Liver tissues were fixed in formalin and embedded in paraffin. Hematoxylin and eosin (HE) staining and Masson staining were performed according to the standard procedure. Histological grade of chronic hepatic fibrosis was determined by a semi-quantitative method based on the criteria described below: grade 0: normal liver, grade 1: few collagen fibrils extended from the central vein and portal tract, grade 2: collagen fibrils extension was apparent but had not yet encompassed the whole lobule, grade 3: collagen fibrils extended into and encompassed the whole lobule, grade 4: diffuse extension of collagen fibrils and pseudo-lobule formed.

Two pathologists who had no knowledge of their sources and each other's assessment examined the stained slide independently.

Flow cytometry of CD_4 and CD_8 positive cells

Sample fluorescence staining was performed using indirect immufluoredence labeling method. Sample cells were washed in 10 mL Na-azide-PBS and centrifuged. Primary mAb to human CD_4 and CD_8 was added to each tube. The tube was vortexed and incubated at 37 ℃ for 30 min, 10 mL azide-PBS was added for inactivation and the cells were centrifuged. The supernatant was sucked away. The second antibody of FITC-IgG was added to each tube. The tube was vortexed and incubated in the dark at 37 ℃ for 30 min. 10 mL azide-PBS was added for inactivation and the cells were centrifuged. The samples were stored at 4 ℃ in the dark for FACS analysis. The primary antibody and secondary antibody were replaced by 30g/L BSA in azide-PBS as negative controls, the primary antibody was replaced by 30g/L BSA in azide-PBS as the second antibody control. The stained samples were analyzed in a FACS 420 flow cytometer (FACS 420 Fluorescence Activited Cell Sorting, Becton. Dickinson, Sunnyvale. California, USA.) The

light source was a 2W argon ion laser using a wave-length of 488 nm. The working power was 300 mW. Single parameter was measured respectively. Usually, 10 000 cells for each sample were analyzed. The analytic data were processed with a HP-Consort 30 computer. The coefficient of variation of the instrument was adjusted within 5% using PI staining chicken red blood cells.

Immunohistochemistry

Liver samples were formalin-fixed, paraffin-embedded and sectioned serially at 5 µm thickness. Immunohistochemistry was performed as described in streptomycin avidin peroxidase immunohischemistry kit (Boster). The sections were treated with 30mL/L H_2O_2 methanol at room temperature for 10 min and then washed with PBS for 5 min. After antigen retrieval, nonspecific binding sites were blocked by normal non-immune goat serum. The sections were incubated with primary antibody overnight at 4 ℃, secondary antibody at 37 ℃ for 30 min, and avidin peroxidase at 37 ℃ for 20 min, followed by DAB visualization. After several washings, the sections were counterstained with hematoxylin. Negative control slides were treated with PBS.

Semi-quantitative PCR

Total RNA was extracted using an RNA isolation kit, and quantity and quality of the RNA extracted were measured on a spectrophotometer. Purified RNA 2 µg and primer Oligo (dT) were used for reverse transcription (Promega). 5 µL reverse transcription template was used for amplification through PCR. The primers were: TGF-β_1, 113 bp: forward: 5'-AGGGCTACCATGCCACTTC-3', reverse: 5'-GCGGCACGCAGCACGGTGAT-3', GAPDH, 299 bp: forward: 5'-GTGAAGGTCGGAGTCAACG-3', reverse: 5'-GGTGAAGACGCCAGTGGACTC-3'. Amplification conditions included initial denaturation for 5 minutes at 94 ℃, 30 cycles of amplification with denaturation at 94 ℃ for 45 seconds, annealing at 61 ℃ for 45 s, and extension at 72 ℃ for 1 min. PCR products were analyzed by agarose gel electrophoresis (15 g/L) and visualized by ethidium bromide staining and ultraviolet illumination. Expression of each TGF-β_1 was scanned by a computer. The obtained values were related to housekeeping gene GAPDH, and the resulting relative ratios were analyzed statistically.

Statistical analysis

Data were analyzed with SPSS software. Quantitative data were presented as mean±SD and compared using one way ANOVA procedure. Frequency data were compared using Ridit procedure.

RESULTS

Anti-fibrosis herbs and anti-fibrosis herbs plus selenium treatment suppressed fibril deposition in and ameliorated liver function of hepatic fibrosis

Specimens from normal control group showed normal structures. Specimens from model control group showed apparent formation of fibrotic septa, encompassing regenerated hepatocytes into pseudo-lobules. Regenerated hepatocytes underwent severe lipoid degeneration. Specimens from AF and AS groups showed only mild fibrogenesis without pseudo-lobule formation. Statistical analysis presented significant differences between either AF group or AS group and model control group in histological gradings, indicating that fibrogenesis in both AS and AF groups was much less severe than that in colchicine group and model control group (Table 1).

Serum content of ALT, AST, HA and LN in AF group and AS group was slightly higher than that of normal control

group, but significantly lower than that in model control group ($P<0.05$). Serum content of ALT, AST, HA and LN in AF group and AS group was also lower than that in colchicine group ($P<0.05$). These data confirmed the histological findings that anti-fibrosis herbs and anti-fibrosis herbs plus selenium could inhibit hepatic fibrogenesis and ameliorate liver function (Table 2).

Table 1 Histological grading of hepatic fibrosis

Group	Grade o	Grade I	Grade II	Grade III	Grade IV
Normal	10	0	0	0	0
Model	0	0	0	0	8[c]
Colchicine	0	1	3	4	1[c]
AF	4	3	1	1	0[a]
AS	3	3	2	1	0[ac]

[a]$P<0.05$, *vs* colchicine group; [c]$P<0.05$, *vs* normal control group.

Table 2 Serum content of ALT, AST, HA and LN

Group	ALT (u/L)	AST(u/L)	HA(μg/L)	LN (μg/L)
Normal	52.5±9.2[a]	137.8±18.7[a]	178±58[a]	59.8±21.8[a]
Model	165.6±32.7[ace]	257.4±22.6[c]	550±68[c]	130.0±30.5[c]
Colchicine	96.2±20.9[c]	215.8±24.6[c]	416±135[c]	106.3±14.2[c]
AF	65.8±26.5[a]	150.8±34.0[a]	228±83[ac]	85.9±15.0[c]
AS	67.3±18.4[a]	154.6±27.3[a]	216±58[ac]	80.6±18.6[c]

[a]$P<0.05$, *vs* colchicine group; [c]$P<0.05$, *vs* normal control group; [e]$P>0.05$, *vs* control group.

Anti-fibrosis herbs and anti-fibrosis herbs plus selenium treatment enhanced immunity of rats with hepatic fibrosis
The percentage of CD_4 and CD_8 and the ratio of CD_4 to CD_8 were significantly lower in model control group than that in normal control group. Both AF group and AS group showed a lower percentage of CD_4 and a lower ratio of CD_4 to CD_8 than normal control group. However, these values were significantly higher than those in colchicine group, suggesting that anti-fibrosis herbs and anti-fibrosis herbs plus selenium could enhance the immunity of rats with hepatic fibrosis (Table 3).

Table 3 Content of CD_4 and CD_8 in thymus

Group	Rats	CD_4(%)	CD_8(%)	CD_4/CD_8
Normal	10	54.1±1.4[a]	34.1±1.2	1.58
Model	8	40.2±2.1[c]	31.7±1.3	1.26[c]
Colchicine	9	42.1±2.0[c]	32.1±0.9	1.31[c]
AF	9	50.8±3.8[a]	34.8±2.1	1.45
AS	9	52.6±3.4[a]	35.9±2.2	1.46

[a]$P<0.05$, *vs* Colchicine group; [c]$P<0.05$, *vs* normal control group.

Anti-fibrosis herbs and anti-fibrosis herbs plus selenium treatment reduced TGF-β_1 expression
Positive staining of TGF-β_1 was found at central vein and Disse's areas but not at hepatocytes on sections of normal controls, whereas on sections of model control group, the positive staining was seen at interstitial cells, inflammatory cells, impaired hepatocytes as well as normal hepatocytes. Fibrotic septa were only slightly stained.

Compared with model control group, the staining index of TGF-β_1 in AF and AS groups was markedly decreased ($P<0.05$ in both groups). TGF-β_1 mRNA was detected in normal rat liver, but the expression level was increased significantly in

model control group. Compared with colchicine group, TGF-β_1 level in AF and AS groups was markedly decreased ($P<0.05$, Table 4). Thus, the data at both transcript and protein levels suggested that anti-fibrosis herbs and anti-fibrosis herbs plus selenium could reduce TGF-β_1 expression in hepatic fibrosis.

Table 4 Level of TGF-β_1 mRNA in relation to GAPDH

Group	Rats	Ratio
Normal	10	0.57±0.11
Model	8	2.34±0.43[c]
Colchicine	9	1.88±0.21[c]
AF	9	1.07±0.31[a]
AS	9	0.98±0.21[a]

[a]$P<0.05$, *vs* Colchicine group; [c]$P<0.05$, *vs* normal control group.

Anti-fibrosis herbs and anti-fibrosis herbs plus selenium treatment reduced NF-κB expression
Positive staining of NF-κB was not found on sections of normal control group. In model control group, NF-κB was extensively expressed in nuclei of hepatocellular cells. The cells positive for NF-κB were diffusely distributed. After treatment with anti-fibrosis herbs and anti-fibrosis herbs plus selenium, the level of NF-κB staining decreased markedly.

DISCUSSION

Hepatic fibrosis is a common pathological process of chronic hepatic disease, resulting in development of irreversible cirrhosis in patients. In recent years, the mechanism of development of hepatic fibrosis has been partly disclosed[2,4,5]. If treated properly at fibrosis stage, cirrhosis could be prevented. The present study demonstrated that administration of anti-fibrosis herbs and selenium was effective in treating hepatic fibrosis in rats based on both histological examination and functional analysis. The underlying therapeutic mechanism may involve enhanced immunity and down regulation of the expression of NF-κB and TGF-β_1.

There are various kinds of chronic liver injuries all over the world, causing great affliction to patients. The incidence of hepatitis in China is high. Searches for effective ways to inhibit fibrogenesis and to prevent the development of cirrhosis are of great significance. Although many agents were tested, there have been no satisfactory agents with ascertained effectiveness and few side effects. Colchicine has been commonly used for anti-fibrosis[21], but its side effect is high and its clinical use is, therefore, limited. Chinese herbs, well known for their wide range of effectiveness and low prices and few side effects, have particular potentials in the treatment of hepatic fibrosis. In this study anti-fibrosis herb treatment for chronic liver injury in rats, prevented hepatic fibrosis from developing of cirrhosis was shown by histological grading. HA and LN have been found to be good serum markers of hepatic fibrogenesis[22]. We showed that the serum content of HA and LN in AF group and AS group dropped markedly when compared with colchicine group, indicating that anti-fibrosis herb could prevent hepatic fibrogenesis. Anti-fibrosis herb could also enhance the immunity of the body by increasing the percentage of CD_4 and the ratio of CD_4 to CD_8 in AF group, especially in AS group, compared with that in colchicine group.

To understand the mechanism, we evaluated the effect of anti-fibrosis herb treatment on the expression of TGFβ_1 at both the protein and mRNA levels as TGFβ1 has been considered to be the key cytokine in acceleration of the cirrhotic procession and over expression of this cytokine was closely associated with fibrogenesis in many ways[23-27]. Our results showed that

both TGFβ_1 and its mRNA expression decreased significantly in AF group and AS group compared with those in control groups, indicating that anti-fibrosis herb down-regulated the expression of this cytokine, which may have contributed to the reduction of fibrosis.

NF-κB is known to be a family of dimeric transcription factors. It was ubiquitously expressed in non-B cells as an inactive form sequestered in cytoplasm by binding to specific inhibitory proteins termed I-κB[28-32]. When cells were stimulated by inducing agents, the I-κB became phosphorylated, ubiquitinated, and degraded. Degradation of I-κB could free NF-κB, which was then translocated into the nucleus, where it activate transcription[33-35]. NF-κB/Rel has been shown to be implicated in the inflammatory response and synthesis of adhesion molecules. Furthermore, NF-κB has been found to be related to cell proliferation and transformation[36]. Down-regulation of NF-κB/Rel activity could decrease the transcription of TGFβ_1 to reduce the liver injury.

Abstract

AIM: Population-based assessment of noncardiac chest pain (NCCP) is lacking. The aim of this study was to evaluate the prevalence, psychosocial factors and health seeking behaviour of NCCP in southern Chinese.

METHODS: A total of 2 209 ethnic Hong Kong Chinese households were recruited to participate in a telephone survey to study the epidemiology of NCCP using the Rose angina questionnaire, a validated gastroesophageal reflux disease (GERD) questionnaire and the hospital anxiety-depression scale. NCCP was defined as non-exertional chest pain according to the Rose angina questionnaire and had not been diagnosed as ischaemic heart diseases by a physician.

RESULTS: Chest pain over the past year was present in 454 subjects (20.6%, 95% CI 19-22), while NCCP was present in 307 subjects (13.9%, 95% CI 13-15). GERD was present in 51% of subjects with NCCP and 34% had consulted a physician for chest pain. Subjects with NCCP had a significantly higher anxiety ($P<0.001$) and depression score ($P=0.007$), and required more days off ($P=0.021$) than subjects with no chest pain. By multiple logistic regression analysis, female gender (OR 1.9, 95% CI 1.1-3.2), presence of GERD (OR 2.8, 95% CI 1.6-4.8), and social life being affected by NCCP (OR 6.9, 95% CI 3.3-15.9) were independent factors associated with health seeking behaviour in southern Chinese with NCCP.

CONCLUSION: NCCP is a common problem in southern Chinese and associated with anxiety and depression. Female gender, GERD and social life affected by chest pain were associated with health care utilization in subjects with NCCP.

INTRODUCTION

Noncardiac chest pain (NCCP) is a common problem and affects 23% of the U.S. population[1]. It is a benign condition with an estimated 10 year mortality of less than 1%[2]. However, the associated morbidity, as a result of inability to work and health care utilization, is enormous[3]. Population-based data of NCCP in Asia are lacking[4,5]. Furthermore, the effects of co-existing anxiety and depression on health care utilization in subjects with NCCP are unknown in Chinese. Various studies have shown an increased psychological morbidity in patients attending specialist clinics for functional gastrointestinal diseases[6-10]. This may be due to a causative effect of psychological factors on gastrointestinal symptoms, or the psychological morbidity may be a result of the functional gastrointestinal disease. Alternatively, psychological factors may influence health-seeking behaviour, and patients with co-morbid anxiety or depression may be more likely to seek medical consultation. Thus the aims of this study were to determine the population prevalence of NCCP, the effects of co-existing anxiety and depression and the health seeking behaviour of Chinese subjects with NCCP.

MATERIALS AND METHODS

Data collection

The telephone interview was conducted over a period of two weeks by a professional team of trained telephone interviewers from the Social Sciences Research Centre, the University of Hong Kong in November 2002. The interviewers went through intense training on the delivery of questionnaire to ensure uniformity and the questions to be understood. Random telephone numbers were generated by computer and dialed automatically. Only numbers corresponding to ethnic Chinese households were used in the study. Office numbers, facsimile machines, and non-Chinese households were excluded. Upon identification of target households, the interviewer asked to speak to the household member with the most recent birthday. This aimed to provide randomization among different members of the household. Baseline demographic data, education, occupation and income were assessed, followed by a translated version of the Rose Angina questionnaire[11], a validated GERD questionnaire[12], a validated translated version of the hospital anxiety depression scale[13-15] and assessment of medical care utilization and impact of the disease on social activity as described below. Overall, 3605 ethnic Chinese households were contacted by telephone. The interview was completed in

2 209 subjects (response rate=61.3%, mean age=40.3±14, 58% female). The demographic characteristics of the study subjects were comparable to the census data of Hong Kong in 2001[16]. This study was approved by the ethics committee of the University of Hong Kong.

Sample size

A previous study demonstrated that the prevalence of NCCP was approximately 23% in Minnesota, USA[1]. To provide a 95% confidence interval ±2% and a meaningful comparison between health care seekers and non-health care seekers, we estimated a sample size of around 2000 of successful cases.

Questionnaire

The Rose angina questionnaire is a standardized method of measuring angina and myocardial infarction in population surveys and has been validated in different ethnic groups[17-26]. 'Definite' angina was defined as chest pain that limits exertion (walking uphill or hurry, or walking at an ordinary pace on the level), is situated over the sternum or in the left chest and left arm, and is relieved within 10 min by rest[11]. 'Possible' angina was defined as chest pain that limits exertion and other criteria for definite angina not fulfilled. NCCP was defined as non-exertional chest pain according to the Rose angina questionnaire and had not been diagnosed as ischaemic heart diseases by a physician[27]. Musculoskeletal-like chest pain was defined as chest pain that worsens on breathing, movement or the presence of chest wall tenderness. The duration and characteristics of the chest pain were recorded. In the development of the Chinese version of the questionnaire, the original instrument was translated, back translated and tested for reproducibility in a sample of thirty patients attending the gastrointestinal clinic. The intraclass correlation coefficient of the translated questionnaire was 0.91. Furthermore, we tested the Rose angina questionnaire in a pilot of 50 patients with known coronary heart diseases proven by coronary angiography and 100 healthy controls. The sensitivity and specificity determined by the pilot study was 68% and 95% for the diagnosis of ischemic heart disease respectively.

Gastrointestinal symptoms were assessed by a translated Chinese version of a validated GERD questionnaire[12]. The GERD questionnaire examined the symptoms of heartburn, acid regurgitation, dyspepsia, dysphagia, globus, odynophagia, hoarseness of voice, chronic cough, asthma and pneumonia in details. In addition, past medical history, medication use, past history of esophageal, gastric, cardiac or pulmonary disease; smoking, alcohol intake, and the intake of tea and coffee were assessed. Part of the results on GERD had been presented elsewhere[28]. The severity and frequency of chest pain and other gastrointestinal symptoms were graded on a five-point Likert scale as follows: 1 (none- no symptoms / none in the past year), 2 (mild- symptoms can be easily ignored / less than once per mo), 3 (moderate- awareness of symptoms but easily tolerated / >= once per month), 4(severe- symptoms sufficient to cause an interference with normal activities / >= once weekly) and 5(incapacitating- incapacitating symptoms with an inability to perform daily activities or require day-off / >= once daily)[29]. GERD was defined as heartburn and/or acid regurgitation over the past year, which has been shown to be specific for the diagnosis of GERD[30, 31]. Patients who had used non-steroidal anti-inflammatory drugs (NSAIDs) / aspirin for at least 3 d at any dosage within 3 mo prior to the survey were considered to be NSAIDs / aspirin users[32]. Anxiety and depression were assessed by the hospital anxiety and depression scale[13]. The Chinese version of this questionnaire has previously been validated[14,15] which consists of 7 questions on anxiety and 7 questions on depression.

Medical care utilization

Medical care utilization of subjects with NCCP was classified into categories including the use of over-the-counter medication, community based medicine, accident and emergency department and admission to hospital. Impact of disease was measured by the proportion of subjects requiring days-off work due to gastrointestinal complaints, and whether subjects reported an adverse effect of the chest pain on their normal social life (social life being affected), *i.e.* symptoms sufficient to cause an interference with normal daily and social activity.

Statistical analysis

Univariate analysis was performed by Student's *t* test for continuous variables and by chi-square test for categorical variables to assess the risk factors associated with NCCP. Multiple logistic regression analysis with sex and age adjustment was then performed to determine the risk factors associated with NCCP. Furthermore, a multiple logistic regression model was designed to determine the factors (severity and frequency of chest pain, presence of heartburn and/or acid regurgitation over the past year, gender, age, educational level (primary school or below, secondary or matriculation and tertiary), occupation (3 levels), anxiety and depression scores and social life being affected by chest pain) associated with health seeking behaviour in NCCP. To find the best model, a backward elimination stepwise procedure was carried out in a way that the factor would be eliminated from the analysis if the corresponding *P* value was greater than 0.2, in order not to miss out too much information in view of the small sample size. A *P* value of 0.05 or less was considered statistically significant and all reported *P* values were 2 sided.

RESULTS

Cardiac chest pain

Chest pain over the past year was present in 454 subjects (20.6%, 95% CI 19-22), of which 147 (6.7%) had 'possible' angina by the Rose angina questionnaire and/or ischaemic heart diseases diagnosed by a physician[11,27].

Noncardiac chest pain

NCCP over the past year was present in 307 subjects (13.9%, 95% CI 13-15). The demographic characteristics of subjects with NCCP, cardiac chest pain or no chest pain are given in Table 1. The prevalence of NCCP was higher in men than in women (16.6% *vs* 11.9%, *P*=0.002). Subjects with NCCP were significantly younger than subjects with no chest pain. However, for subjects with cardiac chest pain, the prevalence was similar between men and women (7.5% *vs* 8%, *P*=0.68) and the mean age was similar to subjects with no chest pain. Aspirin usage was significantly higher in subjects with cardiac chest pain than in subjects with no chest pain (20.6% *vs* 7.7%, *P*<0.001). NSAIDs usage was significantly higher in subjects with either NCCP or cardiac chest pain than in subjects with no chest pain. Cigarette and coffee consumption were the highest in subjects with NCCP, while alcohol consumption was similar between subjects with NCCP and subjects with cardiac chest pain. The education level and socioeconomic status were similar in subjects with NCCP, cardiac chest pain or no chest pain (Table 1). The median duration of NCCP was 24 mo (range 0.1 to 360 mo). Most (96%) subjects with NCCP had mild to moderate chest pain over the central chest area (50%) (Table 2). The frequency of chest pain was less than once per mo in three quarters of the subjects. Of the 307 subjects with NCCP, 155 (50.5%) could be classified as having GERD, while 79 (25.7%) had musculoskeletal-like chest pain. But GERD and musculoskeletal-like chest pain were overlapped

in 15.6% (48/307) of subjects. The gender difference in NCCP between men and women persisted after exclusion of subjects with musculoskeletal-like chest pain (13.1% *vs* 8.5%, *P*=0.001). Figure 1 shows the age and sex- prevalence rates of NCCP and musculoskeletal-like chest pain over the past year. For men with NCCP over the past year, the prevalence was the highest in 18-24 age group, less common in 25-54 age group and increased again after the age of 55 (Figure 1). In contrast, the prevalence of NCCP in women was almost constant from age 18 to 44, and then dropped gradually with age. The overall prevalence of musculoskeletal-like chest pain was similar between men and women (4.2% *vs* 4.0%, *P*=NS), but men aged 18-24 had a higher prevalence when compared to women of similar age (7.9% *vs* 2.6%, *P*=0.034).

Figure 1 Age and sex-specific prevalence rates (per 100) of noncardiac chest pain (NCCP) and musculoskeletal-like chest pain (MSL-CP) over the past year.

[a]The total in each individual cell may be smaller because of subject refusal, [b]*P*<0.001 when compared to subjects with no chest pain, [c]*P*<0.01 when compared to subjects with no chest pain, [d]*P*<0.05 when compared to subjects with no chest pain.

Risk factors for NCCP

By univariate analysis, NCCP was associated with heartburn and/or acid regurgitation, globus, dyspepsia, feeling of acidity in stomach, alcohol and NSAID usage but not with dysphagia, odynophagia, chronic cough, hoarseness of voice, asthma, pneumonia, history of smoking, aspirin usage and coffee intake (Tables 1 and 3). By multiple logistic regression analysis, heartburn and/or acid regurgitation (OR 2.3, 95% CI 1.7-3.1), globus (OR 1.9, 95% CI 1.3-2.8), and NSAIDs use (OR 1.9, 95% CI 1.2-2.9) were independent risk factors associated with NCCP.

Health care utilization, days off work and effects of NCCP on social life

Thirty-nine percent of subjects with NCCP over the past year used one or more forms of treatment for their problems. Among the 307 subjects with NCCP over the past year, 14 (5%) purchased over the counter medication, 85 (28%) visited an outpatient clinic; 10 (3%) visited the accident and emergency department, and 11 (4%) were admitted to regional hospitals for further management. NCCP over the past year was significantly correlated with increased health care utilization (*P*<0.001, OR 3.2, 95% CI 2.4-4.3). A significantly higher proportion of health

seekers with NCCP had moderate to severe chest pain when compared to non-health seekers (39% *vs* 27%, *P*=0.025) (Table 4). However, the proportion of subjects with at least monthly chest pain (28% *vs* 22% *P*=0.265) was similar between health seekers and non-health seekers. GERD (heartburn and/or acid regurgitation) over the past year was more prevalent in NCCP health seekers than in NCCP non-health seekers (67.5% *vs* 40.1%, *P*<0.001). A significantly higher proportion of subjects with NCCP reported their social life was affected by the chest pain (17% *vs* 9%, *P*<0.001, OR 1.9, 95% CI 1.4-2.5) and required days-off (17% *vs* 12%, *P*=0.021, OR 1.4, 95% CI 1.1-1.9) when compared to subjects with no chest pain.

Anxiety and depression score

Subjects with NCCP symptoms over the past year had higher average anxiety (5.5 *vs* 4.1, *P*<0.001) and depression (4.4 *vs* 3.8, *P*=0.007) scores when compared to subjects with no chest pain. However, for subjects with NCCP symptoms, the mean anxiety score and the mean depression score were similar between NCCP subjects who had sought any medical consultation and those who had not (Table 4).

Table 4 Comparison between subjects with noncardiac chest pain over the past year who did and did not seek health care

	NCCP health care seekers (*n*=131)	NCCP non-health care seekers (*n*=176)
Mean age ± SD	39±14	36±14
Female (%)	57.5[a]	42.8
Chest pain severity moderate or worse (%)	39.2[a]	26.5
Chest pain once a month or more (%)	27.5	21.7
Chest pain requiring days-off	35.3[b]	3.1
Presence of GERD (heartburn and/or acid regurgitation) (%)	67.5[b]	40.1
Social life being affected	31.4[b]	6.2
Mean anxiety score	5.8	5.3
Mean depression score	4.7	4.2

[a]*P*<0.05 when compared to non-health seekers, [b]*P*<0.001 when compared to non-health seekers.

Determinants of health care utilization in NCCP

By multiple logistic regression analysis, female gender (OR 1.9, 95% CI 1.1-3.2, *P*=0.023), the presence of GERD (heartburn and/or acid regurgitation) symptoms over the past year (OR 2.8, 95% CI 1.6-4.8, *P*<0.001) and social life being affected by chest pain (OR 6.9, 95% CI 3.3-15.9, *P*<0.001) were independent factors associated with health seeking behaviour of subjects with NCCP.

DISCUSSION

The epidemiology of NCCP is scanty in the literature and most studies are not population-based. Locke *et al* reported a prevalence of 23% in a semi-rural US population[1]. However, chest pain (including both exertional and non-exertional chest pain) with no past history of heart disease was the criteria for the diagnosis of NCCP in the study. Using Rose angina criteria, a population-based study in Mexican American and non-Hispanic white found a prevalence of 30% for chest pain thought not angina[33]. A UK study reported a population prevalence of 24% (Rose angina questionnaire) in 7754 subjects from 24 towns of Britain for "other chest pain"[23]. Recently, a population survey performed in Australia, using a similar definition of NCCP, reported a prevalence of 33% in

672 residents of Penrith[34]. The only independent factor for NCCP was the frequency of heartburn. No particular factor for health seeking behaviour was identified. The criteria of NCCP in our study were similar to the Australian study, but we found a considerably lower prevalence of NCCP (14%) when compared to the Western population. The exact reason is unknown but may be related to the lower prevalence of GERD (both erosive esophagitis and non-erosive reflux disease) in the Chinese population[28,32], as GERD is the most common etiology of NCCP. The gender, age distribution and socio-economic status closely resembled those of the census data of Hong Kong in 2001, suggesting our data are highly representative[16]. Fifty-one percent of subjects with NCCP could be classified as having GERD in our study, suggesting an esophageal cause of the chest pain. Interestingly, both musculoskeletal-like chest pain and GERD were overlapped in 16% of subjects, indicating the difficulty in establishing the etiology of chest pain through a questionnaire. Furthermore, we were not able to exclude panic attacks without proper psychiatric assessment. Nevertheless, we could still obtain useful data about the impact of chest pain of presumably 'noncardiac' in origin in the Chinese community. The prevalence of NCCP was unexpectedly high in young men. It could be partially explained by the higher proportion of young men with musculoskeletal-like chest pain when compared to women of similar age. Further endoscopic and physiological studies are warranted to investigate the exact causes of chest pain in these subjects.

By multiple logistic regression analysis, the presence of heartburn and/or acid regurgitation, globus and NSAIDs intake were independent risk factors for NCCP. The symptoms of GERD and globus suggested an esophageal origin of the chest pain, but the positive association of NSAIDs intake with NCCP was interesting. It is unknown whether these subjects took NSAIDs for the symptomatic relief of chest pain or NSAID intake indirectly linked to esophageal chest pain as a result of erosive damage to the esophageal mucosa[35-38]. Furthermore, it has been shown that subjects receiving 1 500 mg aspirin per day had higher gastric mechanosensory thresholds[39]. Those who failed to increase sensory thresholds were associated with dyspepsia. Similar mechanism may operate to account for the positive association between NSAIDs and NCCP as a result of abnormal visceral perception.

In the United States, it has been estimated that US$8 billion was spent annually for the initial care of patients who were suspected to have an acute coronary syndrome, but subsequently found not to have coronary artery disease[3]. The socio-economic effects were reflected by the higher proportion of NCCP subjects requiring days-off work and reporting an adverse effect of the illnesses on their social life when compared to subjects with no chest pain. It also concurred with our previous findings that quality of life assessment by SF-36 was significantly lower in patients with NCCP than in healthy controls[40].

Few studies have assessed the factors associated with health care utilization in NCCP. In the Australian study mentioned above, no particular factor was found to be associated with health seeking behaviour. We found that the presence of heartburn and/or acid regurgitation were important in motivating health seeking behaviour of subjects with NCCP. Furthermore, female gender was more commonly associated with health care utilization in subjects with NCCP. Despite the higher prevalence of NCCP in men in our study, women were more likely to seek medical attention and correlated with the findings of female predominance in previous non-population based studies[41,42]. We did not find any effect of anxiety and depression on health care utilization, but subjects feeling their social life affected by chest pain were more likely

to seek help.

The major limitation of this study was the diagnosis of NCCP through a questionnaire. In clinical practice, diagnosis of NCCP requires full cardiology evaluation. However, criteria like Rome II are not available for noncardiac chest pain[43], but rather for a sub-group of patient population only (chest pain of presumed esophageal origin). It has been shown in prospective studies that 'possible' angina or exertional chest pain was equally reliable for the prediction of future ischemic events, in both men and women[23,26]. Furthermore, self-reported history of doctor-diagnosis of angina has been shown to be a valid measure of angina in population-based studies[27]. Although the sensitivity of Rose angina questionnaire is variable, it is highly specific for the diagnosis of angina[17-26]. In our pilot study, we found that the translated Chinese version of the Rose angina questionnaire had a sensitivity and specificity of 68% and 95%. We used the combination of 'possible angina' and history of ischemic heart disease diagnosed by a physician for the diagnosis of cardiac chest pain, hoping that it would reduce the number of unrecognized ischemic heart disease in this study. Furthermore, it is unpractical to perform exercise testing or coronary angiograms in all subjects with chest pain in the setting of a population-based study.

In conclusion, NCCP is a common problem in Chinese and associated with anxiety and depression. Female gender, the presence of GERD symptoms over the past year and social life affected by chest pain are independent factors associated with health care utilization in Chinese.

Abstract

AIM: Bowel habits are difficult to study, and most data on defecatory behaviour in the general population have been obtained on the basis of recalled interview. The objective assessment of this physiological function and its pathological aspects continues to pose a difficult challenge. The aim of this prospective study was to objectively assess the bowel habits and related aspects in a large sample drawn from the general population.

METHODS: Over a two-month period 488 subjects were prospectively recruited from the general population and asked to compile a daily diary on their bowel habits and associated signs and symptoms (the latter according to Rome II criteria). A total of 298 (61%) participants returned a correctly compiled record, so that data for more than 8 000 patient-days were available for statistical analysis.

RESULTS: The average defecatory frequency was once per day (range of 0.25-3.25) and was similar between males and females. However, higher frequencies of straining at stool (P=0.001), a feeling of incomplete emptying and/or difficult evacuation (P=0.0001), and manual manoeuvres to facilitate defecation (P=0.046) were reported by females as compared to males.

CONCLUSION: This study represents one of the first attempts to objectively and prospectively assess bowel habits in a sample of the general population over a relatively long period of time. The variables we analyzed are coherent with the criteria commonly used for the clinical assessment of functional constipation, and can provide a useful adjunt for a better evaluation of constipated patients.

INTRODUCTION

Bowel habits are a difficult function to study objectively because of their highly private nature and negative associations. Therefore, it is not surprising that they represent one of the least understood aspects of human behaviour[1]. In the past, most knowledge of bowel habits was drawn from limited data on small groups of subjects (nurses, jail prisoners, elderly people, students)[2-5]. More recently, studies aimed generically at investigating functional gastrointestinal disorders[6-10] have yielded data on large numbers of subjects by means of telephone interviews or mailed questionnaires[11-14]. However, these studies and other reports have all been retrospective in nature and based on the subjects' assertions regarding their recent bowel function[1,15,16]. More objective investigations have assessed small groups of subjects for limited periods of time (*e.g.* one week)[17].

Prospective studies on bowel habits conducted over an adequate period of time in the general population are still lacking. The aim of our prospective study was to objectively assess the frequency and characteristics of defecation in a sample of the general population over a longer period of time.

MATERIALS AND METHODS

During a two-month period a questionnaire was consecutively distributed to 488 relatives or friends of patients attending the outpatient gastrointestinal clinic in six centres located in different regions of Italy (two in the north, two in the centre, and two in the south). A total of 259 women and 229 men received the form. To obtain the most objective possible data on bowel habits, the questionnaire took the form of a diary covering a period of 4 wk in which "yes-no" responses were to be given daily to six questions (Table 1). Drawing upon the Rome II criteria for functional constipation[18], data on the following symptoms and signs were recorded each day, namely number of bowel movements, straining during bowel movements, feeling of incomplete emptying and/or difficult evacuation, manual manoeuvres to facilitate defecation, lumpy or hard stools. In addition, the use of laxatives was recorded.

The questionnaires were anonymous, and the only personal information the participants were required to give was their age and sex. All subjects received an exhaustive explanation about the aim of the study and the structure of the questionnaire.

Each centre received approval from the local ethics commitee, the written consent of all subjects was obtained after they had been given a complete explanation of the aims of the study and the nature of the questionnaire, and the study was conducted in accordance with the Helsinki Declaration (Edinburgh revision, 2000).

For each subject, an overall score for each variable was computed as follows. The average number of bowel movements per day was obtained by taking the total number of defecations reported by the participants and divided by the total number of days in the study period (*i.e.*, 28). The frequency in the use of laxatives was computed in the same way. The frequency of the four variables associated with defecation (straining, feeling of incomplete evacuation, need of manual help, lumpy/hard stools) was evaluated as the ratio between the total number of episodes recorded by the individual and the total number of bowel movements during the study period.

Table 1 Four-week daily diary (Patients giving yes-no responses and number of bowel movements/day were recorded)

Questions	Time						
FIRST WEEK	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday	Sunday
Bowel movements (number/day)							
Straining at defecation							
Feeling of incomplete defecation							
and/or difficult evacuation							
Manual manoeuvres							
Lumpy or hard stools							
Use of laxatives							
SECOND WEEK	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday	Sunday
Bowel movements (number/day)							
Straining at defecation							
Feeling of incomplete defecation							
and/or difficult evacuation							
Manual manoeuvres							
Lumpy or hard stools							
Use of laxatives							
THIRD WEEK	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday	Sunday
Bowel movements (number/day)							
Straining at defecation							
Feeling of incomplete defecation							
and/or difficult evacuation							
Manual manoeuvres							
Lumpy or hard stools							
Use of laxatives							
FOURTH WEEK	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday	Sunday
Bowel movements (number/day)							
Straining at defecation							
Feeling of incomplete defecation							
and/or difficult evacuation							
Manual manoeuvres							
Lumpy or hard stools							
Use of laxatives							

Statistical evaluation

All group means and standard deviations (SD) were calculated by averaging the individual scores. Comparisons among groups were carried out using the chi-square test or non-parametric tests. Correlations between pairs of variables were assessed by means of the non-parametric Spearman's correlation coefficient. P values <0.05 were chosen for rejection of the null hypothesis. Data are presented as mean±SD.

RESULTS

A total of 298 adult subjects (163 women (54.7%), mean age 42.5±15.5 yr and 135 men (45.3%), mean age 42.4±15.9 yr) returned the completed questionnaire. The mean response rate was 61.1 % (females 62.9 %; males 58.9 %, n.s.). Therefore, data for 8 344 d were available for statistical analysis.

The distribution of the participating subjects by age and sex is shown in Table 2. Table 3 reports the frequency of defecation, expressed as the average number of evacuations per day, the frequency of pathological features and sensations at defecation, and the use of laxatives per day. Overall, the frequency of bowel movements averaged one per day (range 0.25-3.25), and was similar between males and females. No significant intra-personal variation in the parameters under examination was detected over the four-week period. Higher frequencies of straining at stool (P=0.001), feeling of incomplete emptying and/or difficult evacuation (P=0.0001),

and manual manoeuvres to facilitate defecation (P=0.046) were reported by females as compared to males.

Table 2 Distribution for age and sex of population under investigation n(%)

years	Women	Men	Total
<20	3 (1.8)	3 (2.2)	6 (2)
21-30	32 (19.6)	39 (28.9)	71 (23.8)
31-40	59 (36.2)	32 (23.7)	91 (30.5)
41-50	22 (13.5)	21 (15.6)	43 (14.4)
51-60	21 (12.9)	20 (14.8)	41 (13.8)
61-70	19 (11.7)	13 (9.6)	32 (10.7)
>70	7 (4.3)	7 (5.2)	14 (4.7)

Table 4 shows the correlations between pairs of defecatory variables. Bowel movement frequency was negatively correlated with other features of defecation and the use of laxatives. Straining, a sensation of incomplete/difficult evacuation, manual manoeuvres, lumpy/hard stools and the use of laxatives were positively correlated with each other.

Concerning the relative weights of the single variables, it might be noted that 15 (5%) subjects showed a low frequency (<3/wk) of defecations, 35 (11.7%) straining during >¼ defecations, 32 (10.7%) incomplete/difficult evacuation during >¼ defecations, 2 (0.7%) manual manoeuvres during >¼ defecations, and 18 (6%) lumpy/hard stools during ¼defecations.

Table 3 Defecatory frequency and defecation-related variables in our population sample (data are expressed as mean±SD)

Sex	No. of defecations/ day	Straining at stool/ defecation	Feeling of incomplete emptying/defecation	Manual help for evacuation/ defecation	Lumpy/hard stools/defecation	Use of laxatives/day

DISCUSSION

Most studies on bowel habits have been based on phone interviews and on the assumption that people would report accurately, but there has been good evidence that bowel movement frequency might be misreported[19,20]. Indeed, it is very difficult to remember and report accurately one's bowel habits over recent months in a 20 min interview. Studies have shown marked discrepancies between recalled data and data that was recorded daily[19,21,22]. Moreover, people without a telephone or who were not at home when contact was attempted would be excluded from any given survey[23]. Another source of bias was the possibility that symptomatic individuals would be more keen to complete the survey process than asymptomatic subjects, which might lead to an overestimation of the frequency of symptoms.

Validated and universally accepted criteria are definitely needed if functional bowel disorders are to become a formally recognized disease entity by physicians, patients, and society[24].

In order to circumvent some of the methodological biases discussed above, for this study a questionnaire designed to elicit the most objective possible data on individual bowel habits was drawn up. With this instrument bowel movement frequency, and sensations and characteristics related to each bowel movement were prospectively recorded by nearly 300 subjects on a daily basis for 4 wk. Moreover, to obtain a geographically representative sample of our population, participants were recruited from different parts of the country.

It may be stressed that the 61% response rate could be considered relatively high, given the nature of the data being sought. Studies employing telephone interviews or mailed questionnaires have yielded a response rate ranging from 19% to 80%. We believe that our high response rate can be attributed to the simplicity of the questionnaire (which examined only six items) and its complete anonymity. A daily dial-in service might have been more reliable, but this is costly to implement and potentially dependent on the socio-cultural environment in which the study is conducted.

It must be pointed out that due to the recruiting procedure used, the individuals who participated in this study were not selected with respect to factors such as social status, education, occupation and, possibly, the prevalence and type of bowel habits reported. However, they were prospectively recruited and not selected based on the basis of factors such as the presence/absence of pathological symptoms. Nevertheless, in light of the high participation rate, it seems reasonable to

postulate that the results of this study provide an acceptable approximation of the prevalence and type of symptoms in a general sample of Italian adults.

We are certain of our findings to be underlined. Firstly, there was a relatively large variation in bowel movement frequency, with an average of one per day, but a range of one evacuation every 4 d to about 3 bowel movements per day, with no differences in distribution between the sexes. It might also be noted that 5% of the participants reported less than 3 evacuations/week. Secondly, the number of subjects who reported abnormal features during >¼defecations was low, in particular, the incidence of manual manoeuvres to facilitate defecation was almost nil (0.7%). However, these variables showed a positive correlation with one another. Thirdly, the prevalence of defecation-related variables (except for the presence of lumpy/hard stools) was significantly different between the sexes, with a higher frequency in women, and interestingly, all of these are variables related with pelvic floor function. The use of laxatives was also rare (5% of the population sample), but much (*P*=0.0001) more frequent among women.

The variables analysed in this study could be helpful in the clinical assessment of functional constipation. Our data furthermore suggest that different symptoms and signs should be attributed to different weights in the evaluation of constipation scores[25,26]. For instance, a value of less than one defecation per week or the use of manual manoeuvres to facilitate defecation could represent clinically important indications for the diagnosis of constipation.

In conclusion, this study represents one of the first attempts to prospectively assess bowel habits in a general population sample over a long period of time. Further studies in "normal" subjects will obviously be needed to confirm these observations.

The following researchers of the Italian Constipation Study (ICS) Group participated in the study: Bassotti G, Chistolini F, Morelli A (Perugia); Bellini M, Alduini P, Mammini C, Rappelli L, Costa F, Stasi C, Mumolo MG, Berni I, Giorgetti S, Marchi S (Pisa); Pucciani F, Iozzi L, Cianchi F, Cortesini C (Firenze); Bocchini R, Cimatti M, Fornasari L, Montaletti I, Pazzi P (Cesena/Forlì); Bove A, Balzano A (Napoli); Battaglia E, Dughera L, Emanuelli G (Torino); Bruzzi P (Genova).

Abstract

AIM: To investigate the association of *FAS* gene polymorphism with coeliac disease (CD) development.

METHODS: *FAS-G670A* gene polymorphism, located in a gamma interferon activation site, was studied in 146 unrelated CD patients and 203 healthy ethnically matched controls. The restriction fragment length polymorphism (RFLP) method was used to identify *FAS-G670A* gene polymorphism.

RESULTS: No significant difference was found in genotype frequency between CD cases and controls. In controls, however, the frequency of the *GG* genotype was significantly higher in women (26.5%) than in men (12.8%) (*OR*= 2.44, 95% *CI* 1.15-5.20, *P*=0.020) and it was also higher in men with CD than controls (*OR*=2.60, 95% *CI* 0.96-7.05, *P*=0.061). The *GG* genotype frequency was significantly higher in patients with most severe villous atrophy (Marsh IIIc lesions) (*OR*=3.74, 95% *CI* 1.19-11.82, *P*=0.025). A significantly less proportion of men suffered from Marsh IIIc lesions than women (*OR*=0.20, 95% *CI* 0.06-0.68, *P*=0.01). The risk of having severe villous atrophy increased with the additive effect of the *G* allele in women (*P*=0.027 for trend, age and gender adjusted).

CONCLUSION: *FAS-G670A* gene polymorphism is associated with the severity of villous atrophy in CD. Female gender is also associated with the severity of villous atrophy.

INTRODUCTION

The pathogenesis of coeliac disease (CD) is unclear. Although the majority of CD patients are HLA-DQ2 or DQ8 positive, only a small percentage of HLA-DQ2 and DQ8 carriers in the healthy European population develop CD[1]. Human genome screening of CD patients and their families support the polygenic inheritance of the disease[2]. Different genes are involved in the disease susceptibility or in determining clinical course and severity of the lesion[3]. Ciccocioppo et al[4] reported the significant correlation between the degree of villous atrophy (VA) and the level of enterocyte apoptosis. FAS (TNFRSF6) expression increased in the abnormal segment of small intestine in CD[4,5]. Therefore, the epithelial FAS engagement might contribute to the development of villous atrophy[4,5]. We studied the association between the *FAS-G670A* gene polymorphism with the severity of VA and the disease susceptibility in a cohort of untreated Caucasian CD patients at the time of presentation and ethnically matched healthy controls.

MATERIALS AND METHODS

Subjects

Before treatment, 146 unrelated CD patients were classified according to modified Marsh classification. Their diagnoses were confirmed only if patients responded to gluten-free diet both clinically and histologically[6], and 203 healthy ethnically matched controls were enrolled in this study.

Methods

Villous atrophy classification The histological features were classified according to the modified Marsh classification[7]. In the original classification, Marsh described subtotal villous atrophy as a destructive lesion and called it the Marsh III lesion. In our study, to assess the severity of the histological features, we classified the Marsh III type lesion into 3 subgroups[8]. Briefly, in all subgroups, histological lesions had the significant intraepithelial lymphocytosis (>30 lymphocytes per 100 epithelial cells). The architectural changes permitted classifying the lesion into three subtypes with increasing severity. They were designated as Marsh IIIa (partial VA) when the villous-crypt ratio was less than 1/1, Marsh IIIb (subtotal VA) when there were still recognizable villi in an otherwise flat mucosa, and Marsh IIIc (total VA) when there was nearly complete absence of villi.

Typing FAS-G670A polymorphism PCR amplification and genotype analysis for *FAS-G670A* were performed according to previously published methods[9]. In brief, genomic DNA was extracted from peripheral blood using a standard proteinase K digestion and phenol/chloroform extraction method and mouthwash method[10]. The *FAS–G670A* polymorphism was typed as described previously by Huang et al[9] with the following minor modifications. PCR: 5 min at 95 ℃, 30 cycles of 30 s at 95 ℃, 30 s at 62 ℃, and 1 min at 72 ℃, followed by a final extension for 7 min at 72 ℃. Primer sequences were 5'-CTA CCT AAG AGC TAT CTA CCG TTC-3' and 5'-GGC TGT CCA TGT TGT GGC TGC-3'. The 332 bp PCR product

was digested with *MvaI* for 5 h at 37 ℃. Allele G yielded three fragments of 99 bp, 189 bp, and 44 bp, whereas allele A yielded two fragments of 99 bp and 233 bp. Digested fragments were separated on 30g/L agarose gels and visualized after ethidium bromide staining (Figure 1).

Figure 1 1: GA genotype, 2: AA genotype, 3: GG genotype, 4: 50 bp DNA marker distinguished alleles G (189 bp) and A (233 bp).

Statistical analysis

Hardy–Weinberg equilibrium test was carried out by using statistical software for linkage analysis[11]. χ^2 statistics and Fisher's exact test were used for comparisons of frequencies. The subjects were classified according to the number of G alleles that they inherited, such as 0 for subjects who were carriers for *A* allele of *FAS*-G670A, *i.e.* AA genotype, 1 for those who were carriers of 1 copy of G allele, *i.e.* AG genotype and 2 for subjects who inherited 2 copies of G allele, *i.e.* GG genotype. Logistic regression was used to fit statistical models to predict the association of *FAS-G670A* polymorphism with the severity of villous atrophy or with susceptibility to CD. All the statistical models were adjusted for age (years) and gender. Associations are expressed as odd ratios (*OR*) with 95% confidence interval (95% *CI*). Estimation of 95% *CI* was based on Wald's method. A two tailed *P* value <0.05 was considered as significant. Statistical analysis was performed with SPSS version 10.07 for windows software.

RESULTS
Susceptibility of CD

The characteristics of study participants are shown in Table 1. The genotype frequencies were in Hardy–Weinberg equilibrium proportions in patients and controls. There was no significant difference in genotype distributions between patients and controls (Table 1). In men, the frequency of *GG* genotype was higher in cases (27.3%) compared to that of controls (12.8%), yielding to *OR* of 2.60, 95% *CI* 0.96-7.05, *P*=0.061. The *GG* genotype was significantly (*P*=0.020) higher in women (26.5%) compared with men (12.8%) in healthy control.

Figure 2 Trend for *GG* genotype frequency in different severity of villous atrophy in untreated CD women, *P*=0.027, adjusted for age.

Association of villous atrophy

In cases, men had a significantly lower frequency of Marsh IIIc compared to women (*OR*=0.20, 95% *CI* 0.06-0.68, *P*=0.01). Genotype and allele frequencies in Marsh III subgroups are presented in Table 2. There was a significant (*P*=0.025) difference of *GG* genotype frequency between Marsh IIIc which had the most severe form of the disease and Marsh IIIa (*OR*=3.74, 95% *CI* 1.19-11.82). In chromosomal analysis, we found a borderline significant association between G allele and Marsh IIIc villous atrophy (*OR*=1.81, 95% *CI* 0.97-3.38, Table 2). However, in women, G allele was significantly associated with this subgroup (*OR*=1.75, 95% *CI* 1.00-3.06, *P*=0.048).

Table 1 Characteristics and genotype frequencies of *FAS-G670A* in untreated CD with villous atrophy

	CD (*n*=146)	Controls (*n*=203)	OR[1] (95%CI)	OR[2] (95% CI)	OR[3] (95% CI)

Table 2 Association of severity of villous atrophy with FAS-G670A polymorphism in untreated CD

Marsh	Genotype analysis			Allelic analysis			
	GG genotype F/M	*GA* genotype F/M	*AA* genotype F/M	OR[1] (95% CI)	*G* allele (%)	*A* allele (%)	OR[2] (95% CI)
IIIa (%)	3/3 (15.0)	17/6 (57.5)	6/5 (27.5)	Reference	35 (44.0)	45 (56.0)	Reference
IIIb (%)	9/5 (21.5)	25/7 (49.2)	15/4 (29.2)	1.63 (0.56-4.76)	60 (46.0)	70 (54.0)	1.10 (0.63-1.93)
IIIc (%)	13/1 (34.1)[3]	18/2 (48.8)	7/0 (17.1)	3.74 (1.19-11.82)	48 (58.5)	34 (41.5)	1.81 (0.97-3.38)

F, women; M, men, *OR*[1], adjusted, for *GG* genotype frequency; [3]*P*=0.025, *OR*[2], adjusted, for *G* allele frequency.

The severity of VA increased additively with increasing number of G alleles in women ($P_{\text{for trend}}$=0.027) (Figure 2).

DISCUSSION

We found a significant association between the *FAS–670 GG* genotype and the severity of celiac disease, particularly in women. However, we did not find significant differences in genotype frequencies between controls and CD patients. This suggested that the *FAS* gene was not a susceptible gene for this disease. The fact that genotype frequencies of patients and controls were in Hardy Weinberg equilibrium confirmed the validity of the typing of the results. The intestinal pathological diagnosis was confirmed by two independent pathologists. Therefore our data suggested an association of *FAS-G670A* polymorphism with the severity of CD.

Since this polymorphism of the *FAS* gene (*TNFRSF6*) is located in the promoter region, it may affect the level of transcription of the FAS protein. Previous work suggested that the substitution of G to A in the position –670 (TTCCAG G/A AA) would change the gamma interferon activation site (GAS) (TTCnnnGAA)[12-14]. This site was involved in interferon gamma and interferon alpha signalling[15]. GAS elements are known to bind to homodimers of a phosphorylated form of the 91-kDa transcription factor, STAT1. Interferon gamma could cause tyrosine phosphorylation of STAT1 by the interferon gamma receptor-associated Janus kinases 1 and 2. Subsequently, phosphorylated STAT1 formed homodimers and translocated into the nucleus where it induced transcription of GAS-containing genes[16]. FAS was significantly upregulated by interferon gamma according to several reports[17-19]. Xu *et al*[20] and De Saint Jean *et al*[21] have implicated STAT1 in this upregulation effect of interferon gamma. We therefore postulate that *FAS*-670G variant containing the GAS (TTCCAGGAA) could be affected by interferon gamma production and increase the transcription of Fas. This may result in different degree of apoptosis in CD with different degrees of VA. Our data confirmed that the risk of having severe villous atrophy increased additively with the number of G alleles. The *GG* homozygote was strongly correlated to the severity of VA in CD. Intermediated by GAS, both interferon gamma and Fas might play an important role in the pathogenesis of villous atrophy. This was in agreement with previous reports showing that mucosal gluten exposure elicited a high level interferon gamma expression in CD[22]. Interferon gamma could increase FAS-induced apoptosis of human intestinal epithelial cells in a dose-dependent manner[23].

Considering the previous reports[24-26], we hypothesize that FAS-*G*670A is functional and further functional tests are necessary. The *FAS-G670A* gene polymorphism contributes to the determination of the severity of small intestinal lesions and opens a new area of research that may help understand the heterogeneity of this disease. Our findings were in the same line of a recent genome-wide family-based linkage study of CD that found a potential susceptible locus at 10q23.1[27] close to the cytogenetic region (10q23.31) of the *FAS (TNFRSF6)* gene[28]. These results may also explain why the different genome-wide studies of families with multiple cases of CD had not uniformly found a similar lod score at chromosome 10q23, since the proportion of patients with severe villous atrophy might differ from each other in those studies.

Our data also showed a gender difference in relation to the severity of VA and in the genotype distribution of *FAS-G670A*. Even though there was no difference of *GG* genotype frequency in women and men among the cases, men had a significantly less proportion of Marsh IIIc VA than women. This might be due to the different immune responses between men and women. Women were more likely to develop Th1 response

(secreting higher amounts of IL-2, interferon gamma, and TNF-beta than men)[29]. In summary, our findings suggest that increased expression of FAS in villous atrophy is in part genetically regulated and the *FAS* gene plays a significant role.

Abstract

AIM: It is difficult to differentiate gallstone dyspepsia and functional dyspepsia by clinical symptoms and signs. We hypothesized that gallstone dyspepsia was related to abnormal gallbladder motility. We aimed to differentiate gallstone dyspepsia from functional dyspepsia by measuring gallbladder motility.

METHODS: We measured gallbladder volume changes in response to gastric distension (saline 500 mL) and fatty meal in 10 normal volunteers (controls) and 62 patients with gallstones and dyspepsia before cholecystectomy. Forty cholecystectomized patients were symptom free or had improvement (group I), while the remaining 22 patients had persistent dyspepsia (group II). Gallbladder volume change and ejection fraction were analyzed and compared among the three groups.

RESULTS: In group I, there were significant decreases in gallbladder volumes 5-25 min after gastric distension, compared to fasting volumes. Compared to normal volunteers and group II, group I had significantly decreased gallbladder volumes 10-20 min after drinking 500 mL of normal saline and 10 to 50 min after eating fatty meal.

CONCLUSION: Our results support the hypothesis that increased gallbladder contraction after gastric distension or fatty meal may be related to dyspeptic symptoms in uncomplicated gallstone disease. These findings may be useful in differentiating functional dyspepsia from gallstone dyspepsia, patients with the latter disease may benefit from laparoscopic cholecystectomy.

INTRODUCTION

Laparoscopic cholecystectomy is the choice of treatment for symptomatic gallstone disease and is performed with increasing frequency. It is clear that gallstone patients with complications (acute cholecystitis, gallstone pancreatitis or jaundice) or severe biliary pain should undergo cholecystectomy. Conversely, for asymptomatic gallstone disease, no treatment should be done. Nonetheless, some patients with uncomplicated gallstone disease, once termed gallstone dyspepsia[1], suffer from mild abdominal symptoms, such as postprandial flatulence, bloating, nausea and belching. Most of these patients also undergo laparoscopic cholecystectomy, but about 20-30% of these cholecystectomized patients still complain of abdominal symptoms after surgery. These symptoms may be associated with preoperatively undiagnosed functional gut disease unrelated to gallstones[2-4]. In order to avoid unnecessary cholecystectomies, it is important to ascertain preoperatively that these mild symptoms of gallstone patients with dyspepsia are really caused by gallstones. New diagnostic methods to predict which patients will benefit from cholecystectomy are therefore necessary.

Gallstone dyspepsia and functional dyspepsia have coexisting symptoms and it is difficult to differentiate from each other based on the dyspeptic symptoms[5-7]. Despite numerous studies, the mechanism of gallstone dyspepsia has not been completely explained[8-10]. In the past, the majority of literature focused on the pathogenesis of gallstone formation. It is postulated that two distinct subgroups of gallstone patients can be identified with regard to gallbladder emptying, including "normal contractors" and "pathologic contractors" or "strong contractors" and "weak contractors"[11-14]. Therefore, we hypothesize that in these patients, gallstone dyspepsia may result from abnormal gallbladder motor activity stimulated by gastric distension or fatty meals. In this study, we investigated the difference in gallbladder contractility in response to gastric distension and fatty meals in healthy volunteers and patients with gallstones and dyspepsia. If so, preoperative assessment of gallbladder contractility with ultrasonography would contribute to better outcomes of cholecystectomy.

