to 50-fold higher affinity to both B7-1 and B7-2 than CD28. The immune suppression mediated by CTLA4-Ig was likely through its inhibition of CD28-B7 interactions, which provide an important positive signal for T-cell proliferation and cytokine release[42]. The different immunomodulating effects of CTLA4 might be caused by varied doses of CTLA4 administered. In previous studies, to achieve maximal immune suppression, 50-500 µg CTLA4-Ig was applied before and after transplantation for several consecutive days. But when fusion protein Id-CTLA4 was used as vaccine in another experiment, only twice administration of 0.1-50 µg Id-CTLA4 was sufficient enough to elicit strong immune response to Id[36]. Vaccination with DNA encoding CTLA4-Ig provided an additional evidence that CTLA4-Ig at low levels could increase both Ab and T-cell proliferation responses[35,43].

In summary, the result suggests that a DNA vaccine encoding AFP and CTLA4 can elicit strong AFP-specific T-cell responses and has distinctive antitumor effect on AFP-producing tumor.

Abstract

AIM: Osteopontin (OPN) is a phosphorylated glycoprotein with diverse functions including cancer development, progression and metastasis. It is unclear how osteopontin is regulated in HepG2 cells. The aim of this study was to investigate the effect of epidermal growth factor on the expression of osteopontin in HepG2 cells, and to explore the signal transduction pathway mediated this expression.

METHODS: Osteopontin expression was detected by RNAase protection assay and Western blot. Wortmannin, a specific inhibitor of PI3K, was used to see if PI3K signal transduction was involved in the induction of osteopontin gene expression.

RESULTS: HepG2 cells constitutively expressed low levels of osteopontin. Treatment with epidermal growth factor increased osteopontin mRNA and protein level in a dose- and time-dependent manner. Application of wortmannin caused a dramatic reduction of epidermal growth factor-induced osteopontin expression.

CONCLUSION: Osteopontin gene expression can be induced by treatment of HepG2 cells with epidermal growth factor. Epidermal growth factor may regulate osteopontin gene expression through PI3K signaling pathway. Several potential targets in the pathway can be manipulated to block the synthesis of osteopontin and inhibit liver cancer metastasis.

INTRODUCTION

Osteopontin (OPN) is a secreted arginine-glycine-aspartate (RGD)-containing phosphoprotein with cell adhesive and chemotactic properties *in vitro* and *in vivo*[1-3]. It is closely associated with infiltrating macrophages in tumors and can directly stimulate macrophage migration, which has made it a key target as a molecule likely to be important in mediating tumor metastasis[4]. It has been shown that osteopontin is up-regulated in many kinds of cancer, including hepatocellular carcinoma[5,6], breast cancer[7-9], prostate cancer[10,11], ovarian cancer[12,13], brain cancer[14,15] and lung cancer[16]. Elevated osteopontin transcription often correlates with increased metastatic potential of cancers.

Epidermal growth factor (EGF) receptor (EGFR) is a member of the ErbB family of ligand-activated tyrosine kinase receptors, which play a central role in the proliferation, differentiation, and/or oncogenesis of epithelial cells, neural cells, and fibroblasts[17,18]. It has been reported that EGF can induce osteopontin expression of breast cancer cells[19], rat kidney epithelial cells[20] and HL60 cells[21], and the induction of osteopontin may involve in signaling pathway related to PKC and tyrosine kinase[22]. The mechanism responsible for osteopontin up-regulation in HCC is unknown, but may involve induction by specific cytokines. We have investigated this hypothesis by testing the effects of epidermal growth factor on osteopontin regulation in hepatocellular carcinoma cell line, HepG2. Using RNase protection assay, Western blot, we found that HepG2 cells constitutively expressed low levels of osteopontin mRNA and protein. EGF is a potent inducer of osteopontin mRNA and protein in HepG2 cells. Wortmannin, a specific PI3-K inhibitor, blocks the EGF-induced OPN expression. Our study suggests that OPN expression induced by EGF is dependent on PI3-K signaling pathway in HepG2 cells.

MATERIALS AND METHODS

Cell line and culture

HepG2 cell line was obtained from Cell Biology Institute (Shanghai, China). Cells were cultured in DMEM (Gibcol BRL) containing 10% fetal calf serum (Hyclone).

Induction of growth factor signaling

Cells were plated at 1×10^5 per well in 6-well plates, and were grown overnight. Next morning, the cultures were washed twice with PBS and maintained in serum-free medium (containing 0.05% BSA) for 24 hours. The cells were then stimulated with the indicated amounts of EGF (Sigma) for the indicated time frames before harvesting and analysis.

To assess signal transduction molecules involved in the induction of osteopontin gene expression, the PI3-Kinase inhibitor wortmannin (Calbiochem) was added to the cells. The cells were pretreated with respective inhibitors or vehicle (DMSO) alone for half an hour and then treated in combination with EGF for 8 hours. Preliminary dose-response experiments had defined the concentrations of 100nM wortmannin to be effective and non-toxic.

DNA constructs and in vitro transcription

Plasmid pGEM-OPN containing osteopontin fragments was constructed in our laboratory. A 486bp of OPN fragment was obtained by reverse transcription-PCR from plasmid pBlueScript-OPN containing full length human osteopontin (a kind gift from Dr. Chambers, Canada) using the sense primer 5'-ATGGATCCGATGACACTGATGATTCTCAC-3' and

antisense primer 5' -GCGAATTCGAATTCACGGCTGACAAA-3' . The resultant BamH1-EcoR1 cDNA fragment was ligated into the vector pGEM, and confirmed by direct sequencing.

To make RNA probes for OPN and β-actin (a linearized plasmid containing β-actin fragment included in the kit), *in vitro* transcription was performed with a commercial kit (Ambion), according to the user' s instructions.

RNA isolation and RNase protection assay

Total RNA was isolated using the RNeasy Mini kit (QIAGEN GmbH, Germany). RNase protection assay was performed with a commercial kit (Ambion). α^{32}P-UTP labeled probes were mixed with sample RNA and co-precipitated. Hybridization was proceeded for 10 minutes at 68 ℃, followed by digestion with RNase A-T1 for 30 minutes at 37 ℃, and separation of hybridized RNA on 5% acrylamide and 8M urea gels. The gels were dried on filter paper for 40 minutes at 80 ℃, and exposed to X-ray film. The autoradiographs were scanned using an AlphaImager 2200 spot densitometer (Alpha Innotech Corporation), and the integrated densities of areas were recorded.

Western blot

Cultured cells were lysed in RIPA buffer (50 mM Tris-HCL pH 7.5, 150 mM NaCl, 1% NP-40, 0.5% Na-deoxycholate,

0.1% sodium dodecyl sulfate). Cell lysates were denatured at 100 ℃ for 5 minutes, and equal amounts of protein were loaded onto 10% SDS-polyacrylamide gels. The separated proteins were transferred to PVDF membranes (ROCHE) and probed with antibodies to osteopontin (Calbiochem). Membranes were stripped and re-probed with antibodies to tubulin as an internal control.

RESULTS

OPN expression in HepG2 cells induced by EGF-treatment

In order to examine the regulators of osteopontin expression in hepatocellular carcinoma cells, HepG2 cells were incubated in serum-free medium and then treated with epidermal growth factor that had been implicated in HCC. As shown in Figures 1 and 2, HepG2 cells constitutively expressed low levels of osteopontin, stimulation of the cells with EGF increased osteopontin mRNA expression as well as protein level in a dose-dependent and time-dependent manner. To quantitate this finding, densitometry of osteopontin mRNA levels was recorded (Figure 1B and Figure 2B). Osteopontin expression was elevated after treatment with EGF within a 8-hour period, expression levels were further increased at 16 hours and 24 hours following treatment.

Figure 1 Dose-dependent effect of EGF on osteopontin expression in HepG2 cells. 1×10^5 cells were plated in 6-well plates. Next morning, cell cultures (near 80% confluent) were incubated in serum-free medium for 24 hours. The cells were stimulated dose-dependently by epidermal growth factor. Positive control denotes cells in normal growth medium containing 10% fetal calf serum. A. Osteopontin mRNA level was analyzed by RNase protection assay on total RNA using a 486 base-pair probe and controlling the loading with a probe for β-actin. B. Quantitation of osteopontin mRNA levels is shown in (A). RDU ratio reflects relative density units dof osteopontin mRNA divided by β-actin mRNA. C. The results from RNase protection assay were confirmed by Western blot of osteopontin protein. Tubulin was served as loading control.

Figure 2 Time course showing effect of EGF on osteopontin expression in HepG2 cells. 1×10^5 cells were plated in 6-well plates. Next morning, cell cultures (near 80% confluent) were incubated in serum-free medium for 24 hours. The cells were stimulated time-dependently by 10 ng/ml EGF. Positive control denotes cells in normal growth medium containing 10% fetal calf serum. A. Osteopontin gene expression was analyzed by RNase protection assay on total RNA using a 486 base pair probe and standardized by comparison to β-actin. B. Quantitation of osteopontin mRNA levels is shown in (A). RDU ratio reflects relative density units of osteopontin mRNA divided by β-actin mRNA. C. Western blot of osteopontin protein by cell lysates confirmed the results from RNase protection assay. Tubulin was served as loading control.

Interference of EGF-induced osteopontin gene expression in HepG2 cells with inhibition of PI3-kinase

We analyzed the involvement of EGF signaling pathway in the induction of osteopontin gene expression. Addition of the PI3-kinase inhibitor wortmannin blocked EGF-mediated increase of osteopontin mRNA levels in HepG2 cells (Figure 3). It should be mentioned that wortmannin only partially reversed EGF-induced osteopontin expression, suggesting that other pathways related to EGF might involve the induction of osteopontin expression.

Figure 3 Phosphatidylinositol 3-kinase pathway dependent of osteopontin expression in HepG2 cells. The PI3-kinase inhibitor wortmannin was used to assess EGF-dependent signal transduction leading to osteopontin gene expression. 1×10^5 cells were plated in 6-well plates. Next morning, cell cultures (near 80% confluent) were incubated in serum-free medium for 24 hours. 100 nM wortmannin was added to the cells 30 minutes before incubation in the presence or absence of 10 ng/ml EGF. A. Osteopontin mRNA level was analyzed by RNase protection assay on total RNA using a 486 base-pair probe and controlling the loading with a probe for β-actin. B. Quantitation of osteopontin mRNA levels is shown in (A). RDU ratio reflects relative density units of osteopontin mRNA divided by β-actin mRNA.

DISCUSSION

Hepatocellular carcinoma (HCC) is one of the most malignant tumors in the world[23]. In China, at least 100 000 new cases occur every year, and the estimated number of HCC-related deaths exceeds 110 000 per year. Recent studies indicate that the incidence of HCC in the US and UK has increased substantially over the last two decades[24,25]. Although remarkable advances in surgery have improved the prognosis of HCC patients, the high rate of intra-hepatic recurrence and metastasis remains a major challenge in HCC therapy[26,27]. Recently, it has been reported metastasis genes or metastasis-associated genes are involved in the migration and dissemination of cancers through certain signaling pathway[28,29]. Therefore, if the signal transduction pathway that regulates the expression of metastasis genes could be defined, some candidate targets via the pathway can be used to block the malignancy-promoting effects of metastasis genes, which will be useful for therapeutic intervention, including controlling the recurrence and metastasis of HCC.

Cytokine osteopontin, one of the metastatic genes, has been found in a number of tumors[5-16], and to be essential for the dissemination of various cancers[30]. Transfection of the cells

with anti-sense OPN RNA reduced the malignancy of the cells and caused the decrease of tumorgenesis[31], while transfection with osteopontin increased their malignant phenotype[32]. Osteopontin was up-regulated in hepatocellular carcinoma and the increase of OPN expression was correlated with the metastatic ability of HCC and invasiveness of liver tumor–derived cell lines *in vitro*[5,6]. In the present study, we found that HepG2 cells constitutively expressed low levels of osteopontin, and EGF induced osteopontin expression in a dose- and time- dependent manner in the cell line. The concentration of EGF in the cells was very low. The induction of osteopontin was prominent at 0.1 ng/ml EGF concentration in our study, while the concentration of EGF was high up to 100 ng/ml in the literature[19,33]. The difference can be caused by many kinds of reasons, one of them may be that the different cells have different response to EGF. To our knowledge, this is the first study to demonstrate that EGF can cause the induction of osteopontin mRNA and protein levels in liver cancer cells. In other cell lines, the up-regulation of osteopontin by EGF was confirmed by overwhelming number of studies, including in kidney epithelial cells[33] and osteoblasts[22].

We then investigated the mechanism of osteopontin regulation by EGF in HepG2 cells. Using wortmannin, a specific inhibitor of PI3K, we found that EGF-induced osteopontin expression was significantly down-regulated. It suggested that the induction of osteopontin by EGF was dependent on PI3K signal transduction pathway in HepG2 cells. On the other hand, our results showed that wortmannin could not totally block EGF-induced osteopontin expression in HepG2 cells, suggesting that other pathways associated with EGF and its receptor may involve in the osteopontin induction.

A conclusion may be drawn from the study that EGF/PI3K signal pathway can regulate the expression of osteopontin in hepatocellular carcinoma cell line, HepG2. Several candidate targets via this pathway can be used for therapeutic intervention of HCC.

Abstract

AIM: To explore the germline mutations of the two main DNA mismatch repair genes (*hMSH2* and *hMLH1*) between patients with hereditary non-polyposis colorectal cancer (HNPCC) and suspected (atypical) HNPCC.

METHODS: Genomic DNA was extracted from the peripheral blood of the index patient of each family, and germline mutations of *hMSH2* and *hMLH1* genes were detected by PCR-single strand conformation polymorphism (*PCR-SSCP*) and DNA sequencing techniques.

RESULTS: For PCR-SSCP analysis, 67% (4/6) abnormal exons mobility in typical group and 33% (2/6) abnormal exons mobility in atypical group were recognized. In direct DNA sequencing, 50% (3/6) mutation of MMR genes in typical group and 33% (2/6) mutation of MMR genes in atypical group were found, and 4/6 (66.67%) and 1/6 (16.67%) mutations of *hMSH2* and *hMLH1* were identified in typical HNPCC and atypical HNPCC, respectively.

CONCLUSION: Mutation detection of the patients is of benefit to the analysis of HNPCC and, PCR-SSCP is an effective strategy to detect the mutations of HNPCC equivalent to direct DNA sequence. It seems that there exist more complicated genetic alterations in Chinese HNPCC patients than in Western countries.

INTRODUCTION

Hereditary nonpolyposis colorectal cancer (HNPCC) is characterized by early onset of colorectal cancer, location of tumors in the proximal colon, and an increased risk of neoplasms of extracolonic organs, including endometrium, stomach, urothelium, small intestine, and ovary[1-6]. The International Collaborative Group on HNPCC (ICG-HNPCC) proposed a set of clinical diagnostic criteria (Amsterdam Criteria I) for HNPCC in 1990 and has revised them recently (Amsterdam Criteria II) to provide a uniformity in collaborative studies[7,8]. According to these criteria, there should have at least three patients in two consecutive generations who had colorectal cancer or the other extracolonic malignancies including endometrial cancer, small bowel cancer, cancer of the ureter and cancer of the renal pelvis. One of them should be a first-degree relative of the other two, one cancer should be diagnosed before age 50, and familial adenomatous polyposis (FAP) should be excluded. In Asia, on the other hand, the Japan Research Society for Cancer of the Colon and Rectum developed the clinical criteria (Japanese criteria) for HNPCC in 1991[9]. According to these criteria, at least two relatives in at least two successive generations should have colorectal cancer, and one of them should be a first-degree relative of the other, also, we called them atypical HNPCC.

Nevertheless, according to those criteria above, all families that are diagnosed as having HNPCC are identified on the basis of a family history of colorectal or other certain malignancies. Sometimes the accuracy and reliability of the family history provided by patients themselves and their relatives or recorded by physicians are questionable, as there is much viability for the family history. Therefore, the requirements for establishing objective strategies to identify this disease are imperative. In the last decade, the progress in genetic study that DNA mismatch repair genes have been identified as being mutated in HNPCC including *hMSH2, hMLHI, hPMS1, hPMS2,* and *hMSH6* makes it possible to identify the cohort of patients through genetic test. Totally, these genes are now believed to account for about 50%-70% of all families with HNPCC and over 90% of the identified mutations focused on the two genes, *hMSH2* and *hMLH1*[10-18]. There are many studies about the procedures of genetic testing of HNPCC, such as microsatellite instability (MSI), PCR-SSCP, immunohistochemistry (IHC) and direct DNA sequencing[19-24]. However, much knowledge and a higher grade of technical development are required, before this strategy becomes applicable to the general population.

It has no doubt that there is a large population of HNPCC in China[25,26]. Unfortunately, there have been few reports about clinical and genetic characteristics of HNPCC[27]. In this study, six HNPCC families and six atypical HNPCC families were enrolled and, the germline mutations of *hMSH2* and *hMLH1* in the index patients from each family were investigated.

MATERIALS AND METHODS

Subjects
The project was approved by the Institutional Review Board and informed consent was obtained from each participant before the procedures were carried out. Personal and family cancer history was obtained from the proband and participating relatives, and cancer diagnosis and deaths were confirmed by review of medical records, pathological reports or death certificates. Families were identified by the Amsterdam or Japanese criteria for HNPCC. Patients and families were classified as the HNPCC group according to the Amsterdam criteria, suspected HNPCC group according to the Japanese criteria and control group without any family history.

Genetic testing

Preparation of peripheral blood samples and DNA amplification Genetic analysis was performed on a blood specimen from the proband in each family. Specimens were collected and immediately frozen in liquid nitrogen. DNA was extracted from blood specimens using the Wizard genomic purification kit (Qiagen, Shanghai) according to the manufacturer's instructions. Each of the exons from hMSH2 and hMLH1 genes was amplified by polymerase chain reaction (PCR). Next, the samples were heat-treated at 95 ℃ for 5 minutes to inactivate the enzyme, and used as the template DNA. All DNA amplification was performed in a 50 μl volume containing 100 ng template DNA, 10^{-3} M Tris-HCl (pH 8.9), 50^{-3}M KCl, 2.5 mom MgCl$_2$, 0.2^{-3}M of each dNTP,10 pmol each primer, and 1U Taq polymerase was subjected to 35 PCR cycles (5 mins at 94 ℃, 40 s at 94 ℃, 60 s at 55 ℃, and 40 s at 72 ℃). Oligonucliotide sequences were designed from the sequences published in Genebank.

PCR-SSCP analysis and direct sequencing

Single-strand conformation polymorphism (SSCP) The technique of single-strand conformational polymorphism (SSCP) was used to identify mutations in the mismatch repair genes[28,29]. Each exon of hMSH2 and hMLH1 was amplified specifically using PCR (details of oligonucleotide sequences and conditions are available from the authors). PCR products were electrophoresed on 10% non-denaturing polyacrylamide gels with an acrylamide: bisacrylaminde ratio of 30:0.8 at 70volt for 12 h at room temperature. DNA was detected by silver staining according to the methods described by others. Those single stranded DNAs that took up an altered conformation appeared as aberrantly migrating bands on the electrophoresis gel.

Direct sequencing

The nucleotide sequence of PCR products showing an abnormal mobility on SSCP was determined by direct sequencing. The PCR products were purified with 1.5% low melted point agrose, and then performed using automated DNA sequencer. Sequence alterations with an allele frequency of at least 5% were considered as normal variants (polymorphisms) and not reported.

Statistical analysis

The genetic differences of the typical HNPCC groups and the suspected HNPCC groups were analyzed for statistical significance using the chi square test. $P<0.05$ was considered statistically significant.

RESULTS

Results of genetic testing

Characterization of the variants of PCR-SSCP and DNA sequencing analysis found in the 12 families/individuals in the study is presented in Table 1. A total of seven abnormal motilities were identified in PCR-SSCP including five in typical group and two in atypical group (part of PCR-SSCP analysis is shown in Figure 1). DNA sequencing found 6/7 (85.7%) abnormal motilities of PCR-SSCP, which were proven to be pathogenic germline mutations of hMSH2 and hMLH1. The other abnormal mobility, an "A" insertion in hMLH1 intron 10 occurred in the C10-1 patient, was proven to be polymorphism.

Figure 1 Results of PCR-SSCP in C13 family (hMSH2-exon11). Arrow shows the abnormal mobility.

Totally, five patients were found to harbor MMR gene mutations in the direct DNA sequencing. Three of six (50%)

Table 1 Characterization of variants in PCR-SSCP and sequence detection

Family	Abnormal mobility	DNA change	Mutation	Group
C4-1	hMLH1 exon18	T insert in 2 081	Frameshift	Typical HNPCC
	hMSH2 exon15	C insert in 2 469	Frameshift	
		G insert in 2 471	Frameshift	
C13-1	hMSH2 exon11	T insert in 1 760	Frameshift	
		A→C missense in 1 688	Tyr563Ser	Typical HNPCC
C11-1	hMSH2 exon13	T to A missense in 2 091	Cys697	
			Terminator Condon	Typical HNPCC
C1-1	hMLH1 exon11	A insert in 934	Frameshift	Atypical HNPCC
C8-2	hMLH1 exon12	C to G missense in 1 198	Leu400Val	
		C to G missense in 1 261	Val421Leu	
		C insert in 1 364 and 1 372	Frameshift	Atypical HNPCC
C10-1	hMLH1 intron10	–	Polymorphism	Typical HNPCC

Figure 2 Results of direct sequencing of exon 11 of hMSH2 in C13 family (A to C substitution in 1 688 and T insertion in 1 706).

patients with HNPCC and 2/6 (33%) patients with suspected HNPCC were found to harbor mutations. However, we found the mutations were complicated as the total number of mutations was more than five and all the mutations we found were novel and of unknown pathogenicity (part of sequence analysis is shown in Figure 2).

In typical HNPCC, the germline mutation of *hMLH1* and *hMSH2* was detected in 3 of 6 HNPCC families. Seven novel mutations were found in 3 exons of *hMSH2* and 1 exon of *hMLH1*, two mutations were detected at 11 exons of *hMSH2* in C13 family, one was the frame shift mutation resulted from an insertion of "T" at 1 760 so that a terminate cordon appeared ahead, the other was "A to C" missense mutation at 1 688 leading to Tyr-Ser substitution. A "T to A" substitution at 2 091 of exon 13 of *hMSH2* in C11 family resulted in a terminate cordon at 697. The mutations in C4 family were worthy of specific comment, as the mutation occurred in *hMLH1* as well as *hMSH2*, there was a frame shift mutation resulted from an insertion of T at 2 081 of exon 18 of *hMLH1*, there were "C, G" inserts at 2 469, 2 471 respectively. However, all families without germline *hMSH2* and *hMLH1* mutations were combined with extracolonic tumors.

In atypical HNPCC, only the germline mutation of *hMLH1* was detected in 2 of 6 HNPCC families, one was the frame shift mutation in exon 11 resulted from an insertion of "A" at 934 in C13 family. In C8 family, the mutation occurred at four locations, one was "C to G" missense mutation at 1 198 leading to Leu400Val substitution, one was "C to G" missense mutation at 1 261 leading to Val421Leu substitution and the other two shift mutations occurred at 1 364 and 1 372 resulted from the A insertion at the two locations respectively. The detailed results of sequencing are shown in Table 2.

Table 2 Comparison of two kinds of HNPCC with PCR-SSCP and sequencing

	Typical HNPCC (*n*=6)	Atypical HNPCC (*n*=6)	*P*
PCR-SSCP	4 (67%)	2 (33%)	0.269
Sequencing	3 (50%)	2 (33%)	0.575

DISCUSSION

To date, HNPCC is defined either by the so-called Amsterdam I+II criteria or by detection of a mutation in one of the mismatch repair genes. Once the positive mutation is identified, predictive testing of family members at risk is available. Screening recommendations for clinically identified families, mutation carriers, and their unaffected relatives at risk must be defined for clinical management[30].

Recently, Watson *et al*[31] published their results about that carrier risk status changes resulted from mutation testing in hereditary non-polyposis colorectal cancer and hereditary breast-ovarian cancer. They concluded that mutation testing could raise the accuracy of carrier risk assessments, and lower the number of persons at high carrier risk. The most common risk assessment change resulted from DNA testing was a change from those at risk to non-carriers. To the extent that these persons were aware of their carrier risk and were obtaining heightened cancer surveillance test, this could be expected to lead to a reduced emotional toll and a reduced pressure on limited medical resources.

A better understanding of the molecular basis of hereditary colorectal cancer syndromes such as hereditary nonpolyposis colorectal cancer syndrome (HNPCC) and familial adenomatous polyposis (FAP) would have profound consequences for both the diagnosis and (prophylactic) treatment of (pre)malignant neoplastic lesions[32] Clinically, when we see a patient with

colorectal cancer with a family history of suspected HNPCC, we need to work out our surgical strategies for this patient, the same as we do for the patients with HNPCC, in whom colonoscopy surveillance or prophylaxis surgeries such as subtotal colectomy are needed. One of the evidences of special surgical treatment has been found to be genetic detection[33,34]. Since HNPCC is resulted from the dysfunction of mismatch repair genes and some reports indicated that mutation of *hMSH2* and *hMLH 1* accounted for 40%-70% HNPCC[35-39], we decided to detect the germline mutation of *hMSH2* and *hMLH1* in this study. In PCR-SSCP analysis of genomic DNA of 12 probands, we identified seven abnormal mobilities, five in typical HNPCC and two in suspected HNPCC and six of them were testified to be mutations by DNA sequencing. When we compared the genetic investigation of two groups we studied, we also concluded that there were no statistical differences in the results of both PCR-SSCP and direct sequence.

We also found that the mutations occurred both in typical HNPCC group and in atypical HNPCC group. Beck *et al* found germline HNPCC mutations in six families in which none fulfilled the Amsterdam criteria. They highlighted that if germline mutations of the mismatch repair genes were common in families with features of HNPCC, but not fulfilling the Amsterdam criteria, then it was very important that all such families were also referred to cancer clinics for assessment and possible genetic testing[40]. It was suggested that many suspected HNPCC patients might not be recognized and might be excluded from genetic counseling[41,42].

Upon reviewing the literature and checking the variants registried in the ICG-HNPCC mutation database (http://www.nfdht.nl), we found that all the mutations were novel. It is rarely reported that there exist multiple mutations in the same exons. However, it seemed to be common in our analysis, two mutations were found at 11 exons of *hMSH2* in C13 family and C8 family. The mutation occurred at four locations, one was "C to G" missense mutation at 1 198 leading to Leu400Val substitution, one was "C to G" missense mutation at 1 261 leading to Val421Leu substitution and the other two shift mutations occurred at 1 364 and 1 372 resulted from the A insertion at the two locations, respectively. Furthermore, it is the first report that the mutation occurred in both *hMLH1* and *hMSH2* in C4 family.

Several techniques for genetic detection of HNPCC have been developed including MSI, immunohistochemistry, SSCP, denaturing gradient gel electrophoresis (DGGE) and sequencing. SSCP was considered inefficient in detecting mutations[43,44] and was expected to miss approximately 20% of point and frameshift mutations. Furthermore, it was unable to detect the whole exon deletions, which occured in some HNPCC families[45]. We chose SSCP first because it was relatively simple, quick and cheap, and did not require special apparatus. In our study, 12 abnormal bands found in SSCP were proven to represent 11 mutations (91.7%). We found it was a practical procedure for the genetic screening of HNPCC.

Given the limitations of current techniques, direct PCR product sequencing analysis is more efficient for detecting mutations, but it is laborious, more expensive in term of reagents and data analysis time and not 100% efficient. It is much more acceptable clinically to take the screening techniques, such as SSCP, first and use sequencing to analyze the details of the mutation. Recently, some studies demonstrated that large genomic rearrangements accounted for 10%-20% of all *hMSH2* mutations, and a lower proportion of all *hMLH1* mutations. Nakagawa[46] used the multiplex ligation-dependent probe amplification (MLPA) method to screen *hMSH2* and *hMLH1* deletions in 70 patients whose colorectal or endometrial tumors were MSI positive, yet no mutation was found by genomic exon-by-exon sequencing of *hMSH2*, *hMLH1*, and *hMSH6*. They

identified five candidates with four different hMSH2 deletions and one candidate with an *hMLH1* deletion.

In summary, our study demonstrates that the Amsterdam criteria are important but inappropriate for the establishment of diagnosis, some atypical families not fulfilling all the Amsterdam criteria probably possess the similar genetic alterations. We conclude that the mutation detection of patients is of benefit to the analysis of HNPCC and, PCR-SSCP is as effective as direct DNA sequence in detecting the mutations of HNPCC. Furthermore, it seems that there exist more complicated genetic alterations in Chinese HNPCC patients than in Western countries.

However, there are also some cases without any mutation, further investigations should be carried out such as detection of other mismatch repair genes as well as detection of gene methylation of *hMLH1*.

Abstract

AIM: To determine the expression of estrogen receptor (ER)β in Chinese colorectal carcinoma (CRC) patients.

METHODS: ERβ expression in CRC was investigated by immunohistochemical staining of formalin-fixed, paraffin-embedded tissue sections from 40 CRCs, 10 colonic adenomas, and 10 normal colon mucosa biopsies. The percentage of positive cells was recorded, mRNA expression of ERα and ERβ in 12 CRC tissues and paired normal colon tissues were detected by RT-PCR.

RESULTS: Positive ER immunoreactivity was present in part of normal epithelium of biopsy (2/10), adenomas (3/10), and the sections of CRC tissue, most of them were nuclear positive. In CRCs, nuclear ERβ immunoreactivity was detected in over 10% of the cancer cells in 57.5% of the cases and was always associated with cytoplasmic immunoreactivity. There was no statistical significance between ERβ positive and negative groups in regard to depth of invasion and nodal metastases. Of the 12 CRC tissues and paired normal colon tissues, the expression rate of ERα mRNA in CRC tissue and corresponding normal colon tissue was 25% and 16.6%, respectively. ERβ mRNA was expressed in 83.3% CRC tissue and 91.7% paired normal colon tissue, respectively. There was no significant difference in ERβ mRNA level between CRC tissues and paired normal colon tissues.

CONCLUSION: A large number of CRCs are positive for ERβ, which can also be detected in normal colonic epithelia. There is a different localization of ERβ immunoreactivity among normal colon mucosae, adenomas and CRCs. ERα and ERβ mRNA can be detected both in CRC tissue and in corresponding normal colon tissue. A post-transcriptional mechanism may account for the decrease of ERβ protein expression in CRC tissues.

INTRODUCTION

Epidemiological data have shown that the risk of colorectal cancer is reduced among postmenopausal hormone users, compared with those who have never used these hormones. Animal models showed that male rats had a higher risk developing colon cancer compared with their female counterparts when exposed to dimethylhydrazine, an experimental carcinogen. The results indicated that 17β-oestradiol (E$_2$) treatment could significantly reduce the frequency of dimethylhydrazine-induced large intestinal tumors in rats[1-3]. These evidences suggest that estrogen maybe involved in the growth of colonic tumors. Estrogen receptor locates at the cellular nuclei of target tissues, estrogen molecules diffuse into cytoplasm, and bind to estrogen receptors, then modulate gene expression by interaction with promoter response elements or other transcription factors. The estrogen receptor discovered in 1986 is named ERα, and another ER subtype identified in 1997 is called ERβ. ERβ protein contains 485 amino acids, with a molecular weight of 54.2 Kda. The DNA binding domain (DBD) contains a two-zinc finger structure which plays an important role in receptor dimerization and in binding of receptors to specific DNA sequence. The DBDs of ERα and ERβ are highly homologous[4]. Up to now, several ERβ isoforms have been identified such as ERβ1, ERβ2, ERβ3, ERβ4, ERβ5, *etc*[5]. However, the physiological significance of these ERβ isoforms is still unknown. Meanwhile, published data about the expression of ERα and ERβ in colon cancer tissues were often controversial[6-20]. Therefore it is reasonable to reevaluate ER status and hormonal modulation of cell growth in colon cancer. In this study, immunohistochemistry and reverse transcription-polymerase chain reaction (RT-PCR) techniques were used to explore the precise mechanism of hormonal modulation of colon cancer.

MATERIALS AND METHODS

Patients and tissues

The study was performed in tissue sections of CRC from 40 patients who underwent surgical resection of colorectal cancer in the Department of Surgery of Renmin Hospital, Wuhan University from June 1998 to December 2000. The age of the patients ranged from 38 to 78 years (average age 65 years). Ten sections of colonic adenoma were studied, and 10 sections of normal colonic mucosa biopsy were used as control. Information about depth of invasion and nodal metastases was obtained from a review of the pathology reports. Fresh tumor tissues and corresponding normal colon tissue were obtained from 12 patients who underwent surgical resection of colon cancer in the Department of Surgery of Affiliated Hospital of Wujing Medical College and Tianjin First Central Hospital from June 2001 to December 2002. The patients were comprised of 8 men and 4 women aged 49-79 years (mean 63.3 years). The tumorous and paired normal tissues were divided into two parts. One part was fixed in 10% formalin, embedded in paraffin and stained with hematoxylin-eosin for pathological diagnosis. The other part was frozen in liquid nitrogen and stored at -80 ℃ until RNA was extracted. ERα and ERβ mRNA were detected by RT-PCR.

Immunohistochemistry

Rabbit anti-rat or human ERβ polyclonal antibody was purchased from Santa Cruz, USA. S-P kit and DAB kit were purchased from Fuzhou Maixin Biotechnology Company.

Formalin-fixed and paraffin-embedded tissue sections from 40 CRCs, 10 colonic adenomas, and 10 normal colonic mucosa biopsies were immunostained by SP technique with the following procedures. The slides were washed in 0.01 M phosphate-buffered saline (PBS). Endogenous peroxidase was

blocked by 0.3% H_2O_2 for 25 minutes, followed by incubation in normal goat serum for 15 minutes at room temperature. Then the slides were incubated with a 1:75 dilution of the primary ERβ polyclonal antibody for 2 hours at room temperature. After that the slides were washed with a reagent (biotinylated anti-immunoglobulin) for 20 minutes at room temperature. After rinsed in PBS, the slides were incubated with the peroxidase-conjugated streptavindin label for 20 minutes at room temperature, and incubated with diaminobenzidine and H_2O_2 for 5 minutes. Finally the sections were counterstained with hematoxylin.

RT-PCR amplification

Total RNA was isolated with TRIZOL reagent (Life Technologies, USA), and quantified by spectrometry (λ260 nm). Only those RNA preparations with 260/280>1.7 were used in this study.

Reverse transcription was performed using a reverse transcription system (revertaid™ first strand cDNA synthesis kit, MBI). RT of RNA was performed in a final volume of 20 μl containing 5×first strand buffer (containing 1 mM Tris-HCl. pH8.3, 1.5 mM KCl and 60 μM $MgCl_2$), 25 μM dNTP mixture, 200 pM random primer, 100 units of Moloney murine leukemia virus reverse transcriptase, 2 μg total RNA. Then DEPC treated water was added to 20 μl. RT reaction procedure was as follows: at 70 ℃ for 1 min→at 37 ℃ for 5 min→at 42 ℃ for 60 min→ at 98 ℃ for 5 min. ERα, ERβ and β-actin were amplified using several pairs of appropriate oligonucleo tide primers as follows: ERα (530 bp): (sense)5'-ATGTGGGAGAGGAT GAGG AG-3', (antisense) 5'-AACCGAGATGATGTAGCCAGCAGC-3'. ERβ (259 bp): (sense) 5'-TAGG GTCCATGGCCAGTTAT-3', (antisense) 5'-GGGAGCCACACT TC ACCAT-3'. β-actin (control) (540 bp): (sense) 5'-GTGGG GCGCC CCAGG CAC CA-3', (antisense) 5'-CTTCC TTAAT GTCAC GCACG ATTTC-3' (Figure 1).

PCR was performed in a final volume of 50 μl containing 4 μl 10×pc buffer, 2.5 U recombinant Taq DNA polymerase (Taraka, Japan), 0.1 mM $MgCl_2$, 100 μM dNTP mixture, and 50 pM of each primer. PCR was performed for 40 cycles (denaturation at 94 ℃ for 1 min, annealing at 55 ℃ for 1 min, and extention at 72 ℃ for 1.5 min). The PCR condition for inter control β-actin was 35 cycles (denaturation at 94 ℃ for 45 seconds, annealing at 60 ℃ for 45 seconds, and extention at 72 ℃ for 45 seconds). The PCR products were separated by electrophoresis on a 2% agarose gel and visualized by ethidium bromide staining and UV illumination.

Figure 1 mRNA expression of ERα and ERβ in paired representative tissues from cancer and adjacent normal mucosa. C: cancer, N: normal mucosa. RT-PCR result of β-actin was used to show equal loading.

Statistical analysis

The association between expression of ERα and ERβ, the significance of ERα and ERβ in groups dichotomized according to clinical and histopathologic characteristics of the patients were compared and assessed by Chi-square test and Student's *t*-test. A *P* value <0.05 was considered significant.

RESULTS

Expression of ERα and ERβ protein

Using immunoperoxidase technique, ERβ immunoreactivity was detected in or near the nuclei of normal colonic mucosa in the same sections of carcinoma. ER immunoreactivity was present in some of normal epithelia (2/10), and adenomas (3/10). Nuclear immunoreactivity was consistently found in part of normal colonic mucosa, and in all areas of the crypt epithelium, and most abundant at the bottom (Figures 2A,2B). One section of rectal tubular adenocarcinoma showed strong positive nuclear and cytoplasmic staining of ERβ (Figure 2C). A few stromal cells, smooth muscle cells and vascular endothelial cells were also positive (Figure 2D). In CRCs, nuclear ERβ immunoreactivity was associated with cytoplasmic immunoreactivity. Some sections showed only cytoplasmic staining of ERβ (Figure 2E), Positive ERβ was detected in more than 10% of the cancer cells in 57.5% of the CRC cases (Figure 3).

Three of the 12 randomly selected cases stained with anti-ERα antibody showed positive. None of the 10 normal colonic mucosa biopsies was stained positive with anti-ERα antibody. There were no statistically significant differences between positive and negative ERβ groups in regard to the depth of invasion, and nodal metastases (Tables 1-2).

Table 1 Expression of ERβ and ERα in CRCs, colonic adenomas and normal colonic mucosa

Group	n	ERα positive (%)	n	ERβ positive (%)
Normal colon mucosa	10	0 (0%)	10	2 (20%)
CRCs	12	3 (25%)	40	23 (57.5%)
Colonic adenoma			10	3 (30%)

ERα and ERβ mRNA expression

Table 3 and Table 4 show that the expression of ERα mRNA in CRC tissue and corresponding normal colon tissue was 25% and 16.6%, respectively. ERβ mRNA was predominantly expressed in CRC tissue and paired normal colon tissue, the positive rate was 83.3% and 91.7%, respectively. There was no statistically significant difference.

DISCUSSION

Several epidemiologic studies have shown that colon cancer might be influenced by steroid hormones[1-3], and estrogen use might be associated with a low risk of colon cancer[21-27]. Some experimental results indicated that estrogen had a trophic effect on colon cancer[1,11-12]. However, the effect of estrogen on colon cancer is controversial according to some reports. For example, Qiu et al[28] reported that estradiol could induce apoptosis in colo205, a colon cancer cell line expressing only ERβ. The question is whether ER expresses in normal colon mucosa or CRC. Earlier studies using biochemical ER-binding assay concluded that there was no ER in human colon. A more recent study concluded that ER was present in normal human colon and CRC tissues. Several immunohistochemical studies from China or Japan have shown that ER was present in normal human colon and CRC tissues[12-18]. Similarly, our immunohistochemical study using ER antibodies (clone number 1D5), which are specific for ERα, showed that ERα was present in normal colon mucosa and CRC. However, the expression rate of ERα was about 20-40%, which was lower than that of ERβ.

In 1997, the second type of ER (ERβ) was cloned, and recent studies indicated ERβ was distributed in human tissues[5]. Several basic studies have shown that different distribution and regulatory mechanism of these two types of ER played different roles[29,30]. ERβ expression in normal colonic epithelium, especially at the bottom portion of colonic crypts, suggests that estrogens may play an important role in the growth and regeneration of normal colonic mucosa. ERβ expression in a large number of CRCs indicates that estrogens may exert effects on these cancers, which may have significant implications for the treatment and prevention of CRC.

According to some published reports, ERα was also present in gastric or colon cancer[11-18]. Our results support this conclusion. However, the positive rate of ERα in CRC was less than that of ERβ in CRC. Some research results indicated that ERα and ERβ could interact with the fos/jun transcription factor complex on AP1 sites to stimulate gene expression. However, they had opposite effects in the presence of estradiol. In the presence of ERα, estradiol functioned as an agonist in the AP1 pathway. In contrast, in the presence of ERβ, tamoxifen and raloxifene behaved as fully competent agonists in the AP1 pathway, while estradiol acted as an antagonist, inhibiting the activity of both tamoxifen and raloxifene[29,30]. It is the presence of two ERs that explains the conflicting experimental results. We deduced that estradiol might have trophic effects via combining with ERα. However, estradiol could inhibit tumour growth by combining with ERβ.

In this study, we found no significant correlation between ERβ expression and clinicopathologic features, including

Duke's types, lymph node metastasis and differentiation. Because of the relatively small sample size in this study, a study using a larger sampled study is necessary to further investigate the relationship between ERβ expression and clinicopathologic characteristics and survival of colorectal cancer patients.

Our RT-PCR results showed that ERα and ERβ mRNA were both expressed in CRC, semiquantitative RT-PCR revealed there was no statistical significance in ERβ mRNA level between CRC tissue and paired normal colon tissue. Our immunohistochemical results showed that some sections were only cytoplasmically stained. Foley *et al*[33] reported that Western blot analysis revealed very low levels of ERα protein in tumor and normal colon tissue. However, malignant colon tissue showed a selective loss of ERβ protein expression when compared to normal colon tissue in the same patient. A posttranscriptional mechanism may account for the decrease of ERβ protein expression in CRC tissue. Another reason is the different expressions of ERβ isoforms in CRC. There are at least 5 different ERβ isoforms, which show different amino acid sequences at the COOH terminus and are differently expressed in tumor cell lines[31-35]. Campbell-Thompson *et al*[35] and Witte *et al*[36] showed that ERβ was the predominant ER subtype between human colon and that the decreased levels of ERβ1 and ERβ2 mRNA were associated with colonic tumorigenesis in females. Their data suggest that there is a change in the relative expression of ERβ isoforms. Therefore, It is possible that the cytoplasmic immunoreactivity in CRC tissue is caused by one of the overexpressed ERβ subtypes. Further study should determine not only whether there are different ERβ isoform expressions between normal colon and CRC, but also whether different isoforms are associated with different responses to estrogens and antiestrogens.

Abstract

AIM: To investigate the effect of ethylene diamine tetraacetic acid (EDTA) on proliferation of rat colonic cells.

METHODS: EDTA was administered into Wistar rats, carcinogenesis induced by 1,2-dimethylhydrazine (DMH) in rats was studied with immunohistochemistry.

RESULTS: Marked regional differences in cell proliferation were found in all groups. In EDTA-treated animals, total labelling indexes in both proximal (10.00 ± 0.44 vs 7.20 ± 0.45) and distal (11.05 ± 0.45 vs 8.65 ± 0.34) colon and proliferative zone size (21.67 ± 1.13 vs 16.75 ± 1.45, 27.73 ± 1.46 vs 21.74 ± 1.07) were significantly higher than that in normal controls ($P<0.05$) and lower than that in DMH group (10.00 ± 0.44 vs 11.54 ± 0.45, 11.05 ± 0.45 vs 13.13 ± 0.46, 21.67 ± 1.13 vs 35.52 ± 1.58, 27.73 ± 1.46 vs 39.61 ± 1.32, $P<0.05$). Cumulative frequency distributions showed a shift of the EDTA distal curve to the right ($P<0.05$) while the EDTA proximal curve did not change compared to normal controls. Despite the changes of proliferative parameters, tumours did not develop in EDTA treated animals.

CONCLUSION: Hyperproliferation appears to be more easily induced by EDTA in distal colon than in proximal colon. Hyperproliferation may need to exceed a threshold to develop colonic tumours. EDTA may work as a co-factor in colonic tumorigenesis.

INTRODUCTION

Colonic epithelial hyperproliferation has been considered as a high risk factor in both human and animal colonic cancer models[1-19]. Evidence from animal studies has shown that experimental colonic tumours induced by procarcinogen 1, 2-dimethylhydrazine (DMH) are of epithelial origin with a similar histology, morphology and anatomy to human colonic neoplasms[2,3,20,21]. Furthermore, prior to the development of colonic cancer, injections of DMH could result in increased colonic crypt cellularity, colonic crypt cell proliferation and colonic crypt proliferative zone[22,23]. This procarcinogen thus provides an adequate model for kinetic and therapeutic studies of the colorectal cancer.

It is important to compare cell proliferation in the distal and proximal colon. As in normal rats, the location of stem cells and the direction of colonocyte migration differ in these two regions[24]. In addition, differences in the incidence, morphology and clinical behaviour of colonic carcinoma in the proximal and distal colon have been reported[25,26].

EDTA is widely used as a vehicle solution in chemical-induced colorectal carcinogenesis. However, little is known about the nature of its effect on cell proliferation. *In vitro*, EDTA could inhibit cell proliferation[27-29] and DNA synthesis[30]. Inhibition on cell growth is not associated with EDTA's chelational stability[28]. *In vivo*, EDTA has been shown to stimulate cell proliferation in a neural crest tumour model[31]. In the present study BrdUrd *in vivo* cell labelling was employed to determine crypt cell proliferation patterns in proximal and distal rat colons from normal, EDTA and DMH-induced colon cancer animals.

MATERIALS AND METHODS

Animals and treatment

Forty eight male Wistar rats (weighing 180-220 g) were divided equally into DMH group and EDTA group. Three animals were housed in each cage in a containment isolator with negative pressure to protect experimenters against the effects of the carcinogen. A specific colonic procarcinogen 1, 2-dimethylhydrazine (DMH, Aldric, Poole, Dorset) at a dosage of 20 mg/kg body weight was administered subcutaneously to the animals weekly for 20 weeks. DMH was dissolved in 1 mM EDTA (BDH Ltd, Poole, Dorset), and adjusted to pH 6.5 with 10% sodium hydroxide (BDH Ltd, Poole, Dorset) immediately before injection. Animals in EDTA group were given weekly subcutaneous injection of EDTA for 20 weeks, and sacrificed 2 weeks after the last injection. In addition, six normal rats were used as controls for BrdUrd immunohistochemistry.

In vivo BrdUrd labelling and tissue sampling

Eighteen rats (6 per group) from normal controls, EDTA-treated group and DMH-treated group were used for a crypt cell proliferation study. Fifteen minutes before removal of the colon, the anaesthetised animals had a peritoneal injection with 50 mg/kg body weight of 2% BrdUrd (Sigma B-5002) between 9 and 11 a.m. to avoid diurnal variation. The colon was removed and rinsed with tap water. Following excision of the caecum and rectum, the remaining colon was divided into proximal and distal halves. A 1-2 cm segment of each end of the proximal and distal colon was discarded. After fixation in 70% ethanol for 4 hours the segments were rolled prior to processing and embedding in paraffin wax.

BrdUrd immunohistochemistry

Several 3 μm thick sections were cut and placed on poly-L-

lysine coated slides. The slides were dewaxed before DNA was denatured in 1M HCl at 37 ℃ for 12 minutes. After rinsed in phosphate buffered saline (PBS, pH 7.1) the sections were incubated with 30 μl of mouse anti-BrdUrd monoclonal antibody (M 744 Dako, Bucks, England) diluted 1:50 in PBS with 0.05% Tween 20 (PBST) with added normal rat serum diluted 1:25 for 60 minutes at room temperature. After a further rinsing in PBS the sections were incubated with biotinylated rabbit anti-mouse F(ab')$_2$ antibody (E 413 Dako, Bucks, England) at a dilution of 1:200 in PBST with added rat serum for 30 minutes at room temperature. The slides were again rinsed in PBS and then incubated with streptavidin-biotin peroxidase complex (K 377 Dako, Bucks, England) for 30 minutes at room temperature. Finally the reaction product was visualised using diaminobenzidine hydrochloride (DAB) (Sigma, Dorset, England) primed with 100 μl of 30% H$_2$O$_2$ (diluted 1:20 with distilled water) for approximately 5 minutes. After DAB was washed off with distilled water the sections were lightly counterstained in Harris haematoxylin before dehydration and mounting in DPX.

Counting and scoring criteria

Only complete well-orientated longitudinally sectioned crypts which extended from the luminal surface into the muscularis mucosae and contained at least 30 cells per hemicrypt were used for analysis. To facilitate scoring each crypt was divided at the base into 2 crypt columns (hemicrypts). Starting at the base of the hemicrypt, cells were numbered up to the luminal surface of the colon to determine the number of cells per hemicrypt. Crypts were then divided into 5 compartments each containing the same number of cells. The number and the position of BrdUrd-labelled cells in the hemicrypt were recorded. The proliferative zone, which was expressed as a percentage, was obtained by calculating the difference between the highest and lowest labelled cells in each hemicrypt and dividing this figure by the total number of cells in the hemicrypt. Labelling index (LI) was determined for the whole hemicrypt, for each compartment and for the proliferative zone as follows, equation=(the number of labelled cells/the number of total cells)×100. Each hemicrypt was then normalised to a notional 100 cell positions. The frequency of BrdUrd positive cells in each of the 100 normalised positions was recorded.

Statistical analysis

Mean and standard error of the mean were calculated where appropriate. Since the sample size for crypt cell proliferation was more than 100 except in one group (normal proximal colon group in which the sample size was 78) and all groups appeared to have normal distribution, a two sided Student's *t* test was used to identify the differences between individual variables. Kolmogorov-Smirnov 2 sample test[16] was used to compare the BrdUrd cumulative labelling frequency curves with reference to the presence of EDTA or DMH treatment and the site of origin of the sample from the colon. Results were considered as significant when $P<0.05$. Statistics were analysed running the SPSS package for Windows.

RESULTS

Characterisation of tumours

All animals survived to the time when they were sacrificed. In the EDTA control animals no macroscopical changes were observed in the mucosa of large intestine after 20 weeks of treatment. However, in the DMH group a total of 66 tumours were found in 23 animals (96%) and 1 rat was tumour free. Most of the tumours (73%) were located in the distal colon. Microscopically, the tumours were either adenoma or

adenocarcinoma. Most rats had one or more types of lesions, indicating that the response to DMH was heterogeneous. The number and distribution of both adenoma and adenocarcinoma are summarised in Table 1.

Table 1 Characterisation of colorectal tumours

Location	Adenoma	Carcinoma	Total (%)
Caecum	0	1	1 (1.5)
Proximal	2	6	8 (12.1)
Flexure	4	4	8 (12.1)
Distal	12	36	48 (72.7)
Rectum	0	1	1 (1.5)
Total	18	48	66

Differences between proximal and distal colon

The number of cells per hemicrypt in the proximal colon was significantly higher than that in the distal colon in all respective groups ($P<0.05$, Table 2). Although the number of labelled cells per hemicrypt was similar in the proximal and distal colon in all groups, the total LI was significantly higher in distal colon compared to proximal colon both in normal control group ($P<0.05$) and in DMH treated animals ($P<0.05$). In EDTA treated group, the total LI in the distal colon was higher than that in the proximal colon with no statistical significance ($P=0.11$). The size of the proliferative zone was higher in distal colon than that in proximal colon in all groups ($P<0.05$) while the LI in proliferative zone did not significantly change. In the normal controls, BrdUrd labelled cells in the proximal colon were located predominantly in compartments 2 and 3 (88.4%), whereas the labelled cells in the distal colon were mostly in compartments 1 and 2 (85.3%). In compartment 1, the LI was significantly higher in the distal colon than in the proximal colon ($P<0.05$), while in compartment 3 the LI was significantly lower in the distal colon than in the proximal colon ($P<0.05$). None of the labelled cells appeared in compartment 5. When the cumulative labelling distribution curves of the proximal and distal colon of normal rats were compared, the distal colon showed a significant shift to the left ($P<0.05$, Figure 1).

Figure 1 Different patterns of cumulative labelling distributions in proximal and distal rat colons of normal controls. The curve was significantly shifted to the right when the proximal colon was compared to the distal colon.

Effect of EDTA

In EDTA-treated animals, the number of cells per hemicrypt, labelled cells per hemicrypt and total LI were all significantly increased in both the proximal and distal colons when compared to normal controls. In addition, the size of proliferative zone in EDTA treated animals was significantly higher in both proximal and distal colons than in normal controls. However, the LI in proliferative zone was not changed. In the proximal colon, the increase in LI was limited

to compartment 3 while in the distal colon the increase in LI was extended from compartment 2 to compartment 4. When compared to the normal controls cumulative frequency distributions of the EDTA distal curve shifted to the right ($P<0.05$, Figure 2) but the EDTA proximal curve did not change ($P>0.05$, Figure 3).

Figure 2 Cumulative labelling distribution in normal, EDTA and DMH treated distal rat colons, respectively. The curve was significantly shifted to the right in EDTA distal colon compared to normal distal colons. The curve was further shifted to the right in DMH distal colon compared to either normal or EDTA distal colon.

Figure 3 Cumulative labelling distribution in normal, EDTA and DMH treated proximal rat colons. The curve of EDTA

treated proximal rat colon did not change compared to the normal proximal curve. Whereas the curve of DMH treated proximal rat colon was initially significantly shifted to the left and then at higher centiles shifted to the right.

Effect of DMH treatment

DMH treatment significantly increased the number of cells per hemicrypt in both proximal and distal colons in comparison with either normal controls or EDTA treated animals. The number of labelled cells per hemicrypt and total LI were also significantly increased following DMH injections in both proximal and distal colons. Additionally, DMH increased the size of the proliferative zone in both proximal and distal colonic crypts. However, the LI of proliferative zone was reduced because of the increased denominator (Table 2). In the proximal colon the increase in LI was in compartments 1, 3 and 4, whereas in the distal colon the increase in LI in DMH rats was most marked in compartments 2, 3 and 4. The extent of LI in compartment 3 in the distal colon was significantly greater than that in the proximal colon ($P<0.05$). Further analysis of the cumulative labelling distributions showed a shift of the DMH distal curve to the 81st centile which was to the right of the plateau of the normal distal colon located at the 61st centile ($P<0.05$) and EDTA distal colon located at the 67th centile ($P<0.05$, Figure 2). In contrast, the cumulative labelling distribution curve in DMH proximal colon demonstrated a shift to the left in the lower crypt cell positions and then shifted to the right high up the crypt compared with normal ($P<0.05$) and EDTA ($P<0.05$) proximal cumulative frequency curves (Figure 3).

DISCUSSION

This study supported the findings that adenoma and adenocarcinoma of intestine could be obtained, using DMH or its metabolites in Wistar rats[20,32,33]. Another advantage of DMH and its metabolites is the specificity for the large bowel. The incidences of cancer at small intestine and extra-intestine were very low[34]. In our study the vast majority of colon tumours occurred distally and were mainly polypoid neoplasms or adenocarcinomas. The types of the proximal colon tumours were reported to be variable histopathologically, dominated

Table 2 Features of proliferative colonic crypt cells in 6 groups

Values represented as $\bar{x}\pm S_x$, NP(76): Normal proximal, 76 hemi-crypts were counted, ND: Normal distal, EP: EDTA proximal, ED-EDTA distal, DP: DMH proximal, DD: DMH distal, LC: Labelled cells per hemi-crypt, CPC: Cells per hemi-crypt, TLI: Total labelling index, LI1: Labelling index of compartment 1, Pzone: Proliferative zone size, LIPZ: Labelling index of proliferative zone Size.

with the mucinous type of adenocarcinoma[35]. The different responses of bowel segments to DMH, and the reasons for the predilection of colonic neoplasia to distal colon as well as the differences in morphological type of tumours between the proximal and distal colon are not fully understood. However it is known that the structure and function of intestinal mucosa differed significantly between humans[36] and experimental animals[37-39]. An understanding of these inherent regional differences may be pivotal in study of the mechanisms of colonic tumorigenesis.

Significant regional differences in the distribution of BrdUrd-labelled cells in proximal and distal rat colon were demonstrated in this study. The differences in distribution of proliferative cells between proximal and distal colons were previously shown with ^{3}H-thymidine autoradiography and immunohistochemistry. ^{3}H-thymidine LI and proliferative zone size were reported to be significantly greater distally than proximally[40]. In the distal colon PCNA expression was strictly confined to the lower third of the crypt, whereas in the proximal colon it was located in the mid-crypt[23].

Sunter noted that the peak LI in the proximal colon was located in the middle third of the crypt while the peak of LI in the distal colon was located in the lower third near the base of the crypt[41]. These findings, together with ours, tended to support the theory of crypt cell origin and colonocyte migration given by Sato and Ahnen[24]. After a double labelling with ^{3}H-thymidine and BrdUrd, Sato and Ahnen investigated the location of stem cells and the direction of colonocyte migration in normal rat colonic crypt, and reported that distal stem cells were located in the crypt base while proximal stem cells in the mid-crypt, thus postulating that colonocytes migrated up toward the luminal surface in the distal colon in contrast to the bidirectional migration, i.e. up toward the luminal surface and down toward the crypt base in the proximal colon.

Our results showed that after EDTA treatment, the number of proliferative colonic crypt cells was significantly increased in the distal and proximal colon. The LI in the proliferative zone in the EDTA animals did not increase which could be attributable to the concomitant increase of the zone size. In the EDTA treated animals, LIs in all compartments in the distal colon increased except the LI in compartment 1, a significant increase of LI in the proximal colon was found in compartment 3 only. This was corroborated by the cumulative labelling distribution curves. In comparison with normal control, the distal curve shifted toward to the right, but the proximal curve did not change. The fact that the proximal curve did not shift might be important. If hyperproliferation preceded tumour formation and was a cause of tumor formation, then these findings indicated that the distal colon was more susceptible. EDTA did not induce colorectal tumours after administration for 20 weeks, but prolonged EDTA treatment might induce tumours. Another hypothesis is that hyperproliferation in EDTA animals is a co-factor in DMH-induced colonic tumour formation.

DMH treatment further increased colonic crypt cell proliferation. Although DMH treatment increased the LI in both the proximal and distal colon, the cumulative labelling distribution was markedly shifted to the right in the distal colon whereas the proximal curve shifted to the left (*i.*e. downwards in the crypt). The distribution of DMH-induced colorectal cancer resembled human colorectal carcinoma[42-44]. We found that when the total colon was exposed to the procarcinogen DMH, 73% of tumours occurred distally and only 12% proximally.

Further investigation is required to understand the differences of tumour distribution, and their relationship to the proliferation of different crypt cells and differentiation patterns in the proximal and distal colon. It has been shown that in the proximal colon, mucous cells were predominant in the lower third of the crypt, whereas columnar cells in the upper third[45]. In contrast, crypts of the distal colon contained only a small number of mucous cells in basal positions. The undifferentiated cells or the cells with the lowest level of differentiation (presumptive stem cells) were the vacuolated cells located near or at the base of crypt[46]. The progeny of the vacuolated cells migrated upward to differentiate into columnar cells and downward to differentiate into mucous cells[47].

In this study we observed a great number of cells in the crypt in the proximal colon than in the distal colon, which was in contrary to published data[39,40]. This disparity might be due to different criteria for recoding the overlapping nuclei, selecting crypts or ascertaining the top of the crypt. In this study longitudinally well-oriented crypts were selected and all visible nuclei were counted.

EDTA increased crypt cell proliferation but all of the increased parameters were significantly lower than those in the DMH group. The number of crypt cells in hyperproliferation induced by a carcinogen might reach or exceed a limited value (threshold) before colonic tumours developed. While proliferative crypt cells that did not exceed this threshold as in the EDTA animals, might act as a promoting agent to stimulate tumour growth. In conclusion, EDTA' s effect of increasing crypt cell proliferation may be a co-factor in this model.

Abstract

AIM: To deduce strategic guideline of gastric mucosa associated lymphoid tissue lymphoma (MALTOMA) by evaluating the long-term outcome of patients in respect to various treatment modalities.

METHODS: A total of 55 patients with MALTOMA from May 1992 to August 2002 were retrospectively reviewed.

RESULTS: Complete remission was obtained in 24 (82.8%) of 29 patients treated with anti *Helicobacter pylori* (*H pylori)* regimen only. The duration to reach complete remission was 12 months (85 percentile, 2-33 months). Five patients showed complete remission with radiation therapy (26-86 months). Two of them were *H pylori* treatment failure cases.

CONCLUSION: *H pylori* eradication is an effective primary treatment option for low grade MALTOMA and radiation therapy could be considered in patients with no evidence of *H pylori* infection or who do not respond to *H pylori* eradication therapy 12 months after successful eradication.

INTRODUCTION

In 1983, Isaacson and Wright introduced the term MALTOMA to characterize primary low grade gastric B-cell lymphoma and immunoproliferative small-intestinal disease[1]. Subsequently, the definition of MALTOMA was extended to include several other extranodal low grade B-cell lymphomas, with a similar histology to payer' s patches, including those of the salivary gland, lung, and thyroid, but gastric form is the most common and best characterized MALTOMA[2].

Low grade MALTOMA is composed of small cells with dense nuclear chromatin and a low proliferation fraction; the converse is true for diffuse large B cell lymphoma. Low grade gastric MALTOMA is a neoplasia with a very indolent course and an excellent prognosis. It has a tendency to remain localized to the gastric wall and seldom involve lymph nodes and bone marrow.

In the past, primary low grade gastric MALTOMA was treated with surgery in the same way as adenocarcinoma. This often necessitated a total gastrectomy due to the multi-focal or diffuse nature of gastric lymphomas. Since the introduction of *H pylori* concept, the association of this bacterium with chronic active gastritis, peptic ulcer and gastric cancer has been demonstrated[3-5]. Furthermore, *H pylori* is suggested to be associated with low-grade gastric MALTOMA. It was proposed that low grade gastric MALTOMA was formed by the immune response to *H pylori* infection in the gastric mucosa[6,7]. The discovery of a causal role for *H pylori* in the development of gastric marginal zone lymphoma of the MALT type has dramatically altered the therapeutic approach to patients with early stage disease[8,9]. According to recent data, durable complete remissions might be achieved in up to 80% of patients with early stage MALTOMA following eradication of the bacteria[9]. In the patients who failed to respond to *H pylori* eradication or had low grade gastric MALTOMA without *H pylori* infection, radiotherapy, chemotherapy or surgery has been tried.

However, the long-term follow-up result of *H pylori* eradication on low grade MALT lymphoma has been seldom reported. Furthermore, a clear-cut time is difficult to define the failure to *H pylori* eradication therapy and currently there has been no standard guideline to assess the result of eradication therapy. Also the time interval to perform endoscopic examination to evaluate histologic and morphologic remission is unclear. Consequently, a suitable strategic guideline to decide subsequent treatment option when one fails has not been well proposed. We aimed to evaluate the long-term outcome of patients with low grade gastric MALTOMA in respect to various treatment modalities. We also tried to deduce suitable strategic guideline to treat low grade gastric MALTOMA.

MATERIALS AND METHODS

Patients

We retrospectively studied 55 patients of primary low grade gastric MALTOMA aged 23 to 74 years from May 1992 to August 2002. All the patients were pathologically confirmed as low grade gastric MALTOMA. The diagnosis of low grade gastric MALTOMA was made according to the criteria of Isaacson[10] and scoring system of Wotherspoon *et al*[11]. The initial staging procedures included a complete physical examination, chest roentgenogram, bone marrow examination, abdominal CT scan and endoscopic ultrasonography (EUS).

Methods

We evaluated the patients' initial presenting symptoms and the status of *H pylori* infection. *H pylori* infection was diagnosed by rapid urease test (CLO™, Delta West, Bentley,

Western Austria), and/or histologic examination. *H pylori* status was considered positive if any of the two tests was positive. Endoscopic findings included the shape, size, location and number of lesions. Gross phenotype was classified according to the endoscopic features into seven types: 1) gastritis: only mucosal color change, 2) granular: small nodules on the lesion, 3) ulcerative: one or more ulceration, 4) ulceroinfiltrative: one or more ulceration with surrounding mucosal infiltration, 5) depressed: depressed or EGC IIc like lesion, 6) protruding: elevated or polypoid, and 7) mixed, and then was categorized into diffuse and localized type according to the pattern of distribution.

RESULTS

Clinical and endoscopic features of patients

The male to female ratio was 1:1.3. The mean age of the patients was 47.8 years (23-74). All but three of the patients were symptomatic at presentation: The main symptoms were abdominal pain (56.4%), indigestion (23.6%), epigastric discomfort (12.7%) and vomiting (1%). A total of 48 (48/53, 90.5%) met the case definition for *H pylori* positivity (Table 1). When each test was considered individually, *H pylori* infection was detected by histology and rapid urease test in 42 (87.5%) and 39 (81.3%) patients, respectively. Initial endoscopic findings are summarized in Table 2.

Table 1 Clinical features of patients and *H pylori* state (*n*=55)

Age (years)	47.8±11.3 (23-74)	
Sex	Male:Female=24:31	
H pylori status[a]	Positive	48 (90.5%)
	Negative	5 (9.5%)

[a]Excluding two cases of unknown *H pylori* status.

Table 2 Endoscopic findings and location of low grade MALTOMA (*n*=55)

Location	No. of cases (%)	Findings	No. of cases (%)
Body only	21 (38.2)	Ulcerative	15 (27.3)
Antrum only	11 (20.0)	Mixed	15 (27.3)
Antrum & body	20 (36.4)	Ulceroinfiltrative	10 (18.2)
Fundus/Cardia	3 (5.4)	Depressed	6 (10.9)
		Gastritis	5 (9.1)
		Protruding	3 (5.5)
		Granular	1 (1.8)

Treatment modalities and outcomes

Treatment modalities included *H pylori* eradication, surgery, radiotherapy and combination therapy (Table 3). A total of twenty nine patients were treated with *H pylori* eradication therapy (omeprazole + amoxicillin + metronidazole or clarithromycin for 2 weeks). All but one was positive in urease test or histologic examination for *H pylori*. Endoscopic ultrasonography was done before *H pylori* eradication and cases with lymph node metastasis or involvement beyond the submucosal layer were excluded. For determination of the response, two months after the end of eradication therapy, biopsy specimens were collected from the multiple sites including the lesion for histologic examination. One additional specimen was obtained for rapid urease test. For the remission failure case, a repeat endoscopy was performed every two to three months until complete remission was achieved. In cases with complete remission, endoscopic examination and biopsy were performed every 6-12 months. Overall *H pylori* eradication rate was 96.4% (27/28). Complete remission of

low grade MALTOMA was achieved in 24 out of 29 cases (82.8%). The median time to get complete remission was 4 months (2-33) (Table 3). In terms of histologic remission of the low grade gastric MALTOMA, the mucosal lesions changed to atrophic or endoscopically normal appearance (Figure 1). There were five treatment failures to *H pylori* eradication therapy. Radiation treatment was given in two patients who failed to respond to anti *H pylori* treatment after 6 months and 9 months of follow-up, respectively. One underwent operation. They all had complete remission in the subsequent follow-up. The remaining two patients were recommended to receive other treatment with persistence of localized MALTOMA.

Figure 1 A: A case with irregular ulceration on the anterior wall of antrum before eradication. B: 3 months after *H pylori* eradication therapy, ulceration was disappeared. C: A case with mucosal nodularities on the posterior wall of the upper body before eradication. D: 2 months after *H pylori* eradication therapy, the lesion was replaced by atrophic mucosa.

Sixteen patients underwent surgery, including 11 total gastrectomies and 5 subtotal gastrectomies (Table 3). Most of them were treated by surgery because they were suspected to have lymph node metastasis or infiltration beyond the submucosal layer in endoscopic ultrasonographic examination. Among the sixteen patients, 4 patients showed lymph node metastasis. Three patients received additional radiation therapy or chemotherapy after surgery because of lymph node metastasis or perigastic fat infiltration of low grade gastric MALTOMA.

Five patients received radiation therapy. These cases included two patients with *H pylori* negativity, two patients with failure to *H pylori* eradication, and one case with recurrence in remnant stomach after surgery (Table 3). The median radiation dose was 30.6 Gy (range 30-39) with a daily fraction of 1.5-1.8 Gy.

The comparative study among different endoscopic types of low grade MALT lymphoma patients who showed failure to eradication treatment disclosed no significant correlation. However, the lesion of localized mass type showed the tendency to higher treatment failure (Table 4).

Table 3 Initial treatments and outcomes of low grade MALTOMA

	H pylori eradication (n=29)	Surgery (n=16)	Radiotherapy (n=5)
Complete remission (%)	24 (82.8%)	16 (100%)	5 (100%)
Failure (%)	5 (17.2%)	0	0
Recurrence (%)	1 (4.2%)	1	0
Median follow-up (months)	24 (2-74)	46.5 (12-120)	35.5 (26-86)
Time to get CR in 85 percentile of patients (interval) (months)	12 (2-33)		

CR: Complete remission.

Table 4 Failures of *H pylori* eradication treatment according to endoscopic findings

Endoscopic types	Treatment cases	Failure cases (%[a])
Diffuse	13	1 (17.7)[b]
Gastritis	2	0 (0)
Granular	1	0 (0)
Mixed	10	1 (10.0)
Localized	16	4 (25.0)[a]
Ulcerative	8	2 (25.0)
Ulceroinfiltrative	3	1 (33.3)
Depressed	4	0 (0)
Protruding	1	1 (100.0)
Total	29	5 (17.2)

[a]Failure rate of each endoscopic type, [b]$P>0.05$ by χ^2 test.

DISCUSSION

The relationship between *H pylori* and low grade gastric MALTOMA is strong, and therefore treatment strategies are aimed at *H pylori* eradication in early stages. Recently, durable complete remissions have been supposed to achieve in up to 80% of patients with early stage MALTOMA following eradication of the bacteria[9]. In the largest MALTOMA study to date, 120 patients with early stage low grade gastric MALTOMA were treated with *H pylori* eradication therapy and followed[12]. After mean follow-up period of 48 months, 81% of patients were in complete remission. Relapse after complete remission occurred in less than 10% of cases, and whether this was always caused by *H pylori* reinfection has been unknown[13-24]. Follow-up is essential in patients with

MALTOMA treated with *H pylori* eradication therapy. Endoscopic follow-up with biopsy for histology and *H pylori*, and EUS at least yearly after remission was recommended[12,25]. Because some residual cells lay dormant after clinical and histological remission was achieved, some investigators insisted that molecular studies should be included in addition to histologic study[20]. At present, histologic study is considered as the gold standard.

Because eradication therapy is never 100% successful, it is also important to choose the most suitable additional treatment for treatment failure. MALTOMA that were not *H pylori* positive or did not respond to eradication therapy could be treated with surgery, radiation, or chemotherapy. Radical gastrectomy has 5- and 10-yr survival rates of 90% and 70%, but lead to significant morbidity[26]. Monotherapy with alkylating agents was tried in MALTOMA patients who did not respond to *H pylori* eradication therapy. In this study, remission could be achieved with chlorambucil in only 58% of the nonresponding patients to *H pylori* eradication therapy[25].

Our results showed 82.8 % of remission induction in low grade gastric MALTOMA by *H pylori* eradication alone with a single relapse. About 50% of patients with low grade gastric MALTOMA showed complete remission by 4 months after *H pylori* eradication. However, delayed response by up to 33 months occurred in one case. Overall, complete remission was achieved within 12 months in 85 percentile. We propose that it is necessary to wait for 12 months after initial eradication therapy of *H pylori* to define the time for *H pylori* eradication failure, because relapse is relatively rare after 12 months and nearby all the cases would have complete remission by 12 months. In addition, other treatment modalities could be used 12 months after initial *H pylori* eradication therapy, such as radiation therapy, surgery or chemotherapy.

A recent series from the memorial Sloan-Kettering Cancer Center and Yonsei Cancer Center reported a 100% complete remission rate with radiation alone. Especially, radiation therapy was chosen in the management of low grade gastric MALTOMA in patients with no evidence of *H pylori* infection or who showed no response to *H pylori* eradication therapy[27,28]. In our study, complete remission was obtained in all the patients after various treatment modalities. All the patients who received radiotherapy tolerated the treatment well and completed the treatment course without significant acute or delayed toxicities. Radiation therapy was superior to surgery or chemotherapy because it had significant advantages of gastric preservation and lower morbidity.

Our results provide further supports to the recommendation by Issacson and Spencer that eradication of *H pylori* is harmless and inexpensive and should be the first-line treatment for localized low grade gastric MALTOMA. If no response is observed by 12 months after eradication therapy, radiotherapy should be considered.

Several investigators evaluated endoscopic appearance of primary gastric lymphoma[29,30]. In low grade gymphoma, endoscopic findings were often interpreted as a benign condition, in contrast to high grade lymphoma, for which carcinoma was the most frequently suspected diagnosis. Our results were consistent with previous reports that low grade gastric MALTOMA was found at a relatively high frequency (94.6%) in the middle third of the stomach[31]. The most frequent endoscopic appearance of gastric lymphoma was ulceration, while the finding of polypoid lesions or other forms (as gastritis or erosions) had a lower frequency[32]. Also in this study, the majority of the endoscopic features of low grade gastric MALTOMA was superficial, such as shallow ulceration or mixed type, and was multiple rather than single. But these cases also exhibited variegated pictures. In terms of the result of *H pylori* eradication therapy, we did not see any correlation

with the endoscopic findings. It might be due to the small number of cases of *H pylori* eradication failure and complexity of endoscopic findings of low grade MALTOMA. However, the lesion of localized mass type showed the tendency to higher treatment failure (Table 4). Nevertheless, if we consider the fact that high grade lymphoma is often accompanied with deep ulceration or protruding mass in the stomach, our results might be valuable on the presumption that mixed type MALTOMA might exist which was responsible for the treatment failure.

Abstract

AIM: To investigate the effect of *Helicobacter pylori* (*H pylori*) infection on the expressions of Bcl-2 family members in gastric adenocarcinoma.

METHODS: Gastric adenocarcinoma and resection margin tissues of 95 patients were studied. Semi-quantitative RT-PCR was used to measure Bid, Bax and Bcl-2 mRNA expressions.

RESULTS: Expressions of Bid and Bax in gastric adenocarcinoma tissues without *H pylori* infection, with cagA⁻ *H pylori* infection and cagA⁺ *H pylori* infection increased significantly in turn (Bid, 0.304, 0.422 and 0.855 respectively, $P<0.05$; Bax, 0.309, 0.650 and 0.979 respectively, $P<0.05$). Bcl-2 mRNA levels increased significantly in gastric adenocarcinoma tissues with cagA⁻ *H pylori* infection and cagA⁺ *H pylori* infection, compared with those without *H pylori* infection (0.696 and 0.849 *vs* 0.411, $P<0.05$). Expressions of Bid, Bax and Bcl-2 in resection margin tissues without *H pylori* infection, with cagA⁻ *H pylori* infection and cagA⁺ *H pylori* infection increased significantly in turn (Bid, 0.377, 0.686 and 0.939 respectively, $P<0.05$; Bax, 0.353, 0.645 and 1.001 respectively, $P<0.05$; Bcl-2, 0.371, 0.487 and 0.619 respectively, $P<0.05$). In *H pylori* negative specimens, expressions of Bid and Bax correlated negatively with that of Bcl-2 respectively in adenocarcinoma tissues (Bid *vs* Bcl-2, $r=-0.409$, $P<0.05$; Bax *vs* Bcl-2, $r=-0.451$, $P<0.05$). In *H pylori* positive specimens, expressions of Bid and Bax did not correlate with that of Bcl-2 in adenocarcinoma tissues (Bid *vs* Bcl-2, $r=0.187$, $P>0.05$; Bax *vs* Bcl-2, $r=0.201$, $P>0.05$), but correlated positively with that of Bcl-2 respectively in resection margin tissues (Bid *vs* Bcl-2, $r=0.331$, $P<0.05$; Bax *vs* Bcl-2, $r=0.295$, $P<0.05$).

CONCLUSION: *H pylori* may enhance Bid, Bax and Bcl-2 mRNA levels and cause deregulation of these apoptosis-associated genes expressions, which may play a role during development of gastric adenocarcinoma induced by *H pylori*.

INTRODUCTION

Helicobacter pylori (*H pylori*) infection is the most common chronic infection in humans and is the major cause of gastritis worldwide. This infection is also accepted as the etiological factor of the majority of peptic ulcers. It has been implicated as a significant contributing factor in the development of gastric malignancy, both gastric MALT lymphoma and gastric adenocarcinoma[1-14], and *H pylori* was classified as a group 1 carcinogen for gastric cancer in 1994 by the WHO and International Agency for Research on Cancer (IARC)[15]. The role of *H pylori* infection in the gastric carcinogenesis is not clear. It might be involved in imbalance between apoptosis and proliferation[16-33]. Bcl-2 family members have been closely related to apoptosis, which could either promote cell survival (Bcl-2, Bcl-x$_L$, A1, Mcl-1, and Bcl-w) or promote cell death (Bax, Bak, Bcl-x$_S$, Bad, Bid, Bik, Bim, Hrk, Bok)[34-36]. In the present study, we investigated the effect of *H pylori* infection on the expressions of Bcl-2 family members in gastric adenocarcinoma and resection margin tissues.

MATERIALS AND METHODS

Tissue specimens

Specimens of gastric adenocarcinoma of 95 patients (72 males and 23 females, age range 31 to 84 years, mean 56 years), who had undergone resection surgical at the Southwest Hospital in Chongqing and had not taken anti-*H pylori* drugs before operation, were collected from 2001 to 2002. Gastric adenocarcinoma tissues were examined microscopically. Resection margin tissues were also examined to verify that they did not contain malignant cells. The histological diagnosis was confirmed by a professional pathologist. The remaining specimens were snap-frozen and stored at -80 ℃ until assayed. Warthin-Starry silver staining and polymerase chain reaction (PCR) analysis for *H pylori* urease gene A (*ure*A) were performed to detect *H pylori* infection. PCR analysis for *H pylori cag*A gene was performed to verify *cag*A⁺ *H pylori* infection. Fifty-eight patients whose both Warthin-Starry staining and PCR for *ure*A showed positive results were diagnosed as suffering from *H pylori* infection and 37 were *cag*A⁺ *H pylori*.

RT-PCR analysis of Bid, Bax and Bcl-2 mRNA

According to references[37,38], primers were designed for β-actin (GenBank accession No.BC013380), 5'-GTG GGG CGC CCC AGG CAC CA-3' (sense) and 5'-CTC CTT AAT GTC ACG CAC GAT TTC-3' (antisense), 540 bp product; for Bid (GenBank accession No.AF087891), 5'-ATG GAC TGT TGA GGT CAA CAA C-3' (sense) and 5'-TCA GTC CAT CCC ATT TCT GGC T-3' (antisense), 588 bp product; for Bax (GenBank accession No.AY217036), 5'-ACC AAG AAG CTG AGC GAG TGT C-3' (sense) and 5'-ACA AAG ATG GTC ACG GTC TGC C-3' (antisense), 332 bp product; and for Bcl-2 (GenBank accession No.M13994), 5'-TGC ACC TGA CGC CCT TCA C-3' (sense), 5'-AGA CAG CCA GGA GAA ATC AAA CAG-3' (antisense), 293 bp product.
    Total RNA was prepared from gastric adenocarcinoma

tissues and resection margin tissues by using TriPure isolation reagent (Roche) according to the manufacturer's protocol. Reverse transcription (RT) was performed for first-strand cDNA by using 2 µg of total RNA and 1 µl of oligo(dT)18 primer in the presence of 5 unit AMV reverse transcriptase (Promega), 20 unit RNase inhibitor, 0.5 mmol/L of each dNTP and 1×buffer in 20 µl for 60 min at 42 ℃. Then 2 µl reverse transcription products were used for PCR. In a total of 20 µl reactive mixture, 5 pmol/L sense primer and 5 pmol/L antisense primer, 0.25 mmol/L of each dNTP, 1×reaction buffer and 1.5 unit Taq polymerase were mixed. The reaction was run for 33 cycles, and each consisted of denaturation at 94 ℃ for 60 s, annealing at 58 ℃ for 60 s, extension at 72 ℃ for 60 s and final extension prolonged for 7 min at 72 ℃. PCR-amplified products (8 µl each) were analyzed on 1.5% agarose gels after ethidium bromide staining. Expression levels of Bid, Bax and Bcl-2 were quantitated using Quantity One quantitation software (Bio-Rad Laboratories) and were reported to be normalized to β-actin levels.

Statistical analysis

All data were presented as means ± standard error. Differences in means were examined by ANOVA, and correlations were analyzed by using Spearman's rank correlation coefficient (SPSS 10.0 for Windows). A P value<0.05 was considered significant.

RESULTS

Effect of H pylori on expressions of Bid, Bax and Bcl-2 mRNA

In gastric adenocarcinoma tissues, expressions of Bid and Bax mRNA in H pylori negative group, cagA$^-$ H pylori infection group and cagA$^+$ H pylori infection group increased in an ascending pattern, respectively ($P<0.05$). Expression of Bcl-2 in H pylori negative group was significantly lower than that in H pylori infection group ($P<0.05$). Levels of Bcl-2 mRNA between cagA$^-$ H pylori infection group and cagA$^+$ H pylori infection group did not show any significant difference.

In resection margin tissues, expressions of Bid, Bax and Bcl-2 mRNA in H pylori negative group, cagA$^-$ H pylori infection group and cagA$^+$ H pylori infection group increased in turn ($P<0.05$) (Figure 1, Tables 1-3).

Table 1 Effect of H pylori infection on expression of Bid

		Adenocarcinoma	Resection margin
H pylori (-)		0.304±0.113	0.377±0.119
H pylori (+)	cagA (-)	0.422±0.149[a]	0.686±0.285[a]
	cagA (+)	0.855±0.305[ac]	0.939±0.383[ac]

[a]$P<0.05$, vs H pylori negative group, [c]$P<0.05$, vs cagA$^-$ H pylori infection group.

Table 2 Effect of H pylori infection on expression of Bax

		Adenocarcinoma	Resection margin
H pylori (-)		0.309±0.123	0.353±0.139
H pylori (+)	cagA (-)	0.650±0.393[a]	0.645±0.327[a]
	cagA (+)	0.979±0.375[ac]	1.001±0.361[ac]

H pylori (-)		0.411±0132	0.371±0.153
H pylori (+)	cagA (-)	0.696±0.318[a]	0.487±0.241[a]
	cagA (+)	0.849±0.352[a]	0.619±0.243[ac]

[a]$P<0.05$, vs H pylori negative group, [c]$P<0.05$, vs cagA$^-$ H pylori infection group.

Correlation among levels of Bid, Bax and Bcl-2 mRNA

In H pylori negative group, levels of Bid and Bax mRNA correlated negatively with that of Bcl-2 in gastric adenocarcinoma tissues (Bid vs Bcl-2,r=-0.409, $P<0.05$; Bax vs Bcl-2, r=-0.451, $P<0.05$). In H pylori positive group, expressions of Bid and Bax did not correlate with that of Bcl-2 in adenocarcinoma tissues (Bid vs Bcl-2, r=0.187, $P>0.05$; Bax vs Bcl-2, r=0.201, $P>0.05$), but correlated positively with that of Bcl-2 respectively in resection margin tissues (Bid vs Bcl-2, r=0.331, $P<0.05$; Bax vs Bcl-2, r=0.295, $P<0.05$).

Figure 1 Effect of H pylori infection on mRNA expressions of Bcl-2 family members in gastric adenocarcinoma and resection margin tissues. A: Expression of Bid in gastric adenocarcinoma, B: Expression of Bid in resection margin, C: Expression of Bax in gastric adenocarcinoma, D: Expression of Bax in resection margin, E: Expression of Bcl-2 in gastric adenocarcinoma, F: Expression of Bcl-2 in resection margin, 1: H pylori negative group, 2: cagA$^-$ H pylori group, 3: cagA$^+$ H pylori group.

DISCUSSION

Bid, Bax and Bcl-2 are representative members of Bcl-2 family. Bid and Bax are pro-apoptosis members. Bcl-2 is an anti-apoptosis member. In the mechanism of regulating apoptosis, Bid as a BH3 domain protein, is one of the initiators to apoptosis and Bax is the key member. Either Bid or Bcl-2 must rely on Bax to induce or inhibit apoptosis[39-43].

Studies have shown that *H pylori* infection could induce Fas antigen (Fas Ag) expression in gastric epithelial cells[44]. In addition, *H pylori* infection was also associated with increased mucosal inflammatory cytokines, including TNF-α[45] and IFN-γ[46]. The cytokines generated during the immune response to *H pylori* also increased expression of Fas Ag in gastric cell lines[47]. Fas Ag, after binding specifically to its ligand (Fas L), trimerizes and activates Caspase-8. Activation of Caspase-8 could result in the cleavage of cytosolic Bid to truncate tBID, which could translocate to mitochondria and initiate apoptosis[48]. Shibayama *et al*[31] found that *H pylori* infection induced the activation of Caspase-8 and the expression of Bid in human gastric epithelial cells, and inhibition of Caspase-8 suppressed the expression of Bid. In the present study, we found that *H pylori* infection upregulated expression of Bid mRNA in both gastric adenocarcinoma and resection margin tissues. That might be due to the upregulation of Fas and the activation of Caspase-8.

Bax is a cytosolic protein and translocates from the cytosol to the mitochondria for integration into the membrane following a proapoptotic stimulus. This action then results in cytochrome C release and initiates apoptosis. We have previously demonstrated that *H pylori* infection could promote Bax protein expression in chronic gastritis and premalignant lesions. Expression of Bax correlated positively with apoptotic index. The apoptotic index in Bax expression positive group in intestinal metaplasia, gastric dysplasia and gastric carcinoma was significantly higher than that in Bax negative group. In the present study, we found *H pylori* infection also increased levels of Bax mRNA in both gastric adenocarcinoma and resection margin tissues, and the effect was stronger in CagA$^+$ *H pylori* group than cagA$^-$ *H pylori* group. These results showed *H pylori* infection might promote apoptosis in gastric adenocarcinoma and its resection margin tissues.

Bc1-2 is an important anti-apoptosis protein. We found that Bcl-2 mRNA levels in *H pylori* negative group in gastric adenocarcinoma tissues were lower than in *H pylori* positive group. In resection margin tissues, Bcl-2 mRNA levels in *H pylori* negative group, cagA$^-$ *H pylori* infection group and cagA$^+$ *H pylori* infection group respectively increased in turn, suggesting that *H pylori* might promote expression of Bcl-2 in both gastric adenocarcinoma and resection margin tissues.

Although *H pylori* could promote expressions of Bid, Bax and Bcl-2, the correlations among them are still unclear. In the present study, it showed that levels of Bid and Bax mRNA were correlated negatively with that of Bcl-2 in gastric adenocarcinoma tissues without *H pylori* infection. This result is correspondent with the findings that apoptosis decreases in tumor tissues. In *H pylori* positive group, levels of Bid, Bax and Bcl-2 mRNA in gastric adenocarcinoma all increased. Besides, levels of Bid, Bax, and Bcl-2 did not correlate with each other. In the resection margin tissues, levels of Bid and Bax mRNA were correlated positively with that of Bcl-2. These results indicated that although *H pylori* could promote expressions of Bid, Bax and Bcl-2, it might play a different role in the development of gastric adenocarcinoma. In benign gastric lesions, *H pylori* infection might mainly upregulate expressions of pro-apoptotic genes such as Bid and Bax, and this effect might be stronger than its upregulatory effect on Bcl-2, which is consistent with the phenomena that *H pylori* infection increases apoptosis in atrophic gastritis and gastric ulcer. During development of gastric adenocarcinoma, upregulatory effect of *H pylori* on anti-apoptotic genes, for example Bcl-2, might increase gradually and counteract pro-apoptosis effect of Bid and Bax, which may induce or worsen deregulation of apoptosis-associated genes expressions during the course of the formation of gastric adenocarcinoma.

Recently, it was found that not only excessive proliferation played an important role in gastric adenocarcinoma, but also reduction of apoptosis contributed to the carcinogenesis of gastric mucosa. The abnormal expressions of Bid, Bax and Bcl-2 induced by *H pylori* might result in inhibition of apoptosis, which may play an important role during development of gastric adenocarcinoma induced by *H pylori*[49]. The detailed mechanism still remains to be studied.

Abstract

AIM: To synthetically analyze and probe into the diagnosis of *H pylori* infection, we followed the principles of evidence-based medicine.

METHODS: A total of 22 papers of prevalence survey and case-control studies were selected for studying about diadynamic methods. Using meta-analysis, we analyzed the different diadynamic methods of *H pylori* in China.

RESULTS: Through meta-analysis, among the five diadynamic methods, the accuracy of polymerase chain reaction (PCR) was the highest (98.47%) and PCR was the most sensitive method (*Sp:* 99.03%).

CONCLUSION: Among the five diadynamic methods, the accuracy of PCR is the highest and PCR is the most sensitive method to diagnose the infection of *H pylori*.

INTRODUCTION

Since *Helicobacter pylori* (*H pylori*) was first isolated in 1982, the association of *H pylori* and related diseases has become the hot spot of gastroenterological studies. The distribution of *H pylori* infection is worldwide, and the prevalence rate of *H pylori* among populations is very high. With the deepening of *H pylori* researches, studies about *H pylori*, which aimed at effectively controlling the infection, were of great significance in preventing and curing the chronic stomach troubles. Because of the independence of each study and limit to the region and sample source, a great majority of studies did not have enough evidence and totally unanimous conclusion, which influenced the reliability of the conclusion. However, meta-analysis method could appraise and analyze synthetically the results of study with the same research purpose[1], thus improving the efficiency of statistics, solving the problem with inconsistent results of studies, and making the conclusion of study more reliable. Therefore, we used meta-analysis to analyze synthetically the results of studies associated with *H pylori* diagnosis so as to express them more accurately.

MATERIALS AND METHODS

Literature selection and data

A Chinese biology and medicine database (CBM) search of non-review articles since 1995 was performed with the MeSH headings "*Helicobacter pylori*", "diagnosis", "polymerase chain reaction", "enzyme-linked immunosordent assay" and "urea enzymes test".
Standard of selection The research objects were the population who could possibly suffer from *H pylori*, and the results of study had intact statistics.
***H pylori*-positive result judgment** *H pylori* cultivation was positive or one or two of the followings were positive: *H pylori* morphology (smear, histology or immunohistochemistry), urea enzyme test (RUT, ^{13}C or ^{14}C-urea breath test), PCR detection, serologic test (ELISA or immunoblotting test, *etc*.).
Standard of rejection The sample size was too small for statistical study, children less than one year old who possibly carried mother' s antibody, studies without definite detection of *H pylori* or strict quality control.
Study on diadynamic methods of *H pylori* The literature search result were classified as follows. Twenty-two reports[2-23] appraised synthetically according to 5 commonly used clinical diagnostic methods, the evaluation targets included sensitivity (*Se*), specificity (*Sp*) and accuracy (π). Bibliographic retrieval results of ^{13}C-urea breath test, ^{14}C-urea breath test, ELISA, RUT and PCR are shown in Tables 1-5.

Methods

In the statistical analysis of data, Meta-analysis method with a fixed effect model and a random effect model was used to reach an integrated conclusion[24-26].

RESULTS

Among the five diadynamic methods, the accuracy of PCR was the highest and PCR was the most sensitive method, specificity of ^{13}C-urea breath test was the highest, the sensitivity and accuracy of RUT were the lowest, specificity of ELISA was the lowest (Table 6).

Table 6 Synthetic evaluation of five diadynamic methods

Diadynamic methods	Se (%)	Sp (%)	π (%)
^{13}C-urea breath test	99.34	95.09	97.78
^{14}C-urea breath test	97.56	94.96	96.40
ELISA	93.96	81.78	90.09
PCR	98.25	99.03	98.47
RUT	95.58	71.19	87.02

DISCUSSION

This study used bibliographic retrieval to collect the relevant materials of *H pylori* infection, and meta-analysis, including combination of statistics in many studies by weight and equalized test, to analyze the diagnosis of *H pylori* infection.

The five diadynamic methods of *H pylori* infection all had a high sensitivity, specificity and accuracy, among which PCR was most sensitive and accurate. ^{13}C-urea breath test was the most specific. As an ideal diadynamic method, it should have the following advantages: a high sensitivity and specificity, minimal incursions into or no damage to patients, simple and convenient in manipulation, less sophisticated technique or equipment, low cost and easy acceptance by patients. However, in fact, it is difficult for one diadynamic method to possess all these qualities. Above all, among the five diadynamic methods of *H pylori* infection, ELISA is the most convenient, which has the lowest cost and damage, therefore, serological positivity can merely explain the situation of whether patients have been infected or being infected. ^{13}C-urea breath test has no harm, and can provide the whole infection information of stomach, which is relatively ideal, but it is difficult to popularize for the need of equipments and high expense. Although ^{14}C-urea breath test can be done by well-equipped hospital and has lower cost than ^{13}C-urea breath test, it has some radioactivity risk. RUT belongs to indirect test, whose intensity is determined by bacterial density of biopsy specimen. PCR is more sensitive than other methods. PCR can also detect *H pylori*, which cannot be detected by other methods, and at present it has been widely used in detection of various kinds of clinical specimens[27]. So which diadynamic methods would be adopted in clinical detection must be determined according to the specific situation and different requirements[28-32].

H pylori infection is common and study of *H pylori* infection involves a wide extent. A large number of researches and works on this aspect have been done in China, and have achieved a great progress, although some problems where found in these studies such as flaw in experimental design, scattered data, deficiency of objective and reliable conclusion. Therefore, many aspects of *H pylori* infection are still to be studied to obtain accurate and consummate results.

Abstract

AIM: Over 90% of drugs are metabolized by the cytochrome P-450 (CYP) family of liver isoenzymes. The most important enzymes are CYP1A2, 3A4, 2C9/19, 2D6 and 2E1. Although CYP2D6 accounts for <2% of the total CYP liver enzyme content, it mediates metabolism in almost 25% of drugs. In order to study its enzymatic activity for drug metabolism, its cDNA was cloned and a HepG2 cell line stably expressing CYP2D6 was established.

METHODS: Human *CYP2D6* cDNA was amplified with reverse transcription-polymerase chain reaction (RT-PCR) from total RNA extracted from human liver tissue and cloned into pGEM-T vector. cDNA segment was identified by DNA sequencing and subcloned into a mammalian expression vector pREP9. A cell line was established by transfecting the recombinant plasmid of pREP9-CYP2D6 to hepatoma HepG2 cells. Expression of mRNA was validated by RT-PCR. Enzyme activity of catalyzing dextromethorphan *O*-demethylation in postmitochondrial supernant (S9) fraction of the cells was determined by high performance liquid chromatography (HPLC).

RESULTS: The cloned cDNA had 4 base differences, e.g. 100 C→T, 336 T→C, 408 C→G and 1 457 G→C, which resulted in P34S, and S486T amino acid substitutions, and two samesense mutations were 112 F and 136 V compared with that reported by Kimura *et al* (GenBank accession number: M33388). P34S and S486T amino acid substitutions were the characteristics of *CYP2D6*10* allele. The relative activity of S9 fraction of HepG2-CYP2D6*10 metabolized detromethorphan *O*-demethylation was found to be 2.31±0.19 nmol· min^{-1}· mg^{-1} S9 protein (*n*=3), but was undetectable in parental HepG2 cells.

CONCLUSION: cDNA of human *CYP2D6*10* can be successfully cloned. A cell line, HepG2-CYP2D6*10, expressing CYP2D6*10 mRNA and having metabolic activity, has been established.

INTRODUCTION

Over 90% of drugs are metabolized by the cytochrome P-450 (CYP) family of liver isoenzymes[1]. The most important enzymes are CYP1A2, 3A4, 2C9/19, 2D6 and 2E1. Although CYP2D6 accounts for <2% of the total CYP liver enzyme content, it mediates metabolism in almost 25% of drugs. Among these are many antipsychotics and antidepressants, beta-blockers, antiarrhythmic agents and opiates[2,3]. *CYP2D6* exhibits extensive polymorphism. Over 40 *CYP2D6* allelic variants have been discovered[4] (http://www.imm.ki.se/CYPalleles/cyp2d6.htm).

Human CYP1A1[5], CYP2B6[5], CYP2A6[6], CYP3A4[7], CYP2C9[8], CYP2C18[9] and a phase II metabolism enzyme UDP-glucuronosyltransferase, UGT1A9[10] have been stably expressed in Chinese hamster lung CHL cells in our laboratory. Among the human hepatic cell lines, HepG2 is derived from a human liver tumor and characterized by many xenobiotic-metabolizing activities as compared to fibroblasts. Therefore, HepG2 cell is useful in the prediction of the metabolism and cytotoxicity of chemicals in human liver[11]. But it does not produce a significant amount of CYP[12,13]. Yoshitomi *et al*[14] have established stable expression of a series of human CYP subtypes, e.g. CYP1A1, CYP1A2, CYP2A6, CYP2B6, CYP2C8, CYP2C9, CYP2C19, CYP2D6, CYP2E1 and CYP3A4, respectively in the HepG2 cells.

In this study human *CYP2D6*10* cDNA was amplified with reverse transcription-polymerase chain reaction (RT-PCR), and a cell line stably expressing CYP2D6.10 was established.

MATERIALS AND METHODS

Materials

Restriction endonucleases and Moloney murine leukemia virus (M-MuLV) reverse transcriptase were supplied by MBI Fermentas AB, Lithuania. PCR primers, DNA sequence primers, random hexamer primers and dNTPs were synthesized or supplied by Shanghai Sangon Biotechnology Co. Expand fidelity PCR system and NADPH were from Roche Molecular Biochemicals. DNA sequencing kit was purchased from Perkin-Elmer Co. TRIzol reagent, G418, Dulbecco's modified Eagle's medium (DMEM) and newborn bovine calf sera were from Gibco. Diethyl pyrocarbonate (DEPC), dextromethorphan HBr and dextrophan D-tartrate were purchased from Sigma/RBI. T4 DNA ligase and pGEM-T vector system were from Promega. HPLC solvents and other chemicals were all of the highest grade from commercial sources.

Methods

Cloning of human *CYP2D6* cDNA from human liver Total RNA was extracted from a surgical specimen of human liver with TRIzol reagent according to the manufacture's instructions. RT-PCR amplifications using expand fidelity PCR system were described before. Two specific 28-mer oligonucleotide PCR primers were designed according to the cDNA sequence of *CYP2D6* reported by Kimura *et al*[15] (GenBank accession no.M33388). The sense primer corresponding to base position -12 to 13 was CYP2D6 F1: 5' -

CTCGAGGCAGGTATGGGGGCTAGAAG-3', with a restriction site of *Xho* I, and the anti-sense one, corresponding to the base position from 1 503 to 1 530, was CYP2D6 R1: 5'-GGATCCTGAGCAGGCTGGGGACTAGGTA-3', with a restriction site of *Bam*H I. The anticipated PCR products were 1.543 kb in length. PCR was performed at 94 ℃ for 5 min, then 35 cycles at 94 ℃ for 60 s, at 62 ℃ for 60 s, at 72 ℃ for 2 min, and a final extension at 72 ℃ for 10 min. An aliquot (10 μL) from PCR was subjected to electrophoresis in a 1% agarose gel stained with ethidium bromide.

Construction of recombinant pGEM-CYP2D6 and sequencing of *CYP2D6* cDNA[8] The PCR products were ligated with pGEM-T vector, and transformed to *E. coli* DH5α. cDNA of *CYP2D6* cloned in pGEM-T was sequenced by dideoxy chain-termination method marked with BigDye with primers of T7, SP6 promoters and two specific primers of 5'-ACCTCATGAATCACGGCAGT-3' (1 088-1 069), and 5'-CCGTGTCCAACAGGAGA-3' (987-1 003). The termination products were dissolved and detected using an automated DNA sequencer (Perkin-Elmer-ABI Prism 310).

Construction of pREP9 based expression plasmid for *CYP2D6*[8] *Xho* I/*Bam*H I fragment having the total span of human *CYP2D6* cDNA in pGEM-CYP2D6 was subcloned to a mammalian expression vector pREP9 (Invitrogen). The recombinant was transformed to *E. coli* Top 10, screened by ampicillin resistant and identified by restriction mapping.

Transfection and selection[8, 16] HepG2 cells were maintained as monolayer cell cultures at 37 ℃ in DMEM supplemented with 10% new born calf sera. HepG2 cells were transfected with the resultant recombinant plasmid, pREP9-CYP2D6, using a modified calcium phosphate method. A cell line named HepG2-CYP2D6 was established by selecting in the culture medium containing G418.

RT-PCR assay of CYP2D6 mRNA expression in HepG2-CYP2D6 and HepG2 cells Total RNA was preprared from G-418-resistant clones by TRIzol reagent. RT-PCR was performed as described before[8], using 200 mmol· L⁻¹ of CYP2D6F1 and CYP2D6R1 primers and 200 mmol· L⁻¹ primers of beta-actin as internal control. The sense and anti-sense primers used for PCR amplification of beta-actin (GenBank accession no. NM_001101) are 5'-TCCCTGGAGAAGAGCTACGA-3' (776-795) and 5'-CAAGAAAGGGTGTAACGCAAC-3' (1 217-1 237), respectively. PCR was performed at 94 ℃ for 2 min, then 35 cycles at 94 ℃ for 30 s, at 62 ℃ for 30 s, at 72 ℃ for 90 s, and a final extension at 72 ℃ for 7 min. The anticipated beta-actin PCR products were 462 bp in length and that of *CYP2D6* were 1 543 bp in length. An aliquot (10 μL) from PCR was subjected to electrophoresis in a 1.2% agarose gel stained with ethidium bromide.

Preparation of postmitochondrial supernant (S9) of HepG2-CYP2D6 The procedure for the preparation of S9 fraction was described before[8]. The protein in S9 was determined by Lowry's method, with bovine serum albumin as standard.

Dextromethorphan *O*-demethylation assays[17-20] CYP2D6 dextromethorphan *O*-demethylation activity of S9 was determined by reversed phase high performance liquid chromatography (HPLC). Briefly, incubation reactions were performed in 50 mmol· L⁻¹ potassium phosphate buffer (pH7.4), containing 3 mmol· L⁻¹ MgCl₂, 1 mmol· L⁻¹ EDTA, 40 mmol· L⁻¹ dextromethophan and 200 μg S9 protein in a final volume of 200 μL. Reactions were initiated by addition of 1 mmol· L⁻¹ NADPH and terminated with 30% acetic acid after incubation for 10 min at 37 ℃. Protein was precipitated by centrifugation at 10 000 *g* for 4 min, and the supernatant was stored at -20 ℃ for analysis. On HPLC analysis, 10 μL of supernatant was injected into a Water HPLC equipped with a Shimadzu RF-535 fluorescence detector. A CLC phenyl column (15 cm×4.5-mm

i.d.) was used to separate the metabolites. The mobile phase consisted of a mixture of 30% acetonitrile, 1% acetic acid, and 0.05% triethylamine in water. The flow rate through the column at 25 ℃ was 0.75 ml· min⁻¹. The excitation and emission wavelengths of the fluorescence detector were 285 nm and 310 nm, respectively. The rates of product formation were determined from standard curves prepared by adding varying amounts of dextrophan D-tartrate to incubations conducted without NADPH.

RESULTS

Construction of human CYP2D6*10 cDNA recombinants
The pGEM-CYP2D6 recombinant was constructed by inserting human *CYP2D6* cDNA into the pGEM-T vector. Selection and identification of the recombinant were carried out by *Xho* I/*Bam*H I endonuclease digestion, agarose gel electrophoresis (Figure 1) and DNA sequencing. Compared with the cDNA sequence reported by Kimura *et al*[15] (GenBank accession no. M33388), differences were found in 100 C→T, 336 T→C, 408 C→G and 1457 G→C, that result in P34S and S486T amino acid substitutions, and two samesense mutations of 112 F and 136 V.

The *Xho* I/*Bam*H I fragment (1.543 kb) containing the complete *CYP2D6* cDNA was subcloned into the *Xho* I/*Bam*H I site of mammalian expression vector pREP9. Selection and identification of the recombinant were carried out by *Xho* I/*Bam*H I endonuclease digestion and agarose gel electrophoresis (Figure 1). The resulting plasmid was designated as pREP9-CYP2D6 and contained the entire coding region, along with 11 bp of the 5' and 35 bp of the 3' untranslation region of *CYP2D6* cDNA, respectively.

Figure 1 Electrophoresis identification of pGEM-CYP2D6 and pREP9-CYP2D6 recombinants. Lane 1: Marker (λ/*Eco*R I and *Hin*d III), 2: PCR products of *CYP2D6* (1.543 kb), 3: Recombinant of pGEM-*CYP2D6* digested by *Xho* I and *Bam*H I, 4: pGEM-T vector (3 kb), 5: Recombinant of pREP9-CYP2D6 digested by *Xho* I and *Bam*H I, 6: pREP9 vector (10.5 kb).

Establishment of cell line HepG2-CYP2D6
HepG2 cells were transfected with pREP9-CYP2D6, and selected with G418. The surviving clones were subcultured and the cell line termed HepG2-CYP2D6 was established.

RT-PCR assay of CYP2D6 mRNA expression in HepG2-CYP2d6 cells
CYP2D6 mRNA expression in HepG2-CYP2D6 cells was detected by RT-PCR with CYP2D6F1 and CYP2D6R1 primers. It was easily to identify a 1.5 kb band from HepG2-CYP2D6 cells, but not from HepG2 cells (Figure 2).

Dextromethorphan O-demethylation activity in HepG2-CYP2D6 cells
The dextromethorphan *O*-demethylation activity in S9 of HepG2-CYP2D6 cells was assayed by reverse HPLC. A typical elution profile of metabolites in supernatant was shown (Figure 3). The retention times for dextrophan and dextromethorphan

were 6.5 min and 16.8 min, respectively. The CYP2D6 enzyme activity towards dextromethorphan O-demethylation was found to be 2.31 ± 0.19 nmol· min^{-1}· mg^{-1} S9 protein (n=3), but was undetectable in parent HepG2 cells.

Figure 2 Identification of CYP2D6 mRNA expression in HepG2-CYP2D6 and HepG2 cells by RT-PCR with beta-actin as internal control. Lane 1: 1 kb ladder marker, 2: RT-PCR products of HepG2 cells showing a 462 bp of beta-actin, 3: RT-PCR products of HepG2-CYP2D6 cells showing a 462 bp of beta-actin and 1.5 kb of CYP2D6.

Figure 3 Representative chromatograms of metabolites in supernatant. 10 µL of supernatant was injected into a Water HPLC equipped with a Shimadzu RF-535 fluorescence detector. A CLC phenyl column (15 cm×4.5-mm i.d.) was used to separate the metabolites. The mobile phase consisted of a mixture of 30% acetonitrile, 1% acetic acid, and 0.05% triethylamine in water. The flow rate through the column at 25 ℃ was 0.75 ml· min^{-1}. The excitation and emission wavelengths of the fluorescence detector were 285 nm and 310 nm, respectively. The retention times for dextrophan and dextromethorphan were 6.5 min and 16.8 min, respectively. The retention time of an unidentified metabolite was 8.9 min.

DISCUSSION

The gene encoding CYP2D6 enzyme is localized on chromosome 22. Three major mutant alleles, termed *CYP2D6*3*, *4*, and *5*, associated with the poor metabolizer (PM) phenotype, were found early on in Caucasians[3]. *CYP2D6* gene has turned out to be extremely polymorphic with 44 alleles described to 10-Nov-2003 (http://www.imm.ki.se/CYPalleles/cyp2d6.htm). Three fairly population specific alleles have been found with *CYP2D6*4* in Caucasians, **10* in Asians and **17* in Africans[3]. The *CYP2D6*10* allele with 100 C→T and 1457 G→C, can result in P34S and S486T amino acids substitute and an unstable enzyme with decreased catalytic activity. This allele occurred from 38% to 70% in Asian population[4]. The most frequent allele in Chinese was *CYP2D6*10* allele with a frequency of about 51.3%[21], it was 57.2% in Guangdong Chinese population[22], 41.17% in Hong Kong Chinese population[23]. The *CYP2D6* cDNA we cloned has the characteristics of *CYP2D6*10* allele with 2 amino acid substitutions of P34S and S486T.

Ramamoorthy *et al*[24] have compared CYP2D6.10 with CYP2D6.1 *in vitro* in a baculovirus expression system using various substrates, such as dextromethorphan, *P*-methoxyamphetamine, 1-methyl-4-phenyl-1, 2, 3, 6-tetrahydropyridine and (+/-)3, 4-methylenedioxymethamphetamine, the ratio of intrinsic clearance (Vmax/Km) of CYP2D6.1 to CYP2D6.10 was 50, 34, 22 and 123, respectively.

Yu *et al*[25] reported that the purified CYP2D6.10 enzyme prepared from *in vitro* and to a high homogeneity was reconstituted with lipid and cytochrome P450 reductase, and exhibited an estimated enzyme efficiency (as Vmax/Km) 50-fold lower for dextromethophan O-demethylation and 100-fold lower for fluoxetine N-demethylation when compared with CYP2D6.1, whereas no measurable catalytic activity was observed for this variant toward codeine.

The intrinsic clearances (Vmax/Km) in reconstituted microsomes expressing CYP2D6.10 were reduced by 135-fold with (+/-)-3, 4-methylenedioxymethamphetamine and by 164-fold with dextromethorphan compared with that of wild-type CYP2D6.1[26].

Bufuralol 1' -hydroxylase activity in microsomes of yeast expressing CYP2D6.10 was rapidly decreased by heat treatment, supporting the idea that the thermal stability of the enzyme was reduced by amino acid replacement. Thermal instability together with the reduced intrinsic clearance of CYP2D6.10 is one of the causes responsible for the known fact that Orientals show lower metabolic activities than Caucasians for drugs metabolized mainly by CYP2D6[27].

Subjects homozygous for *CYP2D6*10* had higher total areas under the plasma concentration-time curve, lower apparent oral clearances, and longer mean plasma half-life of nortriptyline than subjects in the *CYP2D6*1/*1* and the heterozygous groups[28].

The plasma haloperidol concentration/dose ratio was significantly higher in older subjects (at least 50 years old) than in younger subjects with non-*2D6*10* homozygous genotypes, but not for those with *2D6*10* homozygous genotype[29]. No significant differences in plasma concentration of fluvoxamine divided by daily dose of fluvoxamine per body weight ratio were found between subjects with no, one or two *CYP2D6*10* alleles in Japanese subjects[30].

Cai *et al*[31] found that patients with homozygous mutant of *CYP2D6*10* not only had a plasma concentration at peak (Cmax) of propafenone two times as high as those of wild-type genotype, but also showed a two-fold higher inhibitory rate of ventricular premature contractions compared with those with homozygous *CYP2D6*1*.

Venlafaxine, a new antidepressant, is metabolized mainly by CYP2D6 to an active metabolite, O-desmethylvenlafaxine. Cmax and areas under the plasma concentration-time curve of venlafaxine were 184% and 484% higher in the *CYP2D6*10/*10* subjects than in the *CYP2D6*1/*1* subjects[32].

Bufuralol 1' -hydroxylation has been commonly used by pharmaceutical industry to study *in vitro* drug interactions for CYP2D6[33]. Dextromethorphan has been a widely used probe drug for human CYP2D6 activity both *in vitro* and *in vivo*[34]. In humans, dextromethorphan is metabolized to dextrorphan, 3-methoxymorphinan and 3-hydroxymorphinan. CYP2D6 contributes at least 80% to the formation of dextrorphan, and CYP3A4 contributes more than 90% to the formation of 3-hydroxymorphinan. Dextromethorphan as a marker for monitoring both CYP2D6 and CYP3A activities has been found to be practical in human liver microsomal preparation[35].

The expression of CYP2D6*10 mRNA was validated by RT-PCR. The detromethorphan O-demethylation of HepG2-CYP2D6*10 was 2.31 ± 0.19 nmol· min^{-1}· mg^{-1} S9 protein, which was higher than baculovirus expressed CYP2D6 (1.3420 ± 0.1466 nmol· min^{-1}· mg^{-1} protein) and human liver

microsome 0.17 to 0.30 nmol· min[-1]· mg[-1] protein[36]. This cell line is a useful tool for further studies of the function and biochemical mechanism of CYP2D6.10 enzyme.

Abstract

AIM: To investigate the dynamic changes of capillarization and peri-sinusoid fibrosis in an alcoholic liver disease model induced by a new method.

METHODS: Male SD rats were randomly divided into 6 groups, namely normal, 4 d, 2 w, 4 w, 9 w and 11 w groups. The animals were fed with a mixture of alcohol for designated days and then decollated, and their livers were harvested to examine the pathological changes of hepatocytes, hepatic stellate cells, sinusoidal endothelial cells, sinusoid, peri-sinusoid. The generation of three kinds of extra cellular matrix was also observed.

RESULTS: The injury of hepatocytes became severer as modeling going on. Under electronic microscope, fatty vesicles and swollen mitochondria in hepatocytes, activated hepatic stellate cells with fibrils could been seen near or around it. Fenestrae of sinusoidal endothelial cells were decreased or disappeared, sinusoidal basement was formed. Under light microscopy typical peri-sinusoid fibrosis, gridding-like fibrosis, broaden portal areas, hepatocyte′s fatty and balloon denaturation, iron sediment, dot necrosis, congregated lymphatic cells and leukocytes were observed. Type I collagen showed an increasing trend as modeling going on, slightly recovered when modeling stopped for 2 weeks. Meanwhile, type IV collagen decreased rapidly when modeling began and recovered after modeling stopped for 2 weeks. Laminin increased as soon as modeling began and did not recover when modeling stopped for 2 weeks.

CONCLUSION: The pathological changes of the model were similar to that of human ALD, but mild in degree. It had typical peri-sinusoid fibrosis, however, capillarization seemed to be instable. It may be related with the reduction of type IV collagen in the basement of sinusoid during modeling.

INTRODUCTION

In China alcoholic liver disease patients have been on the rise. Acetaldehyde and hydroxy free radicals oxidized from alcohol can injure hepatocytes and activate lipid peroxidation. Hydroxy free radicals are able to activate phagocytes to secrete cytokines and activate hepatic stellate cells (HSC). The activation of HSC leads to the production of various components of extracelluar matrix (ECM). Researchers have reported that peri-sinusoid fibrosis, capilllarization, gridding-like fibrosis, bridging fibrosis and even cirrhosis are most typical morphological changes in alcoholic consumers for more than 10 or even 20 years. But mild and/or moderate drinkers may not experience such severe damages of the liver. Among the ECM produced during fibrosis, types I and IV collagen and laminin are closely related to the formation of capillarization and peri-sinusoid fibrosis. The Tsukamoto-French model has been used to investigate ALD, but it is expensive and complicated. Many researchers like to make use of the gavage model because of its simplicity and convenience, but there are many inconsistent reports about the content of alcohol ingested, the time of modeling, *etc*. In order to probe into the mechanism of ALD and find a more suitable model, we investigated the dynamic changes of capillarization and peri-sinusoid fibrosis, the contents of types I and IV collagen and laminin, *etc*. in male SD rats during modeling so as to explore whether it was acceptable.

MATERIALS AND METHODS

Materials

Male SD rats, weighing 150±5g, were purchased from Beijing Vital River Company. Corn oil was from Carafour Supermarket. Xanthan gum and maltose were from Beijing Chemical Agent Company. Edible alcohol was from Beijing General Alcohol Brewing Company. Carbonyl iron and pirazole were from Sigma, USA. First antibody to type I collagen, type IV collagen and laminin were from Antibody Diagnostic Inc, ADI, USA. PV-6001 Kits were from Power Vision, USA. ZLI-9030 and ZLI9001 were from Beijing Zhongshan Company.

Methods

Fifty-six rats were divided into normal(6), 4 d(8), 2 w(8), 4 w (10), 9 w(12), 11 w(12) groups.

ALD model was induced by intragastric infusion of a mixture made of alcohol (5 g/d· kg), pirazole (30 mg/d· kg), corn oil (3 ml/d· kg), carbonyl iron (35 mg/d· kg, which was decreased to 15 mg after 4 w), a little xanthan gum and maltose once a day for 5 days consecutively, with 2 days off per week, until 9 w. The rats were fed with normal diet and water *ad libitum*.

The rats were executed at the end of 4 d, 2 w, 4 w, 9 w and 11 w, respectively. Harvested livers were split and fixed for electron microscopy, hematoxylin and eosin, and Masson complex staining. A portion was snap frozen for biochemical and molecular analysis. Histological analysis of each liver was undertaken. Further sections were cut from each liver, deparaffinized and subjected to amylopsin antigen retrieval before being immunostained with primary antigen and second envision agents for types I and IV collagen and laminin. Semi-quantitative computation of types I and IV collagen and laminin

was done by the image analyzing system MIS-2000, which was from 3Y Company, USA. The slides for electron microscopic examination were made according to routine protocol, subcellular morphology was investigated and photographed under JEM-1200EX (80KV).

Statistics

SPSS Version 10.0 was used. All values were expressed as mean ±SD. One-way ANOVA was used to determine the

significance of differences among the six groups. $P<0.05$ was considered statistically significant.

RESULTS

HE staining

Normal hepatocytes in neat plates, had big and round nuclei, with a clear profile. Hepatocytes in Four d group became swollen and turbid, or balloon denatured. Sinus stricture was

Figure 5 Changes of type IV collagen after immunohistochemical staining. A: col-IV Normal group, B: Col-IV in 4 d group, C: Col-IV in 2 w group, D: Col-IV in 4 w group, E: Col-IV in 9 w group, F: Col-IV in 11 w group.

Figure 6 Changes of laminin after immunohistochemical staining. A: laminin Normal group, B: Laminin in 4 d group, C: Laminin in 4 w group, D: Laminin in 9 w group, E: Laminin in 11 w group.

evident. Hepatocytes in 2 w group showed bridging balloon denaturation at around-lobules and portal area, dot necrosis and congregating inflammatory cells could be seen. Four w group exhibited evident hepatocytes coagulation necrosis, mesenchymal cells hyperplasia, broadened portal area with fibrosis. In the Nine w group Mallory body and widespread fatty vesicle denaturation in hepatocytes, piecemeal necrosis, congregating inflammatory cells and fibrosis could be seen. Eleven w group had denatured hepatocytes and a little necrosis, hepatic stellate cells showed dark nuclei (Figure 1. A, B, C)

HE-masson staining

Normal group showed very light stain of the basement of central veins of lobules, Which was mildly evident in blood vessels at the portal area. Four d group showed more evident stain of central vein basement, parts of the hepatocytes were surrounded by gridding-like stains. Two w group showed more gridding-like stains. In 4 w group almost all hepatocytes were surrounded by gridding-like fibrosis and thicker basements of central veins were seen. Thick fibers in portal area bridged with those in hepatic lobules. The fibrotic changes in 9 w group deteriorated. In 11 w group the gridding-like fibrosis slightly ameliorated, but no evident changes were seen in central veins and portal areas (Figure 2. A, B, C).

Electron microscopic examination

Normal hepatocytes had round and clear nuclei, many microvilli extended to touch sinusoidal endothelial cells, or encircle hepatic stellate cells. Its mitochondria presented oval profiles and clear crests. Sinusoidal endothelial cells had many fenestrae and flat nuclei, without obvious basement and fibril underneath. HSC showed tight nuclear chromatin, few in number, and without fibril surrounded by. As modeling going on, the microvilli of hepatocytes became swollen and broken, rough endoplasmic reticulum showed turbulence, mitochondria became swollen and crest broken. The nuclei of sinusoidal endothelial cells became darker and thicker, nuclei chromatin grew crassitude. Fewer fenestrae and basement could be seen under which a large amount of fibrils was found. HSC proliferated actively, with nuclear chromatin turned into crassitude, and lots of fibril surrounded lay (Figure 3. A, B, C, D).

Table 1 Dynamic changes of types I and IV collagen and laminin ($\bar{x}\pm s$)

Group	Type I Collagen	Type IV Collagen	Laminin
Normal	0.2874±0.0224	0.3421±.0217	0.2263±0.0010
4 d	0.2811±0.0151	0.2907±0.0109ᵃ	0.2975±0.0034ᵃ
2 w	0.2912±0.0122	0.2463±0.0062ᵃ	0.2962±0.0048ᵃ
4 w	0.3853±0.0401ᵃ	0.3165±0.0049ᵃ	0.3336±0.0091ᵃ
9 w	0.4262±0.0992ᵃ	0.3202±0.0039ᵃ	0.3523±0.0108ᵃ
11 w	0.3734±0.1239ᵃ	0.3249±0.0119	0.3549±0.0120ᵃ

ᵃ$P<0.05$ *vs* normal.

Immunohistochemical staining

The content of type I collagen grew gradually from Two w and reached the peak in Nine w. After 2 week recovery, it dropped a little in 11 week but was still higher than that of normal rats (Figure 4. A, B, C).

The content of type IV collagen in normal rats was moderate, but it rapidly decreased after the infusion of alcohol mixture, and was sustained at a low level during the course of modeling. However, it recovered in Eleven w (Figure 5. A, B, C, D, E, F).

There were few positive stains of laminin in normal rats, but as soon as the modeling began, its content increased rapidly,

maintaining at high levels during the course, and did not return to normal in 11 w group, but much higher than that of normal rats (Figure 6. A, B, C, D, E, Table 1).

DISCUSSION

The viewpoints[1-3] that moderate drinking might be beneficial to heart and vascular system or might improve the ability of senior citizens to cognize imply that the disadvantages of alcohol have not been sufficiently recognized. Investigations on pathological changes of mild and moderate drinkers in the liver, especially capillarization and peri-sinusoid fibrosis are not so profound.

Alcohol abuse has become a severe problem in China. The modeling method for the purpose of ALD research is one of the key factors. ALD may be formed in more than 10 or even 20 years, meanwhile have been found many differences due to their various genotypes[4,5]. As to modeling, pure alcohol intake was difficult in inducing a successful model in a relative short period of time[6]. Tsukamoto-French model can do so by means of consecutive infusion of alcohol into stomach through a gastric fistula and does not need quite a long time, but it is complicated and expensive. At present the most widely used method of modeling is "gavage" of alcohol[7,8]. In order to make a model in a relative short period of time, other assisting materials besides alcohol must be added to promote the pathological progress. But the materials added should be of or about the same mechanism as that of alcohol, and the contents of them have to be restrained in order not to overcome alcohol. The core is whether the model has similar pathological changes to ALD and suitable for drug researches, whether it can illustrate the mechanism of treatment so to serve clinic investigation reliably.

The mechanism of ALD has been thought to have a close relation to many factors such as lipid peroxidation[9], endotoxin[10-13], acetaldehyde and immunological injuries it induced[14-16], gender[17], sediment of iron[18-25], free radicals[26], *etc*. Analysis[27] of alcohol-responsive genes showed that alcohol might injure the liver omnidirectionally, causing not only fatty liver, necrosis and inflammation, hepatocyte apoptosis and hyperhomocysteinemia, but also turbulence in glucose metabolism and DNA damages, *etc*. It has been recognized that the occurrence of fibrosis induced by alcohol or other factors is due to the activation of hepatic stellate cells[28-41]. All materials added besides alcohol such as iron, polyunsaturated fatty acid and endotoxin during modeling should be designed to strengthen the common mechanism. Our model accepted iron as an additive to promote the course of lipid peroxidation. Corn oil had similar functions. Pirazole could delay the course of alcohol to be cleared from plasmid. Meanwhile we used pirazole to cause or promote blood stasis and flatulence of the intestinal tract, this might be due to its stimulating effect on local mucosa. It needs more evidences to say that pirazole can promote endotoxin absorption. But whether the fibrosis model induced by alcohol and CCl_4 is suitable for ALD research should be under further observation[42].

Some researchers reported[43] that capillarization, peri-sinusoid fibrosis and gridding-like fibrosis were typical morphological changes in alcoholic cirrhosis of human beings which are rather different from that of fibrosis or cirrhosis induced by virus infection, yet we do not know whether it would happen in average moderate drinkers, and how the extracellular matrix was involved in changes of types I and IV collagen and laminin. Since there was no unification about the species of rats, the dosage of alcohol and additives used during modeling, we introduced a model established by intragastric infusion of a new mixture of alcohol for 9 weeks consecutively and studied the dynamic changes of types I and IV collagen as

well as laminin, in order to find out whether this model was suitable or not for ALD research[44,45].

The end products of alcohol in the liver include acetaldehyde and hydroxy free radicals which can injure hepatocytes and activate lipid peroxidation. Phagocytes are susceptible to the course, and would excrete many cytokines such as TNF-α, TGF-β1, which in turn activate hepatic stellate cells. Activation of HSC is the key event of various kinds of fibrosis. We found in this model, however, as modeling going on, the pathological changes of hepatocytes and fibrosis were gradually deteriorated, The rats in 2 w group were low in spirit with hair standing and diarrhea, the rats in 4 w group became worse and even died. However, because of sustained alcohol intake, after 4 w the rats seemed to get better in spirits and activities, implying that they might develop some mechanisms to adapt to alcohol intake.

In this model we found that the pathological changes of hepatocytes, HSC, endothelia under electronic microscopy, HE stain, HE-masson complex stain were consistent with that of ALD in human beings. Histological analysis showed that the degree of fibrosis was stages I-II[46,47]. This model may be a good representative of average moderate drinkers who have extensive mild pathological injuries of the liver. Our study may provide some clues for investigation about mild and moderate drinkers in clinic.

Capillarization was a process in which the liver sinusoid became consecutive capillaries with evident basement around. The morphological changes mainly included decreased fenestrae in number or even disappearance in endothelia, and the formation of evident basement[48-51]. The progression of fibrosis was directly linked to the activation of HSC, and always companied by the activation of matrix metalloprotenase2 (MMP-2), without strong expression of the family of tissue inhibitor of matrix metalloprotinases(TIMPS) which was usually observed at the primary stages of fibrosis. Capillarization might not be always stably formed. Our observation demonstrated this might be true, because the content of type IV collagen was low and changed during the modeling, the basement might be mainly composed of laminin. Some of the basements of the liver sinusoid in the rats of 4 w and 9 w groups were not so typical but indeed existed.