MATERIALS AND METHODS

Gallbladder volume was assessed in 72 subjects, including 10 healthy controls and 62 gallstone patients with symptoms of dyspepsia. None of the gallstone patients had past or present signs of complicated gallstone diseases, such as acute cholecystitis, biliary pancreatitis, jaundice or severe biliary pain. Panendoscopy and abdominal ultrasound were done to exclude esophagitis, peptic ulcer, pancreatitis or other organic diseases in all gallstone patients. After an overnight fast, the fasting gallbladder volume was measured ultrasonographically three times within 5 min, with the subjects lying supine or turned partially on their sides. The gallbladder volume was estimated using a real-time ultrasound system (MK-500, ATL, Bothell, WA) with a 3.5-MHz transducer. The largest longitudinal and transverse gallbladder images were recorded. The gallbladder volume was calculated using the computerized sum-of-cylinders method as described by Hopman et al[15]. Then, the gallbladder volume was again measured after the patient drank 500 mL of normal saline at room temperature within a 2-min period. Measurement was made at 5 min

intervals for the first 30 min, then at 10 min intervals between 30 to 90 min after drinking. On the next day, we serially measured gallbladder volumes after the patients ate a fatty meal (fried egg cake) containing protein 9.32 g, fat 20.3 g and carbohydrate 14.4 g, 277.58 Kcal, followed by 100 mL of water. After the measurements, the gallstone patients with dyspepsia underwent laparoscopic cholecystectomy and were monitored in the outpatient department at least for 1 yr after surgery. These patients were allocated to 2 groups according to cholecystectomy outcomes. Forty patients (group I) were symptom free or had improved symptoms after cholecystectomy. Twenty-two patients (group II) complained of persistent dyspepsia after cholecystectomy, with the same symptoms as their preoperative symptoms. Thereafter, we analyzed and compared the differences among the three patient groups (groups I, II and controls) for fasting gallbladder volume, volume changes and ejection fraction in response to gastric distension and fatty meal.

The fasting gallbladder volume was calculated as the mean of three values before meal intake. The postprandial gallbladder volume was expressed as a percentage of the fasting volume. Results are expressed as mean±SE. Statistical analyses were performed using Statistical Package for the Social Sciences (SPSS) software. Comparisons among the three groups were analyzed using the χ^2 test. Differences between means were considered significant at $P<0.05$.

RESULTS

Patient characteristics are shown in Table 1. The fasting gallbladder volume tended to be larger in the two groups of patients with gallstones than in healthy volunteers during either test (Table 1).

Table 1 Characteristics of subjects (χ^2 test)

	Normal (n=10)	Group I (n=40)	Group II (n=22)	P value
Age, (yr)	61.2±12.3	59.5±15.1	62.5±13.4	NS
Sex (M:F)	4:6	14:26	9:13	NS
Weight (kg)	60.9±5.7	59.8±13.8	57.6±9.8	NS
BMI	27.8±3.8	24.8±4.7	24.4±5.7	NS
Fasting gallbladder volume (mL)	26.3±7.4	32.6±14.1	33.9±10.7	<0.05

BMI, body mass index. $P<0.05$ was considered stastistically significant.

In normal volunteers and group II gallstone patients after drinking 500 mL normal saline, the gallbladder volume did not significantly change from the basal fasting level throughout the 90-min observation period (Figure 1). In contrast, in group I patients, within 5 to 25 min after drinking 500 mL of normal saline, there was a significant decrease in the gallbladder volume from the basal fasting volume ($P<0.05$) (Figure 1). The gallbladder volume change (10-20 min) in group I patients was significantly larger than that in healthy volunteers and group II patients ($P<0.05$) (Figure 1).

After the fatty meal, there were significant decreases in gallbladder volume in healthy volunteers and the two groups of gallstone patients throughout the 90-min study period (Figure 2). Group I patients had larger gallbladder volume changes ($P<0.05$) than the other two groups during the early phase (10-50 min) of testing, the lowest residual volume was detected at the 40th min. We also found that the gallbladder volume change was significantly smaller ($P<0.05$) in group II during the early phase (10-40 min) than in healthy volunteers in

response to fatty meal (Figure 2). The ejection fraction was significantly greater ($P<0.05$) in group I than the other two groups 10-50 min after the fatty meal (Figure 3).

Figure 1 Gllbladder volume change after ingestion of 500 mL of normal saline (N.S.) in healthy volunteers (normal controls, n=10), group I (symptom free or symptom improved after cholecystectomy) (n=40) and group II (persistent dyspepsia after cholecystectomy) (n=22) gallstone patients. Values are mean±SE (χ^2 test). [a]$P<0.05$: significant volume change from fasting gallbladder volume. [c]$P<0.05$: significant difference among three groups (group I vs normal group and group II patients).

Figure 2 Gallbladder volume change after fatty meal in healthy volunteers (normal, n=10), group I (symptom free or symptom improved after cholecystectomy) (n=40) and group II (persistent dyspepsia after cholecystectomy) (n=22) gallstone patients. Values are mean±SE (χ^2 test). [a]$P<0.05$: significant difference between normal group and group II. [c]$P<0.05$: significant differences among three groups (group I vs normals and group II patients).

Figure 3 Ejection fraction of gallbladder in healthy volunteers and gallstone patients after oral fatty meal. Values are mean±SE (χ^2 test). [a]$P<0.05$: significant difference between group II (persistent dyspepsia after cholecystectomy) and normal group. [b]$P<0.05$: significant differences among three groups (group I vs normal group and group II).

DISCUSSION

It is clear that complicated gallstone diseases, such as acute cholecystitis, obstructive jaundice, gallstone pancreatitis and severe biliary pain, are good indications for cholecystectomy. With the technical improvements in laparoscopic surgery, many patients with uncomplicated gallstone disease termed gallstone dyspepsia underwent laparoscopic cholecystectomy for only mild gastrointestinal symptoms such as postprandial flatulence, bloating or belching. However, the benefit of cholecystectomy for gallstone patients with dyspepsia has remained debatable[16]. Only about one half of patients were symptom free after cholecystectomy[17,18]. About 20-30% of cholecystectomized patients still complained of dyspepsia, which might have been associated with preoperatively undiagnosed functional gut diseases unrelated to gallstones[2-4]. Because gallstone dyspepsia and functional dyspepsia had coexisting symptoms, it is difficult to differentiate them based on dyspeptic symptoms[5]. In order to avoid unnecessary cholecystectomies, it is important to ascertain preoperatively that the symptoms of gallstone patients with dyspepsia are truly caused by gallstones.

Even with numerous studies, the mechanisms underlying gallstone dyspepsia could not be completely explained[8-10]. Some investigators believed that dyspepsia was associated with functional gut diseases such as antroduodenal reflux and irritable bowel syndrome, rather than with gallstone disease[19,20]. However, Johnson[21] suggested that an association existed between flatulent dyspepsia and gallbladder disease, although it had no direct relationship. In the past, the majority of literature focused on the pathogenesis of gallstone formation rather than on the association of gallbladder motility and clinical symptoms. Using different techniques, investigators showed decreased[10-12], normal[22] or even increased[23] gallbladder contractility compared to normal controls. Moreover, it has been postulated that two distinct subgroups of gallstone patients could be identified with regard to gallbladder emptying, including strong and weak contractors[24,25]. Perhaps the mild abdominal symptoms were related to abnormal gallbladder motility. We identified two distinct groups of patients with gallstones and dyspepsia in terms of gallbladder contractility.

In our study, patients with gallstones and dyspepsia had significantly larger fasting gallbladder volumes, which were similar to a previous report[26]. The symptoms experienced in gallstone patients were traditionally believed to arise from gallbladder spasm, and normal gallbladder contractility was thought to be a prerequisite for the development of symptoms. Heaton reported that gallstones were prone to cause symptoms in younger patients and cited the explanation that younger people perhaps had stronger gallbladder contractions[27]. We also found that group I patients had larger gallbladder volume changes and stronger gallbladder contractions during the early phase of observation in response to 500 mL of normal saline and fatty meals, although there was no significant difference in age among them. We found that in group I patients, symptoms improved after cholecystectomy, that is, patients who had stronger gallbladder contractions in response to gastric distension and fatty meal benefited from cholecystectomy. However, group II patients with impaired gallbladder contractility did not benefit from cholecystectomy because their symptoms were perhaps unrelated to gallbladder motility.

In 1979 Debas *et al* found that antral distension initiated a cholinergic pyloro-cholecystic reflex causing gallbladder contraction in dogs[28]. Intact vagus nerves and cholinergic pathways were required for this reflex. Vagal stimulation via mechanoreceptors in the stomach initiated gallbladder contraction independently of meal composition[29]. Yamamura *et al* found that gastric distension following ingestion of

400 mL of water induced a maximum gallbladder evacuation of 25%, compared with a maximum gallbladder contraction of 44% after ingestion of fatty meal in humans[30]. However, in our study, the gallbladder response to gastric distension following ingestion of 500 mL of normal saline in healthy volunteers and group II gallstone patients was not significantly different from fasting gallbladder volumes. In group I gallstone dyspepsia patients, after drinking 500 mL of normal saline, the lowest gallbladder residual volume (13%) occurred at 15 min, with progressive recovery to the fasting volume thereafter. This saline water induced gallbladder early net emptying most prominently between 5 and 25 min in group I patients. In contrast, after fatty meal, there were significant decreases in gallbladder volumes both in healthy volunteers and the two groups of gallstone patients throughout the study period. The group I gallstone patients had the largest gallbladder volume change at the 40th min of the study. The ejection fraction was significantly increased in group I patients compared to the other two groups 10-50 min after fatty meal, but not thereafter.

Our study showed that gallbladders of group I gallstone dyspepsia patients had greater motility than those of normal individuals and group II patients in response to both gastric distension and fatty meal, which is important for elucidating the pathophysiology of gallstone dyspepsia. To our knowledge, these findings have not been previously reported. The greater motility might have been caused by hypersensitivity of the gallbladder wall to neural stimuli and hormone or by increased serum hormone levels in patients with gallstone dyspepsia. We do not know if gallbladder hypermotility precedes the development of gallstones, accompanies their development or is a relatively late sequel of their appearance. The finding that not all gallstone patients have gallbladder hypermotility also suggests there may be mechanisms for hypermotility other than the gallstones themselves. The primary mechanism is still debated and may indeed differ among individual patients. The gallbladder hypermotility phenomenon requires further studies.

In our study, more patients (34%) did not benefit from cholecystectomy than those in other studies (20-30%). We consider that the difference in the study populations may explain this phenomenon. Previous studies included more patients with acute cholecystitis or severe biliary pain who are better candidates for cholecystectomy[2-4]. The patients in our study were selected because of their relatively mild symptoms of postprandial distress without fever, chills, transient jaundice or severe biliary pain. This is one reason that might explain why others reported better cholecystectomy results.

Most studies of gallbladder motility in the presence of gallstones have shown impaired gallbladder contractility. Thus, our findings have also been noted by others[22-25]. Our study indicated that increased gallbladder contraction was the prerequisite for the development of dyspepsia symptoms. Previous studies included more asymptomatic patients with decreased gallbladder contractions in response to gastric distension and fatty meals.

Increased gallbladder contractility in patients with gallstone dyspepsia may be useful in identifying patients with atypical mild symptoms or possibly with early acalculous cholecystitis. The studies we conducted were noninvasive, inexpensive and within the capability of conducting ultrasonography in modern hospitals. The findings of promptly increased gallbladder contractility in response to intake of 500 mL of normal saline and fatty meal may lend support to including gallbladder contractility studies as part of the dyspepsia differential diagnosis.

Postprandial gallbladder volume changes and relative ejection fraction, determined sonographically, seem to be able to discriminate gallstone dyspepsia from functional dyspepsia.

In clinical practice, this type of diagnostic study may help to determine the appropriate treatment for gallstone patients with dyspepsia.

Abstract

AIM: To explore the relationship between angiogenesis and biological behaviors of primary gallbladder carcinoma (PGBC), the relationship between the expression of inducible nitric oxide synthase (iNOS) and biological behaviors of PGBC and its relationship with the expression of iNOS and angiogenesis of PGBC.

METHODS: The expression of iNOS and micro-vessel density (MVD) were assessed by immunohistochemical method and image analysis system in 40 specimens of PGBC and in 8 specimens of normal gallbladder. The immunostaining results and related clinicopathologic materials were analyzed by statistical methods.

RESULTS: MVD in PGBC was significantly higher than that in normal gallbladder tissue (46 ± 14 vs 14 ± 6, $P<0.05$), and was not related with age, gender, tumor size and histological type. MVD of poorly and undifferentiated tumor tissues was higher than that of moderately-differentiated and well-differentiated tumor tissues (52 ± 9 vs 43 ± 9 vs 33 ± 6, $P<0.01$). MVD of Nevin IV and V stages was higher than that of Nevin I, II and III stages (52 ± 8 vs 37 ± 13, $P<0.01$). MVD of cases with lymphatic or liver metastasis was significantly higher than that without liver metastasis (55 ± 6 vs 42 ± 10, $P<0.05$) or lymphatic metastasis (53 ± 8 vs 38 ± 8, $P<0.01$). The positive level index (PLI) of iNOS in PGBC was 0.435 ± 0.134, and was not related with age, gender, tumor size, histological type, differentiation and clinical stage of PGBC. The PLI of iNOS in cases with lymphatic metastasis was higher than that without lymphatic metastasis (0.573 ± 0.078 vs 0.367 ± 0.064, $P<0.01$). The PLI of iNOS in cases with liver metastasis was higher than that without liver metastasis (0.533 ± 0.067 vs 0.424 ± 0.084, $P<0.05$). There was a significant correlation between PLI of iNOS and MVD in PGBC ($P<0.05$).

CONCLUSION: Angiogenesis of PGBC is significantly related to the biological behaviors of PGBC. The expression of iNOS is related to the biological behaviors of PGBC. The detection of MVD and the expression of iNOS in PGBC can be used as parameters to determine the degree of malignancy and prognosis.

INTRODUCTION

PGBC is a kind of malignant neoplasm with poor prognosis, and accounts for 1.5% of digestive carcinomas[1]. It is difficult to be diagnosed in its early stage. Recent studies have shown its morbidity is gradually increasing[2]. Tumor growth is a multistage process and tumor angiogenesis is one of the key steps in tumor growth, infiltration and metastasis. In many tumors, the expression of iNOS is strong[3]. NO is synthesized from the amino acid L-arginine by iNOS and has many biological functions closely related with carcinogenesis and development of carcinomas, especially with tumor angiogenesis[4]. At present, the study about angiogenesis of PGBC is few and the relationship between angiogenesis and iNOS of PGBC has not been reported. In the present study the expressions of iNOS and MVD of 40 PGBCs and 8 normal gallbladders were investigated by immunohistochemistry and image analysis methods. The clinicopathologic indexes, the relationship between expression of iNOS and angiogenesis of PGBC and significance of the expression of iNOS were discussed.

MATERIALS AND METHODS

Pathological materials

Forty specimens of PGBC were collected between 1996 and 2002 in the Department of Hepatobiliary Surgery, First Hospital of Xi' an Jiaotong University. No treatment was given before operation. Specimens were fixed with formaldehyde and embedded with paraffin. The histological grading of tumor was done on hematoxylin-eosin stained sections. There were 11 males and 29 females, their mean age of patients was 59 years old. Among the 35 adenocarcinomas, 31 belonged to differentiated adenocarcinomas, 2 mucinous adenocarcinomas and 2 undifferentiated adenocarcinomas. There were 2 adenosquamous carcinomas, 1 adenoacanthoma, 1 sarcoma carcinoma and 1 neuroendocrine carcinoma. Eighteen tumours had a size $\geqslant$ 3 cm, 22 had a size<3 cm. Seven were There were well differentiated carcinomas, 14 moderately differentiated, 16 poorly differentiated and 3 undifferentiated. Twenty cases had metastases in lymph nodes, 11 in liver. Eight normal gallbladders were studied as control.

Immunohistochemistry

Tissue samples were fixed in 10g/L neutral-buffered formaldehyde, embedded in paraffin, sectioned (4 μm thick), and deparaffinized. Slides were immersed first in 3 mL/L H_2O_2 at room temperature for 10 min to get rid of the activity of endogenous peroxidase. Then slides were digested with 1 g/L trypsin for 10 min. The slides were washed with distilled water, soaked in PBS for 5 min, then put into microwave at 95 ℃ for 8 min to repair the antigen. Then slides were immersed in goat serum (1.5%) at room temperature for 40 min to block endogenous nonspecific binding sites. Immunostaining was performed with the primary rabbit polyclonal IgG specific for iNOS (dilution, 1:50; Santa Cruz Biotechnology, USA) at room temperature for 2 h. The primary rabbit polyclonal IgG specific for factor VIII-related antigen (dilution, 1:100; Sigma Biotechnology, USA) was used. Then a biotinylated secondary antirabbit antibody

(BOSHIDE Biotechnology, Wuhan, China) diluted 1:200 in PBS was applied on the sections for 20 min, followed by the streptavidin-biotin-peroxidase complex (dilution,1:200; BOSHIDE Biotechnology, Wuhan, China) for 20 min. The color was developed by diaminobenzidine (DAB). The sections were counter-stained with hematoxylin, dehydrated, made transparent, covered and observed. Primary antibody replaced by PBS was used as a negative control. For positive controls, hemangioma was stained for factor VIII-related antigen and gastric carcinoma for iNOS.

Determination of iNOS

Under light microscope the positive cells were stained as brownish yellow in cytoplasm. Determination of iNOS was performed by an image analysis system (IBAS System, Kontron Eledtronik, Germany). According to guide system set operation was made for determination of optical density. The average optical density (AOD) of 100-200 iNOS positive cells was randomly measured with ×20 objective, and the average percentage of positive cells (APCP) was obtained by measuring positive cells and total tumor cells in random 10 high power fields (HPFs) with ×40 objective.The positive level index (PLI) was calculated according to the following formula: PLI= APCP×AOD.

Quantificantion of angiogenesis

Determination of MVD was based upon the method reported by Marrogi *et al*[6]. An all-round observation was first made with ×10 objective, then five areas with the highest density of micro-vessels (hot spots) were selected, and the amount of micro-vessels was counted with ×20 objective (any endothelial cell or endothelial cluster close to tumor cells and connective tissue around tumor cells, which was stained brownish yellow were considered as a single, countable micro-vessel). MVD was counted from an average of five HPFs with ×20 objective (Figure 1).

Figure 1 Distribution of MVD in PGBC tissue, SABC ×200. A: high MVD, B: low MVD.

Statistical analysis

SPSS for Windows (10.0 edition) was used for statistical analysis. All data were expressed as mean±SD. Statistical

differences were evaluated using the unpaired *t* test, *F* test and *q* test. Analysis of linear correlation was used to discuss the relationship between expressions of iNOS and MVD. A *P* value less than 0.05 was considered statistically significant.

RESULTS

MVD and PGBC

Through the stains by polyclonal IgG specific for factor VIII-related antigen, micro-vessels could be identified. The distribution of micro-vessels in PGBC was not even, which was irregular in morphology and differed greatly in quantity (Figure 1). MVD was the highest at the margin of tumor tissues. MVD (46±14) in PGBC was significantly higher than that (14±6) in normal gallbladder tissue (*P*<0.05). MVD in PGBC was not related with age, gender, tumor size and histological type. MVD in poorly and undifferentiated tumor tissues was higher than that of moderately differentiated and well-differentiated tumor tissues (*P*<0.01). MVD of Nevin IV and V stages was higher than that of Nevin I, II and III stages (*P*<0.01). MVD of cases with lymphatic or liver metastasis was significantly higher than that without liver metastasis (*P*<0.05) or lymphatic metastasis (*P*<0.01, Table 1).

iNOS and PGBC

The expression of iNOS in normal gallbladder epithelial cells was negative and occasionally positive in stromal cells. In tissue of PGBC, iNOS was mainly expressed in cytoplasm and few in inflammatory cells around the tumor cells (Figure 2). The PLI of iNOS in 40 PGBCs was 0.435±0.134. It was not related with age, gender, tumor size, histological type, differentiation and clinical stage of PGBC. The PLI of iNOS in cases with lymphatic metastasis was higher than that without lymphatic metastasis (*P*<0.01). The PLI of iNOS in cases with liver metastasis was higher than that without liver metastasis (*P*<0.05, Table 1).

**Figure 2** Positive expression of iNOS in PGBC tissues SABC ×400. A: well-differentiated, B: poorly-differentiated.

iNOS and angiogenesis of PGBC

By serial analysis of sections, high MVD was observed in

areas of high iNOS expression. Linear correlation analysis showed that PLI of iNOS was positively correlated with MVD ($r=0.4021$, $P<0.05$). This demonstrated that expression of iNOS could influence MVD and blood supply of tumor.

Table 1 Relationship between MVD, PLI and clinicopathologic indexes

Group		*n*	MVD	PLI
Age <58yr		17	43±14	0.340±0.048
≥58yr		23	45±11	0.371±0.061
Male		11	46±11	0.376±0.056

DISCUSSION

The formation of new blood vessels known as angiogenesis induced by tumor cells is a critical determinant of tumor progression[5-10]. Unlike normal blood vessels, tumor blood vessels are not mature vessels which are chaotic, irregular and leaky. Studies showed that proliferation, infiltration and metastasis of solid tumor were closely related with tumor angiogenesis[11-16]. In our study we found that the distribution of micro-vessels in PGBC was not even, but irregular in morphology and its quantity differed greatly. MVD was the highest at the margin of tumor tissues. In tumor tissues MVD was higher than that in normal tissues. Our study showed that MVD in PGBC was significantly higher than that in normal gallbladder tissue. Research on mammary cancer showed that MVD was increased in patients with distant metastasis compared with those without distant metastasis[17]. The risk of metastasis would increase by 159% per increase of 10 micro-vessels[18]. This study found that MVD in cases with lymphatic or liver metastasis was significantly higher than that without liver or lymphatic metastasis, which was consistent with other researchers[19-22]. It is generally believed that invasion of tumor cells from tumor tissue with rich vasculature increases and the risk of lymphatic metastasis is increased by invasion of veno-lymphatic anastomosis and lymphatic vessels accompanying blood capillaries.

Calcium-independent iNOS was expressed in macrophages, neutrophils, hepatocytes, cardiac myocytes, chondrocytes, and many other cell types[23-26]. It was mainly induced by cytokines and could generate locally high concentrations of NO for a prolonged period of time and play a variety of regulatory functions *in vivo*[27,28]. In many studies, iNOS positivity was predominantly found in tumor cells[29,30], but in another study a relatively high iNOS immunoreactivity was noted in stromal cells[31]. Our study showed that in PGBC iNOS was mainly expressed in cytoplasm of tumor cells and in few inflammatory cells around the tumor cells. Vakkala *et al*[32] showed that iNOS positivity was observed in mammary cancer cells in 46.5% *in situ* carcinomas and 58.8% invasive carcinomas. Expression of iNOS was related with differentiation of carcinomas *in situ*. In this study PLI of iNOS was not related to age, gender, tumor size, histological type, differentiation and clinical stage of PGBC. The PLI of iNOS in cases with lymphatic metastasis was higher than that without lymphatic metastasis and the PLI of iNOS in cases with liver metastasis was higher than that without liver metastasis. The effects of NO could be tumor promoting or tumor suppressing. High concentrations of NO (umol/L) could be cytotoxic, whereas low concentration (nmol/g or pmol/g) might even protect some cell types from damage and apoptosis[33]. During the initiation of tumor growth, natural killer cells and macrophages could kill tumor cells by a NO-mediated mechanism[34]. However, NO might also suppress antitumor effect, promote tumor angiogenesis and blood flow in tumor neovasculature, and enhance tumor growth, invasion, and metastasis[35]. Jenkins *et al*[36] engineered gene of iNOS into adenocarcinoma cell line DLD-1 to get iNOS-19 subclone which generated NO continuously, and found that in nude mice tumors from iNOS-19 subclone cells grew faster than those derived from wild-type cells and were much markedly vascularized and had a stronger ability to invade. Our conclusion is that NO produced by iNOS in PGBC is in low concentration and can promote tumor angiogenesis, invasion and metastasis of PGBC.

Abstract

AIM: To observe the effects of low molecular weight heparin (LMWH) on platelet surface P-selectin expression and serum interleukin-8 production in rats with trinitrobenzene sulphonic acid (TNBS) induced colitis.

METHODS: Colitis was induced in female Sprauge-Dawley rats by colonic administration of 2, 4, 6-TNBS. LMWH, a dalteparin (150 U/kg, 300 U/kg) was subcutaneously administrated one hour before induction of colitis and went on once a day for 6 days. Then a half dose was given for the next 7 days. Control animals received the same volume of normal saline once a day for 14 days after treated by TNBS. Animals were sacrificed at 24 h, days 7 and 14 after induction of colitis. The colon was excised for the evaluation of macroscopic and histological findings and TNF-α immunohistochemical assay. Platelet surface P-selectin expression was determined by radioimmunoassay and serum IL-8 production was assayed by ELISA method.

RESULTS: LMWH treatment in a dose of 300 U/kg for 14 days significantly improved colonic inflammation by histological examination. Serum IL-8 production in the 300 U/kg treatment group was more significantly decreased at day 14 than that at 24 h ($P<0.05$). However, platelet surface P-selectin expression and TNF-α staining in colonic tissue were not significantly different among the three groups.

CONCLUSION: LMWH has an anti-inflammatory effect on TNBS induced colitis in rats. The effect is possibly related to inhibition of proinflammatory cytokine IL-8, but not involved platelet surface P-selectin expression.

INTRODUCTION

Inflammatory bowel disease (IBD) includes ulcerative colitis (UC) and Crohn's disease (CD), both of which are chronic non-specific intestinal inflammation with unknown etiology. Several studies have shown that IBD exists a hypercoagulant state in active period of the disease and may have microvascular thrombosis in the wall of intestine[1-8]. An abnormal platelet activity has been reported in patients with UC and CD, and plays an important role in inflammation aggravation[9-12]. P-selectin is a membrane glycoprotein, which is expressed on activated platelets and endothelial cells, promotes leukocyte adhesion and migration as well as inflammatory cytokine production. IL-8 is a key proinflammatory cytokine and its production is increased in activated platelets. An up-regulation of platelet IL-8 receptors in patients with IBD has been reported[11].

Heparin is a glycoaminoglycan formed by sulphatedoliposaccharides and varies in the length of polymeric units and therefore has different molecular weights. Low molecular weight heparin (LMWH) is made by partial hydrolysis or enzymatic degradation of unfractionated heparin. Heparin and LMWH prevent the process of blood coagulation and have a natural anti-thrombin effect. In recent years several studies have shown that heparin and LMWH have an obvious anti-inflammatory activity in addition to its traditional anticoagulant effects[9,13,14]. In animal model heparin disaccharides inhibited TNF-α production by macrophages and decreased immune inflammation[15]. Heparin accelerated the healing process of mucosa in colitis in several clinical studies and had anti-inflammatory effects[16-21]. Therefore, administration of heparin can afford both anti-inflammatory and anticoagulant effects. The mechanisms of anti-inflammation of heparin are unknown. The limited studies demonstrated that it was possibly associated with the increase of several growth factors and the decrease of nitric oxide synthesis (NOS) and myeloperoxidase[9,13,14,22,23]. The effects of heparin on platelet surface P-selectin and IL-8 have not been studied. The present study was designed to observe the effects of LMWH on platelet surface P-selectin expression, serum IL-8 production, and TNF-α expression in mucosa of rats with trinitrobenzene sulphonic acid (TNBS)-induced colitis, and to clarify the anti-inflammatory mechanisms of LMWH in the treatment of colitis.

MATERIALS AND METHODS

Animals

Female Sprauge-Dawley rats weighing 200-250 g were used in the study. The animals were fasted for 24 h before the experiment and allowed food and water *ad libitum* after induction of colitis. The study was approved by the Ethic Committee of Wuhan University Medical School.

Induction of TNBS-induced colitis

Colitis was induced by a method of hapten-induced colonic inflammation as previously described[24]. Rats were anaesthetized by intraperitoneal administration of 100g/L urethane. A small

volume of 2, 4, 6-TNBS (Sigma Company) was dissolved in 50% ethanol to a final concentration of 100 mg/mL, and 0.3 mL of TNBS solution was intracolonically administrated with a polypropylene catheter by inserting 8 cm via the anal canal. Rats in a group were given 150 U/kg LMWH (dalteparin made by Pharmacia & Upjohn Company) subcutaneously 1 h before induction of colitis, and went on once a day for 6 d. Then a half dose of LMWH was given for the next 7 d. Treatment of the LMWH 300 U/kg group was the same as the 150 U/kg group, but the dose of LMWH was as high as 300 U/kg. Control animals received the same volume of normal saline once a day instead of LMWH after treated by TNBS.

Animals in each group were sacrificed at 24 h, d 7 and 14 after induction of colitis. The colon was isolated and a segment of colon was excised for the evaluation of macroscopic and histological findings and also for TNF-α immunohistochemical assay. A blood sample was drawn from heart of the rats for determination of platelet surface P-selectin and serum IL-8 before the rats were sacrificed.

Macroscopic evaluation of colonic damage
Macroscopic evaluation of colonic damage was conducted by two authors (HH, LLG) and mucosal hyperemia, ulcers, inflammatory exudation and bleeding were recorded. The most damaged site of the colon was chosen as the part for histological studies. For control group the colon at 8 cm above anus was excised for histological studies.

Histological studies of colonic damage
For histological examination, formalin-fixed tissues were embedded in paraffin and 5 μm -thick sections were stained with hematoxylin and eosin, and evaluated under light microscope by a pathologist (GSG) blinded to the experimental protocol. Colonic damage was assessed by the grades described by Fedorak et al[25]. Mucosal ulceration: 0: no-ulceration; 1: focal ulceration; 2: multifocal-ulceration; 3: diffuse ulceration. Depth of injury was graded as follows: 0: no injury; 1: mucosal involvement only; 2: mucosal and submucosal involvement; 3: transmural involvement. The ulceration and depth of injury grades were scored and put together as a result ranging between the minimum of 0 and maximum of 6.

Determination of platelet surface P-selectin molecules
Platelet surface P-selectin molecules were detected by radioimmunoassay. The kit was purchased from the Institute of Thrombosis and Homeostasis of Suzhou University, China. Briefly, 2 mL of anti-coagulated blood was taken from the heart of rats and platelets were counted under microscope. The blood was fixed by 2g/L glutaraldehyde in PBS solution at room temperature for 30 min and stored at 4 ℃ for determination of platelet surface P-selectin. The fixed blood with 2.5×10^6 platelets was divided into 3 tubes and washed with 1 mL of 0.01mol/L PBS, pH 7.4, per tube and centrifuged at 2 500 rpm for 10 min. Supernatants were removed. 50 μL of SZ-51mab labeled with ^{125}I was added into the reaction tubes and mixed fully. 15 μL of SZ-51mab without ^{125}I was added into control tubes. Each tube was incubated at 37 ℃, washed 3 times with PBS, and centrifuged at 3 000 r/min for 10 min. Cpm of precipitations in each tube was measured by a γ reader.

Determination of serum IL-8 production
Serum IL-8 production was assayed by ELISA sandwich method. The IL-8 ELISA kit was purchased from the Institute of Immunology of the Fourth Military Medical University, China. Briefly, 96-well plates were precoated with monoclonal antibody specific to human IL-8. Serum samples, negative control and diluted IL-8 standard markers were added into the plates. The serum samples were detected according to the procedures described in the protocol. A_{410} value was read by the ELISA reader.

Determination of TNF-α in colonic mucosa
Expression of TNF-α in colonic mucosa was assessed by immunohistochemistry. The regents of TNF-α were purchased from Beijing Zhongshan Biotechnology, China. Positive expression of TNF-α was brown deposited granules in the plasma of neutrophils, monocytes and lymphocytes. The grades of expression of TNF-α in mucosa were classified as follows: 0: no staining; 1: a few maple granules, or a few fine brown granules, not exceeding the 1/4 total area of cytoplasm; 2: uniformity maple in the whole cytoplasm or wide brown granules in the cytoplasm, not exceeding the 1/2 area of cytoplasm; 3: the cytoplasm was full of brown granules with a lower density; 4: the total cytoplasm was full of crassitude dark brown granules, and covered whole nuclei of the cell. One hundred cells were counted under oil microscope, positive cells were recorded and positive cell rate was calculated. The scores of expression of TNF-α were calculated by sum of each grade multiplying its positive cell rate.

Statistical analysis
Data were expressed as mean±SD. Data in different groups were analyzed by ANOVA and post multiple tests (Tukey-Kramer or Student-Newman-Keuls). A P value less than 0.05 was considered statistically significant.

RESULTS

Macroscopic evaluation of TNBS-induced colitis
Control animals subjected to intracolonic administration of TNBS in 500ml/l ethanol showed colonic mucosal injury with ulceration. Signs of the mucosal damage were monitored for 14 d. As early as 24 h after TNBS treatment, colonic mucosa was shown to have hyperemia, congestion, erosion, hemorrhagic ulcerations in the injured site. The damage was still maintained at d 7 and appeared to be multiple ulcerations and partial epithelial necrosis. On d 14, the colonic ulceration still existed. In both doses of LMWH treated groups, mucosal hyperemia, congestion and ulcerations in the injured site were slighter than those in control group. However, mucosal hemorrhage in both LMWH treated groups was severer than that in control group at 24 h, but was resolved on d 7 and 14, respectively.

Histological examination of TNBS-induced colitis
In control group a large number of neutrophils, monocytes and eosinophils infiltrated in mucosa and submucosa at 24 h and the damage reached peak on d 7. As shown in Table 1, the histological grades according to Fedorak et al[25] were greatly higher on d 7 compared with those at 24 h ($P<0.01$). On d 14, the damage of colon was mild, but still had ulceration, chronic inflammatory cell infiltration, vesculitis and granulation tissue formation. In contrast, in both 150 U/kg and 300 U/kg LMWH treated groups colonic damage was mild. Table 1 shows that the histological injury grades in the 300 U/kg LMWH group were decreased at 24 h and on d 7 after treatment, and much obviously on day 14 compared with the control group ($P<0.01$).

Expression of TNF-α in colonic mucosa of TNBS-induced colitis
As shown in Table 2, the scores of expression of TNF-α in mucosa were greatly higher in the first 24 h and decreased on d 7 and 14 after induction of colitis, but there were no

significant differences among the three groups except a difference at 24 h between 300 U/kg LMWH treatment group and 150 U/kg LMWH treatment group.

Table 1 Effect of low molecular weight heparin (dalteparin) in Fedorak grades on mucosa of TNBS-induced colitis in rats

	n	24 h	Day 7	Day 14
Control group	5	1.33±0.54	4.33±0.81[b]	3.67±2.13
150 U/kg LMWH group	4	1.00±0.00	3.33±2.08	1.67±1.15

Platelet surface P-selectin expression and serum interleukin 8 production

Expression of platelet surface P-selectin was increased on d 7 and 14 in all three groups as shown in Table 3, but reached a significant level only in control group. There were no significant differences among these three groups at the three time points, 24 h, d 7 and 14. Production of serum interleukin 8 was higher at 24 h in the three groups, but significantly decreased on day 14 compared with that at 24 h in 300 U/kg LMWH treated group as shown in Table 4.

DISCUSSION

In this study we observed an anti-inflammatory effect of LMWH (dalteparin) in rats with TNBS-induced colitis. This effect was demonstrated by improvement of colonic inflammation with macroscopic and histological alterations in a dose of 300 U/kg of heparin treatment for 14 d. The result was similar to that of Fries *et al*[26], in which they showed that heparin could prevent TNBS-induced colitis, but steroids could not. Our data showed that serum IL-8 production in 300 U/kg LMWH treated group was significantly lower on d 14 than that at 24 h, but we did not find this variation in other groups. Expression of platelet surface P-selectin in control group was significantly increased consecutively at 24 h, d 7 and 14, but expression of platelet surface P-selectin did not increase in LMWH treatment group. We also did not find differences of expression of TNF-α in colonic mucosa between LMWH treatment group and control group. Our results suggested that LMWH (dalteparin) in a high dose had anti-inflammatory effects. The effects were possibly related to the decrease of proinflammatory cytokine IL-8, but not related to platelet surface P-selectin.

We observed dose and time- dependent effects of LMWH in rats with TNBS-induced colitis. Three hundreds U/kg LMWH treatment group showed more histological improvement of colitis, lower TNF-α expression in mucosa and serum IL-8 production than 150 U/kg LMWH treated group. With a continuing LMWH treatment these effects were gradually demonstrated on d 7 and 14. Our result was slightly different from that of Dotan *et al*[18]. They showed that a single dose of 80 μg/kg of LMWH (enoxaparin) was more optimal for amelioration of dinitrobenzene sulphonic acid- and iodoacetamide-induced colitis in rats than a dose of 200 μg/kg and 40 μg/kg of enoxaparin. The mechanism is not known, but may be related to optimal interactions between LMWH fragments and their receptors.

Chowers *et al*[27] found that disaccharides derived from heparin sulfate and heparin could suppress IL-8 and IL-1β production in intestinal epithelial cells *in vivo*. Our result was similar to that of the treatment of LMWH (dalteparin), serum IL-8 was much decreased. Salas *et al*[28] also showed that heparin pretreatment significantly attenuated leukocyte rolling, adhesion, and migration in *ex vivo* but did not affect the expression of cell adhesion molecules or vascular permeability elicited by TNF-α. The effects of heparin involved attenuation of a CD11b dependent adherent mechanism. Nelson *et al*[29] found that *in vitro* heparin tetrasaccharides reduced binding of neutrophils to COS cells expressing P-selectin but not to COS cells expressing E-selectin.

As for the side effects of haparin in the treatment of IBD, intestinal bleeding was mentioned in several studies[30]. Our study also showed more severe intestinal bleeding in LMWH treatment group than in control group at 24 h by macroscopic and histological observations. Thus, we should be cautious of using LMWH for clinical treatment of IBD.

In conclusion, our data indicate that LMWH has an anti-inflammatory effect in TNBS- induced colitis. The mechanism is possibly related to inhibition of proinflammatory cytokine, IL-8, but not to platelet surface P-selectin production.

Abstract

AIM: To test whether *in vitro* incubation of peripheral blood mononuclear cells (PBMC) with interferon (IFN) could efficiently decrease hepatitis C virus-RNA (HCV-RNA) amount and to analyze whether this effect was associated with clinical response to IFN.

METHODS: Twenty-seven patients with histologically proven chronic hepatitis C were given intravenous administration of 6 million units (MU) IFN-β daily for 6 weeks followed by three times weekly for 20 weeks. PBMC collected before IFN therapy were incubated with IFN-β and HCV-RNA in PMBC was semi-quantitatively determined.

RESULTS: Twenty-five patients completed IFN therapy. Eight patients (32%) had sustained loss of serum HCV-RNA with normal serum ALT levels after IFN therapy (complete responders). HCV-RNA in PBMC was detected in all patients, whereas it was not detected in PBMC from healthy subjects. *In vitro* administration of IFN-β decreased the amount of HCV-RNA in PMBC in 18 patients (72%). Eight of these patients obtained complete response. On the other hand, none of the patients whose HCV-RNA in PBMC did not decrease by IFN-β was complete responders. Multiple logistic regression analysis revealed that the decrease of HCV-RNA amount in PBMC by IFN-β was the only independent predictor for complete response (*P*<0.05).

CONCLUSION: The effect of *in vitro* IFN-β on HCV in PBMC reflects clinical response and would be taken into account as a predictive marker of IFN therapy for chronic hepatitis C.

INTRODUCTION

Interferon (IFN) is effective in the treatment of chronic hepatitis C. However, the efficacy of IFN is limited and approximately 20% of patients obtain sustained virological response[1,2]. Even the combination therapy with IFN and ribavirin induces it in 30% to 40% of patients[3-5]. Because IFN is expensive and also has potentially severe adverse effects, it is important to discriminate which patient is responsive to IFN before starting therapy. The low amount of serum hepatitis C virus (HCV)-RNA, viral genotypes other than 1b and the absence of cirrhosis are associated with favorable response[1]. However, accurate prediction is still difficult before IFN treatment and more sensitive markers related to good response are required.

HCV is a hepatotropic virus, but was reported to exist in peripheral blood mononuclear cells (PBMC)[6-8]. The existence of minus strand HCV-RNA[7,9] suggests the proliferation of HCV in PBMC. Both *in vivo* and *in vitro* administration of IFN induce antiviral enzymes such as 2',5'-oligoadenylate synthetase (2-5AS) in PBMC as well as in liver[10,11]. We hypothesized that *in vitro* administration of IFN might exert antiviral effect on HCV proliferating in PBMC. We tested whether *in vitro* incubation of PBMC with IFN could efficiently decrease HCV-RNA amount and also analyzed whether this effect was associated with clinical response to IFN.

MATERIALS AND METHODS

Patients and study design

Twenty-seven patients with chronic hepatitis C were enrolled into this study. Criteria for enrollment were elevation of serum ALT levels, positivity for anti-HCV antibody and serum HCV-RNA, presence of histologically proven chronic hepatitis, and absence of other chronic liver diseases such as autoimmune hepatitis, primary biliary cirrhosis, hemochromatosis, Wilson's disease. Liver histology was obtained from all patients before IFN treatment and evaluated for staging of fibrosis and grade of activity according to the METAVIR scoring system[12,13]. They were given intravenous administration of 6 million units (MU) IFN-β (Feron, Toray Pharmaceuticals, Tokyo, Japan) daily for 6 weeks followed by three times weekly for 20 weeks. Informed consent was obtained from all patients.

The effect of IFN was defined as complete response (CR): sustained loss of serum HCV-RNA and normal ALT levels, partial response (PR): disappearance of serum HCV-RNA at the end of treatment and reappearance after treatment, and no response (NR): positive serum HCV-RNA at the end of treatment.

Serum viral load was defined by multicyclic reverse transcription (RT)-polymerase chain reaction (PCR) method[14,15] and patients were categorized into 2 groups, namely high: $\geq 10^8$ copies/ml, and low: $<10^8$ copies/ml. HCV genotyping was performed with type-specific primers[16].

Effect of IFN-b on PBMC

Twenty ml of peripheral blood was drawn before IFN

treatment. PBMC were separated by gradient centrifugation and washed with phosphate-buffered saline (PBS) seven times. After this procedure the supernatants were negative for HCV-RNA even after two-step PCR as described below. PBMC were suspended in RPMI-1640 medium supplemented with fetal bovine serum (IWAKI, Tokyo, Japan) at a concentration of 2×10^6 cells/mL, plated on a 24-well plate (IWAKI), and cultured at 37 ℃ in a humidified atmosphere with 50mL/L CO_2 in the absence or presence of IFN-β at a concentration of 100 IU/L. After incubation for 72 h PBMC were washed five times with PBS followed by RNA extraction with guanidium thiocyanate. Total RNA was reversely transcribed into cDNA in a 40 μL reaction mixture containing 100 pmoles antisense primer (5'-AACACTACTCGGCTAGCAGT-3') and 200 units of SuperScript II reverse transcriptase (Invitrogen Japan, Tokyo, Japan). The amplification of cDNA was performed for 35 cycles in four temperature steps (at 94 ℃ for 2 min, 37 ℃ for 2 min, 55 ℃ for 2 min and 72 ℃ for 3 min) in a 100 μL reaction mixture containing the template, 1 unit of Taq polymerase (Perkin Elmer, Norwalk, CT), 20 pmol of each outer primer, 2.5 nmol of each deoxyribonucleotide triphosphates, 10 mmol/L Tris HCl, pH 8.3, 50 mmol/L KCl and 0.15 mmol/L $MgCl_2$. After the first PCR, 10 μL of the PCR product was subjected to a second PCR amplification using the inner primer pair under the same conditions as described for the first PCR. Primers were designed from the sequence of 5' non-coding region, an outer primer pair of 242-base span: sense (5'-ACTCCACCATAGATCATCCC-3') and antisense (5'-AACACTACTCGGCTAGCAGT-3') and an inner primer pair of 145-base span: sense (5'-TTCACGCAG-AAAAGCGTCTAG-3') and antisense (5'-GTTGATCCAA-GAAAGGACCC-3'). PCR products were analyzed by gel-electrophoresis. The amount of HCV-RNA in PBMC was determined semi-quantitatively as 2+: positive after first PCR; 1+: negative after first PCR and positive after second PCR; and −: negative after first and second PCR. PBMC from 5 healthy subjects were also examined for the presence of HCV-RNA.

Statistical analysis

Categorical variables were analyzed by the chi-square test. Continuous numeric variables were examined by the Student's t-test (two-tail). Multiple logistic regression analysis was preformed by SPSS for Macintosh to identify independent predictors for CR.

RESULTS

Response to IFN treatment (Table 1)

Twenty-five of 27 patients completed IFN treatment. One discontinued IFN because of retinal hemorrhage, the other could not visit our hospital due to moving. All patients had fever, general fatigue or myalgia. However, no severe adverse effects were seen. Eight patients (32%) maintained normal serum ALT levels with negative serum HCV-RNA after IFN treatment, resulting in CR. Ten patients (40%) were negative for HCV-RNA at the end of treatment but relapsed after the discontinuation of IFN (PR). The other 7 patients (28%) were still positive for HCV-RNA at the end of IFN treatment (NR). The distribution of gender, age and serum ALT levels was not significantly different among three groups. Neither grade of activity nor staging of fibrosis in liver histology was different. Low serum viral load and genotypes other than Ib were associated with favorable response (P<0.05).

HCV-RNA in PBMC (Table 2)

We analyzed the presence of HCV-RNA in PBMC by two-step RT-PCR. All patients were positive for HCV-RNA in PBMC, whereas none of the healthy subjects was positive.

Three patients (12%) revealed 1+; 2 with low serum viral load and 1 with high viral load. The other 22 patients (88%) resulted in 2+. The amount of HCV-RNA in PBMC before the addition of IFN-β was not related to clinical response to IFN.

Table 1 Demographic characteristics and clinical response

Variable	NR[a] (n=7)	PR (n=10)	CR (n=8)	P value
Sex (F:M)	4:3	8:2	6:2	NS

Others	1	3	6	

[a]Complete response (CR): sustained loss of serum HCV-RNA and normal ALT levels, partial response (PR): disappearance of serum HCV-RNA at the end of treatment and reappearance after treatment, and no response (NR): positive serum HCV-RNA at the end of treatment. [b]high:≥10^8 copies/mL, low: <10^8copies/mL.

Table 2 Viral load in PBMC and clinical response

Variable	NR[a] (n=7)	PR (n=10)	CR (n=8)	P value
Viral load[b] (pretreatment)				
−	0	0	0	
1+	0	2	1	NS
2+	7	8	7	
Decrease of HCV-RNA by IFN-β[c]				
Yes	1	9	8	<0.05
No	6	1	0	

[a]Complete response (CR): sustained loss of serum HCV-RNA and normal ALT levels, partial response (PR): disappearance of serum HCV-RNA at the end of treatment and reappearance after treatment, and no response (NR): positive serum HCV-RNA at the end of treatment. [b]The amount of HCV-RNA in PBMC was determined semi-quantitatively as follows; 2+: positive after first PCR, 1+: negative after first PCR and positive after second PCR, and −: negative after first and second PCR. [c]HCV-RNA amount in PBMC was semi-quantitatively determined before and after incubation with IFN-β (100 IU/L).

We studied the effect of in vitro administration of IFN-β on HCV in PBMC. We used 100 IU/L as a concentration of IFN-β because preliminary experiments revealed that 10 IU/L of IFN-β was insufficient to decrease HCV-RNA in PBMC and that 1 000 IU/L of IFN-β did not have more effects than 100 IU/L of IFN-β (data not shown). After incubation with IFN-β the HCV-RNA amount in PBMC decreased in 18 patients (72%), 7 patients: 2+ to −; 8 patients: 2+ to 1+; and 3 patients: 1+ to −. Whereas no decrease was observed in the other 7 patients (28%). Incubation without IFN-β did not lead

to decrease in the amount of HCV-RNA (data not shown), suggesting that this decrease was attributable to the antiviral effect of IFN-β.

We analyzed the relationship between the effect of IFN-β on HCV in PBMC and clinical response. Patients with HCV-RNA decrease were significantly associated with better clinical response, 8 (44%) and 9 patients (50%) obtained CR and PR, respectively. On the other hand, 6 of 7 patients (86%) whose HCV-RNA amount did not decrease by IFN resulted in NR. Multiple logistic regression analysis revealed that the decrease in HCV-RNA amount in PBMC was the only independent predictor for CR ($P<0.05$).

DISCUSSION

In our study 8 patients (32%) obtained CR. IFN-β therapy was as effective as IFN-α in the treatment of chronic hepatitis C as already reported[17-19]. In one patient (4%) IFN treatment was discontinued due to retinal hemorrhage, which was the only major adverse effect observed in this study. Retinopathy was one of the common adverse effects of IFN[20,21]. Low serum viral load and viral genotypes other than Ib were associated with good clinical response in consistent with other studies using IFN-α[22-25].

We could detect HCV-RNA in PBMC before IFN therapy in all cases. HCV-RNA was not found in PBMC from healthy subjects, suggesting that the technique we used was specific for HCV. Several studies demonstrated the presence of HCV-RNA in PBMC[26-30], although the positive rate was variable from 25% to 100%. The *in vitro* administration of IFN-β decreased HCV-RNA in PBMC in 72% patients. Because incubation with medium alone did not affect HCV-RNA amount, this decrease would be attributable to IFN's antiviral effect. In fact Pawlotsky *et al* reported that 2-5AS activity in PBMC from patients with chronic hepatitis C was augmented by incubation with IFN[10]. Furthermore a preliminary experiment showed that *in vitro* addition of IFN at a concentration of 1 000 IU/mL reduced the HCV-RNA amount in PBMC[30]. In our study 7 patients (28%) maintained the same amount of HCV-RNA in PBMC even after incubation with IFN. It should be noted that none of these patients was complete responders. The reason why IFN could not decrease HCV-RNA in these patients is unclear. One possibility is that IFN could not induce antiviral enzymes such as 2-5AS. In this case the breakdown of IFN-induced antiviral system might be responsible. A more likely explanation is that HCV strains in these patients were resistant to antiviral enzymes. Some strains such as those with mutations in NS5A region[31] are refractory to IFN.

Clinical outcome was significantly different between those with decreased HCV-RNA amount in PBMC and those without. Multivariate analysis demonstrated the decrease of HCV-RNA amount in PBMC by IFN as the only independent predictive factor for CR. These data suggest that the effect of *in vitro* IFN-β on HCV-RNA in PBMC reflects clinical response and would be taken into account as a predictive marker of IFN therapy for chronic hepatitis C.

Abstract

AIM: The prognosis of early gastric carcinoma (EGC) is generally excellent after surgery. The presence or absence of lymph node metastasis in EGC is an important prognostic factor. The survival and recurrence rates of node-negative EGC are much better than those of node-positive EGC. This study examined the factors related to lymph node metastasis in EGC to determine the appropriate treatment for EGC.

METHODS: We investigated 748 patients with EGC who underwent surgery between January 1985 and December 1999 at the Division of Gastroenterologic Surgery, Department of Surgery, Chonnam National University Hospital. Several clinicopathologic factors were investigated to analyze their relationship to lymph node metastasis: age, sex, tumor location, tumor size, gross type, histologic type, depth of invasion, extent of lymph node dissection, type of operation, and DNA ploidy.

RESULTS: Lymph node metastases were found in 75 patients (10.0%). Univariate analysis showed that male sex, tumor size larger than 2.0 cm, submucosal invasion of tumor, histologic differentiation, and DNA ploidy pattern were risk factors for regional lymph node metastasis in EGC patients. However, a multivariate analysis showed that three risk factors were associated with lymph node metastasis: large tumor size, undifferentiated histologic type and submucosal invasion. No statistical relationship was found for age, sex, tumor location, gross type, or DNA ploidy in multivariate analysis. The 5-year survival rate was 94.2% for those without lymph node metastasis and 87.3% for those with lymph node metastasis, and the difference was significant (*P*<0.05).

CONCLUSION: In patients with EGC, the survival rate of patients with positive lymph nodes is significantly worse than that of patients with no lymph node metastasis. Therefore, a standard D2 lymphadenectomy should be performed in patients at high risk of lymph node metastasis: large tumor size, undifferentiated histologic type and submucosal invasion.

INTRODUCTION

Early gastric carcinoma (EGC) is defined as a lesion confined to the mucosa or submucosa of the stomach with or without lymph node metastasis[1]. The incidence of lymph node metastasis differs in mucosal and submucosal gastric carcinomas. When invasion extends to the submucosal layer, the incidence of lymph node metastasis increases[2] and submucosal gastric carcinoma is reported to have a poorer prognosis than mucosal gastric carcinoma[3].

We analyzed data from 673 patients with node-negative EGC, and 75 patients with node-positive EGC who had been surgically treated, to evaluate the clinicopathologic factors related to lymph node metastasis in EGC and to determine the appropriate treatment criteria for patients with EGC.

MATERIALS AND METHODS

Between 1985 and 1999, 748 Korean patients with EGC underwent surgery at the Division of Gastroenterologic Surgery, Department of Surgery, Chonnam National University Hospital. Of these, 75 patients (10.0%) were found to have lymph node metastasis.

Medical records were reviewed, and data were abstracted for the following factors: clinical findings, tumor size, tumor location, gross appearance, histologic grade, lymph node involvement, operation type, DNA ploidy pattern, and 5-year survival rate.

The clinical features of the 673 patients with node-negative EGC, and the 75 patients with node-positive EGC were compared. Curative resections were defined as histologic or relative curative resections according to the criteria of the Japanese Research Society for Gastric Cancer[4]. The data were analyzed statistically using a chi-square test and an unpaired Student's *t*-test. Overall survival rates were calculated using the Kaplan-Meier method. Multivariate analysis was performed using the Cox proportional hazards model with the program SPSS 11.0 to test the variables associated with lymph node metastasis in EGC. A *P* value <0.05 was considered statistically significant.

RESULTS

Of the 2 767 patients with gastric carcinoma who underwent surgery in our hospital over the 15-year period, 748 patients (27.0%) were diagnosed as EGC. The incidence of node-positive EGC was 10.0% (75/748) in this study group.

Table 1 describes the clinicopathologic findings in the 673 patients with node-negative EGC, and the 75 patients with node-positive EGC. There was no statistically significant difference between the ages of patients with and without lymph node metastasis. Of the 75 patients with lymph node metastasis, 41 (54.7%) were males and 34 (45.3%) were females. There were 453 males (67.3%) and 220 females (32.7%) in the group of 673 patients with node-negative EGC. There were more males than females in each group and the gender ratio was statistically significant (*P*<0.05). The mean tumor size of patients with node-positive EGC (3.1 cm) was larger than that of patients with node-negative EGC (2.2 cm), and the difference was statistically significant (*P*<0.01). Lymph node metastasis was

present in only 10 patients (13.3%) with a tumor <2.0 cm in size. Of these 75 patients with node-positive EGC, 65 patients (86.7%) were found to have a tumor ≥2.0 cm in size ($P<0.01$). Most gastric carcinomas were located in the lower portion of the stomach, in both node-negative (445 cases, 66.1%) and node-positive EGC patients (55 cases, 73.3%), but the differences in location were not significant. There was no correlation between lymph node metastasis and macroscopic appearance of the tumor. Based on the degree of anaplasia, 10 (13.3%) patients with node-positive EGC had well-differentiated, 14 (18.7%) had moderately differentiated, 45 (60.0%) had poorly differentiated, and 3 (4.0%) had mucinous adenocarcinomas ($P<0.01$). The submucosal invasion was found more frequently in patients with node-positive EGC (81.3%) than in those with node-negative EGC (46.1%, $P<0.01$). Distant metastasis was found in one patient with node-negative EGC. There was no significant difference between node-negative and node-positive EGC patients in the operative type. The curative resection rate for patients with node-negative EGC was similar to that for patients with node-positive EGC (99.7% *vs* 97.3%).

Univariate analysis showed that male sex, tumor size, depth of invasion, undifferentiated type, and aneuploid pattern were significant factors associated with lymph node metastasis in EGC (Tables 1 and 2).

CI, confidence interval.

All of the factors listed in Tables 1 and 2 were examined using a logistic regression analysis. The independent risk factors for lymph node metastasis were larger tumor size, undifferentiated type, and submucosal invasion (Table 3).

The postoperative survival rate of the patients without lymph node metastasis was compared with that obtained from those with lymph node metastasis. The 5-year survival rates were 94.2% for those without lymph node metastasis and 87.3% for those with lymph node metastasis, and the difference was significant ($P<0.05$, Figure 1).