The laminin content showed a consecutive high level during the modeling, and did not return to normal even after 2 week recovery. It implied that decomposition of laminin in this model was slightly tough. It deserves further investigation in human ALD. Thus MMP-2's activity alone may not be able to promote the reverse of capillarization.

The content of type I collagen is less than that of type III collagen in normal rats' liver, but it is not so when fibrosis occurs. In normal rats we saw few fibrils near the sinusoid, as modeling going on, many fibrils appeared around sinusoidal endothelial cells. We postulate that type I collagen may take part in this course. Because most researchers believed that type I collagen was not involved in the formation of basement during capillarization. We conclude that the peri-sinusoid fibrosis may be mainly composed of fibrils consisting of type I collagen. Electron microscopic observation showed that peri-sinusoid fibrils were not prone to decomposition after modeling stopped. Immunohistochemical staining observation was consistent with this.

This model had stable alcohol intake during modeling, this ensured less deaths but resulted in moderate pathological changes. If we increase the content of alcohol intake after 4 w and last it for a longer time, or do not reduce the content of iron intake, there may be more severe injuries of the liver such as cirrhosis, but also more dead animals would come forth which may lead to modeling ending in failure. However, the model still needs further improvements.

Abstract

AIM: To develop a hepatocyte targeting pH-sensitive liposome for drug delivery based on active targeting technology mediated by asialoglycoprotein receptors.

METHODS: Four types of targeting molecules with galactose residue were synthesized and mixed with pH-sensitive lipids DC-chol/DOPE to prepare liposome with integrated property of hepatocyte specificity and pH sensitivity. Liposome 18-gal was selected with the best transfection activity through cellular uptake experiment. Property analysis was made through experiments of competitive inhibition of receptors, red blood cell hemolysis, *in vitro* cytotoxicity test by MTS assay and mediation of inhibitory effects of antisense phosphorothioate ODN on gene expression, *etc.*

RESULTS: Liposome 18-gal had the desired properties of hepatocyte specificity, pH sensitivity, low cytotoxicity, and high transfection efficiency.

CONCLUSION: Liposome 18-gal can be further developed as a potential hepatocyte- targeting delivery system.

INTRODUCTION

Previous studies have suggested a promising future of antisense oligodeoxynucleotide (ODN) in the treatment of viral hepatitis[1-6]. However, as a polyanionic macromolecule, antisense ODN has two major limitations: poor efficiency of cellular uptake and rapid degradation. The realization of its *in vivo* biological effect is accomplished under the mediation of liposome. In recent years, with the advent of cationic liposome and active targeting technology[7-10], liposome technology has been widely applied in the transfer of antisense ODNs for its virtues of high transfection efficiency, protection for the entrapped and ease of chemical modification.

The effectiveness of cationic liposome in the mediation of antisense ODN transfer in clinical trials was reported[11-15], while its deficiency lay in the lack of tissue specificity. To improve the targeting property, active targeting technology based on specific receptor-ligand recognition reaction has been applied.

Hepatocytes exclusively expressed large numbers of high affinity asialoglycoprotein receptors which can recognize the ligand molecules with galactose residues and mediate their endocytosis[16-20]. In this study, four types of targeting molecules bearing galactose residue were synthesized and mixed with the pH-sensitive lipids DC-chol/DOPE to prepare liposome with integrated property of hepatocyte specificity and pH sensitivity.

MATERIALS AND METHODS

Chemicals and reagents

Chloroformylcholesterol, N,N-dimethylethylenediamine, dioleoylphosphatidylethanol- amine, hydrolytic lactose were purchased from Sigma Chemicals (St. Louis, MO), DC-chol was synthesized according to the published methods[21]. Enzymes, vecters, luciferase assay system and Celltiter 96®AQ$_{ueous}$ non-radioactive cell proliferation assay test kit were obtained from Promega Corp (Madison, WI). All other reagents were analytically pure.

Plasmid and transgeneic cell line HepG2.9706[22]

pHCV-neo4 was constructed by cloning the complete 5' NCR (non-coding region) and part C region of fusion protein of Chinese HCV genome into pGL3 luciferase reporter vector in which the start codon was deleted without frameshift. In pHCV-neo4, the expression of luciferase gene could be suppressed by blocking the HCV 5' NCR. Transgenic cell strain HepG2. 9706 with permanent expression of luciferase gene was constructed by selection of the transfected HepG2 cell with pHCV-neo4 using G418.

Phosphorothioate oligodeoxynucleotide

Phosphorothioate ODN HCV363a (5' GAG-GTT-TAG-GAT-TCG-TGC-TCA-TG 3') is a 23-mer sequence complimentary to part of HCV 5' NCR (noncoding region). HCV363s (5' CAT-GAG-CAC-GAA-TCC-TAA-ACC-TC 3') is the reverse complimentary sequence to HCV363a. NSC (non-specific control: 5' GCA-GAG-GTG-AAA-AAG-TTG-CAT 3') is a random sequence with low homology to HCV5' NCR. The oligonucleotides were synthesized with the automatic DNA synthesizer (390Z, Applied Biosystems, Inc) and purified by HPLC (Micro Pure II reverse phase column).

Synthesis of targeting molecule

Four types of amphiphilic glycolipid molecules (octodecyl galactoside, octodecyl lactoside, cholesteryl galactoside, cholesteryl lactoside) bearing galactose residues were synthesized according to the published method[23,24] with some modifications. Hydrophilic groups were galactose and lactose, and hydrophobic groups were octadecanol and cholesterol. Structure confirmation was made through element analysis, nuclear magnetic resonance and mass spectrum (data not shown).

Preparation of liposome

Targeting molecule: DC-chol: DOPE (optimum:6:4 molar ratio) was dissolved in the solvent mixture of ethanol/chloroform

(1:1 v/v), evaporated to a thin film in a rotating evaporator, resuspended in the sterile PBS buffer (pH 7.4) and incubated overnight at 4 ℃ with gentle stirring. The suspension was sonicated in a bath sonicator for 30 minutes and passed through a polycarbonate membrane (pore diameter 0.4 μm) filter for sterility and granular uniformity. The particle size of the liposomes was measured in a dynamic light scattering spectrophotometer (LS-900, Otsuka Electronics, Osaka, Japan). Lipid concentration in stock solution was determined by phosphorus assay.

Plasmid transfection experiment
Cells (HepG2, GLC) were maintained in DMEM supplement with 10% FBS at 37 ℃ under an atmosphere of 5% CO_2 in air. The cells were seeded onto a 96-well plate at a density of 10^4/well and cultivated in 0.2 mL DMEM supplemented with 10% FBS. After 24 h, the culture medium was replaced with DMEM containing plasmid DNA/liposome complexes. Five hours later, the incubation medium was replaced again with DMEM supplemented with 10% FBS and incubated for an additional period of 36 h. The cells were then collected and washed with PBS buffer twice, mixed with 30 μL/well cell lysis solution. Ten minutes later, 100 μL/well luciferase substrate buffer was added and the light produced was immediately measured using a luminometer. The activity was indicated as the relative light units per mg protein. The protein content of the cell suspension was determined by a modified Lowry method using BSA as a standard. In the experiment of competitive inhibiton of receptors, the galactose/glucose solution was added 5 minutes before plasmid DNA/liposome complexes, and all other procedures were the same. All assays were performed in triplicate.

Red blood cell hemolysis experiment
A series of 0.1 mol/L PBS buffer with gradient pH value (4.0, 5.0, 6.0, 7.0, 8.0) were prepared. Eighty μL 1%(v/v) newly prepared chicken red blood cell suspension and 20 μL plasmid DNA/liposome complexes (1:5 wt/wt, lipid concentration: 0.5 μg/μL) were mixed in 100 μL 0.1M PBS buffer of different pH value. The mixture was shaken at 37 ℃, and an aliquot of suspension was taken at the given time periods (10 min, 30 min and 90 min), centrifuged at 1 000×g. Absorbance value of the supernatant was measured at wavelength 540nm in a photometer (Multiscan MS). Controls were set as follows: Parallel control: 100 μL PBS buffer + 80 μL1%(v/v) RBC + 20 μL saline;
Negative control: 120 μL saline + 80 μL1% (v/v)RBC.

In vitro cytotoxicity assay
DNA/liposome (1:5 wt/wt) complexes were diluted with DMEM supplemented with 2% FBS in an index gradient way (index number: 2, initial lipid concentration: 0.5 μg/μL). HepG2 cells were seeded onto a 96-well plate at a density of 10^4/well and cultivated in 0.2 mL DMEM supplemented with 10% FBS. After 24 h, the culture medium was replaced with DMEM containing DNA/liposome complexes prepared, and cells were incubated for an additional period of 24 h. Cytotoxicity was evaluated by MTS assay according to the instructions of Celltiter 96®AQ_{ueous} non-radioactive cell proliferation assay test kit, and commercially available cationic liposome Lipofectin served as the control.

Delivery of phosphorothioate ODN to HepG2.9706 cells
Phosphorothioate ODNs were dissolved in DMEM at various concentrations (0.2 μmol/L, 0.4 μmol/L and 0.8 μmol/L), alone or in combination with liposome18-gal (octadecanol-galactoside:DC-chol:DOPE 1:6:4) at a ratio of 1:5 (wt/wt).

The HepG2.9706 cells seeded onto a 24-well plate at a density of 2×10^4/well were incubated in DMEM supplement with 10% FBS. After 24 h, the culture medium was replaced with DMEM containing phosphorothioate ODNs. Five hours later, the incubation medium was replaced again with DMEM supplemented with 10% FBS and incubated for an additional period of 24 h. Then the activity of luciferase enzyme was determined as in the plasmid transfection experiment.

RESULTS

Analysis of liposomal transfection efficiency and targeting property
Four types of targeting liposomes (denoted as 18-gal, 18-lac, chol-gal and chol-lac respectively) were prepared by mixing glycolipids with DC-chol/DOPE in a molar ratio of 1:6:4, respectively. A fixed amount of (0.4 μg/well) plasmid DNA encoding a luciferase gene was complexed with these liposomes at a ratio of 1:5 (wt/wt). Figure 1 shows the expression of lucifease gene in HepG2 cells (liver cells) and GLC cells (lung cells lacking asialoglycoprotein receptor) treated with the DNA/liposome complexes. The transfection activity of DC-chol/DOPE was similar in the two cell lines, whereas the transfection activity of the targeting liposomes was significantly higher in HepG2 cells than in GLC cells. When compared with the transfection activity of DC-chol/DOPE in HepG2 cells, there was a significant increase in that of 18-gal ($P<0.01$) while a relatively significant decrease in those of 18-lac and chol-lac ($P<0.05$), and no significant difference was observed between those of chol-gal and DC-chol/DOPE ($P>0.05$). In GLC cells, the transfection activity of the targeting liposomes was significantly lower than that of DC-chol/DOPE ($P<0.05$). These results suggested that the addition of pooly soluble and electrically neutral glycoside molecules could impaire the transfection activity of DC-chol/DOPE to some extent. However, asialoglycoprotein receptor-mediated internalization induced by targeting molecules with galactose residues could specifically enhance the transfection activity of targeting liposomes in HepG2 cells, especially that of 18-gal.

Figure 1 Transfection activity of plasmid DNA/liposome complexes in HepG2 cells and GLC cells. Four types of targeting liposomes (18-gal, 18-lac, chol-gal and chol-lac) were prepared by mixing the targeting molecules with DC-chol/DOPE at a molar ratio of 1:6:4, respectively. A fixed amount (0.4 μg/well) of plasmid DNA was complexed with liposomes at a ratio of 1:5(wt/wt). Each value represents $\bar{x}\pm s$ (n=3).

The following experiments were performed with liposome 18-gal. To optimize the lipid composition, the molar ratio of octadecanol-galactoside to lipid DC-chol/DOPE varied from 0:6:4 to 5:6:4. The liposomal transfection activity showed a bell-shape dependence on the molar percentage of octadecanol-galactoside in liposomal composition. The maximum gene

expression (about 3 times that of DC-chol/DOPE) was observed at the ratio of octadecanol-galactoside:DC-chol:DOPE 1:6:4 (Figure 2). When the molar percentage of octadecanol-galactoside exceeded 20%, the colloidal solution was easy to agglomerate into turbidity, and the liposomal tansfection efficiency dropped significantly. Therefore, the maximum molar proportion of octadecanol-galactoside in the liposomal formula should not exceed 20 mol%.

Figure 2 Effect on liposomal transfection activity in HepG2 cells of molar ratio of octadecanol-galactoside (targeting molecules) in liposome composition. The molar ratio of octadecanol-galactoside to lipid DC-chol/DOPE varied from 0:6:4 to 5:6:4. A fixed amount (0.4 µg/well) of plasmid DNA was complexed with liposomes at a ratio of 1:5 (wt/wt). Each value represents $\bar{x} \pm s$ (*n*=3).

A fixed amount of plasmid DNA (0.4 µg/well) was complexed with liposome 18-gal (octadecanol-galactoside:DC-chol:DOPE 1:6:4) in different ratios (1:2.5, 1:5, 1:10, 1:20 wt/wt) to treat HepG2 cells. The greatest gene expression was achieved at the ratio of 1:5-1:10 (Figure 3).

Figure 3 Transfection activity of plasmid DNA/liposome complexes at various ratios (wt/wt) in HepG2 cells. Liposomal composition was octadecanol-galactoside:DC-chol:DOPE 1:6:4 (molar ratio). Plasmid DNA amount was fixed at 0.4 µg/well in all experiments. Each value represents $\bar{x} \pm s$ (*n*=3).

To investigate whether the cellular uptake of liposome 18-gal in HepG2 cells was partly mediated by asialoglycoprotein receptors, the inhibitory effect of 20 mmol/L galactose solution on the transfection activity of liposome 18-gal of different compositions (the ratio of octadecanol-galactoside to DC-chol/DOPE ranging from 0:6:4 to 2:6:4) was measured. As shown in Figure 4A, the transfection efficiency of liposome 18-gal was significantly inhibited (*P*<0.01, the mean inhibition rates were 35%, 40% and 46% respectively) in the presence of galactose, but not that of DC-chol/DOPE(6:4). On the other hand, no significant difference was found in the gene expression of DNA/liposome 18-gal complexes in the presence or absence of glucose (Figure 4B).

Figure 4 Effect of copresence of 20 mmol/L galactose (A) and glucose (B) on transfection activity of liposomes of different composition in HepG2 cells. Cells were transfected with DNA/liposome complexes in the presence (□) and absence (■) of galactose or glucose. A fixed amount (0.4 µg/well) of plasmid DNA was complexed with liposomes at a ratio of 1:5 (wt/wt). Each value represents $\bar{x} \pm s$ (*n*=3).

Figure 5 Fusion of plasmid DNA/liposome complexes with chicken hematocyte at various pH values. ■ DC-chol/DOPE

6:4, ◆ octadecanol-galactoside:DC-chol:DOPE 1:6:4, ▲PBS buffer. Plasmid DNA was complexed with liposomes (lipid concentration: 0.5 μg/μL) at a ratio of 1:5 (wt/wt). The release of hemachrome was determined at 10 min (A), 30 min (B) and 90 min (C). Each value represents $\bar{x}\pm s$ ($n=3$).

Characterization of liposomal pH sensitivity

To characterize the liposomal pH sensitivity, plasmid DNA/liposome complexes were mixed with chicken hematocyte in different pH conditions, and release of hemachrome which indicates cell membrane fusion was determined at 10 min, 30 min and 90 min. As shown in Figure 5, there was no difference ($P>0.05$) at the release of hemachrome in the PBS buffer of various pH values. They were close to the negative control (the mean value of negative control: 10 min, 0.076; 30 min, 0.077; 90 min, 0.082). The membrane fusion of red blood cells with DNA/liposome complexes was significantly dependent on the pH value. There was a significant difference between the release amounts of hemachrome in the intervals before and after pH=6 ($P<0.01$).

In vitro cytotoxicity of liposome

The cytotoxicity of liposome 18-gal was tested and compared with that of lipofectin. As shown in Figure 6, within lipid concentrations of 0.5, 0.25, 0.125 and 0.0625 μg/μL, the cytotoxicity of lipofectin was significantly higher than that of liposome 18-gal and DC-Chol/DOPE at corresponding concentrations, the latter two only demonstrated certain cytotoxicity at the concentration of 0.5 μg/μL (about 25%). When the concentration that generated 25% cytotoxicity (IC_{25}) was compared, the cytotoxicity of lipofectin was 16 (2^4) times higher than that of the other two liposomes. This results confirmed that DC-Chol/DOPE was a type of cationic liposome with low cytotoxicity, and the addition of octadecanol-galactoside in the liposomal formula did not increase the cytotoxicity.

Figure 6 *In vitro* cytotoxicity of cationic liposomes (◆ lipofectin, ■ DC-chol/DOPE 6:4, ▲octadecanol-galactoside:DC-chol:DOPE 1:6:4). The DNA/liposome (1:5 wt/wt) complexes were diluted with DMEM supplemented with 2% FBS in an index gradient way (initial lipid concentration: 0.5 μg/μL). Each value represents $\bar{x}\pm s$ ($n=3$).

Assessment of liposomal activity in mediating phosphorothioate ODNs delivery

HepG2.9706 cells were treated with phosphorothioate ODNs at different concentrations (0.2, 0.4 and 0.8 μmol/L), alone or in combination with liposome 18-gal. As shown in Figure 7, within the range of 0.2-0.8 μmol/L, HCV363a/18-gal complexes had a significantly dose-dependent inhibitory activity on the expression of luciferase gene, and the inhibition rate was 31%, 43% and 54% respectively. HCV363s/18-gal complexes showed stimulating effects on gene expression to some extent. The stimulating effects of sense oligonucleotides on gene expression were also reported by other researchers[25,26], but

the cause has been unclear. NSC/18-gal complexes had nonspecific inhibitory effects on gene expresson of no more than 15%. Treatment with phosphorothioate ODNs alone showed no inhibitory effects on the expression of luciferase gene in HepG2.9706 within the concentration of 0.8 μmol/L.

Figure 7 Effects of phosphorothioate ODNs transfected by liposome 18-gal on luciferase gene expression in HepG2.9706 cells. Phosphorothioate ODNs were dissolved in DMEM at various concentrations (0.2 μmol/L, 0.4 μmol/L, 0.8 μmol/L) and complexed with liposome18-gal (octadecanol-galactoside: DC-chol:DOPE 1:6:4) at a ratio of 1:5 (wt/wt). Each value represents $\bar{x}\pm s$ ($n=3$).

In addition, the effect of administration time on the inhibitory activity of HCV363a/18-gal complexes was also investigated. HepG2.9706 cells were consecutively treated 3 times with HCV363a/18-gal complexes and the activity of luciferase enzyme was determined each time 24h after HCV363a/18-gal complexes were administered. As shown in Figure 8, the inhibitory effects of HCV363a/18-gal complexes increased with the administration time.

Figure 8 Effect of administration time on inhibitory efficiency of HCV363a in HepG2.9706. Phosphorothioate ODN (HCV363a) was dissolved in DMEM at various concentrations (0.2 μmol/L, 0.4 μmol/L, 0.8 μmol/L) and complexed with liposome18-gal (octadecanol-galactoside:DC-chol:DOPE 1:6:4) at a ratio of 1:5 (wt/wt). HepG2.9706 cells were consecutively treated 3 times with HCV363a/18-gal complexes and the activity of luciferase enzyme was determined each time 24 h after HCV363a/18-gal complexes was administered. Each value represents $\bar{x}\pm s$ ($n=3$).

DISCUSSION

In the present study, we synthesized targeting molecules with galactose residue and developed a novel formula for a hepatocyte-targeting pH sensitive liposome. Liposome 18-gal was selected with the best transfection activity that was greatly mediated by asialoglycoprotein receptor in HepG2 cells. The hepatocyte specificity of liposome 18-gal was confirmed by the following facts: (1) There was a significant difference

(P<0.01) in the transfection efficiencies of DNA/18-gal complexes between HepG2 cells (liver cells) and GLC cells (lung cells lacking asialoglycoprotein receptors). (2) Within a certain proportion (<20 mol%), the addition of octadecanol-galactoside greatly increased the transfection efficiency of DC-chol/DOPE in HepG2 cells (maximum: about 3 folds). This effect was significantly inhibited by galactose but not by glucose. In comparison, the transfection activity of DC-chol/DOPE was similar in the presence or absence of galactose or glucose in HepG2 cells.

In the presence of excessive proportion of targeting molecules (>20 mol%, molar percentage in liposome composition), the colloidal solution was easy to form turbidity, and the transfection efficiency of prepared liposomes dropped significantly. It was because that a large amount of electrically neutral targeting molecules reduced the positive charge density of cationic liposome. Studies with phospholipid containing liposomes have shown that an increase in a glycolipid or gangliosides greater than 10 mol% resulted in the solubility of liposome into micelles. Due to the potential shielding of the cationic lipid interaction with plasmid DNA by the carbohydrate head group, a heterogeneous population of mixed micelles could be generated at a high molar percent, thus explaining the bell shaped curve for expression. The poor solubility of glycoside molecules in organic solvent also affected the preparation and property of liposome to some extent.

pH-sensitivity is another important property of liposome, which was considered as a mechanism to amass the enclosed antisense ODN at the action site of cytoplasm[27-29]. In brief, liposome is selectively uptaken by specific cells based on active targeting mechanism. The pH sensitivity inducing the liposomal escape from endosome/lysosome at low pH value makes the entrapped antisense ODN release at cytoplasm to take action. In the present study, the significant dependence on the pH value of membrane fusion of chicken hematocytes with DNA/liposome complexes confirmed the pH sensitivity of the two liposomes, and the similarity of the two liposomes in the memberane fusion experiment strongly indicated the pH-sensitivity of liposome 18-gal as that of DC-chol/DOPE which has been proved to be a pH sensitive liposome[30].

Transgenic cell strain HepG2.9706 with permanent expression of luciferase gene is a convenient cell model purposely constructed to evaluate the inhibitory effect of antisense ODNs on the HCV 5' NCR. The comparison between the effects on gene expression of phosphorothiote ODNs with or without liposome 18-gal mediation showed that liposome 18-gal was highly efficient in mediating the delivery of phosphorothioate ODNs into HepG2.9706 cells.

In conclusion, the liposome 18-gal prepared in this study has the desired properties of hepatocyte specificity, pH sensitivity, low cytotoxicity, and high transfection efficiency. It can be further developed as a potential hepatocyte-targeting ODN delivery system.

Abstract

AIM: Estradiol treatment regulates estrogen receptor (ER) level in normal rat liver. However, little information is available concerning the role of estrogen in regulating liver ER in hepatic fibrosis in rats. The present study was conducted to determine whether estradiol treatment in CCl_4-induced liver fibrosis of female and ovariectomized rats altered liver ERα and its mRNA expression, and to investigate the possible mechanisms.

METHODS: Seventy female rats were divided into seven groups with ten rats in each. The ovariectomy groups were initiated with ovariectomies and the sham operation groups were initiated with just sham operations. The CCl_4 toxic fibrosis groups received 400 mL/L CCl_4 subcutaneously at a dose of 2 mL/kg twice weekly. Estrogen groups were treated subcutaneously with estradiol 1 mg/kg, the normal control group and an ovariectomy group received injection of peanut oil vehicle twice weekly. At the end of 8 weeks, all the rats were killed to detect their serum and hepatic indicators, their hepatic collagen content, and liver ER and ER mRNA expression.

RESULTS: Estradiol treatment in both ovariectomy and sham ovariectomy groups reduced liver levels of ALT (from 658±220 nkat/L to 311±146 nkat/L and 540±252 nkat/L to 314±163 nkat/L, $P<0.05$) and AST (from 697±240 nkat/L to 321±121 nkat/L and 631±268 nkat/L to 302±153 nkat/L, $P<0.05$), increased serum nitric oxide (NO) level (from 53.7±17.1 µmol/L to 93.3±24.2 µmol/L and 55.3±23.1 µmol/L to 87.5±23.6 µmol/L, $P<0.05$) and hepatic nitric oxide synthase (NOS) activity (from 1.73±0.71 KU/g to 2.49±1.20 KU/g and 1.65±0.46 KU/g to 2.68±1.17 KU/g, $P<0.05$), diminished the accumulation of hepatic collagen, decreased centrolobular necrotic areas as well as the inflammatory reaction in rats subjected to CCl_4. The positive signal of ER and ER mRNA distributed in parenchymal and non-parenchymal hepatic cells, especially near the hepatic centrolobular and periportal areas. Ovariectomy decreased ER level (from 10.2±3.2 to 4.3±1.3) and ER mRNA expression (from 12.8±2.1 to 10.9±1.3) significantly ($P<0.05$). Hepatic ER and ER mRNA concentrations were elevated after treatment with estradiol in both ovariectomy (15.8±2.4, 20.8±3.1) and sham ovariectomy (18.7±3.8, 23.1±3.7) fibrotic groups ($P<0.05$).

CONCLUSION: The increase in hepatic ER and mRNA expression may be part of the molecular mechanisms underlying the suppressive effect of estradiol on liver fibrosis induced by CCl_4 administration.

INTRODUCTION

The progression of various forms of chronic liver diseases is more rapid in men than in women. This has been specifically noted in hepatic cirrhosis and hepatocellular carcinoma[1-3]. The specific mechanisms underlying these clinical findings are unclear. Hepatic fibrosis is a consequence of severe liver damage, which occurs in many chronic liver diseases as a forerunner to cirrhosis. We recently found[4] that estradiol treatment inhibited the proliferation of hepatic stellate cells, suppressed hepatic collagen content and reduced hepatic type I collagen in fibrotic rats induced by CCl_4 administration, and thus improved liver fibrosis. The mechanisms of the antifibrogenic effect of estradiol have been hypothesized by an indirect way-a hepatocellular membrane protection and a radical scavenging action.

Chronic fibrotic diseases can differ from each other in etiology. But, in terms of pathogenesis, they share some basic common features[5]. For instance, three serious chronic diseases-atherosclerosis, glomerulosclerosis, and liver fibrosis-have many properties in common. Therefore, factors that affect the development of atherosclerosis or glomerulosclerosis may affect liver fibrosis by similar mechanisms. Studies showed[6] that estradiol could suppress atherosclerosis and glomerulosclerosis in rats by directly affecting the estrogen receptor (ER) on smooth muscle cells and mesangial cells. The liver is not considered as a kind of classic estrogen-dependent tissue, as are the breast and uterus, but livers in both male and female rats have shown to contain high affinity, low capacity of ER and respond to estrogen by regulating liver function[7]. Previous data have shown[4] that tamoxifen, an antiestrogen agent, acts by occupying the estrogen-binding site of the receptor protein, increases fibrogenesis in CCl_4-induced fibrosis of the liver. It was proposed that estrogen might suppress hepatic fibrosis also by a receptor mechanism. In the liver, ERα is the dominant form of ER, while the other subtype, ERβ, has not yet been demonstrated[8]. Hence, only ERα would be further considered in this paper.

Previously published data indicated that 17 β-estradiol treatment could regulate the levels of ER in normal rat liver[9]. However, little information is available concerning the role of estrogen in the regulation of liver ER in fibrotic rats. The present study was conducted to determine whether estradiol treatment in CCl_4-induced liver fibrosis of female and

ovariectomy rats altered the liver ER and its mRNA expression, and to investigate the possible mechanisms.

MATERIALS AND METHODS

Animals

Seventy female Sprague-Dawley rats (obtained from the Experimental Animal Holding Unit of Shaanxi Province, China), weighing 209±19 g, with an average age of approximately 10 weeks, were housed in a temperature-humidity-controlled environment with 12 h light-dark cycles (lights on from 07:00 AM to 19:00 PM) and had free access to food and water. They were randomly divided into seven groups with ten rats in each. Ovariectomy groups were initiated with a bilateral ovariectomy and sham operation groups were initiated with just a sham operation. For two CCl_4 toxic fibrosis groups, with bilateral ovariectomy (CCl_4+Ovx) and sham operation (CCl_4), 400 mL/L CCl_4 in peanut oil was injected subcutaneously at a dose of 2 mL/kg twice weekly, and the first dosage was doubled. The two estrogen groups, with bilateral ovariectomy (CCl_4+Ovx+E) and sham operation (CCl_4+E), were treated subcutaneously with estradiol (benzoic estradiol) 1 mg/kg twice weekly (The Ninth Pharmaceutical Factory of Shanghai, China). All of the above four groups were fed with a modified high fat diet containing 5 g/kg cholesterol and 200 g/kg pig oil. CCl_4 and estradiol were used 2 weeks after operation. A control ovariectomy treated group (Ovx+E) was just given estradiol 1 mg/kg twice weekly. The normal control group (Control) and an ovariectomy group (Ovx) were given normal food and water, and received injection of peanut oil vehicle twice weekly. At the end of a 8-week experimental period, all the rats were fasted overnight and sacrificed by cervical dislocation after anaesthetised by intramuscular injection of sodium pentobarbital (40 mg/kg). Blood was collected from the animals and serum was analysed. The livers were removed immediately.

Estimation of serum indicators and hepatic nitric oxide synthase

Activities of serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT) were assayed by a 917-Hitachi automatic analyzer. Serum nitric oxide (NO) and hepatic nitric oxide synthase (NOS) were measured following the instructions of the reagent kit (purchased from Jiancheng Medical Institute, Nanjing, China).

Histopathological study

Tiver tissues excised from each rat were fixed in 100 mL/L neutral formalin, embedded in paraffin, and stained with hematoxylin-eosin (HE) and Masson's trichrome. Evaluation of hepatic fibrosis was determined by a semi-quantitative method to assess the degree of histologic injury, applying the following scores[10,11]: 0, absence of fibrosis; 1, perivenular and/or pericellular fibrosis; 2, septal fibrosis; 3, bridging fibrosis (incomplete cirrhosis); 4, complete cirrhosis.

Immunohistochemical examination for estrogen receptor-*a*

Liver tissue sections were mounted on slides, deparaffinized in xylene, and rehydrated in alcohol. Estrogen receptor-α(ERα) was assessed and semi-quantitated by immunohistochemistry using a commercial antibody against ERα (Boster, Wuhan, China) followed by DAB detection. For each sample, ten random fields were evaluated for positively stained cells. The results were expressed as the percentage of positive cells to the total number of cells counted.

In situ hybridization for estrogen receptor mRNA of liver tissue

In situ hybridization kit was purchased from Boster Biological

Technology Limited Company (Wuhan, China, No. MK1069α). *In situ* hybridization was performed according to the manufacturer's instructions. Briefly, the paraffin embedded serial sections (thickness of 4 μm) were dried at 80 ℃, and their paraffin was removed by xylene and rehydrated with graded ethanol. The sections were acidified in HCl for 30 min, and blocked in 3 mL of 300 mL/L H_2O_2 for 10 min before digestion in proteinase K for 30 min, and then dehydrated with graded ethanol. After prehybridization at 37-40 ℃ for 2 h, the labeled cDNA probes of ERα were denatured in hybridization buffer at 95 ℃ for 10 min, then at -20 ℃ for 10 min, then added into tissues prehybridized at 37 ℃ overnight. Sections were washed in turn with 2×SSC, 1×SSC, 0.2×SSC, and Buffer I, blocking water was added at room temperature for 20 min, and then mouse anti-digoxin serum at 37 ℃ for 60 min, biotinylated goat anti-mouse serum at 37 ℃ for 30 min, SABC at 37 ℃ for 30 min, finally DAB was added to be stained. After several times of washing, the sections were counterstained with hematoxylin, dehydrated with ethanol, rinsed in xylene and mounted with gum for microscopic examination and photography. For each sample, ten random fields were evaluated for positively stained cells. The results were expressed as the percentage of positive cells to the total number of cells counted.

Statistical analysis

Data were presented as $\bar{x}\pm s$ unless otherwise indicated. Mann-Whitney *u* test for nonparametric and unpaired values, Student's *t*-test or Fisher's exact test was used as appropriate. Results were considered significant when $P<0.05$.

RESULTS

Estimation of serum indicators and hepatic nitric oxide synthase

At the end of a 8-week experimental period, 5 rats died because of infection at the site of injection and hepatic crack due to improper handling. It was evident that CCl_4 produced a marked increase in the activities of serum ALT and AST in both ovariectomy and sham ovariectomy rats. The extent of increase was lower in sham ovariectomy group than in ovariectomy group, but without statistical significance ($P>0.05$). CCl_4 plus estradiol in both ovariectomy and sham ovariectomy groups showed a significant decrease in enzyme levels. However, they were still higher than those of control groups. The enzyme levels in the ovariectomy and estradiol treatment groups were similar to those in control group. The levels of serum NO_2^-/NO_3^- and hepatic NOS activity increased significantly in both ovariectomy and sham ovariectomy rats when CCl_4 was injected, especially in estradiol treatment groups (Table 1). Ovariectomy itself had no influence on the above parameters.

Table 1 Serum ALT, AST, NO_2^-/NO_3^- and hepatic NOS activity ($\bar{x}\pm s$)

Group	*n*	ALT (nkat/L)	AST (nkat/L)	NO_2^-/NO_3^- (μmol/L)	NOS (KU/g)
Control	10	35.8±7.9	64.5±20.8	21.8±13.7	0.65±0.08
Ovx	10	31.6±6.5	66.4±18.3	19.3±11.2	0.54±0.33
Ovx+E	9	38.5±11.2	68.4±21.2	84.8±24.9ac	2.57±1.06ac
CCl_4	9	540±252a	631±268a	55.3±23.1a	1.65±0.46a

aP<0.05, *vs* control; cP<0.05, *vs* CCl_4.

Histopathological changes

The control livers showed a normal lobular architecture with central veins and radiating hepatic cords. Prolonged administration of CCl_4 caused severe pathological damages such as fat accumulation, inflammation, necrosis, and collagen deposition, especially in ovariectomy group. Administration of estradiol reduced the accumulation of hepatic collagen, decreased centrolobular necrotic areas as well as inflammatory reaction in rats subjected to CCl_4. Semi-quantitative hepatic collagen staging scores are shown in Table 2.

Table 2 Effects of ovariectomy and estradiol on histological scores of CCl_4 – induced hepatic fibrosis

Group	n	Hepatic fibrosis scores				
		-	+	++	+++	++++
Control	10	10	0	0	0	0
Ovx	10	10	0	0	0	0
Ovx+E	9	9	0	0	0	0
CCl_4	9	0	2	2	3	1
CCl_4+Ovx[a]	10	0	0	2	5	3
CCl_4+E[a]	8	0	4	2	1	0
CCl_4+Ovx+E[a]	9	0	5	2	2	0

[a]$P<0.05$, vs control.

Immunohistochemical staining and in situ hybridization for estrogen receptor-*a*

By immunohistochemical detection, the positive signal of ERα as brown particles was scattered or diffused only in cytoplasm other than in nuclei of parenchymal (hepatocytes) and non-parenchymal hepatic cells, especially near the hepatic centrolobular and periportal areas. The positive signal of *in situ* hybridization for ERα mRNA also showed brown particles, and distributed in cytoplasm and partly in nuclei (Figure 1).

Figure 1 ERα and ERα mRNA in female rat liver.

It showed that livers of female rats contained ER, and ovariectomy decreased ER level and ER mRNA expression significantly ($P<0.05$). Treatment with estradiol at a high dose restored the liver ER and ER mRNA levels. CCl_4 administration

in control and ovariectomized groups was associated with an increase in ER level and ER mRNA expression, but the difference was not significant in control group ($P>0.05$). Hepatic ER and ER mRNA concentrations were elevated significantly after treatment with estradiol in CCl_4 induced fibrotic rats ($P<0.05$, Figures 2 and 3).

Figure 2 Positive signal of ER in female rat liver (Immunohistochemistry staining PAP method, magnification ×400). 2A: CCl_4 group, 2B: Estradiol treatment group shows increased ER expression compared with 2A.

Figure 3 Positive signal of ER mRNA in female rat liver (*in situ* hybridization staining, SP method, magnification ×400). 3A: CCl_4 group, 3B: Estradiol treatment group shows increased ER mRNA expression compared with 3A.

DISCUSSION

Hormone receptors are generally down regulated by high concentrations of their own ligands. This also seems to be the case with ER in reproductive tissues such as the uterus, ovaries, and mammary glands where estrogens are involved in cell growth and differentiation[12]. In the liver, however, ER has an entirely different function and the hepatic responses to estrogens appear to require high concentrations of estrogens. Some data indicated[9] that treatment with a low (physiological) dose of estradiol could increase ER and ER mRNA in livers of male rats. But the regulation of hepatic ER and ER mRNA in female rats by estrogen has been reported differently[13,14]. The majority of studies concerning estrogenic effects have been performed in ovariectomized female rats. Some data showed[15] that hepatic sinusoidal endothelial cell and Kupffer cell in the livers of female rats contained ER, and they were decreased by ovariectomy. Long-term treatment of 17β-estradiol elevated the level of ER in hepatic sinusoidal endothelial cell and Kupffer cell in ovariectomized rats. On the other hand, ovariectomy has also been reported to increase ER level and decrease ER mRNA level in hepatocytes from female rats[12]. This is somewhat divergent to what was seen in this study, where as ovariectomy decreased ER level and ER mRNA expression in parenchymal and non-parenchymal hepatic cells of female rats, and treatment with estradiol at a high dose restored their levels. These observations confirmed a reported increase in hepatic ER mRNA after estrogen treatment in ovariectomized female rats[16]. An explanation for the mechanism whereby hepatic ER was increased is difficult based on our limited observations. It is possible that the effect of estrogen-treatment on ER levels in ovariectomized female rats was affected indirectly through the pituitary, or by increased hepatic growth hormone receptors. Treatment with 17β-estradiol in combination with growth hormone and dexamethasone was reported to increase ER levels to eightfold, while estradiol treatment alone had a minimal influence on them in cultured hepatocytes from female rats[12]. This may suggest that the regulation of hepatic ER is under a more complex control involving other factors.

It has been shown[17] that prolonged alcohol abuse induced a marked increase in ER levels in livers of both male and female patients, especially in patients who had histological evidence of acute liver damage (alcoholic hepatitis). As we know, CCl$_4$-induced hepatitis and fibrosis shared several characteristics with human hepatitis and fibrosis of different etiologies[18-24]. In this study, prolonged administration of CCl$_4$ induced increases in hepatic ER and ER mRNA expression in female rats, especially in ovariectomized group. The increase extent of ER and ER mRNA was correlated histologically with inflammation, fat accumulation, necrosis, activities of serum ALT and AST, and hepatic collagen diposition. As it is impossible to provide a detailed explanation of the regulation of hepatic ER in normal female rats, we can not establish whether the increase in ER is due CCl$_4$ administration in our study. Further investigations are thus required to clarify this point. Within these limitations, our data indicate that prolonged CCL$_4$ administration can affect ER levels and ER mRNA expression in female rat livers.

In our study, hepatic ER and ER mRNA concentrations were significantly elevated after treatment with estradiol in CCl$_4$-induced fibrotic rats, and the elevation of ER was correlated with a marked decrease in hepatic damage and fibrosis. It suggested that estradiol might suppress hepatic fibrosis by a receptor mechanism. This finding has not been reported previously[25,26] but is in line with the experimental data obtained from cultured hepatic sinusoidal endothelial cells in rats. In the experiment[27], ER was demonstrated in hepatic sinusoidal endothelial cells, and estrogen increased NOS activity and upregulated NO production in the cells through an ER-mediated system, and then regulated the hepatic sinusoidal microcirculation. It has been found that in the liver, NO is produced by hepatic sinusoidal endothelial cells, Kupffer cells, hepatic stellate cells and hepatocytes[28-32], and NO is synthesized by NOS from L-arginine as a substrate[33,34]. It was observed that endogenous NO could protect the liver from lipid peroxidation, damage, and fibrosis[35]. In the present study, estradiol treatment led to a paralleled increase in ER with serum NO and hepatic NOS activity in fibrotic rats. These findings suggest that in liver fibrosis, estrogen may promote NO synthesis through hepatic ER, resulting in improvements of liver damage and fibrosis in rats.

The liver has been found to be extremely sensitive to the action of sex hormones[4,26], estrogen-dependent regulation of hepatic function could occur through ER present in the liver[7]. We demonstrated that administration of estradiol elevated ER levels in hepatic fibrotic rats, and ER was distributed in parenchymal (hepatocytes) and non-parenchymal hepatic cells, especially near the hepatic centrolobular and periportal areas where non-parenchymal cells were mainly located. Although we could not identify the exact location of ER in hepatic cells in the present study, we know that the high affinity ER in Kupffer cells of rat liver could exhibit the same characteristics as that presented in hepatocytes[15]. Therefore, estrogen may modulate Kupffer cell function. Kupffer cells upon stimulation, could produce mediators such as TNF, IL-6 and IL-10, and therefore playing a central role in the regulation of CCl$_4$-induced liver injury and fibrotic progression[17,36-42].

As is generally believed that the expression of specific genes and cell responses to steroid hormones are related to the amount of receptors, the increase in hepatic ER and its mRNA as described in this paper may be part of the molecular mechanisms underlying the suppressive effect of estradiol on liver fibrosis induced by CCl$_4$ administration.

Abstract

AIM: To explore the effect of diabetic duration and blood glucose level on insulin like growth factor 1 (IGF-1) gene expression and serum IGF-1 level.

METHODS: Diabetes was induced into Sprague Dawley rats by alloxan and then the rats were subdivided into different groups with varying blood glucose level and diabetic duration. The parameters were measured as follows: IGF-1 mRNA by reverse transcriptase- polymerase chain reaction (RT-PCR), IGF-1 peptide and serum IGF-1 concentration by enzyme-linked immunosorbent assay (ELISA).

RESULTS: During early diabetic stage (week 2), in comparison with normal control group (NC), IGF-1 mRNA (1.17 ± 0.069 vs 0.79 ± 0.048, $P<0.001$; 1.17 ± 0.069 vs 0.53 ± 0.023, $P<0.0005$, respectively), IGF-1 peptide contents [(196.66 ± 14.9) ng· mg^{-1} vs (128.2 ± 11.25) ng· mg^{-1}, $P<0.0005$; (196.66 ± 14.9) ng· mg^{-1} vs (74.43 ± 5.33) ng· mg^{-1}, $P<0.0001$, respectively] were reduced in liver tissues of diabetic rats. The IGF-1 gene downregulation varied with glucose control level of the diabetic state, and deteriorated gradually further with duration of diabetes. By month 6, hepatic tissue IGF-1mRNA was 0.71 ± 0.024 vs 1.12 ± 0.056, $P<0.001$; 0.47 ± 0.021 vs 1.12 ± 0.056, $P<0.0005$, respectively. IGF-1 peptide was (114.35 ± 8.09) ng· mg^{-1} vs (202.05 ± 15.73) ng· mg^{-1}, $P<0.0005$; (64.58 ± 3.89) ng· mg^{-1} vs (202.05 ± 15.73) ng· mg^{-1}, $P<0.0001$ respectively. Serum IGF-1 was also lowered in diabetic group with poor control of blood glucose. On week 2, serum IGF-1 concentrations were (371.0 ± 12.5) ng· mg^{-1} vs (511.2 ± 24.7) ng· mg^{-1}, $P<0.0005$, (223.2 ± 9.39) ng· mg^{-1} vs (511.2 ± 24.7) ng· mg^{-1}, $P<0.0001$ respectively. By month 6, (349.6 ± 18.62) ng· mg^{-1} vs (520.7 ± 26.32) ng· mg^{-1}, $P<0.0005$, (188.5 ± 17.35 vs 520.7 ± 26.32) ng· mg^{-1}, $P<0.0001$, respectively. Serum IGF-1 peptide change was significantly correlated with that in liver tissue ($r=0.99$, $P<0.001$). Furthermore, No difference was found in the above parameters between diabetic rats with euglycemia and non-diabetic control group.

CONCLUSION: The influence of diabetic status on IGF-1

gene expression in liver tissues is started from early diabetic stage, causing down regulation of IGF-1 expression, and progresses with the severity and duration of diabetic state. Accordingly serum IGF-1 level decreases. This might indicate that liver tissue IGF-1 gene expression is greatly affected in diabetes, thus contributing to reduction of serum IGF-1 level.

INTRODUCTION

Insulin like growth factor-1(IGF-1) is widely present in tissues of mammalian animals and has a number of bioactivities including regulation of metabolism and enhancement of growth and development of tissues[1-4]. Recently its research has attracted much attention. IGF-1may probably be involved in metabolic abnormality and complications associated with diabetes. Liver might be the main source of circulating IGF-1[1,5]. Recent studies have shown that there was early reduction in hepatic tissue IGF-1 gene expression in experimental diabetes[6]. However, further investigation on it is lacking. Upon this basis, we further explored the effect of chronic diabetic status on liver tissue IGF-1 gene expression and IGF-1 concentration in the circulation and hoped to help elucidating the pathogenesis of diabetes related disorder of metabolism and complications and lay a basis for premise of intervention.

MATERIALS AND METHODS

Diabetic animal model

Randomly selected Sprauge Dawley rats, weighing 180-200 g, were injected *ip*, with alloxan saline solutions at a dose of 240 mg· g^{-1} body weight. Rats in non-diabetic normal control group (NC group, $n=28$) were injected *ip*, with an equivalent volume of saline solution[7]. After 48 hours, blood samples were collected. Diabetic model was established in the rats injected with alloxan, whose blood glucose concentration was >20 mmol· L^{-1} (diabetic group, $n=90$). The mean glucose concentration of the NC group was 5.14 ± 0.91 mmol· L^{-1}. The diabetic group was reassigned into 3 subgroups ($n=30$ for each group): ID-1 group [(4.93 ± 0.72)-(4.88 ± 0.67) mmol· L^{-1}], ID-2 group [(11.4 ± 0.56)-(10.86 ± 0.94) mmol· L^{-1}] and ID-3 group [(18.34 ± 1.03)-(17.50 ± 1.05) mmol· L^{-1}] with sixteen rats in each group based on glucose level regulated by pork regular insulin combined with protamine zinc insulin (2:1) injected subcutaneously. Both blood glucose level and aminofructose level were regularly measured.

Measurement of liver tissue IGF-1 mRNA contents

After rats were anaesthetized, 1 g liver tissue of the rats was taken. The total RNAs from the tissues were extracted by one-step method[8,9]. Both quantity and purity of the RNA were determined with the 752 spectrophometer. Through reverse

transcription polymerase chain reaction (RT-PCR), tissue IGF-1 mRNA was semi-quantitated. The RT-PCR kit was provided by Promega Company (USA) and rat β-actin was used as an internal standard[8]. According to IGF-1 gene sequence, we designed RT-PCR IGF-1 upstream/downstream primer sequences 5' CTTTGCGGGGCTGAGCTGGT 3', 5' CTTCAGCGAGCAGTACA 3', respectively. All the primers were synthesized by Shanghai BioEngineer Company. The following was optimal reaction condition: reverse transcription at 48 ℃ for 45 min, denaturation of RNA/DNA hybrid and inactivation of reverse transcriptase at 94 ℃ for 2 min. PCR for 40 cycles, denaturation at 94 ℃ for 30 s, annealing at 60 ℃ for 1 min, extension at 68 ℃ for 2 min, final extension at 68 ℃ for 7 min. RT-PCR was performed on the Perkin Elmer (USA). The RT-PCR bands were 184 bp IGF-1 cDNA and 357 bp β-actin cDNA, respectively. Electrophoresis was carried out on 2% agarose gel containing ethidium bromide and semi-quantitated on the Gel DOC 1000 densitometry (Bio-RAD, USA). IGF-1 mRNA contents were calculated and expressed as cDNA relative densitometric units (ratio of IGF-1 cDNA/β-actin).

Measurement of liver tissue IGF-1 peptide contents

One gram liver tissue was excised from each rat, then frozen in liquid nitrogen and homogenized in a mortar. The homogenates were extracted with 1 mmol· L^{-1} acetic acid (precooled) and centrifuged. The supernatants were collected, then mixed with 0.05 mmol· L^{-1} Tris· HCl (PH 7.8) to neutralization and finally stored under -70 ℃ for future use[10]. An aliquot of the samples treated as above was taken to measure both total protein content by Brodford method and IGF-1 peptide concentration by enzyme linked immunosorbent assay (ELISA, Diagnostic Systems Laboratory, Inc.). DG-3022 type A was used to measure IGF-1 concentration with a maximum absorbance of 450 nm. IGF-1 tissue content was calculated and expressed as IGF-1 ng· mg^{-1} total protein.

Measurement of serum IGF-1 peptide concentration

Serum samples from rat heart blood were frozen immediately for future analysis. The samples were pre-treated before assessment of IGF-1 peptide serum concentration (ng· ml^{-1}) with the methods used in ELISA[11].

Statistical analysis

Data values were presented as $\bar{x}\pm s$. Significance of difference between groups was analyzed by one-way analysis of variance, nonparametric t' pair test, Wilcoxon test and χ^2 test. $P<0.05$ was considered statistically significant.

RESULTS

Blood glucose metabolic parameters

At the end of experiment, ID-I group and NC group had no difference in glucose level, amino fructose level, and body weight. Both blood glucose level and fructose level were significantly higher in ID-2 group and especially in ID-3 group when compared with NC group ($P<0.0001$). Significant differences were also found in the above parameters between ID-2 and ID-3 groups ($P<0.0001$). Within each group, there was no significant difference in aminofructose level (Table 1).

Effects of diabetes on tissue IGF-1 gene expression

Two weeks after diabetic model was established, the liver tissue IGF-1 mRNA contents (IGF-1 cDNA/β-actin cDNA) were decreased in both ID-2 group ($P<0.001$) and ID-3 group ($P<0.0005$) with a drop of 31% and 53% respectively. They were further decreased with progression of diabetes. On month 6, in comparison with NC group, obvious differences were shown in ID-2 group ($P<0.0005$) and ID-3 group ($P<0.0001$) with a drop of 36% and 59%. Between the two diabetic groups with poor diabetic control, ID-3 group had a significantly lower IGF-1 level than ID-2 group. The drop was 5% and 6% at week 2. Between group ID-1 and NC group, there was no significant difference (Table 2, Figure 1).

The change in tissue IGF-1 peptide content (IGF-1 peptide ng· mg^{-1} total protein) nearly paralleled that in mRNA content. At the 2nd week, compared with NC group, ID-2 group ($P<0.0005$) and ID-3 group ($P<0.005$) showed a decrease of 32%, 62%, respectively. Both were further decreased over the time course, with a drop of 34% and 65% by the end of the 6th month ($P<0.0001$). A drop of 2% and 3% was found at week 2. ID-3 group had a significantly lower IGF-1 level than ID-2 group ($P<0.001$). There was no significant difference between ID-1 and NC groups (Table 2).

Data expressed as mean ±SD. *IGF-1relative mRNA contents: IGF-1 cDNA/β-actin cDNA, **tissue IGF-1peptide content: IGF-1 ng·mg⁻¹ total protein. ID-1,-2 ,-3 *vs* NC (for the same period): [b]$P<0.001$, [c]$P<0.0005$. [d]$P<0.0001$; *vs* ID-2 group (for the same period): [e]$P<0.025$, [f]$P<0.0025$, [g]$P<0.001$; *vs* ID-2 (week 2): [h]$P<0.05$, [i]$P<0.01$; *vs* ID-3 (week 2): [j]$P<0.01$.

Figure 1 At month 6 of the experiment, liver tissue IGF-1 cDNA/β-actin mRNA RT-PCR product electrophoresis. (1: Control group, 2: ID-1 group, 3: ID-2 group, 4: ID-3 group).

Figure 2 The trend of change in serum IGF-1, liver IGF-1 and mRNA over time course of DM($r_1=0.99$, $P_1<0.001$; $r_2=0.966$, $P_2<0.001$).

Serum IGF-1 concentration

At week 2, in comparison with NC group, ID-2 and ID-3 groups showed a significant decrease in serum IGF-1 level: 371.0±12.5 ng·mg⁻¹, $P<0.0005$ and 223.2±9.39 ng·mg⁻¹, $P<0.0001$, a drop of 29% and 57%. By the sixth month, serum IGF-1 level was further lowered in both ID-2 and ID-3 groups [(349.6±18.62) ng·mg⁻¹, $P<0.0005$; (188.5±17.35) ng·mg⁻¹, $P<0.0001$, respectively], with a fall of 33% and 63%. A drop of 4% and 6% was found at week 2. ID-3 group had a significantly lower IGF-1 level than ID-2 group ($P<0.001$). There was no significant difference between ID -1 and NC groups.

Relationship between changes in liver IGF-1 mRNA, peptide and serum IGF-1 level

Correlation analysis showed that the trend of serum IGF-1 change was consistent with that occurred in liver IGF-1 peptide ($r_1=0.99$, $P_1<0.001$), and IGF-1mRNA ($r_2=0.99$, $P_2<0.001$) over the time course of diabetes (Figure 2).

DISCUSSION

The study made a preliminary exploration of the effect of chronic diabetic status (e.g. long duration and different glucose levels) on the hepatic IGF-1 gene expression and IGF-1 concentration of circulation.

Insulin like growth factors (IGFs) have similar structures and functions like those of insulin, and can be divided into IGF-1 and IGF-2, the latter of which exerts its biological action on embryonic development and growth. The action of IGF-1 peaks around puberty period and decreases gradually with aging. IGF-1, a single polypeptide with 70 amino acids, was widely expressed in mammal tissues[1,2]. *In situ* hybridization and immunohistochemical techniques have proven the presence of IGF-1 gene expression (IGF-1 mRNA and peptide) in hepatic cells[5]. The liver was found to have the highest concentration among all tissues and was probably the main source of circulating IGF-1[1,5,12], which exert its effect by binding to specific receptors on target cells in endocrine pattern. Human IGF-1 gene is on the long arm of chromosome 12, spanning a minimum of 90 kb which contains 6 exons. Exons 1 and 2 encode 5' untranslated region and amino residue terminal end of IGF-1 peptide, 5' end of Exon 3 encodes carboxyl terminal end of IGF-1 signal peptide. The remaining exon 3 and the main part of exon 4 encode mature IGF-1 peptide including B, C, A, D domains. The 5' end of the remaining exons 4, 5 and 6 encodes signal peptide and 3' untranslated region. Human exon 5 contains stop codon. Gene transcription initiates at exon 1 or 2, varying with tissue specificity. Growth hormone (GH) might affect initiation activity of exon 1 and/or exon 2 to regulate liver IGF-1 gene expression. Insulin may directly regulate liver IGF-1 expression or indirectly by increasing the

number of GH receptors on hepatic cells. Nutritional state and corticosteroid hormones have been found in factors influencing IGF-1 gene expression[1,5].

In our study, liver tissue IGF-1 gene expression was significantly downregulated in rats with poorly controlled blood glucose (ID-3 and ID-2 groups), as compared to that in rats with normally controlled blood glucose (ID-1 group). Among them, the rats with a higher blood glucose (ID-3) showed more abnormal IGF-1 than those with a relatively low blood glucose (ID-2), the severity of which varied with levels of blood glucose. We continued the observation of the rats with the same level of blood glucose for 6 months after 2 weeks and found that the liver tissue IGF-1 gene expression was gradually decreased with the time course in the rats with hyperglycemia, especially severe hyperglycemia. This showed its association with the progression of diabetes, but to a lower degree. It may indicate the effect of chronic diabetic state on IGF-1 gene expression is less significant than that of the severity of blood glucose. However, the discrepancy in IGF-1drop rate between the two conditions may reflect a fraction of other tissue' s contribution to the circulating IGF-1.

Our study, using RT-PCR technique, demonstrated the early reduction in IGF-1 mRNA contents in liver tissues of alloxan-induced diabetic rats, which was consistent with the previous studies using Northern blot and RT-PCR[5,6]. However, Veronica MC and Goya et al did not study the changes in liver tissue IGF-1 protein and effect of different blood glucose level and duration. We furthermore observed the effect of chronic duration and different severity of hyperglycemia on hepatic IGF-1 gene expressions. In our study, liver tissue IGF-1 gene expression was significantly downregulated in the rats with poorly controlled blood glucose (ID-3 and ID-2 groups), as compared with the rats with normally controlled blood glucose (ID-1 group). Among them, the rats with a higher blood glucose (ID-3) showed more abnormal IGF-1 than those with a relatively low blood glucose (ID-2), the severity of the abnormality varied with the level of blood glucose. We continued the observation of rats with the same level of blood glucose for 6 months after 2 weeks and found that liver tissue IGF-1 gene expression continued to go down gradually with the time course in rats with hyperglycemia, especially severe hyperglycemia. This showed its association with the progression of diabetes, but to a lesser degree. It may indicate the effect of chronic state on IGF-1 gene expression is less significant than severity of hyperglycemia. We are the first to find this. We also found that at translation level, hepatic IGF-1 peptide changed in similar extent as that of mRNA content, indicating the same effect of diabetic status on different translational level. We also demonstrated that serum IGF-1 concentration had a parallel change of hepatic tissue IGF-1. Thus further evidence was provided that the liver might remain to be the main endocrine source of IGF-1 in experimental diabetes. However, the discrepancy in IGF-1drop rate between the two conditions might reflect a fraction of other tissue' s contribution to the circulating IGF-1. The IGF-1 down-regulation was prevented when hyperglycemia was corrected by subcutaneous injection of exogenous insulin, suggesting insulin might be a major regulator of IGF-1 gene expression during diabetes and exclude the possible direct influence of alloxan on IGF-1 gene expression.

Diabetes could result in down-regulation of gene expression, the major factors of which might be insulin secretion deficiency and/or its resistance. Some studies showed that tissue IGF-1 gene expression might be affected by systemic or local factors or both in diabetes, i.e. decrease of GH receptors in target cells and its binding affinity[13], and by reduced or absent pulsatile pattern secretion of GH, metabolic abnormality of insulin like growth factor binding proteins (IGFBPs)[6,14], negative nitrogen balance[15,16] etc. All these may probably lead to a decline of

IGF-1. However, the deficiency of insulin or insulin resistance might be the main cause of IGF-1 gene downregulation[1,17]. In diabetes, IGF-1 in most tissues were down regulated at different degrees, varying with specific tissues[1,5,18,19]. In the liver it was down regulated[1,6]. Insulin that corrects hyperglycemia can correct the abnormal IGF-1 gene expression. Our study further supported it. It is known that IGF-1 transcription started at exons 1 and 2 regulated by different initiators and mRNA products that varied in length and affluence with tissue specificity[1,5,18]. The exact mechanism of insulin controlling IGF-1 gene expression remains to be elucidated.

We successfully established the animal model and found that the hepatic tissue IGF-1 gene expression was down regulated in the diabetic rats, the severity of which depended on glucose level and duration of diabetes. Accordingly, circulating IGF-1 was also decreased. The model established in our experiment is expected to mimic human diabetic status which will help us to interpret the role of IGF-1 in diabetic state. Diabetes can lead to a fall in IGF-1 of endocrine origin. IGF-1 it been found that has a number of bioactivities including mediating action of growth hormone, increasing glucose taken by tissues, inhibiting hepatic glycogenesis, improving insulin sensitivity, decreasing oxidation of lipid, lowering free fatty acids, increasing nucleotide synthesis, proliferation and differentiation of cells[20-25]. These researches would inevitably help understand the molecular pathogenesis of disturbances of glucose, lipid, protein metabolism associated with diabetes, diabetic peripheral neuropathy and diabetic foot[4,26-28] and probably might provide the premise of future molecular therapeutic intervention[29,30].

Abstract

AIM: To determine if the T cell memory to HBsAg can persist for a long time after hepatitis B (HB) vaccination.

METHODS: Thirty one vaccine recipients who were healthcare workers (18 females and 13 males aged 34-58 years) from Utrecht University Hospital, Netherlands, and had previously received a standard course of vaccination for hepatitis B were investigated and another 9 unvaccinated healthy volunteers from the same hospital were used as the control. Blood samples were taken just before the experiment to test serum anti-HBs levels and the subjects were classified into different groups according to their serum titers of anti-HBs and vaccination history. Their peripheral blood mononuclear cells (PBMC) were isolated from freshly heparinized venous blood and the proliferative response of T lymphocytes to the recombinant hepatitis B surface antigen (HBsAg) was investigated.

RESULTS: Positive serum anti-HBs was found in 61.3% (19/31) vaccine recipients and a significant *in vitro* lymphocyte proliferative response to recombinant HBsAg was observed in all the vaccinees with positive anti-HBs. Serum anti-HBs level ⩽10 IU/L was found in 38.7% (12/31) subjects. In this study, we specially focused on lymphocyte proliferative response to recombinant HBsAg in those vaccine recipients with serum anti-HBsAg less than 10 IU/L. Most of them had received a standard course of vaccination about 10 years before. T lymphocyte proliferative response was found positive in 7 of the 12 vaccine recipients. These results confirmed that HBsAg-specific memory T cells remained detectable in the circulation for a long time after vaccination, even when serum anti-HBs level had been undetectable.

CONCLUSION: The T cell memory to HBsAg can persist for at least 10 years after HB vaccination. Further booster injection is not necessary in healthy responders to HB vaccine.

INTRODUCTION

Since the introduction of hepatitis B vaccination in the early 1980s, many epidemiological studies have been done to determine the efficacy of the vaccine in eliciting protective immunity against HBV infection. The antibody response to HB vaccine has been found occurring in more than 90% of the healthy vaccinees[1-15]. Kinetic studies showed serum anti-HBs levels decreased with time following vaccination[5,9,14,16]. Several demographic and behavioral factors have been found to be associated with a lower rate of antibody response to hepatitis B vaccine[17,18]. In a considerable percentage of vaccinated persons the anti-HBs level was expected to drop to below 10 IU/L after 5-10 years[5,19,20]. The decline seemed to be proportional to the antibody titer originally obtained[15,21]. The necessity of implementing booster injections for those with their anti-HBs levels less than 10 IU/L has remained to be determined[13,16,20,22,23].

A correlation between *in vivo* antibody production and *in vitro* T cell proliferative response following immunization with HBsAg vaccine has been reported[24,25]. In previous studies we demonstrated that the B cell memory to HBsAg persisted for a long time after HB vaccination[26]. The purpose of this study was to determine whether the HBsAg-specific T lymphocyte memory could persist for a long time after HB vaccination especially in vaccine recipients whose serum anti-HBs level was less than 10 IU/L in an attempt to determine the optimal policy of booster vaccination.

MATERIALS AND METHODS

Lymphocytes donor
Forty healthy healthcare personnel from Utrecht University Hospital, the Netherlands participated in the study. Of them, 31 subjects (18 females and 13 males aged 34-58 years) had previously received a standard course of hepatitis B vaccination of 10 or 20 µg HB vaccine from Merck Sharp & Dohme, West Point, PA, USA (MSD) or Smith Kline and Beecham (SKB, Rixensart, Belgium) at 0, 1, and 6 months about 10 years before. Another 9 unvaccinated healthy volunteers (5 females and 4 males aged 29-57 years) from the same hospital functioned as the control.

Reagents
Recombinant HBsAg free of preservatives was a gift from Merck Sharp & Dohme, West Point, PA, USA. Hepatitis B vaccine used *in vivo* in the study was HB-Vax (MSD). Anti-HBs levels were measured in the study by means of Ausab EIA test (Abbott, Chicago, IL, USA).

Study protocol
The serum from all the volunteers was tested for HBV markers and the subjects were classified into four groups according to their serum titers of anti-HBs and vaccination history. Group I, unvaccinated (*n*=9); group II, vaccinated and with anti-HBs ⩽10 IU/L (*n*=12); group III, vaccinated and with anti-HBs 10-100 IU/L (*n*=6); group IV vaccinated and with anti-HBs greater than 100 IU/L (*n*=13). The unvaccinated healthy

Table 1 Lymphocyte proliferation to HBsAg in controls and vaccine recipients

Group	n	anti-HBs Titer (IU/L)	Net count (mean)	T cell proliferation positive	ConA stimulation (mean ± SD)	Tetanus + diphtheria (mean ± SD)
1	9	unvaccinated	252[a]	0/9 (0%)	61 000±29 058	19 075±13 688
2	12	≤10	2 810[a,b]	7/12 (58%)	55 203±25 071	10 651±7 533
3	6	11-100	4 718[b]	6/6 (100%)	35 273±33 140	19 448±16 171
4	13	>100	12 167	13/13	40 668±20 695	21 266±17 025

net count = mean cpm of medium, [a]P-value of statistical comparison of net counts of group II (anti-HBs ≤10 IU/L) with group I (unvaccinated control): P=0.0093, [b]P-value of statistical comparison of group II with group III + group IV (anti-HBs >10 IU/L): P=0.0022 (Mann-Whitney).

volunteers had no evidence of natural HBV infection (negative in the detection of serum HBsAg, anti-HBc or anti-HBs). Blood from all the subjects was collected, serum was tested for anti-HBs levels and peripheral mononuclear cells (PBMCs) were used for lymphocyte proliferation. All the subjects from whom blood was drawn gave their written informed consent for the study. This study was approved by the Medical Ethical Committee of Utrecht Hospital, the Netherlands, under No 92/82.

Cell culture and proliferation assays

PBMCs were isolated from freshly heparinized venous blood by Ficoll-Hypaque density gradient centrifugation. Blood samples were taken just before the experiment.

PBMCs were suspended in RPMI 1640 culture medium supplemented with 10% heat-inactivated pooled human AB serum (Red Cross Blood Bank, Utrecht, the Netherlands), 25 mM HEPES, 2 mmol/L L-glutamine, 50 U/ml penicillin and 50 μg/ml streptomycin. PBMCs ($4×10^5$ cells/well) from each sample were prepared in 96-well U-bottom plates and stimulated with different doses of HBsAg (10 ng/mL, 30 ng/mL, 100 ng/mL, 300 ng/mL and 1.0 μg/ml) for 7 days at 37 ℃ in 95% humidified air with 5% CO_2. Concanavalin A (Con A) at 240 μg/ml, tetanus toxoid and diphtheria toxoid at 3.3 μg/ml served as each sample's positive control for lymphocyte proliferation. Negative control cultures were made by incubating cells in medium alone. During the final 18 h incubation, the cells were pulsed with 1.0 μCi of (^{3}H)-thymidine per well. Sixteen to twenty hours after the cultures were harvested onto glass filters using a multichannel cell harvester the incorporated (^{3}H)-thymidine was measured by liquid scintillation counting. Since there were individual variations in the concentration of maximal stimulation and 300 ng/mL and 1.0 μg/ml of HBsAg gave the maximal stimulation and the least variability in the triplicates, we chose the maximal stimulation at the concentration of 300 ng/mL and 1.0 μg/ml of HBsAg as the optimal result for each subject. Results were expressed as net counts (the value of (^{3}H)-thymidine incorporation of HBsAg stimulation culture minus the value of (^{3}H)-thymidine incorporation of medium). A net count was considered positive if the value of (^{3}H)-thymidine incorporation was higher than the average in the unvaccinated control group + 2 SD.

Statistical method

ANOVA and Mann-Whitney U-test were used to compare the results between the different groups and the different concentrations.

RESULTS

HBsAg-induced in vitro proliferative response in vaccinated groups

The lymphocyte proliferation correlated with serum antibody levels. The highest proliferative response was observed in those vaccinated with serum anti-HBs greater than 100 IU/L (Table 1).

The difference of proliferative responses between those with serum anti-HBs levels ≤10 IU/L and those with serum anti-HBs level >10 IU/L was statistically significant (P=0.0022). The PBMCs from the unvaccinated control group did not respond to HBsAg (in comparison with those with serum anti-HBs levels ≤10 IU/L, P=0.0093). As shown in Figure 1, neither the proliferative response to diphtheria and tetanus toxoid, nor the response to mitogen ConA did differ significantly between groups I-IV.

Figure 1 T cell proliferation to HBsAg, ConA and Tet/diph toxoid. The lymphocyte proliferation correlates with serum anti-HBs levels. Neither the proliferative response to diphtheria and tetanus toxoid nor to the mitogen ConA did differ significantly between groups I-IV.

Table 2 Lymphocyte proliferation to HBsAg in vaccine recipients with anti-HBs serum levels ≤10 IU/L

Donor	Sex	Time from vacc. to testing (years)	Time of vaccination	Serum anti-HBs (IU/L)	Net count
1	F	12	1983	4	304
2	F	11	1984	9	2 387[a]
3	M	12	1983	0	2 853[a]
4	F	8	1987	0	6 147[a]
5	F	3	1992	9	11 729[a]
6	F	9	1986	9	1 769[a]
7	F	11	1984	0	1 346[a]
8	M	11	1984	0	2 587[a]
9	M	7	1988	10	254

11	F	8	1987	6	475
12	M	11	1984	10	73

[a]If the net count of a subject was more than the net count of unvaccinated control group + 2 SD, it was considered positive. Abbreviation: F = female, M = male.

Lymphocyte proliferative response in vaccine recipients with serum anti-HBs less than 10 IU/L

A positive lymphocyte proliferative response was observed in 7 of the 12 subjects with serum anti-HBs less than 10 IU/L.

Compared with other groups (with anti-HBs >10 IU/L), the mean proliferative response was lower. There was no correlation between the presence of low anti-HBs titer (4-10 IU/L) or the absence of anti-HBs ($\leq$2 IU/L) with the proliferative response, nor with the time from vaccination to testing (Table 2).

DISCUSSION

The humoral immune response to hepatitis B after vaccination has been studied systematically. However, duration and the quality of long term protection from HB infection in healthy vaccinees remain a matter of discussion[1-8]. Especially the T cell response to hepatitis B vaccine has not been fully characterized. Several studies were performed to detect the lymphocyte proliferative response *in vitro* with purified HBsAg, recombinant HBsAg, preS1, preS2 and peptides of HBsAg, but results were not consistent[26-29]. The immune response to HBsAg *in vitro* was difficult to detect and might not be detected in all vaccinated individuals[27]. T cell responses *in vitro* after vaccination in individuals responding to vaccination were significantly diminished after 12 weeks, a time when the antibody response was still vigorous[30]. It has been suggested that there were many variables such as geometry of the wells, the quality of culture media and in particular that of the added serum that influenced the assay results. In addition, the number of cultured PMBCs and duration of the culture might be important[24]. In our previous experiments, we tested the influence of variables such as cell density, culture time and dose of antigen for lymphocyte proliferation. We observed that 1.0 µg/ml HBsAg, 4×10^5 cells/well, use of human AB$^+$ serum and 6 days of culture achieved optimal results. These results confirmed the assay conditions described by G. Leroux-Roels[8].

To our knowledge, few reports have elucidated the long term efficacy of hepatitis B vaccination on T- cell immunity. In the past, a few groups have induced HBsAg-specific lymphocyte proliferative response in culture of fresh PBMCs from the individuals who were just vaccinated with hepatitis B vaccine or received a booster dose during the experiment[24,30,31]. In our study 31 healthy persons (healthcare personnel) volunteered to give blood to test the specific response to hepatitis B. All of them were vaccinated several years ago. Our data showed that a lymphocyte proliferative response to HBsAg should be detected *in vitro* in all the vaccine recipients with positive anti-HBs. This result further confirms that *in vivo* humoral and *in vitro* cellular immune responses to HBsAg are closely correlated. In addition, we found that the HB vaccine has the capacity to stimulate the cellular immune response *in vitro*.

However, the most interesting group in our study was the vaccine recipients with serum anti-HBs levels less than 10 IU/L. We observed positive lymphocyte proliferative responses in 7 of the 12 subjects, although the maximal proliferation was lower than that in vaccine recipients with positive serum anti-HBs. We previously reported that an immunological B cell memory to hepatitis B after a vaccination existed in healthcare personnel though serum anti-HBs titers were decreased with time or not measurable in some cases[32]. The long term efficacy of hepatitis B vaccination was also investigated in China and it was found that the protective efficacy of hepatitis B vaccination was still existed with a low risk of becoming a carrier and a low serum level of neutralizing antibody even at the time of 12 years after vaccination[9]. These findings suggest that immunity can persist for a long time after vaccination even when the serum antibody levels are below 10 IU/L. It is therefore possible that the T cell immune response plays an important role in protecting against hepatitis B virus infection and becoming a carrier in the absence of antibodies, either directly or indirectly by providing help to produce antibodies.

Our group previously showed a sensitive *in vitro* method for the study of B cell memory to HBsAg[33]. A good correlation between *in vitro* mitogen induced IgG anti-HBs spots and immune memory after a booster dose of HB vaccination was observed in naturally infected subjects and vaccine recipients. Our results that 58% of the HB vaccine recipients with anti-HBs $\leq$10 IU/L have kept lymphocyte proliferative responses many years after vaccination could confirm that HB vaccine not only induces humoral immunity but also cell-mediated immunity and that T cell memory often persists longer than serum anti-HBs titers.

We conclude that T cell memory to HBsAg can be demonstrated by lymphocyte proliferation many years after HB vaccination, even in the majority of persons with serum anti-HBs $\leq$10 IU/L. Booster vaccination in those persons is probably not necessary as T cell memory is still existed, which means that the protective antibodies will reappear rapidly or that effector cytotoxic T cells can rapidly eliminate virus infected hepatocytes after exposure to HBV. Our results are of practical value because of high prevalence of hepatitis B in Asia, especially in China.

Abstract

AIM: Human zinc finger protein 191 (ZNF191) was cloned and characterized as a Krüppel-like transcription factor, which might be relevant to many diseases such as liver cancer, neuropsychiatric and cardiovascular diseases. Although progress has been made recently, the biological function of ZNF191 remains largely unidentified. The aim of this study was to establish a *ZNF* 191 transgenic mouse model, which would promote the functional study of ZNF191.

METHODS: Transgene fragments were microinjected into fertilized eggs of mice. The manipulated embryos were transferred into the oviducts of pseudo-pregnant female mice. The offsprings were identified by PCR and Southern blot analysis. *ZNF* 191 gene expression was analyzed by RT-PCR. Transgenic founder mice were used to establish transgenic mouse lineages. The first generation (F1) and the second generation (F2) mice were identified by PCR analysis. Ten-week transgenic mice were used for pathological examination.

RESULTS: Four mice were identified as carrying copies of *ZNF*191 gene. The results of RT-PCR showed that *ZNF* 191 gene was expressed in the liver, testis and brain in one of the transgenic mouse lineages. Genetic analysis of transgenic mice demonstrated that *ZNF* 191 gene was integrated into the chromosome at a single site and could be transmitted stably. Pathological analysis showed that the expression of *ZNF* 191 did not cause obvious pathological changes in multiple tissues of transgenic mice.

CONCLUSION: *ZNF* 191 transgenic mouse model would facilitate the investigation of biological functions of ZNF191 *in vivo*.

INTRODUCTION

Transcriptional regulation is controlled through interactions between DNA and protein complex, the latter contains transcription factors with highly conserved protein motifs. The most well known motifs are helix-turn-helix, helix-loop-helix, and zinc finger. During cell differentiation and development, each of these domains is involved in the binding of transcription factors to their cognate DNA recognition sites, resulting in specific activation or repression of gene expression[1].

Zinc finger gene family belongs to one of the largest human gene families and plays an important role in the regulation of transcription. This large family may be divided into many subfamilies such as Cys_2/His_2 type, glucocorticoid receptor, ring finger, GATA-1 type, GAL4 type, and LIM family[2-4]. In the Cys_2/His_2 type of zinc finger genes, there is a highly conserved consensus sequence TGEKPYX (X representing any amino acid) between adjacent zinc finger motifs. The zinc finger proteins containing this specific structure are named Krüppel-like zinc finger proteins because the structure was first found in *Drosophila* Krüppel protein[1].

ZNF191 is a putative transcription factor belonging to Krüppel-like zinc finger gene family. It contains four Cys_2/His_2 zinc fingers in its C-terminus, and one SCAN box element (also known as LeR domain for leucine-rich) in its N-terminus[5-7]. Biochemical binding studies showed SCAN as a selective heterologous and homologous oligomerization domain[7,8]. Tissue mRNA analysis showed that *ZNF*191 gene was ubiquitously expressed[5,9]. ZNF191 can specifically bind to the TCAT repeats (*HUMTH*01) in the first intron of the human tyrosine hydroxylase (*TH*) gene. *HUMTH*01 may regulate transcription of *TH* gene, which encodes the rate-limiting enzyme in the synthesis of catecholamines[9-11]. The disturbances of catecholaminergic neurotransmission have been implicated in neuropsychiatric and cardiovascular diseases[12-17]. These studies suggested that ZNF191 might be relevant to these diseases. Analysis of amino acid sequence of ZNF191 showed 94% identity with the murine sequence of ZF-12[18]. Mouse *ZF*-12 gene likely represents the murine counterpart of human *ZNF*191. ZF-12 also contains four zinc finger motifs of the Cys_2/His_2 type and one SCAN box. *ZF*-12 mRNA is expressed during embryonic development and in different organs in adult[19]. ZF-12 may play an important role in cartilage differentiation and basic cellular processes[19].

To facilitate the functional studies of ZNF191, we established transgenic mice carrying *ZNF*191 gene. Four transgenic mice were identified by PCR and Southern blot, and used as founders to establish transgenic mouse lineages. The results of F1 identification with PCR showed that *ZNF*191 gene could be transmitted stably. RT-PCR analysis demonstrated that *ZNF*191 gene was expressed in multiple tissues of transgenic mice.

Pathological analysis results demonstrated that over-expression of ZNF191 did not cause obvious pathological changes in multiple tissues of the transgenic mice.

MATERIALS AND METHODS

Plasmid
pcDNA3-ZNF191 containing full length *ZNF*191 cDNA under control of CMV promoter.

Animals
C57, CBA mice were maintained by Shanghai Nanfang Research Center for Biomodel Organism. Transgenic mice were raised and bred in the Laboratory Animal Centre of Second Military Medical University, Shanghai.

Generation of transgenic mice
The 6.5 kb linearized pcDNA3-ZNF191 was purified from agarose gel with QIAGEN gel extraction kit (Qiagen), adjusted to a final concentration of 2 μg/ml in TE buffer and used as DNA solution in microinjection. The first generation (F1) female hybrids of C57 and CBA mice were hormonally superovulated and mated with F1 male hybrids. The next morning fertilized one-cell eggs were collected from the oviduct. The eggs were microinjected with the DNA solution under a microscope. The injected fertilized eggs were transplanted into the oviduct of pseudo-pregnant F1 hybrids of C57 and CBA mice.

Identification of transgenic mice
Founder (G0) mice were identified by PCR and Southern blotting analysis. For PCR analysis, genomic DNA was extracted from tails, and amplified using pcDNA3-ZNF191 primers (P1: 5' -ATGCGGTGGGCTCTATG-3' ; P2: 5' -CGGCTTCCATCCGAGTA-3') which produced a 1 353 bp fragment from mice carrying the transgene. For Southern blotting analysis, genomic DNA was digested overnight with *HindIII* and subjected to electrophoresis in a 0.7% agarose gel and transferred to nylon membrane (Millipore Co., Ltd). Hybridization was performed under stringent conditions with a random-primed (α-^{32}P)-labeled *ZNF*191 cDNA probe.

Expression of transgene
One of the transgenic mouse lineages was used to study the expression of transgene. Total RNA was isolated from tissues with TRIzol reagent (Invitrogen), according to the manufacturer' s instructions. After digestion of the RNA with DNase I (RNase free), first strand cDNA was synthesized by reverse transcription (Promega). RT-PCR reactions were performed using primers (P3:5' -GTACTAGTAGAAGACATGGT-3' , P4:5' -CGCACACAAAAGAACAAATCT-3') for *ZNF*191 cDNA, which produced a 394 bp fragment. PCR reactions were performed 35 cycles at 95 ℃ for 45 s, at 55 ℃ for 1 min, and at 72 ℃ for 1 min. The PCR products were electrophoresed on 1.2% agarose gel.

Transmission of transgene
To study transmission of the transgene in mice, transgenic founder mice were mated with normal C57 mice to produce the first generation (F1) which was identified by PCR analysis using primers P1/P2. F1 mice of the same founder carrying the transgene were mated between brother and sister mice to produce the second generation (F2). F2 mice were also identified by PCR analysis.

Histological examination
Various organs were dissected from the 10 weeks old mice and fixed in 10% formalin. Sections were obtained from

paraffin-embedded tissue samples, stained with H&E, and examined under a microscope and photographed. Pathological analysis was carried out in the Department of Pathology, Changhai Hospital of Second Military Medical University, Shanghai.

RESULTS

Establishment of ZNF191 transgenic mice
The transgene fragment containing full length *ZNF*191 cDNA was microinjected into the male pronuclei of 582 fertilized oocytes of F1 hybrids between C57 and CBA mice. The injected eggs were implanted into the oviducts of 27 pseudo-pregnant foster mothers, of which 15 mice became pregnant and gave birth to 81 offsprings. Four offsprings were identified to carry *ZNF*191 cDNA by PCR and Southern blotting analysis (Figures 1 and 2). The ratio of transgene integration was 4.9% by PCR and Southern blotting analysis.

Figure 1 PCR results in transgenic mice. M: DL-2000 Marker, 1: Negative control (wild type mouse), 2-5: Transgenic founder mice, 6: Positive control (pcDNA3-ZNF191).

Figure 2 Results of genomic DNA Southern blotting analysis in transgenic mice. 1: Negative control (wild type mouse), 2-5: Transgenic founder mice, 6: Positive control (pcDNA3-ZNF191).

ZNF191 transgene expression in multiple tissues of transgenic mice
The transgene was driven by CMV promoter. To study whether it could be expressed in multiple tissues of transgenic mice, we analysed the tissue expression profile of *ZNF*191 transgene by RT-PCR. The results (Figure 3) showed that *ZNF*191 transgene was expressed in the liver, testis and brain.

Figure 3 RT-PCR results in transgene expression. M: DL-2000 Marker, 1-3: Transgenic mice tissues, 4-5: Negative control (non-reverse transcripted RNA), 6:C57 mouse liver, 7: Positive control (pcDNA3-ZNF191).

Figure 4 Morphology of tissues of transgenic mouse. A: Liver, B: Testis, C: Marrow, D: Brain, E: Kidney, F: Spleen.

Genetics of transgenic mice

To establish transgenic mouse lineages, the founder mice were mated to C57 mice to produce F1 mice. Among the 43 mice of first generation, 19 were identified as carrying *ZNF*191 cDNA transgene by PCR analysis. The ratio of transgene transmission was 44.2%. F1 mice from the same founder were mated with each other to produce F2 mice. Sixty-one out of 86 F2 mice were *ZNF*191 transgenic mice, with a transgene transmission ratio of 71%. These results showed that the inheritance of *ZNF*191 transgene was in accordance with Mendel's laws, and the transgene was integrated into the chromosome at a single site and could be transmitted stably.

Pathological analysis of tissues

Pathological analysis was carried out to see whether the expression of *ZNF*191 transgene would cause any pathological changes in tissues of the transgenic mice. The results (Figure 4) showed there were no obvious pathological changes in the tissues examined. Therefore, so far as the tissues examined, the expression of exogenous *ZNF*191 did not cause any pathological consequences in the transgenic mice.

DISCUSSION

Cys_2/His_2 type zinc finger gene family is one of the largest gene families, and each member has repeated zinc finger motifs containing a finger-like structure, in which two cysteines and two histidines could covalently bind to one zinc ion[20]. It is estimated that in this huge family, about one third of the members are *Krüppel*-like genes as characterized by the presence of highly conserved connecting sequences "TGEKPYX" between adjacent zinc finger motifs. Substantial evidences indicate that Krüppel proteins are important players in many physiological processes as transcriptional regulators. *Krüppel*-like zinc finger genes are key transcriptional repressors in the development of *Drosophila*. In mammalian animals and human, these genes have been found involved in embryo development and carcinogenesis. For example, KLF6 was reported as a tumor suppressor gene in prostate cancer[21-23]. Gut-enriched Krüppel-like factor (GKLF) was expressed abundantly in epithelial cells of gastrointestinal tract, and deregulation of GKLF was linked to several types of cancer[24-27].

*ZNF*191 gene is a novel member of the Krüppel-like zinc finger gene family. It was previously cloned from bone marrow and promyelocytic leukemia cell line NB4 using homologous PCR amplification with primers based on conserved sequences of the Krüppel-like family of transcription factors[5]. This first identification suggested that ZNF191 played a role in hematopoiesis. ZNF191 has been found to contain a SCAN domain mediating selective protein oligomerization[6-8]. ZNF191 specifically binds to *HUMTH*01 *in vitro*. The microsatellite *HUMTH*01, located at the first intron of tyrosine hydroxylase (*TH*) gene, is characterized by a TCAT repeated motif and has been used in genetic studies of neuropsychiatric and cardiovascular diseases, in which disturbances of catecholaminergic neurotransmission were implicated[10-17]. Allelic variations of *HUMTH*01 had a quantitative silencing effect on *TH* gene expression *in vitro*, and correlated with quantitative and qualitative changes in the binding by ZNF191[9]. Since TCAT repeated sequence is widespread throughout the genome, this phenomenon might be relevant to the quantitative expression of several genes implicated in complex genetic traits, both

normal and pathological[28-31]. These studies suggested that ZNF191 might be relevant to neuropsychiatric and cardiovascular diseases. It is vital to have a transgenic or knock-out animal model for the study of the biological role of ZNF191. So far, the attempt to produce *ZNF*191 transgenic and knock-out mice has not been reported. To our knowledge, we have generated the first transgenic mice carrying *ZNF*191 transgene and *ZF*-12[+/-] mice (to be reported in an other paper).

In *in vivo* situation, *ZNF*191 transcript was found in various organs[5,9]. Moreover, *ZNF*191 expression was significantly up-regulated in liver cancer (personal communication), suggesting that ZNF191 might be relevant to hepatocellular carcinogenesis. In this study, *ZNF*191 transgene was expressed in multiple tissues, which are capable of expressing endogenous *ZF*-12 *in vivo*. Therefore, the *ZNF*191 transgenic mouse we generated would be an invaluable animal model not only for the investigation of ZNF191 functions in hepatic tissues, but also in other tissues, which may ultimately reveal the undefined biological functions of ZNF191.

Given that ZNF191 has important biological functions and is relevant to many diseases, it is somewhat unexpected that no pathological changes occurred in the ten-week transgenic mice with *ZNF*191 over-expression. It is possible that overexpression of exogenous *ZNF*191 may trigger a negative feedback response to the expression of endogenous *ZF*-12. It remains to be determined whether the expression of endogenous ZF-12 would change in cells overexpressing exogenous ZNF191. On the other hand, liver cancer, neuropsychiatric and cardiovascular diseases involve many factors and usually have a long incubation time before any pathological phenotypes can be observed. So, it is necessary to continue the investigation into possible pathological changes in a long term follow-up.

In conclusion, we reported here the successful generation of a transgenic mouse model expressing *ZNF*191 gene. Future studies should focus on the physiological and pathological changes in this mouse model using powerful analytic methods such as microarray comparisons of gene expression profiles among normal, transgenic, *ZF*-12[+/-] and *ZF*-12[-/-] mice.

Abstract

AIM: To evaluate the effects of depression on parameters of cell-mediated immunity in patients with cancers of the digestive tract.

METHODS: One hundred and eight adult patients of both sexes with cancers of the digestive tract admitted between March 2001 and February 2002 in the Department of Medical Oncology, First Affiliated Hospital of Xi' an Jiaotong University were randomly enrolled in the study. The Zung self-rating depression scale (SDS), Zung self-rating anxiety scale (SAS), numeric rating scale (NRS) and social support rating scale (SSRS) were employed to evaluate the degree of depression and their contributing factors. In terms of their SDS index scores, the patients were categorized into depression group (SDS≥50) and non-depression group (SDS<50). Immunological parameters such as T-lymphocyte subsets and natural killer (NK) cell activities in peripheral blood were determined and compared between the two groups of patients.

RESULTS: The SDS index was from 33.8 to 66.2 in the 108 cases, 50% of these patients had a SDS index more than 50. Similarly, the SAS index of all the patients ranged from 35.0 to 62.0 and 46.3% of the cases had a SAS index above 50. Cubic curve estimation showed that the depression was positively correlated with anxiety and negatively with social support. Furthermore, the depression correlated with the tumor type, which manifested in a descending order as stomach, gallbladder, pancreas, intestine, esophagus, duodenum and rectum, according to their correlativity. Step-wise regression analysis suggested that hyposexuality, dispiriment, agitation, palpitation, low CD_{56} and anxiety were the significant factors contributing to depression. More severe anxiety (49.7±7.5 vs 45.3±6.9, $P<0.05$), pain (6.5±2.8 vs 4.6±3.2, $P<0.05$), poor social support (6.8±2.0 vs 7.6±2.1, $P<0.05$), as well as decline of lymphocyte count (0.33±0.09 vs 0.39±0.87, $P<0.05$) and CD_{56} (0.26±0.11 vs 0.29±0.11, $P<0.05$) were noted in the depression group compared with those of the non-depression patients. However, fewer obvious changes in CD_4/CD_8 ratio and other immunological parameters were found between the two groups.

CONCLUSION: Depression occurs with a high incidence in patients with cancers of the digestive tract, which probably is not the sole factor leading to the impairment of immunological functions in these cases. However, comprehensive measures including psychological support should be taken in order to improve the immunological function, quality of life and clinical prognosis of these patients.

INTRODUCTION

Cancers of the digestive tract continue to be one of the most common malignancies in human worldwide[1-14], in which gastric, esophageal, colorectal and liver cancers are among the top ten malignant tumors in China and account for 63% of total cancer mortality[11]. Depressive symptoms such as pervasive senses of hopeless, helpless, valueless, despair, guilty, punishment and self-deprecatory thinking are often found in cancer patients. When severely enough, it may cause negative effects on the antitumor therapy, immunological function, prognosis, as well as the quality of life[15,16]. However, up to the present, much attention has been paid to the effects of depression on patients with several kinds of malignancies[17-20] except that of the digestive tract. Besides, despite mounting evidence that psychiatric depression heightens risk for cancerous morbidity and mortality, little is known about the detailed mechanisms responsible for this association, which is no doubt of importance in the improvement of therapy for cancer patients.

In the present study, we therefore investigated the effects of depression on cell-mediated immunity and its contributing factors in 108 patients with cancers of the digestive tract by SDS[21] and other questionnaires, as well as immunological parameters including T-lymphocyte subsets and natural killer (NK) cell activities in peripheral blood, in an attempt to provide evidence for the necessities of psychological therapy of these cancer patients.

MATERIALS AND METHODS

Patients

One hundred and eight adult patients of both sexes with cancers of the digestive tract including 24 esophageal, 36 gastric, 4 duodenal, 4 gallbladder, 4 pancreatic, 28 colonic and 8 rectal cancer cases admitted between March 2001 and February 2002 in the Department of Medical Oncology, First Affiliated Hospital of Xi' an Jiaotong University were randomly enrolled in the study. The medical records of these patients were reviewed by investigators and their characteristics such as the family history of cancer and main symptoms were abstracted. Subjects with a history of abnormal mentality or cognitive disorders were excluded from the investigation. All the cancer cases were finally verified by histopathological examinations

and clinically diagnosed as stage I in 14, stage II in 34, stage III in 28 and stage IV in 32 according to TNM classification and the Union International Center of Cancer (UICC) system. The average disease course of the patients was 14±11 months and the average age was 58±9 years with the education background of 7 being graduated from primary school, 25 from junior high school and 76 from senior high school or above. Their performance status (PS) was defined by Eastern Cooperative Oncology Group (ECOG) and social information such as marital and employment status was obtained through an interview. The patients were categorized into depression group and non-depression group in terms of their SDS index scores. The study protocol was in accordance with the guideline for clinical research and approved by the Ethical and Research Committee of the hospital.

Psychological measurements

Zung self-rating depression scale (SDS) The Zung SDS system harbors 20 items of self-evaluation measurements for depressive symptoms[21]. In the study, the patients were asked to rate each of the items regarding how they felt during the preceding week by a 4-point Likert scale with the 4 representing the most unfavorable response. After the scores of 10 reversely-graded items were adjusted in line with that of the sequentially-scored items, a raw score that was turned out from the total value of 20 items was further converted into a depression-judging variable termed as SDS index, based on which the cases were categorized into 2 levels of psychological conditions. Level 1, SDS index below 50, was considered not significant psychopathologically. Level 2, SDS index equal to or above 50, was suggested the presence of depression. It was not meant for SDS index to offer a strict diagnostic guideline but rather denote levels of depression in symptomatology that might be of clinical significance. Overall, the SDS index was shown to be relatively valid with a high internal consistency that was exhibited by an alpha coefficient of 0.84[22].

Zung Self-rating anxiety scale (SAS) Just like Zung SDS system, Zung SAS also has 20 items to be scored with the 4-point Likert scale except that there are 5 reversely-scored items, in which the 4 represents the most unfavorable response[23]. After the scores of 5 reversely-graded items were adjusted in line with that of the sequentially-scored items, a raw score that was turned out from the total value of 20 items was further converted into an anxiety-judging variable termed as SAS index, based on which the cases were categorized into 2 levels of psychological conditions. Level 1, SAS index below 50, was considered not significant psychopathologically. Level 2, SAS index equal to or above 50, was suggested the presence of anxiety.

Numeric rating scale (NRS) NRS consisting of four questions covering pain, nausea, insomnia and appetite was evaluated by using a 0-10 scale, with 0 meaning without symptoms and 10 indicating the situation being as bad as imagined, which was found to be a simple and valid pain measurement in some disease states[24]. In this study, the patients were asked to circle the number that best described the symptom at its worst during a one-week period.

Social support rating scale (SSRS) SSRS was employed to evaluate the levels of objective, subjective and total social support, as well as the utility of this support[25].

Study protocols

Two days before the investigation, each item for the psychological measurements was explained by specialized doctors in order to make the patients understand and complete the questionnaires correctly by themselves in a quiet condition to exclude any possible influence. If it could not be completed by the patients for some reasons as sickness or poor education, family members or physicians in charge were prescribed to do it instead.

On the experimental day, 3.5 ml of peripheral blood was drawn from each patient and anticoagulated by ethylenediaminetetra-acetic acid (EDTA), in which 50 μl of blood was quantified with the Sysmes KX-21 blood counter (Japan) for the measurement of white blood cells, erythrocytes, thrombocytes, and fractions of lymphocytes, granulocytes and monocytes. The other 3.0 ml of blood sample was used to determine natural killer cells (CD_{56}) and T lymphocyte subsets with the EPICS ELITE flow cytometer (American) by individuals blinded to the clinical data of the patients in our immunology laboratory.

Statistical analysis

Experimental data were expressed as $\bar{x}\pm s$. Comparisons between experimental groups were performed by *t*-test to examine the variables with normal distribution and by Mann-Whitney *U* test to assess the other kinds of numerical values. Demographic variables were analyzed by descriptive statistics to evaluate the clinical and sociodemographic characteristics of the studied samples. Curve estimation, stepwise multiple or univariate linear regression and Pearson correlations were adopted to assess the correlation of depression with its possible contributing factors. A *P* value less than 0.05 was considered statistically significant. All statistical procedures were performed with statistical package of SPSS for social science (2000).

RESULTS

Incidence of depression in cancer patients

Questionnaires answered by the enrolled patients were correctly filled in according to the experimental protocol. The scores of SDS 4 grade evaluation are listed in Table 1. In the present study, SDS index was approximately a normal distribution in the 108 cases, ranging from 33.8 to 66.2 and averaging at 50.4±8.8. Fifty percent of the patients had a SDS index score more than 50. Similarly, SAS index of all the patients ranged from 35.0 to 62.0 and averaged at 46.9±7.7, 46.3% of the cases had a SAS index score above 50, 29.6% of the enrolled patients had scores above 50 simultaneously for both SDS and SAS indexes. The social support score was between 28 and 56 and averaged at 43.8±7.2. Curve estimation showed that the depression was positively correlated with anxiety and negatively with social support. Furthermore, the depression correlated with the tumor type, which manifested in a descending order as stomach, gallbladder, pancreas, intestine, esophagus, duodenum and rectum, according to their correlativity.

Factors contributing to depression

Many factors were associated with depression such as cancer pain, anxiety, poor economic status, tumor type, anorexia (X5: I eat as much as I used to), hyposexuality (X6: I enjoy looking at, talking to and being with attractive men/women), dispiritment (X1: I feel downhearted, blue and sad), agitation (X13: I am restless and can not keep still), palpitation (X9: My heart beats faster than usual), fatigue without apparent reasons (X10: I get tired for no reason), CD_{56+}, *etc*. However, step-wise regression analysis suggested that hyposexuality, dispiritment, agitation, palpitation, CD_{56} and anxiety were the significant factors contributing to depression (Table 2).

Effects of depression on cell-mediated immunity

More severe anxiety and poor social support were noted in the depression group compared with those of the non-depression patients. As for the parameter changes of cell-mediated immunity in peripheral blood, an increase of granulocyte count and a decline in T-lymphocyte subsets (CD_3, CD_4 and CD_8), erythrocyte and monocyte counts were observed in depression cases, but did not reach a significant level. Lymphocyte count

Table 1 SDS 4 grading of depressive manifestations in patients with gut cancers

Item	Factors	$\bar{x}\pm s$	Grade 1	2	3	4
X1	I feel downhearted, blue and sad	1.9±0.8	34	50	18	6
X2	Morning is when I feel best	2.6±1.1	18	42	18	30
X3	I have crying spells or feel like it	1.5±0.9	75	14	14	5
X4	I have trouble sleeping through the night	2.1±1.0	42	22	34	10
X5	I eat as much as I used to	2.6±1.0	22	22	46	18
X6	I enjoy looking at, talking to, and being with attractive men/women	2.6±1.1	25	26	26	31
X7	I notice that I am losing weight	2.4±1.0	18	46	22	22
X8	I have trouble with constipation	2.2±1.1	38	30	22	18
X9	My heart beats faster than usual	1.3±0.6	76	16	8	8
X10	I get tired for no reason	2.3±1.1	34	30	22	22
X11	My mind is as clear as it used to be	1.8±0.9	50	30	22	6
X12	I find it easy to do the things I used to do	2.3±0.9	22	42	30	14
X13	I am restless and can't keep still	1.6±0.9	62	22	18	6
X14	I feel hopeful about the future	2.2±0.9	30	30	42	6
X15	I am more irritable than usual	1.7±1.0	58	26	14	10
X16	I find it easy to make decisions	2.3±1.1	34	26	26	22
X17	I feel that I am useful and needed	1.9±1.0	42	42	10	14
X18	My life is pretty full	1.8±0.8	38	50	14	6
X19	I feel that others would be better off if I were dead	1.4±0.7	70	30	2	6
X20	I still enjoy the things I used to do	2.2±1.0	30	42	18	18

DISCUSSION

Depression is a psychotic or neurotic condition characterized by inability to concentrate, insomnia, and feelings of extreme sadness, dejection and hopelessness, which commonly occur in cancer patients. It has been estimated that the incidence of severe depression in these patients is about 3%-50% depending on tumor site, stage, assessment methods, and a lot of other contributing factors, with an average overall incidence of approximately 20%[18,26,27]. However, depression remains an often unrecognised source of suffering among cancer patients, which is partially because of the lack of recognition by clinical physicians. Under such circumstances, particularly when the depression was confused with symptoms resulted from the underlying disease, clinicians were usually inclined to dismiss even severe depression on the assumption that these "symptoms" are understandable[27]. In fact, untreated depression in these patients might cause more frequent clinic visits, higher medical costs, longer hospital stay, as well as incompliance with therapeutic measures, poor quality of life, bad prognosis, and even accidental death[20,28-32].

In the present study, we investigated the effects of depression on the parameters of cell-mediated immunity and its contributing factors in patients with cancers of the digestive tract. To our knowledge, it is one of the few clinical reports in recent years concerning depression in patients with digestive tract cancers. It was revealed that depression occurred in 50% of the cases, which was higher than the average total incidence among all tumor patients. Besides, there was also a higher percentage of cases with both SDS and SAS scores equal to or more than 50 in our study, accounting for 29.6% of the investigated patients. The exact reason for these has not yet been fully elucidated, it

is probably because the gut function relates so closely to people' s daily life that a malignant disorder in the digestive tract might affect the psychological status of patients more easily compared with tumors of the other sites.

Lots of factors are closely related to the depression of cancer patients including physiological, immunological and psychosocial impacts. Although this correlation has been established as a whole in tumor cases[33,34], however, little is known about the contributing factors to the depression in patients with cancer of the digestive tract according to the new bio-psycho-social model. Our study revealed that despite many factors such as cancer pain, poor economic status, tumor type, anorexia (X5), fatigue without apparent reasons (X10) might play a role, hyposexuality (X6), dispiritment (X1), agitation (X13), palpitation (X9), CD_{56} and anxiety were the significant factors contributing to the depression of these patients by step-wise regression analysis.

Impairment of immunologic functions has been noted to be one of the major negative effects exerted by depression in cancer patients[35]. Some immunological parameters such as T lymphocyte subsets and natural killer (NK) cells have been believed to be the major effectual mechanism against tumors[36-43]. For instance, the growth of malignancies was inhibited by activated tumor-specific T cells[44,45] and the depressed activity of NK cells was probably related to tumor enlargement and dissemination[46]. Papadopoulos and his associates[42] reported that the depletion of cytotoxic T cell (CD_{8+}) and NK cell (CD_{56+}) in advanced papillary ovarian cancer might in part explain the poor clinical outcomes of those patients. However, in our study, although significantly reduced NK cells (CD_{56}) and thrombocyte count were found in the depressive patients, T lymphocyte subset, CD_4/CD_8 ratio and other immunological parameters did not exhibit significant alterations between the two groups, suggesting that depression was probably not a necessarily factor leading to impairment of immune functions in patients with cancers of the digestive tract.

In summary, our study reveals that the incidence of depression is as high as 50% in patients with cancers of the digestive tract. Hyposexuality, dispiritment, agitation, palpitation, low CD_{56} and anxiety are the significant factors contributing to the depression. Although significantly reduced NK cells (CD_{56}) and thrombocyte count are found in the depressive patients, T lymphocyte subset, CD_4/CD_8 ratio and other immunological parameters do not exhibit significant alterations between the depressive and non-depressive patients. Comprehensive measures including psycho-logical support therefore should be taken in order to improve their immunological functions, quality of life and clinical prognosis of cancer patients.

Abstract

AIM: To estimate the direct medical costs of gastroenterological diseases within the universal health insurance program among the population of local residents in Taiwan.

METHODS: The data sources were the first 4 cohort datasets of 200 000 people from the National Health Insurance Research Database in Taipei. The ambulatory, inpatient and pharmacy claims of the cohort in 2001 were analyzed. Besides prevalence and medical costs of diseases, both amount and costs of utilization in procedures and drugs were calculated.

RESULTS: Of the cohort with 183 976 eligible people, 44.2% had ever a gastroenterological diagnosis during the year. The age group 20-39 years had the lowest prevalence rate (39.2%) while the elderly had the highest (58.4%). The prevalence rate was higher in women than in men (48.5% vs. 40.0%). Totally, 30.4% of 14 888 inpatients had ever a gastroenterological diagnosis at discharge and 18.8% of 51 359 patients at clinics of traditional Chinese medicine had such a diagnosis there. If only the principal diagnosis on each claim was considered, 16.2% of admissions, 8.0% of outpatient visits, and 10.1% of the total medical costs (8 469 909 US dollars/ 83 830 239 US dollars) were attributed to gastroenterological diseases. On average, 46.0 US dollars per insured person in a year were spent in treating gastroenterological diseases. Diagnostic procedures related to gastroenterological diseases accounted for 24.2% of the costs for all diagnostic procedures and 2.3% of the total medical costs. Therapeutic procedures related to gastroenterological diseases accounted for 4.5% of the costs for all therapeutic procedures and 1.3% of the total medical costs. Drugs related to gastroenterological diseases accounted for 7.3% of the costs for all drugs and 1.9% of the total medical costs.

CONCLUSION: Gastroenterological diseases are prevalent among the population of local residents in Taiwan, accounting for a tenth of the total medical costs. Further investigations are needed to differentiate costs in screening, ruling out, confirming, and treating.

INTRODUCTION

The cost analysis of disease management is essential for health policymaking in resource allocation and medical manpower planning[1-8]. Among all medical specialties, gastroenterology has played a major role because of disease prevalence and advanced technology[9-12]. While the literature about economic assessments in gastroenterology dealt mainly with cost-effectiveness of single pharmaceuticals, diagnostic measures or therapeutic interventions[13-23], analyses of the entire specialty are relatively scarce. One of the reasons might be that the complete utilization data of the total population or a representative sample are not easily available. The more decisive reason is the lack of a standardized analysis framework and operational measures.

The aim of this study was to estimate the direct medical costs of gastroenterological diseases among the population of local residents in Taiwan. Besides the diagnosis-based approach, the costs would also be sorted by diagnostic procedure, therapeutic procedure, and drug. The strength of this study was to use the complete claim data of a representative cohort of 200 000 people within the universal health insurance program in Taiwan. Not only the nominal costs of gastroenterological diseases but also their relative ratio in total medical costs could be measured.

MATERIALS AND METHODS

Data sources

The data of the first 4 cohort datasets (R01-R04) in 2001 from the National Health Insurance Research Database (NHIRD; http://www.nhri.org.tw/nhird/) in Taipei were used for the analysis. The NHIRD owned all claims in electronic form from the national health insurance (NHI) program that has started in 1995 and covered nearly all inhabitants in Taiwan (21 653 555 beneficiaries at the end of 2001)[24]. The NHIRD has retrieved dozens of datasets publicly available for researchers. For each cohort dataset, the NHIRD at first randomly sampled 50 000 people from 23 753 407 people who had ever been insured from March 1, 1995 to December 31, 2000. Then, all insurance claims belonging to these people were drawn to make up one specific cohort dataset.

A cohort dataset included one registration file of the insured people and 6 files of original claim data: inpatient expenditures by admissions, details of inpatient orders, ambulatory care expenditures by visits, details of ambulatory care orders, expenditures for prescriptions dispensed at contracted pharmacies, and details of prescriptions dispensed at contracted pharmacies. The structure of the insurance claim files had been described in details on the NHIRD web site and in other published literature[25-28].

Among the 4 cohort datasets in 2001, there were totally 183 976 eligible people, 22 746 admissions, 1 241 760 inpatient prescription items, 2 607 646 visits (including 234 598 visits for traditional Chinese medicine), 11 765 537 outpatient prescription items, 127 008 dispensed prescriptions at pharmacies, and 513 231 dispensed prescription items at pharmacies. The ambulatory sector included medical care services at clinics of Western medicine, traditional Chinese medicine, and dentistry, and pharmaceutical services at pharmacies. Because the separation of prescribing and dispensing was not yet thoroughly executed in Taiwan, relatively few outpatient prescriptions had been dispensed at independent pharmacies.

Besides, the fee schedule of 4 837 medical service items and the list of 21 146 approved drug items of Western medicine in Taiwan were downloaded from the web site of the Bureau of National Health Insurance (http://www.nhi.gov.tw/, accessed January 12, 2002). Each drug of different brand, strength and form had an official unique identifier for claims. The BNHI also offered a list of ATC codes (the Anatomical Therapeutic Chemical classification system, version 2000)[29] for each drug item.

Study design

The costs of gastroenterological diseases were estimated in 4 dimensions: diagnosis, diagnostic procedure, therapeutic procedure, and drug. The reason for separate approaches was that on the one hand an admission or a visit with a gastroenterological diagnosis might contain service items not related to the gastroenterological diagnosis, and on the other hand a procedure or drug for gastroenterological diseases might not be associated with any gastroenterological diagnosis on the claim because of the coding error or limitation (5 diagnosis fields on an admission claim and 3 on a visit claim).

The age-sex prevalence of patients having any gastroenterological diagnosis during the year was at first calculated. All 5 diagnoses on an admission record and all 3 diagnoses on a visit record were taken into account. Then, medical costs of visits and admissions because of gastroenterological diseases as the principal diagnosis were calculated and stratified by major disease category.

The definition and categorization of gastroenterological diseases were based on the scheme of the Clinical Classifications Software (CCS for ICD-9-CM) developed by the Agency for Healthcare Research and Quality (AHRQ) of the U.S. Department of Health and Human Services[30]. The single-level diagnosis CCS aggregated illnesses and conditions of over 12 000 diagnosis codes within the International Classification of Diseases, 9th Revision, Clinical Modification (ICD-9-CM) into 259 mutually exclusive categories. The single-level CSS categories 6, 12-18, 120, 135, 138-155, 214, 250, and 251 were deemed as gastroenterological diseases. Some codes such as benign neoplasm, injury, and screening that were dispersedly included in other CSS categories were also identified as gastroenterological diseases.

The fee schedule of the NHI included mainly consultation and rehabilitation fees, charges for diagnostic procedures (*e.g.* laboratory tests and radiological examinations), therapeutic procedures (*e.g.* general treatments, radiological interventions and surgeries) and materials, and case payments based on diagnosis-related groups. Among 1 470 items of diagnostic procedures and 2 435 items of therapeutic procedures, 132 and 338 items were related to gastroenterological diseases respectively.

Drugs for treating gastroenterological diseases in the current study included all drug items of the groups A02 (antacids, drugs for treatment of peptic ulcer and flatulence), A03 (antispasmodic and anticholinergic agents and propulsives), A04 (antiemetics and antinauseants), A05 (bile and liver therapy), A06 (laxatives), A07 (antidiarrheals, intestinal antiinflammatory/antiinfective agents), A09 (digestives, including enzymes), C05A (antihemorrhoidals for topical use), P01A (agents against amoebiasis and other protozoal diseases), and P02 (anthelmintics) in the ATC classification system. The items in the group J07BC (hepatitis vaccines) were not included because they were not reimbursable within the NHI. A total of 2 269 drug items for treating gastroenterological diseases had been registered in Taiwan since 1995. Some drugs might be no more available on the market or not reimbursable by the insurance during the study period.

In describing utilization and costs of diagnostic procedures, therapeutic procedures, and drugs related to gastroenterological diseases, the number of recipients, the number of orders, and the total costs were calculated and stratified either by individual item of procedures or by group of drugs at the ATC 3rd and 4th levels. The original monetary values in unit of New Taiwan dollars were converted into U.S. currency based on the average exchange rate in 2001 (1 U.S. dollar [USD]=33.8003 New Taiwan dollars) according to the Central Bank of China in Taiwan (http://www.cbc.gov.tw/, accessed 6 February 2003).

Statistical analysis

The database software of Microsoft SQL Server 2000 was used for data linkage and processing. The regular statistics were displayed.

RESULTS

General information of the cohort

Among the 200 000-person cohort, only 183 976 people were still insured in 2001. There were more men than women (92 566 *vs* 91 394), and the status of sex was unknown in 16 persons (Table 1). The mean age of the eligible people was 33.9 (SD 20.3) years.

Table 1 Age-sex specific prevalence of gastroenterological diseases among cohorts (*n*=183 976) in 2001

Age group in year	No. of patients			Prevalence in percent		
	All	Female	Male	All	Female	Male
Sampling cohort[a]

Total	80 816	44 108	3 6704	43.9	48.3	39.7
Patients with any gastroenterological diagnosis at clinics of traditional Chinese medicine						
<20	1 833	1 005	828	3.6	4.1	3.1
20-39	3 608	2 259	1 349	5.7	7.0	4.3
40-59	2 892	1 687	1 205	6.4	7.3	5.4
>=60	1 310	731	579	5.5	6.3	4.8
Total	9 643	5 682	3 961	5.2	6.2	4.3

[a]Those born after January 1, 2001 were not included in the cohort. The status of sex was unknown in 16 persons. [b] Patients with gastroenterological diseases included 4 persons of

unknown sex. [c]All diagnoses of a patient during the year were taken into account, not confined to principal diagnosis at each admission or visit. [d]The ambulatory sector included physician offices, hospital outpatient departments, and emergency departments of Western medicine, dentistry, and traditional Chinese medicine.

The medical care benefits of these people in 2001 totaled 83 830 239 USD, of which 26 443 645 USD (31.5%) was claimed at the inpatient sector and 57 386 595 USD (68.5%) at the ambulatory sector. The clinics of traditional Chinese medicine and independent pharmacies only accounted for 4.2% (3 499 397 USD) and 0.8% (677 908 USD) of the total costs respectively.

The utilization and costs of all kinds of procedures and drugs among the cohort were as following: 1 119 629 orders of diagnostic procedures summing to 7 858 087 USD (9.4% of the total costs), 774 340 orders of therapeutic procedures with 23 582 229 USD (28.1% of the total costs), and 8 683 664 prescribed or dispensed items of drugs with 21 193 285 USD (25.3% of the total costs).

Age-sex specific prevalence of gastroenterological diseases

Table 1 also displays the number of patients with any gastroenterological diagnosis in 2001 and their prevalence among the eligible cohort, stratified by age group, sex, and setting. Totally, 44.2% of the insured people had at least one gastroenterological diagnosis. The age group 20-39 years had the lowest prevalence rate while the elderly had the highest. The prevalence rate was higher in women than in men (48.5% *vs* 40.0%). But, men had a slightly higher prevalence rate (2.9%) at the inpatient sector than women (2.0%). During the year, 14 888 patients were admitted to hospitals. In other words, 30.4% of inpatients had ever a gastroenterological diagnosis at discharge. Physicians of traditional Chinese medicine made gastroenterological diagnoses in 9 643 patients, i.e. in 5.2% of the entire cohort and in 18.8% of the 51 359 patients having visited the clinics of traditional Chinese medicine during 2001.

Prevalence and costs of gastroenterological diseases by major disease category

Table 2 shows the aggregate costs of visits and admissions due to gastroenterological diseases. The analysis took account of the principal diagnosis into consideration on each claim only, the results were stratified by major disease category, and the numbers of affected patients were also calculated. Totally, 67 073 patients (36.5% of the cohort) were involved and medical care costs in value of 8 469 909 USD (10.1% of the total medical costs) were consumed. On average, 46.0 USD per insured person in a year was spent in treating gastroenterological diseases.

Besides, 16.2% (*n*=3 676) of all admissions, 8.0% (*n*=209 254) of all visits, and 10.4% (*n*=24 429) of all visits to traditional Chinese medicine during 2001 were primarily attributed to gastroenterological causes. While the largest patient group was noninfectious gastroenteritis (9.6% of the cohort), followed by other gastrointestinal disorders (8.7%), abdominal pain (7.7%), gastritis and duodenitis (7.7%), and other disorders of stomach and duodenum (4.2%), the top 5 diagnosis groups with higher total charges were gastroduodenal ulcer (10.6% of the costs related to gastroenterological diseases/1.1% of the total medical costs), other liver diseases (6.7%/0.7%), other gastrointestinal disorders (6.7%/0.7%), hepatitis (6.5%/0.7%), and biliary tract disease (6.0%/0.6%).

Utilization and costs of diagnostic procedures related to gastroenterological diseases

Among the cohort during 2001, 36 004 (19.6%) patients utilized 210 156 (18.8%) diagnostic procedures related to gastroenterological diseases with costs of 1 900 752 USD (24.2%

of the costs for all diagnostic procedures and 2.3% of the total medical costs). The computer tomography with 3 fee items took almost a two-fifth share of the costs for GI-related diagnostic procedures. The other two items with higher costs were abdominal sonography (18.4% of the costs for GI-related diagnostic procedures) and upper GI panendoscopy (13.0%). But, the most common procedures belonged to biochemical tests of blood: glutamic-pyruvic transaminase (GPT) with 47 523 orders and glutamic-oxalacetic transaminase (GOT) with 45 653 orders. Nearly a seventh of the cohort received these two tests (Table 3).

Table 2 Prevalence and costs of gastroenterological diseases among cohorts (*n*=183 976) in 2001 by major disease category, according to principal diagnosis only

CSS[a] code	Single-level CCS diagnosis categories	Patients		Total cost	
		No.	Mean age (SD)	US $	%
6	Hepatitis	6 356	44.3 (16.1)	547 599	6.5%
12	Cancer of esophagus	67	47.4 (22.3)	193 853	2.3%
13	Cancer of stomach	110	64.0 (15.0)	207 765	2.5%
14	Cancer of colon	230	63.2 (14.3)	308 903	3.6%
15	Cancer of rectum and anus	180	65.9 (12.8)	328 540	3.9%
16	Cancer of liver and intrahepatic bile duct	242	60.5 (14.4)	448 114	5.3%
17	Cancer of pancreas	30	67.9 (13.4)	148 490	1.8%
18	Cancer of other GI organs, peritoneum	40	67.5 (11.5)	70 893	0.8%
120	Hemorrhoids	2 110	45.6 (17.1)	236 477	2.8%
135	Intestinal infection	7 727	25.3 (22.2)	175 479	2.1%
138	Esophageal disorders	967	46.9 (20.9)	145 264	1.7%
139	Gastroduodenal ulcer (except hemorrhage)	6 214	48.1 (18.5)	898 028	10.6%

Utilization and costs of therapeutic procedures related to gastroenterological diseases

Among the cohort during 2001, 8 349 (4.5%) patients utilized 60 245 (7.8%) therapeutic procedures related to gastroenterological diseases with costs of 1 066 497 USD (4.5% of the costs for all therapeutic procedures and 1.3% of the total medical costs). The most common general treatments were nasal feeding, insertion of nasogastric tube, and gastric decompression. The most common surgeries were hernioplasty, appendectomy, cholecystectomy, hemorrhoidectomy, and trans-arterial embolization. The utilization of surgeries was far less frequent than that of general treatments (Table 4).

Utilization and costs of drugs related to gastroenterological diseases

Over four-fifths of the cohort received drugs for treating gastroenterological diseases in value of 1 551 250 USD (7.3% of the costs for all drugs and 1.9% of the total medical costs). The most popular drugs were antacids (ATC group A02A) prescribed to 141 185 (76.7%) patients, drugs for treatment of peptic ulcer (A02B) with 29 181 (15.9%) recipients had the largest (33.1%) share of drug costs related to gastroenterological diseases. Table 5 gives a breakdown of the utilization into the fourth level of ATC classification. Despite fewer recipients, proton pump inhibitors (A02BC) were the second in aggregate cost only to H_2-receptor antagonists (A02BA). Another noteworthy fact was that drugs for liver therapy were prescribed to 7.1% of the cohort.

DISCUSSION

The current study offered concrete and considerable details about prevalence and costs of gastroenterological diseases among the population of local residents in Taiwan. The major findings were as the following: 44.2% of the insured people had ever a gastroenterological diagnosis during the study year. 16.2% of admissions, 8.0% of outpatient visits, and 10.1% of the total medical costs were attributed to gastroenterological diseases as principal diagnoses. GI-related diagnostic procedures accounted for 24.2% of costs for all diagnostic procedures and 2.3% of the total medical costs. GI-related therapeutic procedures accounted for 4.5% of costs for all therapeutic procedures and 1.3% of the total medical costs. GI-related drugs accounted for 7.3% of costs for all drugs and 1.9% of the total medical costs.

The current study focused only on the direct medical costs within the health insurance system. Those services beyond the insurance coverage were not taken into analysis. Although the NHI in Taiwan reimbursed visits and drugs at clinics of traditional Chinese medicine, the popular utilization of various kinds of folklore medicine by the Chinese people remained yet unknown.

The feature of the current study was to estimate costs of gastroenterological diseases from 4 dimensions. The reason of adopting such an approach was mentioned in the subsection of study design. It was initially difficult to define diagnoses related to gastroenterological diseases. If directly the ninth chapter (diseases of the digestive system) of ICD-9-CM was chosen, not only the scope of dentistry would be included, but also it would miss some GI-related infections, neoplasms, injuries, symptoms and signs coded in other chapters. The analysis did not proceed from the specialties of gastroenterologists and general surgeons either, because it might include breast, thyroid diseases and others then. Besides, other specialists and general practitioners might take care of gastroenterological diseases, too. Consequently, the current study followed a popular and public grouping system (CSS for ICD-9-CM) from the U.S.A.

to facilitate international comparisons in the future.

The other dimensions of the current study had limitations, too. With respect to diagnostic procedures, some tests, *e.g.* serum albumin, were not specific to diagnosing gastroenterological diseases. Besides, some tests, e.g. serum GOT, GPT, and bilirubin, almost belonged to screening routines on admission, so their utilization could not reflect the prevalence of diseases. Magnetic resonance imaging (MRI) as a popular and expensive procedure was absent in the analysis because the fee schedule of the NHI did not differentiate MRI for abdomen from MRI for other body parts.

With respect to therapeutic procedures, general treatments such as nasal feeding and insertion of nasogastric tube might not be directly related to gastroenterological diseases. In case payments based on diagnosis-related groups, the reimbursement per admission was fixed no matter whether the actual service items aggregately cost more. Because of the discrepancy between nominal and real values, costs of procedures within case payments, i.e. hernioplasty, appendectomy, cholecystectomy, and hemorrhoidectomy, might not be estimated accurately.

Drugs for treating gastroenterological diseases in the current study did not include antineoplastic and immunomodulating agents because these drugs were not specific in indications. Antivirals such as lamivudine or ribavirin were not included in the analysis either because they had been not yet reimbursed by the NHI in Taiwan. Although physicians of traditional Chinese medicine also used ICD-9-CM on claims, the lack of a corresponding classification for traditional Chinese drugs limited the analysis. Furthermore, the widespread use of antacids might be a unique phenomenon that reflected the habit of Chinese physicians in co-prescribing antacids[25].

Finally, it cannot be denied that the diagnoses on insurance claims serve primarily for administrative purposes. They are rather tentative diagnoses than definite ones. Only in combination with conventional epidemiological surveys or data verification, the costs of screening, ruling out, confirming, and treating can be further differentiated.

Abstract

AIM: During liver regeneration cellular proliferation and apoptosis result in tissue remodeling to restore normal hepatic mass and structure. Main regulators of the apoptotic machinery are the Bcl-2 family proteins but their roles are not well defined throughout the liver regeneration. We aimed to analyze the expression levels of *bcl-2* gene family members during resection induced liver regeneration.

METHODS: We performed semi-quantitative RT-PCR to examine the expression level of *bak, bax, bcl-2* and *bcl-x$_L$* in the 70% hepatectomized rat livers during the whole regeneration process and compared to that of the sham and normal groups.

RESULTS: The expression of *bak* and *bax* were decreased whereas *bcl-2* and *bcl-x$_L$* were increased in hepatectomized animals compared to normal liver at most time points. We also reported for the first time that sham group of animals had statistically significant higher expression of *bak* and *bax* compared to hepatectomized animals. In addition, the area under the curve (AUC) values of these genes were more in sham groups than the hepatectomized groups.

CONCLUSION: We conclude that the expressional changes of *bak, bax, bcl-2* and *bcl-x$_L$* genes were altered not only due to regeneration, but also due to the effects of surgical operations.

INTRODUCTION

Liver regeneration is a complex physiological response that takes place after the loss of hepatocytes caused by toxic or viral injury or secondary to liver resection[1,2]. During regeneration, series of reactions take place to maintain the homeostasis and virtually all of the surviving hepatocytes undergo mitosis[3]. Experimentally partial hepatectomy (PH) has been a useful model to study the cellular mechanisms of hepatic regeneration.

Post-hepatectomy-induced proliferative response led to full restoration of the hepatic mass in rats in 14 days[4,5]. Several converging lines of evidence from recent works have established that growth factors and cytokines including hepatocyte growth factor (HGF), tumor necrosis factor-α (TNF-α), interleukin-6 (IL-6), epidermal growth factor (EGF), transforming growth factor-α (TGF-α), fibroblast growth factor (FGF), vascular endothelial growth factor (VEGF), transforming growth factor-β1 (TGF-β1) and hormones such as insulin, glucagon, sex hormones, thyroid hormone, norepinephrine, nitric oxide and vasopressin are important components of liver regeneration[5-9]. Multiple signaling pathways are then activated by these components[10,11].

During liver regeneration, apoptosis occurs as a response to eliminate the defective cells that appear due to rapid cellular divisions after PH, resulting in fine-tuning of the liver size and tissue remodeling[5,12-14]. Therefore, control of apoptosis plays a crucial role in liver regeneration. Among the regulators of apoptosis, the Bcl-2 family of proteins determines the life-or-death of a cell by controlling the releases of mitochondrial apoptogenic factors, cytochrome C and apoptosis inducing factors (AIF), which activate the downstream executional phases, including the activation of the caspases[15,16]. Bcl-2 family of genes consists of both pro- and anti-apoptotic genes and by forming dimers, they exert their function[17]. Since Bcl-2 family of proteins is the most important and critical regulators of apoptosis[18], they should be tightly regulated during regeneration in a time-dependent manner. Existing data suggests the involvement of these proteins in regeneration process during the initial stages of this process[19-23]. These studies investigated the expression of these genes during the first four days after hepatectomy, however the expression pattern of the Bcl-2 family members were not examined throughout the regeneration process. Therefore, the purpose of the present study was to quantitate the expression levels of some members of *bcl-2* family of genes (*bcl-2, bcl-x$_L$, bax, bak*) by using semi-quantitative RT-PCR within a time spectrum that extended to 14 days after hepatectomy, which was needed for the completion of the regeneration process. We also compared the expression levels of these genes with the levels of the corresponding sham group of animals. For this purpose, we used the "area under the curve" method as used in pharmacodynamic studies and other liver injury and stress models.

MATERIALS AND METHODS
Animals
Nine weeks old and 200-250 grams male Sprague-Dawley rats were used. They were housed under controlled environmental

conditions (22 ℃) with a 12-hour light and 12 hour dark cycle in the animal holding facility of Bilkent University, Turkey. All the animals received care according to the criteria outlined in the "Guide for Care and Use of Laboratory Animals" prepared by the National Academy of Science and this study protocol complied with Bilkent University's guidelines on humane care and use of laboratory animals.