Figure 1 Survival curves according to lymph node metastasis. The early gastric carcinoma patients without lymph node metastasis showed a better survival rate than early gastric carcinoma patients with lymph node metastasis (94.2% *vs* 87.3%, $P<0.05$).

DISCUSSION

Early gastric carcinoma (EGC) has been defined as gastric carcinoma in which invasion is confined to the mucosa or submucosa, regardless of lymph node metastasis[1]. The incidence of EGC has increased due to the advances in technical developments regarding both radiological modalities and endoscopy[5]. In our department, 27.0% of the patients had EGC, a rate similar to the 20-40% range previously reported[6]. The prognosis of EGC after curative resection was favorable,

with a 5-year survival rate exceeding 90%[6-8]. Moreover, the survival and recurrence rates of node-negative EGC were much better than those of node-positive EGC[7,8].

The reported incidence of lymph node metastasis in EGC was 2-4% in mucosal carcinoma[9-11], but increased to 15-25% in submucosal carcinoma[12]. Here, we found a 3.7% incidence of lymph node metastasis in mucosal carcinoma and a 16.4% incidence in submucosal carcinoma. The incidence of lymph node metastasis was similar to those in mucosal carcinoma reported by Yamao *et al*[9] and Tsujitani *et al*[10], and lower in submucosal carcinoma reported by other investigators[13,14]. Some investigators have reported that submucosal invasion is one of the predictive risk factors for lymph node metastasis in EGC patients[8,15,16]. Shimada *et al* reported that the number of metastatic lymph nodes occurring in patients with gastric carcinoma was correlated with the survival rate[6]. EGC patients with lymph node metastasis had a lower survival rate than patients without lymph node metastasis. Of note, they suggested that the involvement of three or more lymph nodes could predict a poor prognosis in submucosal gastric carcinoma. Seto *et al*[17] reported a 5-year survival of 74% in patients with more than 4 positive lymph nodes. Folli *et al*[11] also reported a lower 5-year survival, especially for patients who presented more than 3 metastatic lymph nodes.

The presence of lymph node metastasis in EGC worsened the prognosis, as reported by some investigators[8,13] and as observed in this study (87.3% *vs* 94.2%). Nio *et al*[18] reported that the 5-year survival of EGC was 93% for N1 patients and 68.4% for N2 patients. Miwa *et al*[15] observed similar results. When EGC was subdivided into mucosal and submucosal carcinomas, the survival rate for mucosal carcinoma was significantly better than that for submucosal carcinoma[19] because the former had a lower incidence of lymph node metastasis. Nevertheless, submucosal invasion could not always predict a poor prognosis, the survival rates in patients with submucosal carcinoma were the same as those in patients with mucosal carcinoma[20]. In our study, the incidence of lymph node metastasis from submucosal carcinoma (16.4%) was significantly higher than that from mucosal carcinoma (3.7%). However, the 5-year survival rate for patients with submucosal carcinoma (88.6%) did not differ from that for patients with mucosal carcinoma (95.2%), because the curative resection rate was high for both submucosal (97.3%) and mucosal (99.7%) carcinomas. We performed gastrectomy with D2 lymphadenectomy for most patients with submucosal gastric carcinoma. Furthermore, some investigators[12,21] have recommended that a standard D2 lymphadenectomy is essential, even in cases of mucosal carcinoma.

Lymphadenectomy, a prognostic factor that can be influenced by the surgeon, improves the survival rate in gastric carcinoma, although there has been no extensive prospective randomized trial. Viste *et al*[22] reported that the survival of patients who underwent extensive lymph node dissection was higher than that of patients without dissection. Furthermore, lymph node recurrence has been attributed to inadequate lymph node dissection. We found that in patients with submucosal gastric carcinoma, the survival rate with positive lymph nodes was significantly poorer than that with no lymph node metastasis (87.3% *vs* 94.2%, *P*<0.05). Therefore, we recommend gastrectomy with D2 lymphadenectomy as the appropriate operative procedure for patients with submucosal carcinoma of the stomach.

There have been several attempts to identify risk factors predicting lymph node metastasis. Maehara *et al*[6] found that the risk factors for lymph node metastasis in EGC patients were large tumor, lymphatic involvement, and submucosal invasion. Yamao *et al*[9] also reported that lymphatic invasion, histologic type, and large tumor size were independent risk

factors for lymph node metastasis in patients with intramucosal EGC. Abe *et al*[23] reported that submucosal invasion, female sex, large tumor size, and lymphatic vessel involvement were significantly and independently related to the presence of lymph node metastasis in depressed EGC. Baba *et al*[24] reported that there was no metastasis in lesions less than 1 cm in diameter, but the incidence of positive nodes increased with the size of the primary lesion. Wu *et al*[25] reported that poor differentiation, submucosal invasion and large tumor size were independent risk factors for lymph node metastasis in early gastric cancer. Macroscopic classification was not correlated with lymph node metastasis. Sasaki *et al*[26] reported that DNA aneuploidy was a useful indicator of lymph node metastasis in EGC patients. We studied the DNA ploidy pattern in 238 patients with EGC and found that there was a correlation between lymph node metastasis and DNA ploidy pattern in univariate analysis. But we found there was no correlation between lymph node metastasis and DNA ploidy pattern in multivariate analysis (Table 3). In our study, the univariate analysis showed that lymph node metastasis in EGC patients was associated with male sex, large tumor size, submucosal invasion, and undifferentiated histologic grade, while the multivariate analysis showed that metastasis was associated with large tumor size, undifferentiated type and submucosal invasion (Table 3).

In conclusion, this study suggests that tumor size, depth of tumor invasion and undifferentiated histologic grade are risk factors for lymph node metastasis in EGC. Therefore, standard D2 lymphadenectomy should be performed in patients with these high-risk factors.

Abstract

AIM: Many defense factors of the mother's colostrum or milk protect infants from intestinal, respiratory and systemic infections. In the present study, we investigated the effect of colostrum and mature human milk on *E. histolytica* parasites *in vitro*.

METHODS: Samples of human milk were collected from 5 healthy lactating mothers. The medium with human milk at concentrations of 2%, 5% and 10% was obtained.

RESULTS: The lethal effect of *E. histolytica* on the medium supplemented with different concentrations of both colostrum and mature human milk was significant during the first 30 min. We also detected that the results of colostrum and mature human milk were similar. No statistically significant differences were found between same concentrations of colostrum and mature human milk at the same times.
CONCLUSION: Colostrum and mature human milk have significant lethal effect on *E. histolytica* and protect against its infection in breast fed children.

INTRODUCTION

Entamoeba histolytica has a worldwide distribution with a high prevalence in areas with poor hygiene, overcrowding, and low socioeconomic conditions. When ingested, cyst passes through the stomach and excyst in the distal part of the small intestine and colon. *E. histolytica* generally lives in the lumen of the large intestine of man. The emerging trophozoites live in the lumen of the bowel close to the mucosa, where they feed by phagocytosis on particulate matter and bacteria and by pinocytosis on liquid nutrients. As such, they may invade the gut wall and produce ulceration and subsequent dysentery. The parasite may be transported by the blood to extraintestinal locations, such as the liver, lungs, and brain[1-3].

The role of breast milk ingestion in passive and active protection of infants is very important. Some reports showed that the incidence of intestinal and systemic *E. histolytica* infections was decreased in human breast milk fed infants.

This protective effect has been attributed to the anti-infective and anti-inflammatory properties of human breast milk[4,5].

The aim of the present study was to investigate the effects of colostrum and mature human milk on *E. histolytica*. Human colostrum or mature milk, if effective in producing lethal effect on *E. histolytica,* could be useful in preventing infections caused by infected water and food in breast-fed children.

MATERIALS AND METHODS

E. histolytica fresh clinical isolate was obtained from a patient with acute amebiasis. The isolate was cultivated in Robinson medium[6].

Fresh human milk was collected from 5 healthy lactating mothers with no clinical evidence of infection or inflammation, who voluntarily donated up to 10 mL of milk and colostrum samples, with their informed consent, by breast pump (Ameda Egnell SMB Pump, Switzerland), in Ege University Hospital, Izmir, Turkey. None of these mothers received hormones or antibiotics during the postpartum period. Colostrum and mature human milk were obtained during the first 3 d of lactation and the 3rd wk of lactation, respectively. All samples were collected from mothers between 9 and 12 a.m., just before they began to nurse their babies. The colostrum and mature human milk samples were rapidly centrifuged for 15 min at 1 000 *g*. The fresh clear middle layer was collected and immediately frozen (-70 ℃) until the study[7].

Culture methods and evaluation of amoeba-cidal activity

The trophozoites were adapted by three successive subcultures at 36±0.5 ℃. At the end of the period amoebae reached logarithmic growth phase. Trophozoites were chilled for 10 min in an ice water bath, then vigorously shaken to detach amoebae adherent to the walls of the tube. The culture tubes were centrifuged for 2 min (500 r/min) and supernatant was discarded. Once their content was homogenized by repeated inversion. They were counted with a haemocytometer and then 20×10^4 amoebae/mL were transferred to fresh medium. Five tubes including 5 mL medium were prepared for each group. Then, colostrum and mature human milk were added in medium at different concentrations (2%, 5% and 10%). Tubes were incubated at 36±0.5 ℃ for 30, 60, 120, 180 and 240 min respectively. At the end of incubation, only motile parasites were counted with a haemocytometer[8]. All experiments were done in triplicate and repeated at least twice.

Statistical analysis

All values were given as mean±SD. To determine the statistical significance of the difference between study groups, we used nonparametric tests, Kruskal-Wallis analysis of variance and Mann-Whitney test. *P* value less than 0.05 was considered significant.

RESULTS

In the study, we analyzed the lethal effect of colostrum and mature human milk at three different concentrations on *E. histolytica*. The number of living parasite was recorded at the different incubation periods. The results of this experiment showed that the best lethal effect (50% killing) was obtained from all samples

during the first 30 min exposure. We have also observed that there was no living parasite at the end of 12 h incubation.

A significant lethal effect of different concentrations of colostrum on *E. histolytica* was observed during 30 min and 180 min exposure (*P*<0.001) (Figure 1). However, no statistically significant differences were shown between them (*P*>0.05).

When the lethal effect of mature human milk at different concentrations on *E. histolytica* was compared with each other, the difference was statistically significant during 30 min and 180 min exposure (*P*<0.001) (Figure 2). There was no statistically significant difference between 30 and 180 min exposure (*P*>0.005).

The results of colostrum and mature human milk were similar. Colostrum did not prove to be very superior to mature human milk. No statistically significant differences were found between same concentrations of colostrum and mature human milk at 30, 60, 120, 180, and 240 min exposure.

Figure 1 Lethal effect of colostrum at various concentrations on *E. histolytica*.

Figure 2 Lethal effect of mature human milk at various concentrations on *E. histolytica*.

DISCUSSION

Colostrum and mature human milk may play a protective role in breast-fed children exposed to some parasites (such as *G. intestinalis*). Both contain considerable amounts of immunglobulins, mainly the secretory immunglobulin A (s IgA) type that may play a role in such protection. It has been shown that such immunglobulins have antibody specificities, which reflect antigenic stimuli in the intestinal tract[9,10].

The demonstration of antibodies in breast milk may have epidemiological significance in population studies. Antibodies of the IgA class were found in serum and colostrum of parturient women in an endemic area of amebiasis[11]. Grundy *et al*[12] demonstrated sIgA antibodies to *E. histolytica* in milk (31%) and serum (14%) of mothers living in Kenya. They suggested that serum antibodies indicated past or present invasive amoebasis, milk antibodies were more likely to present intestinal infection in endemic areas. Anti-Eh sIgA antibody titers were significantly increased in colostrum samples of mothers of newborn children with diarrhea[13]. The infants,

mostly uninfected, were found to have *E. histolytica* cysts in small numbers (2/1 200 samples), despite the high prevalence of *E. histolytica* in their mothers[14].

Human milk cells (macrophages, lymphocytes, neutrophils) and antibodies could protect intestinal mucosa, remain active in the neonatal intestine and possibly migrate to other tissues[5]. Colostral macrophages might be cytotoxic to trophozoites of *E. histolytica.* This has been shown by direct microscopy[7]. It was proposed that colostral macrophages might interrupt colonization and subsequent invasion in infants who were breast-fed. Although there are many epidemiological studies in endemic areas, studies about colostrum and mature human milk *in vitro* are limited. Gillin *et al* reported that 90% of *E. histolytica* were killed in approximately 3 h with 1% milk. But we could not find any publications containing colostrum and mature human milk together *in vitro*. We established that *E. histolytica* was killed by exposure to colostrum and mature human milk *in vitro*. IgA and lactoferrin amounts in colostrum were richer than mature human milk. However, we obtained similar results from both of them. Fifty percent of *E. histolytica* were killed by all dilutions of both secretions during a 30 min exposure. Thus, the lethal effect did not depend on the amounts of various protectable milk components. Similarly, some studies showed that the lethal effect of sIgA on some parasites did not depend on the amount of sIgA.

In this study, we showed that colostrum and mature human milk had direct lethal effect on *E. histolytica in vitro*. Therefore, when trophozoites that emerge from cysts in the small intestine are exposed to colostrum and mature human milk, they may be killed. Thus, breast fed children have a lower rate of amebiasis than nonbreast fed children.

Abstract

AIM: To study the diagnostic significance of K-ras gene mutations in fecal samples from elderly patients with large intestinal cancer.

METHODS: DNA was extracted in the fecal and tissue samples from 23 large intestinal cancer patients, 20 colonic adenomatoid polypus patients and 20 healthy subjects. The K-ras gene mutations at the first and second bases of codon 12 were detected by the allele specific mismatch method.

RESULTS: The K-ras gene mutation was 56.52%(13/23) in the large intestinal cancer patients, which was notably higher than that in the normal subjects whose K-ras gene mutation was 5%(1/20) (χ^2=12.93, P<0.001). There was no significant difference in comparison with that of colonic adenomatoid polypus patients whose K-ras gene mutation was 30%(6/12) (χ^2=3.05, P>0.05). The K-ras gene mutation at the second base of codon 12 was 92.13%(12/13) in the large intestinal cancer patients. There was no significant difference between the detection rate of K-ras gene mutation in the fecal and tissue samples (χ^2=9.35, P<0.01).

CONCLUSION: Our results indicate that detection of the K-ras gene mutations in fecal samples provides a non-invasive diagnostic method for the elderly large intestinal cancer patients. Its significance in the early diagnosis of large intestinal cancer awaits further studies.

INTRODUCTION

Large intestinal cancer is one of the common malignant tumors in China. Its incidence has been increasing in the elderly, and its death rate is approximately 60% in large intestinal cancer patients over 60 years old. In China, large intestinal cancer is often resulted from the malignancy of colonic adenomas, because the incidence of large intestinal polypus is high in the elderly. It was reported that the detectable rate of large intestinal polypus and adenomatoid polypus was as high as 62.1% and 67.9%, respectively[1]. Therefore, early detection of cancerous adenomas is of great significance in decreasing the incidence and death rate of large intestinal cancer. At present, colonoscopy is the most ideal diagnostic method for large intestinal cancer[2,3], the reported detectable rate of early large intestinal cancer was 36.5% in the elderly[1]. Since colonoscopy is an invasive method and the examined subjects would have some suffering, it has therefore become a topic of general interest to find a non-invasive diagnostic method for large intestinal cancer patients[4-10]. The K-ras gene mutations in fecal samples from the elderly were detected by the allele specific mismatch method, and its diagnostic significance in the large intestinal cancer patients was discussed.

MATERIALS AND METHODS

Reagents

Taq DNA polymerase, dNTPS, DNA fragments, agarose, DNA extraction kits were the products of Promega (Madison,USA). Proteinase K was the product of Merck.

Specimens

The patients enrolled in this study were 23 cases of large intestinal cancer (19 males, 4 females, averaging 68.8 years), 20 cases of colonic adenomatoid polypus and 20 healthy subjects. Their diagnoses were confirmed by endoscopy and biopsy. Of the 23 cases of large intestinal cancer, 5 had well differentiated adenocarcinomas, 10 had moderately differentiated adenocarcinomas, 6 had poorly differentiated adenocarcinomas, and 2 had mucinous adenocarcinomas. The fecal samples were collected from the above patients before undergoing surgery and stored at -30 ℃.

DNA extraction

DNA was extracted from the fecal samples using the DNA extraction kits. The fecal samples were processed according to the following procedures:100-200 g of the fecal samples was diluted in 500 μL of phosphate buffered saline (PBS), pH7.5, and homogenized for 2 min at 1 000 r/min. Then, 500 μL supernatant after the addition of 50 μL hydrolytic buffer was homogenized for 5 min, and centrifuged at 6 000 r/min for 2 min. The precipitate was placed into 500 μL cleaning solution and centrifuged at 6 000 r/min for 2 min. After washed twice and addition of 50 μL lysate and covered by paraffin oil, the precipitate was boiled for 5 min, centrifuged at 13 000 g for 10 min and stored at -30 ℃ before it was used. The DNA in the 16 cancer tissue samples was extracted by proteinase K (10 g/L, thermostatic water bath at 37 ℃ for 24 h), and purified by phenol-chloro-isopentanol extraction, and dissolved in TE buffer after ethanol precipitation for use.

PCR reaction

The oligonucleotide primer was synthesized by the Oligo 1000DNA synthesizer (Beckman). The DNA amplification PCR reaction was carried out in a total volume of 50 μL buffer containing 5 μL of diluted DNA templates, 10 mmol/L Tris-HCl (pH8.8), 1.5 mmol/L $MgCl_2$, 1g/L Triton X-100, 200 mmol/L dNTPs, 50 pmol/L of each primer and 1U of Taq DNA

polymerase. The PCR conditions were as follows: denaturing at 95 ℃ for 1 min, annealing at 55 ℃ for 1 min, extension at 72 ℃ for 3 min. The amplification was performed for 30 cycles. L14841 and H15149 are the primers specific for human cytochrome B gene, COI and ND2 are the primers specific for human mitochondrial cytochrome oxidase COI subunit. These primers were also used in the detection of K-ras gene mutations.

The point mutation at the first and second bases of codon 12 of the K-ras gene was detected by the allele specific mismatch method[11]. The amplification PCR reaction was performed for 45 cycles in a total volume of 50 μL of buffer, but the conditions were slightly modified as the follows: denaturing at 95 ℃ for 1 min, annealing at 58 ℃ for 2 min, extension at 72 ℃ for 1 min. The A set and B set primers were used to detect the presence of K-ras gene mutations at the first and second bases of codon 12. Besides one general primer found in the 2 groups, both Ag and Bc primers were specific for the wild-type K-ras gene. The other primers were used to amplify various mutations of the K-ras gene. The control bands of DNA fragments from the corresponding tumors were validated using an ultraviolet detector after the PCR products were analyzed on a 30g/L agarose gel and visualized by ethidium bromide staining.

The nucleotide sequences of human cytochrome B gene primers and human mitochondrial cytochrome oxidase COI subunits used in the amplification reactions were as follows: L14841: 5' AAAAAGCTTCCATCCAACATCTCAGCATGATGAAA3', H15 149: 5' AAACTGCAGCCCCTCAGAATGATATTTG-TCCTCA3', COI: 5' ACGATGTCTAGTGATGAGTTTGC-TA3', ND2: 5' ACGC CTAATCTACTCCACCTCAATC 3'.

A 300-bp PCR amplification product was detected using L14841 and H15149, and a 1 400 bp PCR amplification product was detected using COI and ND2. The K-ras gene mutation detected at the first base of codon 12 using the A set primers included K-ras A: 5' CAGAGAAACCTTTATCTG 3', K-ras Aa: 5' TGGTAGTTGGAGCTA 3'. K-ras Ac, K-ras Ag and K-ras At differed from K-ras Aa in the last nucleotide, which was replaced by C, G and T respectively[11], and produced a 146 bp DNA amplification fragment.

The K-ras gene mutations detected using the B set primers at the second base of codon 12 included K-ras B: 5' GTAC-TGGTGGAGTATTT3' and K-ras Ba: 5' ACTCTT-GCCTACGCCAA3'. K-ras Bc, K-ras Bg and K-ras Bt differed from K-ras Ba in the last 3' nucleotide, which was replaced by C, G and T respectively[11], and generated a 161 bp DNA amplification fragment.

RESULTS

Sequence of specific human DNA in fecal extraction
The DNA of human cytochrome B gene (a 300 bp amplification fragment) and human mitochondrial cytochrome oxidase CO1 (a 1 400 bp amplification fragment) in the extraction of 10 fecal samples was amplified using the pair of L14841 and H15149 primers and the pair of CO1 and ND2 primers. A 300 bp and a 1 400 bp electrophoretic bands were observed in 9 fecal samples after the PCR products were analyzed on a 15g/L agarose gel and visualized by ethidium bromide staining.

Consistency of K-ras gene mutations in fecal and tissue samples
The K-ras gene mutations in the fecal and tissue samples of 16 large intestinal cancer patients were detected. Of the 16 large intestinal cancer patients, 9 had identical K-ras gene mutation detected both in fecal and tissue samples, none had K-ras gene mutation detected both in fecal and tissue samples, and only 2 had K-ras gene mutation in tissue samples. The consistency test showed that the K-ras gene mutations in fecal and tissue samples were well correlated (χ^2=9.35, P<0.01).

K-ras gene mutation in fecal samples
The K-ras gene mutation was detected in the fecal samples from 23 large intestinal cancer patients. The K-ras gene mutation rate was 56.25% (13/23), which was significantly higher than that (5%, 1/20) in the healthy subjects (χ^2=12.93, P<0.001). There was no significant difference in comparison with that (30%, 6/20) of colonic adenomatoid polypi (χ^2=3.05, P>0.05). The K-ras gene mutation rate was 40%(2/5), 60%(6/10), 66.67%(4/6), and 50%(1/2) in the well, moderately and poorly differentiated adenomas and mucinous adenomas, respectively. The K-ras gene mutation was detected in 2 patients with cancerous colonic adenomatoid polypus, its mutation rate was 30%(6/20) in the fecal samples from colonic adenomatoid polypus patients, which was significantly higher than that in the healthy subjects (χ^2=4.33, P<0.05). The mutation rate of K-ras gene was 23.08%(3/13), 40%(2/5), and 50%(1/2) in the polypi with a diameter less than 1 cm, a diameter of 1-2 cm, a diameter larger than 2 cm, respectively. Among the 13 large intestinal cancer patients, the K-ras gene mutation was detected at the second base of codon 12 in 12 patients (92.31%), GGT was mutated into GAT and GTT in 9 and 3 patients, respectively. The K-ras gene mutation site was observed at the first base of codon 12 in 1 patient, whose GGT was mutated into GTT.

DISCUSSION

A healthy adult excretes approximately 10^{10} epithelial cells every day. A large number of tumor cells will renew and exfoliate into the intestinal cavity of colonic cancer patients every day. A certain amount of DNA can maintain its stability due to the resistance of intestinal tumor cells to various degradation enzymes or due to the impairment of apoptotic mechanism of tumor cells[12]. Based on the above findings, Sidransky et al[13] detected the K-ras gene mutation in the fecal samples from early large intestinal cancer patients in 1992, and found the K-ras gene mutation in the fecal and tissue samples from tumor patients. Since then, several scholars have carried out some similar studies[11,14-16]. However, their research findings have not been popularized and applied due to low PCR amplification rate of DNA in fecal samples. We used the conventional phenol-chloroform extraction method to extract DNA in 10 fecal samples. The PCR amplification product was observed only in 3 faecal samples using the primers specific for mitochondrial DNA of human eukaryotic cells. Then, the PCR amplification reaction was performed in the DNA extraction kits, the amplification rate was as high as 90%(9/10) when the DNA extraction kits used in the detection of DNA in fecal samples were washed twice in hydrolysate to remove the hybrid proteins. In the experiment, we found that the number of templates had a certain effect on the PCR amplification reaction, and could dilute the extract stock to some extent. The results indicated that the amplification rate increased with increase of dilution strength, suggesting that the amount of DNA was quite suitable to its amplification. The effect of some PCR inhibitors present in the PCR amplification reaction was significantly reduced due to the increase of dilution strength. Berndt et al[17] held that these PCR inhibitors were the bile salts and bilirubin present in the fecal samples. Villa et al[14] recovered the purified DNA using purification columns after the absorbent was added to the extract from the fecal samples, and found that the amplification rate was significantly increased, but the cost was rather high. In our experiment, the amplification rate was increased when the DNA extract was approximately diluted, which simplified the procedures of DNA preparation and reduced the cost. However, as the amount of templates in the DNA extract stock from the fecal samples was uncertain, its dilution factor exerted an effect on the DNA

amplification stability. Therefore, the fecal samples with a poor amplification result should be amplified again after the dilution factor of the extract stock was adjusted. This would no doubt increase the cost and time in detecting some fecal samples. In the present study, we detected the K-ras gene mutation in tissue and fecal samples from 16 large intestinal cancer patients, and achieved a rather good consistency (*P*<0.01), indicating that detection of the K-ras gene mutation could reflect the presence of its mutation in the tissues. Since it is much easier to obtain tissue samples than fecal samples in clinic, this method will make it clinically possible to screen colorectal cancer.

Researches showed that the K-ras gene mutation in oncogenes was most frequently found in large intestinal cancer, accounting for 40-50%[18-20]. Smith-Ravin *et al*[11] detected the K-ras gene mutation in the fecal samples from large intestinal cancer patients using the allele specific mismatch method, and found that the mutation rate was 50%. Xiao *et al*[21] detected the K-ras gene mutation in the fecal samples from large intestinal cancer patients using PCR-RFLP, and found the mutation rate was 36.4%. In our study, the detection rate of K-ras gene mutation was 56.25% and 5% in the fecal samples from large intestinal cancer patients and healthy subjects, respectively. There was a very significant difference between the two groups (*P*<0.001), but there was no significant difference in comparison with that of colonic adenomatoid polypus patients (*P*>0.05), suggesting that adenomatoid polypus, a precancerous lesion of large intestinal cancer, is closely related with the development of colonic cancer. According to the literature reports, 90% of large intestinal cancers were resulted from large intestinal adenomatoid polypi. Therefore, early detection and resection of large intestinal adenomatoid polypi could greatly reduce the incidence of large intestinal cancer[2,22]. However, the diagnostic significance of large intestinal cancer at its early stages should be further studied in a larger number of large intestinal cancer patients. Many researchers[23-29] held that the mutation rate of K-ras gene in colonic adenomas would increase with the growth of adenomas. In our study, among the two cases of adenomas with a diameter larger than 2 cm, the K-ras gene mutation was detected in one case, and was also detected in the 2 cases after their colonic adenomatoid polypi were found to be cancerous. This was consistent with the K-ras gene mutation found at the early stages of large intestinal cancer reported both in Chinese and foreign literature. Further researches showed that the K-ras gene mutation was usually resulted from the mutation of GGT to GAT of its codon 12, and 84% K-ras gene mutations were observed at the second base of codon 12. In our study, the mutation site of K-ras gene was observed at the second base of codon 12, accounting for 92.31%(12/13), 69.23% of which was resulted from the mutation of GGT to GAT, and 23.08% was resulted from the mutation of GGT to GTT. This was consistent with that reported in the literature[11,30,31].

The non-invasive method for the detection of K-ras gene mutation in fecal samples reported in this paper is simple to operate and the samples are easy to collect. Its preliminary application in clinic has shown that it is of significance in the diagnosis of elderly large intestinal cancer patients, and can be used in combination with colonoscopy to screen the high risk population for colorectal cancer. It should be further improved because its PCR reaction time is long, which leads to the prolonged detection and is disadvantageous to the detection of large samples.

Abstract

AIM: To evaluate clinical efficacy of four one-week triple therapies in eradicating *Helicobacter pylori* infection.

METHODS: In this clinical trial, 132 patients with duodenal ulcer and chronic gastritis were randomly divided into four groups, and received treatment with OAC (omeprazole 20 mg + amoxicillin 1 000 mg + clarithromycin 250 mg), OFC (omeprazole 20 mg + furazolidone 100 mg + clarithromycin 250 mg), OFA (omeprazole 20 mg + furazolidone 100 mg + amoxicillin 1 000 mg) and OMC (omeprazole 20 mg + metronidazole 200 mg + clarithromycin 250 mg), respectively. Each drug was taken twice daily for one week. The ^{13}C urea breath test was carried out 4-8 weeks after treatment to determine the success of *H pylori* eradication.

RESULTS: A total of 127 patients completed the treatment. The eradication rate for *H pylori* infection was 90.3%, 90.9%, 70.9% and 65.6%, respectively in OAC, OFC OMC and OFA groups.

CONCLUSION: A high eradication rate can be achieved with one-week OAC or OFC triple therapy. Thus, one-week triple therapies with OAC and OFC are recommended for Chinese patients with duodenal ulcers and chronic gastritis.

INTRODUCTION

Eradication of *Helicobacter pylori* infection has become a wide clinical practice for *H pylori* related diseases such as peptic ulcers, and considerable clinical efficacy has been achieved over the past two decades[1-6]. However, many short-term (one week) triple therapy regimens include metronidazole and suffer from the problem of metronidazole resistance, which could significantly decreases clinical efficacy[7-11]. Therefore, it is a very important issue to search for anti-*H pylori* regimens that are highly effective in eradicating *H pylori* infection but without drug resistance[12]. The aim of the present study was to evaluate the clinical efficacy of four short-term triple therapy regimens with clarithromycin.

MATERIALS AND METHODS

Selection of patients

Criteria of selection (1) Those aged 18-70 years. (2) Those with duodenal ulcer (DU) or chronic gastritis (CG) confirmed by gastroscopy. (3) Those who were positive for *H pylori* by a rapid urease test (RUT) and positive by serology, silver or Giemsa staining and histological examination.

Criteria of exclusion (1) Patients who had gastric ulcer or severe gastroesophageal reflux disease, and those who had gastric operation history, hemolytic anemia or family history of hemolytic anemia. (2) Patients who were in lactation or pregnancy. (3) Patients who had combined severe diseases of other system that might affect the medical evaluation of this study. (4) Patients who took the drugs included in this study over the past month. (5) Patients who was allergic to the drugs included in this study.

Methods

Drugs Omeprazole (20 mg/cap, Changzhou fourth Pharmaceutical Factory), clarithromycin (250 mg/tab, Hangzhou Chinese-American Eastchina Pharmaceutical Co. Ltd), furazolidone (100 mg/tab, Guangdong Jiangmen Pharmaceutical Factory), metronidazole (200 mg/tab, Shanghai Ensai Pharmaceutical Co. Ltd) and amoxicillin (250 mg/cap, Kunming Baker Norton Pharmaceutical Co. Ltd) were used.

Regimens Patients were randomly divided into four groups, and receive treatment with OAC (omeprazole 20 mg + amoxicillin 1 000 mg + clarithromycin 250 mg), OFC (omeprazole 20 mg + furazolidone 100 mg + clarithromycin 250 mg), OMC (omeprazole 20 mg + metronidazole 200 mg + clarithromycin 250 mg) and OFA (omeprazole 20 mg + furazolidone 100 mg + amoxicillin 1 000 mg), respectively. Each group took the drugs twice a day for 7 d.

Procedures At the entry, clinical symptoms, demographic data and medical history were recorded, and gastroscopy was performed to establish the endoscopic diagnosis and status of *H pylori* infection. During the gastroscopy examination, four biopsy specimens were taken from stomach: one for a rapid urease test (RUT), one for silver or modified Giemsa staining, and two for histological examination. Serum anti-*H pylori* IgG antibodies were also detected. The patients who were intensive positive by the RUT (positive in five minutes) were initially considered to be qualified for the study. Only those patients who were also positive by serology, *H pylori* staining and histological examination were included in the clinical trial. Patients were followed up on the eighth day to check clinical symptoms, side effects and compliance. A ^{13}C urea breath test was carried out 4-8 wk after completion of the therapy.

Definition of *H pylori* eradication *H pylori* eradication was defined when the ^{13}C urea breath test was negative 4-8 weeks after completion of anti-*H pylori* therapy.

Statistical analysis

H pylori eradication rate was the main analytic target. Total eradication rate and its 95% confidence interval of each regimen was calculated and analyzed by intention-to-treat

analysis (ITT) and per protocol (PP), respectively. The significance in the difference of eradication rate between various regimens was tested by Fisher exact probability and Chi-square test. The possible factors affecting eradication rate was analyzed in a logistic regression model. The difference in the incidence of side effects of each regimen was tested by Fisher exact probability test.

RESULTS

Demographic and clinical data

Of the 132 patients enrolled in the study, 127 (96.2%) completed the treatment and five (3.8%) dropped off. The demographic data and the proportion of DU and CG were not significantly different among the groups (Table 1).

Table 1 Comparison between patient age gender and endoscopic diagnostic results of each group

Group	n	Male/Female	Age (years)	DU/CG
OAC	33	20/13	43.5(18-70)	18/15
OFC	33	19/14	40.8(20-70)	17/16
OMC	33	21/12	41.6(19-69)	18/15
OFA	33	20/13	41.2(20-70)	19/14
Total	132	80/52	42.0(18-70)	72/64

H pylori eradication rates

H pylori eradication rates were significantly different in patients receiving OAC and OFC than in those receiving OMC and OFA ($P<0.05$) (Tables 2 and 3). In the logistic regression model including treatment regimen, age, sex and endoscopes diagnosis, treatment regimens were identified as an independent factor responsible for the difference in the eradication rate (Table 3).

Table 2 *H pylori* eradication rate in each group

Group		Per protocol			Intent to treat	
	n	Eradication rate (%)	Confidence interval (95%)	n	Eradication rate (%)	Confidence interval (95%)
OAC	31	90.3	79.8-95.6	33	84.9	80.1-92.3
OFC	33	90.9	78.5-97.3	33	90.9	79.6-95.4
OMC	31	70.9	64.0-81.7	33	66.7	62.5-76.7
OFA	32	65.6	59.9-72.2	33	63.6	60.2-71.6
Total	127	79.5	72.4-82.5	33	76.5	70.5-81.8

Table 3 *H pylori* eradication rate in each group in relation to endoscopic diagnosis

Group		Duodenal ulcer		Chronic gastritis
	n	Eradication rate (%)	n	Eradication rate (%)
OAC	17	88.2	14	92.9
OFC	17	94.1	16	87.5
OMC	16	68.8	15	73.3
OFA	19	57.9	13	76.9
Total	69	76.8	58	82.8

Incidence of side effects

The incidence of side effects varied among the treatment regimens (Table 4). All of side effects were slight. A compliance of >90% was achieved for all the patients who completed the study.

Table 4 Incidence of side effects in each group

Side effects	OAC (n=31)	OFC (n=33)	OMC (n=31)	OFA (n=32)	Total (n=127)
			Incidence of side effects in each group patients (%)

Fever	0	3.03	0	0	0.79
Somnolence	3.23	0	3.23	0	1.57

DISCUSSION

In 1990, the 14-d bismuth triple therapy was recommended in the Ninth World Gastroenterology Conference in Sydney. Due to its high incidence of side effects (high than 30%) and poor compliance, this regimen has been replaced with other short-term 7-day triple therapy regimens that are more efficient and had fewer and milder side effects[13-19]. These new regimens include OMC 250 and OAC 500, which achieved *H pylori* eradication rates of more than 90% in the MACH-1 study[20-26]. However, the eradication rates with those regimens decreased due to emergence of metronidazole resistance in *H pylori* over the past few years. It has been reported that prevalence of metronidazole resistant *H pylori* strains has increased to more than 70% in China and other countries[27-31]. This accounts for the failure of *H pylori* eradication with metronidazole triple therapy.

With the wide application of anti-*H pylori* therapy and antibiotic abuse, drug resistance in *H pylori* has becomes an increasingly serious problem and a main reason of poor curative effect. At present[30,31], the resistance to clarithromycin in *H pylori* is diverse in the world. South-north difference existed such as the drugs used to treat other infection before (mainly respiratory infection). There are significant difference in the prevalence of metronidazole resistance between developed and developing countries. High prevalence of metronidazole resistance mainly relates to the wide application in parasite infection, dental infection and gynecological diseases in developing countries. Now there is a tendency that metronidazole resistance in *H pylori* is increasing in the developed countries, probably due to the application of anti-*H pylori* therapy. In spite of wide application of treatment with amoxicillin, amoxicillin resistance in *H pylori* was rare.

In order to overcome the problem of metronidazole resistance and to compare the clinical efficacy of triple therapy regimens containing clarithromycin, we carried out this study. We achieved relatively high eradication rates for the clarithromycin-containing regimens OAC and OFC (90.3% and 90.9%, respectively). On the other hand, the eradication rate was relatively low for the metronidazole-containing regimen OMC and OFA. Taken together, we conclude that OAC and OFC are efficient regimens in eradicating *H pylori* infection. Since the cost of furazolidone in OFC regimen is cheap and the *H pylori* eradication rate of OFC regimen is high, we recommend that this regimen be one of choices for *H pylori* eradication.

Abstract

AIM: To elucidate the distinctive pathobiological behavior between signet ring cell carcinoma (SRC) and mucinous adenocarcinoma of the stomach.

METHODS: Based on the histological growth patterns and cell-functional differentiation classifications of stomach carcinoma, we conducted a series of comparative studies. All paraffin-embedded and frozen blocks were collected from the files of Cancer Institute of China Medical University. On the basis of histopathological observation, we applied enzymatic and mucous histochemistry, immunohistochemistry, flow cytometry (FCM) and molecular biology to compare these two categories of gastric cancers in terms of the DNA ploidy, proliferative kinetics, the expression of gastric carcinoma associated gene product and instabilities of mitochondrial DNA (mtDNA).

RESULTS: Gastric SRC was commonly seen in females below 45 years, mostly presenting diffuse growth and ovary or uterine cervix metastasis. The majority of SRC were absorptive and mucus-producing functional differentiation type (AMPFDT), which growth relied on estrogen. Meanwhile, stomach mucinous adenocarcinomas were mostly observed in males over 50 years, prone to massive growth or nest growth and extensive peritoneal infiltration, showing two categories of cell-functional differentiation types: AMPFDT and mucus-secreting functional differentiation type (MSFDT). Expressions of ER, enzyme c-PDE and 67kDaLN-R in SRC were evidently higher than that in mucinous adenocarcinoma, while expressions of LN, CN-IV, CD44v6, and PTEN protein were obviously lower in SRC than that in mucinous adenocarcinoma ($P<0.05$). There was no statistic significance in VEGF, ECD and instabilities of mtDNA ($P>0.05$) between the above two gastric carcinomas.

CONCLUSION: Though SRC and mucinous adenocarcinoma were both characterized by abundant mucus-secretion, they were quite different in morphology, ultrastructure, cell-functional differentiation and protein expression, indicating different mechanisms of carcinogenesis. We concluded that

combining histological growth patterns, cell-functional differentiation types with tumor related markers might be significant in early diagnosis and prognosis assessment for SRC and mucinous adenocarcinoma of the stomach.

INTRODUCTION

SRC and mucinous adenocarcinoma of the stomach were generally confounded as "mucoid carcinoma" until 1964 when Zhang *et al* proposed that the so-called "mucoid carcinoma" included two categories that presented different growth patterns. "Mucoid carcinoma" was finally divided into mucinous adenocarcinoma and SRC in WHO's histological classification of the stomach in 1974. At that time, it remained unclear of the different biological behaviors and metastatic or infiltrative characteristics of these two stomach carcinomas.

From 1962, Cancer Institute of China Medical University began a series of studies on histological growth patterns, cell-functional phenotype classifications and infiltrative, metastatic patterns of stomach carcinoma, and a series of comparative studies on SRC and mucinous adenocarcinoma of the stomach were also carried out the following 40 years. We classified functional differentiation types of gastric cancer by histopathological observation, enzymatic and mucous histochemistry, and detected the expressions of related genes with the help of biological techniques. Different biological behaviors of local infiltration and metastasis of SRC and mucinous adenocarcinoma were investigated at morphological, functional and protein levels.

MATERIALS AND METHODS

All paraffin-embedded and frozen blocks were collected from the files of Cancer Institute of China Medical University. On the basis of histopathological observation, AKP, ACP and LAP were detected by enzymatic histochemistry and various kinds of mucin were detected by mucous histochemistry in order to propose a new cell-functional classification of gastric carcinomas. We observed the expression of ER, cPDE, laminin (LN) and its receptor 67kuN-R, collagen-IV (CN-IV), CD44v6, VEGF, ECD and PTEN proteins by immunohistochemistry, the variation of DNA ploidy, proliferative kinetics by flow cytometry (FCM), and three adjacent regions of mtDNA(D-loop, tRNA[phe] and 12S rRNA) were detected for instabilities via PCR amplification followed by direct DNA sequencing and dHPLC. All procedures were done according to references[1-11].

RESULTS

SRC and mucinous adenocarcinoma were found quite different

in pathological morphology, functional differentiation phenotypes, molecular pathology mechanisms and prognosis as follows.

Morphologic observation

The different growth patterns of mucinous adenocarcinoma and SRC were firstly proposed, following the histological growth classifications of the stomach in 1964. The former presented nest or massive growth, which cancer cells produced and secreted abundant mucus-like substance and then hoarded in the cancerous nest; while the latter presented signet ring cells, widely infiltrated in the stomach wall, accompanied by the formation of "migratory cancerous embolus of lymphatic vessel". SRC had specific cytokinetics: cancer cells were separate, and presented irregular amebocyte shape. Image of ameboidism was often observed emigrating from lymphatic vessel especially in loose part of the stomach (subserosa and submucosa), which suggested the characteristic of widespread growth and invasion. This image was not shown in mucinous adenocarcinoma of nest or massive growth. Meanwhile, the mesenchymal reaction was also quite different between the above two stomach carcinomas: cancerous foci of mucinous adenocarcinoma was mainly enwrapped by collagen fibers, and the argyrophillia fibers were thick and intensive to bundles, surrounding the outside of the cancerous foci; some transition to collagen fibers and even basement membrane-like structures were shown. There were such lymphoid cells and macrophages as inflammatory reaction in adjacent cancerous foci. However, mesenchyma of SRC was loose and in edema, and argyrophilia fibers were reticularly loose, which suggested that the host

immunological reaction was weaker than that of the mucinous adenocarcinoma and coincident with its diffusely infiltrating growth pattern.

Functional differentiation vs invasion and metastatic characteristics

Functional differentiation investigation showed that more than 80.0% of SRC showed AMPFDT: SRC cells not only produced mucus, but also expressed intestinal enzymes of absorption cell markers (AKP and LAP), ACP, and estrogen receptor (ER) in most cancer cells.

Mucinous adenocarcinoma showed specific functional differentiation: 55.3%(21/38) of them showed single MSFDT; 44.7%(17/38) were AMPFDT. The latter was similar to SRC in biological characteristics, while the former did not express intestinal enzymes of absorption cell markers or ER (Table 1).

Tumor related markers

Expressions of ER, enzyme c-PDE and 67kuN-R were evidently higher in SRC than in mucinous adenocarcinoma, while expressions of LN, CN-IV, CD44v6, and PTEN protein were obviously lower in SRC than those in mucinous adenocarcinoma ($P<0.05$). There was no statistic significance in VEGF, ECD and instabilities of mtDNA ($P>0.05$) between the two gastric carcinomas. In SRC, DNA ploidy was different at different pathologic stages: the elevated contents of DNA, polyploid and heteroploid were often seen in early SRC; while the content of DNA was lower and diploid or subdiploid were often presented in advanced SRC. Polyploid and heteroploid were often observed in mucinous adenocarcinoma (Table 1).

Table 1 The comparison of pathobiologic characteristics between SRC and mucinous adenocarcinoma

Pathobiologic characteristics	SRC (AMPFDT)	Mucinous adenocarcinoma	
		AMPFDT	MSFDT
Onset age	Mostly below 50	Same as the left	Mostly over 50[1,2]
Sex	more in female	Same as the left	More in male[1,2]
Infiltrative depth	16.7% (2/12) passing through the serosa		70.0% (7/10) passing through the serosa[1,2]
Growth pattern	Diffuse growth 100.0%(12/12)		Diffuse growth 40.0%(4/10), massive growth 60.0%(6/10)[1,2]
Metastasis rate of lymph node	66.7% (8/12)		80.0%(8/10)[1,2]
Distant metastasis	Often to ovary and uterus, sometimes to bones, marrow, bladder, blepharon or skin of lower extremities	Same as the left	Prone to peritoneal extensive infiltration[1,2]
Tumor related markers			
ER	Positive rate 75.0%(9/12)		Positive rate 10.0%(1/10)[1,2]
c-PDE	Positive rate 80.0%(4/5)		Positive rate 20.0%(1/5)[3]
LN	Few, positive rate 25.0%(2/8)		BM*-like line structure was seen frequently, positive rate 83.3%(5/6)[4]
67KDa LN-R	Positive rate 75.0%(15/20)		Positive rate 25.0%(1/4)[5]
Collagen IV	CN-IV positive fragments or particles only, positive rate 87.5%(7/8)		BM*-like line structure was seen frequently Positive rate 100.0%(6/6)[4]
$CD_{44}V_6$	Positive rate 11.8%(2/17)		Positive rate 62.5%(5/8)[6]
PTEN	Low expression (25.0%, 7/21)		High expression (60.0%) 6/10[8]
VEGF	Positive rate 90.0%(9/10)		Positive rate 100.0%(7/7)[7]
ECD	Negative expression 85.0% (17/20)		Negative rate 75.0%(3/4)[9]
DNA ploidy	Polyploid and heteroploid were often seen in early stage, while diploid and hypodiploid were often seen in advanced stage		Polyploid and heteroploid were often observed[10]
mtDNA variation D-loop region	66.7%(2/3), para-cancerous tissue 33.3%(1/3)		66.7%(2/3), para-cancerous tissue 66.7%(2/3)
12S rRNA	33.3%(1/3)		66.7%(2/3)[11]
Ultrastructure	More mucous secretion. Few desmosome junctions and gap junctions between cells.		Plenty of mucous secretion. Several desmosome junctions and gap junctions between cells
5 year survival rate	15.9%		19.4%

*Basement membrane.

DISCUSSION

The survival rate of both SRC and mucinous adenocarcinoma was extremely low. According to the National Cooperation Group of Stomach Carcinoma, the 5-year survival rate of SRC and mucinous adenocarcinoma of the stomach was only 15.9% and 19.4% respectively mainly because most clinical cases of SRC or mucinous adenocarcinomas were moderate to advanced cancer accompanied with extensive infiltration and metastasis. Metastasis, especially unmanageable metastasis to the remote important viscera was the primary cause of patients' death. Research findings of more than 40 years revealed different infiltrative and metastatic mechanisms of SRC and mucinous adenocarcinoma at morphological, functional and protein levels, based on histological growth patterns and cell functional differentiation phenotypes.

The structural basis of different growth patterns of SRC and mucinous adenocarcinoma was demonstrated by electron microscopic observation and mucus histochemistry by Wang *et al* (Cell Biology Institute of China Medical University) and other Chinese scholars[12]. Under electron microscope, SRC was lack of free ribosomes but rich in rough endoplasmic reticulum (RER), lysosomes, mucus granules, and Golgi complex presented cystiform dilatation, which suggested SRC cells had a strong capability of protein and mucus synthesis. In addition, there were few microvilli on the surface of SRC cell membrane, desmosome junction and gap junction ultimately vanished, the interspaces of cancer cells were enlarged, which suggested that adhesive ability of cancer cells decreased and detachment was easy among cells. Histochemical observation found that these changes were accompanied by releasing of multiple sialomucin, sulfuric acid mucopolysaccharide (AMP), and polysaccharide hydrolases such as acid phosphatase (ACP). These characteristics contributed to the potential of dissolving surrounding tissues, and strong infiltration and metastasis. Nevertheless, cancer cells of mucinous adenocarcinoma were rich in free ribosomes, with scattered RER, and fewer Golgi complex and lysosomes than that of SRC. Further, different from SRC, microvilli and part of desmosome junction and gap junction were shown on the surface of cell membrane. All above characteristics suggested mucinous adenocarcinoma had a stronger adhesive ability than SRC, which partly explained their different growth patterns.

In 1979, Zhang *et al* firstly reported that diffusely growing SRC could show retrograde metastasis from the stomach to cervix and parametrium via "migratory cancerous embolus"[13], which raised two questions at the same time: Why was it often seen that SRC or poorly differentiated adenocarcinoma and undifferentiated carcinoma containing signet ring cell metastasized to cervix and parametrium, but it was rarely seen in mucinous adenocarcinoma? Was there any difference in cell-functional differentiation and associated molecular pathological characteristics apart from morphologic differences?

The authors detected cell-functional differentiation of gastric cancer cells by enzymatic, mucus histochemistry and immunohistochemistry, proposed a new concept of cell-functional classification of stomach carcinoma, and found that the carcinoma of different functional types were quite different in local infiltration and metastasis to remote viscera[1,2]. Based on this study, we extensively investigated the hypostases of different biological behaviors of the above two carcinomas[2]. According to cell-functional differentiation of cancer cells, more than 80.0% of SRC showed AMPFDT, which suggested it was a specific carcinoma cell type with disturbed cell-functional differentiation, possessing both absorptive and mucus-producing functions, and its growth and infiltration relied on ER. SRC not only produced mucus, but also expressed small intestine absorptive cell marker enzymes and ACP. Mucus-producing functional differentiation and the release

of ACP in SRC contributed to hydrolyze mesenchyma surrounding the cancerous foci and invade into normal tissue; and absorptive functional differentiation contributed to absorb nutrition from the host, which accelerated its malignant proliferation. SRC cells customarily expressed ER, which suggested that its growth relied on the existence of estrogen. The reason why SRC was often observed in the female of the premenopause and prone to metastasize to ovary or uterine cervix was its high affinity to organs with a high level of estrogen such as ovary. During the metastasis from the stomach to ovary, "ER (on cancer cells)-estrogen (in the ovary)" affinity linkage might play an important role. Our results suggested that under the prerequisite of hematogenous metastasis, lymphatic metastasis or implantation metastasis to the ovary or cervix, cancer cells with high activities of ER had specific affinity and adaptability to organs rich in estrogen and thus could easily metastasize to the ovary or cervix[2].

Mucinous adenocarcinoma exhibited two functional classifications as AMPFDT and MSFDT. The biological behaviors and part of molecular pathological characteristics of the former were similar to that of SRC; but the latter did not express small intestine absorptive cell marker enzymes, which disabled its absorptive activity, decreased absorption of enough nutrition and restrained the growth and spread. It was probably one reason why mucinous adenocarcinoma was prone to massive or nest growth, and thus exhibited better prognosis than SRC. These two functional classifications of mucinous adenocarcinoma were quite different in onset age, serosa infiltration, dependence on estrogen (ER expression), *etc*. It was suggested that mucinous adenocarcinoma had the heterogeneity both in cell-functional differentiation and biological feature. So special attention should be paid to cell-functional differentiation characteristics in judging malignant biological behaviors and metastatic patterns of mucinous adenocarcinoma.

In order to explore the difference of molecular mechanisms between the above two gastric carcinomas, we also designed a series of molecular pathological markers ranging from cell proliferation and differentiation, extracellular matrix, tumor angiogenesis, tumor suppressor genes, *ect*. Cyclic nucleotide acid phosphodiesterase (cPDE) is a key enzyme degrading cyclic adenosine phosphate (cAMP) and cyclic guanosine phosphate (cGMP), thereby influencing cell proliferation and differentiation. This study revealed that SRC exhibited higher activities of cAMP-PDE and cGMP-PDE than mucinous adenocarcinoma, and it was concluded that SRC cells had stronger abilities of synthesizing and secreting cPDE than mucinous adenocarcinoma. And cAMP-PDE was a reliable enzymatic marker to estimate malignant degree and prognosis of the above two gastric carcinomas[3]. LN was the main ingredient of basement membrane. The studies found stomach cancer cells could not only destroy basement membrane but also unceasingly synthesize the ingredient of its basement membrane. Mucinous adenocarcinoma cells had the capacity of synthesizing, and excreting LN out of the cells, which formed a line-like structure similar to basement membrane. This might be one of the reasons why mucinous adenocarcinoma often grew in a nest or massive shape. SRC synthesized very few LN and there were only a few LN particles in extracellular matrix. This might be related to some characteristics of SRC, such as infiltrative growth and high invasiveness[4]. The quantity and expression intensity of 67KDa LN-R influenced the infiltrative migration of malignant tumor cells. Acting as a kind of LN receptor, 67KDa LN-R usually was involved in the identification of ECM and information convection. Increased expression of 67KDa LN-R in tumor cells would benefit adhesiveness and infiltration. Among the different histological types of gastric cancer, the expression of 67KDa LN-R was

highest in SRC(75.0%,15/20), and lowest in mucinous adenocarcinoma (25.0%,1/4), which might be in relation to their different abilities of infiltration and metastasis[5]. The change of LN expression level was closely correlated to the pathological behaviors of gastric cancer, and could be used as an objective marker to assess the growth ability and the tendency of hematogenous metastasis between the above two gastric cancers. CN-IV was expressed in the above two gastric cancers, but the expression pattern was quite different[4]. In mucinous adenocarcinoma, the basement membrane-like structure containing CN-IV was seen clearly. However, only linear fragments or positive particles containing CN-IV were seen in SRC. The findings suggested that the above two gastric cancers had different capacities of synthesizing and secreting CN-IV hydrolase. CN-IV hydrolase was strong in the interstitial of SRC, and hydrolyzed CN-IV into discontinuous fragments or particles ,which led to the infiltrative growth of cancer cells. The expression of CN-IV in gastric cancer presented negative correlation with its infiltrative growth ability, and could be used as one of the markers to evaluate the poor prognosis of the above two gastric cancers[4] .

CD44v6 took part in specific adhesion processes between cells or cells and matrix. Our results[6,14] showed CD44v6 had a close relation to metastatic potential of gastric cancer cells and the poor prognosis of patients. It was found that the protein expression of CD44v6 was quite higher in mucinous adenocarcinoma than in SRC. This was probably due to the crypt formation and nest or massive growth pattern of mucinous adenocarcinoma. VEGF is correlated with tumor angiogenesis. A lot of evidence showed that VEGF greatly increased the probability of tumor metastasis by accelerating blood vessel growth. But between the above two gastric cancers, the difference of VEGF expression was not significant[7]. Up to now, PTEN/MMAC1/TEP1 gene is the first tumor suppressor gene that was proved to have phosphatase activity. Using immunohistochemistry, we found the expression of PTEN protein in SRC was significantly lower than in mucinous adenocarcinoma. The expression of PTEN protein presented negative correlation with gastric cancer' s pathological grade and prognosis, which indicated that PTEN gene mutation or inactivation might be one of the reasons for the poorer prognosis of SRC compared with mucinous adenocarcinoma[8]. ECD is a kind of transmembrane glycoprotein, which induced the adhesion of homogenous cells. The dysfunction of ECD made the adhesion of homogenous cells impossible. Thus, cancer cells tended to separate from each other and metastasize. ECD presented negative expression in 85% (17/20) of SRC and 75% (3/4) of mucinous adenocarcinoma. So ECD could be used as one of the markers to evaluate the poor prognosis of the above two gastric cancers[9].

There were some studies on tumor related markers from other aspects about the above two gastric cancers. For example, the expression of GST-π was lower in SRC (50.0%,4/8) than that in mucinous adenocarcinoma (66.7%,6/9), and it was related to differentiation degree of cancer cells. The expression of GST-π in well differentiated cells was higher, and it was closely correlated with carcinogenesis and progress of gastric cancer, but there was no significance[15]. S-Tn antigen is a prosoma of saliva acidulated T antigen, and belongs to the embryo or differentiated antigen. It might take part in the early malignant transformation of gastric cancer. It has been reported that the expression of S-Tn antigen in SRC was highest among different histological types of gastric cancers[16], while the mechanism is still unknown.

DNA aneuploidy of tumor cells is one of its malignant characteristics. DNA aneuploidy of gastric cancer is closely related to the remote organic metastasis, especially to the hematogenous metastasis[10]. There were a lot of polyploid and heteroploid cells in early SRC, while most of advanced SRC showed diploid or hypodiploid cells. It suggested that the reduction of DNA content in advanced SRC cells was probably related to the accumulation and crushing of mucus. SRC had the tendency to infiltrate into submucosa in early stage, and this behavior was related to the DNA heteroploidy of cancer cells. Detection of DNA ploidy, especially early detection would help to estimate the malignant level and poor prognosis of the above two gastric cancers.