Experimental groups, partial hepatectomy and sham groups

Three randomly selected three animals were used for each time point. After injecting Ketamine (Ketalar, Park Davis) subcutaneously at a dose of 30 mg/kg, liver resections consisting of 70% of the liver mass were performed in PH group[24]. Sham group of animals underwent the same per operative anesthesia with the PH group. All the surgical operations were done the same as PH, but the liver lobes were not resected. All the operations were performed between 8:00 AM and 12:00 PM to minimize diurnal effects. After the completion of the procedure, the animals were placed under a lamp to prevent the hypotermy and then put into cages (one animal per cage) with continuous supply of food and water. The animals in the PH and corresponding sham groups were sacrificed at 0.5, 2, 8, 18, 36 hours, 3 days, 7 days and 14 days after the operation. The group of animals in which no surgery was performed, as used as normal liver group and mentioned time "0" in quantitated graphs. After sacrifying the animal by cervical dislocation, the remnant liver lobes were excised and washed in DMEM medium, then immediately frozen in liquid nitrogen.

Total RNA isolation and reverse transcription

The RNAs were isolated from all the liver samples using Tripure solution (Roche- Boehringer, Mannheim) according to the manufacturer's protocol. The integrity of the isolated RNA samples was determined by denaturing- (formaldehyde-) agarose gel electrophoresis. The cDNA samples were synthesized from the total RNA samples with the RevertAid First Strand cDNA Synthesis Kit (MBI Fermentas) by using the manufacturer's protocol.

Primer design and semi-quantitative PCR

We designed primers for *bcl-2, bcl-x$_L$* and *bax* by using the cDNA sequences of rat homologues of these genes (GenBank accession numbers of rat homologues of *bcl-2* is NM_016993, *bcl-x$_L$* is U34963, and *bax* is S76511). In the case of *bak*, the cDNA sequences of mouse (Y13231) and human (U23765) were aligned by Blast (NCBI), and primers were chosen from the longest conserved regions by selecting the mouse sequences in the regions of mismatches. As a housekeeping gene, we used *cyclophilin*, and primers were designed by using the rat cDNA sequence (GenBank accession number: M19533). The primer pairs used for each gene were as follows: *cyclophilin*: GGGAAGGTGAAAGAAGGCAT and GAGAGCAGAG ATTACAGGGT; *bcl-2:* CCTGGCATCTTCTCCTTC and TGCTGACCTCACTTGTGG; *bcl-x$_L$*: TCAATGGCAACC CTTCCTGG and ATCCGACTCACCAATACCTG; *bax*: ACGCATCCACCAAGAAGC and GAAGTCCAGAGTC CAGCC; *bak*: CCGGAATTCCAGGACACAGAGGA and CCAAGCTTGCCCAACAGAACCAC.

   In all the reactions, the negative control group was done by using ddH$_2$O instead of cDNA. For each gene, we determined the cycle number of PCR reactions in which the PCR reaction was not saturated. Based on this, we used the following PCR conditions: The initial denaturation step was at 95 ℃, followed by 18 (*cyclophilin*), 33 (*bcl-2*), 37 (*bcl-x$_L$*), 28 (*bax*), 29 (*bak*) cycles of denaturation for 30 seconds at 95 ℃, annealing for 30 seconds at either 55 ℃ (*cyclophilin, bcl-2, bak*) or 52 ℃

(*bcl-x$_L$*), or 60 ℃ (*bax*), and extension for 30 seconds at 72 ℃. A final extension at 72 ℃ for 10 minutes was applied to all the reactions and the PCR products were electrophoresed on a 1.2% agarose gel. Each PCR reaction was replicated three times. The quantitated values for the expression of *bcl-2* family members were normalized with the quantitated values for the *cyclophilin* for each sample respectively by comparing with the expression level of *cyclophilin* in normal liver. The normalized values were then analyzed using Multi-Analyst software and the graphs were drawn.

Calculation of AUC

Area under the curve (AUC) calculations was performed as shown by Tygstrup *et al*[25]. Results of the expression levels of the *bcl-2* family genes by RT-PCR are given as mean ± SEM. As a measure of the change in expression level during the experimental period, the area of the expression level/time curve (AUC: cDNA level x time) was calculated as the sum of the area of the intervals between the samplings for PH and sham groups. Since the time intervals were different, in order to standardize the calculations, we used hour as the unit of X-axis i.e. between 7 days and 14 days, we multiplied with 168 (24x7) to calculate the area under the curve. To determine the hourly changes at the AUC, we divided the AUC values by the hour difference between each two-time points; i.e. between 2 and 8 hour groups, AUC value was calculated and divided by 6.

Statistical tests

For each group of three animals the mean expression level was calculated at the given time points. The means of PH and sham groups were compared using Mann-Whitney test. Since sham group animals seemed to have higher levels of expression of these genes than the hepatectomized animals, one-sided significance level (*P* value) of 0.05 was used. The null hypothesis of no difference between the expression of *bax, bak, bcl-2,* and *bcl-x$_L$* in PH and sham groups was tested versus the research hypothesis that PH group had lower level of expression than the sham group.

RESULTS

Since the transcriptional control of *bcl-2* gene family has been known to be important, we performed semi-quantitative RT-PCR to examine the changes in the expression levels of the transcripts of *bcl-2, bcl-x$_L$, bax* and *bak* in the livers of rats that were subjected to either 70% PH, or sham operation at different time points (Figures 1-4). In all the experiments, the expression at "time 0" was the quantitated expression of each gene in normal livers and accepted as "1" in order to make a comparison with the subsequent time groups.

Expression pattern of pro-apoptotic genes

Two hours after hepatectomy, in 70% PH groups, we observed that the transcript level of *bak* was decreased by twofold compared with that in normal liver (Figure 1, "time 0"). Although *bak* expression levels reached the levels observed in normal liver at 8 hours and 7 days, *bak* was expressed less in comparison with that in the normal liver at other time points (Figure 1, solid circles). On the other hand, in sham group of animals, the expression of *bak* mRNA was higher than that in the normal liver and hepatectomized group at every time point (Figure 1, open circles). The expression of *bak* was significantly higher in sham group than in PH group (*P*<0.001).

   Another pro-apoptotic gene, *bax* mRNA expression, like *bak*, was increased at 0.5 hour after hepatectomy and then decreased to below the level in normal liver by 2 hours (Figure 2, solid circles). During the 14-day period except the increase

at 8 hours after hepatectomy, *bax* expression showed a steady pattern and by 14 days after hepatectomy, it reached almost the expression level of the normal liver (Figure 2, solid circles). The expression of *bax* in sham group did not show any sharp changes and unlike *bak*, it remained close to the levels of normal liver by 14 days (Figure 2, open circles). The test results revealed that the expression of *bax* was significantly higher in sham group than in PH group ($P<0.05$).

Figure 1 A: The expression of *bak* in 70% hepatectomized (PH) and sham (SH) groups shown in 1.2 % agarose gel. B: The quantitated expression of *bak* in 70% PH (−·−) or sham (−o−) groups. Results were expressed as mean ± SEM of triplicate animals with *n*=3 rats per time point. The expressions were quantitated with the expression of *cyclophilin* for each sample and analyzed using the Multi-Analyst software. The expression at "time 0" denoted the quantitated expression of *bak* in normal liver and was accepted as "1". In comparison among the mean values at each time point, it was revealed that the means for *bak* in PH group were significantly less than those in SH group ($P<0.001$ Mann Witney U test).

Figure 2 A: The expression of *bax* in 70% hepatectomized (PH) and sham (SH) groups shown in 1.2% agarose gel. B: The quantitated expression of *bax* in 70% PH (−·−) or sham (−o−) groups. Results were expressed as mean ± SEM of triplicate animals with *n*=3 rats per time point. The expressions were quantitated with the expression of *cyclophilin* for each sample and analyzed using the Multi-Analyst software. The expression at "time 0" denoted the quantitated expression of *bax* in normal liver and was accepted as "1". In comparison among the mean values at

each time point, it was revealed that the *bax* values in PH group were less than those in SH group (one-tailed $P<0.05$, Mann Witney U test).

Figure 3 A: The expression of *bcl-2* in 70% hepatectomized (PH) and sham (SH) groups shown in 1.2 % agarose gel. B: The quantitated expression of *bcl-2* in 70% PH (−·−) or sham (−o−) groups. Results were expressed as mean ± SEM of triplicate animals with *n*=3 rats per time point. The expressions were quantitated with the expression of *cyclophilin* for each sample and analyzed using the Multi-Analyst software. The expression at "time 0" denoted the quantitated expression of *bcl-2* in normal liver and was accepted as "1". Comparing the mean values at each time point, we found no difference in *bcl-2* values between PH and SH group.

Figure 4 A: The expression of *bcl-x_L* in 70% hepatectomized (PH) and sham (SH) groups shown in 1.2 % agarose gel. B: The quantitated expression of *bcl-x_L* in 70% PH (−·−) or sham (−o−) groups. Results were expressed as mean ± SEM of triplicate animals with *n*=3 rats per time point. The expressions were quantitated with the expression of *cyclophilin* for each sample and analyzed using the Multi-Analyst software. The expression at "time 0" denoted the quantitated expression of *bcl-x_L* in normal liver and was accepted as "1". Comparing the mean values at each time points, no difference in *bcl-x_L* values between PH and SH groups was found.

Expression pattern of anti-apoptotic genes

Amongst the anti-apoptotic members of *bcl-2* gene family, *bcl-*

2 mRNA expression did not decrease to below the level in normal liver both in PH and sham groups. Its level was increased 0.5 hour after hepatectomy and peaked at 8 hours and 7 days after hepatectomy, more than 2-fold that of the normal liver (Figure 3, solid circles). In the sham group of animals, the expression of this gene also increased by 0.5 hour after surgery and then followed a steady level until day 14. The expression of *bcl-2* in PH and sham group showed a similar pattern except at 14 day. At this time point, *bcl-2* expression was more than two-fold in sham group compared to PH group (Figure 3, open circles).

The expression of another anti-apoptotic gene *bcl-x_L* showed more than 3-fold increase by 8 hours after hepatectomy whereas at the same time interval, the sham group had almost two-fold increase compared to normal liver. The amount of *bcl-x_L* expression decreased afterwards both in PH and sham group (Figure 4). However, in both groups, the expression level was always above the levels in normal liver at all time points.

AUC calculation

In order to better compare the expression levels of *bak, bax, bcl-2* and *bcl-x_L* during the whole regeneration process, we calculated the AUC values for partially hepatectomized and sham groups, i.e.; the area between the lines connecting cDNA levels of different time and zero. It is important to emphasize that AUC is an arbitrary value but provides a comparison between the total expression of these genes in PH and sham groups. The AUC values for PH and sham groups for each gene analyzed are shown in Table 1. AUC values of all the genes were higher in sham group compared with those in the PH group. Interestingly however, the difference was more obvious for pro-apoptotic genes (*bak* and *bax*) than for anti-apoptotic genes (*bcl-2* and *bcl-x_L*). We detected an 87% and 64% increase in expression levels of pro-apoptotic genes (*bak* and *bax* respectively) in sham group compared to PH group, whereas, this difference was 25% in *bcl-2* and 21% in *bcl-x_L*.

Since the time intervals ranged from 0.5 hour to 7 days, we calculated hourly changes of AUC values in our experiments for each of *bcl-2* family of genes in hepatectomized and sham group of animals. We measured AUC value for each time group and divided this value by the hours of that particular group (Table 2). The values for *bak* and *bax* were found to be significantly higher in sham group than in hepatectomized group (*P*<0.05). No significant difference was found for *bcl-2* and *bcl-x_L* values.

Table 1 AUC of cDNA expression for members of the *bcl-2* family of genes

	AUC (70% PH)	AUC (SH)	Change
bak	324	609	87%
bax	245	402	64%
bcl-2	666	837	25%
bcl-xL	494	601	21%

DISCUSSION

During liver regeneration, apoptosis allows hepatocytes to die without provoking a potentially harmful inflammatory response. The harmony amongst these complex biological responses is crucial since abnormal regeneration may result in fulminant liver failure, cirrhosis and primary liver cancers[26]. Since programmed cell death is a major component of hepatic regeneration mechanism, and the *bcl-2* family members are the main regulators of this cellular death pathway, we concentrated on the expression level of these genes throughout the regeneration of liver induced by partial hepatectomy. For all of the members of this family, it has been shown that the transcriptional activation or suppression is critical[27,28]. Existing data in literature suggests the involvement of these genes in regeneration process however, the expression of these genes has been shown for only 4 days after hepatectomy[19-23]. Liver regeneration is a long lasting event but there have been no studies regarding the expression of these genes during the later stages of liver regeneration. Since apoptosis is a homeostatic mechanism, the expression of the genes that regulate apoptosis should be important during the whole regeneration process. Therefore, in this study, we quantitated the expression levels of *bak, bax, bcl-2* and *bcl-x_L* up to 14 days post-hepatectomy, which is the time needed for the completion of regeneration process. In addition, we also examined the expression of these genes in corresponding sham group of animals.

Our data regarding the expression of *bak, bax* and *bcl-x_L* during early stages of regeneration (within the first four days) were consistent with previous studies[19-23]. However contradictory data have been published about the expression of *bcl-2* in normal liver prior to hepatectomy. It has been reported that by using Northern blot Tzung *et al*[29] did not find any *bcl-2* expression, whereas Kren *et al*[21] did. Similar to our results Masson *et al*[22] also found a basal expression of *bcl-2* by using RT-PCR. Since the source of *bcl-2* is non-parenchymal cells, a more sensitive method such as RT-PCR is a better choice of analyzing its expression.

According to our results, the expression levels of *bax* and *bak* in PH group were lower than those in the normal liver except 0.5 and 8 hours after 70% hepatectomy. On the other hand, the anti-apoptotic genes, *bcl-2* and *bcl-x_L* had higher expression levels than those in the normal liver at most of the time points. Amongst them, the expression of *bcl-x_L* in hepatectomized animals was higher than that of normal liver at all the time points. We observed an overall decrease in the pro-apoptotic genes (*bax* and *bak*) and an increase in the anti-apoptotic genes (*bcl-2* and *bcl-x_L*) expression compared to that in normal liver. Recently, Locker *et al* has also shown increased antiapoptotic regulators and down-regulated proapoptotic regulators by using microarray technology during liver regeneration in mouse[30]. Thus, the increase in the ratio of anti-*vs.* pro-apoptotic gene expression was in favor of survival of the liver tissue throughout the regeneration process.

In our study, we also compared the total expression of these

Table 2 Hourly changes of AUC values for the members of the *bcl-2* family of genes

	bak PH[a]	bak SH[a]	bax PH[a]	bax SH[a]	bcl-2 PH	bcl-2 SH	bcl-xL PH	bcl-xL SH
0.5-2 h	0.94	1.25	1.12	2.36	1.81	1.56	2.53	2.13

168-33 6h	0.98	2.1	0.9	1.2	2.35	3.42	1.37	1.64

[a]*P*<0.05 *vs* the expression of *bak* and *bax* was significantly higher in sham group than that in the hepatectomized group.

genes between sham and partially hepatectomized groups by calculating AUC as used by Tygstrup *et al*[25]. In their study AUC calculation was used to show and compare the mRNA profiles of a set of liver function related and repair related genes in different liver injury and stress models. By comparing AUC values, they have shown that the expressions of several genes related to liver function were reduced[25]. By calculating AUC values, we found an interesting phenomenon that had not been reported in previous studies. The AUC values of all the *bcl-2* family of genes were higher in sham group than that of PH group, suggesting the overall expression levels of apoptotic regulator genes in sham group were increased more than those in the hepatectomized group. Since the sham group of animals had undergone the same period of anesthesia and were sacrificed at the same time, the effect of circadian rhythms on the expression of these genes could be ruled out. In addition, when we measured the hourly changes of the expression of these genes, we found an increase in all the genes that we studied in the sham group compared to PH group except for the first 18 hours in *bcl-x*$_L$. The increase in the case of *bak* and *bax* were statistically significant. This indicated that the expressions of *bak* and *bax* were up regulated in sham group compared to those in hepatectomized group. Therefore, many of the previous findings of expressional changes in transcript levels of *bcl-2, bcl-x*$_L$*, bax* and *bak* might be due to not only regeneration, but also the effects of surgical operations.

The reduction in the expression of proapoptotic *bak* and *bax* in PH group compared to sham group may be related to the enhanced effects of some growth factors on liver proliferation to prevent apoptosis and to ensure the survival of the tissue. It has also been reported that the majority of the rats that had undergone PH, later developed tumors in their remnant liver[31]. Therefore it is tempting to speculate that decreased expression of proapoptotic genes might be responsible for this outcome. However, the cause for the reduction in the expression of anti-apoptotic *bcl-2* family of genes in PH group compared to sham group has been unclear. In the case of *bcl-2*, since it is expressed exclusively by non-parenchymal cells and especially cholangiocytes, removal of a large portion of the liver might be the explanation for this reduction. Thus, it could be speculated that upon removal of a large portion of the tissue, the liver conferred priority to the expression of vitally most important genes.

Abstract

AIM: To observe the frequent complications of stent placement for stricture of the gastrointestinal tract and to find proper treatment.

METHODS: A total number of 140 stents were inserted in 138 patients with benign stricture of the gastrointestinal tract. The procedure was completed under fluoroscopy in all of the patients.

RESULTS: Stents were successfully placed in all the 138 patients. Pains occurred in 23 patients (16.7%), slight or dull pains were found in 21 patients and severe chest pain in 2 respectively. For the former type of pain, the patients received only analgesia or even no treatment, while peridural anesthesics was conducted for the latter condition. Reflux occurred in 16 of these patients (11.6%) after stent placement. It was managed by common antireflux procedures. Gastrointestinal bleeding occurred in 13 patients (9.4%), and was treated by hemostat. Restenosis of the gastrointestinal tract occurred in 8 patients (5.8%), and was apparently associated with hyperplasia of granulation tissue. In 2 patients, the second stent was placed under X-ray guidance. The granulation tissue was removed by cauterization through hot-node therapy under gastroscope guidance in 3 patients, and surgical reconstruction was performed in another 3 patients. Stent migration occurred in 5 patients (3.6%), and were extracted with the aid of a gastroscope. Food-bolus obstruction was encountered in 2 patients (1.4%) and was treated by endoscope removal. No perforation occurred in all patients.

CONCLUSION: Frequent complications after stent placement for benign stricture of the gastrointestinal tract include pain, reflux, bleeding, restenosis, stent migration and food-bolus obstruction. They can be treated by drugs, the second stent placement or gastroscopic procedures depend on the specific condition.

INTRODUCTION

Stricture of the gastrointestinal tract is a common complication associated with various diseases of the gastrointestinal tract. Previously, such conditions were treated surgically in most patients. Operational difficulties and increased expense have limited its application. The recently established non-vascular stent technology could provide a new approach for such patients[1]. The procedure has been proved to be effective, but it has various complications[2-5]. Since 1994, we have placed gastrointestinal stents for benign stricture in 138 patients. Various complications were encountered and treated effectively.

MATERIALS AND METHODS

Materials

Our cohort comprised 138 patients (81 males, 57 females; ages, 18 to 82 years, mean 53.6 years) with benign stricture of gastrointestinal tract. All patients were examined by endoscopy or gastrointestinal barium radiography. Among the 138 patients, 8 had simple sclerosis stricture after radiation therapy for esophageal carcinoma, 86 had achalasia, 36 had esophageal and esophago-gastric anastomosis stricture (complicated with anastomosis fistula in 2), 4 had gastro-duodenal anastomosis stricture, and 4 had esophageal chemical corrosive stricture. All the patients had dysphagia, frequent vomiting, and/or dysphoria before stent placement. The follow-up lasted for 1 week to 8 years.

Methods

Stents were placed in all of the 138 patients under X-ray guidance. For the patients with serious stricture, a probe or saccule was used repeatedly to expand the lesion before stent placement. A total of 140 stents were placed, with two stents at the same site in 2 patients.

RESULTS

Various complications encountered are listed in Table 1.

Table 1 Complications of stent placement for benign stricture of gastrointestinal tract

Type of complication	Patients (n)	Incidence (%)
Pain	23	16.7
Slight or mild	21	15.2
Severe	2	1.5
Reflux	16	11.6
Bleeding	13	9.4
Restonsis	8	5.8
Stent migration	5	3.6
Food-bolus obstruction	2	1.4

Complications were treated according to the specific conditions in each patient. Slight or mild pains (n=21) that did not affect work and rest were not treated (n=12) and that affecting work and rest were treated with analgesics (n=9). For the 2 patients who had severe pain, an analgesic was first

used. This was not effective, peridural anesthesia was conducted and the pain disappeared within 2 days. Sixteen patients had gastro-esophageal or duodenum-gastro biliary regurgitation. Thirteen patients who had gastro-esophageal reflux after stent placement in cardiac achalasia were treated with antacid agent (omeprazole), gastric mucosa protectant (sucralfate) and dynamic medicine (domperidone) for 2 weeks or longer. Administration of medicines was reduced or suspended when symptoms palliated. Thirteen patients exhibited bleeding after stent placement. The bleeding disappeared 2 weeks after venous injection of adrenobazonum. Recurrence of the stricture was observed after stent placement in 8 patients. The second stent was placed in 2 patients under X-ray guidance. Hyperplasia of granulation tissue was cauterized by hot-node therapy in 3 patients under gastroscope and surgically reconstructed in 3 patients. Stent migration was encountered in 5 patients, and the stent was extracted with the aid of a gastroscope. Two patients had food-bolus obstruction. It was removed under gastroscope guidance. No perforation occurred in this series.

DISCUSSION

Complications were frequently encountered after stent placement in benign stricture of gastrointestinal tract[1-3]. The application of this approach would be hampered if these complications were not well treated. The occurrence of complications was related to the material and structure of stents and skill of the operator. It was also associated with the region and nature of pathological changes and physiques of the patients[4–6]. However, treatment of the complications remains difficult.

Pain is one of the common complications after stent placement in benign stricture of gastrointestinal tract, and it usually disappears within 2-4 weeks. The causes of pain are diverse. In terms of stent-related reasons, one is the resulted physical expansion, the other is that pain occurs more frequently in patients with severe lesions. Pain is also closely associated with sites of the lesions. The upper part of the esophagus is sensitive to pain, and mucosa erosion occurs more frequently in lower part due to reflux, resulting in a burning sensation. A stent with a diameter of 16 mm was used for patients with serious stricture, stricture at the upper or lower part of the esophagus. This reduced the pain markedly. Severe pain occurred in 2 patients after stent placement. When omeprazole was suspended, a severe chest pain was complained by the patients 3 days later. Treatment with dolantin was not satisfactory, and venous injection of omeprazole and peridural anesthesia were used for 2 days to relieve the pain. In terms of pain after stent placement, the incidence (16.7%) was slightly higher than those reported previously[7-26]. This may be attributable to the types of lesions and size of the stents. In our series, all patients had benign stricture and large diameter stents were used.

Reflux was mostly associated with pathological changes at the lower part of the esophagus. Expansion by the stents often caused disruption of the lower sphincter of esophagus, resulting in reflux. This problem could cause reflux esophagitis. After stent placement in cardiac achalasia, both reflux and bleeding occurred in three patients and disappeared after treatment with antacid agent, hemostat, and antireflux agent. The incidence of reflux esophagitis (11.6%) in our patients was similar to those previously reported (10-50%). The incidence of bleeding (9.4%) was also similar to those described by other authors[27-34].

Restenosis of the gastrointestinal tract is a thorny problem after stent placement. Benign restenosis is primarily caused by hyperplasia of granulation tissue, this was particularly true, while uncovered stents were used. We adopted one of the procedures for the restenosis including placement of the second stent, or cauterization through hot-node therapy or surgical reconstruction. However, in some patients covered stents could

not be used for anatomical and pathological reasons, such as the ampullary region (open end of the choledochus) or the descending part of the duodenum. Covered stents could easily cause obstructive jaundice, and uncovered stents were used in such patients. The incidence of restenosis in our series (5.8%) was among the range as reported by other authors (3-20%)[35-38].

Stent migration was a complication that occurred within one to four weeks in most patients after stent placement in the gastrointestinal tract. In a few patients it occurred 3 months after stent placement. Typically, this occurred most frequently in patients with covered stents. The displaced stents were extracted under gastroscope guidance. The incidence of stent displacement in our series (3.6%) was in the range as reported previously (0-12.5%)[39-42].

The incidence of food-bolus obstruction reported in other countries ranged from 7% to 20%[1], while it was 1.4% in our series. After stent placement, we provided the patients with a fluid or semi-fluid diet at the early stage, a small amount each time and several times a day. Patient compliance with this advice could explain, at least partially, the low incidence of food-bolus obstruction in our series. When this complication occurred, food-bolus could be removed under gastroscope. Perfortion in the gastrointestinal tract was rare[43-46]. If happened, a second covered stent should be placed or surgery should be conducted immediately.

In patients with malignant pathological changes, stent placement in the gastrointestinal tract was very useful for improving their quality of life. For patients with benign strictures, however, caution was required when placing a stent, especially when it was intended to be permanent. Recoverable stents and biologically degradable stents can be expected to overcome the difficulties and prevent restenosis. This would also reduce the incidence of stent-related complications.

Abstract

AIM: Modified Heller's myotomy is still the first choice for achalasia and the assessment of surgical outcomes is usually made based on the subjective sensation of patients. This study was to objectively assess the long-term outcomes of esophageal myotomy for achalasia using esophageal manometry, 24-hourour pH monitoring, esophageal scintigraphy and fiberoptic esophagoscopy.

METHODS: From February 1979 to October 2000, 176 patients with achalasia underwent modified Heller's myotomy, including esophageal myotomy alone in 146 patients, myotomy in combination with Gallone or Dor antireflux procedure in 22 and 8 patients, respectively. Clinical score, pressure of the lower esophageal sphincter (LES), esophageal clearance rate and gastroesophageal reflux were determined before and 1 to 22 years after surgery.

RESULTS: After a median follow-up of 14 years, 84.5% of patients had a good or excellent relief of symptoms, and clinical scores as well as resting pressures of the esophageal body and LES were reduced compared with preoperative values ($P<0.001$). However, there was no significant difference in DeMeester score between pre- and postoperative patients ($P=0.51$). Esophageal transit was improved in postoperative patients, but still slower than that in normal controls. The incidence of gastroesophageal reflux in patients who underwent esophageal myotomy alone was 63.6% compared to 27.3% in those who underwent myotomy and antireflux procedure ($P=0.087$). Three (1.7%) patients were complicated with esophageal cancer after surgery.

CONCLUSION: Esophageal myotomy for achalasia can reduce the resting pressures of the esophageal body and LES and improve esophageal transit and dysphagia. Myotomy in combination with antireflux procedure can prevent gastroesophageal reflux to a certain extent, but further randomized studies should be carried out to demonstrate its efficacy.

INTRODUCTION

Achalasia is an esophageal motility disorder characterized by failure of lower esophageal sphincter (LES) to relax with swallowing and by the absence of esophageal peristalsis. Up to now, surgical treatment is still the first choice for the disease although dilatation and medication have been reported extensively[1-5]. Because pathophysiological changes of achalasia could not be rectified by any measures, the treatment usually aims at the reduction of LES pressure in order to increase esophageal transit and relieve dysphagia[6].

The outcomes of myotomy for achalasia have been assessed usually according to the subjective sensation of patients in other studies[7], which lack objective criteria. Until now, there have been no reports about the objective evaluation on long-term outcomes of Heller's myotomy for achalasia in a large group of patients in China. The aim of this study was to objectively evaluate the long-term outcomes of Heller's myotomy for achalasia by 24-hour pH monitoring, esophageal manometry, esophageal scintigraphy and esophagoscopy.

MATERIALS AND METHODS

General materials

From February 1979 to October 2000, 176 patients underwent modified Heller's myotomy for achalasia at the Department of Thoracic Surgery, Fourth Hospital, Hebei Medical University. There were 78 men and 98 women, ranging from 8 to 62 years (mean 32.9 years). All patients (100%) had varying extent of dysphagia for a mean of 4.8 years (range 2 months to 37 years) before operation. One hundred and thirteen (64.2%) patients had vomiting, 54 (30.7%) regurgitation at night, 8 (4.5%) chest pain or substernal discomfort and 2 (1.1%) heartburn. Symptoms were evaluated by a clinical scoring system proposed by Eckardt *et al*[8], in which a sum of the individual scores of three major symptoms including dysphagia, heartburn and chest pain was calculated. Each of these symptoms was graded as followings: 0, absent; 1, occasional; 2 daily; 3, with each meal. Therefore, the highest score was 9.

Pre-operative examination

Before surgery, esophagography was performed for all patients, esophagoscopy (Olympus GIF 100) for 114, esophageal manometry (Synectics Medical, Stockholm, Sweden) for 50, 24-hour esophageal pH monitoring (Synectics Medical, Stockholm, Sweden) for 12, esophageal scintigraphy as previously described[9] for 12 patients and 12 normal subjects as controls. Existence of gastroesophageal reflux was defined if a DeMeester score was more than 14.72 by 24-hour esophageal pH monitoring.

Surgery

Myotomy was performed from 5 cm above the esophagogastric junction to 1.5 cm distal to the esophagogastric junction for all of the 176 patients. As an antireflux procedure, Gallone operation[10] was added for 22 patients and Dor operation[11] for 8 patients. Thus, 146 patients underwent esophageal myotomy only, and 30 patients underwent combined esophageal myotomy and antireflux procedure in the present study.

Follow-up study

Fifty-eight patients were followed up from 1 year to 22 years after surgery, with a median follow-up of 14 years. The patients were inquired for dysphagia, heartburn and chest pain. Clinical scores were calculated according to Eckardt et al[8] and compared with preoperative values. According to the method described by Devaney et al[12], the efficacy of operation was graded as excellent (completely asymptomatic), good (mild symptoms requiring no treatment), fair (symptoms requiring occasional treatment such as dilatation or anti-diarrhea medication), and poor (symptoms requiring regular treatment). Postoperatively, esophageal manometry was performed for 30 patients, 24-hour pH monitoring for 22, esophageal scintigraphy for 42, and esophagoscopy for 15.

Statistical analysis

Data on clinical scores, resting pressures of the esophageal body and LES, and DeMeester scores were expressed as mean±SD, and analysed with Student's t test. The incidence of gastroesophageal reflux and esophagitis was assessed with Chi-square test. Statistical analyses were performed using a SPSS 10.0 software package, and the differences were considered as significant if $P<0.05$.

RESULTS

In the present study, 84.5% (49/58) of patients had a good or excellent relief of dysphagia after a median follow-up of 14 years. Table 1 shows pre- and post-operative clinical scores, resting pressures of the esophageal body and LES, and DeMeester scores. Clinical scores and resting pressures of the esophageal body and LES were significantly reduced after Heller's myotomy ($P<0.001$). After a long-term follow-up study, both clinical scores and LES pressures still remained lower than preoperative values, but had a trend of elevation with the lapse of postoperative time (Figures 1 and 2). There were no significant differences in DeMeester score between pre- and post-operative patients ($P=0.512$). DeMeester scores were above normal value in 33.3% (4/12) of preoperative patients, and in 45.5% (10/22) of postoperative patients ($P=0.717$). In contrast, esophagitis was detected with esophagoscopy in 21.9% (25/114) of the patients before surgery and in 46.7% (7/15) after surgery ($P=0.054$). Compared with preoperative patients, the esophageal clearance rate was improved in postoperative patients, but did not reach normal until the fifth minute after swallowing of isotope-labeled semi-liquid food (Table 2).

In group of esophageal myotomy with anti-reflux procedure, clinical scores were similar to those in group of esophageal myotomy alone ($P=0.27$). Also, there was no significant difference in objective parameters including LES resting pressure and DeMeester score between the 2 groups ($P>0.05$) (Table 3). Twenty-four-hour esophageal pH monitoring showed that the incidence of gastroesophageal reflux in patients undergoing esophageal myotomy with anti-reflux procedure was 27.3% (3/11) compared to 63.6% (7/11) in those undergoing esophageal myotomy only ($P=0.087$).

Four patients were found to have varying extents of resumption of esophageal peristalsis by esophageal manometry at 20 months, 7, 15 and 20 years after esophageal myotomy, respectively (Figure 3). Three (1.7%) patients underwent re-operation, of whom 2 underwent myotomy again at 1 year and 4 years after surgery respectively for severe dysphagia due to scar formation around abdominal segment of the esophagus, and the remaining 1 underwent resection of the lower third of the esophagus at the third postoperative year due to repeated bleeding resulted from gastroesophageal reflux. Squamous cell carcinoma occurred in 3 (1.7%) patients at 6, 17 and 18 years after Heller's myotomy, respectively, and esophagectomy was performed for these patients.

Table 1 Objective and subjective parameters from patients with achalasia before and after Heller's myotomy

	Before surgery		After surgery		t	P
	n	mean±SD	n	mean±SD		
Clinical score	176	4.11±0.93	58	1.84±1.26	14.66	0.000
RP of the LES (cm H_2O)	50	31.14±10.54	30	18.05±8.90	5.76	0.000

DeMeester score	11	44.4±38.5	11	55.1±29.3	0.34	0.74

Figure 1 Clinical scores before and at various intervals after Heller's myotomy. Data were expressed as mean±SD. [a]*P*<0.001 *vs* before surgery.

Figure 2 Lower esophageal sphincter (LES) pressure before and at various times after Heller's myotomy. Data were expressed as mean±SD. [a]*P*<0.001 *vs* before surgery.

Figure 3 Esophageal manometric tracings obtained from a 29-y female patient with achalasia before and after Heller's myotomy. A, Preoperative manometry showed simultaneous contractions of the esophagus, suggestive of no pulsive peristalsis. B, Esophageal manometry revealed peristaltic contractions seven years after Heller's myotomy.

DISCUSSION

Achalasia is an uncommon disease. Although there are no epidemiological data in China, its incidence is one per 100 000 population in Western countries[13-16]. The major pathophysiological changes of achalasia are aperistalsis of the smooth muscle portion of the esophagus and absent or incomplete relaxation of LES with swallowing. Neuroanatomic data suggest ganglion cell is degenerated in the esophageal myenteric plexus. Although the cause of achalasia is unknown, it has been hypothesized to be related to class II HLA antigen DQw1[16], and herpes zoster[17] or measles virus infections[18]. The finding of antimyenteric neuron antibodies in achalasia patients has shown it is an autoimmune pathogenesis[19].

In general, aperistalsis of the esophagus in achalasia patients is not reversible after esophageal myotomy. For this reason, its treatment usually aims at the reduction of LES resting pressure. In the currently used methods, medication and dilation have been found to have a certain efficacy, but the duration of dysphagia relief was short[20,21]. Thus, up to now, myotomy has been the first choice for achalasia. In the present study, both LES resting pressure and clinical score were significantly decreased after Heller's myotomy, and 84.5% of patients had a good or excellent relief of dysphagia. This figure was consistent with other reports[22,23]. Furthermore, the relief of clinical symptoms was permanent after Heller's myotomy in the present study. In contrast, the effective relief of symptoms has been reported to present in only 15%-30% of patients one year after intra-sphincter injection of botulium toxin[3,24], and in 50% of patients one year after pneumatic dilatation[3].

Our results of esophageal manometry showed that resting pressure of the esophageal body was also decreased along with the drop of LES pressure after esophageal myotomy. This may be resulted from the reduction or disappearance of intra-esophageal content after Heller's myotomy. Generally, aperistaltic esophagus could not become peristaltic after Heller's myotomy. However, we found that aperistaltic esophagus resumed peristalsis in 4 patients at 20 months, 7, 15 and 20 years after surgery, respectively. In these patients, the mean time of dysphagia was 1.1 years (range 2 months to 8 years) before surgery, which was shorter than that in the entire group (4.8 years), and there were 2 patients with moderate dilation of the esophagus and 2 with mild dilation. Although the reason is unknown, this finding indicates that it is potential for a few achalasia patients to resume their esophageal peristalsis after Heller's myotomy. Chen and colleagues[25] found that the return of peristalsis was seen mainly in patients with a short clinical evolution, and a little esophageal dilation with preserved contractile capacity. Therefore, we suggest that Heller's myotomy should be performed as early as possible once achalasia is diagnosed.

In the present study, DeMeester scores had no significant changes after Heller's myotomy compared with preoperative values. It was reported that gastroesophageal reflux seldom occurred in patients with achalasia before Heller's myotomy, and the reasons for higher DeMeester scores in aperistaltic esophagus were due to the increase of lactic acid resulted from fermentation of retained food in the esophagus[26,27]. In the present study, 24-hour esophageal pH monitoring showed that DeMeester scores were above the normal level in 33.3% of patients before surgery, which is higher than the incidence in normal populations. After Heller's myotomy, gastroesophageal reflux may occur because of the destruction of anti-reflux barrier. Our results also showed that the overall incidence of gastroesophageal reflux was 45.5% in patients undergoing Heller's myotomy. In the literature, the corresponding figure was 25% in those who had undergone esophageal myotomy in combination with anti-reflux procedure[28].

In the present study, 3 (1.7%) patients developed squamous cell carcinoma, while the reported incidence varied between 1.7% and 20%[22,29]. Ribeiro et al[30] indicated that chronic irritation of the esophagus appeared to participate in the process of carcinogenesis in patients with achalasia. Although esophageal emptying has been significantly improved after Heller's myotomy, it could not reach normal level because of the aperistaltic esophagus. For this reason, epithelial hyperplasia of the esophagus caused by chronic irritation before surgery may develop into cancer after surgery. Thus, the incidence of squamous cell carcinoma in achalasia patients who have undergone Heller's myotomy is still higher than that in normal population. For this reason, esophagoscopy should be performed for achalasia patients before surgery and at postoperative follow-up to rule out cancer.

It has been a controversy whether an anti-reflux procedure should be performed with Heller's myotomy[31]. In the present study, the postoperative incidence of gastroesophageal reflux in patients who underwent Heller's myotomy in combination with antireflux procedure was 27.3% compared to 63.6% in those undergoing Heller's myotomy only. In addition, esophagitis was found in 46.7% of patients at postoperative follow-up, and most of them might be resulted from gastroesophageal reflux. However, there were no significant differences in DeMeester and clinical scores between Heller's myotomy only and myotomy in combination with antireflux procedure. Esophageal bleeding resulted from gastroesophageal reflux occurred in one patient who underwent myotomy alone and severe dysphagia occurred in 2 patients who underwent myotomy in combination with anti-reflux procedure due to scar formation around the abdominal segment of the esophagus. Therefore, there is no overwhelming evidence to indicate myotomy in combination with anti-reflux procedure is better than myotomy only for achalasia, and a large number of patients should be studied randomly before the dispute is settled. In our experience, partial rather than total fundoplication should be performed with myotomy because aperistaltic esophagus has a poor emptying ability, and total fundoplication hinders esophageal transit more severely than partial fundoplication does.

Up to now, modified Heller's myotomy is still the best choice for achalasia because of its high rate of symptom relief and permanent efficacy. Heller's myotomy in combination with antireflux procedure could stop gastroesophageal reflux to a certain extent, but a large number of patients should be studied randomly to further demonstrate its efficacy.

Abstract

AIM: To investigate the expression of COX-2 proteins in gastric mucosal lesions and to assess the relationship between COX-2 expression and type, pathologic stage, differentiation, or lymph node metastasis in gastric cancer and the relationship between COX-2 expression and *H pylori* infection in gastric mucosal lesions.

METHODS: Thirty patients with gastric carcinoma underwent surgical resection. Samples were taken from tumor site and paracancerous tissues, and ABC immunohistochemical staining was used to detect the expression of COX-2 proteins. *H pylori* was determined by rapid urea test combined with pathological stating/^{14}C urea breath test.

RESULTS: The positive rate and staining intensity of mutant COX-2 gene expression in gastric cancer were significantly higher than those in paracancerous tissues (66.7% *vs* 26.7%) (*P*<0.01, *P*<0.001). There was a significant correlation between COX-2 and pathologic stage or lymph node metastasis type of gastric carcinoma (76.0% *vs* 20.0%, 79.2% *vs* 16.7%) (*P*<0.05). No correlation was found between COX-2 expression and type or grade of differentiation (*P*>0.05). COX-2 expression of intestinal metaplasia (IM) or dysplasia (DYS) with positive *H pylori* was significantly higher than that with negative *H pylori* (50.6% *vs* 18.1%, 60.0% *vs* 33.3%) (*P*<0.05).

CONCLUSION: COX-2 overexpression was found in a large proportion of gastric cancer tissues compared with matched non-cancerous tissues and was significantly associated with advanced tumor stage and lymph node metastasis. Overexpression of COX-2 plays an important role in tumor progression of gastric cancer. COX-2 may also play a role in the early development/promotion of gastric carcinoma and is associated with *H pylori* infection.

INTRODUCTION

Recently, a number of researches show that COX-2 was expressed at a very high level in gastrointestinal tumors. However, we know less about COX-2 expression in gastric cancer, especially the relationship between COX-2 overexpression and typing, degree, differentiation, lymphonic metastasis of gastric cancer. In this paper, we investigated the expression of COX-2 proteins in gastric mucosal lesions and assessed the relationship between COX-2 expression and the type, pathologic stage, differentiation, or lymph node metastasis in gastric cancer and the relationship between expression of COX-2 and *H pylori* infection in gastric mucosal lesions.

MATERIALS AND METHODS

Materials

Tissue samples were acquired from 30 patients with gastric cancer diagnosed between April 1996 and March 1998 in our hospital, including a piece of tumor tissue and a piece of paracancerous tissue obtained from the surgery. Samples were then fixed quickly into formalin solution at pH 7.0, embedded in paraffin and cut into slices (4 μm thick). Slides were used for HE staining and ABC immunohistochemical staining, the latter was used to detect the expression of COX-2 proteins. *H pylori* was determined by rapid urea test combined with pathological stating/^{14}C urea breath test.

Methods

ABC immunohistochemical staining Polycolone antibody against COX-2 was obtained from Gene Company Limited, ABC immunohistochemical kits and DAB substrate solution were from Vector Laboratories Inc, USA. Slides were treated with 0.01 mol/L citric acid buffer to recover the antigen activity, and developed with routine ABC immunohistochemical staining at an antibody concentration of 1:50, and the second antibody with labeled biotin at 1:200. The negative control was used with PBS buffer replacing the polycolone antibody, and positive control was also set up with a tissue sample with a known positive reaction. The criteria for positive reactions were as follows: positive staining of COX-2 protein located within cytosol, but without stain in the nuclears, being palm yellow to deep palm yellow, even palm red. In evaluation of the positive activity, the positive cell number and reaction level were two useful parameters. When over 10% cells were dyed, it could be considered as a positive expression, and the positive reaction levels were shown as weakly positive (+), moderately positive (++) and strongly positive (+++).

Statistics

Statistical analysis system (SAS) software package was used for χ^2 test, and rank sum test for the degree of group data.

RESULTS

COX-2 expression in gastric cancer tissue and paracancerous tissue

The positive rate and intensity of COX-2 expression in gastric cancer tissue were all significantly higher than those in paracancerous tissues (*P*<0.01, *P*<0.001, Table 1).

Table 2 COX-2 expression in gastric mucosa with *H pylori* infection, *n* (%)

	CG (*n*=30)		IM (*n*=19)		DYS (*n*=11)		GC (*n*=30)	
	Hp+	*Hp -*	*Hp+*	*Hp -*	*Hp +*	*Hp -*	*Hp +*	*Hp -*
n	25	5	9	11	5	6	11	19
COX-2	2(8.0%)	1(0%)	5(50.6%)[a]	2(18.1%)	3(60.0%)[a]	2(33.3%)	8(72.7%)	12(63.5%)

[a]*P*<0.05, IM or DYS (*H pylori* positive) *vs* IM or DYS (*H pylori* negative).

Table 1 COX-2 expression in gastric cancer and paracancerous tissues

	Number	COX-2 expression intensity[b]				Positive rate[d] *n* (%)
		-	+	++	+++	
Gastric cancer	30	10	4	8	8	20 (66.7)
Paracancerous tissue	30	22	6	2	0	8 (26.7)

[b]*P*<0.001 gastric cancer *vs* paracancerous tissue; [d]*P*<0.01 gastric cancer *vs* paracancerous tissue.

COX-2 expression in gastric mucosa with H pylori infection

COX-2 expression of IM or DYS with positive *H pylori* was significantly higher than that with negative *H pylori* (*P*<0.05), (Table 2).

Relationship between COX-2 expression and type, pathologic stage, differentiation, or lymph node metastasis of gastric cancer

The relationship between COX-2 expression and type, pathologic stage, differentiation, or lymph node metastasis of gastric cancer is shown in Table 3. COX-2 positive expression in gastric cancer tissue at the developing stage (76.0%) was significantly higher than that at the early stage (20.0%) (*P*<0.05). The positive rate in gastric cancer with lymph node metastasis (79.2%) was significantly higher than that without lymph node metastasis (16.7%) (*P*<0.05). But the COX-2 positive expression in intestinal gastric cancer (66.7%) was the same as that in gastric type of gastric cancer (66.7%). The positive rate in gastric cancer with low or no differentiation (80%) was not higher than that with high or moderate differentiation (57.1%) (*P*>0.05), (Table 3).

Table 3 COX-2 expression in gastric cancer tissues

Groups	Number	COX-2 *n* (%)
Type		
Intestinal type	24	16 (66.7)
Gastric type	6	4 (66.7)
Stage		
Early stage	5	1 (20.0)
Developing	25	19 (76.0)[a]
Differentiation (Intestinal type)		
High and moderate	14	8 (57.1)
Low and no differentiation	10	8 (80.0)
Lymph node metastasis		
Without metastasis	6	1 (16.7)
With metastasis	24	19 (79.2)[a]

[a]*P*<0.05, developing stage *vs* early stage; metastasis *vs* no metastasis.

DISCUSSION

New COX isozyme-COX-2, is not expressed in normal tissues, but expressed at a high level in inflammatory tissues. It has been shown in animal studies that COX-2 expression can enhance PGE2 production, which induces cell proliferation and bcl-2 expression. These can destroy the balance between proliferation and apoptosis and induce tumors. More and more studies have shown that COX-2 could express at a high level in human colorectal tumor[1-5] and other gastrointestinal tumors[6-8]. COX-2 overexpression was found in well-differentiated epidermoid carcinoma of the esophagus. Ratnasinghe[9] studied the COX-2 expression in epidermoid carcinoma of the esophagus and found that COX-2 expressed at a high level in well- differentiated tissues, at a low positive level in the normal esophagus, and negative in poorly-differentiated tissues. Hao[10] found COX-2 protein expressed at a high level in adenocarcinoma and adenoma of colon, compared with normal mucosal tissues. COX-2 mRNA expressed in tumor tissues at a significantly higher level than that in normal tissues. There was neither a relationship between COX-2 protein expression and proliferation degree or volume of adenoma, nor a relationship between COX-2 expression and tumor differentiation, Duke's stage as well as lymph node metastasis (*P*>0.05). Interestingly, COX-2 expressed in the tissues near adenocarcinoma or adenoma at a higher level than in normal mucosal tissues (*P*<0.0001), but lower than that in adenocarcinoma or adenoma itself (*P*<0.001, *P*<10^5).

It has been found that the positive rate of COX-2 expression in gastric cancer tissue was 60%-70%[6-8]. Ratnasinghe[6] found that COX-2 expressed positively in 36% cardia adenocarcinoma and 60% gastric body adenocarcinoma in his research on 19 patients with cardia adenocarcinoma and 15 patients with gastric body adenocarcinoma. COX-2 overexpression was found in most of gastric body adenocarcinoma and some cardia adenocarcinoma tissues. It is necessary to further confirm the status of COX-2 expression in gastric cancer tissues, especially the characteristics of COX-2 overexpression related to typing, degree, differentiation and lymph node metastasis[11-15]. We studied the COX-2 expression at gene and protein levels in tissues with gastric mucosal lesion, and explored the relationship between COX-2 expression and gastric carcinoma and *H pylori* infection at pathological and pathophysiological levels.

Our study based on 30 tissue samples with gastric cancer as well as paracancerous tissues showed that COX-2 protein expressed at a high level in tumor tissues, which was significantly higher than that in paracarcinoma tissues (*P*<0.01), and also significantly higher in tumor tissues (*P*<0.01). COX-2 positive expression in gastric cancer tissues at the developing stage was significantly higher than that at early stage, the positive rate in gastric cancer with lymph node metastasis was significantly higher than that without lymph node metastasis (*P*<0.05), but the COX-2 positive expression in intestine type of gastric cancer was the same as that in gastric type of gastric cancer. The positive rate in gastric cancer with low or no differentiation was not higher than that with high or moderate differentiation (*P*>0.05). Our results were similar to those of foreign investigators[7,8]. In conclusion, abnormal expression of COX-2 protein was related to the progress of gastric carcinoma as well as lymph node metastasis, while it was not significantly related to the type of gastric cancer and degree of phatological differentiation[13,15].

We also found that COX-2 expression in tissues with *H pylori* positive intestinal metastasis or dysplasia was significantly higher than that in tissues with *H pylori* negative infection. *H pylori* could induce acute and chronic inflammation of gastric mucosa, and the production of cell factors such as IL-8 and IL-1β, and the secondary high COX-2 expression which caused gastric mucosal lesions. *H pylori* infection could also induce gastric mucosal cell proliferation by COX-2 expression. COX-2 gene expression was one of the related factors mediating the progress from gastritis with *H pylori* infection to pre-carcinoma lesions even gastric carcinoma[16,17]. Based on this study, treatment of *H pylori* infection and special COX-2 inhibitor could be useful for the prevention of gastric carcinoma[18].

Abstract

AIM: To study the therapeutic effects of *zhaoyangwan* (ZYW) on chronic hepatitis B and hepatic cirrhosis and the anti-virus, anti-fibrosis and immunoregulatory mechanisms of ZYW.

METHODS: Fifty cases of chronic hepatitis B and posthepatic cirrhosis with positive serum HBsAg, HBeAg, anti-Hbc and HBV-DNA were divided randomly and single-blindly into the treatment group (treated with ZYW) and the control group (treated with interferon). After 3 month treatment, the effects of the treatment group and the control group were evaluated.

RESULTS: The serum ALT normalization was 83.3%(30/36) in the treatment group and 85.7%(12/14) in the control group, with no significant difference (χ^2=0.043, P>0.05). After the course, the negative expression rates of the serum HBV-DNA and HBeAg were 44.4%(16/36) and 50%(18/36) in the treatment group, and 50%(7/14) and 50%(7/14) in the control group, respectively, with no significant difference (χ^2=0.125, χ^2=0.00, both P>0.05). Negative HBsAg and positive HBsAb appeared in 4 cases of the treatment group and 1 case of the control group. Serum anti-HBc turned negative in 6 cases of the treatment group and 1 case of the control group, respectively. After the ZYW treatment, serum CD_3^+, CD_4^+, CD_8^+, CD_4^+/CD_8^+ and NK cell activation were significantly increased. Only serum CD_3^+ and NK cell activation were significantly increased in the control group with a significant difference between the two groups. The serum C_4, C_{1q}, C_3, B and C_9 were significantly increased in the treatment group. In the control group only the serum C_4 was increased. The concentration of serum interferon had no change after treatment with ZYW, while it was significantly increased in the control group after treatment with interferon. The ultrastructure of the liver restored, which helped effectively to reduce the degeneration and necrosis of hepatic cells, infiltration of inflammatory cells and hepatic cirrhosis.

CONCLUSION: ZYW is a pure Chinese herbal medicine. It can exert potent therapeutic effects on chronic hepatitis B and posthepatic cirrhosis. ZYW has similar therapeutic effects to those of interferon. It is cheap and easily administered with no obvious side-effects. It can be widely used in clinical practice.

INTRODUCTION

HBV is highly prevalent in China. HBsAg-positive rate is 8-10% among young adults, some of them may develop chronic hepatitis B (CHB), with poor liver function and positive HBeAg and HBV-DNA. Therefore, it is urgent to improve the immunity of CHB patients to make the virus unable to replicate so as to reduce the damage to the liver and to slow down the progress of CHB to fibrosis and cancer. Anti-virus treatment is the key point[1-7], and great attention has been paid to it. However, no specific therapy has been found. The use of interferon and lamivudine is clinically limited because they are expensive and the patients are easy to relapse[8-14]. An urgent issue of top priority is how to treat CHB and other virus infection with traditional Chinese medicine according to syndrome differentiation. Insufficiency of experience and the complexity of the drug ingredients result in the lack of objective parameters. This study used the proprietary Chinese medicine of *zhaoyangwan* (Morning Sun Pill) invented by Professor Jiang Tingdong. Interferon was used as controls. Fifty patients with hepatitis B were observed for the changes in liver function, cellular immunity function, NK cell activity, serum complement, serum marker of HBV, HBV-DNA, ultrastucture of the liver and serum interferon before and after treatment with ZYW to investigate the mechanisms of the anti-virus, anti-fibrosis activity in the liver and immuno- regulatory of traditional Chinese medicine and to provide theoretic basis for the treatment of chronic hepatic diseases with Chinese herbs.

MATERIALS AND METHODS

Materials
The 50 patients were all HBsAg, HBeAg, Anti-HBc and HBV-DNA positive. Thirty-four were males and 16 females, aged 15 to 57 years, with an average of 38.5 years. They were classified according to the diagnostic criteria devised on the Beijing Conference of Infectious and Parasitic Diseases in 1995. Thirty-eight cases were CHB, 22 cases were post-hepatitis active hepatocirrhosis(in compensation). They had no such chronic diseases as other types of hepatitis, diabetes or tuberculosis.

Methods
The 50 patients were divided into *zhaoyangwan* (ZYW) group and interferon group (control group). The 36 patients in ZYW group took orally 2 packs of ZYW a day, one in the morning and one in the evening, for 3 months. The 14 patients in the control group were administered intramuscularly with α-interferon made by Changchun Bio-product Institute, 3 mU once every other day for 3 months. Vitamins might be added to the patients in both groups, but no other anti-virus, immuno-

regulatory or liver enzyme reduction drugs were used during the treatment. One therapeutic course lasted for 3 months. Serum marker of HBV, T-cell subgroup, NK cell activity, contents of serum complement, and level of serum interferon were examined before and after the treatment, respectively. The liver function was examined once a week. Liver puncture and electrodiaphanoscopy were performed for some patients to observe the ultrastructure of the liver before and after the treatment.

Assay methods
HBVDNA was assayed with PCR, T-cell sub-group with direct method of bacterial ring, NK cell activity with MTT colorimetry, serum compliment with one-direction immunity diffusion, and serum interferon with ELISA, with reagent produced by Endogen of USA. The ultrastructure of the liver was observed under electrodiaphanoscope.

RESULTS

Changes of symptoms and signs before and after treatment
Changes of symptoms and signs in both groups before treatment (BT) and after treatment (AT) are compared in Table 1, which showed that the symptom disappearance rate (DR) of the treated group was similar to or higher than that of the control group, but the sign disappearance rate was lower, with no statistical significance.

Changes of liver function and serum markers before and after treatment
Serum glutamic-pyruvic transaminase (ALT) was evidently improved in both groups. The serum ALT returned to normal in 83.3% (30/36) of the treated group and 85.7% (12/14) of the control group. No significant difference was found between

both groups. (χ^2=0.043, P>0.05). The negative conversion rate of HBVDNA and HBeAg in the treated group was 44.4% (16/36) and 50% (18/36), respectively, while in the control group, it was 50% (7/14) and 50% (7/14), respectively, with no significant difference (χ^2=0.123, χ^2=0.00, both P>0.05). HBsAg turned negative in 4 cases of the treated group and 1 case of the control group, and their HBsAb turned positive. Anti-HBc turned negative in 6 cases of the treated group and 2 cases of the control group.

Changes of T-cell sub-group and NK cell activity before and after the treatment
Serum CD3$^+$, CD4$^+$, CD8$^+$, CD4$^+$/CD8$^+$ and NK cell activity were significantly increased in the ZYW treated group (t=8.921-13.380, all P<0.001), while in the control group, only CD3$^+$ and NK cell activity were significantly increased (t=7.473, 10.101, P<0.001). The results of the two groups were significantly different after the treatment (t=6.812-14.108, all P<0.001), as shown in Table 2.

Changes of serum complement elements before and after treatment
The five serum complement elements, ie. C$_4$, C$_{1q}$, C$_3$, BF, and C$_9$, increased significantly compared with those before the treatment in the ZYW group (t=4.437-24.330, P<0.001), while in the control group, only C$_4$ increased (t=5.044, P<0.001). The results of the two groups were significantly different after the treatment (t=3.972-12.910, P<0.001), as shown in Table 3.

Changes of serum interferon concentration
The serum interferon concentration changed little in the ZYW group, while in the interferon group, it rose significantly. The results of the two groups were significantly different after treatment (t=2.723, P<0.001), as seen in Table 4.

Table 1 Improvement of symptoms and signs in both groups before and after treatment

Table 4 Changes of serum interferon concentration before and after treatment

	Case number	BT	AT	*t*	*P*
Treated group	13	156.25±17.62	155.93±19.76	0.046	>0.05
Control group	8	143.27±21.44	218.72±63.34	3.193	<0.05

After treatment, the serum interferon concentration of the two groups was significantly different (*t*=2.723, *P*<0.05).

Changes of hepatic ultrastructure

Degeneration, necrosis, cholestasis, fibrosis, and lysis of the organelles existed in different degrees in the liver cells before treatment, while after treatment, the necrotic cells of the liver resiled to a certain extent.

Side effects of ZYW

No evident side effects appeared in the ZYW group. Xerostomia and constipation appeared in one case and slight dizziness in another case, but they disappeared automatically with the continuous use of the pills. More side effects appeared in the interferon group, including influenza-like symptoms, symptoms of the digestive tract, sore and painful muscles. However, the patients continued taking their drugs after patient persuasion of the doctors.

DISCUSSION

Some studies indicated that ZYW had two-way immune modulation functions[15]. It could improve the function of Kupffer cells of the liver and the activity of natural killer (NK) cells. It also could induce interferon to produce antiviral activity and turn HBeAg negative. We investigated the effects of ZYW on chronic hepatitis by random single-blind ways. The effects of three-month short-term therapy were good and the over all effectiveness was 83.3%(30/36). Some main symptoms such as fatigue, abdominal distension, nausea, anorexia were improved or disappeared after the treatment. The effects of the treatment group were better than those of the control group and were statistically significantly different. In most patients, the color of facial skin turned from dark and gloomy to bright red, with their vigor improved, hepatosplenomegaly improved, percussive pain of the liver region disappeared and state of general health apparently improved. Liver function tests turned normal in half of the patients including 6 patients with slight jaundice which completely disappeared, and serum bilirubin turned normal after the three-month therapy. In the control group, the rate of ALT normalization was 85.7%(12/14) with no statistical significance compared with the treatment group (*P*>0.05). ZYW has some antiviral activity. After the treatment, the rates of negative conversion of HBVDNA and HBeAg were 44.4%(16/36) and 50%(18/36) in the treatment group. There was no statistical significance compared with the control group, in which the rates were 50%(7/14) and 50%(7/14). The HBsAg of four patients in the treatment group and one patient in the control group turned from positive to negative and their HBsAb turned positive. The HBcAb of six patients in the treatment group and two patients in the control group turned negative. Therefore, ZYW has high antiviral activity and the effectiveness is similar to that of interferon. Because the treatment was short-termed, we did not investigate the incidence of recurrence. If the course of treatment is lasted for six months, it would have better efficiency.

Hepatitis B virus infection is the primary cause of viral hepatitis. Persistent existence of hepatitis B virus in the body is the primary cause of chronic hepatitis B[16-19]. Hepatitis B virus infection leads to chronic hepatitis and persistent damage to the liver function. Low antiviral immunity of the body and abnormal immunity modulation are also the primary cause of chronicity[20-25]. Some studies have found that there are different degrees of low cellular immunity[26,27], which represent deficient T cell immunity and decreased activity of NK cells in patients with chronic hepatitis B and liver cirrhosis. NK cells of the liver are important to antiviral immunity and against tumor metastasis[28-31]. Kakimi *et al*[32] injected lactate(activator of NK-T cell) into HBV-transgenic mouse and found that interferon-γ in the liver of the mouse increased, reproduction of HBV stopped and OK-T cells decreased. They believed that activated OK-T cells could activate NK cells, release lots of cytokines and prevent virus from reproducing. It indicates that NK cell is important in the process of erasing HBV. The results of our study showed that there were different levels of modulation disturbance of cellular immunity, such as elevation of CD3+, CD4+, CD8+ and decrease of CD4+/CD8+ and activity of NK cells in the patients of hepatitis B before ZYW treatment. After ZYW treatment, values of CD3+, CD4+,CD8+ and CD4+/CD8+ and activity of NK cells improved differently, indicating that ZYW can improve cellular immunity, especially the total amount of T lymphocyte and function of NK cells. It remains to be further studied whether it can be used as an activator of NK cells.

Besides, low cellular immunity, the level of blood complement decreased differently in patients with chronic hepatitis B. HBV antigen is highly compatible with liver cells. The complex of HBV-antibody-complement can damage the liver cells by activating the typical route as common complexes, or by adhering to the liver cells as half-antigen through the typical route of antibody-complement[33]. Our study indicated that low serum complement was improved differently in patients with chronic hepatitis B after treatment with ZYW and interferon, especially in the ZYW treated group.

Interferon is a broad-spectrum antiviral protein and has some antiviral activity. It does not kill viruses directly but prevents viruses from replication by mediating RNA-dependent PKR or RHA-activated enzyme. Interferon can also improve phagocytosis of phagocytes and activity of T killer cells and NK cells[29,34-36]. Our study indicated that the activity of NK cells was only slightly elevated in some patients and had no change in patients treated with interferon, indicating that the immuno-modulating function of interferon is not evident. Besides, it is difficult for interferon to be widely used due to its high price and poor tolerance in practice. So other medications which can modulate and improve immunity are suggested to be used in conjunction with interferon, which is mainly used for antiviral treatment.

Liver fibrosis is a pathologic process in which abnormall hyperplasia of fibro-connective tissue develops after inflammatory necrosis has occurred in the liver. The liver can worsen the inflammatory necrosis by cytokines or microcirculation in the liver. The activity of lesions in the liver means the activity of liver fibrosis. Some authors[37] have suggested that drugs that can prevent or slow down liver fibrosis would cure most of chronic hepatosis. Thus, preventing or delaying liver fibrosis and treating viruses are two aspects of chronic hepatitis B therapy. Today drugs for anti-liver fibrosis are rare and the curative effect is not certain. Our study found that ultramicrocirulation in the liver and liver fibrosis were improved differently after ZYW treatment in patients with chronic hepatitis B and early-stage liver fibrosis. Since the case number was small, and it needs to be further studied.

Patina in ZYW is one of its characteristic ingredients that is different from other drugs in treating chronic hepatosis in practice. Modern medicine believes that copper is an important ingredient for blood-production in the body. Taking appropriate copper orally can improve retina cells and hemoglobin in the bone marrow and blood, and stimulate and repair the liver.

Copper combined with protein in the body produces copper-protein compounds which can restrain hepatitis viruses and induce the body to produce interferon. Our results indicated that the liver function and immunity index of the patients with chronic hepatitis B were differently improved after ZYW treatment and the rate of negative conversion of chronic hepatitis B markers was similar to that of interferon group. The level of serum interferon was elevated after ZYW treatment, but the difference was not statistically significant. Because our case number was small, this needs to be further investigated. We believe that ZYW has a good curative effect and fewer side-effects in treating chronic viral hepatitis. It is also cheap and can be easily taken. So it can be widely used in practice.

Abstract

AIM: Intrahepatic extension is the main cause of liver failure
and death in hepatocellular carcinoma patients. The small
GTPase Rho and one of its effector molecules ROCK regulate
cytoskeleton and actomyosin contractility, and play a crucial
role in cell adhesion and motility. We investigated the role
of small GTPase Rho in biological behaviors of hepatocellular
carcinoma to demonstrate the importance of Rho in cancer
invasion and metastasis.

METHODS: Using Western blotting, we quantitated Rho
protein expression in SMMC-7721 cells induced by
Lysophosphatidic acid (LPA). Furthermore, we examined the
role of Rho signaling in regulating the motile and invasive
properties of tumor cells.

RESULTS: Rho protein expression was stimulated by LPA.
Using the Rhotekin binding assay to assess Rho activation,
we observed that the level of GTP-bound Rho was elevated
transiently after the addition of LPA, and Y-27632 decreased
the level of active Rho. LPA enhanced the motility of tumor
cells and facilitated their invasion. Rho played an essential
role in the migratory process, as evidenced by the inhibition
of migration and motility of cancer cells by a specific inhibitor
of ROCK, Y-27632.

CONCLUSION: The finding that invasiveness of hepatocellular
carcinoma is facilitated by the Rho/Rho-kinase pathway is
likely to be relevant to tumor progression and Y-27632 may
be a new potential effective agent for the prevention of
intrahepatic extension of human liver cancer.

INTRODUCTION

Hepatocellular carcinoma is one of the most common cancers
worldwide, especially in Asia[1]. It frequently shows early
invasion into blood vessels together with intrahepatic
extensions and later extrahepatic metastasis[2]. A better
understanding of the processes involved in the development
of the metastasis might improve future prognosis by facilitating
treatment strategies.

Tumor invasion is a complex biological process, during
which tumor cells detach from the primary tumor and infiltrate
the surrounding tissue. This process requires loss of cell
contacts between tumor cells, active cell migration, adhesion
to the extracellular matrix and proteolytic degradation of the
extracellular matrix[3-5]. Rho, a member of the Ras family of
small GTP-binding proteins, has a molecular weight of
approximately 27 kDa and is located under the cell membrane,
potentially functioning in signal transduction pathways[6].
Small GTPase Rho protein is known to work as a molecular
switch for the regulation of signal transduction of intracellular
events related to cell motility, cytoskeletal dynamics, and tumor
progression[7,8]. In the present study, we hypothesized that
Rho protein might be associated with the development of
hepatocellular carcinoma.

Lysophosphatidic acid (LPA) is a product of phospholipid
metabolism. Exogenous LPA binds to surface G protein-
coupled receptors and its biological activities are mediated in
part by the cytosolic small GTPase Rho[9-11]. The motility of
tumor cells could be regulated by the target of Rho, Rho-
associated coiled-coil forming protein kinase(p160ROCK),
through reorganization of the actin of cytoskeleton[12]. A recently
described specific inhibitor of p160ROCK, the (+)-(R)-trans-
4-(l-Aminoethyl)-N-(4-pyridyl) cyclohexanecarboxamide
dihydrochloride (Y-27632), was reported to inhibit Rho-
mediated cell migration as well as smooth muscle contraction
both *in vivo* and *in vitro*[13-15].

Given the recent interest in the participation of Rho in cell
migration, we analyzed the role of Rho associated signal
transduction pathways during the LPA-induced transmigration
of human hepatocellular cells, and more importantly the activity
of Rho regulated by LPA and inhibitor of p160ROCK.

MATERIALS AND METHODS

Cell lines and treatment

SMMC-7721 cell, originally isolated from a poorly differentiated
hepatocellular carcinoma, was used in all experiments. SMMC-
7721 cell was cultured in modified minimum essential medium
(MEM) containing 2-fold concentrated amino acids and
vitamins supplemented with 10% fetal calf serum (FCS) at
37 ℃ in a humidified atmosphere of 5% CO_2 in air. The cells
were used within 15-20 passages after the initiation of cultures.
Before each experiment, cells were cultured under serum-free
conditions (in medium containing 0.1% bovine serum albumin)
for 24 h.

Western blot analysis

Cells were starved in serum-free culture medium for 24 h and
subsequently treated with LPA at 37 ℃ for various times. The
cells were washed twice with PBS and lysed in ice-cold lysis
buffer (20 mM Tris, pH 7.4, 150 mM NaCl, 1% Triton X-100,
1 mM EDTA, 1 mM EGTA, 2.5 mM sodium pyrophosphate,
1 mM glycerolphosphate, 1 mM sodium orthovanadate, 1 μg/ml
leupeptin, and 1 mM phenylmethylsulfonyl fluoride). The
extracts were centrifuged to remove cellular debris, and
protein content of the supernatants was determined using the
Bio-Rad protein assay reagent. Samples were resolved by SDS-
polyacrylamide gel electrophoresis and transferred to

Hydbond-P. The transferred samples were incubated with the anti-rho antibody indicated, and then incubated with HRP-conjugated IgG, and the immunoblotted proteins were visualized with ECL reagents.

Rho activation assay

A commercial pull-down assay (Rho activation assay kit, Upstate) was used to measure the effect of LPA and Y-27632 on Rho activity in SMMC-7721 cells. The cells were washed twice with modified MEM and incubated in fresh modified MEM without serum for 24 h, 25 μM LPA with or without Y-27632 (25 μmol/L) was added and the cell suspension was centrifuged at the indicated time after LPA addition, and then the cell pellet was lysed (lysis buffer, Upstate) and the activated Rho pull-down assay was performed according to the manufacturer's protocol. A protein assay was performed prior to beginning pull-down assay to equalize the total protein concentration of each treatment group. Positive and negative controls were also performed according to the manufacturer's protocol. Briefly, lysates of cells were preincubated with 100 μM nonhydrolyzable GTPγS (positive Rho activation) or 100 μM GDP (negative Rho activation) prior to undergoing precipitation by the Rhotekin GTP-Rho binding domain.

Morphological changes by Rho-kinase pathway

The cells were cultured in serum-free culture medium, and the dishes were incubated for an additional period of 24 hours. LPA (5 μmol/L) was then added to the dishes with or without different concentrations of Y-27632 (5, 25, 125 μmol/L) and cultured for 1 hour. The cells were examined using a phase-contrast microscope.

Cell motility assay

Random motility was determined by using the gold-colloid assay[16]. Gold colloid was layered onto glass coverslips and placed into 6-well plates. Cells were seeded onto the coverslips and allowed to adhere for 1 h at 37 ℃ in a CO₂ incubator (12 500 cells/3 ml in serum-free medium). To stimulate the cells, the serum-free medium was replaced with 5% FBS containing LPA (5 μmol/L) with or without Y-27632 (25 μmol/L) and allowed to incubate for 24 h at 37 ℃. The medium was aspirated and the cells were fixed with 2% gluteraldehyde. The coverslips were then mounted onto glass microscope slides and areas of clearing in the gold colloid corresponding to phagokinetic cell tracks were counted.

Cell invasion assay

Chemotactic directional migration was evaluated using a modified Boyden chamber[17,18]. In this invasion assay, tumor cells had to overcome a reconstituted basement membrane by a sequential process of proteolytic degradation of the substrate and active migration. Costar transwells (pore size 8 μm) were coated with matrigel, dried at 37 ℃ in an atmosphere of 5% CO₂, and reconstituted with serum-free medium. Cells (3×10⁴) were plated in the upper chamber in medium containing LPA with or without Y-27632 and allowed to migrate for 4.5 h. Nonmigrating cells were removed from the upper chamber with a cotton swab and migrating cells adherent to the underside of the filter were fixed and stained with Mayer's hematoxylin solution and counted with an ocular micrometer. All experiments were performed in triplicate, and at least 10 fields/filter were counted. Data were expressed as relative migration (number of cells/field) and represented as $\bar{x}\pm s$ of at least three independent experiments.

Statistical analysis

All data were expressed as $\bar{x}\pm s$. Statistical analysis was done by statistical package of SPSS for window release 9.0. Differences between the mean were tested with the Mann-Whitney test. $P<0.05$ was considered statistically significant.

RESULTS

Increase of Rho protein levels as a result of LPA treatment

Using Western blot analysis with Rho polyclonal antibody, we detected the changes of the level of Rho family protein in SMMC-7721 cell extracts. The protein level of Rho rapidly increased within 5 h and reached the nearly maximal level at 25 h after the treatment with LPA, with more than 2-fold increase over the untreated control value (Figure 1).

Figure 1 Changes in levels of Rho family protein in SMMC-7721cells induced by LPA. The levels of Rho protein were analyzed by Western blot analysis. The data shown are expressed as $\bar{x}\pm s$ from three different experiments.

Inhibition of LPA-induced Rho activation by Y-27632

We measured the intracellular levels of the GTP-bound active form of Rho by the pull-down assay system[19]. Activated GTP-Rho was precipitated by the Rho-binding domain of Rhotekin, a downstream Rho effector that specifically binds to only activated GTP-Rho[20]. The level of GTP-bound Rho was elevated transiently after the addition of LPA and reached the peak level at 30 min after LPA addition, whereas Y-27632 decreased the level of active Rho. Since the total amount of Rho in each lysate was almost constant, Y-27632 inhibited Rho activation. This result was controlled by equalizing the harvested protein levels from each treatment with an appropriate dilution of buffer determined by a protein concentration assay prior to beginning the pull-down assay. A positive and negative control for active or inactive Rho was also performed in parallel. Lysates of cells were preincubated with nonhydrolyzable GTPγS (positive Rho activation) or GDP (negative Rho activation) prior to undergoing precipitation by Rhotekin. Similar levels of active Rho were detected in cells grown on LPA and in cells incubated with GTPγS. Thus, the result indicated that LPA might stimulate an increase in activated Rho and Y-27632 might inhibit the activation of Rho.

Morphological changes induced by Rho-kinase inhibitor and LPA

The effect of Y-27632 on morphologic changes induced by LPA in serum-starved SMMC-7721 cells was observed under a phase-contrast microscope. In serum starvation, cells formed relatively cohesive colonies, and after addition of LPA, they formed dissociated and scattered lamellipodial extensions at the cells' edges. Addition of Y-27632 at a concentration of 25 μmol/L or more inhibited these LPA-induced morphologic changes, and SMMC-7721 cells remained cohesive with each other.

Inhibition of LPA-induced motility and invasion by Y-27632

To evaluate the effect of Rho-mediated cellular motility, we

assessed the treated cell line in colloidal-gold random motility assay. Cells were seeded onto glass coverslips overlaid with a gold colloid and stimulated with LPA to induce motility. Discernable and quantifiable tracks were left as the cells moved and phagocytized the gold colloid. As determined by the trypan blue dye exclusion assay, the reduction in cell motility was not caused by a decrease in the number of viable cells. At 24 h after stimulation, the cells treated with LPA were 2.2 fold more motile than their untreated counterparts ($P<0.01$) and Y-27632 significantly suppressed the LPA-induced motility (Figure 2).

As shown in Figure 3, when the cells were tested for their ability to invade through a matrigel-coated filter in response to a chemoattractant, the LPA-treated cells were 2.3 fold more invasive than the untreated cells. Addition of Y-27632 at a concentration of 25 μmol/L significantly inhibited the LPA-induced invasion ($P<0.01$). Taken together, these data suggested that treatment of SMMC-7721 cells with Y-27632 could lead to the inhibition of LPA-mediated motility and invasion.

Figure 2 Tumor cell random motility determined by gold-colloid assay. Cells were seeded onto the coverslips and allowed to adhere for 1 h and then incubated in FBS containing LPA with or without Y-27632 for 24 h. The areas of clearing in the gold colloid corresponding to phagokinetic cell tracks were counted and represented as $\bar{x}\pm s$ from triplicate experiments. [a]$P<0.01$ LPA treated cells *vs* SMMC-7721 control cells, [b]$P<0.01$ Y-27632 treated cells *vs* LPA treated cells.

Figure 3 Inhibition of LPA-induced tumor cell invasion by Y-27632. Serum-starved cells were seeded onto porous filters. After incubation of the filters with Y-27632 in the presence of LPA 25 μM for 4.5 h to permit penetration of the cells, nonmigrating cells were removed from the upper chamber and migrating cells adherent to the underside of the filters were counted in a minimum of 10-high power fields. Data were expressed as relative migration (number of cells/field) and represented as $\bar{x}\pm s$ from triplicate experiments. [a]$P<0.01$ relative to SMMC-7721 control cells.

DISCUSSION

Generally, metastasis has been found to be a multistep process, which includes detachment of cancer cells from primary tumor, migration, adhesion and invasion of cancer cells into the blood or lymphatic vessels, extravasation out of the vessel, and finally, interactions with the target tissue and the formation of metastatic foci in distant organs[21,22]. In spite of recent advances in diagnostic and therapeutic methods, the prognosis of HCC patients with intrahepatic metastasis was poor[1]. Accordingly, analysis of the mechanism of the migration of cancer cells might lead to new strategies for preventing the progression of hepatocellular carcinoma. The molecular and cellular mechanisms of intrahepatic metastasis have not been fully understood, although cell motility mediated by Rho signaling pathway was recently shown to play a critical role in metastasis of various tumor cells.

Rho is a small GTPase that was found to play an essential role in a variety of cellular processes[6,23]. The active GTP-bound form was involved in cytoskeletal responses to extracellular signaling pathways, resulting in the formation of stress fibres and focal adhesions[24]. Other Rho effects included important roles in signaling pathways that control gene transcription, cell cycle regulation, apoptosis, and tumor progression[25]. Rho proteins could oscillate between an active GTP-bound state and inactive GDP-bound state. The ratio between these two forms is regulated by two classes of proteins: GTPase-activating proteins (GAPs), which promote hydrolysis of GTP bound to the active form and accumulation of the inactive GDP-bound form, and guanine nucleotide exchange factors (GEFs), which promote the exchange of GDP for GTP and therefore induce accumulation of the activated GTP-bound form. In resting cells, inactive GDP-bound Rho proteins were found in the cytosol in complex with another class of regulatory proteins, nucleotide dissociation inhibitors (RhoGDIs). Upon activation, dissociation of RhoGDIs from the complex was required to enable interaction with GEFs and exchange of GDP for GTP[26,27]. To exert their function, activated Rho proteins need to associate with the cell membrane and this in turn depends on their posttranslational modification.

It has been demonstrated that the role of Rho in inducing the invasion could be substituted for by one of its downstream effectors, the Rho-associated kinase (ROCK)[28]. Invasion by tumor cells is a process composed of proteolytic degradation of extracellular matrix barriers and the migration of the cells through the modified region. Contraction of the actomyosin system is important for cell migration, and ROCK regulates the myosin light chain (MLC) phosphorylation by direct phosphorylation of MLC and by inactivation of myosine phosphatase, which was found to result in an increase in actomyosin-based contractility[29,30]. Lysophosphatidic acid is a simple phospholipid that nonetheless has the properties of an extracellular growth factor, mediating diverse cellular responses through the activation of multiple signal transduction pathways. LPA could trigger actin-cytoskeletal events through Rho GTPases, thereby influencing transcellular migration[31]. LPA could induce MLC phosphorylation through Rho activation, leading to the stimulation of cell contractility and motility of fibroblasts and cancer cells[32].

Overexpression of Rho family members increases migration and invasion in various cell lines and culture models, this suggests that such an overexpression in carcinomas might profoundly affect metastatic potential *in vivo*[33]. The result of Western blot showed that the level of activation of Rho was augmented by LPA. In our study, we extended this observation by providing the evidence that a specific inhibitor of Rho kinase, Y-27632, could inhibit LPA induced Rho activation by GTP-bound Rho pull-down assay. The Rho pathway through a G protein-coupled receptor appeared to be an important process of LPA-mediated signaling.

Y-27632 had an excellent selectivity to inhibit Rho-kinase as compared to other kinases, such as protein kinase C and myosin light-chain kinase in a cell-free system[34]. Thus, Y-

27632 is a powerful tool to investigate the role of the Rho/ Rho-kinase system, especially *in vivo*, although more potent Rho-kinase inhibitors have been synthesized[35]. Y-27632 was reported to inhibit transcellular invasion and reduce the extent of local peritoneal metastases by MM1 rat hepatoma and also *in vivo* dissemination of prostate cancer cells[36]. In the present study, Y-27632 blocked LPA -mediated SMMC-7721 cell transmonolayer invasion, suggesting the essential role of Rho– Rho kinase pathway in LPA -mediated cell migration. We also observed that Y-27632 induced morphological changes in SMMC-7721 cells, characterized by remaining relatively cohesive colonies, suggesting that Rho-kinase was necessary as a downstream effector of Rho for cell morphologies. Previous reports also demonstrated that Y-27632 inhibited LPA-induced morphologic changes in various cell lines *in vitro*.

As cell migration, invasion, cellular proliferation, and survival are advantageous to tumor cells for the formation of metastases, the finding that invasiveness of hepatocellular carcinoma is facilitated by the Rho/Rho-kinase pathway is likely to be relevant to tumor progression and the Rho/Rho- kinase may be useful as a prognostic indicator and also in the development of novel therapeutic strategies. Y-27632 may be a new potentially effective agent for the prevention of intrahepatic extension of human HCC.

Abstract

AIM: Gallstone disease is increasing in sub-saharan Africa (SSA). In the west, the majority of stones can be dissolved with bile salts, since the major component is cholesterol. This medical therapy is expensive and not readily accessible to poor populations of SSA. It was therefore necessary to analyze the chemical composition of biliary stones in a group of patients, so as to make the case for introducing bile salt therapy in SSA.

METHODS: All patients with symptomatic gallstones were recruited in the study. All stones removed during cholecystectomy were sent to Houston for x-ray diffraction analysis. Data on age, sex, serum cholesterol, and the percentage by weight of cholesterol, calcium carbonate, and amorphous material in each stone was entered into a pre-established proforma. Frequencies of the major components of the stones were determined.

RESULTS: Sixteen women and ten men aged between 27 and 73 (mean 44.9) years provided stones for the study. The majority of patients (65.38%) had stones with less than 25% of cholesterol. Amorphous material made up more than 50% and 100% of stones from 16 (61.53%) and 9 (34.61%) patients respectively.

CONCLUSION: Cholesterol is present in small amounts in a minority of gallstones in Yaounde. Dissolution of gallstones with bile salts is unlikely to be successful.

INTRODUCTION

Biliary lithiasis has been a common disease in Europe and the USA for decades. Over half of the cases are asymptomatic, usually detected by an abdominal ultrasound[1]. For a very long time, biliary stone disease was said to be rare in Sub-Saharan Africa (SSA). Archampong reported a 0.4% prevalence of all admissions in the Korle Bu Teaching Hospital in 1969 in Ghana[2]. Today the prevalence of gallstone disease has increased considerably with the widespread use of ultrasonography[3].

This increase has also been observed in African populations of Jamaica[4] and SSA[2,5].

Many studies to identify risk factors for biliary lithiasis in the West have focused on hypersaturation of cholesterol in bile in the nucleation process, a critical step in the genesis of bile stones[1,6]. The high concentration of cholesterol in gallstones has been the basis for the widespread use of bile acids, a nonsurgical treatment for the dissolution of gall bladder stones. These stones account for as much as 80% of Western stones[6]. Unfortunately, gall bladder stone composition is heterogeneous, and differs within and without populations around the world[3-8].

The increasing frequency of biliary stones in SSA, with its different epidemiological factors and diseases, prompted us to carry out a chemical analysis of gallstones. This study would demonstrate the role of cholesterol in our stones and therefore the necessity of using bile salts for gall stone dissolution in SSA.

MATERIALS AND METHODS

This was a cross-sectional study of a series of stones removed from patients at the University Hospital Center (UHC) of the University of Yaounde I from January 1, 1989 to December 31, 1998. All stones removed during surgery were placed on sterile gauze to air dry, transferred into a paper envelope bearing the name, age, and sex of the patient as well as the date. The first batch of stones from 19 patients was sent to the Urolithiasis laboratory in Houston, Texas in January 1996. A second collection of stones from 7 patients was sent to the same laboratory in May 1999.

All stone specimens were first examined for shape, size, and color. They were classified as cholesterol, black or brown pigmented stones, examined under a polarized microscope. The composition of the nidus, the internal and external shells was determined by X-ray diffraction as described previously[9]. The percentage of cholesterol, calcium carbonate, and amorphous material such as black bilirubinate, black phosphate, glycoproteins and salts was determined. A descriptive analysis was done for stones from each patient. Patients who were able to pay for a serum cholesterol assay did so. Hemoglobin electrophoresis was not asked in this mainly adult population who did not give histories of sickle cell disease or crisis.

RESULTS

Patient population

There were 26 Cameroonian patients, all black Africans, aged between 27 and 73 years (mean 44.9 years). There were 16 women and 10 men, a 1.6 female to male sex ratio. The men were aged between 36 and 62 years whereas 6 women were less than 35 years (23.07%). All our patients resided in the city. They consumed mainly an African traditional diet made of local vegetarian menus mixed with imported processed Western items such as rice and wheat. The serum cholesterol level was normal in all 10 patients who did it.

Stone analyses

The percentage of cholesterol in the stones by weight is

depicted in Table 1. Seventeen patients (65.38%) had stones with less than 25% cholesterol. Of these, 11 (42.30%) had cholesterol free stones. Seven patients (26.92%) and 9 others (34.61%) had stones with 50% and 80% cholesterol content, respectively.

Calcium carbonate was detected in stones from 4 (15.38%) patients, three of whom were female. Two of these females had mixed stones containing cholesterol, calcium carbonate and amorphous material.

Table 2 shows the distribution of amorphous material by weight in these stones. Stones from 16 (61.53%) patients contained more than 50% amorphous material. The entire stone was made of amorphous material in 9 (34.61%) cases.

Table 1 Percent by weight of cholesterol in the gallstones from 26 patients

% by weight	Males	Females	Patient (%)
0	6	5	11 (42.30)

DISCUSSION

The results from this hospital-based nonrandomized study cannot be extrapolated to the community due to several limitations. In this group there were no children. Yet, it is known that children with hemolytic diseases develop cholesterol-poor, bilirubin-rich gallstones[2]. Even in children without hemolytic disease, the composition of gallstones was different from those of adults in Leeds, England[7]. Limitations to recruiting a potentially representative population of patients include poverty, in the absence of a financial scheme for health care coverage, ignorance and cultural factors that dissuade people from attending hospital services. Nonetheless, this pilot study permits us to raise the hypothesis that dissolution of gall bladder stones with bile salts is not a cost-effective alternative to surgical treatment.

A recent series of biliary lithiasis revealed a 4-fold increase of symptomatic gall bladder stone disease in Ghana from 1966-1999. This series also reported that the majority of Ghanaian stones were not cholesterol rich. Furthermore, cholesterol stones were more common in females and only 34% of their stones contained 75% or more of cholesterol by weight. They also showed that the external appearance of the stone was a poor predictor of its composition[2]. This means that even in the poorer regions of the world, such as Sub-Saharan Africa, all attempts should be made to chemically analyze stones.

The treatment of gallstone diseases runs the gamut from bile salts dissolution, to fragmentation with laser[10], pulverization with extracorporeal shock wave lithotripsy[11], endoscopic

extraction, and classical surgery, whereas noninvasive medical therapy is appealing, bile acid therapy is only effective in some cholesterol gallstones. Bile acids are not effective in treating calcium bilirubinate or calcium carbonate/phosphate stones. It is therefore imperative that the composition of the stone be determined to tailor treatment for the individual patient[12].

To determine stone composition, there are many possibilities offered by different technologies. On simple X-ray, radiologically undetectable stone calcification reduces the probability of dissolution and calcified structures appearing in stones during treatment are composed of calcium carbonate. A radio-opaque stone would suggest that medical therapy is unlikely to succeed. Stone composition is also determined on computed tomography. Results from polarizing microscopy of gall bladder bile suggest that the presence of cholesterol crystals is a sensitive measure of cholesterol and vaterite microspheroliths confirm presence of calcium carbonate in the gallstone[13].

In the less technically developed areas the chemical composition of stones was determined from its external appearance. This has been shown to be inaccurate. Frequently the stones are homogenized and chemically analyzed. Our stones were analyzed with X-ray diffraction where cholesterol, calcium carbonate, and amorphous material were detected. The components of the amorphous material (bilirubine, glycerophosphates and bile salts) were not identifiable on X-ray diffraction. Infra-red spectroscopy and scanning electron microscopy were used to show that black and brown pigment gallstones differ in microstructure and micro-composition, suggesting that they form by different mechanisms. Black carbonate and brown stones layered structure suggests that stone growth is dependent on cyclical changes in biliary substances[14]. This may explain the permissive or causal role endogenous hormones have in gallstone formation[15] Stone formation begins with nucleation where the interaction of pronucleators and antinucleators leads to formation of cholesterol crystals and these develop into gallstones[6,16]. Hepatic cholesterol hypersecretion is associated with the increased unsaturated fatty acid proportion in biliary phospholipids and gallbladder mucin secretion, thereby causing rapid crystal nucleation[17]. It is evident that gallstone disease has a multifactorial causation, including gall bladder infection,[18] decreased gall bladder motility after surgery for obesity and/or weight loss[19], ileal disease (Crohn's)[20], hemolytic diseases[2], familial hypercholesterolemia[21], and metabolic defects in hepatic bilirubin glucuronidation[22].

A shortcoming in our study is the absence of hemoglobin electrophoresis in a population where the prevalence of the sickle trait varies between 10% and 20% and that of the disease is about 1%[2]. We did not explore many of the risk factors mentioned above largely due to technical and financial limitations. The absence of calcium in the stones of 22 (84.61%) patients correlates with a small number of gallstones detected on plain X-ray of the abdomen in our region. The extremely infrequent occurrence of pure cholesterol gallstones is a strong argument against the introduction of oral dissolution agents in SSA.

CONCLUSION

There is a corresponding variation in prevalence of cholesterol rich stones as a variation in composition of gallstones. This variation seems to be related to genes and the environment. Stone composition determines the therapeutic approaches in each locality. This pilot study suggests that oral bile salt dissolution therapy would not be effective in 70% of our patients. As populations in SSA undergo epidemiologic transition from infectious diseases to noncommunicable diseases, there will be increasing prevalence of biliary lithiasis.

Abstract

AIM: To evaluate if HB vaccination can yield a booster effect on the anti-HBs level of those naturally acquired HBV positive markers.

METHODS: Sera were collected from 1399 newly enrolled university students aged between 18-20 years at the entrance medical examination in 2001. Forty-four students (28 males and 16 females) with positive serum anti-HBs and anti-HBc markers served as an observation group and another 44 students (24 males and 20 females) without any HBV markers as the control. HB vaccination was given to all the students without positive serum HBsAg according to 0, 1, 6 month regimen and the peripheral venous blood was sampled from those of both observation and control groups for anti-HBs detection one month after the second and third doses. Anti-HBs levels were measured by ELISA.

RESULTS: The seroconversion rate of anti-HBs in the control group was 100% after the second dose, but the geometric mean titers (GMTs) were low. The tendency of serum anti-HBs changes after the 3rd dose was completely different between the two groups. Although more than half of those with positive anti-HBs and anti-HBc showed a mild increase of anti-HBs levels after the 2nd boosting dose (mean anti-HBs level was 320:198 mIU), but the increase of serum anti-HBs titer was much smaller than that in the control group. The averages of their initial serum anti-HBs levels and the levels after the 2nd and 3rd doses were 198, 320 and 275 mIU respectively. All the subjects from the control group had an obvious increase in their serum anti-HBs levels which was nearly 4 times the baseline level (302:78 mIU).

CONCLUSION: HB vaccination can not enhance anti-HBs levels in those with positive serum anti-HBs and anti-HBc markers.

INTRODUCTION

HB vaccination program has been well developed for neonates and younger adults in China. Nowadays, according to Chinese regulation all the newly enrolled university students are required to have their blood detected for HBsAg and those with negative HBsAg are eligible to receive HB vaccination. Since it has been well demonstrated that an additional dose can induce a booster effect on vaccinees' serum anti-HBs titers, it is natural for most people to get the idea that the more doses they get, the more benefits they will gain. Our previous survey in a group of university students showed that HBsAg carrier rate in those of the 18-20 age group was about 4-6% and when gained entrance to the university more than 50% students with positive serum anti-HBs or anti-HBc or both were vaccinated each year. Is it necessary to vaccinate the people with positive anti-HBc and anti-HBs markers? To answer this question, we followed up the newly enrolled students from a university to observe the changes of their serum anti-HBs titers after HB vaccination, especially those with positive serum anti-HBs and anti-HBc markers before. The changes of serum anti-HBs titers in students without any HBV markers before the vaccination were observed after HB vaccination as the experimental control. The results might be helpful for the establishment of a scientific, reasonable and economic vaccination program against HBV infection in the adult population.

MATERIALS AND METHODS

Reagents

Ten μg of yeast recombinant HB vaccine (Lot No: 2990104-1) was produced in Kangtai Biological Pharmaceutical Company, China. ELISA kits of HBV markers were from Sino-American Biotechnology Company, Luoyang, China. ELISA kit of Measles antibody was provided by Institute of Virus, Chinese Center of Disease Control and Prevention, Beijing, China.

Subjects and vaccination methods

Forty-four students with positive serum anti-HBs and anti-HBc and 44 without any HB markers who experienced a regular medical examination in one college were selected to be investigated after vaccinated with HB vaccine according to 0, 1, 6 month scheme, in which the vaccine was intramuscularly injected into the deltoid muscle. All the subjects were also injected measles vaccine one week before the first dose of HB vaccination. An informed consent was given by each participant before the beginning of observation.

Determination of serum anti-HBs antibody

Serum anti-HBs antibody was measured respectively at one

month after the 2nd and 3rd doses of HB vaccine. The sera were randomly chosen from 35 subjects with positive anti-HBs and anti-HBc to measure the antibodies (IgG) to both measles and HBsAg according to the manufacturer's instructions. The resulting value was determined according to Holliger formula: mIU=418×[EXP×0.9(S-N)/(P-N)-1] in the light of OD values. mIU of anti-HBs titers greater than 10 was considered as positive anti-HBs. *t* test was used to compare GMTs between groups and the difference was considered significant when *P*<0.05.

RESULTS

Anti-HBs titers before and after HB vaccination in those with positive anti-HBs and anti-HBc

The tendency of serum anti-HBs changes after the 3rd dose was completely different between the two groups. Although more than half of those with positive anti-HBs and anti-HBc markers showed a mild increase of serum anti-HBs titer after the 2nd booster dose, the increase of serum anti-HBs titer (mean anti-HBs level was 198:320 mIU) was much smaller than that in the control group, in which 100% subjects had an obvious increase in their serum anti-HBs levels which was nearly 4 times their baseline (302:78 mIU).

It was interesting to note that the serum anti-HBs levels did not change in most of the subjects with positive anti-HBs and anti-HBc markers after the 3rd dose. The mean serum anti-HBs level of the baseline, after the 2nd and 3rd doses was 198, 320 and 275 mIU (Table 1) respectively.

Effect of a boost dose on antibody titers of HBsAb and measles Ab

In order to confirm that all the subjects in this study had a normal immune competence, the serum antibodies to measles were detected in 35 subjects and an increased antibody level was observed in 91.4% (32/35) subjects after a booster dose. A comparison of antibody levels before and after a booster dose was made and the difference was statistically significant (*P*<0.05, Table 2).

Table 2 Effect of a boost on antibody titers of HBsAb and measles Ab

Boost	A-HBsAb		B-HBsAb		C-HBsAb		MealsesAb	
	No.	GMT	No.	GMT	No.	GMT	No.	GMT

After	44	320	44	275	44	302	35	1 207

Comparison of anti-HBs induced by HB vaccination before and after a boost in HBV negative group, *P*<0.05.

DISCUSSION

Hepatitis B vaccination has been implemented for 20 years, however, the disease remains a global problem[1-4]. Although the safety and efficacy of HB vaccine have been well demonstrated[5-16], few papers regarding the immune response of those with positive anti-HBs and anti-HBc to HB vaccination are available. In this study, we observed if a booster effect and a better protection against HBV infection could be obtained after HB vaccination in those with positive serum anti-HBs and anti-HBc markers.

It has been well demonstrated that the HB vaccine-induced antibody might gradually decline or was even undetectable some years after primary immunization[17-20]. It is not clear if such persons could be protected against HB infection following exposure to HBV[21]. Although some studies have proved that memory cells to HBsAg might exist in vaccinees for a long time even the serum anti-HBs was undetectable[19,22,23]. Whether additional booster doses should be used has been under discussion[17-20,23-25]. Considering the available data on measles vaccine, which showed that loss of detectable antibody following vaccination was correlated with the waning of immunity[26], a booster HB vaccination might be necessary.

Our data revealed that the serum anti-HBs levels in the subjects with positive serum anti-HBs and anti-HBc markers did not significantly increase one month after the 2nd dose of HB vaccination. Although a mild increase was seen in some cases, the elevation of serum anti-HBs levels in the observatory

group was much less than that in the control in which 100% subjects had an obvious increase of serum anti-HBs levels that was nearly 4 times their baseline. After the 3rd dose, anti-HBs levels remained unchanged in most of the subjects with positive serum anti-HBs and anti-HBc markers compared with that in the control, in which a sharp increase of serum anti-HBs levels was observed after the 3rd dose. The phenomenon might be related to the following possibilities. First, the subjects with positive serum anti-HBs and anti-HBc markers before the vaccination might not be in a normal condition of immune competence during the observation period. In the present study, their increased response to measles after the booster dose was observed in 91.4% (32/35) subjects. Because measles vaccination has been well practiced in China and normally all the subjects have to be vaccinated in their early age, the increased immunological response could prove that the subjects had the normal immune competence. Second, the immune response to viruses can damage the host via the formation of immune complexes, or directly damage the infected cells. Thus, the poor response to the HB vaccine might probably relate to the damage caused by HBV before the vaccination.

HB vaccination program is implemented in children and adults in China. But the problem is that our current vaccination regimen is not completely suitable for adult vaccination. An appropriate vaccination program for the adult population has to be established to prevent the prevalence of HBV. Our results indicate that it is not necessary to vaccinate those with positive serum anti-HBs and anti-HBc because no significant increase of anti-HBs titers was observed after a standard HB vaccination. It suggests that the vaccine-induced anti-HBs can not be elevated in those infected with HBV naturally before the HB vaccination.

Abstract

Historically, mast cells were known as a key cell type involved in type I hypersensitivity. Until last two decades, this cell type was recognized to be widely involved in a number of non-allergic diseases including inflammatory bowel disease (IBD). Markedly increased numbers of mast cells were observed in the mucosa of the ileum and colon of patients with IBD, which was accompanied by great changes of the content in mast cells such as dramatically increased expression of TNFα, IL-16 and substance P. The evidence of mast cell degranulation was found in the wall of intestine from patients with IBD with immunohistochemistry technique. The highly elevated histamine and tryptase levels were detected in mucosa of patients with IBD, strongly suggesting that mast cell degranulation is involved in the pathogenesis of IBD. However, little is known of the actions of histamine, tryptase, chymase and carboxypeptidase in IBD. Over the last decade, heparin has been used to treat IBD in clinical practice. The low molecular weight heparin (LMWH) was effective as adjuvant therapy, and the patients showed good clinical and laboratory response with no serious adverse effects. The roles of PGD2, LTC4, PAF and mast cell cytokines in IBD were also discussed. Recently, a series of experiments with dispersed colon mast cells suggested there should be at least two pathways in man for mast cells to amplify their own activation-degranulation signals in an autocrine or paracrine manner. The hypothesis is that mast cell secretogogues induce mast cell degranulation, release histamine, then stimulate the adjacent mast cells or positively feedback to further stimulate its host mast cells through H_1 receptor. Whereas released tryptase acts similarly to histamine, but activates mast cells through its receptor PAR-2. The connections between current anti-IBD therapies or potential therapies for IBD with mast cells were discussed, implicating further that mast cell is a key cell type that is involved in the pathogenesis of IBD. In conclusion, while pathogenesis of IBD remains unclear, the key role of mast cells in this group of diseases demonstrated in the current review implicates strongly that IBD is a mast cell associated disease. Therefore, close attentions should be paid to the role of mast cells in IBD.

INTRODUCTION

Historically, mast cells were known as a key cell type involved in type I hypersensitivity[1]. Until last two decades, this cell type was recognized to be widely involved in a number of non-allergic diseases in internal medicine including chronic obstructive pulmonary disease (COPD), Crohn's disease, ulcerative colitis, liver cirrhosis, cardiomyopathy, multiple sclerosis and rheumatoid arthritis, *etc*. (Table 1). This article will focus solely on the relationships between mast cells and inflammatory bowel disease, give evidence for a hypothesis of self-amplification mechanism of mast cell degranulation in gut and discuss the potential therapies for the treatment of inflammatory bowel disease (IBD).

Table 1 Mast cells involved in non-allergic diseases in internal medicine

Disease	Evidence
Chronic obstructive pulmonary disease (COPD)	Mast cell hyperplasia in epithelia and bronchial glands[2,3], tryptase and histamine release in BALF[4]
Cor pulmonale	Mast cell hyperplasia in bronchial and vascular tissues[5]
Bronchiectasis	Increased numbers of degranulated mast cells in lung tissue, and higher tryptase concentrations in BALF[6]
Acute respiratory distress syndrome (ARDS)	Mast cell hyperplasia[7] and degranulation[8]
Bronchiolitis obliterans-organizing pneumonia	Mast cell hyperplasia[9] and degranulation[10]
Cystic fibrosis	Mast cell hyperplasia[11] and degranulation[12] in lung
Interstitial lung diseases	Mast cell hyperplasia[13] and degranulation[14]
Silicosis	Mast cell hyperplasia[15]
Sarcoidosis	Mast cell hyperplasia[16], and degranulation[17] in lung
Lung cancer	Mast cell hyperplasia[18]
Tuberculosis	Mast cell degranulation[19]
Gastritis	Mast cell hyperplasia[20] and degranulation[21]
Peptic ulcer	Mast cell hyperplasia[22] and degranulation[23]
Hepatocellular carcinoma	Mast cell hyperplasia[24]
Ulcerative colitis	Mast cell hyperplasia[25,26] and degranulation[27]
Crohn's disease	Mast cell hyperplasia[28] and degranulation[29]
Liver cirrhosis	Mast cell hyperplasia[30]
Hepatitis	Mast cell hyperplasia[31,32]
Pancreatitis	Mast cell hyperplasia and degranulation[33]
Atherosclerosis	Mast cell hyperplasia[34]
Myocardial infarction	Mast cell hyperplasia and degranulation[35,36]
Congenital heart disease	Mast cell hyperplasia and subtype change[37]
Myocarditis	Mast cell hyperplasia[38]
Cardiomyopathy	Mast cell hyperplasia[39] and degranulation[40]
Diabetes	Mast cell hyperplasia[41]
Thyroiditis	Mast cell hyperplasia[42]
Osteoporosis	Mast cell hyperplasia[43]
Glomerulonephritis	Mast cell hyperplasia[44]
Nephropathy	Mast cell hyperplasia[45]
Multiple sclerosis	Mast cell hyperplasia[46]
Rheumatoid arthritis	Mast cell degranulation[47]
Osteoarthritis	Mast cell hyperplasia[48]
Rheumatic arthritis	Mast cell hyperplasia[49]

MAST CELLS

Morphology

Mast cell is the cell that contains numerous metachromatically stained basophilic granules in its cytoplasm. It has various sizes between species with diameters of up to 30 μm reported in humans, and from 3.5 μm to 22 μm in rodents[28,50]. In human lung, for example, the range of mast cell diameters has been reported to be between 9.9 μm and 18.4 μm[51] and in human skin between 4 μm and 18 μm[52]. The shape of mast cell varies as well, it has been described as polyhedral, fusiform, ovoid, and rectangular, and appears dependent on tissue locations. Mast cell nuclei are usually round or oval and have peripherally dispersed heterochromatin[53].

Up to 40% of the volume of mast cell is occupied by membrane-enclosed secretory granules[54]. There are 50 to 500 secretory granules in one mature human mast cell, each with a diameter ranging from 0.2 to 0.5 μm. Within a given mast cell, these granules are usually of a uniform size, but there is variability from cell to cell[55]. Mast cell granules originate from the Golgi apparatus, which is responsible for the synthesis and organization of the preformed mediators contained therein[56].

Mediators

Upon activation mast cell can release its mediators to fulfill its biological functions. Among preformed mediators, histamine is a primary amine synthesized from histidine in the Golgi apparatus, from where it is transported to the granule for storage in ionic association with the acidic residues of glycosaminoglycans side chains of heparin and proteinases[57,58]. The histamine content of mast cells dispersed from human lung and skin is similar at 2 to 5 pg/cell, and the stored histamine ranges from 10 to 12 μg/g in both tissues[53]. As only mast cell and basophil contain histamine in man, and few basophils in human tissue histamine can be used as a marker of mast cell degranulation.

Proteoglycans in human mast cells include heparin and chondroitin sulphate, which contains several highly sulphated glycosaminoglycan side chains attached to a single chain protein core. They comprise the major supporting matrix of the mast cell granule with the sulphate groups binding to histamine, proteinases and acid hydrolases.

Neutral proteases of mast cells are also preformed mediators. Three mast cell unique neutral proteinases (tryptase, chymase and carboxypeptidase) have been isolated in man and there is evidence also for a proteinase with antigenic and enzymatic properties similar to those of neutrophil cathepsin G in mast cells[59,60]. Mast cell tryptase, chymase and carboxypeptidase are reliable markers of mast cell degranulation. Based on their content of proteinases, mast cells can be classified into two types in man, with MC_T cells defined as those containing tryptase but not chymase, and MC_{TC} cells as those containing both tryptase and chymase[61]. Subsequently both carboxypeptidase[62] and cathepsin G like proteases[63,64] have been found to be localised exclusively in the MC_{TC} population.

Newly generated mediators include eicosanoids and platelet activating factor (PAF). Eicosanoids are a group of newly generated mediators of mast cells. Immunological activation of mast cells results in the liberation of arachidonic acid from phospholipids in the cell membrane. This 20-carbon fatty acid is then rapidly oxidized along either of two independent pathways, namely the cyclooxygenase pathway to form PGD_2 and the lipoxygenase pathway to form LTC_4. These are the only two eicosanoids produced by human mast cells[65]. PAF is also a product of phospholipid metabolism in mast cells.

Mast cell cytokines may constitute a third category in that they may be both preformed and newly synthesized. For instance, it has been reported that approximately 75%, 10%, 35%, and 35% of mast cells contain IL-4, IL-5, IL-6 and TNFα, respectively in the nasal mucosa and bronchus[66]. Mast cell contains also IL-1β, IL-3, IL-8, IL-9, IL-10, IL-13, IL-16, IL-18, IL-25, granulocyte-macrophage colony-stimulating factor (GM-CSF), stem cell factor macrophage chemotactic peptide (MCP)-1, 3, 4, regulated on activation of normal T cell-expressed and secreted protein (RANTES) and eotaxin[67].

Mast cell activation

Mast cell activation is a crucial step in mast cell involved events because it seems that only activated mast cells are able to cause pathophysiological changes. There are a number of compounds that can activate mast cells. They are antigens, anti-IgE and ionophores. Skin mast cells but not those of lung, tonsil or gut can be activated by other diverse compounds including substance P, VIP, C5a and C3a, somatostatin, compound 48/80, morphine, pepstatin, MBP, PAF, platelet factor 4 and very-low-density lipoproteins[68,53]. Stem cell factor[69], eosinophil cationic protein[70] and tryptase[71] have also been found to be able to activate human mast cells.

The mechanisms of mast cell activation differ with different classes of triggers. Human skin mast cells are able to respond to non-crosslinking stimuli, such as neuropeptides, morphine, and complement fragments[68]. IgE-dependent mast cell activation is a complicated process. It involves a specific IgE bound to its high affinity receptor (FcεR1) on the surface of mast cells, a multivalent antigen (Ag) crosslinking specific IgEs bound to FceR1 and a signal transduction and translation process in mast cells.

Models for mast cell degranulation

While normal human mast cell line is not available, dispersed and purified mast cells are essential for investigating mast cell functions. Human mast cells have been dispersed from skin, lung, tonsil, synovium heart and intestine tissues by incubation with collagenase and hyaluronidase. These dispersed cells have appreciable morphological and functional properties of mast cells. Since dispersed cells can be evenly distributed in experiment, it is the most popular method at present. However, the purity of mast cells with this system is only 0.5-10% depending on tissues.

Chopped tissue fragments were also used for mast cell degranulation study. We found that it was difficult to evenly distribute cells in tissue fragments, therefore causing large experimental errors.

Laboratory animal tissues or mast cells are widely used in mast cell degranulation study. Thus, rat and mouse peritoneum, guinea pig lung and cultured mouse bone marrow derived mast cells are the most popular models. However, it is always adequate to use human mast cells to investigate the pathophysiological process of human disease.

INCREASED NUMBERS OF MAST CELLS IN IBD

As early as in 1980, Dvorak and colleagues[28] reported that the number of mast cells was markedly increased in the involved area of the ileum of patients with Crohn's disease. In 1990, Nolte et al.[72] found that the mast cell count in patients with ulcerative colitis was increased compared with that in control subjects and patients with Crohn's disease. In an individual patient, the mast cell count obtained from inflamed tissue was greater than that of normal tissue. This finding was taken further by King et al.[26] in 1992 that the number of mast cells in active ulcerative colitis was 6.3 in active inflammation, 19.5 at the line of demarcation and 15.8 in normal mucosa. The accumulation of mast cells at the visible line of demarcation between normal and abnormal mucosa suggested that mast cells played a crucial role in the pathogenesis of the disease, either causing further damage or limiting the expansion of damage. Recently, a report[73] provided us an even more convincing evidence and clear picture on the elevated number

of mast cells in inflammatory bowel disease. Nishida and colleagues found that there were greater numbers of mast cells than macrophages in the lamina propria of patients with inflammatory bowel disease though this was not found in patients with collagenous colitis. Interestingly, increased numbers of mast cells were observed throughout the lamina propria, particularly in the upper part of lamina propria, whereas increased numbers of macrophages were only seen in the lower part of lamina propria in patients with inflammatory bowel disease. This could result from that accumulated mast cells released their proinflammatory mediators, and these mediators, at least tryptase[74] and chymase[75], induced macrophage accumulation in the lower part of lamina propria. Dramatically increased numbers of mast cells were also observed in the hypertrophied and fibrotic muscularis propria of strictures in Crohn's disease compared with normal bowel (81.3/mm^2 vs 1.5/mm^2)[76].

Not only the number of mast cells was elevated[77], but also the contents of mast cells were greatly changed in inflammatory bowel disease in comparison with normal subjects. Laminin, a multi-functional non-collagenous glycoprotein, which is normally found in extracellular matrix was detected in mast cells in muscularis propria (but not those in submucosa), indicating that mast cells may be actively involved in the tissue remodeling in Crohn's disease[76]. Similarly, the number of TNF-α positive mast cells was greater in the muscularis propria of patients with Crohn's disease than that in normal controls[78]. In the submucosa of involved ileal wall of Crohn's disease, more TNF-α positive mast cells were found in inflamed area than uninflamed area. Since those TNF-α positive mast cells were mail cell type that expressed TNF-α in ileal wall, the successful treatment of Crohn's disease with anti-TNF-α antibody could well be the consequence that the antibody neutralized the excessively secreted TNF-α from mast cells. This indirectly proved the important contribution of mast cells to the development of Crohn's disease. Increased number of IL-16 positive mast cells, which was correlated well with increased number of CD4$^+$ lymphocytes, was also observed in active Crohn's disease[79], indicating that this chemokine may selectively attract CD4$^+$ lymphocytes to the involved inflammatory area[80,81]. In chronic ulcerative colitis, increased number of substance P positive mast cells was observed in gut wall, particularly in mucosa[82], indicating the possibility of neuronal elements being involved in the pathogenesis of the disease.

Increased number of mast cells was also seen in a number of diseases closely related to inflammatory bowel disease. Primary sclerosing cholangitis and chronic sclerosing sialadenitis showed similar marked mast cell infiltration pattern with inflammatory bowel disease[83]. Focal active gastritis is a typical pathological change in Crohn's disease[84], in which large number of mast cells accumulate at the border of the lesions[20]. In the animal models, increased number of mast cells in gastrointestinal tract was observed in dogs with inflammatory bowel disease in comparison with healthy dogs[85]. When given 3% dextran sulphate sodium for 10 days[86] or water avoidance stress for 5 days[87], pathological changes such as mucosal damage and edema were developed in rats, and these were accompanied by mast cell hyperplasia and activation. However, the same treatment had little effect on mast cell deficient Ws/Ws rats, implying the importance of mast cells in the development of inflammatory bowel disease.

EVIDENCE OF MAST CELL DEGRANULATION IN IBD

As early as in 1975, Lloyd and colleagues observed that there were marked degranulation of mast cells and IgE-containing cells in the bowel wall of patients with Crohn's disease[29], and this observation later became an important investigation area for understanding the pathogenesis of Crohn's disease. In 1980, Dvorak et al. described in more detail the degranulation of mast cells in the ileum of patients with Crohn's disease[28] with transmission electron microscopy technique. Similarly, with electron microscopy technique, degranulation of mast cells was seen in the intestinal biopsies of patients with ulcerative colitis[88]. Using immunohistochemistry technique with antibodies specific to human tryptase or chymase, both of which are exclusive antigens of human mast cells, mast cell degranulation was found in the mucosa of bowel walls of patients with Crohn's disease, ulcerative colitis[89] and chronic inflammatory duodenal bowel disorders[90].

INVOLVEMENT OF HISTAMINE IN PATHOGENESIS OF IBD

Using segmental jejunal perfusion system with a two-balloon, six channel small tube, Knutson and colleagues found that the histamine secretion rate was increased in patients with Crohn's disease compared with normal controls, and the secretion of histamine was related to the disease activity, indicating strongly that degranulation of mast cells was involved in active Crohn's disease[91]. The highly elevated mucosal histamine levels were also observed in patients with allergic enteropathy and ulcerative colitis[27]. Moreover, enhanced histamine metabolism was found in patients with collagenous colitis and food allergy[92], and increased level of N-methylhistamine, a stable metabolite of the mast cell mediator histamine, was detected in the urine of patients with active Crohn's disease or ulcerative colitis[93,94]. Since increased level of N-methylhistamine was significantly correlated to clinical disease activity, the above finding further strongly suggested the active involvement of histamine in the pathogenesis of these diseases.

Interestingly, mast cells originated from the resected colon of patients with active Crohn's disease or ulcerative colitis were able to release more histamine than those from normal colon when being stimulated with an antigen, colon derived murine epithelial cell associated compounds[95]. Similarly, cultured colonrectal endoscopic samples from patients with IBD secreted more histamine towards substance P alone or substance P with anti-IgE than the samples from normal control subjects under the same stimulation[96]. In a guinea pig model of intestinal inflammation induced by cow's milk proteins and trinitrobenzenesulfonic acid, both IgE titers and histamine levels were higher than normal control animals[97].

As a proinflammatory mediator, histamine is selectively located in the granules of human mast cells and basophils and released from these cells upon degranulation. To date, a total of four histamine receptors H_1, H_2, H_3 and H_4 have been discovered[98] and the first three of them have been located in human gut[99,100], proving that there are some specific targets on which histamine can work in intestinal tract. Histamine was found to cause a transient concentration-dependent increase in short-circuit current, a measure of total ion transport across the epithelial tissue in gut[101]. This could be due to the interaction of histamine with H_1-receptors that increased Na and Cl ions secretion from epithelium[102]. The finding that H_1-receptor antagonist pyrilamine was able to inhibit anti-IgE induced histamine release and ion transport[103] suggests further that histamine is a crucial mediator responsible for diarrhea in IBD and food allergy. The ability of SR140333, a potent NK1 antagonist in reducing mucosal ion transport was most likely due to its inhibitory actions on histamine release from colon mast cells[104].

INVOLVEMENT OF MAST CELL PROTEASES IN PATHOGENESIS OF IBD

Tryptase is a tetrameric serine proteinase that constitutes some

20% of the total protein within human mast cells and is stored almost exclusively in the secretory granules of mast cells[105] in a catalytically active form[106]. The ability of tryptase to induce microvascular leakage in the skin of guinea pig[107], to accumulate inflammatory cells in the peritoneum of mouse[74] and to stimulate release of IL-8 from epithelial cells[108], and the evidence that relatively higher secretion of tryptase has been detected in ulcerative colitis[109] implicated that this mediator is involved in the pathogenesis of intestinal diseases. However, little is known about its actions in IBD. Recently, proteinase activated receptor (PAR)-2, a highly expressed receptor in human intestine[110] was recognized as a receptor of human mast cell tryptase[111]. Colonic administration of PAR-2 agonists up-regulated PAR-2 expression, induced granulocyte infiltration, colon wall edema and damage and stimulated an increased paracellular permeability of colon mucosa[112]. PAR-2 agonists were also able to stimulate intestinal electrolyte secretion[113]. Interestingly, some 60% and 46% of mast cells in ulcerative colitis tissues expressed PAR-2 or TNF-α, respectively. PAR-2 agonists were able to stimulate TNF-α secretion from mast cells[114] and secreted TNF-α could then enhance PAR-2 expression in a positive feedback manner[113]. These findings indicated further the importance of TNF-α and mast cells in the pathogenesis of IBD.

Chymase is a serine proteinase exclusively located in the same granules as tryptase and could be released from granules together with other preformed mediators. Large quantity of active form chymase (10 pg per mast cell) in mast cells[115] implicates that this mast cell unique mediator may play a role in mast cell related diseases. Indeed, chymase has been found to be able to induce microvascular leakage in the skin of guinea pig[116], stimulate inflammatory cell accumulation in peritoneum of mouse[75], and alter epithelial cell monolayer permeability *in vitro*[117]. However, little is known about its actions in IBD. Mast cell carboxypeptidase is a unique product of MC_{TC} subtype mast cells. There is some 10 pg in each mast cells. No information about the relationship between mast cell carboxypeptidase and IBD is available, but the successful coloning of mast cell carboxypeptidase from human gut tissue and obtaining of recombinant human mast cell carboxypeptidase [chen 2004] will certainly help to initiate the investigation of the role of mast cell carboxypeptidase in IBD. It is astonished to learn the fact that the potential roles of mast cell neutral proteinases in IBD have been almost completely ignored till today. Since they are the most abundant granule products of mast cells and have been demonstrated to possess important actions in inflammation, they should certainly contribute to the occurrence and development of IBD.

INVOLVEMENT OF HEPARIN IN PATHOGENESIS OF IBD

Over the last decade, heparin, a unique product of human mast cells and basophils, has been used to treat IBD in clinical practice. Using combined heparin and sulfasalazine therapy, Gaffney and colleagues successfully treated 10 patients with ulcerative colitis poorly controlled on sulfasalazine and prednisolone[119]. Similarly, Evans *et al.* found that heparin was effective in treating corticosteroid-resistant ulcerative colitis[120], and Yoshikane *et al.* reported that heparin was very effective in the treatment of disseminated intravascular coagulation (DIC) caused by ulcerative colitis[121]. Recently, heparin was even suggested as a first line therapy in the treatment of severe colonic inflammatory bowel disease[122], but should be administered in hospitalized patients only because of the risk of possible serious bleeding[123]. To overcome bleeding side effect, low molecular weight heparin (LMWH) was employed as adjuvant therapy[124], and the patients showed good clinical and laboratory response with

no severe adverse effects[125,126].

Apart from anticoagulation activity, the mechanisms by which heparin was able to treat IBD were considered to include its ability to inhibit the recruitment of neutrophils, reduce production of pro-inflammatory cytokines[127] and restore the high-affinity receptor binding of antiulcerogenic growth factor[128,129]. The ability of heparin to inhibit neutrophil activation, adhesion, and chemotaxis was also found in a mouse model of inflammatory bowel disorder[130,131], suggesting that balanced interactions between mast cells and neutrophils might be important for the development of IBD. In rat models of IBD, heparin revealed its ability to attenuate TNF-α induced leucocyte rolling and CD11b dependent adhesion[132], reduce serum IL-6 level and improve microcirculatory disturbance in rectal walls[133,134]. Thus, preformed mast cell mediators seemed to have dual actions on the pathogenesis of IBD. On the one hand, tryptase, histamine, and TNF-α can cause damage in the intestinal wall, and on the other hand, heparin can protect the intestinal wall from damage.

INVOLVEMENT OF PGD2, LTC4 AND PAF IN PATHOGENESIS OF IBD

It was reported that mast cells in the actively involved areas of ulcerative colitis released greater amount of PGD2, in parallel to histamine and LTC4[135]. In a rat experimental colitis model, the time for stimulating PGD2 release was initiated within 1 h and increased 4 fold within 3 h[136]. This was accompanied by a significant granulocyte infiltration, indicating the likelihood of involvement of PGD2 in IBD. The basal release of LTC4 was enhanced in the gut of Crohn's disease patients[137], but the meaning of this enhancement still remains uninvestigated.

It was found that mast cell activators, calcium ionophore A23187 and anti-IgE, were able to stimulate more PAF release from colon with ulcerative colitis than from normal colon, and this increased PAF release could be inhibited by steroids and 5-aminosalicylic acid[138,139]. The increased secretion of PAF was detected in the stool of patients with active Crohn's disease, but not in that of patients with irritable bowel syndrome[140]. The level of PAF was also higher in colonic mucosa of patients with Crohn's disease than in colonic mucosa of healthy controls[141]. These indicated that PAF might be involved in the pathogenesis of Crohn's disease[142]. The elevated level of PAF in colon was likely to be the result of increased production by colonic epithelial cells[143], lamina propria mononuclear cells[144] and mast cells, and decreased PAF acetylhydrolase (the major PAF degradation enzyme activity)[145]. In patients with ulcerative colitis, colonic production of PAF was increased in comparison with control patients[146], and the level of PAF in the stool of patients with ulcerative colitis was much higher than that in the stool of healthy volunteers[147]. Since increased colonic production of PAF was correlated to local injury and inflammation[146], it implicats strongly that PAF is involved in the pathogenesis of ulcerative colitis. However, a randomized controlled trial with a specific PAF antagonist SR27417A showed that this compound had no significant effect on patients with active ulcerative colitis though it was safe in humans[148].

INVOLVEMENT OF CYTOKINES IN PATHOGENESIS OF IBD

Dozens of proinflammatory cytokines were reported to be involved in the pathogenesis of IBD, but only several of them have been considered to be therapeutic targets. TNF-α was considered being secreted mainly from intestinal mast cells in IBD[78], and bacteria and anti-IgE were able to substantially enhance their release from mast cells[149]. The released mast cell products TNF-α and histamine could then synergistically stimulate ion secretion from intestinal epithelium[150]. The anti-

TNFα therapy will be described below. In IBD, most intestinal mast cells produce IL-3, and this increased expression of IL-3 could be inhibited by administration of steroid[151]. IL-10, a cytokine which can be produced by human mast cells[152], was reported to have some anti-inflammatory role in IBD[153]. However, the results from clinical trials were heterogeneous[154]. IL-1 was found to be excessively released from patients with ulcerative colitis and could stimulate the short-circuit current response to IL-1[155]. As for IL-3, steroid could significantly inhibit IL-1 release in IBD[156]. Mast cells from healthy controls did not produce IL-5, but mast cells from patients with intestinal inflammatory disease could release a relatively large amount of IL-5[157]. However, the effect of IL-5 on IBD needs to be investigated. It is still in early days to understand the role of cytokines in IBD, therefore it is difficult to draw a conclusive line on the issue whether cytokine related therapy is beneficial for IBD.

HYPOTHESIS OF SELF-AMPLIFICATION MECHANISM OF MAST CELL DEGRANULATION IN GUT

Tryptase has been proved to be a unique marker of mast cell degranulation *in vitro* as it is more selective than histamine to mast cells. Inhibitors of tryptase[71,158] and chymase[159] have been discovered to possess the ability to inhibit histamine or tryptase release from human skin, tonsil, synovial[160] and colon mast cells[161,162], suggesting that they are likely to be developed as a novel class of mast cell stabilizers. Recently, a series of experiments with dispersed colon mast cells suggested there should be at least two pathways in man for mast cells to amplify their own activation-degranulation signals in an autocrine or paracrine manner, which may partially explain the phenomena that when a sensitized individual contacts allergen only once the local allergic response in the involved tissue or organ may last for days or weeks. These findings included both anti-IgE and calcium ionophore were able to induce significant release of tryptase and histamine from colon mast cells[163], histamine was a potent activator of human colon mast cells[164] and the agonists of PAR-2 and trypsin were potent secretagogues of human colon mast cells[165]. Since tryptase was reported to be able to activate human mast cells[71] and H_1 receptor antagonists terfenadine and cetirizine[166] were capable of inhibiting mast cell activation, the hypothesis of mast cell degranulation self-amplification mechanisms is that mast cell secretogogues induce mast cell degranulation, release histamine, then stimulate the adjacent mast cells or positively feedback to further stimulate its host mast cells through H_1 receptor, whereas released tryptase acts similarly to histamine through its receptor PAR-2 on mast cells (Figure 1).

Figure 1 Hypothesis of self-amplification mechanism of mast cell degranulation in gut.

Figure 2 Association of mast cells with IBD therapies.

Figure 3 Balance between "pro-inflammatory" and "anti-inflammatory" mast cell mediators in IBD.

RELATIONSHIP BETWEEN THERAPIES FOR IBD AND MAST CELLS

Although aminosalicylates and corticosteroids remain the mainstream therapeutic drugs for the treatment of IBD[167], the mast cell related therapy should be given some close attentions. Besides heparin therapy mentioned above, anti-TNFα monoclonal antibody[168,169], infliximab in particular[170] showed promising results in treating Crohn's disease. Thalidomide, an agent with antiangiogenic and immunomodulatory properties[171], possessed inhibitory activity towards TNFα[172] and was therapeutically effective in IBD[173]. Mast cell tryptase inhibitor APC2059 was also effective and safe in treating ulcerative colitis[174]. Even 5-aminosalicylic acid, an aminosalicylate drug was an effective inhibitor of anti-IgE induced histamine and PGD2 release from human intestinal mast cells[175]. Thus the beneficial effects of 5-aminosalicylic acid on IBD were at least partially due to its mast cell stabilizing activity. Similarly, the effective treatment of IBD by corticosteroids might also be partially associated with its action on mast cells as significantly reduced numbers of mast cells were observed in the colon throughout steroid therapy[176].