Recently, researchers have paid more attention to the relationship between the damage of mtDNA and carcinogenesis. mtDNA is a 16 569-bp double stranded, closed circular molecule, which encodes polypeptides participating in oxidative phosphorylation and synthesis of ATP. Compared to nuclear DNA, mtDNA is more susceptible to damage, because of the lack of protective action by histones and the limited capacity of damage repairing system as in yeast and most nuclear genomes. Mitochondrial D-loop and hypervariable region suffered the attack of ROS easily. Chomyn *et al* considered that mtDNA was not necessary to the start-up of necrosis, but it influenced the speed of necrosis because the decrease or damage of mtDNA would result in the increase of ROS[17]. Our study found that there was no statistic significance in instabilities in D-loop region between gastric cancerous and para-cancerous tissues. There was a significant correlation between differentiation degree of gastric cancer and variant frequencies of 12S rRNA-tRNA[phe]. The poorly differentiated gastric cancers were more prone to 12S rRNA-tRNA[phe] variations. But there was no significance between SRC and mucinous adenocarcinoma[11]. This result needs to be proved by larger sample studies. The relationship between mtDNA and gastric cancer would further be clarified.

There were several molecular biology studies about gastric SRC and mucinous adenocarcinoma. MSI is a frequent genetic change in gastric cancer. Up to now, the average rate of MSI was 33.9% among 29 sites that have been detected, and phenotypes of MSI were different in gastric cancers due to their different pathological types[18,19]. MSI-positive frequency of SRC was significantly higher than mucinous adenocarcinoma of the stomach, which indicated that the occurrence and progress of the above two gastric cancers probably had different molecular mechanisms. Loss of heterozygous (LOH) is one of MSI phenotypes. The fractional allelic loss (FAL) (the odds of LOH positive marker number and MSI marker number) was related to infiltrative ability of gastric cancer cells and different growth patterns of gastric cancer. Our studies suggested that there might be different allelic deletion between SRC and mucinous adenocarcinoma, which might clarify that the different heredity phenotypes and biological behaviors of the above two gastric cancers were closely correlated with MSI and LOH. We plan on marking MSI and screening LOH site so as to discover minimal deletion fragment nearby these sites by molecular biology and LCM technique. This would lead us to detect some unknown TSGs and study the molecular biological mechanisms of different biological behaviors of the above two gastric cancers.

In conclusion, from the view of histological growth patterns and cell-functional differentiation types of gastric cancer, we investigated various kinds of pathobiological behaviors of gastric SRC and mucinous adenocarcinoma. On the basis of this, we studied on tumor related markers for early diagnosis and prognosis evaluation of gastric cancer, so to instruct clinical surgical treatment scientifically and effectively, and improve survival rate and survival quality. In our cancer institute, the 5 year survival rate of gastric cancer has risen from 19.6% to 58.5%, approaching international advanced level[20]. Along with the preliminary accomplishment of human genome project, the studies on tumor genomics are advancing with

every passing day. A lot of tumor related genes will be found, and their roles need to be clarified in occurrence, progress and prognosis of the above two gastric cancers. Meanwhile, little literature has been reported on the morphogenetic or histogenetic mechanisms and early diagnostic markers of gastric SRC and mucinous adenocarcinoma, and there is still much dispute in this field. All these problems need further research.

Abstract

AIM: To investigate the inhibitory effect of dietary and medicinal formula Ganfujian granule on diethylnitrosamine (DEN)-induced hepatocarcinoma in rats.

METHODS: Male SD rats had free access to water containing 0.1 g/L DEN for 16 weeks, during which the rats fed with standard diet or administration of Ganfujian granule (30.4 g/Kg in diet). At weeks 4, 8, 12 and 16 of hepatocarcinogenesis 5 rats of each group were sacrificed, and at week 20 another 30 rats were sacrificed from each group. The end point for survival observation was at week 28. Immunochemistry methods were used to examine the effect of Ganfujian granule on the process of hepatocarcinogenesis including proliferation of hepatocytes and cell cycle modulation.

RESULTS: Ganfujian granule could reduce and delay the incidence of hepatocarcinoma in rats and prolong the survival of animals. In addition, Ganfujian granule had a marked inhibitory effect on high expression of cyclin dependent kinase (CDK4) during the whole process of hepatocarcinogenesis and cyclin D1 at week 16 and the number of proliferating cell nuclear antigen (PCNA) positive cells in different stages of hepatocarcinogenesis.

CONCLUSION: Ganfujian granule can reduce and delay the incidence of hepatocarcinoma in rats by exerting direct or indirect effects on cell cycle and inhibiting uncontrolled proliferation of hepatocytes.

INTRODUCTION

Liver cancer is one of the common malignancies in the world, especially in Asia and Africa. Despite many advances in the treatment of this disease in recent decades, its long-term therapeutic outcome remains poor and prognosis is devastating. Prevention seems to be the best strategy in lowering the present prevalence of the disease. Much work has been done in the prevention of liver cancer, including monitoring of high risk populations (residents in areas of high incidence, cirrhosis of various causes and patients with chronic hepatitis)[1,2], extensive immunization to prevent HBV infection[3], and use of interferon to alleviate HCV infection, both providing hope of lowering or delaying the complication of hepatic cirrhosis or progression to liver cancer in chronic hepatitis patients[4]. More and more efforts have been made in search of natural materials and foods as a means of chemical prevention of liver cancer[5]. Characterized by low toxicity and effectiveness, traditional Chinese herbs have aroused more interest in the prevention of tumors[6]. Ganfujian granule is an oral granule consisting of dietary and medicinal Chinese herbs for preventing liver cancer, developed by our laboratory based on the basic traditional Chinese medicine (TCM) theories of "invigorating spleen and soothing liver" as the key principle in combination with our clinical experience in preventing and treating liver cancer. Our previous experiments have demonstrated that Ganfujian granule can effectively prevent the formation of liver preneoplastic lesions[7]. In the present study we attempted to observe the effect of Ganfujian granule on DEN induced liver cancer in rats and to explore the potential preventive mechanism from the perspective of modulation of proliferation of hepatocytes.

MATERIALS AND METHODS

Materials

Male SD rats (160-180 g in body mass) were obtained from the Animal Center of the Second Military Medical University of Shanghai. DEN and 2-bromo-3' -deoxyuridine (BrdU) marker were from Sigma, CDK4 sheep monoclonal antibody and cyclin D1 monoclonal antibody were from Santa Cruz, PCNA and BrdU test kit from DAKO.

Methods

Animal model The rats had free access to food and water throughout the study. The basal diet was a standard diet. The Ganfujian granule-containing diets were prepared by mixing 3.04% Ganfujian granule with the standard diet (the Ganfujian granule amount for the rats was converted from the kg body mass daily for adults). After a 5 d acclimatization period, 165 rats were assigned into group I (carcinogen-exposed control) and group II (Ganfujian granule treatment). Fresh sterile water was used to prepare DEN solution of 100 µg/mL concentration, to which the rats had free access. The rats in group I were fed with basal diet and those in group II with Ganfujian granule containing diet. At wk 16 DEN water was discontinued and the food for the animals in group II was changed into basal diet. Five rats from each group were sacrificed at wk 4, 8, 12 and 16 of DEN hepatocarcinogenesis. Livers of the rats were resected, cut into 3 mm slices and fixed. Another 30 rats from each group were sacrificed at wk 20 to observe incidence rate of liver cancer. The remaining animals were raised continuously to observe survival. The end point of observation was at wk 28.

Immunohistochemical staining The liver tissues were fixed in 40g/L buffered formaldehyde and processed for embedding in paraffin, cut into 4 µm thick slices, deparaffinized with

xylene and washed with alcohol, and then processed for immunohistochemistry by using a streptavidin-biotin-peroxidase complex methods. Cyclin D1 rat monoclonal antibody, CDK4 rabbit polyclonal antibody and PCNA rat monoclonal antibody were used as primary antibodies. As controls, known positive tissue sections were used, and for negative controls exposure to the primary antibody was omitted.

To determine labeling index (LI), 5 rats from each group at wk 20 received intraperitoneal injections of 2-bromo-3'-deoxyuridine(BrdU) 35 mg/kg body mass 1 h before death, BrdU incorporation into nuclei was determined immunohistochemically with a ' BrdU test kit' .

Analysis and quantification of staining results

Staining of cyclin D1 and CDK4 foci in liver tissue section was analyzed and quantified using an image analyzer (HPIAS-1000 highly clear color pathological graph analysis system). With the gray scale unified, five different fields were selected for each section to conduct automatic measurement by selecting the mean gray scale as the index of measurement, ×400. The system uses 256 as the maximal gray of white and 0 as the minimal gray of black. The smaller the mean gray scale, the higher the positive reaction. The brownish yellow particles and dark blue particles covering the nuclei represented the positive signal of PCNA and BrdU respectively. The number of positive liver cells was counted. Ten un-overlapped high power fields (×40) of the same transmigration were used for counting the positive and negative cells (100 cells).

Statistical analysis

Data relative to tumor incidence were analyzed by Fisher' s exact test. Survival functions were analyzed by the log-rank analysis. The differences between groups were analyzed by Student' s t test, and the two-tailed statistical significance was determined. The statistical calculations were carried out by SPSS and NOSA software packages.

RESULTS

General effects of ganfujian granule

The liver surface of rats in the group I grew coarse gradually between 4-8 wk of DEN hepatocarcinogenesis, on which small granules of local focus were seen. Light microscopy showed that liver cells became degenerative and locally necrotic. Cirrhosis was evidently seen in 40% at wk 12, and at wk 16, cirrhosis was seen in all the rats (100%). More and larger nodules were seen on the liver surface, the liver became smaller, and deranged pseudolobuli of different sizes were seen histologically. Early cancer change was seen in 20% rats. At wk 20, all the 30 rats (100%) developed hepatocarcinoma. Liver impairment of group II was milder than that of group I at various stages of hepatocarcinogenesis. No cirrhosis was seen at wk 12, 60% developed cirrhosis at wk 16, but no cancerous change was observed, and at wk 20, 24 of the 30 rats (80%) developed liver cancer. Fisher' s exact test analysis showed that the incidence rate of liver cancer between the two groups was significant ($P<0.05$). Using 28 wk as the end point of observation, the longest survival of rats in group I was 20 wk, and 28 wk in group II. Log-rank test showed that survival of rats in group II was longer than rats in group I, and risk of death in group I was lower than that in group II ($P<0.05$, Figure 1).

Changes in expression of PCNA and BrdU

The number of PCNA positive hepatocytes increased gradually with progression of hepatocarcinogenes is at the early stage, and showed a tendency of sharp increase after 12 wk. Two-

tailed t test showed that the number of PCNA positive hepatocytes of group II was lower than that of group I, and the difference between two groups was evident between 12 and 20 wk ($P<0.05$), (Table 1). The number of BrdU positively labeled hepatocytes was also smaller in group II at wk 20 of hepatocarcinogenesis (28.80 ± 0.65 vs 45.71 ± 1.90, $P<0.05$).

Table 1 Effect of Ganfujian granule on positive expression of PCNA during hepatocarcinogenesis (n=5, mean±SD)

Group	4 wk	8 wk	12 wk	16 wk	20 wk
Control	15.22±3.28	21.50±3.04	21.06±0.32	31.10±7.06	41.77±1.01
Treatment	10.88±3.22	12.20±1.87	6.38±0.18a	10.11±0.78a	16.14±0.43a

a$P<0.05$ vs control.

Effects of Ganfujian granule on expression tendency of cell-cycle modulators

The gray scale of positively stained cyclin D1 of hepatocytes in rats treated with DEN decreased continuously, that is, positive expression of cyclin D1 showed an increasing tendency, reaching the peak at wk 16-20 of hepatocarcinogenesis. Positive expression of CDK4 reached the peak at wk 8, decreased gradually afterwards, and rose again gradually at wk 20. Linear regression correlation analysis showed that there was no significant correlation between two modulators ($P>0.05$). Positive expression of CDK4 in group II was significantly lower than that in group I during different stages of hepatocarcinogenesis ($P<0.05$) and the expression of cyclin D1 was significantly lower at wk 12 and 20 ($P<0.05$), (Figure 2).

DISCUSSION

Carcinogenesis is a multi-stage process characterized by continuous change in specific heredity and phenotype. The whole process of carcinogenesis is accompanied by subsequent activation of a group of protooncogenes and inactivation of

cancer suppressor genes, leading to continuous accumulation of uncontrolled proliferation of cells[8]. Therefore, the liver backgrounds such as nodular cirrhosis and viral hepatitis, and abnormal expression of related genes and proteins play crucial roles in the process of carcinogenesis. In our model of using DEN as the chemical carcinogen, the rat liver underwent different stages of inflammatory change, cirrhosis, carcinogenesis and progression. The incidence rate of liver cancer was 100%. Almost all these liver cancers developed on the basis of cirrhosis. This process might imitate the pathogenesis of human liver cancer to some extent[9,10]. Therefore, our model provides necessary evidence for dynamic observation of the whole process of hepatocarcinogenetic evolution from cancer initiation to malignant transformation based on the change of cell proliferation modulations.

Ganfujian granule is composed of dietary and medicinal Chinese herbs including Chinese yam (*Rhizoma Dioscoreae*), hawthorn fruit (*Fructus Crataegi*) and Chinese date (*Fructus Ziziphi Jujubae*). It is atoxic for long-term use. As a basic formula, it has achieved good therapeutic effects in clinical treatment of liver diseases. In the present study, we observed its effect on DEN induced liver cancer in rats and found that in group I 100% of these rats presented with nodular cirrhosis at wk 16, of which 20% were accompanied by early cancer change at wk 20, all rats developed liver cancer. The longest survival of rats was 20 wk. In group II, cirrhosis was found in 60% rats at wk 16, liver cancer was found in 80% at wk 20. The longest survival of rats was 28 wk. Statistical results showed that Ganfujian granule reduced and delayed the occurrence of liver cancer in rats and prolonged survival of these animals.

Abnormal proliferation of cells is the main feature of carcinogenesis, and therefore exploration of drugs that can affect malignant proliferation of liver cells is of primary importance in chemical prevention of liver cancer. PCNA, a polypeptide chain derived and purified from the cell nucleus, is directly involved in DNA replication. It has been found that the content and positive expression of PCNA were a common index for proliferation of hepatocytes at late G1 stage and early S stage[11]. As BrdU may seep into cells during DNA synthesis, it can be used to reflect the number of S stage cells. Both PCNA and BrdU are good indexes reflecting proliferation of cells. The positive expression of two proteins was mainly found in the pre-cancerous proliferation focus and cancerous liver tissue during DEN induced hepatocarcinogenesis[9]. Their high expression suggested that the ability of cell proliferation became stronger, and this was closely related to malignant cell proliferation and carcinogenesis[12,13]. In the early stage of our experimental model, PCNA positive hepatocytes increased gradually and this increasing tendency became more evident between 12 and 20 wk (the period during which cirrhosis-liver cancer formed). The inhibitory effect of Ganfujian granule on PCNA positive cells was most prominent during this period. In addition, Ganfujian granule also reduced the number of BrdU positively labeled cells at wk 20, suggesting that Ganfujian granule had the action to suppress malignant proliferation of hepatocytes in experimental liver cancer.

The events of cell cycle are normally controlled by the clock within the cell, which is reflected by periodic activation of cyclin D/CDK complex. Irregular regulation may lead to abnormal cleavage of cells and is closely related to malignant transformation of cells[12-15]. In our experiment, we found that positive expression of cyclin D1 tended to increase gradually during DEN induced hepatocarcinogenesis, reaching the peak

at the end stage of carcinogenesis. On the other hand, positive expression of CDK4 was active during the early stage of carcinogenesis, became weaker during the middle stage, and rose gradually in the late stage. In group II, positive expression of CDK4 at various stages of carcinogenesis and that of cyclin D1 at wk 16 were significantly lower than those in group I. These findings indicate that DEN induced hepatocarcinogenesis was accompanied by continuous accumulation of cell cycle positive modulators such as cyclin D and CDK, leading to disturbance of cell cycle and uncontrolled proliferation. Ganfujian granule can suppress over-expression of these modulators, regulate the process of cell cycle and capture over-proliferation of hepatocytes that escape the G1-S check-point so as to suppress uncontrolled proliferation and hepatocarcinogenesis.

Based on the results from our experiment, it is concluded that the dietary and medicinal formula Ganfujian granule is able to reduce and delay the occurrence of liver cancer by affecting the abnormal expression of multiple proteins related to cell proliferation cycle at different stages of hepatocarcinogenesis. As a liver cancer chemical preventive agent, clinical application of Gangfujian granule is promising.

Abstract
Acute colonic obstruction due to malignancies is an emergency that requires surgical treatment. Elderly patients or inoperable tumors require intestinal decompression that is a simple colostomy in almost all cases. This "manoeuvre" leads the patient to a percentage of mortality/morbidity and to a bad quality of life due to acceptance of stoma. The introduction of enteral metal stent inserted endoscopically has, in our opinion, provided a new way to obtaining the definitive palliation of inoperable colo-rectal cancer with a simple method. We reported our case-series and we analyzed the current literature and costs of treatments.

INTRODUCTION
Curative resection of colorectal cancer is not feasible in more than 25% of patients presenting obstruction due to extensive local tumor infiltration, distant metastases, or severe comorbidities.

In the treatment of patients with inoperable malignant obstruction, maintenance of gastrointestinal luminal patency is of paramount importance, and in view of this palliative cures are challenging.

Surgical treatment still remains the optimal treatment for high-risk patients with large bowel obstruction, although morbidity and mortality rates are relatively high. Moreover, surgical decompression with a palliative colostomy may be a major source of morbidity, and increase the time of hospitalization, need for further medical care, and reduces quality of life. In the last decade the health care industry has introduced really sophisticated visceral prothesis. In recent years we have been challenged in stenting occlusive colo-rectal cancer bridging patients from emergency to elective surgery. With this work we reported our experience in treating inoperable colonic neoplastic obstruction, proposing definitive palliation for both obstructive symptoms and continuous oral intake, positioning enteral stents. This endoscopic treatment, in high-risk or inoperable patients, can avoid surgical approach with colostomy, greatly enhancing the quality of life.

Evaluation of the outcome of this treatment cannot ignore cost analysis that appears favorable in our and other opened experiences.

CASE SERIES
A retrospective review performed on 4 patients presenting incomplete colonic obstruction secondary to left-side colon cancer received a colonic stent at our institution between June 2000 and July 2003.

Clinical and radiographic criteria for patient eligibility to this treatment included (a) symptoms of obstruction with constipation for a period longer than 48 h, abdominal distension, nausea, vomiting, or abdominal pain, and (b) conventional radiologic evidence of colon-rectal obstruction (confirmed by abdominal computed tomography).

We excluded patients if they manifested clinical evidence of bowel perforation and free intraperitoneal air on abdominal radiograph, peritonitis, massive gastrointestinal bleeding, a fixed rectal mass.

All patients underwent baseline endoscopic evaluation for delineation of tumor length and demarcation. In all cases, histopathologic findings from biopsy revealed adenocarcinoma. After adequate explanation regarding discouraging complications (including difficulty of insertion because of propagation of the tumor, possible perforation on insertion and expansion of the stent, stent migration and tumor ingrowth), informed consent was given by each patient and family.

Case 1
In July 2000 a 90-year-old man came to our department because of rectal bleeding, appearing 1 mo before, and ileus symptoms. At admission the physical examination demonstrated abdomen distension and a rectal mass on finger exploration. Laboratory tests revealed an anaemic condition alone. American Society of Anesthesiologists (ASA) status was III. Then the patient underwent nasogastric decompression and received intravenous fluid supplements. CT of the abdomen and pelvis showed a rectal mass involving the whole wall thickness. Colonoscopy identified a substenotic rectal mass, measuring 4 cm in length, 8 cm away from the dentate line, which was dilatated with a TTS-balloon (BE-6 OLYMPUS - Europe, Amburg, Germany). We decided to stent the lesion and opted for this kind of temporary treatment because of stent supply times. Balloon dilation showed an improvement of abdominal symptoms with gas and liquid stools transit. In the meantime we supported the patient with a liquid diet and total parenteral nutrition. Small enemas were also administered. On d 10 after admission, we inserted a Wallstent prothesis (Schneider, Bulach, Switzerland) measuring 9 cm in length and 22 mm in diameter. The patient's symptoms improved immediately after stent placement with passage of stools and flatus from the anus. He died 6 mo after stent placement due to progression of the initial disease without constipation symptoms or signs.

Case 2
In July 2002 a 75-year-old man was admitted complaining of

abdominal pain and constipation for 3 d. Family history was positive for familiarity with neoplastic colonic disease (one sister had died). Past history: in 1984 radical cystectomy with urostomy for bladder carcinoma, chronic renal failure, in 1994 surgical clearing for choledocholithiasis, cerebral ischaemia and outcomes of lacunar encephalopathy, left hemiparesis, sclero-hypertensive cardiomyopathy, ventricular extrasystoles. In the last 6 mo, a body mass loss of 10 kg and poor appetite were noted. The patient had also been suffering from hypogastric pain for a month. For this reason, on 27 of July 2002 he underwent colonoscopy that revealed a circular stenosis 75 cm away from the anal verge, in the distal transverse colon (near splenic flexure) line, and unable to get through. Biopsy of this tissue demonstrated a histopathological finding of a well-differentiated adenocarcinoma. On August 28, 2002 he was referred to our institution because of ileus symptoms.

At physical examination, his abdomen was markedly distended. Laboratory tests disclosed hyper blood urea and hyper-creatinine level, malnutrition with a total protein level of 5.4 g/dL (normal value 6.4-8.3 g/dL), a white blood cell count of 8.500/mm^3 (with normal differential cell and platelet counts), a hemoglobin level of 12 g/dL, a hematocrit of 36%. The ASA status was IV.

Plain abdominal Rx at admission showed fluid line. He was then subjected to total parenteral nutrition and a nasogastric tube to reduce gastrointestinal pressure. On the following days, ileus was temporally improved, on September 4, he underwent definitive colonic decompression using a Wallstent (Boston Scientific Microvasive, Minnesota, USA) measuring 9 cm in length and 22 mm in diameter (Figure 1). After one year he is still alive, follow-up control was scheduled for the 30th 2003.

Case 3

An 85-year-old woman was admitted to our department in October 2002 suffering from rectal bleeding first noted the year before. On admission the patient was diagnosed with ileus symptoms due to ulcered, exophytic substenotic recto-sigmoid neoplasm, 5 cm long starting 14 cm from the anal verge as a result of colonoscopic examination. Laboratory studies disclosed malnutrition (total protein level of 5.6 g/dL) and anaemia (hemoglobin level of 10.7 g/dL, hematocrit of 33.5%). ASA status was IV. Plain computed tomography revealed tumor shadow of the sigmoid and the cephalic side of the colon was markedly dilated with fluid collection. Swelling of intraperitoneal lymph nodes and an abundant bilateral pleural effusion were also noted. We inserted a Precision Ultraflex prosthesis (Boston Scientific Microvasive, Minnesota, USA), measuring 9 cm in length and 25 mm in diameter. We obtained immediate recovery of colonic transit (Figure 2). She was discharged after 2 d and died after 45 d.

Case 4

A 61-year-old woman, without any medical history, had its beginning in March 2003, when she noted relapsing episodes/events of sub-occlusion and a body mass loss of 10 kg. At hematologic examinations, carcino-embryonic antigen and carbohydrate antigen 19-9 levels were significantly elevated at 8 000 ng/mL and over 10 000 U/mL, respectively. Plain computed tomography performed on May 29 showed multiple liver metastases, ascites and peritoneal carcinomatosis. Colonoscopic examination showed a circular stenosis at the sigmoid. Histopathological findings demonstrated adenocarcinoma. Initial support therapy was sought at a medical institute and then she was referred to ours for the required treatment. ASA-status was IV. A water-soluble contrast-media enema performed just after the colonoscope introduction, demonstrated a 3 cm

long stenosis. A Precision Ultraflex stent, measuring 9 cm in length and 25 mm in diameter, was selected and positioned. The day after stent insertion, we saw a full canalization. The patient was discharged on the 3rd hospital day and she is still alive (end of follow-up: August 2003).

Figure 1 Radiologic sequence of stenting procedure in left transverse colon.

Figure 2 Endoscopic view of Wallstent positioned in the sigmoid colon with recovery of intestinal transit.

Before stent placement, all the patients underwent one or more colonic enemas, depending on the site of obstruction for cleaning the colon below the stricture. The patients were placed in the supine position only using a suitable combination of intravenous medication appropriate for a colonoscopic procedure as sedation and analgesia. There was no routine

administration of antibiotics. Vital signs (pulse rate and oxygen saturation) were monitored continuously.

As regards the stent placement technique used, once the colonoscope was inserted, a water-soluble contrast media was injected for careful assessment of the length and the morphology of the stricture by fluoroscopy. Then, an Amplatz superstiff guidewire (Boston Scientific Microvasive, Minnesota, USA) was inserted through the colonoscope channel and advanced as far as possible into the proximal bowel, and kept *in situ*. The instrument was then removed and reinserted adjacent to the wire. The stent was then deployed over the guidewire and across the stenosis. Using fluoroscopy, the stent was placed with each end equidistant from the tumor margins except for the first case. Deployment was performed under fluoroscopic and endoscopic guidance. Finally, endoscopic and X-ray images were used to assess the accuracy of the stent position.

Dedicated enteral stents were used (Enteral Wallstent/Precision Ultraflex endoprostheses). We chose enteral stents about 5 cm longer than the stricture, 1 or 2 cm of the stent to extend beyond both ends of the tumor.

We did not dilate the strictures before stent placement, except for the first patient, because neoplasms were not totally obstructing, but it should be remembered that this procedure could increase the risk of colonic perforation.

To determine the stent position and the relief of colonic obstruction until the patients were discharged, a conventional radiograph of the abdomen was obtained and changes in bowel gas patterns were analyzed within 24 h of stent placement and each subsequent day thereafter.

All patients tolerated the procedures well, which were technically successful.

There were no immediate technical complications associated with stent placement, and no perforation, major bleeding, or death related to endoscopic procedure. Each of the patient's symptoms improved immediately after stent placement with passage of stools and flatus from the anus. Initially the patients were able to take at least liquids, later they assumed a low-residue diet. The only delayed complication was dislodgment of 1 stent (25%) after one month.

The average survival time was 22.5 wk, and ranged from 6 to 48 wk. Two patients were alive at the end of the study period, two died because of the natural disease history. No patients showed clinical symptoms of obstruction at the time of death or termination of the study, all tolerated oral semi-solid feedings.

DISCUSSION

Malignancy is the major cause (85%) of acute colonic obstruction (ACO) and 10-30% of patients with colonic cancer had a large-bowel intestinal occlusion at presentation[1-3].

Therefore, not surprisingly, ACO is considered as a surgical emergency, traditionally treated with surgical intervention that, though effective, was associated with high morbidity (10-36%) and mortality (6-30%) rates[4].

Emergency surgery, mainly in acutely ill patients, often results in a diverting colostomy alone, which may be associated with a morbidity rate of 20-40% and a mortality rate of more than 10%[5].

Indeed, many of these patients have already reached an advanced stage of the disease at the time of diagnosis. For patients with advanced tumors no longer resectable, widespread metastatic disease, peritoneal carcinomatosis, unfortunately the only therapeutic options have been palliative, with colostomy being the only reasonable and often unavoidable surgical option[6]. Besides, many of these patients were elderly (up to 50% between 70 and 89 years old) and instable because of

significant co-morbidities, all this made them of high surgical risk[7-9]. Moreover this treatment option entailed a significant decrease in quality of life, with major psychological repercussions[10]. In addition, this unfortunate group of patients had short life expectancies (mean survival of patients who had hepatic metastases at the time of surgery was only 4.5 mo)[11] and it was of paramount importance to keep them out of hospital. So, it is therefore preferable to seek more comfortable therapeutic approaches.

The primary goal of a non-surgical approach for treating ACO is to avoid the need of emergency surgical treatment in non stabilized patients. Such non-surgical alternatives to colostomy as balloon dilation[12] and ablative methods (cryotherapy, electrocoagulation, laser photocoagulation)[13,14], have been used in inoperable patients or with unresectable tumors. Laser therapy (LT) has gained considerable support by virtue of reports of its high initial success in luminal diameter increasing. Nd:Yag laser therapy was considered the treatment of choice for endoscopic palliation of advanced rectal carcinoma. In 1986 Mathus-Vliegen reported a success rate of 85-95% (5, 15). The drawbacks of LT were expensive equipment, time consuming sessions, lack of immediate relief of symptoms, need for repeated sessions to maintain patency, needs to repeat sessions, even every 5 to 9 wk[12,16,17], significant (13%)[18,19] risk of major complications like stenosis, perforation[20], fistula (3.2%), abscess (1.7%) and bleeding (4.1%), as published by Gevers *et al*[21].

In conclusion, LT is affected by such shortcomings as the need to be repeated periodically to maintain patency and limited applicability restricted solely to selected patients[22] with tumors in distal locations.

In recent years, enteral stenting has emerged as an effective alternative to the surgical approach. However, the concept of colonic decompression using "stent" in obstructing colonic tumors, in the absence of peritonitis[23], is not new. Initial reports were published in the early 1990s with some promising results but containing only a handful of patients, Lelcuk in 1986[24] and Keen[25] in 1992 passed a nasogastric tube respectively through the tumor to relieve obstruction. In 1991 the first report describing use of a metal stent in the rectum was published by Dohmoto[26]. The following year, in a small series of four and two patients respectively, Spinelli in 1992[27] and Itabashi in 1993[28] confirmed the feasibility of inserting self-expanding metal stents for immediate relief of acute colonic obstruction due to rectal malignant tumors. In 1998 De Gregorio[29] published a large multicenter retrospective study (24 pts) evaluating the success of the placement of colorectal stents for palliation, reporting a 100% technical success and a 96% clinical improvement. Using various kinds of stent, in 25 patients, Baron's group[30] had less impressive results. They failed to put in the stents in 6% of their patients because of technical problems and only 85% of their stented patients had relief from obstruction.

The question as to which strictures by site are amenable to colonic endolumenal stenting (CELS) is not well addressed in literature by many authors. Similarly their description of the sites of lesions they have stented is unclear. The most commonly reported cases of CELS in literature were of lesions within the rectum and rectosigmoid, which was unsurprising as 70% of the obstructing colonic strictures were located in the left colon[1,31].

While the initial series excluded patients thought to have lesions located in difficult anatomical positions[32]. To date location has not appeared to be a limitation for CELS[30,33,34], neither did the length of the tumor. If the lesion was not successfully or totally covered by the stent, an additional stent could be placed.

Distal extent of disease does not limit suitability for

stenting, although lesions less than 5 cm from the anal verge (dentate line) might be inappropriate[35,36] and difficult to palliate with a metal stent, because of perianal trauma occurring due to stent irritation[37]. Despite the recent advances in stent technology, the search for the ideal enteral stent has not stopped. Enteral stents should be flexible enough to allow placement but should remain in position once deployed[38].

Initially since dedicated colonic stents were not available, a variety of stents originally designed for use elsewhere were used, as reported in literature studies, including the preferred enteral Wallstent®[39-41]. Others were Endocoil® (Euromed Inc), esophageal nitinol Strecker stent, Gianturco self-expanding Z-stent, Ultraflex® Instent Esophacoil®[28,30,34,39,40,42-45]. There was no noticeable difference in the outcomes using any of the above stents.

Metallic stents are of two types, expandable or self-expanding (so-called self-expanding metal stents, or SEMS). Because of their flexibility SEMS are easier to deploy than rigid tubes and allow peristalsis to continue, but they usually have a narrow lumen and are prone to tumor ingrowth. Some of these mesh type stents have been coated with polyurethane or other materials to prevent occlusion by tumor although this may increase the likelihood of dislocation. Covered stents have the advantage of resisting tumor ingrowth but tend to be less stable and more rigid, they require a larger delivery system, and are more likely to migrate. They are thus more difficult to deploy at distant locations through a tortuous delivery path[46]. Uncovered stents are more flexible, and at least one can be passed through the working channel of an endoscope. However, when used for long-term palliation of malignant obstruction, they are subjected to tumor ingrowth and resultant obstruction. Most authors now use SEMS made of nitinol, a nickel/titanium alloy, which has <<shape memory>> meaning that once deployed, it adopts a preformed shape, an advantage over expandable systems that require dilation. Stent technology is currently evolving rapidly, and devices are now being developed specifically for colorectal applications.

The mean technical success, defined as successful stent placement and deployment, ranged from 64% (40) and 100%[32,28,39,47]. Failure to stent deployment was usually a result of inability to pass a guide wire through a lesion, other reasons for technical failure, apart from tight or tortuous stenosis through which the guide wire could not be passed[30,34,40,44,45] included insufficient length of the stent to span the entire stricture, inadequate introducer lengths[30,44], floppy introducer system and incorrect deployment of the stent (42). A higher rate of successful stent placement could be achieved with more distal lesions. The most proximally placed stents described in literature till now have been in the right and proximal transverse colon[30,34].

The stent placement procedure is generally painless and neither anesthesia nor analgesia is provided. It was frequently sufficient to provide a suitable combination of intravenous medication for a simple colonoscopy procedure[9,17]. Clinical success, that is relief of obstructive symptoms, defined as colonic decompression within 96 h without endoscopic or surgical reintervention after stent placement (this time interval was chosen because it was integral to the definition used in nearly all the papers reviewed) has been reported in 75-96%[2,23,30].

Stent placement complications were common to many authors, distinguishing the early from late ones. In previously published series[9,29,34,45,48] the complication rate has been reported to range from 14% to 42%, most complication being minor. In the literature surveyed these were successfully managed with medical or supportive treatment in the majority of cases. Less seen complications included minor rectal bleeding, anorectal pain, temporary incontinence (11%)[42], fecal impaction (8%)[40] and severe tenesmus. Rectal bleeding

(0-100%) was usually hemodynamically insignificant and self-limited. It could result from mucosal irritation, pressure necrosis of the stent in the colonic mucosa, or friability of the tumor itself[49]. Anorectal pain (5-100%) might occur and was usually mild and transient, lasting for only 3-5 days, it was easily controlled by analgesia[39,45,49]. Severe tenesmus occurred during the first 48 hours and might be controlled with non-steroid anti-inflammatory drugs. It seemed to be related to insertion of the stent in a lower portion of the rectum[50]. However, Camuñez[51] described a patient who was readmitted twice because of persistent analgesic therapy, and was offered a colostomy which ultimately was refused.

Stent migration, restenosis, and perforation were the major complications encountered with colonic stent placement. Stent dislocation (0-44%) and obstruction (0-33%) were reported as the most common major complications described, but are not usually serious. Stent migration has been reported to occur in as many as 40% of cases and was usually detected on follow-up radiographs within 1 week of insertion. Camuñez[22] believed the cause of stent migration was shrinkage of the tumours as a result of adjuvant chemotherapy. Generally, it appeared that predisposing factors included inappropriate stent selection as covered stent or those with too narrow diameter (with weak radial expansive strength), colonic angulation and post-operative chemotherapy or radiation therapy[38,49,52]. Consequently, specific monitoring to check for possible reduction in tumor size and assess the advisability of stent extraction, is recommendable in patients receiving adjuvant therapy. When stent migration occurred, the stent might generally be passed spontaneously or require endoscopic removal and redeployment[49]. Some stents which became dislocated and were expelled did not necessarily require replacement, since bowel function was adequately maintained.

Restenosis has been reported in up to 25% of cases and was usually due to malpositioning of the stent, as well as impaction with stool or food matter (it has been recommended that patients with colorectal stent ingest a low-residue diet and use stool softeners to lessen the likelihood of stent obstruction)[38,53] but especially tumor ingrowth. Stent obstruction was usually amenable to a variety of nonoperative measures such as further coaxial restenting[30] and laser therapy[42]. However it would be interesting to point out that in Dohmoto' study 15% of patients needed a palliative colostomy to treat stent occlusion related to tumor ingrowth.

Restenosis due to tumor overgrowth (extension of tumor above or below the stent) could also be treated with a second stent. It could be best prevented by deploying the original stent 2-3 cm above or below the lesion when possible.

The most serious and potentially devastating complication of colonic stent placement was colonic perforation, reported in 0-16% of cases[49,54,55]. Perforation can be either early or late, it should be suspected in patients who complain of abdominal pain during or immediately after the stenting procedure. Colonic perforation may have different causes, related either to the method itself or to the stent. One of the major causes is excessive balloon dilation of the stricture, causing full-thickness tear of the mucosa. Baron *et al*[30] reported colonic perforation in four patients, associated with balloon dilation of the stricture at the time of stent placement in three of the patients. Without balloon dilation, perforation rate might fall below 5%. Therefore, this practice is no longer recommended[56], and stents are allowed to slowly self-expand.

Fortunately, it is possible to achieve stent placement even in patients with tight strictures without employing dilatation when modern stents are used. In addition, as perforation is more likely to occur during guidewire manipulation, the introduction of a wide range of soft-tipped guide-wires may contribute further to prevention of perforation. In the experience

of many authors[34,44,22] perforation due to manipulation of guidewires and catheters has been asymptomatic, and it has been possible to complete the procedure in all cases. Late perforation could occur (though it is rare) due to pressure necrosis and erosion through the colon. Histologically, the side of the cancerous lesion compressed by the stent was thin and consisted of a serosal layer alone. Granulomatous change was detected histologically in normal mucosa that was in contact with the metallic stent. These histological changes were caused by direct compression or ischemic damage due to the self-expanding stent. Therefore, if SEMS is inserted in patients with complete obstruction due to advanced carcinoma infiltrating the serosa, Kusayanagi' s experience suggests that a risk of perforation might develop approximately 2 months later[49,57]. Several authors concluded that the possibility of colonic perforation as a potential complication must be kept constantly in mind and that consequently close clinical observation was required particularly in the days immediately following stent placement[22].

Because of the continual changes in design, it is difficult to compare complication rates among different kinds of stent. However, some general conclusion may be drawn. The decreasing diameters of delivery systems make perforation a rare occurrence, and it is generally related to pre-stenting treatments.

Indeed, certain authors, prior to stent placement, pretreated the neoplastic strictures endoscopically first to canalize an obstruction using laserltherapy[17,48], argonplasma or coagulation, others used mechanical dilatation with endoluminal balloon catheters[30,41]. Nevertheless, the added efficacy of these approaches is unproven, and certainly they increase the risk.

Patients stented for palliation usually underwent clinical follow-up, conventional abdominal radiographs were obtained at monthly intervals. Period of patency was defined as the period from stent placement to the recurrence of symptoms of obstruction in clinically successful cases[58]. No absolute data exist on the mean time to occlusion of stents, also because this procedure has been carried out in a small total number of patients in the same short follow-up periods. Hence, assessment of stent patency and long-term behavior are difficult to define and data coming from literature are wide-ranging. Thus, according to Baron[30], stent duration ranged from 2 to 64 wk (mean 17.3 wk). Kusayanagi' s data[57] was also in this range. According to him the mean time before re-obstruction was approximately 10 wk and the median follow-up for Repici[59] was 21 wk (range 1-46). Moreover, no recurrence of obstruction was observed during the follow-up period. For Camuñez[51] follow-up lasted an average of 138±93 d (range: 36-334 d), and the estimated primary stent patency rate was 91% at 3 and 6 mo. Even for mortality rate existing data in literature are controversial. For some authors[17,60] no deaths have been reported directly attributable to the stenting procedure, on the contrary, Spinelli[48] had a mortality rate of 3%.

Until now we have seen that, when LBO due to cancer has progressed beyond the stage of any curable intervention, there are only two options to relieve the obstruction by colostomy or by use of a stent, since both are capable of relieving acute obstruction and stenting clearly offers a preferable quality of life. Another important issue to consider is their cost, considering the fact that the principal cost determinants for the stenting option was the cost of the stent itself and the duration of in-hospital treatment[61,62]. Few publications examined the cost impact of stenting compared to surgical decompression. One study[34], concerning the cost of the stenting procedure compared with a control group undergoing only surgical treatment for malignant colorectal obstruction, showed that the overall cost of treating the stented group was 19.7% lower. According to Zollikofer' s data [63], a British

study[64], comparing the cost of management by stenting 16 patients with acute large bowel obstruction with 10 unselected patients previously managed by surgical decompression, estimated that the cost of a palliative care was less than half of that of a surgically decompressed case. These cost savings were due mainly to the shorter hospital stay associated with stenting. Other factors were fewer surgical procedures, reduced operating time and fewer days in intensive care room. On the other hand, these data have much more relevance considering that the often hidden cost of stoma care in the community cannot be overlooked, about Euro 100 per mo is required for disposable stoma bags for each patient.

CONCLUSION

Malignant neoplasm of the left colon and rectum may lead to bowel obstruction in 10% to 30% of cases. Acute malignant obstruction of the large bowel is considered as a surgical emergency. Controversy currently exists as to optimal approach among surgical and nonoperative techniques in the case of patients with unresectable cancer or with a high ASA-grade. Physicians are often faced with the dilemma of finding the right balance between the need for timely aggressive intervention and the patient' s underlying debilitated state. Recently several reports have indicated that, to reestablish luminal patency, the use of a stent may be a valid alternative to traditional surgical approach often consisting of a definitive colostomy. This treatment option entails serious disadvantages, namely substantial morbidity, and an obvious decrease in quality of the remaining life, with important psychological repercussions. The stent insertion is a combined endoscopic-radiologic technique that enables decompression of acute colonic obstruction with immediate restoration of bowel function, allowing all the pathophysiologic changes of obstruction to reverse. This procedure is feasible and successful in fully relieving the obstruction in almost all cases. Neither balloon dilation nor laser therapy is universally recommended prior to colorectal stenting to canalize a neoplastic obstruction, because of unproven efficacy and certainly increased risk.

We believe that the advantages of minimally invasive management of malignant acute large bowel obstruction are of particular and clear interest for geriatric population, because many of them often are not particularly good surgical candidates and so they are not suitable for definitive curative surgery.

In our experience there is evidence that is possible to stent a tumor in more proximal difficult tract like the left transverse colon near the splenic flexure. In the future stent technology and design will continue to evolve with the aim of improving safety parameters. In addition to this, the suggestion that stents impregnated with chemotherapeutic agents or composed by radioactive wire, may also help the tumor growth control, represents a very exciting area of interest.

Surgeons should become familiar with this technique, since it offers an alternative to surgical therapy for patients in critical general conditions, improving their quality of life and reducing the costs of the whole treatment. Therefore, we recommend that enteral stenting be considered as an alternative to traditional surgical therapy for definitive palliation in patients with malignant enteral obstruction.

Abstract

A 74-year-old man was admitted to the hospital because of chemotherapy for relapsed non-Hodgkin's lymphoma (NHL). The patient became febrile and experienced diarrhea after chemotherapy. Although ceftazidime and amikacin sulfate were administered as empiric therapy, diarrhea was continued. After several days, stool cytotoxin assay for clostridium difficile (*C. difficile*) was positive and he was diagnosed as having antibiotics-associated colitis (AAC). Although antibiotics were discontinued and both oral vancomycin and metronidazole were administrated, disease was not improved. To rule out the presence of an additional cause of diarrhea, colon fiberoscopic examination was performed. It revealed multiple deep ulcerative lesions at right side colon, surface erosive and minute erosive lesions in all continuous colon. Pseudomembranes were not seen. These findings are compatible with AAC without pseudomembranes. There are no reports that the rifampin is effective on refractory AAC. However, we administered oral rifampin for the current patient. The reasons are 1) conventional antibiotics were not effective, 2) rifampin has excellent *in vitro* activity against *C. difficile,* and 3) the efficacy of rifampin on relapsing colitis due to *C. difficile* is established. After administration of rifampin, fever alleviated and diarrhea was improved. Because AAC may result in significant mortality, patients with refractory or fulminant AAC should be treated with oral rifampin from outset.

INTRODUCTION

Antibiotics-associated colitis (AAC) due to *clostridium difficile* (*C. difficile*) is a nosocomial infection that may result in significant morbidity and mortality. AAC is capable of causing toxigeneic colitis in susceptible patients such as those receiving chemotherapy. Approximately, 50% cases having endoscopic evidence of pseudomembranous colitis revealed exudative and puntate raised plaques with slip areas. The remainder had milder degrees of colitis without pseudomembranes[1,2]. The clinical features of AAC without pseudomembranes are thought to be similar to those seen with pseudomembranes colitis, but of less severity[3,4]. Patients with mild colitis are improved only by discontinuation of antibiotics. However, most patients are now treated with vancomycin (VCM) or metronidazole capable of eradicating *C. difficile* infection because of high mortality from AAC. The typical response to VCM therapy is improvement in diarrhea within a few days.

The recommendation is not established for patients with fulminant AAC. Colectomy may be life-saving in patients with severe AAC who fail to respond to antibiotic therapy. However, the surgical mortality is approximately 50%[5].

We described a refractory patient having AAC without pseudomembranes. This patient was refractory to metronidazole and VCM. We administered oral rifampin for the current patient and he gained improvement. This is the first report that rifampin is effective for refractory or fulminant AAC.

CASE REPORT

A 74-year-old man was admitted to our hospital in May 2002 because of chemotherapy for relapsed non-Hodgkin's lymphoma. He presented a huge mass of NHL at lumber. He was treated with 3 courses of VeMP combination chemotherapy[6]. After the first VeMP chemotherapy, he complained of diarrhea. Fosfomycin calcium (FOM) was administered and diarrhea was stopped. There was no side effect during the second course of VeMP chemotherapy. During the third chemotherapy, he became febrile without diarrhea, we administered ceftazidime (CAZ) and amikacin sulfate (AMK) as empiric therapy. Fever alleviated immediately. Considering the high frequencies of relapse in patients treated with VeMP, we stopped VeMP therapy and started CHOP therapy (cyclophosphamide, adriamycin, vincristine, and predonisolone) on 6 August. Because the patient became febrile and experienced diarrhea from d 4, we administrated lactomin. On d 8, the patient developed massive watery diarrhea (over 1 500 mL/d) with exacerbation of fever, respiratory distress and marked hypovolemia. Ultrasound examination revealed massive ascites and pleural effusion. Although bolus methylprednisolone was administered promptly and CAZ and AMK as empiric therapy, the patient remained febrile and watery green diarrhea was not controlled. Salmonella, Shigella, campylobacter, cryptosporidium, fecal viruses and parasites were negative in repeated stool cultures. Because *C. difficile* toxin was detected using an enzyme immunoassay (Meridian Diagnostics, Inc., Cincinnati, OH, USA) in stools on day 13, the patient was diagnosed as having AAC. Although CAZ and AMK were stopped and oral VCM and metronidazole 250 mg

daily were started concomitantly, symptom did not improve. Colonoscopic examination revealed multiple deep ulcerative lesions at right side colon, surface erosive and minute erosive lesions in all continuous colon. Pseudomembranes were not seen. Biopsy reveals an outpouring of fibrin, mucus, and inflammatory cells from a microulceration of the surface epithelium. These findings are compatible with AAC without pseudomembranes. Because VCM and metronidazole were not effective, the enteral use of rifampin 600 mg twice daily was started on d 23. In the following several days, fever alleviated and diarrhea was improved (Figure 1).

Figure 1 A: Multiple deep ulcerative lesions at right side colon, B: Surface erosive and minute erosive lesions in all continuous colon, C: After administration of rifampin.

DISCUSSION

We described a patient having refractory AAC without pseudomembranes. The current patient presented severe watery diarrhea, malaise, fever, leukocytosis and dehydration. Administration of VCM and metronidazole was not effective. Some treatment regimens as the second therapy for refractory AAC have been tried, but none has been completely effective in randomized clinical trials. Although there have been some reports of the efficacy of oral teicoplanin for the treatment of antibiotics-associated colitis[7,8], oral teicoplanin is not available in Japan. Colectomy was not required, because the current patient had a substantial comorbid disease and was extremely ill.

Rifampin had excellent *in vitro* activity against *C.difficile* with minimum inhibitory concentrations averaging <0.2 µg/mL[9,10] and the efficacy of rifampin on relapsing colitis due to *C. difficile* was established[11]. Thus, we administered rifampin 600 mg twice daily. Diarrhea and abdominal pain resolved promptly. Although there are no reports that rifampin is a useful agent for refractory and severe AAC, patients should be treated with oral rifampin from the outset.

Abstract

Inflammatory fibroid polyp is one of the chronic inflammatory diseases in the digestive tract, which often mimics the submucosal tumor. Precise diagnosis is possible after removal of the detected lesion. Endoscopic removal is recommended as a safe and efficient method of the treatment. In this report the authors present a case of inflammatory fibroid polyp located in the cardia, which has been removed endoscopically. Twelve months later, recurrence of the lesion was noted and the patient was referred to surgical resection.

INTRODUCTION

Inflammatory fibroid polyp (IFP) in the digestive tract is one of the chronic inflammatory diseases, which most often is located in the stomach. Precise diagnosis of IFP remains difficult because available methods such as barium swallow or even endoscopy with endoscopic ultrasonography (EUS) provide only nonspecific, insufficient information. Some cases of IFP can macroscopically mimic gastric cancer[1,2]. Hence, it is most important to exclude malignancy by histology on the detected lesion. In the case of submucosal lesions, standard biopsies are insufficient in obtaining adequate diagnostic tissue. Then endoscopic tumor excision or polypectomy is recommended. However the curative significance of endoscopic treatment in patients with IFP is still under discussion. We would like to report a rare case of IFP, localized within the esophago-gastric junction, which recurred 12 mo after endoscopic removal.

CASE REPORT

A 48-year-old male with symptoms of dysphagia for solids and epigastric pain of moderate intensity, lasting for 3 weeks, was admitted to the hospital. No weight loss was noted. The patient had no history of any other diseases including parasites and allergies. No abnormalities were found upon physical examination and laboratory results (hematology, serum biochemistry, urine analysis) were within normal ranges. Gastrofiberoscopy revealed an elevated, round, polypoid tumor, 15×20 mm with small ulceration in the center filled

with necrotic tissue (Figures 1, 2). The tumor was located exactly within the esophagogastric junction and significantly reduced the lumen of the cardia. The surface of the lesion was covered with hypertrophic mucosus. On retroflexion, the tumor was entirely within the confines of the stomach, suggesting the possibility of complete endoscopic excision (Figure 3). EUS showed a low echoic but rather homogenous tumor which did not invade the muscular layer. No other pathologies in the upper part of gastrointestinal tract were found. Endoscopic biopsies showed normal mucosa and attention was directed to endoscopic removal. Macroscopically radical endoscopic excision of the tumor, completed with argon plasma coagulation of its basement was performed under general anesthesia, and removed lesion was investigated by pathologists. Histological examination revealed a superficially ulcerated and well-circumscribed but nonencapsulated submucosal tumor, which extended partly into the cardiac mucosa. The tumor was composed of fibrous tissue with abundant small blood vessels and numerous eosinophils admixed with plasma cells and lymphocytes (Figure 4A,B). The lymphoid aggregates were also occasionally seen within the tumor and in adjacent tissues (Figure 4B). The inflammatory fibroid polyp was diagnosed. One day after the endoscopic procedure, the patient was discharged from the hospital with no postoperative complications noted.

Twelve months after the treatment, the patient was admitted to the hospital with the same symptoms as previously. Gastrofiberoscopy revealed the presence of the tumor in the cardia with an endoscopic appearance mostly as described above. The recurrent tumor was larger, 25×39 mm as shown on barium contrast radiography, and was more proximally located. In light of these findings the patient was referred to surgical treatment. Proximal gastrectomy with local lymphadenectomy, via laparotomy and distal esophagectomy via right thoracotomy with esophago-gastrostomy within the posterior mediastine were performed. Histological appearance of the recurrent tumor was identical with the first one. Postoperative course was uneventful and the patient was discharged 15 d after surgery. No significant changes within 4-mo follow-up were observed. Follow-up fiberoscopy performed 3 mo after the surgery showed no pathological signs within the esophago-gastrostomy.

Figure 1 Endoscopic view of inflammatory fibroid polyp (IFP) located in cardia. An elevated, round, polypoid tumor can be seen.

Figure 2 Inflammatory fibroid polyp of cardia. A small ulceration can be seen in the center of the lesion filled with necrotic tissue.

Figure 3 Retroflexion of endoscope. The tumor is indented into the stomach.

Figure 4 Histologic appearance of primary inflammatory fibroid polyp of cardia. A superficially ulcerated tumor can be observed involving cardiac mucosa and submucosa, and consists of fibrovascular tissue as well as numerous eosinophils admixed with plasma cells and lymphocytes. (HE; A: magn. ×100; B: magn. ×200).

DISCUSSION

In 1953 Helwig and Rainer proposed the term of inflammatory fibroid polyp for eosinophilic granuloma of the stomach which presently is generally accepted[3]. IFP arises from submucosa of the gastrointestinal tract. It consists of loose connective tissue with a rich vasculature and abundant fibrous component. Usually the lesion was sessile or polypoid with ulceration of the overlying mucosa[4]. IFP was mainly located in the pyloric region of the stomach, less frequent in the ileum, and only occasionally in the colon or esophagus[4-6]. Small lesion is usually asymptomatic until pyloric stenosis or small bowel obstruction occurs. In the case described in the present report, a relatively small IFP was detected due to symptoms of

dysphagia. Its localization in the esophago-gastric junction has not been reported previously. Although IFP was nonneoplastic in nature[4,6], its cause remains unclear. Fibroblastic[4] or vascular origin of IFP[7] has been considered. Eosinophilic infiltration which sometimes may occur as a submucosal tumor was also related to parasitic infections such as gastric anisakiasis[8,9].

However, endoscopists should always suspect submucosal mesenchymal tumors of being gastrointestinal stromal tumor (GIST), leiomyoma or leiomyosarcoma especially when tumor macroscopically mimics a malignant lesion. Biopsy specimens using standard forceps may not be adequate for histological diagnosis when tumor is covered with normal mucosa. Then endoscopic excision/polypectomy preceded with EUS should be the best diagnostic method. There were some reports concerning the curative role of endoscopic removal of IFP[10-12]. However, our results indicate the possibility of local recurrence of IFP after endoscopic treatment. Thus we recommend endoscopic removal as the most valuable diagnostic method for providing the specimens to accurate histological assessment. It may be reserved as the curative procedure in elderly and high-risk patients as has been proposed previously[11] and should be repeated if necessary. Elevation of the tumor after submucosal saline or xylocaine injection can be helpful in making decision of endoscopic removal, and may indicate the possibility of complete, radical dissection. In other cases, minimal invasive surgery, *i.e.* laparoscopic resection, may be considered. To date only a single report has been available about recurrent eosinophilic granuloma of the ileum in a 2-year-old child[13].

Abstract

This is a rare case of a patient with mental disorder, who ingested nineteen pieces of fragmented bamboo chopsticks. We managed the multiple gastric foreign bodies with a sclerotherapy overtube, and these multiple fragmented bamboo chopsticks were retrieved successfully using the endoscopic method. There were only multiple erosions with hemorrhage over the mucosa of fundus and body of stomach, no fragments adhered or perforated through the gastric wall. The mucosa of esophagus was intact. The patient tolerated the procedure well and without any major complications. Multiple sharp elongated gastric foreign bodies can be successfully and safely retrieved by using protective sheath of oropharynx without assistance with laparoscopy or surgical intervention. This renders an option for the endoscopists to manage multiple elongated gastric foreign bodies.

INTRODUCTION

Foreign body ingestion is a common problem in the emergency department. Most ingestions may be accidental, but may also be a result of contributory factors as mental disorder, bulimia, alcohol consumption, and prison inmates[1]. When foreign bodies are ingested, they will usually pass spontaneously through the whole alimentary tract and out to the feces. The risk of perforation of gastrointestinal tract is only 1%[2]. Ten to twenty percent of the objects will have to be removed endoscopically, about 1% will require surgery[1]. However, sharp and pointed foreign bodies, as well as elongated materials in the stomach, can be very challenging and difficult to manage by endoscopy. Long and sharp foreign bodies should be removed immediately before they pass from the stomach to the intestine, as 15% to 35% of them will cause intestinal perforation[3]. Elongated materials such as toothbrushes, toothpicks, and bones are the most common foreign bodies in the stomach that require surgery for their removal[4,5]. Here, we report a rare case of a patient with mental disorder, who ingested nineteen pieces of fragmented chopsticks. The problem was treated successfully using the endoscopic method.

CASE REPORT

The case of a 24 year-old man had a history of substance dependence. He had used amphetamine for years, intermittently in the first three years and thereafter nearly everyday. As he developed a physical tolerance to amphetamine, he then turned to alcohol abuse. He was admitted to a psychiatry ward because of his drug and alcohol addictions. Two weeks after he was discharged from the psychiatry ward, he stayed at home doing nothing and continued alcohol abuse. His mother described his behavior as being mood swinging from depression to mania. He suffered from insomnia, having had hot temper, restlessness, to being bed-ridden and mental disturbed. He was forced by his mother to admit to a daytime psychiatric ward again for substance dependence. After admission, he committed to suicide by swallowing fragmented bamboo chopsticks. His roommate found that he swallowed small pieces of chopsticks and complained of epigastric pain 4 d after admission. The nurse was notified and called the doctor to check him up. As the patient stated that he began to swallow in fragmented bamboo chopsticks piece by piece at meals 4 d before. On physical examination, his abdomen was found to be soft, but he had tenderness over the epigastric area, and he produced a normally active bowel sound. A plain abdomen radiography didnot show foreign body. An upper gastrointestinal panendoscopy was performed on March 14, 2000 to ascertain if he had indeed ingested chopsticks. In the left lateral decubitus position, the patient was given local anesthetic. Afterward, he was given intravenous hyoscine-N-butylbromide (20 mg) and sedated with intravenous midzolam (5 mg). There were food residues mixed with plenty of fragmented bamboo chopsticks with one or two sharp ends in the fundus and body of the stomach (Figure 1). We placed a "flexible overtube" (Sumitomo®, Japan) through the mouth to esophagus and used Dormia basket to grasp the blunt end of fragmented bamboo chopsticks out of the overtube. The blunt ends were grasped tightly at the uppermost part, and withdrawn through the esophago-cardiac junction without any difficulty. Small fragments could be easily and repeatedly passed through the esophagus into the channel of the overtube, whereas the larger fragments (more than 10 cm long) stuck at the oropharnx where the angle is almost rectangular (Figure 2). To remove the long fragments we withdrew the gastroscope together with the overtube. Since five of the fragments were more then 10 cm, we repeated this operation 5 times. Sumitomo®overtube which is quite flexible and elastic could be passed through the oropharynx to the esophagus repeatedly and easily without causing injury to the esophagus. The fragmented chopsticks were mixed with food debris, making blunt ends difficult to be found and grasped. It took 2 h to accomplish the procedure. In all, a total of nineteen fragmented bamboo chopsticks were retrieved (Figure 3). After removal of the fragmented bamboo chopsticks, the esophagus and stomach were thoroughly examined. There were multiple erosions and hemorrhage spots over the mucosa of the fundus and the body, fortunately no fragment pieced through the gastric wall. The mucosa of esophagus was intact. The patient was observed for 2 d, he had no complaint except mild epigastric pain that could be controlled by antacids. He was referred for psychiatric evaluation and discharged uneventfully.

Figure 1 Plenty of fragmented bamboo chopsticks mixed with food debris in fundus and body of stomach.

Figure 2 Impaction of a large piece of fragmented bamboo chopsticks (more than 10 cm long) impacted in channel of Sumitomo sclerotherapy overtube (Simulate picture).

Figure 3 Retrieval of nineteen fragmented bamboo chopsticks.

DISCUSSION

About 80% to 90% of small indigestible objects that entered the stomach could eventually pass through the intestinal tract. However, sharp foreign bodies might lodge in the esophagus and lead to esophageal perforation, retroesophageal abscess, mediastinitis, and esophagoaortic fistulae[4]. It was very difficult to remove sharp and pointed foreign bodies, as well as elongated objects in the gastrointestinal tract by endoscopic management and they have become a technical challenge[5]. Objects that are longer than six centimeters are difficult to pass through the duodenal sweep. If the objects are greater than two centimeter in diameter, they may not pass through the pylorus. Ingested objects longer than six centimeters in children or 13 centimeters in adults should be promptly removed endoscopically due to the high incidence of penetration and entrapment in the bowel[6]. Up to 15% to 35% of sharp and pointed foreign bodies ingested would penetrate the wall of the gastrointestinal tract[3]. Indicating that when a sharp or pointed foreign body is found in the stomach or duodenum during an endoscopic evaluation, emergent endoscopic removal of the foreign body is mandatory, even if the patient is asymptomatic.

Adults ingesting pointed objects are mostly prisoners or psychiatric patients, and carried a higher complication rate and surgical rate than when that of accidental ingestion. In the review of Gracia *et al.*, there were 22 deliberate ingestors, five of whom had complications of perforation. There was also a high rate of endoscopic failure, up to 80%[7]. Bamboo chopsticks are commonly used in China and Far Eastern Asia. In this present case, the young psychiatric patient swallowed fragmented bamboo chopsticks to attract attention of others.

We have tried using the Dormia basket to hold the blunt ends of the fragments and remove them piece by piece, but we failed to remove them because the long bamboo chopsticks would get trapped at the oropharynx. Sometimes the grip of the Dormia basket would be lost when it passed the oropharynx. The endoscopy overtube technique is especially useful in extracting multiple foreign bodies at one time. It could facilitate rapid reinsertion of the endoscope after each retrieval and protect the esophageal mucosa as well as cricopharygeus muscles from injury[8,9]. Werth *et al.* used a protective Terblanche sclerotherapy overtube to remove multiple gastric foreign bodies[10]. Yong *et al.* removed a dinner fork from the stomach by using a double snare method to align the axis of the objects and facilitate its withdrawal[11]. Wishner *et al.* recommended laparoscopy assisted removal via gastrostomy to remove a swallowed toothbrush[12].

In this case, there were multiple fragmented bamboo chopsticks with various lengths. They measured up to 10 cm each with a sharp broken end. The long chopstick could only be retrieved along with the overtube, because the long chopstick and Dormia Basket could have entrapped in the inner channel of the overtube at the oropharynx level. As a result, repeated intubations of the overtube were necessary. Fortunately, these gastric foreign bodies were successfully and safely retrieved without assistance with laparoscopy or surgical intervention. Therefore, we recommend using repeated insertion of Sumitomo® sclerotherapy overtube, which is flexible and easy to pass through the oropharynx, to extract the ingested sharp foreign bodies. The maneuver is safe although time-consuming. This renders an option for endoscopists to manage multiple elongated and pointed gastric foreign bodies.

Abstract

AIM: To study the role of hypermethylation in the loss of retinoic acid receptor *b₂* (*RARb₂*) in esophageal squamous cell carcinoma (ESCC).

METHODS: The role of hypermethylation in *RARb₂* gene silencing in 6 ESCC cell lines was determined by methylation-specific PCR (MSP), and its methylation status was compared with *RARb₂* mRNA expression by RT-PCR. The MSP results were confirmed by bisulfite sequencing of *RARb₂* promoter regions.

RESULTS: Methylation was detected in 4 of the 6 cell lines, and the expression of *RARb₂* was markedly downregulated in 3 of the 4 methylated cell lines. The expression of *RARb₂* was restored in one *RARb₂*-downregulated cell line with the partial demethylation of promoter region of *RARb₂* after 5-aza-2′-deoxycytidine (5-aza-dc) treatment.

CONCLUSION: The methylation of the 5′ region may play an important role in the downregulation of *RARb₂* in some ESCC cell lines, suggesting that multiple mechanisms contribute to the loss of *RARb₂* expression in ESCC cell lines. This study may have clinical applications for treatment and prevention of ESCC.

INTRODUCTION

Retinoids, the important factors in modulating cell growth, differentiation, apoptosis and suppressing carcinogenesis *in vitro* and *in vivo*, are a group of natural and synthetic vitamin A analogs. In many animal models, such as cancers of skin, lung, prostate and esophagus, retinoids could suppress or reverse epithelial carcinogenesis[1]. The effects of retinoids are mainly mediated through two classes of nuclear receptors: the retinoic acid receptors (RARs) and retinoid X receptors (RXRs) which belong to a steroid/thyroid hormone-receptor superfamily. Each of them is composed of 3 subtypes (α, β and γ), of which *RARb* is expressed as three isoforms: *b1*, *b2* and *b4*[2]. Most human cells express *RARb2* as the major isoform. Many studies have confirmed that altered expression or function of the retinoid receptors may be related to malignant transformation of human cells[3,4].

RARb2 was decreased in many tumors, including lung carcinoma, breast cancer and esophageal cancers[5-7]. A study of esophageal cancer demonstrated that loss of *RARb* expression was an early event associated with esophageal carcinogenesis and the status of squamous differentiation[6], however the mechanisms underlying the inactivation of *RARb2* expression in cancer, especially the esophageal cancer, have not been well known yet. In breast cancer, no mutation or polymorphism was detected within the *b*RARE promoter, which was located in the promoter regions of target genes, and the lack of correlation between *RARb2* expression and LOH at chromosome 3p24 was demonstrated in esophageal cancer[8,9]. The *RARb2* promoter was characterized by an island, which was located in the 5′-untranslated region, and increasing data showed that aberrant methylation of the CpG islands in tumors was associated with transcriptional repression of tumor suppressor genes, such as *p*16 in esophageal cancer[10]. To clarify the epigenetic mechanism of *RARb2* loss or reduction in ESCC cell lines, we analyzed the methylation status of the *RARb2* promoter region by MSP assay and bisulfite sequencing. Our results indicated that downregulation of *RARb2* expression was associated with the aberrant methylation of the CpG islands in some ESCC cell lines, but not in others.

MATERIALS AND METHODS

Reagents and chemicals

5-aza-dc (Sigma, St. Louis, MO) was dissolved in pure ethanol at a stock concentration of 2 mM, and stored in aliquots at -70 ℃.

ESCC cell cultures and treatments

Six cell lines were used in this study: KYSE180, KYSE410, KYSE450, KYSE510, COLO680N, and TE12 were purchased from DSMZ (Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH). Each of the cell lines was cultured in either 90% RPMI 1640 medium (Invitrogen, Carlsbad, CA) or 45% RPMI 1640/45% Ham's F-12 medium (Invitrogen) with 100 mL/L fetal bovine serum at 37 ℃ containing 50 mL/L CO₂. In the demethylation experiment, the cells with lower *RARb₂* expression were treated with 5-aza-dc at a final concentration of 5 μmol/L for 96 h. The growth medium with or without the drug was changed every 24 h.

DNA preparation

The esophageal cell cultures were digested with trypsin-EDTA before collection. Genomic DNA from cell lines was extracted by proteinase-K digestion and phenol/chloroform extraction as described previously[11]. DNA was dissolved in TE buffer and stored at -20 ℃.

RNA isolation and semi-quantitative RT-PCR

Total RNAs were isolated from ESCC cell lines with Trizol reagent (Invitrogen) according to the manufactures' instructions. RNA quality was assessed with agarose gel electrophoresis and spectrophotometric analysis. Ten μg of total RNA of each sample was treated with 2 μL DNase I (10 units/μL, Promega, Madison, WI), 1 μL LRNasin (40 units/μL, Promega) at 37 ℃ for 15 min to remove contaminated DNA. First strand cDNA was reversely transcribed from 5 μg of total RNAs using SuperScript™ first-strand synthesis system for RT-PCR II kit (Invitrogen) at 42 ℃ for 80 min and 0.5-1 μL aliquots of the cDNA was then subjected to RT-PCR. The primers used for the amplification of *RARb2* were as follows: sense 5'-ATCGATGCCAATACTGTCGA-3', antisense 5'-GACTCGATGGTCAGCACTG-3' [8]. As, *GAPDH* was used as an internal control to ensure quality and quantity of cDNA for each RT-PCR. A product with 241 bp was generated, and PCR products were analyzed on 20g/L agarose gels. The PCR assay for each sample was repeated at least twice.

Methylation-specific PCR

Bisulfite modification of genomic DNA from primary esophageal cancer cell lines was carried out essentially as described previously[12]. Briefly, 2 μg of genomic DNA was denatured with freshly prepared NaOH (final concentration 0.3 mol/L) for 15 min in a 37 ℃ water bath, 30 μL of freshly prepared 10 mmol/L hydroquinone (Sigma) and 520 μL of freshly prepared 3.6 mol/L sodium bisulfite (Sigma) at pH 5 were added and mixed. The samples were then incubated under mineral oil for 16 h at 50 ℃. The modified DNA was purified with a Wizard DNA clean-up system (Promega). After purification, the samples were treated with NaOH (0.3 M) for 15 min at 37 ℃. The DNA was ethanol-precipitated and re-suspended in water for MSP analysis.

The bisulfite-induced changes affecting unmethylated (U) and methylated (M) alleles were detected by nested PCR. The primers for the first round PCR were as follows: sense 5'-AAGTGAGTTGTTTAGAGGTAGGAGGG3', and antisense 5'-CCTATAATTAATCCAAATAATCATTTACC-3' [13]. The amplification was performed under the following modified conditions: pre-denaturation at 95 ℃ for 5 min; 35 amplification cycles (denature at 95 ℃ for 15 s; annealing at 53 ℃ for 15 s; and extension at 72 ℃ for 30 s) and final extension at 72 ℃ for 5 min for the first round of PCR. The PCR products were diluted (1:10 dilution) and used in the second round of PCR with the primers: forward 5'-TTGAGAATGTGAGTGATTTGA-3', reverse 5'-AACCAATCCAACCAAAACAA-3' for the unmethylated sequence; and forward 5'-TCGAGAACGCG-AGCGATTCG-3', reverse 5'-GACCAATCCAACCGAAA-CGA-3' for the methylated sequences[14]. The amplification was performed under following conditions: pre-denaturation at 95 ℃ for 5 min; 35 amplification cycles (denature at 95 ℃ for 15 s; annealing at 52 ℃ for 15 s; and extension at 72 ℃ for 15 s for U-primers) and pre-denaturation at 95 ℃ for 5 min; 20 amplification cycles (denature at 95 ℃ for 15 s; annealing at 62 ℃ for 15 s; and extension at 72 ℃ for 15 s M-primers). DNA from normal lymphocytes was used as negative control for methylated alleles, and placental DNA treated *in vitro* with SssI methyltransferase (New England biolabs, Beverly, MA) was used as positive control for methylated genes. The product of 146 bp was generated, and the PCR products were analyzed on 25g/L agarose gels and photographed. The controls without DNA were performed in each set of PCR, and MSP assay for each sample was repeated at least twice.

Bisulfite sequencing

The PCR products amplified with primers specific either for the methylated or for the unmethylated DNA were purified and cloned into the pMD-T vector (Takara, Dalian, China) according to the manufacture's protocol. Recombinants were transformed into *Escherichia coli*. Plasmid DNA was isolated and integrated PCR fragments were verified by enzyme digestion and PCR. The cloned PCR fragments were further analyzed by automated sequencing (Bioasia, Shanghai, China).

RESULTS

Expression of RARb2 in ESCC cell lines

The expression of the *RARb2* mRNA was detected in the six ESCC cell lines by RT-PCR. Figure 1 shows representative examples of RT-PCR and MSP results. Markedly downregulation of *RARb2* expression was observed in the cell lines KYSE410, KYSE510 and COLO680N as shown in Figure 1A.

Methylation analysis of the RARb2 promoter region

Using MSP method, both the methylated and unmethylated alleles were found in the four cell lines except KYSE180 and TE12 in which only the unmethylated alleles were present (Figure 1B). The quantitation of the unmethylated or the methylated products varied in different cell lines. To confirm the reliability of the nested MSP method, PCR products amplified with primers specific either for the methylated (cell lines KYSE410) or for the unmethylated (cell line KYSE180) DNA were cloned and sequenced. Bisulfite sequencing of 4 individual clones of PCR products from cell line KYSE180 revealed no methylation of CpGs within the promoter region, whereas the methylated products showed dense methylation within the CpG islands in cell line KYSE410 (Figure 2).

Association between RARb2 promoter methylation and downregulation of its expression in ESCC cell lines

The reduction of *RARb2* mRNA expression was observed in three of the four cell lines that had partially methylated alleles, however the another one cell line showed strong *RARb2* gene expression, which suggesting that the aberrant methylation might play other roles except leading to gene silencing.

Restoration of RARb2 expression after 5-aza-dc treatment

To confirm whether *RARb2* promoter methylation could be further linked to downregulation of its expression, the cancer cell lines which showed evidently decreased expression of *RARb2* and cell line KYSE180 without methylated alleles were treated with the demethylating agent (5-aza-dc). To determine the effects of demethylating agent, we analyzed the methylation status in KYSE410 cells after 5-aza-dc treatment, and partial demethylation was detected by MSP as shown in Figure 3A. In addition, the MSP product was still observed after treatment because 5-aza-dc only inhibited methylation of newly synthesized DNA. The level of *RARb2* mRNA was not changed in cell line KYSE180 before and after demethylating treament. Among the three cell lines where *RARb2* genes were methylated, the treatment led to up-regulation of *RARb2* mRNA expression only in cell line KYSE410 (Figure 3B). The other two cell lines showed no detectable re-expression of *RARb2* mRNA after 5-aza-dc treatment (data not shown). These data indicated that *RARb2* promoter methylation was closely associated with downregulation of *RARb2* expression in some ESCC cell lines.
Figure 1 *RAR*β*2* expression and methylation in ESCC cell lines. A: RT-PCR analysis of *RARb2* expression, *GAPDH* was used as internal control. B: MSP analysis of *RARb2* promoter methylation status, (U) lanes and (M) lanes represent amplification of unmethylated and methylated alleles, respectively. *In vitro* methylated DNA (IVD) and normal human peripheral lymphocytes (NL) serve as positive and negative methylation controls, respectively.

Figure 2 Sodium bisulfite sequencing of *RARb2* in the cell lines that were found to include only unmethylated alleles (cell line KYSE180) or partial methylated alleles (cell line KYSE410) by MSP.

Figure 3 Treatment with the indicated concentrations of 5-aza-dc induced demethylation and *RARb2* mRNA expression in ESCC cell lines. A: MSP analysis shows partial demethylation of the *RARb2* promoter region after 5-aza-dc treatment. B: RT-PCR analysis of *RARb2* mRNA expression before and after 5-aza-dc treatment in cell lines that were found to have either positive (cell line KYSE180) or reduced (cell line KYSE410) baseline *RARb2* expression, *GAPDH* was used as internal control.

DISCUSSION

There were two major *RARb2* antineoplastic mechanisms in breast cancer cell lines, which were RA-dependent and RA-independent apoptosis[15,16], however little was known how *RARb2* performed its anticancer activity. A growing evidence indicated that *RARb2* was required for the growth inhibitory action of RA. In *RARb2*-negative cancer cells, RA-induced growth inhibition and decreased tumorigenicity could be restored by expression of *RARb2*; on the contrary, in *RARb2*-positive cancer cells, RA effects could be abolished by inhibition of *RARb2* expression[17-19]. Another study indicated that not only expression but also up-regulation of *RARb* was linked to retinoid sensitivity in esophageal cancer cell lines[20], and our previous study also suggested that RA resistance in EC109 cells paralleled with the loss of *RARb2* inducibility[21]. A clinical trial using N-4-(ethoxycarbophenyl) retinamide, a synthetic retinoid, demonstrated that cancer incidence among the treatment groups with severe esophageal dysplasia was decreased by 43.2% compared with the placebo group[22], whereas this was not the case for recent clinical trials of 13-cis retinoic acid in the treatment of advanced esophageal cancer patients, for which an explanation was that the loss of *RARb* expression could lead to the resistance to treatment with 13-cis RA in esophageal cancer[23,24]. Recent study suggested that hypermethylation of *RARb* might play an important role in the early stage of esophageal squamous cell carcinogenesis[25]. However, the mechanisms of *RARb2* suppression remained largely unknown in esophageal cancer.

Genetic and epigenetic mechanisms may be involved in progressive decrease in *RARb2* mRNA expression during esophageal carcinogenesis. *RARb* was localized on chromosome 3p24, and LOH occurred frequently on chromosome arm 3p in many cancers, including esophageal cancer[2]. However, no correlation was observed between the expression of *RARb* and the LOH on chromosome 3p24 in ESCC; moreover, no mutations or other genetic alterations were found in different cell lines without *RARb2* mRNA expression[9,26,27]. Thus, other mechanisms for *RARb2* suppression should be considered. DNA methylation, which led to the inactivation of all kinds of essential genes, such as *HLA class I, E-cadherin, FHIT* and *p16*, was an important mechanism for gene silencing or suppressing in ESCC[10,28-30]. In addition, Arapshian *et al*[31] concluded that methylation of the RARE region might be particularly important in *RARb2* suppression. Data presented in this report demonstrated that epigenetic silencing of the *RARb2* gene promoter might be an important event, and that downregulation of *RARb2* expression was closely associated with *RARb2* gene promoter methylation in some ESCC cell lines. In our study, of the three *RARb2*-downregulated cell lines, only the one poorly differentiated cell line showed evidently re-expression of *RARb2* with the partial demethylation of its promoter region, indicating that repression was, at least in part, mediated by methylation in the poorly differentiated cell lines, and multiple mechanisms were involved in the gene silencing in the other two cell lines. Our results suggested that a relationship between methylation status and decreased *RARb2* expression only existed in some differentiated ESCC cell lines or ESCC. Previous study has demonstrated that for breast carcinoma a relationship between methylation status and decreased *RARb2* expression in breast cancer was found only in invasive grade II lesions[13]. There was mounting evidence that suggested epigenetic modifications might be a mechanism responsible for the lack of *RARb2* expression in many epithelial cancers or cancer cell lines, such as breast cancer, colon cancer and prostate cancer[8,13,32,33]. Taken together the further analysis of the cytogenetic data of the cell lines, we found that there was

no deletion in 3p in the cell line exhibiting re-expression of *RARb2*. We therefore speculate that methylation may be at least one of the major mechanisms resulting in loss of *RARb2* expression in such cell lines. It has been reported that in ESCC cell lines without any structural alteration, hypermethylation at CpG sites was the important mechanism for transcription inactivation of the *FHIT* gene[30]. Given that the *RARb2* gene is recognized as a putative tumor suppressor gene, restoration of its function may have implications for both cancer therapy and prevention.

Notely, demethylation could only lead to the restoration of *RARb2* expression in 1/3 ESCC cell lines without 3p deletion, but not in the other cell lines with 3p deletion, indicating that there were other mechanisms, such as deletion, involved in the loss of *RARb2* expression in ESCC cell lines. It was reported that differential function of coactivators and corepressors might determine the level of *RARb* induction that might mediate retinoid action in colon cancer cells[34]. In lung cancer cell lines, loss of *RARb* gene expression was linked to aberrant histone H3 acetylation, so the aberrant acetylation status might have effects on *RARb2* expression[35]. In addition, orphan receptor COUP-TF have been identified to play a key role in modulating *RARb* expression and retinoid sensitivity in cancer cells[36]. Thus, multiple mechanisms may contribute to the loss of *RARb2*.

In conclusion, this study not only shows a high frequency of methylation of *RARb2* promoter region but also provides the first evidence that downregulation of *RARb2* is closely associated with DNA methylation in ESCC cell lines. These findings will be helpful to further understand the mechanisms underlying tumor progression in ESCC, and subsequently improve the prevention and treatment.

Abstract

AIM: To explore the expression of heparanase gene, CD44v6, MMP-7 and *nm23* proteins in human gastric carcinoma as well as their relationship with the clinicopathological factors.

METHODS: Reverse transcription polymerase chain reaction (RT-PCR) was used to measure the expressions of heparanase mRNA in 43 human gastric carcinomas and 10 adjacent normal gastric tissues. Streptavidin-peroxidase (S-P) two step method was used to measure the immunohistochemical expression of CD44v6, MMP-7 and *nm23* protein in 43 human gastric carcinomas.

RESULTS: The expression of heparanase gene was positive in 29 cases of gastric cancer with a positive rate of 67.4%, which was significantly higher than those in adjacent normal gastric tissues ($P<0.05$). The heparanase mRNA expression was significantly related to advanced stage of disease, serosal infiltration, lymph node metastasis and size of tumors ($P<0.05$), but not related to tumor location, gross and histological types of the cancer, peritoneal dissemination and liver metastasis ($P>0.05$). The positive rate of CD44v6, *nm23* and MMP-7 proteins was 76.7%, 37.2% and 60.5%, respectively. The CD44v6 protein expression was significantly related to serosal infiltration, lymph node metastasis and TNM stage of disease ($P<0.05$). The *nm23* protein expression was significantly related to the tumor gross appearance, lymph node and peritoneal metastasis ($P<0.05$). The MMP-7 protein expression was significantly related to serosal infiltration and TNM stage of disease ($P<0.05$). In an attempt to measure the association between these agents, we found that the expression of heparanase mRNA had significantly negative correlation with the expression of CD44v6 and MMP-7 protein ($P<0.05$), the expression of MMP-7 protein had significantly positive correlation with the expression of CD44v6 protein ($r=0.568$, $P<0.05$), the expression of MMP-7 protein had no correlation with the expression of *nm23* protein ($P>0.05$), and the expression of *nm23* protein had no correlation with the expression of CD44v6 protein ($P>0.05$).

CONCLUSION: Despite their different mechanisms of action, heparanase, CD44v6 and *nm23* may play important roles in the invasive infiltration and lymph node metastasis

in gastric carcinomas. Instead of metastatic spreading, MMP-7 may be just related to the invasion of gastric carcinomas. However, co-detection of these factors may be important to predict metastatic spreading in such patients.

INTRODUCTION

Invasion and metastasis of gastric carcinomas involve many processes including adherence, degradation, motility, and angiogenesis and escaping from immune surveillance. However, the penetration through the barrier formed by the basement membrane (BM) and extracellular matrix (ECM) is critical for invasion and metastasis of cancerous cells. This barrier is mainly composed of structural proteins and glycosaminoglycans. The former mainly includes collagen, laminin and fibronectin, whereas the latter chiefly consists of heparan sulfate proglycans (HSPGs) which is formed by a core protein and several covalent-binding heparan sulfate (HS) side chains. In the past decade, the damage of structural proteins has been considered to be a critical step for tumors' invasion and metastasis[1-3]. Previous researches mostly focused on property of some enzymes such as matrix metalloproteinases (MMPs) which use structural proteins as substrates. However, we should never neglect the effect of hydrolytic enzymes which use HSPGs as substrates, as well as their roles in degrading the BM and ECM. Heparanase is an endoglycosidase cloned out by Vlodavsky *et al* in 1999, which degrades the HS chain of HSPGs[1,2]. Recently, protein or messenger RNA (mRNA) expression of heparanase has been identified in various cancer cells, and the overexpression of heparanase protein or mRNA in tumour cells has been reported to correlate with the metastatic potential of tumour cells *in vitro* and *in vivo* as well as with poor prognosis[4-7]. However its role in gastric carcinomas is still not clearly clarified. In the present study, the expression of heparanase mRNA in gastric carcinomas and its correlation with clinicopathological features were investigated.

nm23, a metastasis suppressor gene, was reported to be associated with the tumor invasion and metastasis[8,9]. CD44v6, a highly glycosylated cell surface protein, was reported to be involved in cell-cell and cell-matrix interactions and thought to take part in cell motility, tumor growth, and invasion[10]. MMP-7, a member of matrix metalloproteinases family, was reported to play an important role in the degradation of connective tissue which is associated with the development of tumor metastases[11]. However, their roles in gastric carcinomas have not been clearly illustrated. In current study, CD44v6, *nm23* and MMP-7 protein expression in gastric carcinomas and their relationship with each other were also investigated.

MATERIALS AND METHODS

Patients

Between Oct 2002 and May 2003, 43 patients with gastric carcinoma underwent radical gastrectomy (D2 or D3), as subtotal or total gastrectomy in the Department of Gastrointestinal Surgery at the First Affiliated Hospital of Sun Yat-sen University. The age and sex of the patients, as well as the location, macroscopic type, histological grade, stage and depth of the invasion of the tumor, histological lymph node metastasis, and type of surgical procedures were retrieved from the patients' records. Pathological diagnosis and classifications were done according to the UICC standard published in 1997. Histological grouping based on UICC TNM classification was confirmed by histological examination.

mRNA extraction

The gastric tissues were obtained from those duly informed patients whose consents were obtained for the use of their subsequent resected tissues. The present study conformed to regulations of the Ethic Committee of the First Affiliated Hospital of Sun Yat-sen University. Tissue samples of approximately 1 g were collected immediately after each gastrectomy. Non-cancerous gastric tissues were obtained from regions distant from the tumours. Half of the both cancerous and non-cancerous tissues were fixed in 40g/L buffered formaldehyde and embedded in paraffin. Sections (4 mm thick) were prepared with haematoxylin-eosin staining for histopathological diagnosis and with immunohistochemical staining. The other half of the tissues was stored in RNAlater (Sigma, USA) at 4 ℃ overnight, then transferred to a clean freezing tube and stored at -80 ℃ for mRNA extraction. Before starting the study, histopathological examination had confirmed that no cancerous cells had contaminated the non-cancerous gastric tissues. Total RNA from tissues was isolated using RNeasy Mini Kits (Qiagen, USA) according to the manufacturer's protocol. Complementary DNA (cDNA) was synthesized from 2 μg of total RNA in a 25 μL reaction mixture. The 25 μL reaction mixture contained 2 μg RNA solution, 1 μL oligo d(T)18 (0.5 μg/μL), 1 μL M-MLV reverse transcriptase (Promega,USA), 1 μL RNasin ribonuclease inhibitor (Promega, USA) and 2 μL dNTP. The integrity of RNA was checked electrophoretically and quantified spectrophotometrically.

Real-time reverse transcription[6,12,13]

The following primers such as forward primer 5'-TTC GAT CCC AAG AAG GAA TCA AC-3' and reverse primer 5'-GTA GTG ATG CCA TGT AAC TGA ATC-3' were used for heparanase. The PCR reaction was run for 40 cycles under the following conditions: denaturation at 94 ℃ for 3 min, denaturation at 94 ℃ for another 30 s, annealing at 50 ℃ for 30 s and extension at 72 ℃ for 1 min with an extra 10-min extension for the last cycle. We determined the nucleotide sequence of this PCR product and confirmed that it was identical to the expected fragment of cDNA of heparanase. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) transcripts were monitored as a control to quantify the transcripts of the genes in each sample. GAPDH-specific sequences were amplified using the forward primer 5'-CAG GGG GGA GCC AAA AGG-3', reverse primer 5'-GGC AGT GGG GAC ACG GAA-3', which yielded a 378-bp product. After completion of these amplification cycles, 10 μL of each PCR product was electrophoresed at 50-80V for 30-40 minutes on a 10g/L agarose gel in Tris boric acid EDTA buffer together with 100 bp DNA ladder marker (TaKaRa Biotechnology(Dalian) Co.,Ltd) and was stained with ethidium bromide.

Immunohistochemistry

Streptavidin-peroxidase (S-P) two step method was used for the immunohistochemical detection of CD44v6, *nm23* and MMP-7 proteins. Immunohistochemical detection of CD44v6, *nm23* and MMP-7 was performed with monoclonal antibodies (Maixin Biological, Fuzhou, China) against CD44v6, MMP-7 and *nm23*/NDP kinase.

The sections were first washed for 3 min with phosphate buffered saline (PBS) 3 times and then blocked with a solution of 30mL/L hydrogen peroxide in ethanol for 10 min at room temperature. After that they were immersed in 30mL/L normal horse serum for 10 min also at room temperature. Primary antibodies to CD44v6, *nm23* and MMP-7 were incubated for 1 h at room temperature. The ultrasensitive S-P kit (Maixin Biological, Fuzhou, China) was used to detect the resulting immune complex. The procedures of blocking, linkage, and labeling of binding reaction were carried out according to manufacturer's instructions. The peroxidase activity was visualized by DAB kit (Maixin Biological, Fuzhou, China), the sections were finally counterstained with hematoxylin and the negative control was processed by incubation with non-immune rabbit IgG in substitution for the primary antibody.

To evaluate the expression of CD44v6, only cell membrane staining equivalent to normal control was considered positive, while for *nm23* and MMP-7, only cytoplasmic staining equivalent to normal control was considered positive. Slides were examined and scored by two pathologists ignorant of the clinical details. Those slides exhibiting diffuse immunostaining or presenting more than 50% of tumor cells were classified as (++), more than 10% but less than 50% as (+) and those with immunoreactivity less than 10% were classified as (−). (+) and (++) were combined together as positive cases for statistical analysis.

Statistics

Statistical analyses were done with the SPSS 10.0 for Windows program. Frequency tables were analyzed with the Pearson Chi-square test or Fisher's exact test. The relationships between heparanase and *nm23* and CD44v6 and MMP-7 in gastric tumor tissues were evaluated statistically using the Kendall rank correlation test. Statistical differences with *P* values less than 0.05 by two-tailed tests were considered significant.

RESULTS

Clinical findings

The subjects included 26 men and 17 women. Their average age at the time of surgery was 58.5±13.4 years (ranging from 29 to 86 years). Ten cases of gastric cancer located at the upper third of the stomach, 7 at the middle third and 26 at the lower third. Of these 43 patients, 3 had peritoneal metastasis, 2 had liver metastasis, 35 had serosal invasion, and 27 had lymph node metastasis. Histopathological diagnoses of the patients were made according to the guidelines for classification of the primary gastric cancer. Thirty patients were classified as adenocarcinoma, 5 as mucinous carcinoma and 8 as signet-ring cell carcinoma. For histological differentiation, 4 were well differentiated, 10 were moderate differentiated and 29 were poorly differentiated. For TNM staging, 6 patients belonged to stage I, 8 belonged to stage II, 13 belonged to stage III, and 16 belonged to stage IV. None of the patients had received preoperative chemotherapy.

Relationship between heparanase gene expression and clinicopathological features in gastric carcinomas

The expression of heparanase mRNA was positive in 29 cases of gastric cancer with a positive rate of 67.4%. While its expression rate in the 10 cases of non-cancerous gastric tissues

was 10.0% (1 case). The difference was statistically significant (*P*<0.05) (Figure 1).

Figure 1 Expression of heparanase mRNA in gastric carcinomas. a: non-cancerous tissue, b-f: cancerous tissue, g: marker (100 bp DNA ladder marker).

From Table 1, we could find that the mRNA expression of heparanase was not correlated with tumor location, gross appearance, histological characteristics, peritoneal dissemination and liver metastasis (*P*>0.05). It was correlated with tumor size, serosal infiltration, lymph node metastasis, distant metastasis and TNM staging of gastric carcinomas (*P*<0.05). In 14 cases of negative expression of heparanase mRNA, only 5 cases had lymph node metastasis. However, in 29 cases of positive expression of heparanase mRNA, twenty-two had lymph node metastasis, among which N_1 was in 11 cases, N_2 in 3 cases and N_3 in 8 cases. The difference between these two groups was statistically significant (*P*<0.05).

Relationship between CD44v6, nm23 and mmp-7 protein expression and clinicopathological features in gastric carcinomas

The expression of CD44v6 protein was positive in 33 cases of gastric cancer with a positive rate of 76.7% and the intensity of its immunoreactivity in cancer tissue was scored as (+) in 27

patients and (++) in 6 patients. The expression of *nm23* protein was positive in 16 cases of gastric cancer with a positive rate of 37.2% and the intensity of its immunoreactivity in cancer tissue was scored as (+) in 10 patients and (++) in 6 patients. The expression of MMP-7 protein was positive in 26 cases of gastric cancer with a positive rate of 60.5% and the intensity of its immunoreactivity in cancer tissue was scored as (+) in 20 patients and (++) in 6 patients (Figure 2).

The expression of CD44v6 protein was significantly correlated with lymph node metastasis, TNM staging and serosal infiltration ($P<0.05$). The expression of *nm23* protein was significantly correlated with the tumor gross appearance, peritoneal metastasis and lymph node metastasis ($P<0.05$). The expression of MMP-7 protein was significantly correlated with serosal invasion and TNM staging (Table 1).

Correlation between heparanase mRNA expression and CD44v6, nm23 and MMP-7 protein expression

The expression of heparanase mRNA had significant negative correlation with the expression of CD44v6 and MMP-7 protein ($P<0.05$) (Table 2). The expression of MMP-7 protein had significant positive correlation with the expression of CD44v6 protein ($\gamma=0.568$, $P<0.01$). The expression of MMP-7 protein had no correlation with the expression of *nm23* protein ($P>0.05$).

The expression of *nm23* protein had no correlation with the expression of CD44v6 protein ($P>0.05$).

Table 2 Correlation between the expression of heparanase mRNA and the expression of CD44v6, *nm23* and MMP-7 protein

Items	Number of cases	Heparanase (+)	Correlation coefficient	*P* value
CD44v6			-0.440	0.004
(-)	10	3		
(+)	33	26		
Nm23			-0.021	0.889
(-)	27	18		
(+)	16	11		
MMP-7			-0.352	0.023
(-)	17	8		
(+)	26	21		

DISCUSSION

In normal human tissues, heparanase mRNA is chiefly distributed in placenta and lymphatic tissues. Contrarily in the connective tissues and most of the epithelial cell, its expression is rare or even absent[1-3]. Vlodavsky *et al.*[1] confirmed that

heparanase could promote the metastasis of tumor by gene transfection experiments. They transfected non-metastatic Eb cells with a full-length human heparanase cDNA using a pcDNA3 expression plasmid. As a result, the transfected cells expressed high levels of heparanase mRNA and high heparanase activity. Ninety percent of the DBA/2 mice injected with heparanase-transfected Eb cells died by d 34, whereas 60% of the mice inoculated with mock-transfected cells were alive at that time. The livers of mice inoculated with hepranase-transfected cells were infiltrated with numerous Eb lymphoma cells. In contrast, metastatic lesions could not be detected by gross examination in the liver of the mice with mock-transfected and control Eb cells. Few or no lymphoma cells infiltrated the liver tissue. Furthermore, transient transfection of the heparanase gene into B16-F1 mouse melanoma cells with low metastatic potential followed by intravenous inoculation resulted in a 400-500% increase in lung metastases. All these implied that heparanase might play an important role in tumor invasion and metastasis.

In the present study, the positive rate of heparanase mRNA expression in gastric carcinomas (67.4%) was significantly higher than that of non-cancerous gastric tissues (10%) (P<0.05). Heparanase mRNA tended to express more in those patients with serosal invasion, lymph node metastasis, advanced stage of diseases, distant metastasis and larger size of tumors (P<0.05). The results indicated that heparanase mRNA was closely related with the clinicopathological features that reflected the invasion and metastatic potential and prognosis. Up to now, invasion depth, lymph node metastasis or distant metastasis and TNM stage were considered to be the prognostic factors for gastric carcinomas[14,15]. That heparanase mRNA expression statistically related with these factors implied that the invasion and metastasis induced by heparanase might indicate a poor prognosis of the gastric carcinomas. This needs to be confirmed by further survival analysis.

According to the researches on other kinds of carcinomas, the mechanisms by which heparanase accelerates invasion and metastasis can be summarized as the following two points. First, heparanase is responsible for degrading HSPGs side chain HS which is the chief component of the BM and ECM but not degraded by MMPs. Second, the degradation of HSPGs by heparanase leads to the release of various growth factors and cytokines trapped in HSPGs which regulate the angiogenesis, tissue repair, inflammation and lipid metabolism[12,16,17]. In our study, we observed that heparanase mRNA expression often occurred in patients with serosal infiltration and advanced stage of disease, which might imply the important role of heparanase in damaging and penetrating the BM in gastric carcinomas.

The metastasis in gastric carcinomas occurs not only through lymphatic and hematogenous ways but also by direct infiltration. It is still unknown of the definite roles of heparanase in the metastasis of gastric carcinomas. We found none of the patients with liver metastasis expressed heparanase mRNA, while those with lymph node metastasis were significantly related with the expression of heparanase mRNA (P<0.05). We supposed that heparanase was involved in lymphatic metastasis of gastric carcinomas instead of hematogenous metastasis. To draw a further conclusion, larger sample investigations on gastric carcinoma are needed, since the cases with liver metastasis in our study were few. However, Endo et al[12] found there was no correlation between heparanase expression and lymph node metastasis in gastric carcinomas. In their study, 65%(20/31) patients with positive expression of heparanase mRNA had venous metastasis, compared with 47%(15/32) in negative mRNA expression. They thought heparanase was involved in hematogenous metastasis of gastric carcinomas instead of lymphatic metastasis.

The nm23 was the first identified metastasis suppressor gene. In 1988, Steeg et al.[18] discovered murine nm23 cDNA by using differential colony hybridization between murine K-1735 melanoma cell lines that varied in metastatic potential in vivo. They found that the nm23 mRNA levels of two low metastatic potential cell lines were quantitatively higher than that of five related but highly metastatic cell lines. Later, the examination of protein levels exhibited a similar pattern[19]. This discovery aroused much interest in the role of nm23 in progression of carcinomas. Up to now, eight members of the human nm23 family have been reported and are found in multiple subcellular compartments. Homologs in other species are known as nucleoside diphosphate kinases (NDP kinase or ndpk) or, in Drosophila, as abnormal wing discs (awd)[20]. Two highly homologous genes have been described so far, both located at the long arm of chromosome 17, coding for the 18.5 and 17 kD proteins nm23-H1 and nm23-H2, respectively. The nm23-H1 and nm23-H2 gene products have been shown to be identical to human nucleoside diphosphate (NDP) kinases A and B[19]. nm23 has been considered as an antimetastatic gene for most malignancies, but the role of nm23 gene in gastric carcinomas is still not completely known.

In our study, we found that nm23 had a significant association with lymph node metastasis and peritoneal dissemination. In 27 patients with lymph node metastasis 21 were nm23 negative, while in 16 patients without lymph node metastasis only 6 were nm23 negative. The difference was statistically significant (P<0.01). In 40 patients without peritoneal metastasis, 27 were nm23 negative, but in 3 patients with peritoneal metastasis all were nm23 positive. The difference was also statistically significant (P<0.05). It indicates that nm23 suppresses lymphatic metastasis and peritoneal metastasis in gastric carcinomas. Our study also demonstrated that decreased expression of nm23 was related to tumor's gross type. Other researches showed similar results and proposed nm23 was related to 5 year survival of the patients[21]. However Yoo et al.[22] found there was no significant difference in 5-year survival rates between patients with nm23-positive and nm23-negative tumors (P>0.05) and denied nm23 to be a predictor of outcome of patients with gastric carcinomas.

CD44 is a highly glycosylated cell surface protein. In normal tissues, CD44 is expressed in a variety of epithelial and mesenchymal cells, as well as in blood cells and glial cells of the central nervous system[10,23]. Tremendous interest in CD44 was generated when Gunthert and colleagues conferred metastatic potential on a non-metastatic cell line by transfecting a variant of CD44[23, 24]. CD44 has two isoforms, one has been termed CD44 standard (CD44s) and the other CD44 variant (CD44v). The mRNA of CD44s contains no variant exons, while CD44v may contain one or more variant regions, such as CD44v6 or CD44v3-v7. CD44v6 now is considered to be involved in cell-cell and cell-matrix interactions and take part in cell motility, tumour growth, invasion and metastasis[10,23,25].

Our results demonstrated that CD44v6 was significantly related to lymph node metastasis, serosal invasion and TNM stage. Twenty-four out of 27 patients with lymph node metastases were CD44v6 positive, while 9 out of 16 patients without lymph node metastasis were CD44v6 positive. The difference was statistically significant (P<0.05). Twenty-seven out of 29 stage III and IV patients were CD44v6 positive but only 6 out of 14 stage I and II patients were CD44v6 positive. Their difference was also statistically significant (P<0.05). These indicated that CD44v6 might be a useful predictor of lymph node metastasis in gastric carcinomas. Joo et al.[26,27] obtained almost the same results as ours. But Yamaguchi et al.[28] tended to consider CD44v6 protein to have an important role in hematogenous metastasis of gastric carcinomas.

MMPs are a family of zinc-dependent endoproteinases whose enzymatic activity is directed against components of

the ECM. Up to now, 24 different vertebrate MMPs have been identified, of which 23 are found in humans. On the basis of substrate specificity, sequence similarity, and domain organization, vertebrate MMPs can be divided into six groups: collagenases; gelatinases; stromelysins; membrane-type MMPs; matrilysins and other MMPs. MMP-7 is also called matrilysin[29,30]. The mechanism of MMP-7 in gastric carcinomas is still unclear. Our study demonstrated that only serosal invasion and advanced stage of disease were closely related to MMP-7 protein expression and it had no correlation with other clinicopathological features. In 26 MMP-7 positive cases, 24 cases had serosal invasion while for 17 MMP-7 negative cases, only 11 cases had serosal invasion ($P<0.05$). Yonemura *et al*.[31] found MMP-7 had not only significant positive correlation with serosal involvement but also with lymph node metastasis, poor differentiation and peritoneal dissemination. Patients with MMP-7-positive tumor had significantly poorer survival and more frequently died of peritoneal recurrence than did those with MMP-7-negative tumors. So MMP-7 was considered to be a good indicator of peritoneal dissemination. This was confirmed later by the study using MMP-7-specific antisense oligonucleotide which could inhibit peritoneal dissemination in human gastric cancer[32]. However, our study did not show any correlation between MMP-7 expression and peritoneal metastasis.

According to the studies on other kinds of carcinomas, MMPs facilitate tumor cell invasion and metastasis by at least three distinct mechanisms. First, proteinase removes physical barriers to invasion through degradation of ECM macromolecules such as collagens, laminins, and proteoglycans. Second, MMPs have the ability to modulate cell adhesion. Finally, MMPs may act on ECM components or other proteins to unkown hidden biologic activities[11]. Liu *et al*.[33] investigated immunohistochemically MMP-7 expression in 214 gastric carcinomas and found MMP-7-positive tumor cells were preferentially found in deeply invading nests, especially at the invasive front. The mean MMP-7 labeling index (LI) at the invasive front was significantly higher in tumors invading or penetrating the muscularis propria and in stages II - IV than within the submucosal layer and in stage I, respectively ($P<0.001$). Our study also showed serosal invasion and advanced stage of disease were closely related to MMP-7 protein expression. Liu *et al*[34] also found Ki-67 antigen, an indicator of cell proliferation, was absent in MMP-7 positive tumor cells and vice versa and concluded that MMP-7 expression was related inversely with proliferative activity of tumor cells. So it could be deduced that MMP-7 might participate in the penetration of BM and ECM in gastric carcinomas instead of promoting cell proliferation. Recently, two studies demonstrated that MMP-7 upregulation was closely related with the *H pylori* cag pathogenicity island and this implied a certain role of MMP-7 in carcinogenesis of gastric carcinomas[35,36].

Invasion and metastasis of gastric carcinomas are a multistep process. As far as we know, the relationship between heparanase, CD44v6, *nm23* and MMP-7 has not been reported. In our study, we found the expression of heparanase mRNA had significant negative correlation with the expression of CD44v6 and MMP-7 protein. Although heparanase and MMPs both acted on BM and ECM, their substrates were different. Heparanase mainly used HS as substrate while MMPs mainly used structural proteins as substrates. This might account for the negative correlation between the expression of heparanase mRNA and MMP-7 protein. But what exactly caused this is worthy of further studying. That the expression of MMP-7 protein had significant positive correlation with the expression of CD44v6 protein further confirmed that MMPs have the ability to modulate cell adhesion. Why there was no correlation

between the expression of MMP-7 and *nm23* protein? Might it be caused by their different mechanisms? Further studies will be needed to elucidate their relationship in tumors.

Abstract

AIM: To study the expression of vascular endothelial growth factor C (VEGF-C) and chemokine receptor CCR7 in gastric carcinoma and to investigate their associations with lymph node metastasis of gastric carcinoma and their values in predicting lymph node metastasis.

METHODS: The expression of VEGF-C and CCR7 in gastric carcinoma tissues obtained from 118 patients who underwent curative gastrectomy was examined by immunohistochemistry. Among these patients, 39 patients underwent multi-slice spiral CT (MSCT) examination.

RESULTS: VEGF-C and CCR7 were positively expressed in 52.5 and 53.4% of patients. VEGF-C expression was more frequently found in tumors with lymph node metastasis than those without it ($P<0.001$). VEGF-C expression was also closely related to lymphatic invasion ($P<0.001$), vascular invasion ($P<0.01$), and TNM stage ($P<0.001$). However, there was no significant correlation between VEGF-C expression and age at surgery, gender, tumor size, tumor location, Lauren classification, and depth of invasion. CCR7 expression was significantly higher in patients with lymph node metastasis compared with those without lymph node metastasis ($P<0.001$) and was also associated with tumor size ($P<0.01$), depth of invasion ($P<0.001$), lymphatic invasion ($P<0.001$), and TNM stage ($P<0.001$). However, the presence of CCR7 had no correlation to age at surgery, gender, tumor location, Lauren classification, and vascular invasion. Among the 39 patients who underwent MSCT examination, only CCR7 expression was related to lymph node metastasis determined by MSCT ($P<0.05$). In the current retrospective study, the sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and accuracy of VEGF-C and CCR7 expression in the diagnosis of lymph node metastasis for patients with gastric carcinoma were 73.8%, 70.2%, 72.6%, 71.4% and 72.0%, and 82.0%, 77.2%, 79.4%, 80.0% and 79.7%, respectively. After subdivision according to the combination of VEGF-C and CCR7 expression, receiver operating characteristic (ROC) analysis showed that the accuracy of the combined examination of VEGF-C and CCR7 expression in predicting lymph node metastasis was relatively high (area under ROC curve [Az]=0.83).

CONCLUSION: The expression of VEGF-C and CCR7 is related to lymph node metastasis of gastric carcinoma and both of them may become new targets for the treatment of gastric carcinoma. Furthermore, the combined examination of VEGF-C and CCR7 expression in endoscopic biopsy specimens may be useful in predicting lymph node metastasis of gastric carcinoma and deciding the extent of surgical lymph node resection.

INTRODUCTION

Lymph node metastasis is an important prognostic factor for patients with gastric carcinoma[1-4]. In spite of this, the function of intratumor lymphatic vessels in lymph node metastasis of gastric carcinoma is unclear. Recently, the molecular pathway that signals for lymphangiogenesis and relatively specific markers for lymphatic endothelium have been described allowing analyses of tumor lymphangiogenesis to be performed[5-8]. Many experimental studies indicated that lymphangiogenic factors (VEGF-C and VEGF-D) could stimulate lymphangiogenesis in tumors by binding to their receptors (VEGFR-3) on the lymphatic endothelial cells and inducing proliferation and growth of new lymphatic capillaries, then enhance the incidence of lymph node metastasis in animal models[9-12]. A recent study by Orlandini *et al.*[13] demonstrated that β-catenin was a negative regulator of VEGF-D mRNA stability, therefore VEGF-D expression might only be responsible for the nodal metastatic behavior in tumors that have lost or reduced expression of β-catenin. In addition, there was apparent discrepancy of VEGF-D expression in tumors reported by different authors[14-18]. Thus, here we only investigate the role of VEGF-C in promoting lymph node metastasis in gastric carcinoma.

It has long been unclear as to why particular cancers preferentially metastasize to certain sites. However, a recent report by Muller *et al.*[19] provided evidence for preferential homing of breast cancer to metastatic sites. The findings indicated that the chemokine receptors CXCR4 and CCR7 were found on breast cancer cells and their ligands were highly expressed at sites associated with breast cancer metastases. In addition, both CCL19 and CCL21 (chemokines, ligands of CCR7) are highly expressed in lymph nodes, therefore the migration of tumor cells positive for CCR7 towards lymph nodes may share many similarities with leukocyte trafficking,

which is critically regulated by chemokines and their receptors[20]. A recent study by Takanami *et al.*[20] has demonstrated that CCR7 was related to the development of lymph node metastasis in nonsmall cell lung cancers. Here, we aim to explore the association of CCR7 expression with lymph node metastasis in gastric carcinoma. Furthermore, activation of lymphatics by VEGF-C may promote production of chemoattractants such as CCL21 by lymphatic endothelial cells and thereby facilitate tumor cell positive for CCR7 expression entry into lymphatics[21], so the other aim of this study is to investigate the value of the combined examination of VEGF-C and CCR7 expression in predicting lymph node metastasis of gastric carcinoma.

MATERIALS AND METHODS

Patients and tumor samples

One hundred and eighteen patients, who had undergone curative gastrectomy for gastric carcinoma between 2001 and 2002 in the Department of General Surgery, Ruijin Hospital affiliated to Shanghai Second Medical University, Shanghai, China, were enrolled in this study. All of the resected primary tumors and regional lymph nodes were histologically examined by hematoxylin and eosin staining according to the TNM classification. Among these patients, 39 cases preoperatively underwent MSCT examination by using the method previously reported[22].

Immunohistochemical staining

Formalin-fixed and paraffin-embedded sections of tumor tissue obtained from resected stomach were cut 4 μm thick, dewaxed in xylene and rehydrated in graded alcohol, then immersed in 30 mL/L hydrogen peroxide in methanol for 30 min to inhibit endogenous peroxidase activity. The sections were boiled in EDTA (0.01 mol/L,, pH 8.0) for 20 min for antigen retrieval. After being rinsed in phosphate-buffered saline (PBS), the sections for CCR7 staining were treated sequentially with avidin and biotin (Biotin blocking system) (Dako) to block the endogenous biotin-like molecules. Then, all sections were incubated with normal goat serum for 10 min for blocking nonspecific reaction. The sections were then incubated with primary antibody at 37 ℃ in humid chambers for 1 h. The rabbit anti-human VEGF-C ployclonal antibody (Zymed) was at a 1:100 dilution, and the mouse anti-human CCR7 monoclonal antibody (BD PharMingen) was at a 1:300 dilution. After washing 3 times with PBS, the sections for CCR7 staining were then incubated for 10 min at room temperature with biotinylated secondary antibody (goat anti-mouse IgM) and streptavidin conjugated to horseradish peroxidase, respectively, whereas the sections for VEGF-C staining were reacted with EnVision plus (Dako) for 30 min at room temperature. After being rinsed 3 times with PBS, the sections were incubated with 3, 3'-diaminobenzidine tetrahydrochloride (DAB) (Dako), then rinsed with distilled water, counterstained with haematoxylin, dehydrated with alcohol and xylene, and mounted routinely. Negative controls were performed in all cases by omitting the first antibody.

Evaluation of immunohistochemical staining

Two pathologists evaluated and interpreted the results of immunohistochemical staining, without knowledge of the clinical data of each patient. The immunohistochemical expression of VEGF-C was defined as positive if distinct staining was observed in at least 30% of tumor cells[23]. CCR7 expression in the cancer tissue was classified as positive if more than 10% tumor cells were immunoreactive. Very faint or equivocal immunoreaction was ignored.

Evaluation of lymph node status by MSCT

Two radiologists prospectively analyzed the CT images. Lymph nodes were considered involved when the short-axis diameter was more than 6 mm for the perigastric lymph nodes and more than 8 mm for the extraperigastric lymph nodes[24]. The preoperative N staging obtained by MSCT was compared with the pathological findings according to the TNM classification (UICC).

Statistical analysis

Statistical analyses were performed using the χ^2 test and ROC analysis. $P<0.05$ was considered statistically significant. All the statistical analyses were performed using SAS 6.04 software.

RESULTS

Expression of VEGF-C and CCR7 in gastric carcinoma and adjacent normal mucosa

In adjacent normal gastric mucosa, no or faint cytoplasmic staining of VEGF-C was seen in the parietal cells, but almost all epitheial cells were negative. Moderate to strong staining of VEGF-C protein was identified in the cytoplasm of immunoreactive cancer cells (Figure 1). Furthermore, in a few cases, some stromal cells were also positive for VEGF-C. The percentage of patients positive for VEGF-C was 52.5%(62/118). In adjacent normal gastric mucosa, no or very weak staining of CCR7 was also found, whereas moderate to strong staining of CCR7 was found mainly in cell membrane and/or cytoplasm of immunoreactive cancer cells as well as a few lymphocytes (Figure 2). The percentage of patients positive for CCR7 was 53.4%(63/118). Among these samples, there were 2 specimens with 1 metastatic lymph node adjacent to the primary tumor. It turned out that not only the primary tumors but also the metastatic lymph nodes were positive for both VEGF-C and CCR7 expression in both cases (Figures 3 and 4).

Association of VEGF-C and CCR7 expression with clinicopathological features

The correlation between VEGF-C and CCR7 expression and clinicopathological factors is summarized in Table 1. VEGF-C expression was more frequently found in tumors with lymph node metastasis than those without it ($P<0.001$). VEGF-C expression was also closely related to lymphatic invasion ($P<0.001$), vascular invasion ($P<0.01$), and TNM stage ($P<0.001$). However, there was no significant correlation between VEGF-C expression and age at surgery, gender, tumor size, tumor location, Lauren classification, and depth of invasion. The CCR7 expression was significantly higher in patients with lymph node metastasis compared with those without lymph node metastasis ($P<0.001$) and was also associated with tumor size ($P<0.01$), depth of invasion ($P<0.001$), lymphatic invasion ($P<0.001$), and TNM stage ($P<0.001$). However, the presence of CCR7 had no correlation to age at surgery, gender, tumor location, Lauren classification, and vascular invasion.

Relationship between expression of VEGF-C and CCR7 and lymph node metastasis of gastric carcinoma determined by MSCT

As shown in Table 2, among the 39 patients who underwent MSCT examination, CCR7 expression was related to lymph node metastasis determined by MSCT ($P<0.05$), whereas there was no significant correlation between VEGF-C expression and lymph node metastasis determined by MSCT (Figures 5-7). However, both VEGF-C and CCR7 expression were closely

related to lymph node metastasis determined by pathological examination ($P<0.01$). In addition, the accuracy of MSCT in determining the N stage was 69.2%(27/39) (Table 3). Findings at MSCT were concordant with pathological findings in 15 of 20 N_0 tumors (75.0%), 5 of 10 N_1 tumors (50.0%), and 7 of 9 N_2 tumors (77.8%), respectively. The sensitivity, specificity, PPV, NPV, and accuracy of MSCT in predicting lymph node metastasis were 84.2%(16/19), 75.0%(15/20), 76.2%(16/21), 83.3%(15/18), and 79.5%(31/39). However, the sensitivity, specificity, PPV, NPV, and accuracy of VEGF-C and CCR7 expression in the diagnosis of lymph node metastasis for patients with gastric carcinoma were 68.4%(13/19), 75.0%(15/20), 72.2%(13/18), 71.4%(15/21) and 71.8%(28/39), and 73.7% (14/19), 75.0%(15/20), 73.7%(14/19), 75.0%(15/20) and 74.4%(29/39), respectively (Table 2).