The ineffective treatment of ulcerative colitis by mast cell stabilizer, cromolyn sodium[177] was most likely due to the drug that did not affect release of histamine from colon mast cells[178]. However, it was recently found to be effective in treating chronic or recurrent enterocolitis in patients with Hirschsprung's disease[179]. In 1992, Eliakim and colleagues found that ketotifen, a mast cell stabilizer, was able to significantly decrease mucosal damage of ulcerative colitis in an experimental colitis model[180] and inhibit accumulation of PGE2, ITB4 and LTC4 in ulcerative colitis colon mucosa organ-culture[181], suggesting that this anti-asthma drug may be useful for the treatment of IBD. Indeed, ketotifen was revealed to be effective in treating IBD with 5-aminosalicylate intolerance[182], and acute ulcerative colitis in

children[183], most likely through inhibition of mast cell and neutrophil degranulation[184].

It was surprising to learn that even immunomodulatory drug methotrexate, which showed promise in Crohn's disease therapy[185] was able to inhibit heparin synthesis in mast cells[186], suggesting that the beneficial action of methotrexate on Crohn's disease might be due to the reduction of heparin secretion from mast cells. Nicotine, an addictive component of tobacco, had a dual effect on IBD. It could ameliorate disease activity of ulcerative colitis but deteriorate disease process of Crohn's disease[187]. Since nicotine was reported to be able to induce degranulation of mast cells[188], its dual action on IBD could be related to the locally imbalanced quantities of mast cell products, such as histamine and heparin. The association of these therapies with mast cells strongly indicates that mast cells are key cells in the development of IBD (Figure 2).

CONCLUSION

Mast cells are a key cell type, which is actively involved in the pathogenesis of IBD. The different actions of mast cell mediators in IBD suggest that there must be a balance between 'pro-IBD' and 'anti-IBD' mast cell mediators (Figure 3). Breaking this balance may cause diseases. There are at least two pathways, histamine pathway and tryptase pathway, for mast cells to amplify their degranulation signals. Each of them is likely to act in either autocrine or paracrine manner. These mast cell degranulation signal amplification mechanisms may be the key event in the pathophysiological process of long-lasting local response of mast cell associated diseases such as IBD, asthma and rhinitis.

Abstract

AIM: To investigate the tryptase and histamine release ability of human colon mast cells upon IgE dependent or independent activation and the potential mechanisms.

METHODS: Enzymatically dispersed cells from human colons were challenged with anti-IgE or calcium ionophore A23187, and the cell supernatants after challenge were collected. Both concentration dependent and time course studies with anti-IgE or calcium ionophore A23187 were performed. Tryptase release was determined with a sandwich ELISA procedure and histamine release was measured using a glass fibre-based fluorometric assay.

RESULTS: Both anti-IgE and calcium ionophore were able to induce dose dependent release of histamine from colon mast cells with up to approximately 60% and 25% net histamine release being achieved with 1 μg/mL calcium ionophore and 10 μg/mL anti-IgE, respectively. Dose dependent release of tryptase was also observed with up to approximately 19 ng/mL and 21 ng/mL release of tryptase being achieved with 10 μg/mL anti-IgE and 1 μg/mL calcium ionophore, respectively. Time course study revealed that both tryptase and histamine release from colon mast cells stimulated by anti-IgE initiated within 10 sec and reached their maximum release at 6 min following challenge. Pretreatment of cells with metabolic inhibitors abolished the actions of anti-IgE as well as calcium ionophore. Tryptase and histamine release, particularly that induced by calcium ionophore was inhibited by pretreatment of cells with pertussis toxin.

CONCLUSION: Both anti-IgE and calcium ionophore are able to induce significant release of tryptase and histamine from colon mast cells, indicating that this cell type is likely to contribute to the pathogenesis of colitis and other mast cell associated intestinal diseases.

INTRODUCTION

Increased numbers of mast cells have been found in the epithelium of intestine of the patients with ulcerative colitis and Crohn' s disease[1,2]. Through releasing its proinflammatory mediators including tryptase, histamine, heparin, and other preformed or newly synthesized mast cell products[3], mast cells actively participate in the pathogenesis of inflammatory bowel diseases[4].

Tryptase is a tetrameric serine proteinase that constitutes some 20% of the total protein within human mast cells and is stored almost exclusively in the secretory granules of mast cells[5] in a catalytically active form[6]. Upon degranulation, tryptase is released from mast cells along with chymase, histamine, and other mast cell products. In recent years, evidence has been emerging that this major secretory product of human mast cells may be a key mediator of allergic inflammation and a promising target for therapeutic intervention[3] as it has been found to be able to induce microvascular leakage in the skin of guinea pig[7], bronchoconstriction[8] in allergic sheep airways, inflammatory cell accumulation in peritoneum of mouse[9] and release of IL-8 from epithelial cells[10].

For more than four decades, histamine has been widely used as a marker of mast cell degranulation *in vitro*, and numerous anti-allergic drugs such as sodium cromoglycate, lodoxamide, salbutamal, ketotifen, terfenadine and cetirizine[11,12] and salmeteral[13] were reported to be able to inhibit anti-IgE induced histamine release from human tonsil, skin or lung mast cells. However, little is known of the properties of tryptase release from human mast cells, and even histamine release properties of human colon mast cells were relatively less studied. We therefore parallelly investigated the tryptase and histamine release properties of human colon mast cells by using the same preparations of challenged mast cells in the current study.

MATERIALS AND METHODS

Reagents

The following compounds were purchased from Sigma (St. Louis, USA): collagenase (type I), hyaluronidase (type I), bovine serum albumin (BSA, fraction V), penicillin and streptomycin, calcium ionophore A23187, antimycin A, 2-deoxy-D-glucose, pertussis toxin. Goat anti-human IgE (inactivated) was from Serotec (Kidlington, Oxford, UK). FCS and minimum essential medium (MEM) containing 25 mM *N*-2-hydroxylethylpiperazine-*N*' -2-ethane sulphonic acid (HEPES) were from Gibco (Paisley, Renfrewshire, UK). A polyclonal antibody and a monoclonal antibody against tryptase were donated by Dr Andrew F. Walls (University of Southampton, UK). Histamine plate was from RefLab (Copenhagen, Denmark). HEPES and all other chemicals were of analytical grade.

Dispersion of mast cells

Human colon tissue was obtained from patients with carcinoma of colon at colectomy. Only macroscopically normal tissue was used for the study. After removing fat, tissue was washed and chopped finely with scissors into fragments of 0.5-2.0 mm³, and then incubated with 1.5 mg/ml collagenase and 0.75 mg/ml

hyaluronidase in MEM containing 2% fetal calf serum (1 g colon/10 ml buffer) for 70 min at 37 ℃. Dispersed cells were separated from undigested tissue by filtration through nylon gauze (pore size 100 μm diameter), washed and maintained in MEM (containing 10% FCS, 200 U/ml penicillin, 200 μg/ml streptomycin) on a roller overnight at room temperature. Mast cell purity, as determined by light microscopy after stained by alcine blue, ranged from 3.5% to 5.4%.

Mast cell challenge

Dispersed cells were resuspended in HEPES buffered salt solution (HBSS, pH 7.4) with $CaCl_2$ and $MgCl_2$ (complete HBSS), and 100 μl aliquots containing $4\text{-}6\times10^3$ mast cells were added to a 50 μl anti-IgE, calcium ionophore or control buffer alone and incubated for 15 min at 37 ℃. The reaction was terminated by the addition of 150 μl ice cold incomplete HBSS and the tubes were centrifuged immediately (500 g, 10 min, 4 ℃). All experiments were performed in duplicate. For the experiments with pertussis toxin, cells were incubated with 0.1 or 1.0 μg/ml pertussis toxin for four hours at 37 ℃, and then washed with HBSS before adding stimulus. Similarly, for the experiments with metabolic inhibitors, cells were incubated with 2-deoxy-D-glucose (10 mM) and antimycin A (1 μM) for 40 min at 37 ℃ before challenged with stimulus. For the measurement of total histamine concentration, in certain tubes the suspension was boiled for 6 min. Supernatants were stored at -20 ℃ until use.

Tryptase and histamine measurement

Tryptase concentrations were measured with a sandwich ELISA procedure with a specific polyclonal antibody against human tryptase as the capture antibody and AA5 a monoclonal antibody specific for human tryptase as the detecting antibody[14]. Histamine concentrations were determined using a glass fibre-based fluorometric assay[15].

Statistical analysis

Data are shown as mean±SEM for the number of experiments (*n*) indicated, and the paired Student's *t* test was applied to evaluate two independent samples. In all analyses *P*<0.05 was taken as statistically significant.

RESULTS

Effect of anti-IgE and calcium ionophore on tryptase and histamine release from colon mast cells

Both anti-IgE and calcium ionophore were able to induce a dose dependent release of histamine from colon mast cells with up to approximately 60% and 25% net histamine release being achieved with 1 μg/mL calcium ionophore and 10 μg/mL anti-IgE, respectively. Increasing the concentrations of calcium ionophore up to 10 μg/mL and anti-IgE up to 100 μg/mL failed to provoke any further release of histamine from colon mast cells (Figure 1). Dose dependent release of tryptase was also observed when dispersed colon mast cells were incubated with calcium ionophore or anti-IgE. Up to approximately 19 ng/mL and 21 ng/mL release of tryptase were achieved with 10 μg/mL anti-IgE and 1 μg/mL calcium ionophore, respectively. Only as little as 0.1 μg/mL calcium ionophore and 1 μg/mL anti-IgE were required to elicit a significant release of tryptase. Similar to histamine release, increasing the concentrations of calcium ionophore to more than 1 μg/mL and anti-IgE more than 10 μg/mL did not stimulate more tryptase release from colon mast cells (Figure 2). There was a significant correlation between the quantities of histamine and tryptase released in response to anti-IgE (Pearson correlation: *r*=0.939, *P*=0.005) and calcium ionophore (Pearson correlation: *r*=0.973, *P*=0.001).

Time course study revealed that both tryptase and histamine release from colon mast cells stimulated by anti-IgE initiated within 10 sec when cells were incubated with the stimulus, the release was then steadily increased while incubation periods were prolonged. Tryptase and histamine reached their maximum release at 6 min following incubation. Prolonging the incubation period from 6 min to 15 min had little effect on the release of tryptase and histamine (Figure 3). The time course pattern of tryptase release provoked by calcium ionophore was similar to that induced by anti-IgE with approximately 45% tryptase released within 10 sec. This was different from the time course for calcium ionophore induced histamine release, which showed as much as approximately 70% of histamine released within 10 sec of challenge (Figure 4).

Inhibition of anti-IgE and calcium ionophore induced tryptase and histamine release by pertussis toxin and metabolic inhibitors

Pretreatment of cells with metabolic inhibitors abolished the actions of anti-IgE as well as calcium ionophore. Tryptase and histamine release, particularly that induced by calcium ionophore was inhibited by pretreatment of cells with pertussis toxin (Table 1, Table 2).

Table 1 Effects of pertussis toxin and metabolic inhibitors on anti-IgE induced histamine and tryptase release from colonic mast cells

Treatment	Net mediator release (ng/mL)	
	Tryptase	Histamine
Untreated	11.4±2.7	14.0±3.2
Pertussis toxin 0.1 μg/mL	3.2±1.3[a]	5.4±1.7[a]
1.0 μg/mL	4.0±1.6[a]	4.0±1.9[a]
Metabolic inhibitors	-2.1±1.7[a]	-2.6±1.7[a]

The values shown are mean±SEM of four separate experiments performed in duplicate. [a]$P<0.05$ compared with the untreated group (paired Student's *t* test). Metabolic inhibitors=1 μM antimycin A+10 mM 2-deoxy-D-glucose.

Table 2 Effects of pertussis toxin and metabolic inhibitors on calcium ionophore induced tryptase and histamine release from colonic mast cells

Treatment	Mediator release (ng/mL)	
	Tryptase	Histamine
Untreated	13.8±2.4	34.3±3.4
Pertussis toxin 0.1 μg/mL	4.0±1.6[a]	2.7±2.8[a]
1.0 μg/mL	1.4±1.8[a]	-0.1±1.3[a]

The values shown are mean±SEM of four separate experiments performed in duplicate. [a]$P<0.05$ compared with the untreated group (paired Student's *t* test). Metabolic inhibitors=1 μM antimycin A+10 mM 2-deoxy-D-glucose.

DISCUSSION

We have reported for the first time the *in vitro* tryptase release ability of human colon mast cells. This is particularly important when tryptase and histamine, the two major mast cell mediators were investigated in the same experiments, which would not only prove that the two mediators were released from mast cells unnecessarily at a constantly parallel ratio, but also revealed that histamine was released slightly faster than tryptase upon degranulation.

Approximately 25% histamine and 10% tryptase (presumably 10 pg tryptase per mast cell[16], and 5000 cells in each test tube) were released from colon mast cells in response to IgE dependent provocation, indicating that only a proportion of mast cells was activated or the granule contents in activated mast cells were partially released. The maximum release of histamine and tryptase was induced by 10 μg/mL rather than higher concentrations of anti-IgE, suggesting that colon mast cells would give their maximum response to a sufficient stimulation, but not an excess stimulation, which showed a self-protection mechanism of colon mast cells.

Approximately 45% degranulation occurred within 10 sec of IgE dependent stimulation, suggesting that colon mast cells were able to quickly respond to allergen challenge, but they required about 6 min to reach their full capacity (maximum histamine or tryptase release). The time course also revealed that histamine was released slightly faster than tryptase upon degranulation, and this was particularly evident with calcium ionophore. The peak histamine release induced by anti-IgE and calcium ionophore occurred at 6 min following stimulation of colon mast cells, and appeared much faster than the occurrence of peak histamine release with lung mast cells, which required at least 15 min to reach its peak following anti-IgE and calcium ionophore stimulation[17].

Pretreatment of cells with metabolic inhibitors antimycin A, which blocks the oxidative phosphorylation process of cells, and 2-deoxy-D-glucose which blocks anaerobic metabolism pathway in cells, abolished the actions of anti-IgE as well as calcium ionophore, indicating that the induced release of these two mediators was a non-cytotoxic process, and was dependent on cell energy supply. Tryptase and histamine release, particularly that induced by calcium ionophore was inhibited by pretreatment of cells with pertussis toxin, suggesting that the degranulation process elicited by anti-IgE and calcium ionophore was associated with activation of G-protein coupled receptors.

Over the last decade, a number of functions of mast cell tryptase have been discovered. However, the mechanism by which tryptase acts on cells is still unclear. The finding that proteinase-activated receptor-2 (PAR-2) on cos cells could be a receptor for tryptase[18] suggested that the effects of tryptase on various types of cells were associated with this type of receptor. Since both tryptase[7,15] and PAR-2 agonists[19] were able to activate human mast cells, it is likely that there is a self-amplification mechanism of mast cell degranulation, which would contribute largely to the pathogenesis of mast cell related diseases including inflammatory bowel diseases. The report that induction of intestinal inflammation in mouse by activation of PAR-2[20] and PAR-2 as an anti-inflammatory signal for colonic lamina propria lymphocytes in a mouse model of colitis[21] suggested the potential roles of PAR-2 in inflammatory bowel diseases.

Histamine has long been accepted as a specific marker of mast cell degranulation. Tryptase however, is seldom used in the same way though it has been employed as a specific marker of mast cells since 1980's. Based on the results in the current study and the evidence that these two mediators are located in the same secretory granules of mast cells, we believe that human tryptase can serve as an indicator of mast cell degranulation *in vitro*. In conclusion, both anti-IgE and calcium ionophore are able to induce a significant release of tryptase and histamine from colon mast cells, indicating that this cell type is likely to contribute to the pathogenesis of colitis and other mast cell associated intestinal diseases.

Abstract

AIM: To investigate the ability of histamine to modulate tryptase release from human colon mast cells and the potential mechanisms.

METHODS: Enzymatically dispersed cells from human colons were challenged with histamine, anti-IgE or calcium ionophore A23187 (CI), and the cell supernatants after challenge were collected. Tryptase release was determined with a sandwich ELISA procedure.

RESULTS: Histamine at concentrations from 1 ng/mL was able to induce a "bell" shape dose related release of tryptase from colon mast cells. The maximum release of tryptase was approximately 3.5 fold more than spontaneous release. As little as 10 ng/mL histamine showed a similar potency to 10 µg/mL anti-IgE in induction of tryptase release. Histamine induced release of tryptase initiated at 10 s when histamine (100 ng/mL) was added to cells, gradually increased thereafter, and completed at 5 min. Both pertussis toxin or metabolic inhibitors were able to inhibit histamine induced tryptase release. When histamine and anti-IgE were added to colon mast cells at the same time, the quantity of tryptase released was similar to that induced by anti-IgE alone. The similar results were observed with CI. However, when various concentrations of histamine were incubated with cells for 20 min before adding anti-IgE or CI, the quantity of tryptase released was similar to that was induced by histamine alone.

CONCLUSION: Histamine is a potent activator of human colon mast cells, which represents a novel and pivotal self-amplification mechanism of mast cell degranulation.

INTRODUCTION

It has been reported that mast cells and their inflammatory mediators are closely associated to a number of intestinal diseases including idiopathic inflammatory bowel disease[1], chronic ulcerative colitis[2], Crohn's disease[3] and collagenous colitis[4]. Through release their proinflammatory mediators including histamine, tryptase, chymase, heparin and some cytokines[5], mast cells actively participate in the pathogenesis of these intestinal diseases.

Tryptase is a tetrameric serine proteinase that constitutes some 20% of the total protein within human mast cells and is stored almost exclusively in the secretory granules of mast cells[6] in a catalytically active form[7]. Relatively higher secretion of tryptase has been detected in ulcerative colitis[8], implicating that this mediator is involved in the pathogenesis of intestinal diseases. Evidence is emerging that tryptase may be a key mediator of allergic inflammation and a promising target for therapeutic intervention[9] as it has been found to be able to induce microvascular leakage in the skin of guinea pig[10], bronchoconstriction[11] in allergic sheep airways, inflammatory cell accumulation in peritoneum of mouse[12] and release of IL-8 from epithelial cells[13]. Moreover, tryptase has long been recognised as a marker of mast cells[14,15], and an indicator of mast cell degranulation *in vivo*[16,17]. However, the application of tryptase as a unique marker of mast cell degranulation in mast cell challenge study *in vitro* was only started recently[18]. This was largely due to the lack of adequate assay to detect this mast cell product.

Histamine, on the other hand, has been widely employed as a marker of mast cell degranulation in mast cell challenge studies over the last four decades. But as a activator of mast cells it has hardly been examined. Since increased levels of histamine or enhanced histamine metabolism have been observed in collagenous colitis, food allergy[19], Crohn's disease[20], ulcerative colitis[20,21] and allergic enteropathy[21], this proinflammatory mediator is likely to participate in the pathogenesis of these diseases. In the current study, we investigated the potential of histamine to activate human colon mast cells *in vitro* in order to understand further the role of histamine in inflammatory bowel diseases.

MATERIALS AND METHODS

Reagents

The following compounds were purchased from Sigma (St. Louis, Mo., USA): CI, histamine dihydrochloride, collagenase (type I), hyaluronidase (type I), antimycin A, 2-deoxy-D-glucose, pertussis toxin, bovine serum albumin (BSA, fraction V), penicillin and streptomycin, extravidin peroxidase, *o*-phenylene diamine, biotin conjugate sheep anti-mouse immunoglobulins, extr-avidin peroxidase. Minimum essential medium (MEM) containing 25 mM *N*-2-hydroxylethylpiperazine-*N*'-2-ethane sulphonic acid (HEPES) and FCS was from Gibco (Paisley, Renfrewshire, UK). Goat anti-human IgE (inactivated) was from Serotec (Kidlington, Oxford, UK). A polyclonal antibody and a monoclonal antibody against tryptase were donated by Dr. Andrew F. Walls (University of Southampton, UK). HEPES and all other chemicals were of analytical grade.

Dispersion of mast cells

The mast cell dispersion procedure was similar to that described

previously[21,22]. Human colon tissue was obtained from patients with carcinoma of colon at colectomy. Only macroscopically normal tissue was used for the study. After removal of fat, the tissue was washed and chopped finely with scissors into fragments of 0.5-2.0 mm³, and then incubated with 1.5 mg/mL collagenase and 0.75 mg/mL hyaluronidase in MEM containing 2% fetal calf serum (1 g colon/10 mL buffer) for 70 min at 37 ℃. Dispersed cells were separated from the undigested tissue by filtration through a nylon gauze (pore size 100 μm diameter), washed and maintained in MEM (containing 10% FCS, 200 U/mL penicillin, 200 μg/mL streptomycin) on a roller overnight at room temperature. Mast cell purity, as determined by light microscopy after staining by Alcine blue, ranged from 3.6% to 5.8%.

Mast cell challenge

Dispersed cells were resuspended in HEPES buffered salt solution (HBSS, pH 7.4) with 1.8 mM $CaCl_2$ and 0.5 mM $MgCl_2$ (complete HBSS), and 100 μL aliquots containing $4-6\times10^3$ mast cells was added to 50 μL histamine, anti-IgE, CI or buffer alone and incubated for 15 min at 37 ℃. The reaction was terminated by the addition of 150 μL ice cold incomplete HBSS and the tubes were centrifuged immediately (500 g, 10 min, 4 ℃). All experiments were performed in duplicate. For the experiments with pertussis toxin, cells were incubated with 0.1 or 1.0 μg/mL pertussis toxin for four hours at 37 ℃, and then washed with HBSS before adding stimulus. Similarly, for the experiments with metabolic inhibitors, cells were incubated with 2-deoxy-D-glucose (10 mmol/L) and antimycin A (1 μmol/L) for 40 min at 37 ℃ before challenged with stimulus. Supernatants were stored at -20 ℃ until use. As reported previously that 10 μg/mL anti-IgE and 1 μg/mL CI were the optimal concentrations for the induction of tryptase released from human colon mast cells[18], therefore they were selected as the standard concentrations throughout the study.

Tryptase measurement

Tryptase concentrations were measured using a sandwich ELISA procedure with a specific polyclonal antibody against human tryptase as the capture antibody and AA5 a monoclonal antibody specific for human tryptase as the detecting antibody[23].

Statistical analysis

Data were shown as mean±SEM for the number of experiments (*n*) indicated, and the paired Student's *t* test was applied to evaluate two independent samples. In all analyses, *P*<0.05 was taken as statistically significant.

RESULTS

Induction of tryptase release by histamine

Histamine at the concentration of 1 ng/mL was able to induce a 'bell' shape dose related release of tryptase from colon mast cells. The maximal release of tryptase was approximately 3.5 fold more than spontaneous release provoked by 100 ng/mL histamine. Relatively less tryptase was released when 1 000 ng/mL and 10 000 ng/mL histamine were incubated with mast cells. As little as 10 ng/mL histamine showed a similar potency to 10 μg/mL anti-IgE in induction of tryptase release from colon mast cells (Figure 1).

Time course for histamine induced tryptase release

Histamine induced release of tryptase initiated at 10 s when histamine (100 ng/mL) was added to cells, gradually increased thereafter, and completed at 5 min (Figure 2).

Effects of pertussis toxin and metabolic inhibitors on histamine induced tryptase release

Tryptase release induced by histamine was reduced to the

baseline level by pretreatment of colon mast cells with pertussis toxin or metabolic inhibitors. The same treatment was also able to slightly decrease the spontaneous tryptase release from mast cells (Table 1).

Figure 1 Histamine, anti-IgE and calcium ionophore (CI) induced tryptase release from colon mast cells. The values shown are mean±SEM for six separate experiments. Stimulus or HBSS alone was incubated with cells for 15 min before termination of the reactions. [a]*P*<0.05 compared with spontaneous release group (paired Student's *t* test).

Figure 2 Time course for histamine (100 ng/mL) induced release of tryptase from colon mast cells. Data shown are mean±SEM of five separate experiments.

Table 1 Effects of pertussis toxin (1.0 μg/mL) and metabolic inhibitors on histamine induced tryptase release from colon mast cells

Treatment	Tryptase release (ng/mL)		
	Hist 100 μg/mL	Hist 1 000 μg/mL	Buffer alone
Untreated	32±5.5	30.5±3.9	20.5±2.8
Pertussis toxin	17.1±1.8[a]	16.7±1.7[a]	17.6±2.7
Metabolic inhibitors	18.8±3.5[a]	17.5±1.9[a]	16.3±1.9

The values shown are mean±SEM of five separate experiments performed in duplicate. [a]*P*<0.05 compared with the untreated group (paired Student's *t* test). Metabolic inhibitors=1 μM antimycin A+10 mM 2-deoxy-D-glucose. Hist=histamine.

Effect of histamine on anti-IgE and CI induced tryptase release

When 100 ng/mL or 1 000 ng/mL histamine and anti-IgE were added to colon mast cells at the same time, tryptase release was significantly less than that induced by addition of the corresponding concentration of histamine alone. The similar results were observed when the same concentrations of histamine were added to cells at the same time with CI, though there was no significant difference between histamine alone and histamine plus CI (Figure 3). However, addition of various concentrations of histamine to colon mast cells 20 min before placing anti-IgE or CI, tryptase release was similar to that induced by the corresponding histamine alone, except for 10 ng/mL histamine with CI, indicating a synergistic action between them (Figure 4).

Figure 3 Effect of co-addition of histamine (hist) and anti-IgE or calcium ionophore (CI) on tryptase release from colon mast cells. The values shown are mean±SEM for six separate experiments. Various concentrations of histamine and anti-IgE or CI were added to cells at the same time, and then incubated with cells for 15 min before termination of the reactions. $^aP<0.05$ compared with the corresponding histamine alone group (paired Student's *t* test).

**Figure 4** Effect of histamine (hist) on anti-IgE or calcium iono-phore (CI) induced tryptase release from colon mast cells. The values shown are mean±SEM for six separate experiments. Various concentrations of histamine were incubated with cells for 20 min before addition of anti-IgE or CI. $^aP<0.05$ compared with the corresponding histamine alone group (paired Student's *t* test). Pred.hist + anti-IgE or CI=the sum of tryptase release induced by histamine alone and anti-IgE or CI alone.

DISCUSSION

The finding that histamine is a potent activator of human colon mast cells demonstrated a novel and pivotal self-amplification mechanism of human mast cell degranulation, that is mast cells release histamine upon degranulation, and then the released histamine activates the adjacent mast cells. Thus, there are at least two self-amplification mechanisms in human mast cells upon degranulation, including tryptase and PAR-2 feedback process previously reported[22,23] and histamine inducing tryptase release.

Histamine appeared a potent secretogogue of tryptase, as little as 10 ng/mL histamine could share a similar potency of 10 µg/mL anti-IgE. This was a surprising result, but it clearly demonstrate a novel self-amplification mechanism of mast cell degranulation as the concentration of histamine inside the mast cell granules was estimated over 100 m mol/mL[24]. Interestingly, histamine concentration at 1 000 ng/mL or above was able to induce less tryptase release from mast cells than 100 ng/mL, which may represent a novel self-protection mechanism of mast cells. Histamine induced tryptase release started slower than that elicited by anti-IgE, CI[18] or tc- LIGRLO[23], but completed 1 min earlier than that induced by anti-IgE and CI, indicating that it has its own activation-degranulation passway in mast cells. Pretreatment of cells with metabolic inhibitors antimycin A which blocks the oxidative phosphorylation process of cells, and 2-deoxy-D-glucose which blocks anaerobic metabolism pathway in cells, abolished the action of histamine, indicating that histamine induced release of tryptase is a non-cytotoxic process depending on cell energy supply. Tryptase release provoked by histamine was also inhibited by pretreatment of cells with pertussis toxin, suggesting that the degranulation process is associated with the activation of G-protein coupled receptors[25].

When histamine and anti-IgE were placed to mast cells at the same time, the quantity of released tryptase was similar to that elicited by anti-IgE alone, much less than that provoked by histamine alone, implicating that tryptase released from colon mast cells was mainly induced by anti-IgE, rather than by histamine. The reason for this was that the initiation of anti-IgE induced tryptase release was quicker than that induced by histamine, and mast cells only accepted one type of stimulation at a time[26,27]. Similar phenomena were observed with CI, and CI provoked mast cell degranulation apparently faster than that induced by histamine. In contrast, addition of various concentrations of histamine to colon mast cells 20 min before placing anti-IgE or CI, tryptase release was similar to that induced by the corresponding histamine alone, which proved further that colon mast cells were only able to respond to one optimal activation at a time, and the desensitized mast cells did not respond to any further stimulation. This behavior is an effective self-protection mechanism of mast cells. However, a synergistic action between 10 ng/mL histamine and CI, but not anti-IgE was observed, suggesting that mast cells experiencing a non-optimal stimulation may still have ability to respond to a further stimulation. In conclusion, histamine is a potent activator of human colon mast cells, and represents a novel and pivotal self-amplification mechanism of mast cell degranulation.

Abstract

AIM: To investigate the ability of agonists of PAR-2 to stimulate release of tryptase and histamine from human colon mast cells and the potential mechanisms.

METHODS: Enzymatically dispersed cells from human colons were challenged with tc-LIGRLO, tc-OLRGIL, SLIGKV, VKGILS, trypsin, anti-IgE or calcium ionophore A23187, and the cell supernatants after challenge were collected. Tryptase release was determined with a sandwich ELISA procedure and histamine release was measured using a glass fibre-based fluorometric assay.

RESULTS: Both PAR-2 agonists tc-LIGRLO-NH_2 and SLIGKV-NH_2 were able to induce dose dependent release of tryptase and histamine from colon mast cells. More than 2.5 fold increase in both tryptase and histamine release was provoked by 100 µmol/mL tc-LIGRLO-NH_2, in comparison with only 2.0 fold increase being stimulated by SLIGKV-NH_2. The reverse peptides tc-OLRGIL-NH_2 and VKGILS –NH_2 at the concentrations tested had no effect on the release of these two mediators. The maximum tryptase release elicited by tc-LIGRLO-NH_2 was similar to that induced by anti-IgE (10 µg/mL) or calcium ionophore (1 µg/mL), though the latter was a more potent stimulus for histamine release. Both histamine and tryptase release in response to tc-LIGRLO-NH_2 were completed within 3 min. Trypsin at concentrations from 1.0 to 100 µg/mL was capable of provoking a dose dependent release of tryptase as well as histamine with a maximum of 16 ng/mL tryptase and 14 ng/mL histamine release being achieved. An approximately 80% and 70% inhibition of trypsin induced release of tryptase and histamine were observed with SBTI, respectively. Pretreatment of cells with metabolic inhibitors or pertussis toxin abolished the actions of tc-LIGRLO-NH_2, SLIGKV-NH_2 and trypsin.

CONCLUSION: The agonists of PAR-2 and trypsin are potent secretagogues of human colon mast cells, which are likely to contribute to the development of inflammatory disorders in human gut.

INTRODUCTION

PAR-2 is a 7-transmembrane G protein-coupled receptor, which can be activated by serine proteinase trypsin and mast cell tryptase[1], and some synthetic peptides corresponding to the N-terminal tethered ligand sequences that are unmasked by proteolytic cleavage including SLIGKV in man[2] and SLIGRL in rodent[3].

In gastrointestinal tract, PAR-2 activation has been found to be actively involved in a number of inflammatory processes including induction of granulocyte infiltration, colon edema, tissue damage in mouse[4,5], induction of gastric mucus secretion and mucosal cytoprotection[6] in rat, excitation of submucosal neurons of guinea pig small intestine[7,8] and activation of ion secretion from human colon[9]. Moreover, upregulation of expression of PAR-2 in ulcerative colitis[10] suggested a strong possibility of involvement of mast cell tryptase and trypsin in inflammatory bowel disease.

Indeed, increased numbers of mast cells were observed in chronic ulcerative colitis[11] and Crohn' s disease[12], elevated histamine levels or enhanced histamine metabolism were found in collagenous colitis, food allergy[13], Crohn' s disease[14], ulcerative colitis[14,15] and allergic enteropathy[15] and increased levels of tryptase were detected in ulcerative colitis[16], indicating that these two proinflammatory mediators are involved in the pathogenesis of certain gastrointestinal diseases.

We have reported previously that mast cell tryptase was able to activate mast cells[17,18], which presents a self-amplification mechanism of mast cell degranulation. Since the receptor of tryptase, PAR-2 was localized on human mast cells[19] and PAR-2 agonists were reported to be capable of activating rat peritoneal mast cells[20], it is likely that PAR-2 agonists and trypsin may have ability to activate human mast cells. We therefore examined the effect of trypsin and PAR-2 agonists on tryptase and histamine release from human colon mast cells in the current study.

MATERIALS AND METHODS

Reagents

The following compounds were purchased from Sigma (St. Louis, USA): collagenase (type I), hyaluronidase (type I), soy bean trypsin inhibitor (SBTI), bovine serum albumin (BSA, fraction V), penicillin and streptomycin, calcium ionophore A23187, antimycin A, human trypsin, 2-deoxy-D-glucose, pertussis toxin. Goat anti-human IgE (inactivated) was from Serotec (Kidlington, Oxford, UK). FCS and minimum essential medium (MEM) containing 25 mM N-2-hydroxylethylpiperazine-N'-2-ethane sulphonic acid (HEPES) were from Gibco (Paisley, Renfrewshire, UK). Peptides SLIGKV-NH_2, VKGILS-NH_2, trans-cinnamoyl-Leu-Ile-Gly-Arg-Leu-Orn-amide (tc-LIGRLO) and trans-cinnamoyl-Orn-Leu-Arg-Gly-Ile-Leu-amide

(tc-OLRGIL) were >98% purity and from Meilian Corporation (Xian, China). A polyclonal antibody and a monoclonal antibody against tryptase were donated by Dr Andrew F. Walls (University of Southampton, UK). Histamine plate was from RefLab (Copenhagen, Denmark). HEPES and all other chemicals were of analytical grade.

Dispersion of mast cells

The mast cell dispersion procedure was similar to the one described previously[21,22]. Human colon tissue was obtained from patients with carcinoma of colon at colectomy. Only macroscopically normal tissue was used for the study. After removal of fat, tissue was washed and chopped finely with scissors into fragments of 0.5-2.0 mm^3, and then incubated with 1.5 mg/mL collagenase and 0.75 mg/mL hyaluronidase in MEM containing 2% fetal calf serum (1 g colon/10 mL buffer) for 70 min at 37 ℃. Dispersed cells were separated from undigested tissue by filtration through nylon gauze (pore size 100 μm diameter), washed and maintained in MEM (containing 10% FCS, 200 U/mL penicillin, 200 μg/mL streptomycin) on a roller overnight at room temperature. Mast cell purity, as determined by light microscopy after stained by alcine blue, ranged from 3.5% to 5.5%.

Mast cell challenge

Dispersed cells were resuspended in HEPES buffered salt solution (HBSS, pH 7.4) with 1.8 mM CaCl$_2$ and 0.5 mM MgCl$_2$ (complete HBSS), and 100 μL aliquots containing 4-6×10^3 mast cells were added to a 50 μL tc-LIGRLO, tc-OLRGIL, SLIGKV, VKGILS, trypsin, control secretagogue or buffer alone and incubated for 15 min at 37 ℃. The reaction was terminated by the addition of 150 μL ice cold incomplete HBSS and the tubes were centrifuged immediately (500 g, 10 min, 4 ℃). All experiments were performed in duplicate. For the experiments with pertussis toxin, cells were incubated with 0.1 or 1.0 μg/mL pertussis toxin for four hours at 37 ℃, and then washed with HBSS before adding stimulus. Similarly, for the experiments with metabolic inhibitors, cells were incubated with 2-deoxy-D-glucose (10 mmol/L) and antimycin A (1 μmol/L) for 40 min at 37 ℃ before challenged with stimulus. For the measurement of total histamine concentration

in certain tubes, the suspension was boiled for 6 min. Supernatants were stored at -20 ℃ until use.

Tryptase and histamine measurement

Tryptase concentrations were measured with a sandwich ELISA procedure with a specific polyclonal antibody against human tryptase as the capture antibody and AA5 a monoclonal antibody specific for human tryptase as the detecting antibody[23]. Histamine concentrations were determined using a glass fibre-based fluorometric assay[17].

Statistical analysis

Data are shown as mean±SEM for the number of experiments (n) indicated, and the paired Student's t test was applied to evaluate two independent samples. In all analyses $P<0.05$ was taken as statistically significant.

RESULTS

Induction of tryptase release by agonists of PAR-2

Both PAR-2 agonists tc-LIGRLO-NH$_2$ and SLIGKV-NH$_2$ were able to induce dose dependent release of tryptase from colon mast cells (Figure 1). More than 2.5 fold increase in tryptase release was provoked by 100 μmol/mL tc-LIGRLO-NH$_2$, even at a concentration as low as 1.0 μmol/mL tc-LIGRLO-NH$_2$ was able to elicit a 2.2 fold increase in the release of tryptase. Although the potency of SLIGKV-NH$_2$ appeared slightly weaker than that of tc-LIGRLO-NH$_2$, it could still stimulate as much as two fold increase in the release of tryptase from colon mast cells. The reverse peptides tc-OLRGIL-NH$_2$ and VKGILS –NH$_2$ had no effect on the release of tryptase when being added at the concentrations from 0.1 to 300 μmol/mL (Figure 1). The quantity of tryptase released elicited by tc-LIGRLO-NH$_2$ (100 μmol/mL) was similar to that induced by 10 μg/mL anti-IgE or 1 μg/mL calcium ionophore. Trypsin at the concentrations of 1.0-100 μg/mL was capable of provoking a dose dependent release of tryptase with a maximum of 16 ng/mL tryptase being released by 100 μg/mL trypsin (Figure 1). Approximately 80% trypsin induced release of tryptase was diminished by SBTI when trypsin and SBTI were added to cells at the same time (Figure 1).

Figure 1 Effects of tc-LIGRLO, tc-OLRGIL, SLIGKV, VKGILS, trypsin, anti-IgE and calcium ionophore A23187 (CI) on tryptase release from colon mast cells. The values shown are mean±SEM for four separate experiments. Stimulus or control was incubated with cells for 15 min before termination of the reactions. ^{a}P<0.05 compared with buffer alone group (paired Student's t test).
Figure 2 Effects of tc-LIGRLO, tc-OLRGIL, SLIGKV, VKGILS, trypsin, anti-IgE and calcium ionophore A23187 (CI) on histamine release from colon mast cells. The values shown are mean±SEM for four separate experiments. Stimulus or control was incubated with cells for 15 min before termination of the reactions. [a]P<0.05 compared with buffer alone group (paired Student's *t* test).

Induction of histamine release by agonists of PAR-2

Both PAR-2 agonists tc-LIGRLO-NH$_2$ and SLIGKV-NH$_2$ were also able to induce a dose dependent release of histamine from colon mast cells. More than 2.5 and 2.0 fold increases in histamine release were provoked by 100 μmol/mL tc-LIGRLO-NH$_2$ and SLIGKV-NH$_2$, respectively. However, histamine release elicited by tc-LIGRLO-NH$_2$ (100 μmol/mL) was less than that induced by anti-IgE (10 μg/mL) and only half of that provoked by calcium ionophore (1 μg/mL). The reverse peptides tc-OLRGIL-NH$_2$ and VKGILS-NH$_2$ had no effect on the release of histamine when being added at concentrations up to 300 μmol/mL (Figure 2). Trypsin at the concentrations from 1.0 to 100 μg/mL was capable of provoking a dose dependent release of histamine with a maximum of 14 ng/mL histamine being released by 100 μg/mL trypsin. Approximately 70% trypsin induced release of histamine was reduced by SBTI when trypsin and SBTI were added at the same time to cells (Figure 2).

Time course for tc-LIGRLO-NH$_2$

The release of tryptase and histamine in response to tc-LIGRLO-NH$_2$ was maximized within 3 min following addition of 100 μmol/mL tc-LIGRLO-NH$_2$ to colon mast cells. The maximum release of tryptase and histamine was then maintained for at least 15 min (Figure 3). When tc-LIGRLO-NH$_2$, anti-IgE and calcium ionophore were incubated with cells for a prolonged period of 30 min, the amount of tryptase and histamine released appeared not being increased (Table 1).

Table 1 Effects of tc-LIGRLO, tc-OLRGIL, anti-IgE and calcium ionophore A23187 (CI) on tryptase and histamine release from colon mast cells following 30 min incubation period

Concentration of stimulus		Tryptase (ng/mL)	Histamine (ng/mL)
Buffer alone		8.2±0.6	9.5±1.7
tc-LIGRLO	100 μmol/mL	22±3.0[a]	17±1.3[a]
tc-OLRGIL	100 μmol/mL	8.4±2.8	10±1.9
Anti-IgE	10 μg/mL	19±4.1[a]	19±4.8[a]
CI	1.0 μg/mL	13±0.6[a]	34±4.3[a]

The values shown are mean±SEM for four separate experiments performed in duplicate. [a]P<0.05 compared with buffer alone group (paired Student's *t* test).

Figure 3 Time course for tc-LIGRLO (100 μM) induced release of tryptase (—■—) and histamine (—●—) from colon mast cells. Data shown are mean±SEM of four separate experiments.

Effects of pertussis toxin and metabolic inhibitors on tryptase and histamine release

Tryptase release induced by tc-LIGRLO-NH$_2$, SLIGKV-NH$_2$ and trypsin was abolished by pretreatment of colon mast cells with metabolic inhibitors or pertussis toxin (Table 2). The same treatment was also able to almost completely inhibit histamine release from mast cells (Table 3).

Table 2 Inhibition of tc-LIGRLO, SLIGKV, trypsin, anti-IgE or calcium ionophore A23187 (CI) induced tryptase release from colon mast cells by pertussis toxin (1 μg/mL) and metabolic inhibitors

Concentration of stimulus		% inhibition of tryptase release	
		Pertussis toxin	Metabolic inhibitors
tc-LIGRLO	100 μmol/mL	85±9.6[a]	91±3.9[a]
SLIGKV	100 μmol/mL	91±4.8[a]	94±3.6[a]
Trypsin	10 μg/mL	100±0[a]	95±4.0[a]
Anti-IgE	10 μg/mL	87±10[a]	99±0.5[a]
CI	1.0 μg/mL	84±8.8[a]	89±4.7[a]

The values shown are mean±SEM for four separate experiments performed in duplicate. [a]P<0.05 compared with the uninhibited control group (paired Student's *t* test).

Table 3 Inhibition of tc-LIGRLO, SLIGKV, trypsin, anti-IgE or calcium ionophore A23187 (CI) induced histamine release from colon mast cells by pertussis toxin (1 μg/mL) and metabolic inhibitors

Concentration of stimulus		% inhibition of histamine release	
		Pertussis toxin	Metabolic inhibitors
tc-LIGRLO	100 μmol/mL	92±5.4[a]	98±2.0[a]
SLIGKV	100 μmol/mL	95±5.9[a]	92±3.8[a]
Trypsin	10 μg/mL	84±6.8[a]	88±8.7[a]
Anti-IgE	10 μg/mL	84±5.2[a]	99±1.1[a]
CI	1.0 μg/mL	97±2.4[a]	99±0.1[a]

The values shown are mean±SEM for four separate experiments performed in duplicate. [a]$P<0.05$ compared with the uninhibited control group (paired Student's t test).

DISCUSSION

The finding in the current study that PAR-2 agonists were able to activate human mast cells fulfilled our hypothesis that human mast cells possess a self-amplification mechanism to IgE dependent activation through their mediator tryptase. That is to say that upon activation, mast cells release tryptase, and the released tryptase then activates their neighbouring mast cells or acts on its host mast cells through PAR-2.

The maximum 22.5 ng/mL tryptase and 21 ng/mL histamine release induced by tc-LIGRLO-NH$_2$ were comparable to those induced by 10 μg/mL anti-IgE, indicating that the PAR-2 agonist is a potent stimulus of mast cells. SLIGKV was also able to provoke a significant tryptase and histamine release from colon mast cells, but its action appeared slightly weaker than tc-LIGRLO-NH$_2$. This could be due to the structural difference between the two molecules. As little as 1.0 μmol/mL tc-LIGRLO-NH$_2$ was able to stimulate a significant release of tryptase and histamine, suggesting further that this compound is a potent mast cell secretagogue, and the concentration of the stimulus is easy to be achieved under physiological conditions. It was little surprised to observe that trypsin was able to activate colon mast cells as there should be a relatively high concentration of trypsin in human intestinal tract, and some of them should be able to penetrate through the epithelial lining of intestine, particularly when paracellular permeability of colon was increased upon PAR-2 activation[4]. Nevertheless, it should be interesting to learn the physiological or pathophysiological role of mast cell activation by trypsin in gastrointestinal tract in future. The fact that reversed peptides of PAR-2 agonists had little effect on tryptase and histamine release from colon mast cells proved further the specificity of the PAR-2 agonists on mast cells. The maximum release of tryptase and histamine from colon mast cells was achieved at 3 min after adding tc-LIGRLO-NH$_2$ to cells, suggesting that its action on mast cells was slower than that of neuropeptide substance P, which reached peak histamine release within 20 sec of incubation[24], but faster than that induced by anti-IgE and calcium ionophore, which required at least 6 min to complete[21].

The inhibition of trypsin induced tryptase and histamine release by SBTI, a mixed type of inhibitor of tryptic enzymes[25], indicating that the process was not cytotoxic and required an intact catalytic site of trypsin. Pretreatment of cells with metabolic inhibitors antimycin A which blocks the oxidative phosphorylation process of cells, and 2-deoxy-D-glucose which blocks anaerobic metabolism pathway in cells, abolished the actions of tc-LIGRLO-NH$_2$, SLIGKV, trypsin, anti-IgE as well as calcium ionophore, indicating that the release of tryptase and histamine induced by them was a non-cytotoxic process,

and was dependent on cell energy supply. Tryptase and histamine release provoked by tc-LIGRLO-NH$_2$, SLIGKV, trypsin, anti-IgE and calcium ionophore were also inhibited by pretreatment of cells with pertussis toxin, suggesting that the degranulation process elicited by them was associated with the activation of G-protein coupled receptors[26].

Over the last decade, a number of functions of mast cell tryptase have been discovered. These include induction of microvascular leakage[27], accumulation and activation of eosinophils and neutrophils[28,29], provocation of release of IL-8 from epithelial cells[30]. Similarly, PAR-2 agonists were found to be able to provoke the inflammatory response in the rat paw[31,32] and mediate eosinophil infiltration and hyperreactivity in allergic inflammation of the airway[33]. Of particular importance is the finding that the delayed onset of inflammation was observed in protease-activated receptor-2-deficient mice[34]. These highlighted the crucial role of tryptase and its receptor PAR-2 in inflammation. The finding that PAR-2 agonists were able to activate human colon mast cells in the current study added a new concept to the tryptase and PAR-2 theory, indicating further the importance of them in the pathogenesis of inflammation. In conclusion, the agonists of PAR-2 and trypsin are potent secretagogues of human colon mast cells, which are likely to contribute to the development of inflammatory disorders in human gut.

Abstract

AIM: To investigate the ability of protease inhibitors to modulate tryptase release from human colon mast cells.

METHODS: Enzymatically dispersed cells from human colon were challenged with anti-IgE or calcium ionophore A23187 in the absence or presence of tryptase and chymase inhibitors, and tryptase release was determined.

RESULTS: IgE dependent tryptase release from colon mast cells was inhibited by up to approximately 37%, 40% and 36.6% by chymase inhibitors Z-Ile-Glu-Pro-Phe-CO_2Me (ZIGPFM), N-tosyl-L-phenylalanyl-chloromethyl ketone (TPCK), and α_1-antitrypsin, respectively. Similarly, the inhibitors of tryptase leupeptin, N-tosyl-L-lysine chloromethyl ketone (TLCK) and lactoferrin were also able to inhibit anti-IgE induced tryptase release by a maximum of 39.4%, 47.6% and 36.6%, respectively. The inhibitory actions of chymase inhibitors, but not tryptase inhibitors on colon mast cells were enhanced by preincubation of them with cells for 20 min before challenged with anti-IgE. At a concentration of 10 µg/mL, protamine was able to inhibit anti-IgE and calcium ionophore induced tryptase release. However, at 100 µg/mL, protamine elevated tryptase levels in supernatants. A specific inhibitor of aminopeptidase amastatin had no effect on anti-IgE induced tryptase release. The significant inhibition of calcium ionophore induced tryptase release was also observed with the inhibitors of tryptase and chymase examined. The inhibitors tested by themselves did not stimulate tryptase release from colon mast cells.

CONCLUSION: It was demonstrated for the first time that both tryptase and chymase inhibitors could inhibit IgE dependent and calcium ionophore induced tryptase release from dispersed colon mast cells in a concentration dependent of manner, which suggest that they are likely to be developed as a novel class of anti-inflammatory drugs to treat chronic of colitis in man.

INTRODUCTION

It has been reported that increased number of mast cells and mast cell degranulation are closely associated with a number of gastrointestinal diseases including idiopathic inflammatory bowel disease[1], chronic ulcerative colitis[2], Crohn's disease[3-5], gastritis[5] and collagenous colitis[6,7], irritable bowel syndrome[8,9] and chronic inflammatory duodenal bowel disorders[10]. Through releasing their proinflammatory mediators including histamine, tryptase, chymase, heparin and some cytokines[11], mast cells actively participate in the pathogenesis of these intestinal diseases.

Tryptase is a tetrameric serine proteinase that constitutes about 20% of the total protein within human mast cells and is stored almost exclusively in the secretory granules of mast cells[12] in a catalytically active form[13]. Relatively higher secretion of tryptase has been detected in ulcerative colitis[14], implicating that this mediator is involved in the pathogenesis of intestinal diseases. Evidence is emerging that tryptase may be a key mediator of allergic inflammation and a promising target for therapeutic intervention[15] as it has been found to be able to induce microvascular leakage in the skin of guinea pig[16], bronchoconstriction[17] in allergic sheep airways, inflammatory cell accumulation in peritoneum of mouse[18] and release of IL-8 from epithelial cells[19]. Moreover, tryptase has been proved to be a unique marker of mast cell degranulation *in vitro* as it is more selective than histamine to mast cells[20].

In recent years, inhibitors of tryptase[21,22] and chymase[23] were discovered to possess the ability to inhibit histamine release from human skin, tonsil, synovial[24] and colon mast cells[25], suggesting these inhibitors are likely to be developed as a novel class of mast cell stabilizers. However, little is known of the actions of tryptase and chymase inhibitors on tryptase release from human colon mast cells. We therefore investigated the effects of these two groups of inhibitors on IgE dependent or independent tryptase release from human colon mast cells in the current study.

MATERIALS AND METHODS

Dispersion of mast cells

Human colon tissue was obtained from patients with carcinoma of colon at colectomy. Only macroscopically normal tissue was used for the study. After removal of fat, tissue was washed and chopped finely with scissors into fragments of 0.5-2.0 mm³, and then incubated with 1.5 mg/mL collagenase (Sigma) and 0.75 mg/mL hyaluronidase (Sigma) in minimum essential medium (MEM) containing 2% fetal calf serum (1 g colon/10 mL buffer) for 70 min at 37 ℃. Dispersed cells were separated from undigested tissue by filtration through nylon gauze (pore size 100 µm in diameter), washed and maintained in MEM (Gibco) (containing 10% FCS, 200 U/mL penicillin, 200 µg/mL streptomycin) on a roller overnight at room temperature. Mast cell purity, as determined by light microscopy after stained by alcine blue, ranged from 3.5% to 5.4%.

Mast cell challenge

Dispersed cells were resuspended in HEPES buffered salt solution (HBSS, pH 7.4) with $CaCl_2$ and $MgCl_2$ (complete HBSS), and 100 µL aliquots containing 4-6×10³ mast cells

were added to a 50 μL anti-IgE (Serotec, UK), calcium ionophore (Sigma), or inhibitor in complete HBSS and incubated for 15 min at 37 ℃. The reaction was terminated by addition of 150 μL ice cold incomplete HBSS and the tubes were centrifuged immediately (500 g, 10 min, 4 ℃). All experiments were performed in duplicate. Supernatants were stored at -20 ℃ until tryptase concentrations were determined.

Inhibition of release of tryptase

For some experiments, protease inhibitor was preincubated with cells for 20 min before anti-IgE or calcium ionophore was added. Protease inhibitor and anti-IgE or calcium ionophore were also added to cells at the same time (no preincubation period). Data were expressed as the percentage inhibition of tryptase release, taking into account tryptase release in the presence and absence of the inhibitor. As for our previous experiments, the optimal tryptase release from colon mast cells was induced by 10 μg/mL anti-IgE or 1 μg/mL calcium ionophore[20], and therefore they were chosen as standard concentrations throughout the study.

Tryptase measurement

Tryptase concentrations were measured with a sandwich ELISA procedure with a specific polyclonal antibody against human tryptase as the capture antibody and AA5 a monoclonal antibody specific for human tryptase as the detecting antibody[26].

Statistical analyses

Statistical analyses were performed with SPSS software. Data were expressed as mean±SEM. Analysis of variance indicated significant differences between groups with ANOVA. For the preplanned comparison of interest, Student's t test was applied. For all analyses, $P<0.05$ was taken as statistically significant.

RESULTS

Effects of secretagogues and inhibitors on tryptase release from mast cells

At 15 min following incubation, anti-IgE at 10 μg/mL and calcium ionophore at 1 μg/mL were able to induce 41.6±4.3 ng/mL and 38.8±3.0 ng/mL tryptase release from colon mast cells, respectively, whereas at the same time point spontaneous tryptase release (buffer alone) was 22.4±3.2 ng/mL. The same concentrations of anti-IgE and calcium ionophore were also able to provoke a significant tryptase release from colon mast cells following a 35 min incubation period (Table 1). All protease inhibitors tested had no stimulatory effect on colon mast cells following a 15 min or a 35 min incubation period (data not shown).

Table 1 Spontaneous and anti-IgE or calcium ionophore induced tryptase release from human colon mast cells

Compound		Tryptase released (ng/mL)	
		15 min	35 min
Buffer alone		22.4±3.2	20.5±2.8
Anti-IgE	10 μg/mL	41.6±4.3[a]	37.6±2.6[a]
CI	1.0 μg/mL	38.8±3.0[a]	38.4±3.6[a]

The values shown are mean±SEM for six separate experiments. [a]$P<0.05$ compared with buffer alone control (Student's t test).

Inhibition of anti-IgE induced tryptase release from mast cells

The concentration dependent inhibition of anti-IgE induced release of tryptase from colon mast cells was observed when anti-IgE and various concentrations of chymase inhibitors ZIGPFM, TPCK, and α_1-antitrypsin were added to cells at the same time. Up to approximately 37%, 40% and 36.6%

inhibition of IgE dependent tryptase release were achieved with ZIGPFM, TPCK, and α_1-antitrypsin, respectively (Figure 1). As little as 10 ng/mL ZIGPFM was able to significantly inhibit IgE dependent tryptase release. Preincubation of ZIGPFM and TPCK with cells for 20 min before challenged with anti-IgE was able to moderately enhance their inhibitory actions on cells (Figure 2).

The inhibitors of tryptase leupeptin, TLCK and lactoferrin were also able to inhibit anti-IgE induced tryptase release in a concentration dependent manner, and a maximum of some 39.4%, 47.6%, and 36.6% of inhibition was achieved with 200 μmol/mL leupeptin, 100 μmol/mL TLCK, and 30 μmol/mL lactoferrin, respectively (Figure 1). Preincubation of inhibitors of tryptase with cells for 20 min before anti-IgE was added had little effect on their abilities to inhibit anti-IgE induced tryptase release (Figure 2). A specific inhibitor of aminopeptidase, amastatin had no effect on anti-IgE induced tryptase release. When 10 μg/mL protamine was added to cells at the same time with anti-IgE, or when 1.0 μg/mL protamine was preincubated with cells before addition of the stimulus, anti-IgE induced tryptase release was significantly inhibited. However, when 100 μg/mL protamine and anti-IgE was added to cells at the same time, tryptase concentrations measured in cell supernatants were much higher than those induced by anti-IgE alone (Table 2).

Table 2 Effect of protamine on anti-IgE or calcium ionophore (CI) induced tryptase release from human colon mast cells

Protamine concentration (μg/mL)	% inhibition of tryptase release			
	No preincubation		20 min preincubation	
	Anti-IgE	CI	Anti-IgE	CI
0.1	4.0±2.3	5.1±4.5	nd	nd
1.0	17.3±5.2	16.7±4.6	21.4±3.8[a]	19.5±2.9[a]
10	20.9±4.3[a]	17.1±3.8	-0.7±1.8	-9.7±11
100	-54.7±13[b]	-24.9±8.9[b]	nd	nd

The values shown are mean±SEM for six separate experiments. Protamine was either added to cells at the same time with anti-IgE or CI, or preincubated with cells for 20 min before challenged with anti-IgE or CI. [a]levels of tryptase reduced in comparison with the uninhibited control ($P<0.05$, Student's t test). [b]levels of tryptase elevated in comparison with the uninhibited control ($P<0.05$, Student's t test). nd=not done.

Inhibition of calcium ionophore induced tryptase release from mast cells

The concentration dependent inhibition of calcium ionophore induced tryptase release from colon mast cells was observed when calcium ionophore and various concentrations of chymase inhibitors ZIGPFM, TPCK, and α_1-antitrypsin were added to cells at the same time. Up to approximately 27.6%, 35.3% and 23% inhibition of IgE dependent tryptase release were achieved with ZIGPFM, TPCK, and α_1-antitrypsin, respectively (Figure 3). Preincubation of the inhibitors with cells for 20 min before challenged with calcium ionophore enhanced the inhibitory ability of ZIGPFM, but not TPCK (Figure 4).

Calcium ionophore stimulated tryptase release was also reduced by addition of the various concentrations of inhibitors of tryptase to cells. Leupeptin, TLCK and lactoferrin were able to inhibit calcium ionophore stimulated tryptase release by up to approximately 27.1%, 44.1% and 38.2% respectively, when they were added to cells together with calcium ionophore (Figure 3). The extent of inhibition by leupeptin and TLCK was not affected by preincubation of them with cells for 20 min before calcium ionophore was added (Figure 4). Protamine at a concentration of 1 μg/mL was also able to inhibit calcium ionophore induced tryptase release (Table 2).

Figure 1 Inhibition of anti-IgE (10 μg/mL) induced tryptase release from dispersed colon mast cells by protease inhibitors. The inhibitors and anti-IgE were added to cells at the same time (no preincubation). Data are presented as mean±SEM for four to six separate experiments performed in duplicate. [a]$P<0.05$ compared with the responses with uninhibited controls. AT=α_1-antitrypsin; LF=lactoferrin.

Figure 2 Inhibition of anti-IgE (10 μg/mL) induced tryptase release from dispersed colon mast cells by protease inhibitors. The inhibitors were preincubated with cells for 20 min before anti-IgE was added. Data are presented as mean±SEM for four to six separate experiments performed in duplicate. [a]$P<0.05$ compared with the responses of uninhibited controls.

Figure 3 Inhibition of calcium ionophore (1 μg/mL) induced tryptase release from dispersed colon mast cells by protease inhibitors. The inhibitors and anti-IgE were added to cells at the same time (no preincubation). Data are presented as mean±SEM for four to six separate experiments performed in duplicate. [a]$P<0.05$ compared with the responses with uninhibited controls. AT=α_1-antitrypsin; LF=lactoferrin.
Figure 4 Inhibition of calcium ionophore (1 µg/mL) induced tryptase release from dispersed colon mast cells by protease inhibitors. The inhibitors were preincubated with cells for 20 min before calcium ionophore was added. Data are presented as mean±SEM for four to six separate experiments performed in duplicate. [a]P<0.05 compared with the responses of uninhibited controls.
DISCUSSION

We have found for the first time that inhibitors of tryptase and chymase were able to inhibit anti-IgE and calcium ionophore induced tryptase release from dispersed human colon mast cells, which may indicate a potential of a novel therapy for inflammatory bowel disease or other mast cell related intestinal diseases.

Up to approximately 40% inhibition of IgE dependent tryptase release from colon mast cells was observed with inhibitors of chymase, indicating that a chymase activity was involved in the process of IgE dependent gut mast cell degranulation. This was consistent with our previous finding that chymase inhibitors inhibited IgE dependent histamine release, which has indirectly proved that tryptase and histamine are likely to share a similar degranulation process. Unlike inhibition of histamine release, preincubation of ZIGPFM and TPCK with cells for 20 min before challenged with anti-IgE appeared to further reduce the quantity of tryptase released from mast cells, implicating that there may be some difference between tryptase and histamine release processes. Similar to chymase inhibitors, tryptase inhibitors inhibited up to some 47.6% anti-IgE induced tryptase release from colon mast cells, which implicated that a tryptase activity was likely to be involved in the process of colon mast cell degranulation. Once again, this was consistent with our previous finding that tryptase inhibitors were able to inhibit IgE dependent histamine release.

Since the majority of these inhibitors at the concentrations used in the current study were able to inhibit more than 95% tryptase or chymase activity in enzyme assays[27], the incomplete inhibition of tryptase release from mast cells may suggest that some pathways other than tryptase and chymase pathways are involved in the anti-IgE induced degranulation of gut mast cells. A specific inhibitor of aminopeptidase amastatin, which did not inhibit chymotrypsin and trypsin activities[28], was used as an irrelevant protease inhibitor control. It had no significant effects on anti-IgE induced tryptase release from colon mast cells, which proved the specificity of actions of tryptase and chymase inhibitors on tryptase release from mast cells.

Calcium ionophore is a calcium carrier that could help to elevate the calcium concentration in cytoplasms of mast cells[29], and therefore acts on the downstream site of the process of mast cell degranulation. The inhibition of calcium ionophore induced tryptase release by the inhibitors of tryptase and chymase in the current study might also suggest the

involvement of tryptase and chymase activities in mast cell degranulation process was at the downstream site and most likely after influx of calcium ions into mast cells. The evidence that tryptase and chymase are sited in the granules of mast cells in their fully active form supports further the likelihood that these two mast cell serine proteases are involved in IgE dependent activation of colon mast cells. The results that tryptase levels were elevated when 100 µg/mL protamine was added to cells at the same time with unexpected anti-IgE. This was most likely due to the tetrameric structure of tryptase being dissociated by protamine[30], thus more tryptase monomers existed in supernatants, and were recognized by AA5 as an intact tryptase molecule.

Some of the latest reports on tryptase inhibitors demonstrated the importance of these potential anti-inflammatory drugs. Inhaled APC366 was able to attenuate allergen-induced late-phase airway obstruction in asthma[31], and APC2059 could improve the symptomatic scores of patients with mildly to moderately active ulcerative colitis in an open-label pilot study[32]. Our findings in the current study may at least partially explain why tryptase inhibitors could treat these diseases. Moreover, the successful treatment of acute ulcerative colitis[33] and Crohn's disease[34] with mast cell stabilizer ketotifen further strongly suggests that inhibitors of tryptase and chymase are likely to become a novel class of anti-inflammatory drugs with their anti-inflammatory actions and mast cell stabilizing properties.

In conclusion, the inhibitors of both tryptase and chymase are able to inhibit anti-IgE dependent and calcium ionophore induced tryptase release from colon mast cells, indicating that they are likely to be developed as a novel class of anti-inflammatory drugs to treat chronic colitis in man.