Figure 1 Expression of VEGF-C was observed mainly in the cytoplasm of gastric carcinoma cells (original magnification ×200). A: diffuse gastric carcinoma; B: intestinal gastric carcinoma.

Figure 2 Expression of CCR7 was observed mainly in the cytoplasm and membrane of gastric carcinoma cells (original magnification ×200). A: diffuse gastric carcinoma; B: intestinal gastric carcinoma.

Figure 3 Expression of VEGF-C was observed mainly in gastric carcinoma cells in metastatic lymph node (original magnification ×400).

Figure 4 Expression of CCR7 was observed mainly in gastric carcinoma cells in metastatic lymph node (original magnification ×400).

Figure 5 CT scan shows a metastatic lymph node (confirmed by pathologic examination) (arrow) 10 mm in short-axis diameter, which is adjacent to the primary lesion of gastric carcinoma (arrowhead).

Figure 6 The same patient as Figure 5, expression of CCR7 was observed in the cytoplasm and membrane of gastric carcinoma cells (original magnification ×400).

Figure 7 The same patient as Figure 5, expression of VEGF-C was observed in the cytoplasm of gastric carcinoma cells (original magnification ×400).

Negative	57	7	6	10	34

Value of the combined examination of VEGF-C and CCR7 expression in predicting lymph node metastasis

As shown in Table 1, in the current retrospective study, the sensitivity, specificity, PPV, NPV, and accuracy of VEGF-C and CCR7 expression in the diagnosis of lymph node metastasis for patients with gastric carcinoma were 73.8% (45/61), 70.2% (40/57), 72.6% (45/62), 71.4% (40/56) and 72.0% (85/118), and 82.0% (50/61), 77.2% (44/57), 79.4% (50/63), 80.0% (44/55) and 79.7% (94/118), respectively. To further investigate the value of the combined examination of VEGF-C and CCR7 expression in predicting lymph node metastasis, we divided patients into four groups: group A, CCR7(+) and VEGF-C(+); group B, CCR7(+) and VEGF-C(-); group C, CCR7(-) and VEGF-C(+); group D, CCR7(-) and VEGF-C(-). In groups A, B, C, and D, the percentage of patients with lymph node metastasis was 85.4% (41/48), 60.0% (9/15), 28.6% (4/14), and 17.1% (7/41), respectively (Table 4). In addition, ROC analysis showed that the accuracy of the combined examination of VEGF-C and CCR7 expression in predicting lymph node metastasis was relatively high (area under ROC curve [Az]= 0.83) (Figure 8). When the patients with positive expression of both VEGF-C and CCR7 were regarded as those with lymph node metastasis, the PPV in the diagnosis of lymph node metastasis reached to 85.4% (41/48). In addition, when the patients with negative expression of both VEGF-C and CCR7 were regarded as those without lymph node metastasis, the NPV reached to 82.9% (34/41).

Figure 8 ROC curve generated from the combination of VEGF-C and CCR7 expression shows area under curve to be 0.83.

DISCUSSION

Tumor cells can disseminate within the body by a number of mechanisms, such as direct invasion of surrounding tissues, lymphatic spread and hematogenous spread. The role of angiogenesis involving blood vessels in facilitating the growth and hematogenic spread of solid tumors has been well established. The ability of tumor cells to induce angiogenesis is considered a prerequisite for tumor growth, invasion, and successful metastasis, and the angiogenic switch is recognized as one of the key events in tumorigenesis[25-30]. In contrast, studies of the lymphatic system have been hindered by the lack of specific markers for tumor-associated lymphatic vessels and growth factors that control lymphatic development and lymphatic vessel growth (lymphangiogenesis), although the importance of the lymphatic system as a pathway for lymph node metastasis has been well recognized. In the past few years, with the identification of proteins such as hyaluronan receptor LYVE-1[31], prox-1[7], podoplanin[32], and desmoplakin[33] specifically expressed on lymphatic vessels and the discovery of molecules (VEGF-C and VEGF-D) that can drive lymphatic vessel growth, occurrence of tumor lymphaniogenesis and its correlation with lymph node metastasis has been proved in animal models and clinicopathological studies.

Nine recently reported animal studies have provided the first direct *in vivo* evidence that tumours are able not only to induce lymphangiogenesis but also to enhance lymph node metastasis[8-12,34-37]. Yanai *et al*[37] constructed a VEGF-C transfectant (AZ-VEGF-C) from the AZ521 human gastric carcinoma cell line, which ordinarily shows little nodal metastatic potential and little VEGF-C expression. They orthotopically implanted transfected tumor cells into the stomachs of nude mice. The number of mice developing lymph node metastases and the number of lymph node metastases per mouse with nodal metastases were higher than with implants of mock-transfected control cells. In addition, the number of vessels stained for VEGFR-3 in tumors and surrounding tissues was higher for AZ-VEGF-C than for controls. Furthermore, recent studies in human head and neck cancer[38,39] and melanoma[40] have demonstrated the existence of proliferating intratumoral lymphatic vessels. Clinical studies using the RT-PCR, *in situ* hybridization, and/or immunohistochemistry have revealed significant associations between lymph node metastasis and VEGF-C or VEGF-D expression in human primary tumors of the breast, colon, rectum, prostate, testis, esophagus, stomach, thyroid, lung, pleura, head-and-neck squamous cells, uterine cervix, and endometrium[41]. Because of the reasons above-mentioned, we only investigated the VEGF-C expression in gastric carcinoma.

The findings of the current study demonstrated a positive correlation of VEGF-C expression with both lymph node metastasis and lymphatic invasion in gastric carcinoma. Our results were consistent with those of previous reports[23,42-47]. A study by Yanai *et al*[37] indicated that VEGF-C was a specific lymphangiogenic growth factor with an important role in lymph node metastasis of gastric carcinoma in an animal model. In addition, the studies by Yonemura *et al*[42,43] showed that VEGF-C mRNA level was closely related to VEGFR-3 mRNA level and the number of VEGFR-3-positive lymphatic vessels in human gastric carcinoma. Thus, VEGF-C may stimulate lymphangiogenesis in gastric carcinoma by binding to their receptors (VEGFR-3) on the lymphatic endothelial cells and inducing proliferation and growth of new lymphatic capillaries, then enhance the incidence of lymph node metastasis in gastric carcinoma. However, our present study showed that VEGF-C expression was closely related to lymph node metastasis determined by pathological examination, but not by MSCT examination, although the accuracy of MSCT in the diagnosis of the lymph node metastasis for 39 patients with gastric carcinoma reached to 79.5%. Nevertheless, Hashimoto *et al*[48] demonstrated that VEGF-C mRNA expression was correlated with lymph node metastasis diagnosed by magnetic resonance (MR) imaging in cervical cancer. So further study must be made. Furthermore, our present study showed that the VEGF-C expression was correlated with vascular invasion in gastric carcinoma. Other investigators[42,45] also found a positive correlation between VEGF-C expression and vascular invasion in gastric carcinoma. In addition, a study by Amioka *et al*.[23] showed that VEGF-C expression in tumor cells was closely related to the microvessel density (MVD) in gastric carcinoma. As we all know, VEGF-C is a ligand for VEGFR-2 and VEGFR-3. VEGFR-2 is mainly expressed on vascular endothelial cells. However, VEGF-C displays greater affinity for VEGFR-3 than VEGFR-2, and only the mature 21-kDa form of VEGF-C can bind to VEGFR-2[36]. As a result, VEGF-C may also be correlated with angiogenesis in gastric carcinoma, but the activity of tumor angiogenesis by VEGF-C may be weak. Further study is needed to investigate the biological effect of VEGF-C on angiogenesis in gastric carcinoma.

Chemokines are chemoattractant cytokines that bind to specific G-protein-coupled receptors on target cells; these target cells follow chemokine concentration gradients into selected

tissues. Through their interactions with target cells, these small proteins induce cytoskeletal rearrangement and directional migration. Chemokines are involved in physiologic and pathologic regulation of leukocyte trafficking[41]. Recent studies showed that chemokine receptor CCR7 was expressed in the tumor cells of breast cancer[19], nonsmall cell lung cancer[20], esophageal squmous cell carcinoma[49], and gastric carcinoma[50]. In addition, both CCL21 and CCL19 (chemokines, liagands of CCR7) show most abundant expression in lymph nodes. CCL21 is expressed in the high endothelial venules of lymph nodes and in the T-cell zone of lymph nodes. CCL19 is expressed predominantly by stromal cells within the T-cell zones of lymph nodes[19]. Previous studies showed that lymphatic endothelial cells also produced CCL21[51, 52]. *In vitro* experiments showed that actin polymerization and pseudopodia formation, which were needed for the invasion of malignant cells into tissues and for efficient metastasis, could be induced by CCL21 and CCL19 in tumor cells with CCR7 expression[19,49,50]. Thus, the migration of tumor cells positive for CCR7 towards lymph nodes may share many similarities with leukocyte trafficking. In addition, CCR7 may help retain tumor cells in the lymph nodes where the CCR7 ligands are rich.

Wiley *et al*.[53] examined the role of CCR7 in regional lymph node metastasis in a murine melanoma model. They transduced a murine melanoma cell line, B16, with CCR7 and, surprisingly, transduction with this single gene was sufficient to substantially increase the metastasis to draining lymph nodes of B16 cells, which otherwise have a low propensity to spread, and metastasis was completely blocked by adding neutralizing anti-CCL21 antibodies. In the model used by Wiley *et al.*, transduced cells were injected subcutaneously, thus mimicking lymphgenic metastasis of melanoma cells from the skin. Of interest, intravenous application of CCR7-transduced B16 melanoma cells did not show increased spread of the tumor cells to lung or peripheral lymph nodes. In clinicopathologic studies, a positive correlation of CCR7 expression with lymphatic invasion and lymph node metastasis has been found in nonsmall cell lung cancer[20], esophageal squmous cell carcinoma[49], and gastric carcinoma[50]. Here we investigate the role of chemokine receptor CCR7 in directional migration of gastric carcinoma cells towards lymph nodes.

The findings of the current study demonstrated that the CCR7 expression in the cytoplasm and / or member of gastric carcinoma cells was closely correlated with lymphatic invasion, lymph node metastasis, and TNM stage, but was not correlated with vascular invasion. Our findings were consistent with those reported by Mashino *et al*[50]. In addition, the study by Mashino *et al*[50] showed that CCR7 expression was closely related to histological classification, whereas the current study showed that there was no significant correlation between CCR7 expression and Lauren classification. The main reason for this discrepancy was that there was no significant correlation between Lauren classification and lymph node metastasis among the 118 patients, although the incidence of lymph node metastasis in diffuse gastric carcinoma (50.9%) was higher than that in intestinal gastric carcinoma (45.3%). Furthermore, the current study showed that the CCR7 expression was closely correlated with lymph node metastasis determined not only by pathological examination but also by MSCT examination.

Many factors affect prognosis in patients with gastric carcinoma, including tumor size, lymph node metastasis, depth of tumor invasion, distant metastasis, histological classification, and surgery performed. Of these, lymph node metastasis is one of the most important factors. Therefore, preoperative evaluation of lymph node status is essential. With the development of endoscopic or laparoscopic resection of small, localized gastric carcinoma, the pretherapeutic evaluation of

lymph node metastasis has become more important. For preoperative N staging, endoscopic ultrasonography (EUS), CT, and MR imaging have been used[4,54-58]. However, the paraaortal and celiacal regions are often beyond the scope of the EUS[55], and comparative studies demonstrated that the accuracy of CT in N staging was higher than that of MR imaging[57,58]. Therefore, among these three methods, CT may be superior to EUS and MR imaging in predicting lymph node status for patients with gastric carcinoma. In the current study, the accuracy of MSCT in N staging was 69.2%. Notably, the accuracy of MSCT in predicting lymph node metastasis reached to 79.5%, and the sensitivity and specificity was 84.2% and 75.0%, respectively. However, although spiral CT could detect lymph nodes small than 5 mm and the sensitivity for detecting metastasis-positive nodes was remarkably higher than that for detecting metastasis-negative nodes[59], both overstaging and downstaging still existed because lymph node size was not a reliable indicator for lymph node metastasis of gastric carcinoma[60]. Furthermore, Maruyama computer program can also be used to predict lymph node metastasis for patients with gastric carcinoma. Analysis of eight prognostic parameters such as gender, age, macroscopic type, location, position, diameter, histological classification, and depth of invasion using this computer program can gain the information on the expected frequency of metastasis in the 16 lymph node stations of each patient with gastric carcinoma[61, 62]. However, to date, the prospective study for evaluating the accuracy of this computer program has not been reported. Two retrospective studies[61,62] showed that the accuracy of Maruyama computer program in predicting lymph node metastasis was relatively high, but the specificity was too low. In addition, only clinicopatologic parameters were included in this computer program, whereas the molecular biologic features of gastric carcinoma were neglected.

Recently, a study using the microarray technology showed that lymph node metastasis of gastric carcinoma could be precisely predicted from the view of molecular biologic features. In this study, investigators developed an equation to achieve a scoring parameter for the prediction of lymph node metastasis on the basis of 12 genes with statistically significant differences in expression between node-positive and node-negative tumors. In the prospective study, the lymph node status of all nine test cases was correctly predicted[63]. In the current retrospective study, the sensitivity, specificity, PPV, NPV, and accuracy of VEGF-C and CCR7 expression in the diagnosis of lymph node metastasis for patients with gastric carcinoma were 73.8%, 70.2%, 72.6%, 71.4% and 72.0%, and 82.0%, 77.2%, 79.4%, 80.0% and 79.7%, respectively. Especially when the combined examination of VEGF-C and CCR7 expression was performed, the PPV and NPV reached to 85.4% and 82.9%, respectively. However, the PPV and NPV of MSCT in predicting lymph node metastasis was only 76.2% and 83.3%, respectively, among 39 patients. In addition, successful lymph node metastasis requires a complex series of related steps, such as detachment of cancer cells, invasion into the lymphatic vessels, transfer within the lymphatic vessels, embedding in the lymph nodes and proliferation in the lymph nodes. Therefore, lymphangiogenesis and directional migration of gastric carcinoma cells towards lymph nodes may only be two main steps involved in lymph node metastasis. Thus, we hypothesize that an equation established on the basis of many factors involved in the metastasis-associated steps can predict the lymph node status for patients with gastric carcinoma more accurately, especially when it is combined with Maruyama computer program and MSCT.

In conclusion, the current study demonstrates that expression of VEGF-C and CCR7 is related to lymph node metastasis of gastric carcinoma and both of them may become

new targets for the treatment of gastric carcinoma. Furthermore, the combined examination of VEGF-C and CCR7 expression in endoscopic biopsy specimens may be useful in predicting lymph node metastasis of gastric carcinoma and deciding the extent of surgical lymph node resection.

Abstract

AIM: To compare the expression patterns of cholecystokinin-B (CCK-B)/gastrin receptor genes in matched human gastric carcinoma and adjacent non-neoplastic mucosa of patients with gastric cancer, inflammatory gastric mucosa from patients with gastritis, normal stomachs from 2 autopsied patients and a gastric carcinoma cell line (SGC-7901), and to explore their relationship with progression to malignancy of human gastric carcinomas.

METHODS: RT-PCR and sequencing were employed to detect the mRNA expression levels of CCK-B receptor and gastrin gene in specimens from 30 patients with gastric carcinoma and healthy bordering non-cancerous mucosa, 10 gastritis patients and normal stomachs from 2 autopsied patients as well as SGC-7901. The results were semi-quantified by normalizing it to the mRNA level of β-actin gene using Lab Image software. The sequences were analyzed by BLAST program.

RESULTS: CCK-B receptor transcripts were detected in all of human gastric tissues in this study, including normal, inflammatory and malignant tissues and SGC-7901. However, the expression levels of CCK-B receptor in normal gastric tissues were higher than those in other groups ($P<0.05$), and its expressions did not correlate with the differentiation and metastasis of gastric cancer ($P>0.05$). On the other hand, gastrin mRNA was detected in SGC-7901 and in specimens obtained from gastric cancer patients (22/30) but not in other gastric tissues, and its expression was highly correlated with the metastases of gastric cancer ($P<0.05$).

CONCLUSION: Human gastric carcinomas and gastric cancer cell line SGC-7901 cells coexpress CCK-B receptor and gastrin mRNA. Gastrin/CCK-B receptor autocrine or paracrine pathway may possibly play an important role in the progression of gastric cancer.

INTRODUCTION

Human beings have developed highly efficient cell-cell communication to integrate and coordinate the proliferation of individual cell types, among which growth factors and hormones play a pivotal role. Gastrointestinal peptides, including gastrin and cholecystokinin (CCK), are a structurally diverse group of molecular messengers that play an important role in the control of appetite and hormonal secretion. Gastrin is secreted by gastrin (G) cells located in the antral part of the stomach, and identified as the circulating hormone responsible for stimulation of acid secretion from the parietal cells. It stimulates gastric enterochromaffin-like (ECL) cells to release histamine, which in turn increases acid secretion via histamine H_2- receptors in parietal cells[1-3]. Recently, it has been demonstrated that gastrin plays a significant role in the proliferation and differentiation of gastric and intestinal epithelial cells[4-6].

Previous studies have shown that hormones and receptors are key molecules in regulating cell growth, differentiation and apoptosis[7]. Cholecystokinin-B (CCK-B)/gastrin receptor belongs to the seven transmembrane G-protein-coupled receptor superfamily and is mainly expressed in parietal cells and ECL cells of gastrointestinal tract. It has been reported that CCK-B receptor on the basolateral cell membrane domain was immunoreactive and showed high-affinity binding sites for gastrin[8]. It has been widely accepted that gastrin, a trophic factor, promotes growth of cancer cells both *in vitro* and *in vivo* through CCK-B receptors, and that expressions of gastrin gene and CCK-B receptor are closely related to the development, progression and invasion of cancer cells, in particular, colorectal and pancreatic cancers[9,10]. Taken together, we propose that gastrin/CCK-B receptors may play an important role in the development and progression of gastric cancers. To test this viewpoint, we detected the levels of gastrin and CCK-B mRNA transcripts in human gastric cancer cell line SGC-7901 and in gastric tissues including gastric cancers and their corresponding normal mucosa tissues, gastritis and normal autopsied stomach specimens.

MATERIALS AND METHODS

Gastric tissues

Thirty gastric cancer specimens (including 12 moderate and 18 low differentiation adenocarcinomas, 22 with and 8 without local lymph node metastases) and surrounding non-tumour mucosa surgically resected from gastric corpus were confirmed histopathologically. Two normal autopsied gastric mucosa specimens were authorized by the Pathology Department of West China Medical School of Sichuan University. Ten gastritis specimens from gastroscopic examination were histopathologically confirmed by Pathology Department of Guiyang Medical College. Tissue samples were immediately stored in RNA protection solution (Omega).

Cell culture

SGC-7901 cells were cultured in RPMI 1640 medium supplemented with 100 mL/L newborn calf serum, 100 units/mL penicillin, and 100 µg/mL streptomycin in a humidified environment of 50 mL/L CO_2 in air at 37 ℃.

Table 1 PCR primers

	Antisense (509-489)	5' -GAGGCGTACAGGGATAGCAC-3'		

CCK-B: cholecystokinin-B.

Reverse transcription

Total RNA was extracted from gastric samples or 10^6 cells using TRIzol (Invitrogen) reagent according to the manufacturer' s recommendations. Five microgramme of total RNA was used as a template for the first-strand cDNA synthesis when the reaction mixture consisted of 120 units of MMLV (Maloney murine leukemia virus) reverse transcriptase, 5 μmol/L random hexamer oligonucleotide primer, 10 mmol/L dithioerythritol, 2 mmol/L dNTP, and 1×first-strand buffer in a total volume of 20 μL. RNA was denatured at 65 ℃ for 15 min and immediately chilled on ice, and then incubated for 10 min at room temperature before reverse transcriptase was added. The reverse transcription was performed for 60 min at 37 ℃ and terminated by heating to 95 ℃ for 10 min.

PCR analysis of CCK-B receptor and gastrin

The primers used for PCR amplification in the study are listed in Table 1. Two microliter of reverse transcripts was amplified by PCR in a total volume of 50 μL containing 0.1 μmol/L oligonucleotide primers for CCK-B receptor or gastrin and β-actin, respectively, 250 μmol/L dNTP, 2 mmol/L $MgCl_2$, and 1×PCR buffer. cDNAs were denatured for 5 min at 95 ℃ before 2.5 units *Taq* DNA polymerase was added. The conditions of touch-down PCR were at 94 ℃ for 45 s, at 68-62 ℃ for 1 min for CCK-B receptor or at 60-55 ℃ for 1 min for gastrin with decreasing 1 ℃ per cycle at beginning, and at 72 ℃ for 1 min for 35 cycles. PCR products were visualized by agarose gel electrophoresis and ethidium bromide staining.

Semi-quantitative analysis of CCK-B/gastrin receptor gene expression

PCR was performed simultaneously by adding the specific primers for both CCK-B/gastrin receptor and β-actin in a single reaction system after reverse transcription. PCR products were separated by 15 g/L agarose gel and the results of electrophoresis were photographed. The level of CCK-B/gastrin receptor mRNA expression *vs* β-actin was semi-quantified by Lab image software and the data were expressed as mean±SD and followed statistical analysis through one-way ANOVA, Student-Newman-Keuls multiple comparisons and independent-samples *t* test by SPSS 10.0. Statistical significance was assumed when $P<0.05$.

Sequencing

The PCR products of CCK-B/gastrin receptor amplified from the gastric tissues were separately purified by a gel extraction kit, and sequenced by an ABI sequencing machine. The sequences were compared with the GenBank database using BLAST analysis.

RESULTS

Expression of CCK-B receptor gene in human gastric tissues and SGC-7901 cells

CCK-B receptor expression was indicated by the presence of

a 316-bp PCR product, and the gastrin gene expression yielded a 266-bp PCR product while the β-actin mRNA as an internal control revealed a 190-bp product on agarose gel. Figure 1 shows the expression of CCK-B/gastrin receptor detected in all specimens taken from normal, inflammatory, cancerous gastric tissues and SGC-7901 cells.

Then, all of the samples were further divided into three groups including normal (surrounding healthy and autopsied gastric tissues, $n=32$), inflammatory ($n=10$) and malignant groups ($n=30$) which were subdivided into the local lymph node metastases ($n=22$) and non-metastases ($n=8$) groups, or moderate (12) and low (18) differentiation adenocarcimoma groups. Data were analyzed by one-way ANOVA. As shown in Figure 2, the expression level of CCK-B receptor mRNA in surrounding healthy gastric tissues is significantly higher than that in neoplastic and inflammatory tissues ($P<0.05$) while there are neither significant differences between metastases and non-metastases groups nor between groups with different differentiations ($P>0.05$).

Gastrin gene expression in human gastric cancer tissues and SGC-7901 cells

Gastrin mRNA was detected on both SGC-7901 cells and gastric cancer specimens (22/30), among which 86.4%(19/22) with local lymph node metastases, and 10.0%(3/30) without metastases. The positive expression rate of gastrin mRNA in metastatic cases was significantly higher than that in lymph node metastasis-negative cases ($P<0.05$). Gastrin mRNA was detected in 9 out of 12 gastric adenocarcinoma specimens with moderate differentiation and in 13 out of 18 cancerous specimens with poor differentiation. Statistical analyses showed no significant difference between the poor and moderate differentiation groups ($P>0.05$). Surprisingly, gastrin mRNA transcripts were detected neither in normal gastric tissues nor in inflammatory ones (Figure 1).

Figure 1 Expression of CCK-B receptor (below) and gastrin (above) mRNA in human gastric tissues and gastric cancer cell line. Total RNA extracted from matched tumor (C1, C2) and non-neoplastic (N1, N2) gastric tissues of patients with gastric

cancer, inflammatory gastric mucosa (I1 and I2) from patients with gastritis, normal stomachs from two autopsied patients (A1, A2) and SGC-7901 cells (7901) were analyzed by RT-PCR. The second lane (C) corresponds to the negative control (H_2O). The results are representatives of all specimens. Cck-br and gastrin stand for cholecystokinin B receptor and gastrin gene, respectively. β-actin: β-actin gene. M: marker (bp).

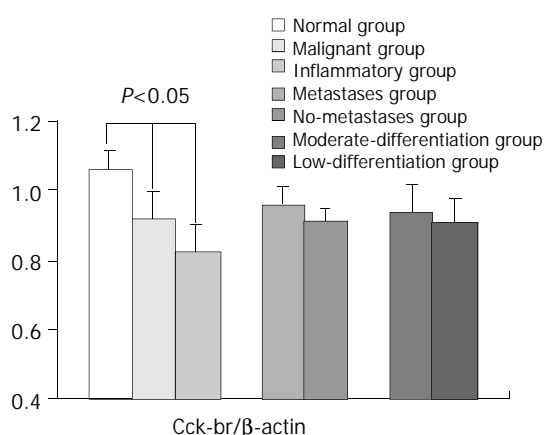

Figure 2 Semi-quantitative analysis of CCK-B receptor expression in human gastric tissues. The expression levels of CCK-B receptors were higher in normal group than in malignant and inflammatory groups, but there was no significant difference compared with other groups. Cck-br/β-actin: ratio of the intensities of the bands of CCK-B receptor *vs* β-actin on agarose gel. The results are expressed as mean±SD in every group.

Confirmation of CCK-B receptor and gastrin genes from samples

The gene sequence identities of CCK-B receptor/gastrin amplified from four different gastric tissues were 100% and 96%, respectively, as compared with CCK-B receptor/gastrin gene sequences from GenBank (Figure 3).

DISCUSSION

CCK-B receptor is widely distributed throughout the human gastrointestinal tract, pancreas, lung and some neuroendocrine tissues. It mediates the normal physiological function of gastrin. Gastrin has proliferative effects on various malignancies including gastric, colorectal, pancreatic, medullary thyroid cancers, small cell lung cancer as well as tumors of the central and peripheral nervous systems through CCK-B receptors[11-17].

Coexpression of gastrin gene and CCK-B receptor in cancer tissues *in vivo* or cell lines *in vitro* may suggest the existence of autocrine or paracrine pathways, through which gastrin exerts its physiological or pathological effects. All of the gastric specimens tested expressed CCK-B receptor mRNA, but only gastric cancer samples (22/30) expressed gastrin transcript and the expression levels of gastrin mRNA were closely correlated with the progression and metastasis of malignant tumors. However, there was no correlation between the expression level of gastrin mRNA and the grade of tumor differentiation. Taken together, our results suggested that the existence of an autocrine or paracrine pathway of gastrin/CCK-B receptors might play an important role in the pathogenesis, especially in the progression, of gastric carcinomas.

SGC-7901 cells were originated from metastatic lymph nodes of a Chinese patient with gastric cancer in 1981. Coexpression of CCK-B receptor and gastrin gene in this cell line provided further evidences that the gastrin/CCK-B autocrine loop might be involved in the development of human gastric cancer. This autocrine loop has also been proved to be functional in human colorectal[9], pancreatic[18] and lung[19,20] carcinomas.

Using semi-quantitive method, we demonstrated that the expression levels of CCK-B receptor mRNA in normal gastric tissues were higher than those in gastric cancer and gastritis, and its expression did not correlate with the grade of differentiation and metastases of gastric cancers. Henwood's group[21] reported that a significantly increased expression of CCK-B receptor protein was seen along the pathway from normal gastric tissues, gastritis to gastric adenocarcinoma by immunohistochemistry. Other malignant tumors also showed the inconsistency with a published paper[22].

Recent insights into CCK receptors have improved our understanding of new receptor isoforms including CCK-C receptor, intron 4-containing splice variant of CCK-B receptor and glycine-extended gastrin receptor besides classic CCK-A and CCK-B receptor subtypes[23-25]. These new receptor subtypes have been found to present in many human malignancies and cell lines and to have a functional role in mediating gastrin's proliferative effects on malignancies[26,27].

Apart from CCK receptor heterogeneity, post-translational processing of pro-gastrin is known to increase glycine-extended gastrin and progastrin other than the amidated forms known to be biologically active. Although extended forms have limited biological activities in the stimulation of gastric acid secretion, it has been found that they exist in many cancers and cultured cell lines and have amidated gastrin-independent trophic activities[28-32]. Unfortunately, to date, no specific receptors have been characterized and no specific antagonists are available, making it difficult to study their potential effects on the pathogenesis of carcinomas.

In conclusion, the coexpression of gastrin gene and CCK-B receptors in SGC-7901 cells and gastric carcinoma tissue suggests that a functional autocrine loop exists and may play an important role in the pathogenesis and progression of human

Figure 3 Sequence analyses of CCK-B receptor/gastrin mRNA from samples. L08112.1: Human brain CCK-B/gastrin receptor gene from GenBank. NM_000805: Homo sapiens gastrin gene from GenBank. Cck-br and gastrin: CCK-B receptor and gastrin gene sequences from specimens, respectively. The results showed are representatives of four samples.

gastric carcinomas. However, human tumor cells can express different CCK-B receptor subtypes and different bioactive forms of gastrin amidated and non-amidated, and that complex networks may exist among these components. More studies are needed for their roles in the development of human gastric carcinomas.

Abstract

AIM: To investigate the correlation between mitogen-activated protein kinase (MAPK) signal transduction pathway and multidrug resistance (MDR) in MGC803 cells.

METHODS: Western blot was used to analyze the expression of MDR associated gene in transient vincristine (VCR) induced MGC803 cells, which were treated with or without the specific inhibitor of MAPK, PD098059. Morphologic analysis of the cells treated by VCR with or without PD098059 was determined by Wright-Giemsa staining. The cell cycle analysis was performed by using flow cytometric assay and the drug sensitivity of MGC803 cells which were exposed to VCR with or without PD098059 was tested by using MTT assay.

RESULTS: Transient exposure to VCR induced P-gp but not MRP1 or GST-π expression in MGC803 cells and the expression of P-gp was inhibited by PD098059. Apoptotic bodies were found in the cells treated with VCR or VCR+PD098059. FCM results indicated that more MGC803 cells showed apoptotic phenotype when treated by VCR and PD098059 (rate: 31.23%) than treated by VCR only (rate: 18.42%) ($P<0.05$). The IC_{50} (284±13.2 μg/L) of MGC803 cells pretreated with VCR was 2.24-fold as that of negative control group (127±17.6 μg/L) and 1.48-fold as that of the group treated with PD098059 (191±27.9 μg/L).

CONCLUSION: This study shows that the expression of P-gp can be induced by transient exposure to VCR and this induction can be prevented by PD098059, which can block the activity of MAPK. MAPK signal transduction pathway may play some roles in modulating MDR1 expression in gastric cancer.

INTRODUCTION

Multidrug resistance (MDR) is a major factor in the failure of many forms of chemotherapy[1-4]. Several different molecular mechanisms will switch on in MDR cells, the most investigated mechanisms with known clinical significance are: (1) activation of transmembrane proteins effluxing different chemical substance from the cells, including mainly P-glycoprotein (P-gp) encoded by MDR1 and multidrug resistance related protein (MRP); (2) activation of the enzymes of the glutathione detoxification system (especially GST-π); (3) alteration of the genes and proteins involved in the control of apoptosis (especially p53 and Bcl-2)[5-14]. MDR associated genes are expressed in a large proportion of human tumors, and its expression in several different forms of cancer was shown to be associated with a lack of response to combination chemotherapy. MDR1 expression is usually low or undetectable prior to treatment, but it is frequently increased during the progression of the disease and, most noticeably, after chemotherapy[15-20]. The increased expression of MDR1 mRNA can be found in some drug-sensitive cancer cells by transient exposure to different chemotherapeutic drugs[21-24].

The signal transduction pathway of the mitogen-activated protein kinase (MAPK) plays a critical role in cell proliferation, differentiation and apoptosis. The ERK1/2 (Ras/Raf-1/MEK1/2/ERK1/2) signal transduction pathway is a subfamily of MAPK. The expression of MDR and the activation of MAPK are increased in cancer cells after treatment with various therapeutic drugs. The selective inhibitor of MEK1/2, PD098058, has been shown to significantly reverse the drug resistance of drug resistant cell line L1210/VCR[25]. The mechanism is unclear. Whether MAPK plays a role in MDR, and whether the alteration of MEK can regulate the expression of MDR need to be elucidated.

Our study was to observe the expressions of associated genes of MDR of human gastric cancer cell line MGC803 by their transient exposure to vincristine (VCR) and the effect on MDR by the specific inhibitor of MEK1/2, PD098059.

MATERIALS AND METHODS

Reagents
Human gastric cancer cell line MGC803 was obtained from Tumor Research Institute (China Medical University, Shenyang). RPMI1640 medium was the product of Gibco (USA). Chemical drug vincristine was purchased from Hualian Co. (Shanghai, China). PD098059 was the product of Promega (USA). Rabbit anti-human P-gp, MRP1, GST-π polyclonal antibody were products of Oncogen (USA). Alkaline phosphatase- conjugated goat anti-rabbit IgG was purchased from Zhongshan Co. (Beijing).

Morphological analysis of cells
After treated with VCR (20 μg/L) or VCR (20 μg/L)+ PD098059 (10 μmol/ L) for 24 h, 48 h, MGC803 cells were analyzed by wright-Giemsa staining, and the morphology of cells was examined under optic microscope.

Cell cycle analysis

MGC803 cells (1×10^8/L) were seeded into 12-well plates and cultured in 1 mL RPIM medium. After cultured for 4 h, cells were treated with VCR (20 μg/L), PD098059 (10 μmol/L) or VCR (20 μg/L) + PD098059 (10 μmol/L) for 24 h, 48 h, 96 h. Cells were harvested and washed with ice-cold PBS twice, centrifuged (120×g, 5 min) and supplemented with ice-cold 70 mL/L ethanol overnight. Cells were treated with RNase (200 mg/ L) at 37 ℃ for 1 h after washed with ice-cold PBS twice, then centrifuged (120 g, 5 min), treated with PI (20 mg/L) for 30 min in dark room at 4 ℃. Cell cycle was analyzed by flow cytometer and CELLQuest software.

MTT assay of drug sensitivity

Cells (1×10^8/L) pretreated with VCR (20 μg/L) for 72 h were plated into 96-well plates and cultured in 100 μL RPMI medium. After cultured for 4 h, cells were divided into two groups: one group was treated with various concentrations of VCR (1 μg/L, 10 μg/L, 100 μg/L, 1 000 μg/L), the other group was treated with a fixed concentration of PD098059 (10 μmol/L) and various concentration of VCR (1 μg/L, 10 μg/L, 100 μg/L, 1 000 μg/L). The unpretreated MGC803 was treated with various concentration of VCR (1 μg/L, 10 μg/L, 100 μg/L, 1 000 μg/L) as negative control group. After treated for 72 h, 20 μL of 5 g/L MTT [3-(4,4- dimeththiazol-2-yl)2,5-diphenylterazolium bromide] in PBS was added to each well, incubated for 4 h at 37 ℃ and the formed formazan crystals were dissolved in 100 μL of DMSO. The absorbance was recorded at 570 nm on a microplate reader (BIORAD). Drug sensitivity is expressed as IC_{50} for cells, which the concentration of drugs that caused a 50% reduction in the at 570 nm relative to untreated cells (controls).

Western blot analysis

MGC803 cells were harvested after treated with VCR (20 μg/L) or VCR (20 μg/L)+ PD098059 (10 μmol/L) for 24, 48, 72 h. A total of 2×10^7 cells were lysed in 200 μL RIPA buffer containing phenylnethy fluoride (PMSF, 100 mg/ L), Aprotinin (2 mg/ L), 50 mmol/ L Triscl pH 7.4, 150 mmol/ L NaCl, 1 g/L SDS, 10 g/LTriton-100, 1 mmol/ L EDTA pH 8.0. Protein samples were sonicated on ice, lysed for 40 min at 4 ℃, then centrifuged (15 400 g, 20 min) at 4 ℃. The supernatant was transferred to a new tip on ice and then the amount of the protein calculated. Protein samples were separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDSPAGE), transferred to a PVDF membrane. The membrane was incubated in a blocking solution containing 50 g/L fat free milk powder for 1 h, then probed with rabbit anti-human P-gp polyclonal antibody overnight, and incubated with alkaline phosphatase-conjugated goat anti-rabbit IgG for 2 h. The membrane was then stained by blue tetrazolium (NBT) and 5' -bromo-4-chloro-3 - indolyphosphate (BCIP) solution. The integrated density value (IDV) was analyzed by Fluorchem software.

Statistical analysis

Data were analyzed by chi square test. $P<0.05$ was considered as significant.

RESULTS

Apoptosis of cells treated with VCR and PD098059

The apoptotic bodies were observed in the MGC803 cells after treated with VCR (20 μg/L) or VCR (20 μg/L)+ PD098059 (10 μmol/L) for 48 h (Figure 1A, B, C).

The apoptosis of MGC803 cells was detected by flow cytometric analysis. The rate of apoptotic cells treated with VCR for 72 h was 18.41%, and that treated with VCR and PD098059 for 72 h was 35.61%. There was a significant difference between them ($P<0.05$). The apoptotic rates of MGC803 cells untreated and treated with PD098059 only were 8.46% and 6.26%. There was no significant difference between them ($P>0.05$) (Figure 2).

Figure 1 A: Untreated MGC803 Cells(apoptotic bodies could not be found), B: MGC803 cells treated with VCR 48 h (apoptotic bodies could be found), C: MGC803 cells treated with VCR+PD098059 48 h (apoptotic bodies could be found).

Drug sensitivity of cells treated with VCR and PD098059

The IC_{50} of MGC803 pretreated with VCR for 72 h followed by treatment with various concentrations of VCR was 284±13.2 μg/L. It was 2.24-fold as that of negative control group (127±17.6 μg/ L), and 1.48-fold as those of cells treated with various concentrations of VCR (191±27.9 μg/L). And, the concentration of PD098059 was fixed. It showed that the drug-resistance of MGC803 pretreated with VCR was increased and PD098059 could reverse the drug resistance induced by VCR partially.

Expression of MDR1, MRP1 and GST-p

Western blot was used to detect the expression of MDR associated genes. The expression of P-gp in MGC803 cells gradually increased after treated with VCR for 24-72 h (Table 1, Figure 3). But the expression of MRP1 and GST-π did not increase significantly (Table 1, Figure 3). The expression of P-gp was inhibited when MGC803 cells were treated with VCR and PD098059 for 24-72 h (Table 1, Figure 3).
Figure 2 Cell cycle analysis of MGC803. A: Untreated MGC803 cells at 72 h (G_0G_1: 48.20%; G_2M: 28.18%, S: 14.16%, apoptosis: 8.46%), B: MGC803 cells treated with VCR (20 ng/mL) after 72 h (G_0G_1: 37.62%; G_2M: 20.05%, S: 24.92%, apoptosis: 18.41%), C: MGC803 cells treated with VCR (20 ng/mL) +PD098059 (10 nmol/mL) after 72 h (G_0G_1: 32.53%; G_2M: 13.91%, S: 18.95%, apoptosis: 35.61%), D: MGC803 cells treated with PD098059 (10 nmol/mL) only after 72 h (G_0G_1: 49.27%; G_2M: 27.56%, S: 16.91%, apoptosis: 6.26%).

Table 1 IDV of expression of MDR associated gene

Group	VCR (MDR1)	VCR (MRP1)	VCR (GST-π)	VCR+PD098059 (MDR1)
Untreated MGC803 cells	116±7.5	38±14.5	122±16	54±9.5
Positive control	192±8.6	64±13.2	144±21	105±9.5
24 h	159±9.5	34±9.3	123±19.5	63±16.7
48 h	172±7.6	30±11.5	110±15.6	64±21.1
72 h	196±15.1	33±15.5	110±13.6	58±9.5

Figure 3 The expression of associated gene of MDR in MGC803 cells treated with VCR or VCR+PD098059 24h-72 h. A: The expression of MDR1 of MGC803 cells treated with VCR increased. B,C: The expression of MRP1 and GST-π of MGC803 cells treated with VCR did not increase. D: The expression of MDR1 was inhibited when MGC803 cells treated with VCR and PD098059. E: The protein level of β-actin was detected to assess the loading amount in each well in SDS-PAGE. Lane 1, untreated cells; Lane 2, positive control cells; Lane 3, cells treated for 24 h; Lane 4, cells treated 48 h; Lane 5, cells treated for 72 h.

DISCUSSION

Different tumors are different in sensitivity to chemotherapeutic drugs, and drug resistance can be induced by chemotherapy. The failure of cancer chemotherapy is mainly due to the overexpression of associated genes of MDR. Cytotoxic drug resistant cell lines have been induced after long-term exposure to gradient concentrations of cytotoxic drugs. Whether the expression of MDR could be induced by transient exposure to chemotherapeutic drugs has aroused. Chaudhary *et al* have found that the expressions of MDR1 mRNA in drug sensitive leukemia cell line K562 increased by short-term exposure to different chemotherapeutic drugs[21]. Schondorf *et al* also found that MDR1-mRNA was detectable in each cell line when short-term cultures of 6 established ovarian cancer cell lines were exposed to one of three anticancer drugs at concentrations equivalent to the clinically achievable plasma peak concentration. The method described here was easy to perform and could be of striking value in predicting the development of tumor chemoresistance[24]. Our results of western blot showed that the expression of P-gp in MGC803 cells increased significantly but the expressions of MRP1 and GST-π did not increase after induction by VCR for 72 h and the MTT assay showed that the drug resistance of MGC803 cells pretreated with VCR was 2.24-fold as that of untreated MGC803 cells. It suggested that the expression of MDR1 in MGC803 cells could be induced after transient exposure to VCR.

Mitogen-activated protein kinases (MAPKs), found in all eukaryotes, are common participants in signal transduction pathway from the membrane to the nucleus, and play an important role in cell proliferation, differentiation and apoptosis[26-28]. The mammalian MAPK family includes ERK1/2, JNK/SAPKs, ERK4 and *etc*. ERK1/2 is the most important subgroup among them. ERK1/2 signal transduction pathways contain at least three protein kinases. They are Raf-1, MAPK/ERK kinases1/2(MEK1/2) and ERK1/2. Raf-1 is activated by Ras, then phosphorylates two residues, either serine or threonine, to activate MEK1/2[29,30]. MEK1/2 activates ERK1/ERK2 by

phosphorylating a tyrosine and a threonine residues[31].

Signal transduction pathways play critical roles in pathogenesis and progress of tumor. The activation of MAPK and expression of MDR can be induced by anti-cancer drugs[32]. But the relation between them is not clear. Kisucka et al found PD098059 significantly reduced the survival of murine vincristine resistant L1210/VCR cells with a decrease of LC_{50} to vincristine from 2.65 mmol/ L to 0.67 mmol/L. The result of the study demonstrated that the inhibitor of MEK1/2 signaling pathway was a reversal agent of VCR resistance in L1210/VCR cells, but the precise mechanism of PD098059 in modulation of MDR is not resolved yet, and the role of ERK-mediated phosphorylation cascade could be considered[25]. Ding et al found that PD098059 re-sensitised the Taxol resistant human ovarian cancer cell line A1847/TX at least 20-fold, but when MDR1 cDNA was stably expressed in the wild-type cell line to generate a highly Taxol-resistant sub-line, 1847/MDR5, MAPK kinases again became activated. This result demonstrated that the increased activity of the signaling pathway in the Taxol-resistant lines was directly attributable to MDR1 overexpression and was not due to the effects of Taxol itself, and that MAPK regulated the expression of MDR1[33]. It has been found that the expression of MDR1 can block apoptosis induced by the Fas ligand cascade. Expression of MDR1 resulted in a decrease in the rate of production of active caspase 3, a key effector caspase in the apoptotic cascade, upon Fas ligation[11]. The ERK1/2 pathway has also been shown to inhibit caspase-3 activation[34]. Another possibility is that MDR1 may have additional physiological functions, for instance, MDR1 induces novel Na^+ and Cl^- dependent pathway for transmembrane H^+ efflux that results in intracellular alkalization[35]. Apoptosis induced by chemotherapeutic drugs is prevented by intracellular acidification and the induction of apoptotic events such as DNA laddering can be inhibited by increasing the intracellular pH in this manner. In a recent study, Wittstein et al demonstrated that inhibition of the ERK1/2 pathway using PD098059 resulted in re-alkalinisation of vascular endothelial cells in perfusion experiments[36]. Thus alterations in cellular pH may provide the stimulus for a variety of signaling pathways and responses mediated by both MDR and ERK1/2. The relation between MAPK and MDR1 is not clear yet. MAPK signal pathway may combine with other different mechanisms to modulate the expression of MDR1. Our study showed that PD098059 could reduce the drug resistance and enhance the killing action of VCR, and rates of apoptosis of MGC803 cells which were treated with VCR only increased from 18.41% to 35.61% when treated with PD098059 and VCR. It showed that PD098059 could reverse the drug resistance partially by reducing the IC_{50} of MGC803 cells pretreated by VCR from (287±13.2) μg/L to (191±27.9) μg/L. At the same time, the expression of P-gp was inhibited by PD098059. It was suggested that when MGC803 cells were treated with VCR, the stimulation may be transducted by activation of MAPK signaling pathway to MDR1 gene and the expression of MDR1 increased. As a result, VCR was transported out of cells and multidrug resistance developed. The inhibitor of MEK1/2, PD098059 could reduce the expression of mdr1 and drug resistance of cells exposed to VCR by blocking the ERK1/2 signal transduction pathway. The precise mechanism between MDR1 and MAPK signal transduction pathway needs further study.

Abstract

AIM: To evaluate the role of mitochondrial microsatellite instability (mtMSI) in gastric carcinogenesis.

METHODS: MtMSI was measured with PCR-single strand conformation polymophism (PCR-SSCP) in 68 cases of advanced gastric cancer, 40 cases of chronic gastritis, 30 cases of intestinal metaplasia and 20 cases of dysplasia.

RESULTS: MtMSI was observed in 12.5% (5 of 40) of chronic gastritis, 20.0% (6 of 30) of intestinal metaplasia, 25.0% (5 of 20) of dysplasia and 38.2% (26 of 68) of gastric cancer. These findings showed a sequential accumulation of mtMSI in the histological progression from chonic gastritis to gastric cancer. An association of mtMSI with intestinal histological type and distal location was found (P=0.001 and P=0.002), whereas no significant correlation was found between mtMSI and age at diagnosis, sex, tumor size, depth of invasion, lymph node spread and clinical stages (P>0.05).
CONCLUSION: MtMSI may play an early and important role in the gastric carcinogenesis pathway, especially in the intestinal type and distal gastric cancer.

INTRODUCTION

The mechanisms of carcinogenesis in the gastric mucosa remain unclear. Genetic instability is strongly involved in neoplastic transformation and progression[1-7]. In gastrointestinal carcinomas, such genetic instability may be classified into two different forms in which hypermutability occurs either due to chromosomal instability or due to microsatellite instability (MSI)[8-11]. MSI represents an important form of genomic instability associated with defective DNA mismatch repair in tumors. Although the MSI in nuclear DNA (nMSI) of gastric cancer has been established, little attention was paid to the MSI in mitochondrial DNA (mtMSI) in this cancer. In the present study, we analysed the mtMSI in gastric cancer and its premalignant lesions to elucidate whether

mtMSI led to the progression from chronic gastritis to gastric cancer, via intestinal metaplasia and dysplasia.

MATERIALS AND METHODS

Tissue samples

Forty cases of chronic gastritis, 30 cases of intestinal mataplasia and 20 cases of dysplasia obtained from patients undergoing upper endoscopy for dyspepsia and 68 cases of surgically resected gastric cancer tissues were studied. Tissues from non-tumor or non-inflammatory gastric mucosa, showing no dysplasia or metaplasia, were used as a control in analysis of mtMSI. Hematoxylin-eosin (HE) staining was used for the histopathological diagnosis, evaluation and grading of gastritis, atrophy, intestinal metaplasia, dysplasia and cancer. Genomic DNA was isolated by standard proteinase-K digestion and phenol-chloroform extraction protocols. None of the patients with gastric cancer included in the present series had received chemotherapy or radiation therapy before operation.

mtMSI detection

PCR-single strand conformation polymorphism (PCR-SSCP) was performed to amplify the microsatellite sequence of mtDNA using published primers[18]. The primer consisted of 2 D-loop regions and 5 coding regions (Table 1). The reaction conditions and procedures were similar to those reported by Hebano *et al*[12].

Each PCR was digested by appropriate restriction enzymes and electrophoresed at 300 V at 22 ℃ for 2 h on a 75g/L polyacrylamide gel containing 50 mmol/L boric acid, 1 mmol/L EDTA and 25g/L glycerol. After silver staining, PCR products that showed mobility shifts were directly sequenced using an appropriate internal primer and analyzed using the 373A automated DNA sequencer (Perkin Elmer Cetus). All analyses were repeated twice to rule out PCR artifacts.

Table 1 Sequences of primer for PCR analysis

Repeat sequence	mtDNA region	Position	Annealing (℃)	Primer (5′ -3′)
(C)n	270-425	D-loop	58	TCCACACAGACATCAATAACA AAAGTGCATACCGCCAAAAG
(CA)n	467-556	D-loop	55	CCCATACTACTAATCTCATCAA TTTGGTTGGTTCGGGGTATG

(C)6 and (A)8	12 360-12 465	ND5	55	CACCCTAACCCTGACTTCC GGTGGATGCGACAATGGATT
(CCT)3 and (AGC)3	12 940-13 032	ND5	55	GCCCTTCTAAACGCTAATCC TCAGGGGTGGAGACCTAATT

Statistical analysis

Chi-square test with Yates' correction was used. A P value <0.05 was considered statistically significant.

RESULTS

Sixty-eight gastric cancer samples and 90 benign gastric mucosal lesions were screened for mtMSI at seven repeat sites using the PCR-RFLP method. Figure 1 exhibits a representative mobility-shift band compared with normal counterpart. mtMSI was observed in 26 out of 68 cases (38.2%) of gastric cancer, 5 out of 40 cases (12.5%) of chronic gastritis, 6 out of 30 cases (20%) of intestinal metaplasia, and 5 out of 20 cases (25.0%) of dysplasia (Table 2).

The clinicopathological characteristics of mtMSI-positive cases were compared with those of cases that were mtMSI-negative (Table 3). An association of mtMSI with intestinal histological type and distal location was found ($P=0.001$ and $P=0.002$), whereas no significant correlation was found between mtMSI and age at diagnosis, sex, tumor size, depth of invasion, lymph node spread and clinical stages ($P>0.05$).

DISCUSSION

Carcinogenesis is a long-term, multistep process driven by multiple genetic and epigenetic changes in susceptible cells, which gain a selective growth advantage and undergo clonal expansion. Genetic instability is an important factor in the rapid accumulation of these genetic changes. Much attention has been directed to the genetic events in nDNA, such as activation of oncogenes, inactivation of tumor suppressor genes, and defects of mismatched DNA repair genes[13,14]. However, several aspects in the process of carcinogenesis are still unclear. It has been shown that somatic mutations in mtDNA were detected in various human tumors[15-18]. In addition, microsatellite instability has also been shown in mtDNA of colorectal and gastric carcinomas[18-20]. Further studies demonstrated that repeated mononucleotide alteration, missense mutation, and small deletion in NADH dehydrogenase genes and alteration in polycytidine (C)*n* tract in the D-loop region of mtDNA could occur in colorectal carcinomas[18]. These results imply that mtMSI of colorectal carcinomas may likely result from certain deficiencies in DNA repair. Therefore, it has been proposed that somatic mutations and mtMSI play a role in tumorigenesis and development of cancer[21,22]. To study the role of mtMSI in gastric carcinogenesis, we analyzed 68 cases of gastric cancer using seven microsatellite markers known to be altered in gastrointestinal carcinomas. MtMSI was found in 38.2% of patients with gastric cancer, implying that mtMSI may play an important role in the occurrence of a part of gastric cancers.

The majority of gastric carcinomas, particularly the "intestinal" type, which is most common in populations at high risk, were preceded by a precancerous stage, characterized by the following sequencial steps, namely chronic gastritis, intestinal metaplasia, and dysplasia[23,24]. Although numerous cytogenetic and molecular genetic studies have been performed on gastric adenocarcinomas, fundamental data pertaining to precursor lesions which could substantially clarify our understanding of the tumorigenesis in gastric mucosa are not available. This is the first study to examine the frequency of mtMSI in intestinal metaplasia and dysplasia, two premalignant lesions of gastric cancer in individuals without gastric cancer. If mtMSI plays an early and significant role in gastric carcinogenesis, one might expect to find mtMSI in metaplastic and dysplasia tissues before the development of cancer. In this study, mtMSI was detected in 12.5% of chronic gastritis, 20.0% of intestinal metaplasia, and 38.2% of gastric cancer tissues examined. These findings showed a sequential accumulation of mtMSI in the histological progression from chronic gastritis to cancer via intestinal metaplasia and dysplasia, suggesting an early and important role of mtMSI in the gastric carcinogenesis pathway, and they may define a subset of individuals susceptible to gastric cancer.

Cancers from different mutational pathways are thought to have different clinical features. nMSI+ gastric cancer was characterized by older age, antral location, intestinal type, lower prevalence of lymph node metastasis, and a lower pTNM stage[25,26]. However, the clinicopathologic characteristics of mtMSI+ gastric cancers remain unclear. In the current study, we did not find an obvious relationship between mtMSI and tumor size, depth of invasion, node metastasis or clinical stages, indicating a limited role of mtMSI in predicting the prognosis of gastric carcinomas. Gastric carcinomas can be divided into "intestinal" type and "diffuse" type. A distinct genetic pathway has been found in gastric carcinogenesis of different histological subtypes and their tumor progression[27-29]. Increased beta-catenin mRNA levels and mutational alterations of APC and beta-catenin gene were present in intestinal type gastric cancer[30,31], whereas epigenetic inactivation of E-cadherin via promoter hypermethylation might be an early critical event

in the development of undifferentiated tumors[32-35]. In this study, a marked difference in mtMSI was noted in gastric cancer. MtMSI was much more frequent in intestinal-type gastric cancers as compared with diffuse-type gastric cancer, suggesting that mtMSI is a predisposing event in intestinal type of gastric cancer. In contrast to mtMSI-negative gastric cancer, mtMSI-positive gastric tumors tended to exhibit a predominant distal location, similar to nMSI-positive gastric tumors.

The mechanisms underlying mtMSI in gastric mucosa remain unclear. In gastric mucosa, reactive oxygen species (ROS) are commonly released in inflamed gastric mucosa as a result of infection with *Helicobacter pylori* (*H pylori*), especially CagA+ strains, and they might be responsible for mtMSI-positive gastric cancer[36-38]. Mitochondrial genome was particularly susceptible to oxidative damage and mutation because of the high rate of ROS generation and inefficient DNA repair system in the organelle[39,40]. ROS and defective DNA repair were the two causes of increased damage proposed to explain mtMSI in *H pylori* -associated gastric cancer[41-43]. A possibly important role of *H pylori* in the development of mtMSI-positive gastric cancer needed to be further studied.

Although gastric cancer is a common disease, molecular markers for its early diagnosis are lacking. Mitochondrial DNA mutations occurred in a wide variety of cancers and might be usefull in the detection of cancer[44]. Indeed, some authors have implied that mitochondrial genome instability is so common and the enrichment of mutations in cancer is so significant that some mutations probably confer a selective or replicative advantage to those cells that have acquired such mutations[21]. Others have suggested that mtDNA mutations may enhance the toxicity of anti-cancer treatments[45-48]. Thus, the existence of mtDNA mutations in cancer may impact diagnosis and treatment and may be important in understanding the progression of some cancers. Given the early involvement of mtMSI in the multistep gastric carcinogenesis model, detection of mtMSI could serve as a surrogate marker for the risk of gastric cancer development[49]. It might help to identify high-risk patient, by determining mtMSI of preneoplastic lesions, such that close monitoring or potential intervention can be performed. Because the majority of patients with intestinal metaplasia and dysplasia will not progress to cancer and only a proportion of these patients harbore mtMSI, it is conceivable that patients with intestinal metaplasia and dysplasia displaying mtMSI are at greater risk of developing gastric cancer than those without mtMSI.

In conclusion, a high frequency of mtMSI can be found in gastric cancer and its premalignant lesions. Taking into consideration of the progressive increase in mtMSI frequency from premalignant to malignant lesions, our results suggest the early involvement and continuous accumulation of mtMSI in gastric cells that have entered the multistep gastric carcinogenesis pathway. The role of mtMSI in premalignant gastric lesions as a surrogate marker of the risk of gastric cancer development warrants further investigation.

Abstract

AIM: To detect the micrometastasis of gastric carcinoma in peripheral blood circulation using immunomagnetic beads sorting technique and RT-PCR technique, and to discuss its significance and the difference between the two methods.

METHODS: Density gradient centrifugation was used to isolate mononuclear cells from peripheral blood, immunomagnetic beads sorting technique and RT-PCR technique were used to detect the disseminated carcinoma cells. HE, immunocytochemical and immunofluorescence staining were also used to identify the characteristics of the cells separated with immunomagnetic beads sorting technique.

RESULTS: Cells expressing cytokeratin were separated and enriched from the peripheral blood specimens of patients suffering from gastric carcinoma or chronic gastritis. After HE staining, two kinds of cells with little cytoplasm were found. Majority of these cells had small and round nuclei, even chromatins and the thickness of nuclear membrane was normal. Immunohistochemical staining indicated that there were CD34 and CD45 expression on the cell membrane of this kind of cells and these cells also showed expressed human telomerase reverse transcriptase by immunofluorescence staining, but the expression of carcinoembryonic antigen was absent. So, these cells might hematopoiesis precursors. Another kind of cells had larger and abnormal nuclei with thicker nuclear membranes. Massed chromatins and poly-nucleoli were found in the nuclei. These cells expressed human telomerase reverse transcriptase and carcinoembryonic antigen, but CD34 and CD45 were not found on the cell membrane. So, these cells were considered as gastric carcinoma cells escaping from the original focuses and existing in the peripheral blood circulation. Carcinoma cells were found in 25 of 60(41.7%) specimens of peripheral blood from patients with gastric carcinoma, while there were no such cells separated from the blood specimens of chronic gastritis patients. The difference of positive rates of disseminated carcinoma cells between two groups was markedly significant ($P<0.005$). The expressions of CK20 mRNA in peripheral blood specimens were examined with RT-PCR. CK20 mRNA was detected from 32 of 60(53.3%) peripheral blood specimens in the group of gastric carcinoma patients, while none of the specimens from patients suffering from chronic gastritis had CK20 mRNA. Significant difference was also found between two groups ($P<0.005$). Statistic analyses also showed that there was a significant difference between the positive rates of two methods in detecting the disseminated carcinoma cells from the peripheral blood circulation of gastric carcinoma patients ($P<0.05$).

CONCLUSION: The results demonstrated that there were disseminated carcinoma cells in the peripheral blood circulation of some patients with gastric carcinoma. Disseminated carcinoma cells can be detected from the peripheral blood samples with immunomagnetic beads sorting technique and RT-PCR technique. The positive rate of RT-PCR technique is higher than that of immunomagnetic beads sorting technique in detecting micrometastasis.

INTRODUCTION

Gastric carcinoma is one of the most common causes of cancer mortality in China and is responsible for approximately 160 000 deaths annually. The disease is often advanced at first presentation, and only 30-40% patients undergoing surgery have a curative resection. Metastasis and relapse are the common reasons leading to death of patients[1-6]. During the development of malignant neoplasm of non-hematopoietic system, a few of tumor cells escape from the original focus and disseminated into the lymph system, blood circulation, bone marrow, liver, kidney and other organs, which is called micrometastasis. It cannot be detected by any routine biochemical and histopathological assays or any graphical methods such as X-ray, CT, MRI, *etc.*[7-11]. At the same time, the patients have not any obvious symptoms. Minute focus would grow rapidly and develop to metastasis and relapse. So, to develop an efficient diagnostic method for the detection of micrometastasis is of great clinical significance[12-14]. In this study, immunomagnetic beads sorting technique and RT-PCR technique were used to detect the micrometastatic carcinoma cells in peripheral blood circulation of patients suffering from gastric carcinoma; HE staining was utilized to observe the cells' morphology changes; immunocytochemical staining and immunofluorescence staining were also used to identify the characteristics of the cells separated by immunomagnetic beads sorting technique. The significance of the micrometastatic carcinoma cell detection and the difference between the two methods were also discussed.

MATERIALS AND METHODS

Specimens

Eighty specimens of peripheral blood from sixty advanced gastric cancer patients and twenty chronic gastritis patients were collected from the Department of Endoscope of the Tongji Hospital of Tongji University. The final diagnoses of these patients were determined pathologically. The blood specimens were anti-coagulated with heparin (5 U/mL).

Separation of mononuclear cells

We carefully layered a maximum of diluted whole blood with Hank's solution over 10 mL Ficoll-Paque and centrifuged for 25 min at 2 400 r/min at room temperature, aspirated the mononuclear cells located at the plasm-Ficoll-Paque interface. We then washed the mononuclear cells once by 10 mL Hank's solution and centrifuged them at 600 r/min for 10 min.

Immunomagnetic beads separation

MACS carcinoma cell enrichment and detection kits were purchased from Miltenyi Biotech, the beads were coated with cytokeratin7 (CK7) and cytokeratin 8 (CK8). The mononuclear cells were diluted with 10 mL Dilution-Buffer and 1.3 mL MACS CellPerm Solution for 5 min. After incubated with 1.3 mL MACS CellFix solution for 30 min, the solution was centrifuged at 2 000 rpm for 10 min. Then, the sediment was mixed with 7.5 mL MACS CellStain solution and centrifuged, these two procedures were repeated again. The sediment acquired was incubated with 50 µL MACS CellStain solution, 50 µL FcR blocking regent and 50 µL MACS cytokeratin microbeads for 45 min, and after that, the mixture was centrifuged at 2 000 rpm for 5 min. The sediment was diluted with 500 µL dilution buffer and flew through the MACS column in magnetic field. The column was washed with 500 µL Dilution Buffer apart from magnetic field. The solution obtained included CK+ cells and was smeared on slides. The slides were fixed with acetone and stained with HE.

Immunocytochemical detection of CD34 and CD45 expressions in CK⁺ cells

Immunohistochemical detection of CD34 and CD45 expressions was perpormed through a two-step procedure and the kits were purchased from Immunotech Co.

Immunofluorescence detection for hTERT and CEA expression in CK⁺ cells

Immunofluorescence detection of human telomerase reverse transcriptase (hTERT) and carcinoembryonic antigen (CEA) expression was operated through two-step procedure and the kits were purchased from Sigma Co.

RT-PCR

Total RNA was extracted with Trizol (Gibco. Co) and resuspended in sterile RNase-free water for storage at -70 ℃. RT-PCR analysis was performed as follows. RNA was incubated at 60 ℃ for 10 min and chilled to 4 ℃ immediately before being reverse transcribed. Reverse transcription of 1 µg total RNA using antisense primers was performed in a volume of 20 µL for 40 min at 65 ℃, containing 200 U MMLV reverse transcriptase, 1×buffer RT, 1 MU/L RNasin, 2.0 mmol/L dNTP and 0.2 µmol/L oligo (dT) as a primer (All primers were synthesized by Life Technology, Shanghai). The primers of CK20 and β-actin were as follows: CK20 (485 bp) upstream primer: 5' AAG GCT CTG GGA GGT GCG TCT C3', downstream primer: 5' CAG TGT TGC CCA GAT GCT TGT G3'; β-actin (317 bp) upstream primer: 5' ATC ATG TTT GAG ACC A3', downstream primer: 5' CAT CTC TTG CTC GAA GTC CA3' [15]. The samples were heated to 94 ℃ for 5 min to terminate the reverse transcription reaction. The amplification reaction mixture consisted of 10×buffer 5 µL, 0.2 mmol/L dATP, dGTP, dCTP and dTTP respectively, 2.5 U TaqDNA polymerase, and 0.2 µmol/L each of sense and antisense primers including CK20 and β-actin respectively in a final volume of 50 µL. The reaction mixture was first heated at 94 ℃ for 5 min and amplification was carried out for 35 cycles at 94 ℃ for 1 min, at 58 ℃ for 1 min, at 72 ℃ for 1 min, followed by an incubation at 72 ℃ for 10 min. A volume of 10 µL RT-PCR products was added in 20 g/L agarose gel containing 0.5 mg/L EB and visualized with UV illumination after electrophoresis.

Statistic analysis

Experimental results were analyzed with Chi-square tests and *P*<0.05 was accepted as the level of significance.

RESULTS

Detection of micrometastasis by immunomagnetic sorting technique

After immunomagnetic separation, CK⁺ cells were separated in all of the peripheral blood specimens from gastric carcinoma and chronic gastritis patients. There were two kinds of cells on the slides after HE staining. Because of the application of CellPerm solution, the cytoplasm of these cells decreased obviously. One kind of these cells had small and round nuclei, even chromatins and the thickness of nuclear membrane was normal. The other kind of cells had larger nuclei, which had abnormal forms and thicker membrane. Massed chromatins and more than one nuclei could also be found in this kind of cells.

Immunocytochemical and immunofluorescence staining

Immunohistochemical staining showed that there were CD34 (Figure 1) and CD45 (Figure 2) expressions on the cell membranes of the first kind of cells and these cells also had positive expressions of hTERT (Figure 3) after immunofluorescence staining, but the expression of CEA was negative. So this kind of cells might be hematopoiesis precursors (Figure 4)[17-20]. The other kind of cells had positive hTERT and CEA (Figure 5) expressions after immunohistochemical staining, but expression of CD34 and CD45 was absent. According to the morphology and the outcome of immunohistochemical and immunofluorescence staining, these cells were considered as the disseminated carcinoma cells escaped from the primary neoplasm focus (Figure 6)[17,21-23]. The first kind of cells was found on all slides, while the other kind of cells was only found on the slides from some gastric carcinoma patients (25/60), the positive rate was about 41.7%(Table 1). There was a significant difference between two groups (*P*<0.005).

Detection of micrometastasis by RT-PCR technique

CK20 mRNA was detected in 32 blood specimens from gastric carcinoma patients; the positive rate was 53.3% (Figure 7). While no CK20 mRNA was detected from the blood specimens of patients with chronic gastritis. There was a significant difference between these positive rates (*P*<0.005,Table 2).

Table 1 Comparison of tumor cells detected with immunomagnetic beads technique

Patients	+	-	Total	%
Gastric carcinoma	25	35	60	41.7
Chronic gastritis	0	20	20	0.0
Total	25	55	80	41.7

χ^2=10.26, *P*<0.005.

Table 2 Comparison of tumor cells detected with RT-PCR

Patients	+	-	Total	%
Gastric carcinoma	32	28	60	53.3
Chronic gastritis	0	20	20	0.0
Total	32	48	80	53.3

χ^2=15.63, *P*<0.005.

Figure 1 Immunohistochemical staining showed that there was CD34 expression on the membranes of the cells, these cells had small and round nuclei, even chromatins and the thickness of nuclear membrane was normal (amplification ×1 000).

Figure 2 Immunohistochemical staining showed that there was CD45 expression on the membranes of the cells, these cells had small and round nuclei, even chromatins and the thickness of nuclear membrane was normal (amplification ×1 000).

Figure 3 Immunofluorescence staining the cells, which had small and round nuclei, even chromatins and the thickness of nuclear membrane was normal (amplification ×200), had positive expressions of hTERT.

Figure 4 The cells, which had small and round nuclei, even chromatins and the thickness of nuclear membrane was normal (HE staining, amplification×1 000), might be hematopoiesis precursors.

Figure 5 The cells, which had larger nuclei, abnormal forms and thicker membrane, and massed chromatins and more than one nuclei could also be found in this kind of cells, had positive expression of CEA (Immunofluorescence staining, amplification ×200).

Figure 6 The cells, which had larger nuclei, abnormal forms and thicker membrane, and massed chromatins and more than one nuclei could also be found in this kind of cells, had positive expressions of CEA and hTERT, and negative expressions of CD34 and CD45, were considered as the disseminated carcinoma cells escaped from the primary neoplasm focus (HE staining, amplification ×1 000).

Figure 7 RT-PCR for CK20 and β-actin. M: Marker; Lanes1-4 blood from gastric cancer; Lanes5-6 blood from chronic gastritis.

Difference between positive rates of these two methods

Statistic analysis indicated that the difference between the positive rates of these two methods which were used to detect the disseminated carcinoma cells was significant ($P<0.05$, Table 3), that is to say the positive rate of RT-PCR was higher than that of immunomagnetic bead separation technique.

Table 3 Comparison of positive rates between two methods

RT-PCR	Immunomagnetic bead separation		Total
	+	-	
+	25	7	32
-	0	28	28
Total	25	35	60

$\chi^2=5.14$, $P<0.05$.

DISCUSSION

The first reporter of micrometastasis is Ashworth who claimed that he had found cells similar to tumor cells from the peripheral blood circulation of a carcinoma patient in 1869. After that more than twenty methods have been used to detect micrometastasis on about 5 000 patients. But the latest researches indicated that those so called tumor cells were components of hematopoietic tissues, especially prokaryotic cells[24,25].

In this study, immunomagnetic beads sorting technique and RT-PCR technique were used to detect the micrometastatic gastric carcinoma cells from peripheral blood circulation and the difference of these two methods was also discussed. There are many components in peripheral blood. It has been found that tumor cells had the similar density with mononuclear cells and they located in the same layer after density gradient centrifugation[26,27]. So we removed about 90% hemocytes from blood specimens with Ficoll's solution and mononuclear cells mixed with carcinoma cells were enriched. Because gastric carcinoma is derived from epithelial tissue, so carcinoma cells could express CK, a particular component of epithelial tissue[28,29]. To separate micrometastatic gastric carcinoma cells expressing CK, immunomagnetic beads coated with anti-CK7 and anti-CK8 antibodies were used to incubate or those mononuclear cells that had been reacted with MACS CellPerm. Anti-CK7 and anti-CK8 antibodies combined with CK in the plasma of carcinoma cells by antigen-antibody reaction. So, the cells expressing CK combined with magnetic beads and detained in the magnetic field. To define the origin and characteristics of these cells, HE, immunocytochemical and immunofluorescence staining were performed. Two kinds of cells were separated after staining. Majority of these cells had small and round nucleusi, and their chromatins were even. These cells' nuclear membranes had normal thickness and expressed CD34 and CD45. They also expressed hTERT, but no CEA. Normally, CD34 and CD45 in hematopoiesis precursors, could also express hTERT[30-32]. So, these cells might be hemaptooietic precursors. Minority of these cells had larger and abnormal forms of nuclei that had thicker nuclear membrane. Massive chromatins could be observed in these cells. These cells expressed hTERT and CEA, but the expressions of CD34 and CD45 were absent on the membrane of cells. Usually, hTERT and CEA could be found in tumor cells and CEA was a marker of carcinoma derived from digestive tract[33-35], so these cells were gastric carcinoma cells escaped from the primary focuses and existed in peripheral blood circulation. This kind of cells was detected from 25 of 60 patients suffering from gastric carcinoma, while no cells were acquired from chronic gastritis patients.

CK is a component of cell skeleton and distributes in cells deriving from ectoderm. CK20, a member of this family has been found to have a stricter selectivity to epithelial tissue[28,36]. CK8 and CK9 mRNA could be detected in blood circulation with nested RT-PCR in healthy subjects, but CK20 mRNA could not be detected[37]. In this study, anti-CK7 and anti-CK8 but not anti-CK20 antibodies were coated on the beads, this should take responsibility for the separation of those hematopoietic precursors in the process of immunomagnetic beads sorting. If the immunomagnetic beads were coated with CK20, cells derived from epithelial tissue would be separated from hemocytes. These cells should be gastric carcinoma cells escaped from primary gastric carcinoma focus. Traditional methods for detecting disseminated tumor cells such as cell morphology, flowcytometer and cytogenetics were not so sensitive[38-40]. It has been found that immunomagnetic beads sorting technique has a high sensitivity to 1/10^5[41], but it has a complicated procedure and a high cost and is not so practical in clinical application. In recent years, convenient RT-PCR was invented and it has a high efficiency in detecting the micrometastasis of peripheral blood circulation, bone marrow, lymph tract and peritoneal cavity. It could detect one tumor cell diluted with one-milliliter body fluid or one gram tissue and it has been presently regarded as the most effective method to detect the disseminated carcinoma cells[42].

In this study, RT-PCR was also used to detect micrometastatic gastric carcinoma cells. According to the researches of Soeth and Burchill[15,37], CK20 was selected as the target gene for amplification. Because of the RNase existing in blood circulation, mRNA free to live cells would be decomposed rapidly. This means that there were live cells expressing CK20 mRNA existing in blood specimens when CK20 mRNA was detected from the peripheral blood circulation of patients. On the other hand, hemocytes came from mesoderm and there were no epithelial cells in blood circulation. So, when CK20 was amplified from blood circulation, there must be tumor cells in the specimen. If the specimen was extracted from a gastric carcinoma patient, the tumor cells might be gastric carcinoma cells. In this study, CK20 mRNA was detected from 32 of 60 specimens extracted from gastric carcinoma patients, but not from patients with chronic gastritis. This also confirmed that there were carcinoma cells in the peripheral blood circulation of gastric carcinoma patients.

Statistical analysis also indicated that the positive rate of detection of disseminated carcinoma cells with RT-PCR technique was higher than that with immunomagnetic beads sorting technique. This might be related with the high sensitivity of RT-PCR, which cell morphology and immunocytochemistry could not possess[43,44]. On the other hand, it is cheaper in detecting disseminated carcinoma cells with RT-PCR than immunomagnetic beads sorting technique, so it is more worthy of clinical practice. Immunomagnetic beads sorting technique could directly separate micrometastatic carcinoma cells with high behaviors of metastasis. Those tumor cells separated with immunomagnetic beads sorting technique could be cultured and the characteristics of the cells could be determined, so it is more valuable for further research[45].

In conclusion, our results indicate that there are micrometastatic carcinoma cells in the peripheral blood circulation of patients suffering from gastric carcinoma. Immunomagnetic beads sorting technique and RT-PCR technique can detect the disseminated carcinoma cells in the peripheral blood circulation. RT-PCR technique has a higher positive rate and a lower cost than immunomagnetic beads sorting technique, so it is worthy of clinical practice. Immunomagnetic beads sorting technique can directly separate carcinoma cells, so this method is more valuable for research work.

Abstract

AIM: To study the relationship between hypoxia or epidermal growth factor (EGF) and the overexpression of vascular endothelial growth factor (VEGF) in hepatocellular carcinoma (HCC) and the signal transduction pathway of the transcription of VEGF in hepatoma cells.

METHODS: Cobalt chloride and recombinant human EGF were used to stimulate the hepatoma cell lines HepG$_2$. VEGF mRNA was detected by using of semi-quantitative polymerase chain reaction (RT-PCR). Specific inhibitors of phosphatidylinositol 3-kinase (PI3K) and p42/p44 mitogen activated protein kinase (MAPK) were used to observe the effects of the two kinases on the regulation of the transcription of VEGF in hepatoma cells.

RESULTS: The expression of VEGF mRNA in HepG$_2$ cells cultured in serum-free medium was 0.117. However, 100 µmol/L cobalt chloride for 24 h increased the expression of VEGF mRNA and VEGF mRNA increased gradually with the increase of the concentration and duration of cobalt chloride. Also, 25 ng/mL recombinant human EGF stimulated the expression of VEGF in HepG$_2$ cells and the expression increased with the increase of EGF concentration. 5 µmol/L LY294002 inhibited the expression of VEGF stimulated by cobalt chloride or recombinant human EGF and the inhibition decreased step by step with increase of the concentration of LY294002. But even 20 µmol/L LY294002 could not completely block the expression of VEGF. In contrast, PD98059 had no inhibitory effects on the transcription of VEGF stimulated by cobalt chloride or recombinant human EGF.

CONCLUSION: The overexpression of VEGF in HCC could be promoted by hypoxia and EGF expression in HCC. The signal transduction pathway of VEGF transcription in HepG$_2$ cells may be through PI3K pathway, but not through p42/p44 MAPK pathway.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common cancers in China. Owing to the improvement of surgical technique and early diagnostic methods, the resection rate of HCC has increased. However, the postoperative relapse rate remains high, which has become one of the main obstacles to the therapy of HCC. The mechanisms leading to the relapse are still unclear. Much effort has been done to make it clear. Recently, neovascularization, commonly observed in HCC, has been suggested to play important roles in the relapse of HCC[1-3]. Vascular endothelial growth factor (VEGF) is one of the most potent proangiogenic agents to date. It is confirmed that there is overexpression of VEGF in HCC tissue. However, the mechanisms of VEGF overexpression in HCC are still unclear.

Phosphatidylinositol 3-kinase (PI3K) is a kind of lipid kinase which generates specific inositol lipids that are implicated in many cellular processes, such as cell growth, proliferation, survival, differentiation and cytoskeletal changes[4,5]. MAP kinases are a family of serine/threonine kinases activated through a signaling pathway triggered by numerous agonists such as growth factors, hormones, lymphokines, extracellular matrix components, tumor promoters and stress factors[6]. It has become clear that MAPKs regulate almost all cellular processes, from gene expression to cell death. Recently, both PI3K and p42/p44MAPK pathways have been both found to play important roles in the regulation of angiogenesis[7-9].

The objective of the current study was to investigate the mechanisms leading to the overexpression of VEGF in HCC *in vitro* and the possible roles of PI3K and p42/p44 MAPK in the regulation of VEGF transcription in hepatoma cells.

MATERIALS AND METHODS

Cell culture
The HepG$_2$ cells (a hepatocellular carcinoma cell line), provided by the Center of Cell Culture in Xiangya Medical College, were cultured in DMEM supplemented with 100 mL/L fetal bovine serum (FBS) and incubated at 37 ℃ in a 50 mL/L CO$_2$ atmosphere. The cells were cultured overnight in DMEM without FBS before intervention.

Reagents
Hypoxia-inducer cobalt chloride (Sigma) and recombinant human epidermal growth factor (rhEGF, Promega) were used to stimulate the cells. Before stimulation, LY294002 (Promega) and PD98059 (Promega) were used to pretreat the cells to test the function of PI3K and p42/p44 MAPK, respectively.

Treatment procedures and drugs
Seven groups included: 1. no stimulation group (NS); 2. cobalt chloride group (CC), 100-400 µmol/Lcobalt chloride stimulated the cells for 3-24 h; 3. EGF group (EGF), 25-200 ng/mL rhEGF stimulated the cells for 24 h; 4. cobalt chloride plus LY294002 group (CCL), 5-20 µmol/LLY294002 stimulated the cells 30 min before cobalt chloride treatment; 5. EGF plus LY294002 group

(EL), 5-20 µmol/L LY294002 stimulated the cells 30 min before rhEGF stimulation; 6. cobalt chloride plus PD98059 group (CCP), 25-100 µmol/L PD98059 stimulated the cells 30 min before cobalt chloride treatment; 7. EGF plus PD98059 group (EP), 25-100 µmol/L PD98059 stimulated the cells 30 min before rhEGF treatment.

Reverse transcription-polymerase chain reaction (RT-PCR)

After incubation for a given duration, the cells were harvested and the total RNA was extracted by using the TRIZOL Reagent (GIBCO BRL., USA). One microgram of RNA was reversely transcribed into cDNA in 20 µL reverse transcriptional system containing 50 mmol/L Tris-HCl, 75 mmol/L KCl, 3 mmol/L $MgCl_2$, 0.5 µg oligo-dT primer, 0.5 mmol/L deoxynucleotide triphosphate (dNTP), 20U RNasin and 200 U murine Moloney leukemia virus (M-MLV) reverse transcriptase (Promega Corp., Madison, WI), at 37 ℃ for 1 h. After reverse transcription, 5 µL of product was added to PCR buffer containing 10 mmol/L Tris-HCl, 1.5 mmol/L $MgCl_2$, 50 mmol/L KCl, 1 g/LTriton-X-100, 0.2 µmol/L forward primer, 0.2 µmol/L reverse primer, 200 µmol/L dNTP and 2.5U DNA polymerase (SANGON, SHANGHAI). The PCR was performed in a DNA thermal cycler (Perkin Elmer, USA) with a program of denaturing at 94 ℃ for 5 min; denaturing at 94 ℃ for 30 s, annealing at 55 ℃ for 30 s, extension at 72 ℃ for 1 min, the amplification was carried out for 30 cycler. The reaction was stopped in a final extension at 72 ℃ for 5 min. The forward and reverse primers for human VEGF and beta actin were purchased from SANGON (SHANGHAI) and their nucleotide sequences were listed below: VEGF: forward primer: 5' -TTGCTGCTCTACCTCCAC-3' ; reverse primer: 5' -AATGCTTTCTCCGCTCTG-3' beta actin: forward primer: 5' -ACACTGTGCCCATCTAGGAGG-3' ; reverse primer: 5' -AGGGGCCGGACTCGTCATACT-3' The sizes of PCR products were: 417 bp for VEGF, 680 bp for beta actin, respectively.

PCR products were loaded on a 20 g/L agarose gel with ethidium bromide, and band intensity was quantified by photo image analyzer (Stratagene Eagleeye II). The ratio of band intensity of the sample to the internal standard was calculated in the four reactions that contained significant amounts of both sample and standard, which stood for the amount of expression of VEGF mRNA.

Immunocytochemistry

The cells were fixed in cool acetone and sections were stained for VEGF based on streptavidin-biotin-horseradish peroxidase complex formation mentioned before[10]. In brief, the slides were treated with target retrieval solution. Monoclonal anti-VEGF antibody JH121 (200 µg/mL, NEOMARKERS, USA) was used at a dilution of 1:50. The peroxidase reaction was developed using diaminobenzidine and slides were washed. Nuclei were lightly counterstained with hematoxylin. Negative controls were performed using PBS instead of the monoclonal antibody. Two investigators independently evaluated the results of immunocytochemistry.

Statistical analysis

ANOVA was used appropriately. For the test, a P value of less than 0.05 was considered as significant. All statistics were calculated through SPSS 10.0 software.

RESULTS

The effects of cobalt chloride and rhEGF on the expression of VEGF mRNA in HepG₂ cells

The amount of expression of VEGF mRNA in HepG₂ cells cultured in DMEM without FBS was 0.117. With the increase

of the concentration of cobalt chloride, the expression of VEGF mRNA increased ($P<0.05$) (Figure 1). And also with the increase of the duration of cobalt chloride stimulation, the expression of VEGF mRNA also increased. rhEGF also stimulated the expression of VEGF mRNA in HepG₂ cells in a dependant manner of concentration and duration (Figure 2).

Figure 1 Cobalt chloride stimulated the expression of VEGF mRNA in HepG₂ cells in a concentration-dependant manner.

**Figure 2** rhEGF stimulated the expression of VEGF mRNA in HepG₂ cells in a concentration-dependant manner.

Figure 3 Negative expression of VEGF protein in HepG₂ cells cultured in DMEM without serum. Immunocytochemistry ×400.

Figure 4 Expression of VEGF protein in HepG₂ cells stimulated by cobalt chloride (400 µmol/L, 24 h) immunocytochemistry ×400.
Figure 5 Expression of VEGF protein in HepG$_2$ cells stimulated by rhEGF(25 ng/mL, 24 h) immunocytochemistry ×400.

The effects of cobalt chloride and rhEGF on the expression of VEGF protein in HepG$_2$ cells

There was no positive staining in HepG$_2$ cells cultured in DMEM without FBS. Cobalt chloride or rhEGF stimulated the expression of VEGF protein in the cytoplasm of HepG$_2$ cells (Figure 3-5), which demonstrated the results of RT-PCR.

Effects of LY294002 or PD98059 on VEGF transcription stimulated by cobalt chloride or rhEGF in HepG$_2$ cells

A 5 μmol/L LY294002 inhibited the expression of VEGF stimulated by cobalt chloride or recombinant human EGF and the inhibition decreased step by step with increase of the concentration of LY294002 ($P<0.05$). But even 20 μmol/L LY294002 did not completely block the expression of VEGF mRNA (Figure 6). In contrast, PD98059 had no inhibitory effects on the transcription of VEGF stimulated by cobalt chloride or recombinant human EGF ($P>0.05$) (Figure 7).

Figure 6 LY294002 inhibited the expression of VEGF mRNA in HepG$_2$ cells stimulated by cobalt chloride.

Figure 7 PD98059 had no effect on the expression of VEGF mRNA in HepG$_2$ cells stimulated by cobalt chloride.

DISCUSSION

Neovascularization was essential for tumour growth and metastasis[1-3]. The mechanisms underlying the neovascularization in malignancies have been the "hot spot" in the cancer research. VEGF is one of the growth factors proven to be specific and critical for blood vessel formation. In clinical experiment, we have demonstrated that there is VEGF overexpression in HCC and the level of VEGF expression in HCC is correlated not only with microvessel invasion of cancer cells, but also with the survival[11]. So it is very important to make clear the mechanisms and signal transduction pathways that control the VEGF expression in HCC. This would help us find new targets to prevent the neovascularization in HCC so as to preclude the relapse and metastasis of HCC.

Hypoxia, one of the fundamental characteristics of the tumour microenvironment, was demonstrated to be involved in the progression and metastasis of malignancy[12-16]. In the current study, we have shown that hypoxia-inducer cobalt chloride could induce the expression of VEGF in HepG$_2$ cells in a concentration and duration-dependant manner. We have also shown that rhEGF could stimulate the expression of VEGF in HepG$_2$ cells in the same manner. As a result, we could draw a conclusion that both hypoxia and EGF might be the fundamental stimulators of VEGF overexpression in HepG$_2$ cells.

Phosphatidylinositol 3-kinase (PI3K) was a kind of lipid kinase[17-21]. The lipid product of PI3K, phosphatidylinositol-3,4,5-trisphosphate (PIP$_3$), recruited a subset of signaling proteins with pleckstrin homology (PH) domains to the membrane, where they were activated. These proteins included protein serine-threonine kinases (Akt and PDK1), protein tyrosine kinases (Tec family), exchange factors for GTP-binding proteins (Grp1 and Rac exchange factors), and adaptor proteins (GAB-1). Ultimately, these proteins initiated complex sets of events that controlled protein synthesis, actin polymerization, cell survival, and cell cycle entry.

Recently, PI3K has been demonstrated to be involved in the regulation of the transcription of VEGF in certain types of cells. Overexpression of VEGF mRNA has been found in endothelial cells in which the PI3K pathway has been activated[22]. LY294002, the specific inhibitor of PI3K, could inhibit the expression of VEGF in endothelial cells. In addition, PI3K was found to be involved in the regulation of VEGF transcription in cancer cells. In the prostate cancer cell line, LY294002 could completely block the expression of VEGF[23]. Maity *et al* also demonstrated PI3K was essential in the regulation of VEGF transcription in glioma cell line U87MG[24]. In the current study, we have shown that LY294002 inhibit VEGF transcription stimulated by cobalt chloride or rhEGF in a concentration and duration dependant manner. To our knowledge we demonstrated for the first time that PI3K was involved in the regulation of the signal transduction pathway of VEGF transcription in the hepatoma cells. At the same time, we observed that even 20 μmol/L LY294002 could not block the VEGF mRNA expression completely, which was likened to the results of Zhong[23] and Maity[24]. So there was PI3K-independent pathway in the regulation of VEGF transcription in HepG$_2$ cells.

MAPKs were important signal transducing enzymes, unique to eukaryotes, that were involved in many facets of cellular regulation, such as gene expression, cellular proliferation and programmed cell death[25-27]. Recently, MAPKs has been shown to be involved in the regulation of neovascularization. Rak *et al* have shown that in the Ras-transforming mouse fibroblast cell line 3T3RAS, VEGF expression was not blocked by LY294002, but by PD98059, the specific inhibitor of p42/p44 MAPK[28]. This result suggested that p42/p44 MAPK was involved in the regulation of VEGF transcription in 3T3RAS cells. In the current study, we did not observe PD98059 could

preclude VEGF transcription in HepG$_2$ cells, which indicated p42/p44 MAPK was not involved in the regulation of VEGF transcription in HepG$_2$ cells.

In conclusion, hypoxia and EGF were two stimulators to the VEGF overexpression in hepatoma cells. VEGF transcription might be regulated by PI3K pathway and other PI3K-independent pathway, but not by p42/p44 MAPK pathway.

Abstract

AIM: Transcatheter arterial embolization (TAE) of the hepatic artery has been accepted as an effective treatment for unresectable hepatocellular carcinoma (HCC). However, embolized vessel recanalization and collateral circulation formation are the main factors of HCC growth and recurrence and metastasis after TAE. Vascular endothelial growth factor (VEGF) plays an important role in tumor angiogenesis. This study was to explore the inhibitory effect of VEGF antisense oligodeoxynucleotides (ODNs) on VEGF expression in cultured Walker-256 cells and to observe the anti-tumor effect of intra-arterial infusion of antisense ODNs mixed with lipiodol on rat liver cancer.

METHODS: VEGF antisense ODNs and sense ODNs were added to the media of non-serum cultured Walker-256 cells. Forty-eight hours later, VEGF concentrations of supernatants were detected by ELISA. Endothelial cell line ECV-304 cells were cultured in the supernatants. Seventy-two hours later, growth of ECV-304 cells was analyzed by MTT method. Thirty Walker-256 cell implanted rat liver tumor models were divided into 3 groups. 0.2 mL lipiodol (LP group, n=10), 3OD antisense ODNs mixed with 0.2 mL lipiodol (LP+ODNs group, n=10) and 0.2 mL normal saline (control group, n=10) were infused into the hepatic artery. Volumes of tumors were measured by MRI before and 7 d after the treatment. VEGF mRNA in cancerous and peri-cancerous tissues was detected by RT-PCR. Microvessel density (MVD) and VEGF expression were observed by immunohistochemistry.

RESULTS: Antisense ODNs inhibited Walker-256 cells' VEGF expression. The tumor growth rate was significantly lower in LP+ODNs group than that in LP and control groups (140.1±33.8%, 177.9±64.9% and 403.9±69.4% respectively, F=60.019, P<0.01). VEGF mRNAs in cancerous and peri-cancerous tissues were expressed highest in LP group and lowest in LP+ODNs group. The VEGF positive rates showed no significant difference among LP, control and LP+ODNs groups (90%, 70% and 50%, H=3.731, P>0.05). The MVD in LP+ODNs group (53.1±18.4) was significantly less than that in control group (73.2±20.4) and LP group (80.3±18.5) (F=5.44, P<0.05).

CONCLUSION: VEGF antisense ODNs can inhibit VEGF

expression of Walker-256 cells. It may be an antiangiogenesis therapy agent for malignant tumors. VEGF antisense ODNs mixed with lipiodol embolizing liver cancer is better in inhibiting liver cancer growth, VEGF expression and microvessel density than lipiodol alone.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignant tumors in human beings[1,2]. In China, HCC is responsible for 130 000 deaths every year and the second cause of cancer deaths[3]. Surgical resection is still the only potentially curative treatment for HCC, particularly for small HCC[3,4]. To date, the resection rate for HCC is unfortunately less than 30%[3,5,6]. Since HCC's blood supply is derived almost exclusively from hepatic arteries, transcatheter arterial embolization (TAE) of the hepatic artery has been accepted as an effective treatment for unresectable HCC[5-10]. Although embolic materials and technique have been improved during the last decade, the outcome of TAE is not satisfactory. It hardly leads to tumor necrosis totally. The 3-year survival rate is about 14-35%[11-14]. Recanalization of the embolized vessel and collateral circulation formation, which are related with tumor angiogenesis, are the main factors of HCC growth, recurrence and metastasis after TAE[15,16]. In TAE, HCC cells undergo coagulative necrosis, a pathologic feature of anoxia. Anoxia and hypoxic liver injury are caused by the absolute and relative deficiency of oxygen, respectively. It is well known that hypoxia tension is a key factor of the gene expression of angiogenic factors such as VEGF, acidic and basic fibroblast growth factors (FGF), platelet derived growth factor (PDGF). These factors could promote tumor angiogenesis, growth, recurrence and metastasis[17,18]. It is possible that in addition to elimination of cancer cells, TAE may play a role in enhancing some cells' malignant potency and ability to escape anoxia and ischemia after treatment.

VEGF is a key mediator of pathological angiogenesis. Many researchers found that it overexpressed in many solid tumor tissues including HCC, and was associated with tumor growth, recurrence, metastasis and patient's prognosis[19-23]. It has been reported that preoperative TAE enhanced VEGF expression in both HCC cells and non-carcinoma liver cells. Antisense RNA could inhibit and block gene expression effectively[24-26]. In this study, we devised antisense ODNs specific to VEGF mRNA, and observed their inhibitory effects on VEGF expression in Walker-256 cell lines *in vitro*, and the anti-tumor effect of them mixed with lipiodol arterial embolization on Walker-256 cell transplanted rat liver cancer models.

MATERIALS AND METHODS

Cell culture

Walker 256 carcinosarcoma cells were purchased from China

Center for Type Culture Collection. After recovery, the cells were inoculated in the abdominal cavity of male pathogen-free Wistar rats, weighing 100-120 g (supplied by Department of Experimental Animal, Tongji Medical College). Three days later, cancerous ascites was aspirated and cultured in RPMI-1640 containing 50 mL/L fetal calf serum (FCS) (Gibco, Grand Island, NY) and equilibrated with 950mL/L air and 50mL/L CO_2. Cells were passaged every 2 d. The cells at passage 3 were used for experiments.

Oligodeoxynucleotides (ODNs)

Phosphorothioate ODNs were synthesized by Shanghai Sangon Biological Engineering Technology and Service Co., LTD. The sequences of ODNs were designed as follows: antisense ODNs: 5' -GCA GTA GCT GCG CTG ATA GCG C-3' , complementary to the linkage area of VEGF exon 2 and exon 3; sense ODNs: 5' -GCA CTA TCA GCG CAG CTA CTG C-3' , equivalent to the linkage area of VEGF exon 2 and exon 3.

Cell proliferation studies

Walker-256 carcinosarcoma cells were planted into a 24-well plate at 1×10^5/well (1 mL/well) and cultured in non-serum medium. Ten μL of 0.25, 0.5, 1.0, 2.0 μmol/L antisense ODNs and sense ODNs was added to the media every 24 h. Ten μL of non-serum medium was added to the blank control wells. Forty-eight hours later, the supernatant fluids were collected. The concentration of VEGF was measured by ELISA. Two hundred μL of supernatant fluids was added triplicate to a 96-well plate to culture ECV-304 cells (endothelial cell line, purchased from China Center for Type Culture Collection, 1×10^4/well), equilibrated with 950 mL/L air and 50 mL/L CO_2. Seventy-two hours later, ECV-304 cells were collected. MTT method was used to detect the growth of ECV-304 cells.

Tumor model and treatment schedule

Walker-256 carcinosarcoma cells were inoculated subcutaneously in the right flank of rats with 10^7 tumor cells in approximately 0.1 mL of cell suspension. Tumors were palpable 7 d after transplantation. Fresh tumor tissues were isolated and cut into 1 mm³ size. Following midline laparotomy, the Walker 256 carcinosarcoma tissue pieces were implanted into the left hepatic lobe of rats. Seven days later, after anesthesia and laparotomy, the gastroduodenal artery was retrograde catheterized with a Portex PE10 tube (inner diameter 0.28 mm, external diameter 0.61 mm, Neolab, Germany) under a binocular operative microscope (Suzhou Medical Instruments Factory, Jiangsu, China) and infused embolic materials to perform TAE. The common hepatic artery and right hepatic artery were temporarily ligated during infusion. Thirty tumor-bearing rats were randomly divided into 3 groups, 10 rats each. LP group: the hepatic arteries were embolized with 0.2 mL lipiodol (Lipiodol Ultra-Fluid; Andre Guerbet, Aulnay-Sous-Bois, France), LP+ODNs group: the hepatic arteries were embolized with 3OD antisense ODNs mixed with 0.2 mL lipiodol, control group: 0.2 mL normal saline was infused into hepatic arteries. Then the gastroduodenal artery was ligated and the abdominal cavity was closed.

MR scans were performed on 1.5-Tesla system (Magnetom Vision, Siemens, Germany) supplemented by a cervical coil before and 7 d after TAE. T1-weighted (TR/TE, 450/12 ms) and T2-weighted (TR/TE, 2800/96 ms) transverse SE images (slice thickness 2 mm) were acquired using acquisition times of 7:25 and 6:16 min, respectively. Tumor volume was determined from MR measurements of the largest and smallest diameters and calculated according to the following formula: Tumor volume (mm³, V) = largest diameter (mm) × [smallest diameter (mm)]²/2. The tumor growth rate = $V_{post}/V_{pre}\times100\%$.

The rats were sacrificed 7 d after TAE. Liver cancerous and peri-cancerous tissues were dissected. Some of them were frozen at -70 ℃ for RNA isolation. The reminders were fixed in 40g/L formaldehyde, dehydrated and embedded in paraffin. Five-μm sections were stained with hematoxylin-eosin for light microscopy and measurement of the degree of tumor necrosis.

RNA isolation and RT-PCR analysis

Total RNA was extracted from liver cancerous and peri-cancerous tissues using the TRIzol reagent (Gibco). Reverse transcription of 5 μg total RNA was performed in a volume of 20 μL for 60 min at 37 ℃, containing AMV 5U, Oligo dT 0.050 μg, RNasin 20 U, 10 mmol/L dNTP 2 μL. The samples were heated to 95 ℃ for 5 min to terminate the reverse transcription reaction. By using a Perkin-Elmer DNA thermocycler 2 400 (Perkin-Elmer, Norwalk, CT), 2 μL cDNA mixture obtained from the reverse transcription reaction was then amplified for VEGF and G_3PDH. G_3PDH was used as a housekeeping gene and amplified with VEGF as control. The amplification reaction mixture consisted of 10×buffer 2.5 μL, 5 mmol/L dNTP 0.5 μL, 25 mmol/L $MgCl_2$ 1.5 μL,10 pmol/L each of sense and antisense primers, Taqase 5U. The reaction mixture was first heated at 95 ℃ for 5 min and amplification was carried out for 35 cycles at 94 ℃ for 30 s, at 60 ℃ for 30 s, and at 72 ℃ for 30 s, followed by incubation for 10 min at 72 ℃. The PCR primers used were: VEGF, sense 5' -GAA GTG GTG AAG TTC ATG GAT GTC-3' and antisense 5' -CGA TCG TTC TGT ATC AGT CTT TCC-3' ; G_3PDH, sense 5' -TCC CTC AAG ATT GTC AGC AA-3' and antisense 5' -AGA TCC ACA ACG GAT ACA TT-3' . The length of PCR products for VEGF and G_3PDH was 394 bp and 309 bp. PCR products were checked with 15 g/L agarose gel electrophoresis stained with ethidum bromide.

Immunohistochemical analysis

Five micron paraffin-embedded tissue sections were deparaffinized and rehydrated. Rabbit anti-mouse vWF, VEGF monoclonal antibody and SABC kit were provided by Beijing Zhongshan Biological Technology Co., Ltd. Immunohistochemical studies were performed by SABC methods according to the manufacturer' s instructions. VEGF staining was evaluated semiquantitatively on the basis of the percentage of positive cells, and classified as follows: diffusely positive (+++) when positive cells accounted for more than 50% of the total cells, moderately positive (++) when positive cells were 16-50%, weakly positive (+) when positive cells accounted for 5-15%, and negative (-) when positive cells accounted for less than 5%. For MVD determination, 5 areas were randomly selected and counted at a magnification of 200. Briefly, the stained sections were screened at a magnification of 40 under a light microscope to identify 3 regions of the section with the highest microvessel density. Microvessels were counted in these areas at a magnification of 200, and the average number of microvessels was recorded.

Statistical analysis

Experimental results were analyzed with analysis of variance (ANOVA) and Kruskal-Wallis rank test. The difference between 2 groups was analyzed by SNK-q and Dunn test respectively. Statistical significance was determined at $P<0.05$.

RESULTS

VEGF concentration in supernatant of walker-256 cells

After incubated with walker-256 cells for 48 h, antisense ODNs decreased the concentration of VEGF in the supernatant of walker-256 cells in a dose-dependent manner, whereas no significant changes were seen in sense ODNs (Table 1).

Table 1 Concentration of VEGF in supernatant of Walker-256 cells (pg/ml)(mean±SD)

Group	0.25 μmol/L	0.5 μmol/L	1.0 μmol/L	2.0 μmol/L
Antisense ODNs	84.2±2.2	79.2±2.6	74.4±2.1	65.2±2.0
Sense ODNs	89.2±1.9	90.4±2.6	88.2±1.9	88.6±2.5
Control	90.2±1.9	90.8±1.8	89.4±2.1	90.4±1.7
F values	7.877	23.132	49.906	133.636
P values	0.021[1]	0.002[1]	0.000[1]	0.000[1]

[1]SNK-*q* test: The difference between sense ODNs and control groups was not statistically significant.

Cell proliferation study

The supernatants of Walker-256 cells that were incubated with antisense ODNs could inhibit the growth of ECV-304 cells in a dose-dependent manner. No significant effects were seen in those incubated with sense ODNs (Table 2).

Table 2 Inhibitory effect of supernatants of Walker-256 cells cultured with ODNs on ECV-304 proliferation (OD) (mean±SD)

Group	0.25 μmol/L	0.5 μmol/L	1.0 μmol/L	2.0 μmol/L
Antisense ODNs	0.339±0.012	0.332±0.006	0.327±0.008	0.321±0.019

Control	0.357±0.010	0.359±0.008	0.356±0.005	0.360±0.009
F values	2.477	5.573	12.931	7.296
P values	0.164	0.043[1]	0.007[1]	0.025[1]

[1]SNK-*q* test: The difference between sense ODNs and control groups was not statistically significant.

Tumor growth and histopathological findings

Seven days after implantation, the tumor was located in the left lobe of liver as a solitary mass. There was no statistical difference between the volumes of tumors in control group, LP group and LP+ODNs group (212.3 ± 117.5 mm^3, 174.6 ± 106.5 mm^3, 173.9 ± 91.8 mm^3 respectively) before TAE treatment. Seven days after the treatment, all tumors grew. The volumes and growth rates in LP group (286.0 ± 186.4 mm^3, $177.9\pm64.9\%$, respectively) and LP+ODNs group (337.6 ± 98.1 mm^3, $140.1\pm33.8\%$, respectively) were significantly less than those in control group (823.3 ± 426.1 mm^3, $403.9\pm69.4\%$, respectively, $P<0.01$) (Table 3).
Table 3 Volumes and growth rates of transplanted liver tumors (mean±SD)

Group	Volume of pre-TAE(mm³)	Volume of post-TAE(mm³)	Growth rate (%)
Control	212.3±117.5	823.3±426.1	403.9±69.4
LP	174.6±106.5	286.0±186.4	177.9±64.9
LP+ODNs	173.9±91.8	337.6±98.1	140.1±33.8
F values	0.432	14.319	60.019
P values	0.653	0.000[1]	0.000

[1]SNK-*q* test: The difference between antisense LP and LP+ODNs groups was not statistically significant.

Hematoxylin-eosin (H & E) stained sections of the liver specimens showed a poorly differentiated carcinoma, which was spherical or ovoid in shape. Tumor cells arranged in irregular nests and signs of malignancy including hyperchromatosis, polymorphism and numerous mitoses were detected. The mass had a sharp demarcation from the surrounding normal hepatic parenchyma, its capsules were thin and composed of collagen fibers, which were caused by the compression of the tumor. The tumor showed inhomogeneous signs of hypervascularization consisting mainly of small arteries and capillaries. Seven days after therapy, spotty and scattered necrosis were seen in all cases of control group (Figure 1A). Satellite nodules could be seen in some tumors. In LP group, the necrotic area was increased. Many patched necrotic zones were seen in tumor tissues (Figure 1B). In LP+ODNs group, the tumor necrotic area was much wider. It showed a big area of central necrosis. The residual tumors could be seen only in the margin of tumor (Figure 1C).

Figure 1 Pathological changes of tumor tissues 7 d after TAE. A: Control group showing spotty and scattered necrosis. B: LP group showing many patched necrotic zones. C: LP+ODNs group showing big areas of central necrosis. Hematoxylin-eosin ×40.

Figure 2 RT-PCR analysis of VEGF mRNA level in cancerous and peri-cancerous tissues using G$_3$PDH as internal control. Control group: 1 tumor, 2 peri-tumor. LP group: 3 tumor, 4 peri-tumor. LP+ODNs group: 5 tumor, 6 peri-tumor, 7 marker.

RT-PCR analysis of VEGF mRNA expression

VEGF mRNA expression was detected in cancerous and peri-cancerous tissues. The expression level in cancerous tissue was higher than that in peri-cancerous tissues. The VEGF mRNA levels in cancerous and peri-cancerous tissues in LP group were higher than those in control group, and those in LP+ODNs group were lower than those in control and LP groups (Figure 2).

Table 4 Expression of VEGF and MVD by immunohistochemical staining (*n*=10)

Group	MVD (mean±SD)	VEGF				
		+++	++	+	-	Positive rate (%)
Control	73.2±20.4	3	2	2	3	70
LP	80.3±18.5	3	4	2	1	90
LP+ODNs	53.1±18.4	1	2	2	5	50
Test values	*F*=5.440			*H*=3.731		
P values	0.010[1]			0.1545		

[1]SNK-*q* test: The difference between LP and control groups was not statistically significant.

Immunohistochemical analysis of VEGF protein expression and MVD

VEGF immunoreactivity was observed mainly in the cytoplasm of tumor cells, and also frequently in hepatic cells in peri-cancerous tissues. The distribution of strong VEGF-staining zones and microvessels was mainly in the survival nidui and margins of the tumor. The positive rate of VEGF in LP group, control group and LP+ODNs group was 90%, 70% and 50% respectively, and the difference was not statistically significant (*P*=0.065) (Table 4, Figure 3). The MVD in LP+ODNs group (53.1±18.4) was significantly less than that in control group (73.2±20.4) and LP group (80.3±18.5). Although the MVD in control group and LP group showed no significant difference, but abundant tumor vessels were seen in residual nidui in LP group (Table 4, Figure 4).

DISCUSSION

Many authors have reported the effects of TAE on VEGF expression of HCC. An *et al*[27] found that preoperative TAE enhanced VEGF expression in both HCC cells and non-carcinoma liver cells. Kobayashi *et al*[28] reported that the frequency of Bcl-2 positive cells was higher in HCCs undergone TAE than that in HCCs not undergone TAE, and the immunohistochemical staining intensity for VEGF was higher in Bcl-2 positive than in Bcl-2 negative area. Suzuki *et al*[29] reported that the serum levels of VEGF in HCC patients increased significantly 7 d after TAE. Guo *et al*[30] reported that blockage of hepatic arterial blood supply resulted in decreased blood perfusion and increased expression of metastasis-associated genes VEGF and MMP-1 of transplanted liver cancer in rats. The results in this study showed that VEGF mRNA and protein had an increasing tendency after TAE. These findings suggested that TAE could enhance the expression of VEGF in HCC cells. The rationale is based on the following points: TAE was hard to lead to total tumor necrosis and to make the tumor tissue anoxia further. Hypoxia induced transcription of VEGF mRNA was mediated by the binding of hypoxia-inducible factor 1 (HIF-1) to an HIF-1 binding site located in the VEGF promoter[31-33]. VEGF plays an important role in each stage of tumor angiogenesis. The overexpression of VEGF in cancerous and peri-cancerous tissues of HCC could certainly promote tumor

Figure 3 Immunohistochemical staining of VEGF in tumor tissues 7 d after TAE, showing strong expression in LP group and low expression in LP+ODNs group. A: Control group, B: LP group, C: LP+ODNs group. SABC ×200.

Figure 4 Immunohistochemical staining of vWF in tumor tissues 7 d after TAE, showing plenty of microvessels in LP group and a few microvessels in LP+ODNs group. A: Control group, B: LP group, C: LP+ODNs group. SABC×200.

angiogenesis and collateral vessels formation, and enhance the possibility of recurrence and metastasis[34-37]. In this study, although we found that the MVD in LP group was higher than that in control group, but the difference was not significant and abundant tumor vessels were seen in residual nidui in LP group. It must be due to tumor angiogenesis enhancement caused by VEGF overexpression after TAE. In clinical setting, we also found that the collateral vessels were increased with the time of increased TAE. These vessels are very small and hard to catheterize, resulting in the embolized HCC tissue receiving blood and escaping from anoxia stress. Some HCC vessels not embolized completely would grow acceleratedly and were prone to recurrence and metastasis. So it is very important to reduce VEGF expression and collateral vessel formation after TAE.

Antisense ODNs have shown great efficacy in selective inhibition of gene expression. They are designed and synthesized artificially, and can enter cells directly to hybridize with complementary mRNA and decrease protein expression. They have been used as an important tool to inhibit the expression of oncogenes and/or growth factors and some of them have been used as drugs in tumor gene therapies[38-41]. In this study, antisense ODNs were designed to complement the region between exon 2 and exon 3 of VEGF gene. They could inhibit 4 kinds of VEGF molecules' expression[42,43]. To enforce their stability, ODNs were modified by phosphorothioate. Our previous study showed fluorescence labeled ODNs could transfect Walker-256 cells and keep in them for about 48 h (in press). The *in vitro* experimental results in this study showed that VEGF antisense ODNs could decrease VEGF expression of cultured Walker-256 cells in a dose-dependent manner. Similar effect has been reported on other tumor cell lines[41, 44-46]. In *in vivo* study, we also found that VEGF antisense ODNs could inhibit VEGF expression of liver tumor tissues after TAE, reduce tumor MVD and growth rate in walker-256 cell transplanted rat liver cancer models. These imply that VEGF antisense ODNs could be used as an antiangiogenesis agent to inhibit HCC' s overexpression and collateral vessel formation after TAE.

Intravenous injection is the routine means for phosphothioate ODNs in clinical administration. However, intravenous infusion is not an ideal route for VEGF antisense ODNs in HCC treatment. First, it has a very short lifetime after injection into animal bodies. To enhance the target cell transfection rate and therapeutic effect, it is needed to increase the dose of antisense ODNs. A higher dose of ODNs may result in more side effects such as dose-dependent hypotension, complement activation, and transient prolongation of thromboplastin time[47-50]. Second, systemic administration of VEGF antisense ODNs might inhibit physiological angiogenesis, such as wound healing, menstruation. In this study, we mixed antisense ODNs with lipiodol and used them as an embolic agent in liver tumor TAE therapy. To infuse the agents into the left hepatic artery (the tumor was planted in the left lobe of the rat liver) and to make each tumor receive the same amount of agents, we catheterized the gastroduodenal artery retrograde and ligated the common hepatic artery and right hepatic artery temporarily during infusion. The results showed that antisense ODNs mixed with lipiodol was better in inhibiting tumor growth rate, VEGF expression and MVD than lipiodol alone. These indicated that antisense ODNs used in combination with lipiodol and transcatheter artery embolization were the ideal route in HCC treatment. The rationale is based on the following points. The blood supply of HCC is mainly from hepatic artery. ODNs hepatic artery infusion could increase the concentration in tumor tissue and reduce the dosage and systemic side-effects. When injected to the hepatic artery, lipiodol could stay in tumor tissue for a long time (several months), and could even be absorbed by tumor cells[51,52]. When mixed with lipiodol, the latter could act as a carrier, ODNs would give off slowly from it. It would prolong the contact time of ODNs and tumor cells, which is very important to increase the transfect rate. Our previous *in vivo* experimental study showed that fluorescence labeled ODNs could stay in tumor tissue for about 6 d when used in combination with lipiodol hepatic artery embolization on Walker-256 cell transplanted rat liver cancer models (in press). This is why the long-term inhibitory effect on VEGF expression and MVD was achieved in this study.

In conclusion, TAE can increase the formation of microvessels in residual tumor tissues. VEGF plays an important role in liver cancer angiogenesis and collateral vascular formation after TAE treatment. VEGF antisense ODNs are able to inhibit tumor cells' VEGF expression. VEGF antisense ODNs can inhibit the residual tumor angiogenesis and growth and reduce the possibility of metastasis and recurrence. The combination of TAE and VEGF antisense ODNs will be a hopeful strategy for HCC treatment.

Abstract

AIM: To investigate the molecular mechanism of alpha-fetoprotein (AFP) on regulating the proliferation of human hepatocellular carcinoma cells.

METHODS: Alpha-fetoprotein purified from human umbilical blood was added to cultured human hepatocellular carcinoma Bel 7402 cells *in vitro* for various treatment periods. The expression of *c-fos*, *c-jun*, and *N-ras* mRNA involved in proliferation and differentiation of cells was analyzed by Northern blot, and the expression of mutative p53 and p21^{ras} proteins was determined by Western blot.

RESULTS: The results showed that AFP (20 mg/L) stimulated mRNA expression of these oncogenes in Bel 7402 cells. The expression of *c-fos* mRNA increased by 51.1%, 60.9%, 96.0%, and 25.5% at 2, 6, 12, and 24 h, respectively. The expression of *c-jun* and *N-ras* mRNA reached to the maximum which increased by 81.3% and 59.9% as compared with the control after 6 h and 24 h incubation with AFP, respectively. Western blot assay also demonstrated that AFP promoted the expression of mutative p53 and p21^{ras} proteins, and the increased rate of those proteins was 13.0%, 39.9%, and 70.9%, as well as 35.2%, 102.6%, and 46.8% at 6, 12, and 24 h, respectively, as compared with the control. Both human serum albumin (the same dosage as AFP) and monoclonal anti-AFP antibody failed to stimulate the expression of these oncogenes, but anti-AFP antibody could block the functions of AFP.