Abstract

AIM: To investigate the ability of protease inhibitors to modulate histamine release from human colon mast cells.

METHODS: Enzymatically dispersed cells from human colon were challenged with anti-IgE or calcium ionophore A23187 in the absence or presence of tryptase and chymase inhibitors, and histamine release was determined.

RESULTS: IgE dependent histamine release from colon mast cells was inhibited by up to approximately 37%, 26% and 36.8% by chymase inhibitors Z-Ile-Glu-Pro-Phe-CO$_2$Me (ZIGPFM), N-Tosyl-L-phenylalanyl-chloromethyl ketone (TPCK), and α_1-antitrypsin, respectively. Similarly, inhibitors of tryptase leupeptin, N-tosyl-L-lysine chloromethyl ketone (TLCK), lactoferrin and protamine were also able to inhibit anti-IgE induced histamine release by a maximum of some 48%, 37%, 40% and 34%, respectively. Preincubation of these inhibitors with cells for 20 min before challenged with anti-IgE had small effect on the inhibitory actions of these inhibitors on colon mast cells. A specific inhibitor of aminopeptidase amastatin had no effect on anti-IgE induced histamine release. The significant inhibition of calcium ionophore induced histamine release was also observed with the inhibitors of tryptase and chymase examined. Apart from leupeptin and protamine, the inhibitors tested by themselves did not stimulate colon mast cells.

CONCLUSION: It was demonstrated that both tryptase and chymase inhibitors could inhibit IgE dependent and calcium ionophore induced histamine release from dispersed colon mast cells in a concentration dependent of manner, which suggest that they are likely to be developed as a novel class of anti-inflammatory drugs to treat chronic of colitis in man.

INTRODUCTION

It has been reported that mast cells and their inflammatory mediators are closely associated with a number of intestinal diseases including idiopathic inflammatory bowel disease[1], chronic ulcerative colitis[2], Crohn's disease[3] and collagenous colitis[4]. Through release their proinflammatory mediators including histamine, tryptase, chymase, heparin and some cytokines[5], mast cells actively participate in the pathogenesis of these intestinal diseases.

As a proinflammatory mediator, histamine is selectively located in the granules of human mast cells and basophils and released from these cells upon degranulation. To date, a total of four histamine receptors H$_1$, H$_2$, H$_3$ and H$_4$ have been discovered[6] and the first three of them are located in human gut[7,8], which prove that there are some specific targets that histamine can work on in intestinal tract. Indeed, increased levels of histamine or enhanced histamine metabolism have been observed in collagenous colitis, food allergy[9], Crohn's disease[10], ulcerative colitis[10,11] and allergic enteropathy[11], indicating that this mediator is involved in the pathogenesis of these diseases.

For more than four decades, histamine has been widely used as a marker of mast cell degranulation *in vitro*, and numerous anti-allergic drugs such as sodium cromoglycate, lodoxamide, salbutamal, ketotifen, terfenadine and cetirizine[12,13] and salmeteral[14] were reported to be able to inhibit anti-IgE induced histamine release from human mast cells. In recent years, inhibitors of tryptase[15,16] and chymase[17] have been discovered to possess the ability to inhibit histamine release from human skin, tonsil and synovial mast cells[18], suggesting these inhibitors are likely to be developed as a novel class of mast cell stabilizers. However, little is known of the actions of tryptase and chymase inhibitors on histamine release from human colon mast cells. We therefore investigated the effects of these two groups of inhibitors on IgE dependent or independent histamine release from human colon mast cells in the current study.

MATERIALS AND METHODS

Dispersion of mast cells

Human colon tissue was obtained from patients with carcinoma of colon at colectomy. Only macroscopically normal tissue was used for the study. After removal of fat, tissue was washed and chopped finely with scissors into fragments of 0.5-2.0 mm^3, and then incubated with 1.5 mg/mL collagenase (Sigma) and 0.75 mg/mL hyaluronidase (Sigma) in minimum essential medium (MEM) containing 2% fetal calf serum (1 g colon/10 mL buffer) for 70 min at 37 ℃. Dispersed cells were separated from undigested tissue by filtration through nylon gauze (pore size 100 μm diameter), washed and maintained in MEM (Gibco) (containing 10% FCS, 200 U/mL penicillin, 200 μg/mL streptomycin) on a roller overnight at room temperature. Mast cell purity, as determined by light microscopy after stained by alcine blue, ranged from 3.5% to 5.4%.

Mast cell challenge

The challenge procedure was performed as described previously[19]. Dispersed cells were resuspended in HEPES

buffered salt solution (HBSS, pH 7.4) with $CaCl_2$ and $MgCl_2$ (complete HBSS), and 100 μL aliquots containing $4\text{-}6\times10^3$ mast cells were added to a 50 μL anti-IgE (Serotec, UK), calcium ionophore (Sigma), or inhibitor in complete HBSS and incubated for 15 min at 37 ℃. The reaction was terminated by addition of 150 μL ice cold incomplete HBSS and the tubes were centrifuged immediately (500 g, 10 min, 4 ℃). All experiments were performed in duplicate. For the measurement of total histamine concentration, in certain tubes the suspension was boiled for 6 min. Supernatants were stored at -20 ℃ until histamine concentrations were determined.

Inhibition of release of histamine

For some experiments, protease inhibitor was preincubated with cells for 20 min before anti-IgE or calcium ionophore being added. Protease inhibitor and anti-IgE or calcium ionophore were also added to cells at the same time (no preincubation period). Data were expressed as the percentage of inhibition of histamine release, taking into account of histamine release in the presence and absence of the inhibitor. As for our previous experiments, the optimal histamine release from colon mast cells was induced by 10 μg/mL anti-IgE or 1 μg/mL calcium ionophore[20], and therefore they were chosen as standard concentrations throughout the study.

Histamine measurement

Histamine concentrations were determined using a glass fibre-based fluorometric assay[15]. The procedure involved the binding of histamine to a glass-fiber matrix (RafLab, Copenhagen, Denmark) and its detection spectrophotometrically with Perkin-Elmer LS 2 detector (Denmark) following addition of o-phthaldialdehyde (OPT). Histamine release was expressed as a percentage of total cellular histamine levels, and corrected for the spontaneous release measured in tubes in which cells had been incubated with the HBSS diluent alone.

Statistical analyses

Statistical analyses were performed with SPSS software. Data were expressed as mean±SEM. Where analysis of variance indicated significant differences between groups with ANOVA, for the preplanned comparisons of interest, Student's t test was applied. For all analyses, $P<0.05$ was taken as statistically significant.

RESULTS

Effects of protease inhibitors on histamine release from mast cells

At 15 min following incubation, leupeptin at concentration 200 μmol/mL and protamine at 100 μg/mL were able to provoke small but nevertheless significant histamine release from colon mast cells (Table 1). The same concentration of leupeptin was also capable of eliciting histamine release following a 35 min incubation period (Table 2). All the other protease inhibitors tested had no stimulatory action on colon mast cells. Leupeptin and protamine at all other concentrations did not induce a significant histamine release from colon mast cells. In the same experiments, anti-IgE and calcium ionophore were able to induce up to 11% and 21.8% net histamine release, respectively.

Inhibition of anti-IgE induced histamine release from mast cells

The concentration dependent inhibition of anti-IgE induced release of histamine from colon mast cells was observed when anti-IgE and various concentrations of chymase inhibitors ZIGPFM, TPCK, and α_1-antitrypsin were added to cells at the same time. Up to approximately 37%, 26% and 36.8% inhibition of IgE dependent histamine release were achieved with ZIGPFM, TPCK, and α_1-antitrypsin, respectively (Figure 1). Preincubation of ZIGPFM and TPCK with cells for 20 min before challenged with anti-IgE was able to slightly enhance their inhibitory actions (Figure 2).

The inhibitors of tryptase leupeptin, TLCK, lactoferrin and protamine were also able to inhibit anti-IgE induced histamine release in a concentration dependent manner, and a maximum of 48%, 37%, 40% and 34% inhibition was achieved with 200 μmol/mL leupeptin, 100 μmol/mL TLCK, 30 μmol/mL lactoferrin and 100 μg/mL protamine, respectively (Figure 1). In contrast to inhibitors of chymase, preincubation of inhibitors of tryptase with cells for 20 min before the addition of anti-IgE had little effect on their abilities to inhibit anti-IgE induced histamine release (Figure 2). A specific inhibitor of aminopeptidase, amastatin had no effect on anti-IgE induced histamine release (data not shown).

Table 1 The effects of protease inhibitors on histamine release from human colon mast cells at 15 min incubation period

Compound	Concentration	Net histamine release (%)
ZIGPFM	0.001 μmol/mL	-0.9±0.8

	60 μmol/mL	0±0.7
	200 μmol/mL	5.1±0.5[a]
Protamine	1.0 μg/mL	1.2±2.9
	10 μg/mL	1.0±2.5
Anti-IgE	10 μg/mL	10.1±2.5[a]
Calcium ionophone	1.0 μg/mL	21.8±3.8[a]

The values shown are mean±SEM for four to six separate experiments. Spontaneous histamine release from these cells was 9.8±1.7%. [a]$P<0.05$ compared with buffer alone control (Student's t test).

Inhibition of calcium ionophore induced histamine release from mast cells

The concentration dependent inhibition of calcium ionophore induced histamine release from colon mast cells was observed when calcium ionophore and various concentrations of chymase inhibitors ZIGPFM, TPCK, and α_1-antitrypsin were added to cells at the same time. Up to approximately 35%, 24% and 23.6% inhibition of IgE dependent histamine release were achieved with ZIGPFM, TPCK, and α_1-antitrypsin, respectively (Figure 3). Preincubation of TPCK with cells for 20 min before challenged with calcium ionophore slightly enhanced its inhibitory ability, whereas the same treatment did not improve the inhibitory ability of ZIGPFM (Figure 4).

Calcium ionophore stimulated histamine release was also reduced by addition of the various concentrations of inhibitors of tryptase to cells. Leupeptin, TLCK, lactoferrin and protamine were able to inhibit calcium ionophore stimulated histamine release by up to approximately 25%, 26%, 25% and 32%, respectively when they were added to cells together with calcium ionophore (Figure 3). The extent of inhibition by leupeptin and TLCK was increased when colon mast cells were preincubated with them for 20 min before calcium ionophore was added. However, the same treatment failed to improve the inhibitory action of protamine (Figure 4).

DISCUSSION

We have found that inhibitors of tryptase and chymase were able to inhibit anti-IgE and calcium ionophore induced histamine release from dispersed human colon mast cells, which may indicate a potential of a novel therapy for inflammatory bowel disease or other mast cell related intestinal diseases.

Up to approximately 37% inhibition of IgE dependent histamine release from colon mast cells was observed with inhibitors of chymase, indicating that a chymase activity was involved in the process of IgE dependent gut mast cell degranulation. This was consistent with our previous findings with human skin, lung[17] and synovium tissues[18], which demonstrated that chymase was involved in the mast cell activation-degranulation process. Comparing mast cells from different human tissues, the order of extent of maximum inhibition by chymase inhibitors was skin (82%) > lung (80%) > synovium (69%) >colon (37%). This might represent a novel type of mast cell heterogeneity, and could also be resulted from an inhibitor of chymase, chymostatin was not used for colon cells, but for the cells from other tissues.

Similar to chymase inhibitors, tryptase inhibitors inhibited

Figure 1 Inhibition of anti-IgE (10 μg/mL) induced histamine release from dispersed colon mast cells by the protease inhibitors. The inhibitors and anti-IgE were added to cells at the same time (no preincubation). Data are presented as mean±SEM for four to six separate experiments performed in duplicate. [a]$P<0.05$ compared with the responses with uninhibited controls. AT=α_1-antitrypsin; LF=lactoferrin.

Figure 2 Inhibition of anti-IgE (10 μg/mL) induced histamine release from dispersed colon mast cells by the protease inhibitors. The inhibitors were preincubated with cells for 20 min before anti-IgE was added. Data are presented as mean±SEM for four to six separate experiments performed in duplicate. [a]P<0.05 compared with the responses with uninhibited controls.

Figure 3 Inhibition of calcium ionophore (1 μg/mL) induced histamine release from dispersed colon mast cells by the protease inhibitors. The inhibitors and anti-IgE were added to cells at the same time (no preincubation). Data are presented as mean±SEM for four to six separate experiments performed in duplicate. [a]P<0.05 compared with the responses with uninhibited controls. AT=α_1-antitrypsin; LF=lactoferrin.

**Figure 4** Inhibition of calcium ionophore (1 μg/mL) induced histamine release from dispersed colon mast cells by the protease inhibitors. The inhibitors were preincubated with cells for 20 min before calcium ionophore being added. Data are presented as mean±SEM for four to six separate experiments performed in duplicate. [a]P<0.05 compared with the responses with uninhibited controls.
up to some 48% anti-IgE induced histamine release from colon mast cells, which implicated that a tryptase activity was likely to be involved in the process of colon mast cell degranulation. Once again, this was consistent with our previous findings with cells from other human tissues including skin, tonsil[15] and synovium[18]. Comparing mast cells from different human tissues, the order of extent of maximum inhibition by tryptase inhibitors was skin (90%) > synovium (70%) > colon (48%) > tonsil (35%).

Since the majority of these inhibitors at the concentrations used in the current study were able to inhibit more than 95% tryptase or chymase activity in enzyme assays[20], the incomplete inhibition of histamine release from mast cells may suggest that some pathways other than tryptase and chymase pathways are involved in the anti-IgE induced degranulation of gut mast cells. A specific inhibitor of aminopeptidase amastatin, which did not inhibit chymotrypsin and trypsin activities[21], was used as an irrelevant protease inhibitor control. It had no significant effects on anti-IgE induced histamine release from colon mast cells, which proved the specificity of actions of tryptase and chymase inhibitors on mast cells. The observation that preincubation of the inhibitors with cells for 20 min before challenged with anti-IgE had little impact on inhibition of IgE dependent histamine release was unexpected, nevertheless it may suggest that the actions of these inhibitors are rather rapid and the involvement of tryptase and chymase activities in anti-IgE induced histamine release is likely at the downstream site of the degranulation process. Since calcium ionophore is a calcium carrier that can help to elevate the calcium concentration in cytoplasms of mast cells, and therefore acts on the downstream site of the process of mast cell degranulation, the inhibition of calcium ionophore induced histamine release by the inhibitors of tryptase and chymase in the current study might also suggest that the involvement of tryptase and chymase activities in mast cell degranulation process was at the downstream site and most likely after influx of calcium ions into mast cells. The evidence that tryptase and chymase are sited in the granules of mast cells in their fully active form supports further the likelihood that these two mast cell serine proteases are involved in IgE dependent activation of colon mast cells.

Over the years, many compounds including sodium cromoglycate, lodoxamide, salbutamal, ketotifen, terfenadine and cetirizine have been recognized as mast cell stabilizers or histamine receptor antagonists, and used as anti-allergic drugs in clinical practice. However, only less than 40% inhibition of IgE dependent mast cell degranulation could be achieved with these compounds, much less than that with inhibitors of tryptase and chymase in the similar experimental system[15,17]. Moreover, mast cell stabilizer drug ketotifen was successfully used to treat acute ulcerative colitis[22] and Crohn's disease[23]. These strongly suggest that inhibitors of tryptase and chymase are likely to become a novel class of anti-inflammatory drugs with their anti-inflammatory actions and mast cell stabilizing properties.

In conclusion, inhibitors of both tryptase and chymase are able to inhibit anti-IgE dependent and calcium ionophore induced histamine release from colon mast cells, indicating that they are likely to be developed as a novel class of anti-inflammatory drugs to treat chronic colitis in man.

Abstract

AIM: To clone and express the human colon mast cell carboxypeptidase (MC-CP) gene.

METHODS: Total RNA was extracted from colon tissue, and the cDNA encoding human colon mast cell carboxypeptidase was amplified by reverse-transcription PCR (RT-PCR). The product cDNA was subcloned into the prokaryotic expression vector pMAL-c2x and eukaryotic expression vector pPIC9K to construct prokaryotic expression vector pMAL/human MC-CP (hMC-CP) and eukaryotic pPIC9K/hMC-CP. The recombinant fusion protein expressed in *E.coli* was induced with IPTG and purified by amylose affinity chromatography. After digestion with factor Xa, recombinant hMC-CP was purified by heparin agarose chromatography. The recombinant hMC-CP expressed in *Pichia pastoris* (*P.pastoris*) was induced with methanol and analyzed by SDS-PAGE, Western blot, N-terminal amino acid sequencing and enzyme assay.

RESULTS: The cDNA encoding the human colon mast cell carboxypeptidase was cloned, which had five nucleotide variations compared with skin MC-CP cDNA. The recombinant hMC-CP protein expressed in *E.coli* was purified with amylose affinity chromatography and heparin agarose chromatography. SDS-PAGE and Western blot analysis showed that the recombinant protein expressed by *E. coli* had a molecular weight of 36 kDa and reacted to the anti-native hMC-CP monoclonal antibody (CA5). The N-terminal amino acid sequence confirmed further the product was hMC-CP. *E. coli* generated hMC-CP showed a very low level of enzymatic activity, but *P. pastoris* produced hMC-CP had a relatively high enzymatic activity towards a synthetic substrate hippuryl-L-phenylalanine.

CONCLUSION: The cDNA encoding human colon mast cell carboxypeptidase can be successfully cloned and expressed in *E.coli* and *P. pastoris*, which will contribute greatly to the functional study on hMC-CP.

INTRODUCTION

Mast cells and their inflammatory mediators have been implicated to play a pivotal role in intestinal diseases such as inflammatory bowel disease[1-7], collagenous colitis[8,9], intestinal anaphylaxis[10,11] and irritable bowel syndrome[11,12]. Mast cell neutral proteases constitute more than 50% granule proteins in mast cells. They are tryptase, MC-CP, chymase, and a cathepsin G-like protease[13-16]. Upon degranulation, these neutral proteases are released and carry out numerous functions in tissues nearby or distant as pro-inflammatory mediators. Recently it was found that mast cell products tryptase and histamine might play an important role in the amplification of degranulation signals in human[17-21].

hMC-CP is a distinctive carboxypeptidase, which is exclusively located in MC_{TC} mast cells, possesses pancreatic carboxypeptidase A (CPA)-like activity, but has a closer amino acid sequence identical to carboxypeptidase B (CPB)[13,22]. The evolution analysis demonstrated that MC-CP originated from a gene duplication along the pancreatic CPB lineage rather than along the pancreatic CPA lineage[22,23]. Although hMC-CP has been detected in skin, lung, and intestinal tissues with immunohistochemistry[13,22,24], and hMC-CP genes from skin and lung were cloned[22,23,25], hMC-CP gene from intestinal tissue is still unknown.

Investigations on the structures and functions of human tryptase and chymase have made impressive progress and a number of potent functions of these two mast cell proteases were found in last decade. These include induction of microvascular leakage in skin of guinea pig[26], stimulation of inflammatory cell accumulation in peritoneum of mouse[27,28] and modulation of mast cell degranulation[29,30], indicating that they may be key mediators of allergic inflammation and promising targets for diagnosis and therapeutic intervention[31-35]. However, little is known about the function of hMC-CP except for its ability to cleave angiotension I[13]. This could be resulted from lack of sufficient amount of hMC-CP. In the current study, a procedure for cloning and expression of hMC-CP was developed and enzymatically active human intestinal recombinant MC-CP was produced.

MATERIALS AND METHODS

Materials

RNA extract kit, total RNA purification system, multi-copy *Pichia* expression kit were purchased from Invitrogen (Carlsbad, CA, USA). First strand cDNA synthesis kit, restriction endonucleases, T_4 DNA ligase, the expression vector pMAL-c2x, *E.coli* hosts TB1 and amylose resin were obtained from Biolabs (Beverly, MA,USA). Antibiotics, isopropyl thio-β-D-galctopyranoside (IPTG), heparin agarose, extr-Avidin peroxidase, biotinlated sheep anti-mouse IgG, for *E.coli* growth medium and *P. Pichia* growth medium were from Sigma (Saint Louis, MO, USA). Qiaquick gel extraction kit and *Taq* polymerase were from Qiagen (Hilden, Germany). Protein molecular weight markers were from Bio-Rad (Hercules, CA, USA). A monoclonal antibody against human mast cell carboxypeptidase (CA5) was donated by University of Southampton, UK. All other chemicals were of analytical grade.

Tissue preparation

Human colon tissue was obtained from patients with carcinoma

of colon at colectomy. Only macroscopically normal tissue was used for the study. The specimens were kept in liquid nitrogen until use.

Extraction of RNA
Total cellular RNA was extracted from normal colon tissues according to the manufacturer's protocol. The purity of RNA was confirmed by formaldehyde denaturing agarose gel electrophoresis, and the concentration of RNA was determined with a spectrophotometer (DU640, Beckman).

Synthesis of cDNA
cDNAs were generated from total RNA by using the ProtoScript™ first strand cDNA synthesis kit. A total of 10 μL of RNA (1 μg), 2 μL of oligo (dT) primer and 4 μL of 2.5 mM dNTP were heated at 70 ℃ for 5 min. Reverse transcription was performed for 1 h at 42 ℃ in a solution (20 μL of total volume) containing 1 μL of 25U/μL M-MuLV reverse transcriptase. The reaction was terminated by incubating the mixture at 95 ℃ for 5 min, and placed on ice immediately.

PCR amplification and cloning of cDNAs
Based on the published DNA sequence of human skin mast cell carboxypeptidase[22], a pair of primers (P1: 5'-GCTATGAGGCTCATCCTGCCTGT-3'; P2: 5'-GCTTTAGGAAGTATGCTTGAGGATATAC-3') were used to amplify hMC-CP cDNA. A hot-star PCR protocol was followed under the condition: at 95 ℃ for 15 min prior to amplification, then at 94 ℃ for 30 s, at 57 ℃ for 30 s, and at 72 ℃ for 1 min. The amplification was carried out for 30 cycles, followed by incubation at 72 ℃ for 10 min. The PCR products were analyzed with 1% agarose gel electrophoresis, and recovered with a Qiaquick gel extraction kit. The purified PCR product was cloned to pGEM-T Easy vector, forming a new plasmid pGEM/hMC-CP. The ligation mixtures were transformed into *E.coli* Dh5α. The positive recombinant clones were seeded on LB/agar plates with 100 μg/mL ampicillin, and the clones were further determined by PCR and DNA sequencing using a DNA sequencer (ABI 377 PRISM).

Construction of expression vector
To express hMC-CP in *E. coli*, an expression plasmid comprising the expression vector pMAL-C2x and *hMC-CP* cDNA was constructed. For this construction, a pair of specific primers (P3: 5'-GCTGAATTCATCGAGGGAAGGATCCCAGGCAGGCACAGCTAC-3'; P4: -GCTCTGCAGTTAGGAAGTATGCTTGAGGATATAC-3') were designed and used to amplify the coding region of the mature hMC-CP. The forward primer contained the recognition sequences for *Eco*R I, coding sequences for Factor Xa rEcognition sequence and the N-terminal region of the mature hMC-CP, and the reverse primer contained the rEcognition sequences for *Pst* I, and the coding sequence of the C-terminal region of the mature hMC-CP. pGEM/hMC-CP was used as the template for PCR. The resulting PCR fragments and pMAL-c2x plasmid were digested with *Eco*R I and *Pst* I. The fragments of interests were recovered from agarose gel, purified and ligated by T4 DNA ligase, which resulted in the expression plasmid pMAL/hMC-CP. The ligation mixtures were used to transform *E.coli* TB1 cells. The positive recombinant products were selected on LB agar plates with 100 μg/mL ampicillin, and confirmed by PCR and DNA sequencing.

To express hMC-CP in pichia pastoris, aNother expression plasmid comprising the expression vector pPIC9K and hMC-CP cDNA was constructed. For this construction, a pair of specific primers (P5: 5'-GCTGAATTCATCCCAGGCAGGCACAGCTAC-3'; P6: -TACGCGGCCGCTTAGGAAG

TATGCTTGAGGATATAC-3') were designed and used to amplify the coding region of the mature hMC-CP. The forward primer contained the recognition sequences for *Eco*R I, and the reverse primer contained the recognition sequences for *Pst* I. pGEM/hMC-CP was used as the template for PCR. The resulting PCR fragments and pPIC9K plasmid were digested with *Eco*R I and *Not* I. The fragments of interests were recovered from agarose gel, purified and ligated by T4 DNA ligase, which resulted in the expression plasmid pPIC9K/hMC-CP. The ligation mixtures were used to transform *E.coli* DH5α cells. The positive recombinant products were selected on LB agar plates with 100 μg/mL ampicillin. The nucleotide sequences of cDNA insert and flanking sequence were verified. The expression plasmid pPIC9K/hMC-CP was linearized by digestion with *Bgl* II. Competent cells of *P. pastoris* GS115 were prepared for electroporation with the linearized plasmid pPIC9K/hMC-CP. The electroporation was performed in a 2 mm gap cuvette at 2.0 kV, 25 μF, and 200Ω using a gene-pulser (Bio-Rad). Transformants were screened for a His[+] pheNotype on minimal dextrose (MD) agar plates. MD and minimal methanol (MM) plates were used to identify Mut[s] clones. YPD plates containing Geneticin at a final concentration of 0.25, 0.5, 0.75, 2.0, 3.0, 4.0 mg/mL were used to screen multiple inserts for further expression.

Expression of recombinant hMC-CP
E.coli TB1 cells harboring the expression plasmid pMAL/hMC-CP were inoculated into LB medium containing 100 μg/mL ampicillin overnight at 37 ℃ in an orbital shaker (220 rpm). IPTG was added to a final concentration of 0.3 mM before the culture mixture was transferred to a 23 ℃ air shaker.

For the expression of hMC-CP in *P. pastoris*, a single colony of GS115 harboring the expression plasmid pPIC9K/hMC-CP was inoculated into 200 mL of buffered minimal glycerol complex medium (BMGY), and grew at 30 ℃ until the culture reached an A_{600}=2.0. Cultured cells were harvested by centrifugation and transferred to 1/10 of the original culture volume of buffered minimal methanol complex medium (BMMY), then grew at 30 ℃. Methanol was added to a final concentration of 0.5% (v/v) every 24 h to maintain induction.

Purification of recombinant hMC-CP
At 24 h after induction, the bacterial cells were harvested by centrifugation at 5 000 g for 10 min at 4 ℃. The pellet was resuspended in 50 mL ice-cold cells lysis buffer (20 mM Tris, 200 mM NaCl, 0.01% Triton X-100) at pH 8.0, then sonicated 6 times for 10 s (300 w) at 30 s intervals. The clarified cell extract was obtained by centrifugation at 20 000 g for 20 min, at 4 ℃.

Amylose resin was used for purification of the fusion protein, and equilibrated with the running buffer (20 mM Tris, 200 mM NaCl, pH8.0), then the cell extract was loaded onto the column at a flow rate. The fusion protein was eluted from column with a buffer containing 10 mM maltose. In order to obtain the recombinant hMC-CP, the fusion protein was cleaved with factor Xa in 20 mM Tris, pH 8.0, containing 100 mM NaCl, 2 mM $CaCl_2$. The digestion was performed at 23 ℃ for 3 h. The above cleavage mixture was applied to heparin agarose in an equilibration buffer (20 mM Tris, 200 mM NaCl, pH8.0), and eluted from heparin agarose by the elution buffer containing 20 mM Tris, 2 M NaCl, pH 8. The fractions containing hMC-CP were collected and stored at -80 ℃. The procedures above were mainly performed at 4 ℃.

SDS-PAGE and Western blotting analysis
SDS-PAGE was performed on a 15% polyacrylamide gel. The gel was then stained with 0.25% Coomassie brilliant blue R-250

or transferred to polyvinylidene fluoride (PVDF) membranes for Western blotting. The membranes were incubated for 1 h at room temperature in PBS containing 4% BSA and 0.02% Tween-20 in order to prevent nonspecific binding. After incubated with CA5, biotinylated sheep anti-mouse antibody followed by extr-avidin peroxidase was added to the strips. The immunoreactive protein was visualized by DAB.

N-terminal amino acid sequence analysis

Protein was sequenced by automated Edman degradation on a model 491A protein sequencer (Applied Biosystem). Purified protein was applied to a SDS-PAGE. After blotting, the polyvinylidene difluoride membranes were stained with Coomassie brilliant blue R-250, the protein bands of interest were cut out for N-terminal amino acids sequence determination.

Protein assay

Protein concentration was determined using the method of Bradford with the protein assay dye reagent concentrator (Bio-Rad) and bovine serum albumin (BSA) was used as a standard protein.

Enzyme activity assay

In this study, the hMC-CP activity was measured spectrophometrically by hydrolyzing a substrate of synthesis peptide of hippuryl-L-phenylalanine[13]. The rate of hydrolysis of hippuryl-L-phenylalanine was determined by measuring the increase in absorbance at 254 nm. The assay mixtures contained 1 mM substrate in 0.05 M Tris-HCl, pH 7.5, 0.5 M NaCl. $\triangle A_{254}$/minute from the initial linear portion of the curve was determined. Unit definition: One unit hydrolyzes one micromole of hippuryl-L-phenylalanine per minute at pH 7.5 and 25 ℃. Bovine pancreatic CPA (51 U/mg, Sigma) was used as positive control.

RESULTS

RT-PCR amplification of hMC-CP cDNA

RT-PCR was performed with total RNA template extracted from human colon tissues. The PCR product showed a single band about 1 250 bp on 1% agarose gel (Figure 1A).

Figure 1 Agarose gel electrophoresis of PCR product. A: hMC-CP cDNA (lane 1: DNA molecular marker; lane 2: hMC-CP cDNA). B: coding region of mature human colon MC-CP cDNA (lane 1: DNA molecular marker; lane 2: PCR product of colon MC-CP cDNA).

DNA sequencing revealed that the human colon MC-CP cDNA had 1 254 bp. The DNA sequence and deduced amino acid sequence of human colon MC-CP are shown in Figure 2. The DNA sequence of human colon MC-CP cDNA was identical to the skin MC-CP except for five nucleotides at the positions 109, 575, 576, 708, 737: C→G, C→T, T→C, A→C, A→T (nucleotide numbering starts from the first codon of mature enzyme). Only the fourth (A1035→C) of the nucleotide differences described above did Not represent an altered amino acid residue in the putative protein products. The other 4

Figure 2 Nucleotide sequence and deduced amino acid sequences of mature human colon MC-CP. The nucleotide variations and amino acid substitutions different from the skin MC-CP are underlined and boxed, respectly.

nucleotide variations caused 3 amino acid substitutions at the positions 146, 301, 355. The human colon MC-CP had Gly[146], Ile[301] and Ile[355] residues, whereas the skin MC-CP had Arg[146], Thr[146] and Asn[355] residues. In contrast, the colon MC-CP cDNA was 100% identical to the lung MC-CP cDNA.

Construction of expression vector

A 924 bp of PCR product was obtained following amplification of the coding region of the mature hMC-CP (Figure 1B). DNA sequencing showed that the recombinant pMAL/hMC-CP and pPIC9K/hMC-CP plasmids had the correct open reading frame coding for 308 amino acids mature polypeptide and no substitutions were introduced by PCR.

Expression of recombinant hMC-CP in E.coli

As shown in Figure 3A, a high level of expression of an induced protein of about 80 kD was achieved after the *E.coli* harbouring expression plasmid pMAL/hMC-CP, which was in agreement with the expected molecular mass of the fusion protein MBP (45 kDa) and hMC-CP (36 kDa). Figure 3B showed a band at about 80 kDa (expected in *E.coli* cells with IPTG induction) reacted to CA5, suggesting that the recombinant protein had a good immunological activity. The best expression of the recombinant protein after IPTG induction was at 23 ℃ for 16 h (Figure 4). The recombinant products generated by the above procedures were mainly insoluble inclusion body with a small proportion of the soluble recombinant proteins (Figure 5).

In *P. pastoris* expression, 2 colonies resistant to 4.0 mg/ml Geneticin were screened and used for the expression of recombinant protein. There was a substantial quantity of recombinant proteins in cell-free supernatant, and SDS-PAGE showed a major band of approximately 37 kDa (Figure 6A), which reacted to CA5 on Western blot (Figure 6B).

Figure 7 SDS-PAGE analysis of fusion protein cleavage (lane 1: cleaved by factor Xa; lane 2: uncleaved by factor Xa; lane 3: molecular weight marker).

Purification of rhMC-CP

Maltose-binding protein (MBP) was used as a fusion partner to provide a "tag" which could be used for the subsequent purification. The yield of the recombinant fusion protein was 12 mg/L of bacterial culture. The purified fusion protein showed a single protein band of approximately 80 kDa on SDS-PAGE.

After the fusion protein cleavage, SDS-PAGE analysis showed that the fusion protein was completely cleaved by factor Xa (Figure 7). The cleavage mixtures were loaded to heparin agarose, and the target protein showed one band about 36 kDa on SDS-PAGE, which was corresponding to the molecular weight of the native hMC-CP published previously (Figure 8A). About 1.2 mg pure recombinant protein was obtained from 5 mg fusion protein following the above procedures. The Western blot showed that this 36 kDa protein band strongly

reacted to CA5 (Figure 8B), suggesting that the recombinant protein had a good immunology activity. The N-terminal sequence of the purified recombinant protein expressed in *E.coli* was IPGRHSYAKY, and no additional amino acids were found at the N-terminus.

Figure 8 Analysis of purified recombinant protein. A: SDS-PAGE analysis of purified recombinant protein. B: Western blot analysis of purified fusion protein with CA5. Lane 1: purified fusion protein after MBP affinity chromatography; lane 2: purified recombinant hMC-CP after heparin agarose affinity chromatography.

Analysis of enzymatic activity

The purified recombinant hMC-CP expressed in *E.coli* had a very low level of enzymatic activity. In contrast, enzymatic activity in cell-free supernatant of *P. pastoris* culture was 11.7 U/mg secreted protein.

DISCUSSION

A cDNA of human colon hMC-CP was cloned and active enzyme was expressed in the current study, which will offer an essential tool for investigating the functions of hMC-CP, a zinc containing metalloexopeptidase.

Our result revealed that the human colon MC-CP cDNA comprised 1 251 bp, which agreed with the skin and lung mast cell carboxypeptidase[22,23,26]. The hMC-CP was predicted to be translated as a 417 amio acid preproenzyme which includes a 15 amino acid signal peptide, a 94 amino acid activation peptide and 308 amino acid mature mast cell carboxypeptidase. When comparison of the DNA sequence of human colon MC-CP cDNA with skin MC-CP cDNA, five variations were found which caused 3 amino acid substitutions, but there was Not any difference between the human colon and skin MC-CP. The meaning of these variations between tissues in man requires more investigations.

Since the role of hMC-CP in man remains unclear and human mast cells contain large amount of MC-CP, there is a pressing need to investigate the functions of this enzyme. One of the difficulties in investigating the potential functions of MC-CP over the years was that it was uneasy to obtain a substantial quantity of the active enzyme. Purification of MC-CP from human tissues was not only hard to perform, but also difficult to collect enough tissues for purification. Therefore, development of an efficient heterologous expression system for the production of recombinant hMC-CP is an alternative for obtaining a sufficient quantity of hMC-CP. There are a number of options for heterologous recombinant expressions, among them *E.coli* expression system is the most convenient and frequently used, therefore, *E.coli* expression system was used to express hMC-CP. The pMAL-C2x plasmid[36,37], a vector that allows the fusion of the target protein N-terminus to the MBP tag, made the purification of recombinant proteins much easier.

The extra residue(s) is often added to the C-terminus or N-terminus of recombinant protein. In this study, a pair of specific primers were designed. The upstream primer contained the sequences for a factor Xa recognition site just before the sequence for N-terminus of hMC-CP, and the downstream primer contained a terminator. The PCR product was inserted into the expression vector pMAL-c2x, which yielded the recombinant protein without extra residues after the fusion protein was cut with factor Xa. The result of N-terminal amino acid sequencing also showed that the N-terminus of recombinant hMC-CP had no extra residue.

After induction with IPTG, the recombinant protein was expressed in *E.coli*, with a molecular weight of about 80 kDa. This was in agreement with the expected molecular mass of the fusion proteins MBP (45 kD) and HMC-CP (36 kD). It was reported that the target gene fused to bacterial gene could improve the expression level and increase the solubility of recombinant proteins[37]. The expression vector pMAL-2x containing *malE* gene of *E.coli* encoding MBP was used for fusion expression. The target gene was inserted downstream from the *malE* gene, which resulted in the expression of hMC-CP fused to MBP. The solubility of recombinant proteins generally could be increased when the cell culture temperature decreased[38]. In our case, although the culture temperature was reduced to 23 ℃, insoluble recombinant proteins were still the major products. Since purification of recombinant proteins from inclusion body was a complicated process, we only used soluble products to isolate active recombinant hMC-CP.

Fusion protein was purified with one–step affinity chromatography with maltose. Once the fusion protein was isolated, it was necessary to remove the tag. In this study, the linker sequence recognized by factor Xa was designed between the MBP and target protein, because there were no such sequences in MBP and hMC-CP. After the fusion protein cleavage, usually ion exchange chromatography and hydroxyapatite chromatography were used in separating the protein of interest from MBP[36,39]. But in this study, the recombinant protein was purified by heparin agarose chromatography as MC-MBP could tightly bind to heparin[40]. In comparison with ion exchange chromatography and hydroxyapatite chromatography, heparin agarose chromatography was simpler and more convenient. Approximately1.2 mg target protein was obtained from 5 mg fusion protein following the established procedures. N-terminal amino acid sequencing showed that the first 10 amino acids of the recombinant hMC-CP were in good agreement with the human skin and lung MC-CP. Western blotting analysis showed that the recombinant protein had the similar immuno-reactivity with its natural counterpart, indicating that the recombinant hMC-CP could be used as an antigen to produce a specific antibody.

Our studies revealed that the purified recombinant hMC-CP expressed in *E.coli* had a very low level of enzymatic activity to substrate hippuryl-L-phenylalanine. It might be possible that the *E. coli* expression system is a prokaryotic expression system, which can not carry out post-translation modifications. In order to obtain higher levels of enzymatic activity of recombinant hMC-CP, we used *P. pastoris* to express hMC-CP. The enzymatic assay showed that the hMC-CP expressed in *P.asptoris* had a relatively high activity (11.7 U/mg secreted protein) towards hippuryl-L-phenylalanine. It is possible that *P.asptoris* is an eukaryotic expression system, which has the ability to perform eukaryotic post-translational modifications, such as glycosylation, disulfide bond formation and proteolytic processing[41]. Our result showed that the supernatant of *P.pastoris* culture had the highest enzymatic activity on the second day after induction by methanol, the enzymatic activity would decrease when induction time increased. It is possible that the secreted recombinant protein was degraded with the increase of induction time.

In conclusion, cDNA encoding human colon MC-CP can

be cloned and expressed in *E.coli* and *P.asptoris*. The expression of recombinant hMC-CP can facilitate its functional study including its role in intestinal diseases.

Abstract

AIM: To investigate the effect of β-ionone on the growth and apoptosis of gastric adenocarcinoma cell line SGC-7901.

METHODS: Using MTT, fluorescence dye (Hoechst-33258), transmission electron microscopy and the TUNEL assay, we examined growth and apoptosis of SGC-7901 cells treated with β-ionone at various concentrations (*i.e.* 25, 50, 100 and 200 μmol/L) for 24 h, 48 h.

RESULTS: The growth of SGC-7901 cells was inhibited by β-ionone. Seven days after treatment with β-ionone at four concentrations, the inhibition rates were 12.04%, 30.59%, 78.25% and 94.15%, respectively. The IC_{50} value of β-ionone for SGC-7901 cells was estimated to be 89 μmol/L. The apoptotic morphology was demonstrated in SGC-7901 cells treated with β-ionone by Hoechst-33258 staining and electron microscopy. Apoptosis was also shown in β-ionone-treated SGC-7901 cells by the TUNEL assay.

CONCLUSION: β-ionone can inhibit cell proliferation and induce apoptosis of SGC-7901 cells. However, the mechanism needs to be further investigated.

INTRODUCTION

Following the dietary guidelines[1,2] that emphasize the importance of fruits, vegetables and grains could lead to an estimated 35% reduction in cancer deaths[3], fruits, vegetables and grains are potential sources of anticarcinogenic agents[4-11], such as nondigestible carbohydrates and micronutrients including β-ionone, ascorbic acid, γ-tocopherol, isoprenoids and folic acid. Epidemiological evidence suggested that intake of these constituents could lead to a reduced risk of chronic diseases such as cancer and cardiovascular disorders[3,12-14]. β-ionone, enriched in many fruits, vegetables and grains, is a common intermediate product of up to 22 000 isoprenoids[15] and could exert potent anticarcinogenic and antitumor activities at the pharmacological level[16,17]. It has been documented that β-ionone could suppress the proliferation of melanoma, breast cancer and meningioma cells[18-21]. β-ionone has also been shown to have an effect on apoptosis of vascular endothelial cells[22] and tumor cells[23,24]. Although its exact mechanisms are not clear, the inhibitory effect of β-ionone on the proliferation of rapidly dividing cells has been demonstrated. In many instances, growth inhibition following terminal differentiation or anticancer drug treatment results in apoptosis.

Gastric cancer is one of the most frequent neoplasms in China and some other parts of the world[25-33]. Chemoprevention is always used as the main treatment for advanced cancer, and has been under intense investigation[34-49]. Understanding the mechanisms through which β-ionone suppresses the proliferation of gastric adenocarcinoma cells could provide a way to prevent this disease in general population. Therefore, in this study, we explored whether and how β-ionone induced apoptosis of human gastric adenocarcinoma cells.

MATERIALS AND METHODS

ƅ-ionone

β-ionone, 4-(2, 6, 6-trimethyl-1-cyclohexenyl)-3-buten-2-one with >95 % purity, was purchased from Sigma (USA). It was dissolved in absolute ethanol and diluted to the following concentrations: 25, 50, 100 and 200 μmol/L.

Cell culture

Human gastric adenocarcinoma cell line, SGC-7901 (Cancer Research Institute of Beijing, China), was cultured in RPMI 1640 medium (pH 7.2-7.4), supplemented with fetal calf serum 10%, penicillin (100 U/ml) and streptomycin (100 μg/ml) at 37 ℃ with a humidified atmosphere of 5% CO_2. The cells were sub-cultured with a mixture of ethylenedinitrile tetraacetic acid (EDTA) and trypsin (Sigma).

MTT assay for determination of cell growth

SGC-7901 cells were seeded in eight 96-well plates, each well containing 3.0×10^3 cells. After 24 h, different concentrations of β-ionone were added with. On the next day, 0.05 mL of 1.0 mg/ml 3-(4,5-dimethylthiazole-2-yl)-2,5-dipenyltetrazolium bromide (MTT, Sigma) was added to one of the eight plates. After 4 h, culture media were discarded followed by addition of 0.2 ml dimethyl sulfoxide (DMSO) and vibration for 2 min. The absorbance was measured at 570 nm using a model 550 microplate Reader. β-ionone concentration required to inhibit the net increase in the 48 h cell count by 50 % (IC_{50}) was calculated based on the plots of data from three or more evaluations. The means were obtained on each of seven days and used to draw a curve of cell proliferation. The inhibitory rates (IR) on the 7th day were calculated as follows:

$$IR(\%)=\frac{\text{Total absorbance in negative control (7 d)} - \text{Total absorbance in the tested group (7 d)}}{\text{Total absorbance in negative control (7 d)}} \times 100\%$$

Hoechst-33258 staining for determination of morphological changes of apoptotic cells

Morphological changes of apoptotic cells were determined by fluorescence microscopy. Briefly, the cells were collected and fixed in 100% ethanol, stained with 0.5 mmol/L Hoechst-33258 (Sigma) for 3 min at 37 ℃, then visualized under a fluorescence microscope with ultraviolet (UV) excitation at 300-500 nm. The cells with nuclei containing condensed chromatin or cells with fragmented nuclei were defined as apoptotic cells.

Observation of apoptotic cells with transmission electron microscopy

The cultured SGC-7901 cells treated with β-ionone at different concentrations were scraped off and harvested. Subsequently, the cells were immersed with Epon 821, embedded in capsules and converged at 60 ℃ for 72 h, and then ultrathin sections (60 nm) were prepared and stained with uranyl acetate and lead citrate. The ultrastructure of cells was examined by transmission electron microscopy.

TUNEL assay for determination of apoptosis cells

The TUNEL reaction could preferentially label DNA strand breaks generated during apoptosis, and allow discrimination of apoptosis from necrosis and primary DNA strand breaks induced by cancer chemoprevention agents. SGC-7901 cells were treated for 24 h and 48 h with β-ionone at various concentrations and collected by centrifugation. Specimens were fixed immediately in 4% formaldehydum polymerisatum and embedded in paraffin. Apoptosis of SGC-7901 cells was evaluated by using an *in situ* cell death detection kit (Roche Co. Ltd, Germany). The sections were deparaffinized in xylene and rehydrated through graded alcohol, treated with proteinase K and then 0.3% H_2O_2, labeled with fluorescein dUTP in a humidified box for 1 h at 37 ℃. The cells were then combined with POD-horseradish peroxidase, colorized with diaminobenzidine tetrahydrochloride (DAB). Controls consisted of omission of fluorescein dUTP. Cells were visualized under a light microscope. The apoptotic index (AI) was calculated as follows: AI=(number of apoptotic cells/total number counted)×100%.

Statistical analysis

Data were expressed as mean±SD. Analysis of data was performed using the Student's *t* test or one-way ANOVA. $P<0.05$ was considered as statistically significant.

A: SGC-7901 cells in the control group, B: experimental SGC-7901 cells treated with β-ionone showing early changes of apoptosis in which nuclear chromatin condensation and cell shrinkage were observed.

Figure 4 Apoptotic cells induced by β-ionone (200 μmol/L 48 h) in SGC-7901 cells detected TUNEL assay (×400).

RESULTS

Inhibition of SGC-7901 cell proliferation by b-ionone

SGC-7901 cells were treated with β-ionone at various concentrations for 1-7 days, and the cell viability was determined as described above by MTT assay. As shown in Figure 1, β-ionone inhibited the growth of gastric adenocarcinoma cells in a dose- and time-dependent manner. The growth of the cells treated with β-ionone at concentrations of 100 and 200 μmol/L was significantly slower than that of the negative control within 7 days ($P<0.05$). SGC-7901 cells incubated with 25 and 50 μmol/L of β-ionone grew slower, albeit not significantly than the negative control. β-ionone at 100 μmol/L and 200 μmol/L had an inhibitory effect of more than 90% on tumor cell growth 3 days after treatment. The inhibitory rate at the four progressively increasing concentrations of β-ionone was 12.04%, 30.59%, 78.25% and 94.15% 7 days after treatment. The IC_{50} value for β-ionone was estimated to be 89 μmol/L.

Morphological changes of apoptotic SGC-7901 cells treated with b-ionone

SGC-7901 cells in the negative control group exhibited a round shape, clear edge and homogeneous staining (Figure 2A). However, after 24 h and 48 h exposure to β-ionone, SGC-7901 cells began to show morphologic features of apoptosis, such as cell shrinkage, chromatin condensation and nuclear pyknosis (Figure 2B). The ultrastructural changes were observed by electron microscopy showing early changes of apoptosis including nuclear chromatin condensation and cell shrinkage (Figures 3A & 3B).

Apoptosis detected by TUNEL assay in SGC-7901 cells treated with b-ionone

The cells with positive staining in the nuclei were defined as apoptotic cells (Figure 4). The results showed that after treatment of SGC-7901 cells with β-ionone at different concentrations for 24 h and 48 h, the AIs were significantly increased in a dose- and time-dependent manner (Table 1).

Table 1 Apoptotic index (AI) of SGC-7901 cells treated by β-ionone

β-ionone (μmol/L)	AI (%)[a]	
	24 h	48 h
0	0.15±0.087	-
25	0.12±0.03	0.87±0.23[b]
50	0.47±0.15	3.43±1.00[b]
100	1.67±0.53[b,c]	8.50±19.2[b,c]
200	4.78±1.32[b,c,d]	11.85±3.83[b,c,d]

a: X experiments were performed and Y cells were counted in each experiment, b: $P<0.05$, comparison between 24 h and 48 h, c: $P<0.05$ compared with negative control, d: $P<0.05$ as determined by one-way ANOVA.

DISCUSSION

Epidemiologic studies have revealed a strong inverse association between frequency of intake of plant-derived foods and cancer incidence[3]. β-ionone, widely distributed in fruits and vegetables, has been found to be a common intermediate product of up to 22 000 isoprenoids[15] and many other phytochemicals. It could exert broad and potent anticarcinogenic and antitumor activities when fed at pharmacological levels. β-ionone could also suppress the proliferation of melanoma and breast cancer cells[16-18]. However, the effects of β-ionone on gastric adenocarcinoma cells have not been reported.

Isoprenoid-mediated suppression of cell growth is clearly independent of a mutated *ras* function. β-ionone could suppress the proliferation of B16 and HL-60 cells that express ki-ras and n-ras, respectively. The study from Mo et al[16] showed that β-ionone also suppressed the proliferation of Caco-2 and MCF-7 cells which express wild-type ras. The action, like that of lovastatin, is independent of ras function. Both β-ionone and lovastatin can arrest HL-60 promyelocytic leukemia cells in the G_1 phase of the cell cycle in a concentration-dependent manner. The present study demonstrated that β-ionone inhibited the growth of human gastric adenocarcinoma SGC-7901 cells in a dose- and time-dependent manner. The inhibition rates were 12.04%, 30.59%, 78.25% and 94.15% 7 days after treatment with β-ionone at 25, 50, 100 and 200 μmol/L, respectively. The IC_{50} value for β-ionone was estimated to be 89 μmol/L.

Apoptosis, also known as programmed cell death, is a natural process of cell suicide which plays a critical role in the development and homeostasis of metazoans[50,51]. It is a complex process regulated by a variety of factors such as Bcl-2[52], Fas[53] and p53[54]. The isoprenoid-mediated initiation of apoptosis might be independent of a mutated p53 function. β-ionone could initiate apoptosis in B16 and MCF-7 cells which express wild type p53 and in Caco-2 cells which express mutated p53 as well as in p53-null HL-60 cells[55]. However, whether β-ionone has any effect on the other apoptotic pathways in cancer cells is not understood.

In conclusion, β-ionone can inhibit cell growth and proliferation and induce apoptosis of SGC-7901 cells. However, the mechanism by which β-ionone blocks cell proliferation and induces apoptosis of SGC-7901 cells needs to be further investigated.

Abstract

AIM: To investigate the expression of pathological factors of VEGF-C and its receptor FLT-4 in primary gastric cancer and adjacent normal tissues.

METHODS: The expression of VEGF-C and FLT-4 was studied in 80 primary gastric cancers and adjacent normal tissues from the same patients by semi-quantitative reverse transcriptase-polymerase chain reaction (RT-PCR) and immumohistochemistry.

RESULTS: Both primary gastric cancer and adjacent normal tissue could express VEGF-C and FLT-4, and FLT-4 expression was also detected in endothelial cells of stromal blood vessels and lymphatic vessels. There was a significant difference in expression of VEGF-C between primary tumor and adjacent normal tissue samples ($P=0.01$), and a statistical correlation between VEGF-C and FLT-4 expression in tumors ($P=0.00886$). With regard to VEGF-C expression, there was a significant difference between moderate-poor differential type and high differential type ($P=0.032$), and a significant difference between positive and negative lymph node metastases ($P=0.024$). However, there was no significant difference between positive and negative serosal invasions ($P=0.219$).

CONCLUSION: VEGF-C and its receptor FLT-4 play a role in the development of gastric cancer, and the tumors with expression of VEGF-C and FLT-4 are more likely to have lymph node metastasis.

INTRODUCTION

Invasion and metastasis are the characteristics of malignant tumor. Epithelial malignancy spreads predominantly through lymphatic system, and its metastatic degree is closely related to patient' s prognosis[1]. However, very little is known about the mechanism of lymphangiogenesis and lymph node metastasis. Recent studies have shown that VEGF-C can bind to specific receptor VEGFR3/FLT-4 that express in lymphatic endothelium, stimulate lymphangiogenesis, and promote lymphatic metastasis[2-4]. We investigated the expression and significance of VEGF-C and its receptor FLT-4 in gastric cancer.

MATERIALS AND METHODS

Materials
Reagents Trizol liquid, AMV reverse transcriptase, Oligd(T)$_{14}$, RNAsin, dNTP, Taq DNA polymerase were purchased from Shanghai Sangon Biological Engineering Technology and Service Co.Ltd, PCR primers were synthesized by Shanghai Sangon Biological Engineering Technology and Service Co. Ltd. The antibodies of VEGF-C and FLT-4 were purchased from Santa Cruz Company.
Clinical data A total of 80 patients with primary gastric cancer were analyzed, with a mean age of 53.5 years, arranging from 38 to 72 years. Routine pathological diagnosis showed that 59 cases were adenocarcinoma and 21 cases were signet carcinoma. Among them, 54 cases presented lymph node metastasis, and 26 cases had no lymph node metastasis.

Methods
Detection of expression of VEGF-C AND FLT-4 Expression of VEGF-C and FLT-4 was assessed in each gastric cancer sample and its adjacent normal tissues by semi-quantitative RT-PCR.
RNA extraction Total RNA was extracted by Trizol one-step procedure, and suspended in DEPC-treated reverse osmosis-H$_2$0, and conserved at -70 ℃ for reverse transcription. RNA yield and purity were determined by standard UV spectrophotometric assay. The ratio of A260/A280 was 1.80.
First strand cDNA synthesis Five μg of the total RNA was dissolved in 20 μl of mixture containing 2 μl 10× first-strand buffer, 20 U AMV reverse transcriptase, 2 μl dNTP, 20 U RNAsin, 500 ng Oligd(T)$_{14}$, and DEPC-treated reverse osmosis-H$_2$O. The reaction conditions were as follows: at 42 ℃ for 60 min, and at 95 ℃ for 5 min. The first strand cDNA was stored at -20 ℃ until use.
PCR amplification The primers of VEGF-C, FLT-4 and β-actin were synthesized according to the primer design principles, all primers span an intron to control against amplification of genomic DNA sequences. Four μl first strand cDNA was amplified in 20 μl volume. The primers of VEGF-C yielded 206 bp product as follows: 5' -end primer: 5' -AAGGAGGCTGGCAACATAAC-3' , 3' -end primer: 5' -CCACATCTGTAGACGGACAC-3' . Following an initial denaturation at 94 ℃ for 5 min, the samples were amplified by 30 cycles of denaturation at 94 ℃ for 30 s, annealing at 58 ℃ for 30 s, extension at 72 ℃ for 30 s, and ended by extension at 72 ℃ for 10 min. The primers of FLT-4 yielded a 298 bp product as follows: 5' -end primer: 5' -AGCCATTCATCAACAAGCCT-3' , 3' -end primer: 5' -GGCAACAGCTGGATGTCATA-3' . Following an initial denaturation at 94 ℃ for 5 min, the samples were amplified by 28 cycles of denaturation at 94 ℃ for 30 s, annealing at 58 ℃ for 1 min, extension at 72 ℃ for 1 min, and ended by extension at 72 ℃ for 10 min. The primers of β-actin, which was amplified with VEGF-C and FLT-4 as an internal control, yielded a 644 bp product as follows: 5' -end primer: 5' -ACGTTATGGATGATGATATCGC-3' , 3' -end primer: 5' -CTTAATGTCACGCACGATTTCC-3' . The PCR products

were separated on 1.7% agarose gel, stained with ethidium bromide, and analyzed with Quantity one 4.1.0 software. The ratios of VEGF-C/β-actin, and FLT-4/β-actin were used to semiquantify the levels of VEGF-C and FLT-4.

Immunohistochemistry Immunohistochemical studies of VEGF-C and FLT-4 expression in gastric cancer and adjacent normal tissues were performed by the avidin-biotin-peroxidase technique, as previously described[5].

Statistical analysis Statistical analyses were made with SPSS software, version 10.0.

RESULTS

Results of RT-PCR

Eighty primary gastric cancers and adjacent normal tissues from the same patients were examined for the expression of VEGF-C and FLT-4 by RT-PCR. In 80 cases of primary tumors, VEGF-C and FLT-4 were expressed in 58 (72.5%) and 51 (63.75%) cases, respectively. However, in 80 adjacent normal samples, VEGF-C and FLT-4 were expressed in 13 (16.25%) and 16 (20%), respectively. The expression of VEGF-C and FLT-4 in primary gastric cancer was significantly different from that in adjacent normal tissues (P=0.01 and P=0.038 respectively, Figure 1, Table 1).

Figure 1 Semi-quantitative RT-PCR amplified products of VEGF-C and FLT-4 in primary gastric cancer and adjacent normal tissues. Lane-M: puc mix marker 8 (1 116, 883, 692, 501, 404, 331, 242, 190, 147, 110, 67, 34, 26, 19) bp, 644 bp: internal standards, 298 bp: FLT-4 expression, 206 bp: VEGF-C expression, Lane 1: Control of VEGF-C positive expression in placenta, Lane 6: Control of FLT-4 positive expression in placenta, Lanes 2,4: VEGF-C expression in primary gastric cancer, Lanes 3,5: VEGF-C expression in adjacent normal tissues, Lanes 7,9: FLT-4 expression in primary gastric cancer, Lanes 8, 10: FLT-4 expression in adjacent normal tissues.

Table 1 Expression of VEGF-C and FLT-4 in primary gastric cancers and adjacent normal tissues detected by semi-quantitative RT-PCR (mean±SD)

	Cases	VEGF-C	FLT-4
Primary gastric cancers	80	0.555±0.399[a]	0.335±0.261[b]
Adjacent normal tissues	80	0.146±0.311[c]	0.153±0.275[d]

[a]P=0.01 *vs* group c, [b]P=0.038 *vs* group d.

Meanwhile, in 58 cases of gastric cancer with VEGF-C positive expression, FLT-4 was coexpressed in 42 cases (82.35%), but 22 cases of gastric cancer with VEGF-C negative expression showed FLT-4 expression in 9 cases (40.91%). The VEGF-C expression in primary tumors was significantly correlated with FLT-4 (P=0.00886).

Result of immunohistochemistry

Human placenta served as a positive control. Positive expression of VEGF-C and FLT-4 showed brown staining in the cytoplasm of tumor or normal cells, more than 500 cells were calculated in different microscopic fields of slides, and percentage of positive cells was evaluated. Staining intensities were scored according to the following scale: - , no cells stained; +, less than 25% of cells stained; ++, 26% to 50% of cells stained; +++, 51% to 75% of cells stained; ++++, more than 75% of cells stained.

Immunohistochemical staining revealed that VEGF-C was expressed in 55 of 80 primary tumors (68.75%) and 11 of 80 adjacent normal tissues (13.75%), FLT-4 was expressed in 49 of 80 primary tumors (61.25%) and 14 of 80 adjacent normal tissues (17.5%), FLT-4 also expressed in endothelium of small blood and lymphatic vessels. There was a significant difference in the expression of VEGF-C and FLT-4 between gastric cancer and adjacent normal tissues (Table 2, Figure 2).

Table 2 Expression of VEGF-C and FLT-4 in primary gastric cancers and adjacent normal tissues detected by immumohistochemistry

Positive expression	Primary gastric cancer (cases)		Adjacent normal tissue (cases)	
	VEGF-C	FLT-4	VEGF-C	FLT-4
+	3	2	2	3
++	7	8	4	5
+++	20	18	3	3
++++	25	21	2	3

Figure 2 Expression of VEGF-C and FLT-4 in gastric cancer. A: VEGF-C positive expression in gastric cancer, ×400. B: FLT-4 positive expression in gastric cancer, ×200. (←endothelial cells of vessels).

Pathologic factors affecting expression of VEGF-C

Several pathological factors, including histological type, lymph node metastasis, serosal invasion, were investigated to predict the expression of VEGF-C in gastric cancer. The results showed that there was a significant difference in expression of VEGF-C between moderately-poorly differentiated type and highly differentiated type (P=0.032), and a significant difference between positive lymph node metastasis and negative lymph

node metastasis (*P*=0.024). However, there was no significant difference between positive and negative serosal invasions (*P*=0.219, Table 3).

Table 3 Correlation between pathological factors and VEGF-C expression in 80 primary gastric cancers

Pathological factors	No. of cases	VEGF-C mRNA (mean±SD)	P
Histological type			
Moderately-Poorly differential	51	0.485±0.345	P=0.032
Highly differential	29	0.200±0.290	
Lymph node metastasis			
Positive	54	0.579±0.290	P=0.024
Negative	26	0.282±0.314	
Serosal invasion			
Positive	59	0.567±0.268	P=0.219
Negative	21	0.390±0.330	

DISCUSSION

In the 1970's, Folkman first found that tumor growth and metastasis were dependent on intratumoral angiogenesis. Since then, a large number of studies have emphasized the angiogenesis of tumors, but the roles of lymphatic vessels in tumor growth and metastasis were neglected. However, it is well known that lymphatic metastasis is mainly responsible for the spread of epithelial malignant tumors, and its metastasis degree is closely related to the prognosis of patients. Consisting of simple endothelium, without tight junction, and incomplete, even defect of basic membrane, accordingly, the permeability of small lymphatic vessels is larger than that of small blood vessels, and it is beneficial to tumor metastasis. However, up to now, it is still controversial about intratumoral lymphangiogenesis, mechanism of lymphangiogenesis and relationship between lymphangiogenesis and tumor metastasis.

VEGF-C family is a group of highly conservative secreted glycoproteins, which regulate vasculogenesis, lymphangiogenesis, and vascular permeability, and have been implicated in many physiological and pathological processes[6-8]. VEGF-C is a member of the VEGF family, its encoding gene is located in 4q34, VEGF-C has 7 extrons and shares 30% autologousity with VEGF. The studies showed that VEGF-C expressed in normal placenta, ovary, small intestine, skeleton muscle, spleen, colon, *etc.* [9-12].

VEGFR-3/FLT-4, which belongs to the platelet-derived growth factor for receptor subfamily of receptor tyrosine kinase, was extensively expressed in embryonic tissues[13-16]. In adult however, VEGFR-3/FLT-4 was mainly expressed in lymphatic endothelia, so it was regarded as a special marker of lymphatic endothelia. The density and distribution of lymphatic vessels could be detected by VEGFR-3/FLT-4 antibody[17-21].

Recent studies showed that, the binding of VEGF-C to its special receptor FLT-4, could induce tyrosine phosphorylation of receptors, activate MAPK via intracellular kinase reaction, and finally promote proliferation of lymphatic endothelia, and lymphangiogenesis[22-25].

Karpanen's results showed that VEGF-C could promote growth of tumor cells, which was correlated with the growth of lymphatic vessels around tumors and the intralymphatic spread of cancer[26]. Several clinical studies have proved that overexpression of VEGF-C in solide tumors, such as squamous cell carcinomas of head and neck, thyroid carcinoma, prostate cancer, gastric cancer, colorectal carcinoma, breast cancer, esophageal squamous carcinoma, cervical cancer, lung cancer, was relevant to lymphatic spread[27-31].