CONCLUSION: The data indicate that AFP can stimulate the expression of some oncogenes to enhance the proliferation of human hepatocellular carcinoma Bel 7402 cells.

INTRODUCTION

Alpha-fetoprotein is the major serum protein in human embryos, and is synthesized by embryonic liver and yolk sac. During the embryonic growth course, AFP expresses much more (3 g/L), and falls to the adult level (0.02×10^{-3} g/L) after one-year birth. Although many investigations for the function of AFP had been carried out, the biological role of AFP is still a riddle so far. Because the composition and the sequence of the amino acid resides of AFP were very similar to those of human serum albumin, thus, people always think that the function of AFP just like human serum albumin, which functions to transport materials and stabilize blood colloid osmotic pressure in the life course of the fetus. However, the concentration of serum AFP increases apparently with liver cancer or liver optimum regeneration in humans. AFP always accompanies with the growth of liver cells, and it is possible that AFP may be related to the proliferation of tumor or fetal cells. Some investigations had showed that AFP could be individually synergy with other growth factors to promote the growth of many tumor or normal cells[1-6]. Alpha-fetoprotein (MW 69 ku) is a kind of biomacromolecules, and it is impossible to directly permeate the cells to regulate cell proliferation. We previously found that AFP could enhance growth of human hepatocellular carcinoma Bel 7402 and NIH3T3 cells, and there were two typical receptors of AFP existed on the membranes of these cells[7,8]. However, it has not been reported in former investigations how AFP influences the expression of oncogenes which are mediated by AFP receptors to regulate growth of human hepatocellular carcinoma cells. This study used human hepatocellular carcinoma Bel 7402 cell line, which is closely related to AFP, to observe mRNA expression of the oncogene *c-fos*, *c-jun*, and *N-ras*, and protein expression of mutative p53 and p21^{ras}, which are correlated with cell proliferation, after treated with AFP. Additionally, the study explored some molecular mechanisms for AFP-mediated growth of human hepatocellular carcinoma cells.

MATERIALS AND METHODS

Materials

Human hepatocellular carcinoma Bel 7402 cells, crude AFP, and monoclonal anti-AFP antibody were provided by Endocrine Research Group of the Department of Biochemistry and Molecular Biology, Health Science Center, Peking University; RPMI 1640 medium was purchased from GIBCO; Fetal calf serum (FCS) was from the Blood Research Institute of Chinese Medicine Science Academy (Tianjin, China); Human serum albumin (HSA) and MOPS were purchased from Sigma Company; Diethyl pyrocarbonate (DEPC), sodium dodecyl sulfate (SDS), agarose, and Tris were obtained from Bio-Rad Company; Total RNA extraction kit was purchased from Promega Company; α-^{32}P-dCTP was bought from YaHui Biology Engineer Company (Beijing, China); *N-ras*, *c-fos*, *c-jun,* and β-actin cDNA probes were from the Department of Endocrinology, Northwestern University (Chicago); Random primer labeling kit was the product of Takara company (Japan); Salmon sperm DNA, fraction V of bovine serum albumin (BSA), and Ficoll-400 were bought from the Jingke Chemical

Reagents Company (Beijing, China); Monoclonal antibodies for mutative p53 and p21[ras] were from NEOMARKERS Company.

Methods

Purification of human AFP Human AFP was prepared by the method as described elsewhere[9]. Briefly, human cord blood AFP was precipitated by ammonium sulfate and passed through an anti-AFP antibody affinity chromatography column. The AFP-positive fractions were collected and concentrated. The purity of prepared AFP was 92.7% determined by SDS-polyacrylamide gel electrophoresis (SDS-PAGE). The protein was stored at -80 ℃ until analysis.

Cells culture Human hepatocellular carcinoma Bel 7402 cells (1.5×10^4/mL) were cultured in RPMI 1640 medium supplemented with 100 mL/L FCS at 37 ℃ in a humidified atmosphere of 50 mL/L CO_2. The cultured medium was changed after 24 h.

RNA isolation and Northern blot analysis The cells were treated with AFP (20 mg/L), HSA (20 mg/L), anti-AFP antibody (40 mg/L), or AFP (20 mg/L) + anti-AFP antibody (40 mg/L) for 2, 6, 12, and 24 h, respectively. Total cellular RNA was isolated from Bel 7402 cells using a TRIzol reagent kit (Promega, Madison, WI) according to the manufacturer's protocol. Then, RNA was quantitated by the absorbance at 260 nm, and RNA (10-20 μg/lane) was fractionated by electrophoresis through 10 g/L formaldehyde agarose gel. The fractionated RNA was transferred in 20×SSC buffer to the nitrocellulose membrane (Millipore Corporation, Bedford, MA) using the standard procedure[10]. These membranes were hybridized with α-^{32}P labeled probe, and washed using the standard protocol. The membranes were then exposed to the X-ray film at -80 ℃.

Purification of protein and Western blot analysis The cells were treated with AFP (20 mg/L), HSA (20 mg/L), anti-AFP antibody (40 mg/L), or AFP (20 mg/L) + anti-AFP antibody (40 mg/L) for 6, 12, and 24 h, respectively. After washed three times with PBS (pH 7.4, 0.15 mol/L), the cells were lyzed in 10 μL of lysis buffer containing 2 mL/L Triton X-100, 500 mmol/L NaCl, 500 mmol/L sucrose, 1 mmol/L EDTA, 0.15 mmol/L spermine, 0.5 mmol/L spermidine, 10 mmol/L HEPES (pH 8.0), 200 μmol/L phenylmethylsulfonyl fluoride, 2 mg/L leupeptin, 2 mg/L pepstatin, 24 000 IU/L aprotinin, and 7 mmol/L β-mercaptoethanol. Proteins (40 μg) were subjected to SDS-PAGE, and transferred to the PVDF membrane for immunodetection. The SDS-PAGE molecular weight markers (Bio-Rad) verified the correct location of the visualized bands. The membranes were blocked with 50 mL/L nonfat milk in PBS-Tween, probed with anti-p53 or anti-p21 antibody, and followed by secondary antibody (goat anti-mouse IgG-alkaline phosphatase). Immunoreactive proteins were detected using a color develop system (NBT/BCIP) by the standard procedure[10].

RESULTS

Expression of c-fos mRNA

Northern blot analysis demonstrated the overexpression of *c-fos* mRNA in Bel 7402 cells after treated with AFP for 2, 6, and 12 h. The data showed that AFP (20 mg/L) treated for 2 h significantly increased the expression of *c-fos* mRNA in Bel 7402 cells by 51.1% compared with the control group. The expression of *c-fos* mRNA continuously increased by 60.9% and 96.0% when treated with AFP for 6 h and 12 h, respectively, and declined thereafter to 25.5% increase at 24 h, compared with control group (Figure 1). However, HSA at the same dosage (20 mg/L) as AFP and anti-AFP antibody (40 mg/L)

had no significant influence on the expression of *c-fos* mRNA in Bel 7402 cells. Anti-AFP antibody partially blocked an increase in the expression of *c-fos* mRNA by AFP (Figure 2).

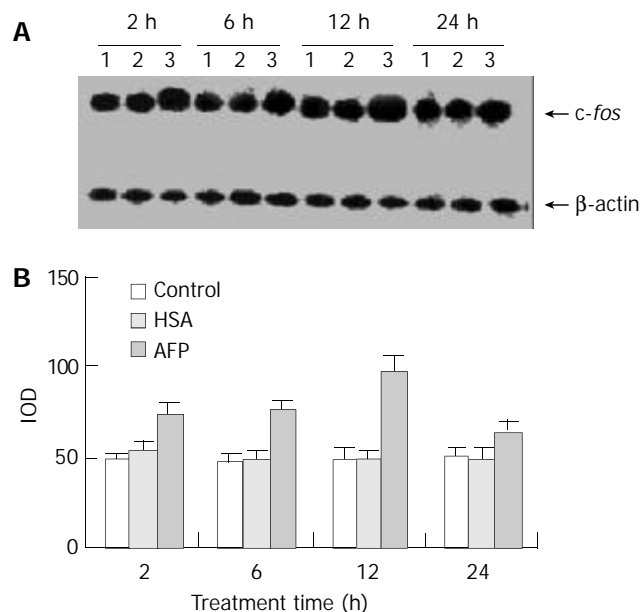

Figure 1 Effects of AFP (20 mg/L) or HSA (20 mg/L) on the expression of *c-fos* mRNA in human hepatocellular carcinoma Bel 7402 cells analyzed by Northern blot. The cells were incubated with AFP or HSA for 2, 6, 12, and 24 h, respectively. A: Autoradiogram of Northern blot. Lane 1: control group; Lane 2: HSA treated group; Lane 3: AFP treated group. B: Densitometric intensity of absorbance (IOD) of *c-fos* mRNA expression in Bel 7402 cells. The data were selected from 3 independent experiments.

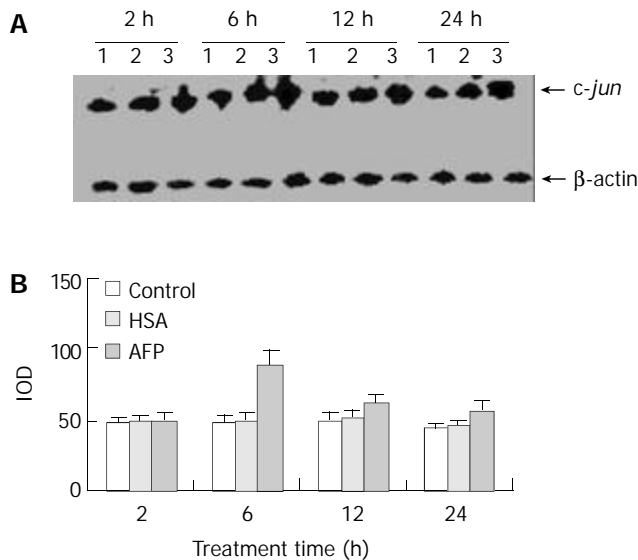

Figure 2 Effects of AFP (20 mg/L), HSA (20 mg/L), anti-AFP antibody (40 mg/L), and AFP (20 mg/L) + anti-AFP antibody (40 mg/L) on *c-fos* mRNA expression in human hepatocellular carcinoma Bel 7402 cells analyzed by Northern blot after 2 h treatment. A: Autoradiogram of Northern blot. Lane 1: control group; Lane 2: HSA treated group; Lane 3: AFP treated group; Lane 4: anti-AFP antibody treated group; Lane 5: AFP + anti-AFP antibody treated group. B: Densitometric intensity of absorbance (IOD) of *c-fos* mRNA expression in Bel 7402 cells. The data were selected from 3 independent experiments.

Expression of c-jun mRNA

AFP (20 mg/L) had no significant influence on the expression

of *c-jun* mRNA in human hepatocellular carcinoma cells when treated for 2 h, but when treated for 6 h the expression of *c-jun* mRNA increased obviously, the increase rate was 81.3%, but when treated for 24 h, increased rate fell to 14.6% as compared with the control group (Figure 3). However, HSA (20 mg/L) at the same dosage as AFP and anti-AFP antibody (40 mg/L) had no significant influence on the expression of *c-jun* mRNA in Bel 7402 cells. Anti-AFP antibody partially inhibited an increase in the expression of *c-jun* mRNA by AFP (Figure 4).

Figure 3 Effects of AFP (20 mg/L) or HSA (20 mg/L) on the expression of *c-jun* mRNA in human hepatocellular carcinoma Bel 7402 cells analyzed by Northern blot. The cells were incubated with AFP or HSA for 2, 6, 12, and 24 h, respectively. A: Autoradiogram of Northern blot. Lane 1: control group; Lane 2: HSA treated group; Lane 3: AFP treated group. B: Densitometric intensity of absorbance (IOD) of *c-jun* mRNA expression in Bel 7402 cells. The data were selected from 3 similar experiments.

Figure 4 Effects of AFP (20 mg/L), HSA (20 mg/L), anti-AFP antibody (40 mg/L), and AFP (20 mg/L) + anti-AFP antibody (40 mg/L) on the expression of *c-jun* mRNA in human hepatocellular carcinoma Bel 7402 cells analyzed by Northern blot after 6 h treatment. A: Autoradiogram of Northern blot. Lane 1: control group; Lane 2: HSA treated group; Lane 3: AFP treated group; Lane 4: anti-AFP antibody treated group; Lane 5: AFP + anti-AFP antibody treated group. B: Densitometric

intensity of absorbance (IOD) of *c-jun* mRNA expression in Bel 7402 cells. The data were selected from 3 independent experiments.

Figure 5 The effects of AFP (20 mg/L) or HSA (20 mg/L) on the expression *N-ras* mRNA in human hepatocellular carcinoma Bel 7402 cells analyzed by Northern blot. The cells were incubated with AFP or HSA for 2, 6, 12, and 24 h, respectively. A: Autoradiogram of Northern blot. Lane 1: control group; Lane 2: HSA treated group; Lane 3: AFP treated group. B: Densitometric intensity of absorbance (IOD) of *N-ras* mRNA expression in Bel 7402 cells. The data were selected from 3 similar experiments.

Figure 6 Effects of AFP (20 mg/L) or HSA (20 mg/L) on the expression of p21ras in Bel 7402 cells analyzed by Western blot. The cells were incubated with AFP or HSA for 6, 12, and 24 h, respectively. A: Western blot analysis. Lane 1: control group; Lane 2: HSA treated group; Lane 3: AFP treated group. B: Densitometric intensity of absorbance (IOD) of p21ras protein. The data were selected from 3 similar experiments.

Expression of N-ras mRNA

Northern blot analysis showed that AFP (20 mg/L) had no significant influence on the expression of *N-ras* mRNA in Bel 7402 cells when treated for 2 h and 6 h, but *N-ras* mRNA was overexpressed when treated with AFP (20 mg/L) for 12 h and 24 h. The increased ratios were 22.6% (12 h) and 59.9% (24 h), respectively, compared with the control group, and HSA (20 mg/L) did not significantly affect the expression of *N-ras* mRNA (Figure 5).

Expression of p21ras protein

Western blot analysis demonstrated that AFP significantly enhanced the expression of p21ras protein in Bel 7402 cells by 35.2%, 102.6%, and 46.8% at 6, 12, and 24 h, respectively, compared with the control group. However, HSA (20 mg/L) did not influence the expression of p21ras protein (Figure 6).

Expression of mutative p53 protein

The data showed that AFP significantly influenced the expression of mutative p53 protein in Bel 7402 cells by 13.4%, 39.9%, and 70.6% at 6, 12, and 24 h, respectively, compared with the control group. However, HSA (20 mg/L) did not affect the expression of mutative p53 protein (Figure 7).

Figure 7 Effects of AFP (20 mg/L) or HSA (20 mg/L) on the expression of mutative p53 protein in Bel 7402 cells analyzed by Western blot. The cells were treated with AFP or HSA for 6, 12, and 24 h, respectively. A: Western blot analysis. Lane 1: control group; Lane 2: HSA treated group; Lane 3: AFP treated group. B: Densitometric intensity of absorbance (IOD) of p53 protein. The data were selected from 3 similar experiments.

DISCUSSION

Many investigations have shown that AFP receptors exist on the membrane of various tumor cells[5,7,8,11-13], and play an important role in regulating growth of the cells[7,8,14]. The receptor may mediate intercellular signal transduction which influences the expression of genes related to proliferation, and the expression of these genes is the most direct factor that controls cell cycle. Our results showed that AFP stimulated the expression of *c-fos*, *c-jun*, and *N-ras* mRNA in hepatocellular carcinoma Bel 7402 cells. Both *c-fos* and *c-jun* have the characteristics of early response genes. When treated with AFP, the two oncogenes in Bel 7402 cells express promptly, thereafter the expression of these oncogenes dramatically declines. Previous researches had showed that AFP promoted the proliferation[1-6] and some oncogene expression of many tumor cells[15,16]. Cell growth was regulated by various factors, in which, some oncogene coding proteins have an important function in modulating growth and differentiation of the cells. *c-fos* and *c-jun* are the immediate early genes (IEG) with the characteristics of early response gene. When Bel 7402 cells were treated with AFP, the expression of these oncogenes had the characteristics of dynamics, which was independent on the translation of RNA. Additionally, IEG coding regulated-proteins can control the expression of some later response genes through the activation of nuclear transcription factors. Furthermore, c-*Fos* and c-*Jun* proteins can interact with each other to form a heterodimer (*Fos-Ju*n) called AP-1 (activator

protein-1). The dimer has leucine zipper structure, which has stronger binding affinity to DNA, and is the third messenger of signal transduction. The AP-1 protein is a nuclear transcription factor, which can regulate gene transcription by binding to a gene transcription-regulated element, and can increase transcriptional activation of downstream target genes. A previous study showed that the transcriptional properties of AP-1 depended on the site of cAMP-response elements to influence the expression of growth-related genes in hepatocellular carcinoma[17]. Therefore, we thought that AFP regulated cell cycle of Bel 7402 cells, which was related to the expression of early-response genes. Our result also showed that AFP promoted the expression of *N-ras* in Bel 7402 cells. The *N-ras* gene is closely related to cell proliferation, and p21ras, the *N-ras* coding protein, is an important intermediate of tyrosine-protein kinase (TPK) signal pathway in the cells to regulate growth-related gene expression. Therefore, we suggested that AFP could affect signal transduction to regulate growth of Bel 7402 cells probably through stimulating the expression of *N-ras*.

The wild type p53 is a very important tumor suppressor gene to inhibit proliferation of tumor cells. Some studies had showed that hepatocellular carcinoma was closely related to abnormal expression of p53 gene[18,19]. Additionally, p53 and beta-catenin mutation rates were inversely correlated in hepatocellular carcinoma[20]. The inactivation of p53 was an important cause of aberrant accumulation of beta-catenin, which was involved in both cell-cell interactions and wnt pathway-dependent cell fate determination in many cancer cells[20]. A previous study found that p53 mutation was correlated significantly with invasiveness including vascular permeation of hepatocellular carcinoma cells, and p53 mutation in the primary lesion was useful as an indicator of the biological behavior of recurrent hepatocellular carcinoma[21]. It showed that mutative p53 protein played a critical role in cell proliferation of hepatocellular carcinoma. The p53 gene could influence AFP expression to regulate the biological behavior of tumor cells[22,23]. Our data had showed that AFP could enhance the expression of mutative p53 protein. When p53 gene is mutated, it can not suppress the growth of tumor cells, on the contrary, it possesses the functions of oncogenes. There are two types of mutative p53 genes in tumor cells, one of the mutative p53 genes can restrain the growth-suppressing activity of wild type p53 gene, then display apparently its negative regulation; the other type of mutative p53 genes can cooperate with *ras* gene to actuate cell transformation, and then become a dominant oncogene, which promotes the growth of tumor cells. Because *Ras* protein is an important intermediate in TPK signal transduction pathway, we analyzed the expression of *N-ras* mRNA, and then further detected its protein in this study. The results showed that AFP promoted the expression of p21ras protein in Bel 7402 cells. The functions of p21ras protein are similar to those of guanylate binding protein, and it can phosphorylate the intermediate in the downstream of TPK signal pathway to activate mitogen-activated protein kinase (MAPK) and to participate in intercellular signal transduction. The p21ras protein can transduce the signal from TPK to threoine/serine protein kinase chain through Ras-Raf-MAPK signal pathway. These responses further activate some transcription factors which promote gene expression to enhance the growth of various cells. Our results demonstrated that AFP increased the expression of p21ras. Therefore, we speculated that AFP affected the expression of p53 and p21ras proteins through AFP receptor-mediated signal transduction pathway to accelerate the proliferation of Bel 7402 cells. Similar to the findings in this study, our previous study found that AFP enhanced the growth of HeLa and NIH3T3 cells through stimulating the expression of some oncogenes[8,15,16], suggesting

that AFP might unselectively regulate proliferation of tumor cells in different tissues and species.

The mechanism for growth-promoting activity of AFP is still unclear. It has been known for a long time that AFP has the ability to transport the substances essential for cell proliferation to enter the cells. Studies have indicated that AFP is an important protein in the embryos to regulate growth of the fetus[24], and required for female fertility, but not essential for embryonic development[25]. Up to date, it is not clear whether the biological function of AFP is involved in regulating cell proliferation. Some studies indicated that AFP inhibited immune response to promote the growth of tumor cells *in vivo*[26,27]. Escaping from the surveillance of immune system was the primary cause for malignant growth of tumor cells. Hepatocellular carcinoma cells can escape from the surveillance of immune system through altering the expression of tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) receptors[28], which can sustain the growth of tumor cells *in vivo*. However, our *in vitro* study could not establish the immune response without immune factors to affect the expression of the oncogenes in Bel 7402 cells. Therefore, it could not explain that AFP inhibited immune response to affect cell growth. Because AFP is a macromolecule, it is impossible to enter the cells through the cell membrane directly. Although AFP can transport some substances required for cell proliferation, it is not enough to completely support cell proliferation. Many studies found that AFP receptors existed on the membrane surface of various tumor cells, and mediated signal transduction to regulate the expression of the genes. The expression of these genes was the ultimate determination factor in regulating cell growth. Our results showed that AFP had the ability to stimulate the expression of the oncogenes *c-fos*, *c-jun*, and *N-ras* in Bel 7402 cells, and the response of these genes to AFP was various. Both the expression of *c-fos* and *c-jun* responded early, whereas the expression of *N-ras* and mutative p53 gene responded thereafter. Some oncogenes such as p53 and ras are important prognostic molecular markers in human hepatocellular carcinoma[29]. According to previous studies[5,7,8] and our results, we considered that the action of AFP was via TPK signal transduction pathway to stimulate the expression of some oncogenes which could regulate the growth of tumor cells. Many investigations had showed that the expression of some oncogenes was up-regulated in hepatocellular carcinoma, and some factors such as intergrin gene, p28/gankyrin, and HLA class I could influence cell proliferation of hepatocellular carcinoma[30-32]. However, some studies had shown that treatment of tumor cells *in vitro* with high dosage of AFP (1-10 μmol/L) significantly suppressed the growth of tumor cells, because AFP positively regulated cytochrome c-mediated caspase activation, apoptosome complex formation, and low-dose cytochrome c-mediated signals[33,34]. The mechanisms for how AFP regulates the expression of these genes and signal transduction, and why it is not essential for embryonic development[24], although it promotes the growth of some tumor cells[1-8] remain to be studied.

A previous study showed that AFP could coordinate other growth factors existed in HSA and serum to promote the growth of porcine granulosa cells, and AFP could function to modulate growth factor-mediated cell proliferation during development and neoplasia[4]. To further verify the up-regulation of these oncogenes was mediated by AFP, this study used HSA as a negative control due to similar amino acid sequences of AFP as HSA. The results showed that HSA or anti-AFP antibody did not stimulate the expression of these genes in Bel 7402 cells, but anti-AFP antibody efficiently blocked the function of AFP, which can be explained that AFP specifically stimulated the expression of these oncogenes in human hepatocellular carcinoma Bel 7402 cells.

Abstract

AIM: To evaluate long-term effect of ethanol embolization for the treatment of hepatocellular carcinoma (HCC) with severe hepatic arterioportal shunt (APS), compared with Gelfoam embolization.

METHODS: Sixty-four patients (ethanol group) and 33 patients (Gelfoam group) with HCC and APS were respectively treated with ethanol and Gelfoam for APS before the routine interventional treatment for the tumor. Frequency of recanalization of shunt, complete occlusion of the shunt, side effects, complications, and survival rates were analyzed between the two groups.

RESULTS: The occlusion rate of APS after initial treatment in ethanol group was 70.3%(45/64), and recanalization rate of 1 month after embolization was 17.8%(8/45), and complete occlusion rate was 82.8%(53/64). Those in Gelfoam group were 63.6%(21/33), 85.7%(18/21), and 18.2%(6/33). There were significant differences in recanalization rate and complete occlusion rate between the two groups (*P*<0.05). The survival rates in ethanol group were 78% at 6 months, 49% at 12 months, 25% at 24 months, whereas those in Gelfoam group were 58% at 6 months, 23% at 12 months, 15% at 24 months. The ethanol group showed significantly better survival than Gelfoam group (*P*<0.05). In the ethanol group, there was a significant prolongation of survival in patients with monofocal HCC (*P*<0.05) and Child class A (*P*<0.05). There were no significant differences in survival rate in the Gelfoam group with regard to the number of tumor and Child class (*P*>0.05). The incidence rate of abdominal pain during procedure in ethanol group was 82.8%. There was no significant difference in postembolization syndromes between two groups. Procedure-related hepatic failure did not occur in ethanol group.

CONCLUSION: Ethanol embolization for patients with HCC and severe APS is efficacious and safe, and may contribute to prolongation of the life span versus Gelfoam embolization.

INTRODUCTION

Hepatocellular carcinoma is frequently associated with arterioportal shunts. Kido and Ngan *et al*[1,2] reported that APS in HCC occurred in 60%, and Okuda *et al*[3] reported that severe APS of main or right or left portal veins occurred in 30% of patients with HCC. Severe APS led to life threatening conditions (*e.g.*, esophageal varices, ascites and hepatic encephalopathy) as a result of portal regurgitation or portal hypertension[4-7]. To improve portal hypertension caused by severe APS in patients with HCC, APS needs to be treated. To date, Gelfoam and steel coil are the most commonly used embolic materials[8-10]. However, any long-term effect of embolization of APS with steel coil or Gelfoam on survival have not been proved, although they produced a good short-term effect as reported[8-10]. It has been a hot issue how to choose an ideal embolic material to occlude APS. In this study, we used ethanol as the embolic material to treat the APS before the routine interventional treatment for 64 patients. The purpose of this study was to evaluate the long-term effect of the transcatheter arterial embolization (TAE) of APS with new embolic material in patients with HCC and APS, in comparision with the most commonly used material: Gelfoam.

MATERIALS AND METHODS

Patients

Among 596 patients with HCC treated with transcatheter arterial chemoembolization (TACE) or transcatheter arterial infusion chemotherapy (TAI) at the 3rd Affiliated Hospital of Sun Yat-sen University from February 1999 to March 2003, 161(27%) patients with severe APS were identified by digital subtraction angiography (DSA). We excluded patients with Child class C disease and patients who underwent the treatment of surgical resection, percutaneous local ethanol injection, microwave coagulation, or systemic chemotherapy throughout the study period. According to the exclusive criteria, 64 of 161 patients were excluded from this study. Ninety-seven patients were enrolled in our study (78 men and 19 women, ranging from 21 to 78 years of age; mean age, 57.9). All the patients were treated with TAI or TACE after undergoing embolization of APS.

Written informed consent was obtained from the patients involved in this study. We divided the patients into 2 groups: ethanol group, in which APS was treated with ethanol for 64 patients from April 2000 to March 2003, and Gelfoam group, in which APS was treated with gelatin sponge particles for 33 patients from February 1999 to March 2000. The clinical characteristics of two therapeutic groups were illustrated in Table 1. Although this was a retrospective nonrandomized

study, there were no significant differences between two groups in background factors (Table 1).

Table 1 Clinicopathologic characteristics of patients with HCC and APS

Characteristics	Ethanol group (n=64)	Gelfoam group (n=33)	P value
Age (y)	56.4±21.4	52.3±26.6	0.42
Sex (M/F)	52/12	25/7	0.72
Child classification			
Child class A	35(55%)	20(61%)	
Child class B	29(45%)	13(39%)	0.56
Serum total bilirubin (mg/ml)	1.6±1.5	2.0±1.8	0.31
Serum albumin (g/dl)	3.6±0.8	3.4±1.1	0.30
Number of tumors			
1	15(23%)	11(33%)	
2~3	19(30%)	8(24%)	
≥4, diffuse	30(47%)	14(43%)	0.32

Treatments

Firstly, arteriography of hepatic common artery was performed to visualize the arterial vascularization of the liver and to identify the location, severity and direction of vessels of APS. Secondly, a 3-F microcatheter was superselectively inserted into the dominant artery of APS through a 5-F catheter. The embolic material was injected to occlude APS. All diagnostic studies and treatments of APS were performed during the same procedure.

Ethanol group: 2-3 mL absolute ethanol was injected slowly and gently at the rate of about 1 mL/min after 2 mL 10g/L lidocaine was injected through catheter. About 5-10 min later, a repeated DSA was performed to evaluate the occlusive extent of APS. If persistence of APS was shown, another 2-3 mL ethanol was injected repeatedly until the occlusion of APS was confirmed with angiography.

Gelfoam group: Gelatin sponge particles (size, 1 mm×1 mm× 1 mm) were mixed with contrast media (Iopamilon, Schering, Berlin, Germany) and were injected with 1-mL tuberculin syringe under fluoroscopic monitoring until a slow flow or stasis of APS was demonstrated. Then arteriography was done again to confirm the occlusion of APS. If APS could not be occluded with Gelatin sponge particles (size, 1 mm×1 mm×1 mm) and microcatheter, a 4F Rösch hepatic catheter or 4F cobra catheter would replace the 3-F microcatheter and be inserted into or by the way of the feeding artery of shunt. Then several large pieces of Gelfoam (beyond 1×1×1 mm) were used to occlude the shunt.

After embolization of APS, the routine interventional therapy was done for the tumor, as reported[11-15]. After catheter was inserted into feeding artery of tumour, pirarubicin (THP)/lipiodol(LPD) emulsion was injected through catheter for the patients without tumour thrombus in main portal vein. THP/LPD was prepared with the following procedure. THP (60-80 mg) was dissolved in 3-10 mL of 50 g/L glucose and then mixed with 3-10 mL LPD at a 1:1 ratio repeating approximately 10 times. Then gelatin sponges embolization of feeding artery was performed. We only injected pirarubicin (60-80 mg) which was dissolved in 100 mL of 50g/L glucose for the patients with tumour thrombus in main portal vein.

Criteria for evaluating embolic effect

Recanalization of APS was defined as APS was shown again at arterial phase of DSA 1 month postprocedure in the patients who had the complete occlusion of shunt after initial treatment. Complete occlusion of APS was defined as APS was not demonstrated in DSA for 2 times consecutively.

Follow-up protocol

All patients were followed up by means of spiral CT scan of liver and laboratory tests such as concentrations of α-fetoprotein, liver function before and after treatment. Change of APS was evaluated with DSA which was performed 1 and 2 mo after initial treatment. Then all patients should be followed up every 2-3 mo. When elevation of tumor markers (α-fetoprotein), persistence of APS or recurrence of tumor were observed, patients were readmitted for angiography and treatment as before.

Statistical analysis

The cumulative proportional survival rates were calculated according to the Kaplan-Meier method. The starting point was defined as the day of initial treatment. The significance of differences between background clinical characteristics of the patients groups (ethanol and Gelfoam) was assessed with the χ^2 test and Student's t test. The significance of difference in survival rates between patients was evaluated by the generalized Wilcoxon test. Values of $P<0.05$ were considered significant.

RESULTS

Results of occlusion of APS

In the ethanol group, APS was occluded completely at the initial treatment in 45(70.3%) patients. Among them, recanalization of APS 1 month post-procedure was shown in 8(17.8%). There were 30(46.9%) patients with APS 1 month after initial treatment, which included incomplete occlusion of APS in the initial treatment, recanalizational and newly occurred APS. Of them APSs were occluded completely after a second treatment in 16 patients. The rate of complete occlusion of APS in ethanol group was 82.8%(53/64) totally (Figures 1A-F).

In the Gelfoam group, 21(63.6%) patients had the complete occlusion of APS in the initial treatment. Recanalization of APS occurred in 18(85.7%) patients of them 1 mo after initial treatment. Thirty (90.6%) patients were with APS 1 mo after initial treatment, which consisted of incomplete occlusion of APS in the initial treatment, recanalization and newly occurred APS. In 3 patients of them, APS were occluded completely after another treatment. The complete occlusion rate of APS in Gelfoam group was 18.2%(6/33) totally.

The recanalization rate of APS in ethanol group was lower than that in Gelfoam group (χ^2=24.91, $P<0.05$), and the complete occlusion rate of APS in ethanol group was higher than that in Gelfoam group (χ^2=32.06, $P<0.05$).

Survival

The survival rate in the ethanol group were 78% at 6 mo, 49% at 12 mo, and 25% at 24 mo. The median survival was 11 mo. By comparison, the survival rates in the Gelfoam group were 58% at 6 mo, 29% at 12 mo, 15% at 24 mo, and the median survival was 7 mo. The survival rates in the ethanol group were significantly higher than those in the Gelfoam group ($P<0.05$) (Figure 2).

In the ethanol group, the survival rates of patients with single HCC nodule were 92% at 6 mo, 70% at 12 mo, and 55% at 24 mo. The survival rates of patients with two or three HCC nodules were 73% at 6 mo, 55% at 12 mo and 22% at 24 mo. The survival rates of patients with multiple HCC nodules or diffuse HCC were 68% at 6 mo, 33% at 12 mo and 15% at 24 mo. The survival rates of patients with monofocal HCC were significantly higher than those of patients with multifocal HCC ($P<0.05$) (Figure 3). The survival rates of patients of Child class A were 91% at 6 mo, 60% at 12 mo, and 38% at 24 mo. The survival rates of patients of Child class B were 62% at 6 mo, 35% at 12 mo and 13% at 24 mo. The survival rates of patients of Child class A were higher than those of patients of Child class B ($P<0.05$) (Figure 4).
Figure 1 Multiple HCC nodules in a 34-year-old patient. A: CT image obtained during the arterial phase showed the predominant enhancement of the medial segment of left lobe and the enhancement of left portal branches, which represent APS. B: Hepatic arteriogram demonstrated the arterioportal shunt. C: The microcatheter was inserted into the feeding artery of APS. DSA showed the strong or fast blood flow of APS. D-E: Hepatic arteriogram showed that the arterioportal shunt was no longer visible after embolization with a microcoil and ethanol. F: Follow-up CT scan showed lipiodol accumulation in multiple HCC nodules, and liver necrosis was not seen in the distribution of the hepatic artery which had been treated with ethanol.

Figure 2 Cumulative survival curves for patients with HCC and APS in two therapeutic groups are shown. The survival rates for patients in the ethanol group were significantly higher than those in the Gelfoam group (*P*<0.05).

Figure 3 Cumulative survival curves for patients with HCC and APS in relation to number of tumors are shown in ethanol group. The survival rates of patients with monofocal HCC and APS were significantly higher than those of patients with multifocal HCC and APS (single lesion *vs* two or three lesions, *P*<0.05; two or three lesions *vs* four or more lesions, *P*<0.05).

Figure 4 Cumulative survival curves for patients with HCC and APS according to the Child class were shown in ethanol group. The survival rates of patients of Child class A were higher than those of Child class B (*P*<0.05).

In the Gelfoam group, the survival rates of patients with single HCC nodule were 62% at 6 mo, 38% at 12 mo, and 19% at 24 mo. The survival rates of patients with two or three HCC nodules were 61% at 6 mo, 26% at 12 mo and 12% at 24 mo. The survival rates of patients with multiple HCC nodules or diffuse HCC were 60% at 6 mo, 28% at 12 mo and 0 at 24 mo. The survival rates of patients of Child class A were 60% at 6 mo, 25% at 12 mo, and 18% at 24 mo. The survival rates of patients of Child class B were 68% at 6 mo, 30% at 12 mo and 15% at 24 mo. There were no significant differences in survival rates with regard to the number of tumor, and Child class (*P*>0.05).

Side effects and complications

In the ethanol group, a short-period intense abdominal pain occurred in 53(82.8%) patients during the process of ethanol injection, and mild abdominal pain in 9(14.1%) patients, and indolence in 2(3.1%) patients. Postembolization syndromes (such as nausea, vomiting, fever, and abdominal pain) occurred

in 50(78.1%) patients in ethanol group, and 30(90.9%) patients in Gelfoam group. There was no significant difference between the 2 groups (χ^2=1.66, P>0.05). No patient died of procedure-related hepatic failure. In ethanol group, all feeding artery remained patent in the follow-up DSA arteriograms, and liver necrosis in the distribution of the hepatic artery which had been treated with ethanol was not seen in all patients according to the follow-up CT scans.

DISCUSSION

Hepatocellular carcinoma is frequently associated with arterioportal shunts. In our series, severe APSs were verified in 27% of patients with HCC by DSA. Severe APS leads to or aggravates portal hypertension which leads to life-threatening conditions such as esophageal varices, refractory ascites, refractory diarrhea and hepatic encephalopathy[4-7,16,17]. Additionally, severe APSs have an influence on the performance of TAI or TACE for the treatment of HCC[18]. The persistence of APS may possibly result in the poor prognosis of HCC. For the reasons as above, severe APS needs to be treated effectively.

Many embolic materials have been used to treat APS in patients with HCC[8,9,19-23]. Of those Gelfoam and steel coil were the most commonly used. Clark[9] and Tarazov[8] reported that Gelfoam and steel coil emboli for the treatment of APS could not prolong the survival of patients with HCC, although they had a good short-term effect on the control of gastric bleeding and ascites. Those effects may be attributable to certain actions of those embolic materials. Firstly, Gelfoam embolization was likely to result in inadvertent embolization, and cause the occlusion of feeding artery of tumor, which would influence the procedure of TAI or TACE for the treatment of tumor. Secondly, the recanalization of APS occurred easily as a result of the development of collateral vessels and the absorption of Gelfoam two to four weeks after embolization. In our study, the recanalization rate of APS was 85.7% 1 month after embolization with Gelfoam. Similarly, the embolization with steel coil also produced the recanalization of APS as a result of the development of collateral anastomoses[8].

Ethanol is a liquid embolic agent that causes immediate vascular sclerosis and occlusion by a combination of direct toxic effect on the vascular wall and clumping of damaged erythrocytes and denatured proteins[24-26]. It has been used widely in the treatment of renal cell carcinoma, esophageal varices, and arteriovenous malformations[24-35]. Similar to the treatment of arteriovenous malformation, injecting ethanol into APS results in clot formation, denudes the endothelium and causes embolization by penetrating into the capillaries. As an embolic material, ethanol is superior to Gelfoam in the treatment of APS. First, ethanol can pass to and occlude the capillaries and veins of shunt, and does not lead to the occlusion of feeding artery of tumor. Thus it produces a more complete occlusion of APS than Gelfoam. Second, ethanol is a kind of long-acting embolic material, and it rarely develops the collateral anastomoses after embolization with ethanol. It has a low recanalization rate of APS. Third, ethanol also has a direct tumoricidal effect. Our results showed the recanalization rate of APS 1 month after embolization with ethanol was 17.8%, and complete occlusion rate was 82.8%, which were better than those of Gelfoam group (P<0.05).

Furuse et al[10] reported that the survival rate of patients with HCC and APS after steel coil embolization were 45% at 6 mo, 12% at 12 mo, and 6% at 2 yr, and it could not prolong the survival of patient with HCC after the treatment of APS. However, Liu et al[36] reported that the survivals of HCC patients without APS were higher than those of patients with APS. It indicated that the persistence of APS was an important

prognostic factor. In our study, the complete occlusion rate of shunt in ethanol group was higher than that in Gelfoam group (P<0.05). The survival rate of patients in the ethanol group was 78% at 6 mo, 49% at 12 mo, 25% at 24 mo, which were higher than those of Gelfoam group (P<0.05). Our results suggest that the embolization of APS with ethanol provides a survival advantage over that with gelfoam in patient with HCC. In addition, there was a significant prolongation of survival in patients with monofocal HCC and Child class A in ethanol group (P<0.05). However, there were no significant differences in survival rates in Gelfoam group with regard to the differences in the number of tumor and Child class (P>0.05). It was suggested that the survival rate was also related to the stage and invasive extent of tumor, and general state of patients. On the other hand, the persistence of severe APS was the important factor which influenced the survival of patient with HCC and APS.

The most common complication of embolization of APS with ethanol was abdominal pain caused by destruction of the vascular endothelium when ethanol was injected[24,25]. The incidence was 82.8% in our study. It could be alleviated immediately when we stopped injecting ethanol. There was no severe complication related to ethanol embolization. In our study, liver necrosis was not seen in the distribution of the hepatic artery which had been treated with ethanol in the follow-up CT scans. The postembolization syndromes were related to the specific treatment of tumor, and there was no significant difference between the two groups.

In conclusion, ethanol embolization for patients with HCC and severe APS is efficacious and safe, and may contribute to prolongation of the life span versus Gelfoam embolization.

Abstract

AIM: To evaluate the expression of transforming growth factor-alpha (TGF-α) and hepatitis B surface antigen (HBsAg) in human hepatocellular carcinoma (HCC) tissues and its significance.

METHODS: Seventy specimens of HCC tissues were detected by immunohistochemical method. Five specimens of normal human liver tissues were used as control.

RESULTS: The TGF-α positive expression rates in HCC and its surrounding tissues were 74.3%(52/70) and 88.1%(52/59), respectively. TGF-α positive granules were mainly in the cytoplasm and fewer existed on the karyotheca. The TGF-α positive expressing rate in well differentiated HCC was significantly higher than that in moderately and poorly differentiated HCC ($P<0.05$). The TGF-α positive expression also was observed in intrahepatic bile ducts (part of those were hyperplastic ducts). The HBsAg positive expression rates in HCC and its surrounding tissues were 21.4%(15/70) and 79.7%(47/59), respectively. HBsAg positive granules were in the cytoplasm, inclusion and on the karyotheca. There was a prominent positive correlation between TGF-α and HBsAg expression in HCC surrounding tissues ($P<0.05$, $\gamma=0.34$). TGF-α was usually existed with HBsAg in regenerated and/or dysplastic liver cells. In the five normal liver tissues, TGF-α and HBsAg were not detectable in hepatocytes and bile ducts.

CONCLUSION: Hepatitis B virus infection is closely related with hepatocarcinogenesis. The overexpression of TGF-α in the liver seems to be associated with the regeneration of hepatocytes injured by HBsAg. The continued expression of TGF-α might lead to dysplasia of liver cells and development of HCC. Furthermore, TGF-α might play a role in morphogenesis and regeneration of intrahepatic bile ducts.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a common malignant tumor in China with poor prognosis[1-8]. Substantial evidences have supported the concept that hepatitis B virus (HBV) infection is a causative factor for HCC[9-12]. The idiographic mechanisms of HBV in hepatocarcinogenesis had not been clearly defined yet. Transforming growth factor-alpha (TGF-α) is a multipeptide, which can promote cellular proliferation and transformation[13-15]. The normal hepatocytes almost had no expression of TGF-α mRNA except the epitheliums of bile ducts in human normal liver tissues[16]. It was also thought to be an autocrine regulator of normal growth and regeneration in the rat liver. There was also a close relationship between TGF-α and hepatocarcinogenesis[17-19]. In order to find the relationship between TGF-α and HBV infection in hepatocarcinogenesis, the expression of TGF-α and HBsAg in HCC tissues was studied by immunohistochemical method. Such studies have been rarely reported in China.

MATERIALS AND METHODS

Specimens

Tissue samples were obtained from seventy cases of HCC in Xijing Hospital from January1988 to January 1995. Among them, fifty-nine cases of HCC had surrounding tissues. Five cases of normal human liver tissues were obtained from autopsy (excluding liver disease). All specimens were fixed in 40 g/L methanal solution, embedded in wax, and cut into 5 µm thick serial sections.

Reagents and methods

Mouse anti-human TGF-α was purchased from Santa Cruze, UAS. Mouse anti-human HBsAg and SABC kit were purchased from Wuhan Boster Co. Ltd. The expression of TGF-α and HBsAg was detected by SABC immunohistochemical method. In the control group, the primary antibody was substituted by PBS or normal mouse serum. All paraffin embedded sections were deparaffinized and rehydrated, and pretreated for 20 min at 75 ℃ in a microwave oven. After being treated with 1 mL/L H_2O_2 for 30 min to block the endogenous peroxidase, the sections were incubated with 20 mL/L fetal calf serum for 30 min to reduce nonspecific binding. Then the primary HBsAg and TGF-α antibodies were applied to the sections and incubated at 4 ℃ overnight. The sections were subsequently incubated with goat anti mouse IgG at 37 ℃ for 30 min, followed by incubation with SABC at 37 ℃ for 30 min, and stained with DAB-H_2O_2 for 5-10 min and counterstained with hematoxylin. Results estimation: the specimens with no positive cells or positive cells <10% were negative (-); with light brownish yellow cells or positive cells between 10-50% were weakly positive (±); with deep brownish yellow cells or positive cells >50% were positive (+).

Statistical analysis

Chi-square test was used to analyse the results. The expression of TGF-α and HBsAg were compared by analysis of coherence.

RESULTS

The expression of TGF-*a* and HBsAg in HCC

The TGF-α positive expression rates in HCC and its surrounding tissues were 74.3%(52/70) and 88.1%(52/59), respectively. The positive cells mainly existed diffusely and fewer existed in foci. The positive stainings were like brown-yellow granules, and were mainly located in the cytoplasm and/or fewer located on the karyotheca (Figure 1). There was a prominent difference in TGF-α distribution between HCC and its surrounding tissues (χ^2=3.93, P<0.05). The TGF-α positive expression rate in well differentiated HCC was significantly higher than that in moderately and poorly differentiated HCC (χ^2=9.11, P<0.05, Table 1). TGF-α positive expression also was observed in intrahepatic bile ducts (part of those were hyperplastic ducts). In the five cases of normal liver tissues, TGF-α was undetectable in hepatocytes and bile ducts.

Table 1 TGF-α expression in different HCC differentiation

Differentiation	n	Positive cases	Positive rate (%)
Well	15	15	100.0
Moderately	48	34	70.8
Poorly	7	3	42.9

The HBsAg positive expression rates in HCC and its surrounding tissues were 21.4%(15/70) and 79.7%(47/59), respectively. The positive cells mainly existed diffusely and fewer existed in foci. The positive stainings were like brown-yellow granules or floccules. They were located in the cytoplasm, inclusion and on the karyotheca (Figure 2). There was a prominent difference in HBsAg distribution between HCC and its surrounding tissues (χ^2=43.5, P<0.05). HBsAg expression was negative in the five cases of normal liver tissues.

The PBS blank controls and normal mouse serum substituted controls were negative for immunohistochemical staining.

Figure 2 HBsAg positive stainings as brownish yellow granules in the cytoplasm of HCC tumor cells. SABC ×400.

Relationship between TGF-*a* and HBsAg expression

There was not a prominent correlation between TGF-α and HBsAg expression in HCC tissues, but there was a prominent positive correlation between TGF-α and HBsAg expression in HCC surrounding tissues (P<0.05, γ=0.34, Table 2). TGF-α was usually existed with HBsAg in regenerated and/or dysplastic liver cells. These cells had increscent or double nucleus, prominent or anomalous nucleolus, high ratio of nucleus/ cytoplasm, *etc*. (Figures 3 and 4).

Table 2 Relation between TGF-α and HBsAg expression in HCC surrounding tissues

| TGF-α	n	HBsAg +	HBsAg -
+	52	44	8
-	7	3	4
Total	59	47	12

Figure 3 Location of immunohistochemical staining of TGF-α expression in regenerated and/or dysplastic liver cells. SABC ×400.

Figure 4 Location of immunohistochemical staining of HBsAg expression in regenerated and/or dysplastic liver cells. SABC ×400.

DISCUSSION

TGF-α was found in culture medium of fibroblasts transformed by some retroviruses in 1970s and nominated because of its ability to transform and induce the renal fibroblasts to proliferate. It is composed of 50 amino acid residues, with a 30% to 40% amino acid homology to epidermal growth factor (EGF), and binds the EGF receptor in the cellular membrane[20]. TGF-α was secreted by many transformed cells and involved in embryonic development. In human cancers, studies showed that TGF-α could serve as a tumor marker and as a marker for the malignant potential of a tumor[21]. Thus far, the types of carcinomas with which abnormal TGF-α expression has been associated include liver[22], gastrointestinal[23], breast[24], skin[25], lung[26], brain[27] and ovarian cancers[28]. TGF-α might play a role in the processes involved with tumor initiation and

growth. In cell lines, TGF-α has been found to be associated with autocrine and/or paracrine types of cellular growth initiation and with increased levels of oncogene expression[29,30]. It could promote the hepatocellular proliferation, differentiation, regeneration and tumor cell growth[31]. Transgenic mice that overexpressed TGF-α developed liver tumors between 12 and 15 months of age[22]. In our study, we found the TGF-α expression in the HCC and its surrounding tissues was significantly higher than that of normal liver tissues. The positive rate of TGF-α expression in well differentiated HCC was higher than that in moderately and poorly differentiated HCC. These may suggest the involvement of TGF-α in cellular transformation and provide a supporting evidence for the autocrine stimulation model. Increased expression of TGF-α might be the events of human primary hepatocarcinogenesis. In the later stages of HCC, there might be the other factors responsible for decreasing expression of TGF-α. Furthermore, we also found that intrahepatic bile ducts (part of these were hyperplasia ducts) were stained positive for TGF-α, suggesting that TGF-α might play a role in morphogenesis and regeneration of intrahepatic bile ducts.

Up to now, the close relationship among hepatitis B virus, liver cirrhosis and HCC has been approved[32], but the mechanisms have not been clearly defined yet. One hypothesis is that chronic HBV infection caused prolonged liver cellular injury, inflammation and cellular death. The hepatic regeneration after liver necrosis, along with DNA damage from genotoxic agents generated during the inflammatory response, was thought to increase the risk of HCC development[33]. Because of HBV replication in liver cells, HBV major envelope protein, HBsAg was often overexpressed. It accumulated to toxic levels in the endoplasmic reticulum of hepatocytes. This could lead to the chronic injury of hepatocytes, inflammation and cellular death by immune reaction[34]. In our study, we found the positive expression rate of HBsAg in the HCC surrounding tissues was higher than that of HCC tissues. There was a prominent difference in HBsAg distribution between the HCC and its surrounding tissues (χ^2=43.5, $P<0.05$). This suggested HBsAg might have more closely involved in hepatic cells injury than in hepatocarcinogenesis.

TGF-α is a potent mitogen for hepatocytes. It can induce hepatocytes to proliferate. Though we did not found the correlation between TGF-α and HBsAg in the HCC tissues, we found there was a prominent positive correlation between TGF-α and HBsAg in the HCC surrounding tissues. They were usually existed in regenerated and/or dysplastic liver cells. These cells had increscent or double nucleus, prominent or anomalous nucleolus and high ratio of nucleus/cytoplasm, *etc*. These data suggest that TGF-α overexpression in the liver seems to be associated with the hepatocellular regeneration injured by HBsAg. HBsAg may up-regulate the expression of TGF-α. Continued overexpression of TGF-α could lead to hepatocellular proliferation and dysplasia. These might have contributed to hepatocarcinogenesis and HCC growth.

Abstract

AIM: To investigate the mutational features of adenomatous polyposis coli (APC) gene and its possible arising mechanism in hereditary non-polyposis colorectal cancers (HNPCC).

METHODS: PCR-based *In Vitro* Synthesized Protein Test (IVSP) assay and sequencing analysis were used to confirm somatic mutations of whole APC gene in 19 HNPCC cases.

RESULTS: Eleven cases with 13 mutations were determined to harbor APC mutations. The prevalence of APC mutation was 58%(11/19). The mutations consisted of 9 frameshift and 4 nonsense ones, indicating that there were more frameshift mutations (69%). The frameshift mutations all exhibited deletion or insertion of 1-2 bp and most of them (7/9) happened at simple nucleotide repeat sequences, particularly within (A)n tracts (5/9). All point mutations presented C-to-T transitions at CpG sites.

CONCLUSION: Mutations of APC gene were detected in more than half of HNPCC, indicating that its mutation was a common molecular event and might play an important role in the tumorigenesis of HNPCC. Locations of frameshift mutations at simple nucleotide repeat sequences and point mutations at CpG sites suggested that many mutations probably derived from endogenous processes including mismatch repair (MMR) deficiency. Defective MMR might affect the nature of APC mutations in HNPCC and likely occur earlier than APC mutational inactivation in some patients.

INTRODUCTION

Familial colorectal cancer (CRC) can be mainly divided into 2 distinct classes, hereditary non-polyposis colorectal cancers (HNPCC) and familial adenomatous polyposis (FAP). HNPCC is an autosomal dominant inherited disease characterized by an increased predisposition to colorectal and some extracolonic cancers and presents with particular clinicopathological and molecular features[1]. Affected individuals often carry germline alterations at mismatch repair (MMR) genes, such as hMsh2, hMlh1, hPsm1 and hPsm2, which lead to microsatellite instability (MSI) and replication errors (RER). FAP is caused by the germline mutation of tumor suppressor gene APC and manifested by the development of hundreds of colorectal adenomas, some of which will inevitably undergo malignant transformations if not removed. APC mutations can be detected in both FAP and non-FAP tumors including HNPCC and sporadic colorectal ones, somatic mutation of which is a common defect in sporadic colorectal tumor and FAP, both sharing similar mutational spectra and distribution[2,3-5]. It is accepted that adenoma-carcinoma sequence of CRC was initiated by APC mutation in majority of non-HNPCC[2,6]. Adenoma in HNPCC featured aggressiveness and followed by an alternative and rapidly evolving pathway. There was evidence that HNPCC lacked loss of heterozygosity (LOH) of APC gene, being quite different from FAP[7]. It showed that all adenomas from *Min* mice demonstrated LOH, had significantly less numbers of somatic APC mutations compared with those from Msh2 deficient Min (Apc+/-Msh2-/-), which had a 2-fold higher rate of somatic Apc mutations (10/adenoma) than the non-neoplastic intestinal mucosa (5/sample), and did not demonstrate LOH. The results proved that somatic APC mutation rather than LOH, was a likely mechanism in the development of adenomas in Apc+/-Msh2-/- mice[8].

Studies also revealed[9,10] that APC gene might play a role in chromosomal segregation, with mutations in APC disrupting this function and causing chromosomal (or karyotypic) instability (CIN). MSI and CIN were two different forms of genetic instability occurring in CRC. In MI+ sporadic and HNPCC tumors, defective repair of mismatched bases resulted in an increased mutation rate at the nucleotide level and consequent widespread MSI with diploidy while a large fraction of others had CIN, leading to an abnormal chromosome number (aneuploidy). In HNPCC, mutations of APC, p53 and K-ras-2 genes and LOH of tumor-suppressor genes were significantly less frequent (*P*=0.03 or 0.0006), but transforming growth factor beta type II receptor mutation was significantly more frequent (*P*=0.000001) than those in non-HNPCC[7]. Summarized data from Jass[11] supported that the frequency of APC mutation was significantly lower in MSI-H colorectal tumors (39%, 36/92) and HNPCC (44%, 21/48) than in MSI-L (51%, 18/35) and MSS (58%, 241/417). However, the situation was quite different for 5q LOH in MSI-H tumors (3%;1/32) and HNPCC (10%;1/10), which were significantly less than MSI-L (47%;17/49) and MSS (57%;113/199). This suggested that MSI instead of APC mutation probably confered a growth advantage in the context of early tumorigenesis of HNPCC and MSI-H tumors. Here we focused on APC gene to analyze its mutational frequency and features in carcinomas from HNPCC, which would be helpful to understand the effect of MMR deficiency on APC mutation in the early stage of carcinogenesis.

Based on the fact that both somatic and germline mutations of APC gene were dispersed throughout the 5' half of the sequence, vast majority of which were premature ones and led to truncated proteins[3-5]. A Coupled In Vitro Synthesized

Protein Test (IVSP) was therefore used to selectively and rapidly detect any mutations leading to stop codons[12-14]. The assay was proved very efficient and only a small proportion of nontruncating APC mutations like missense mutations were reported to be missed[15]. The study aimed at exploring the possible arising mechanism of somatic APC mutation and its role through investigating frequency and mutational features of the gene in HNPCC.

MATERIALS AND METHODS

Sample collection and DNA extraction

HNPCC was determined according to ICG criteria based on the family history[16], fresh tumor samples of the patients were from resected and histologically verified colorectal carcinomas. Genomic DNA and RNA of tumors and matched normal-looking colonic mucosa were isolated by standard procedures. Nineteen samples were collected from paired carcinomas and adjacent normal tissues in HNPCC patients.

Determination of APC mutation

Whole APC gene with at least 15 exons (8.5Kb) was divided into 5 overlapping segments (seg.), Exon 1-14 was defined as seg. 1 and exon 15 amplified with four overlapping segments as seg. 2-5. The RT-PCR primer-pair sequence for seg. 1 and PCR primer-pairs for seg. 2-5 was similar to those reported[12,13,15]. IVSP assay, which selectively detected truncating mutations, was used to screen mutations of whole APC gene segment by segment. All samples showing producible truncated protein bands were sequenced using Sequenase 2 (United States Biochemical) with ^{35}S-labled dATP, dried sequence gels were exposed to XAR (Kodak) film at room temperature overnight.

Table 1 Spectra of APC mutations in carcinomas from HNPCC patients

Tumor ID	APC nt change	Codon	Target sequence
Point mutations			
T27	C>T	332	CpG
T533	C>T	1 338	CpG
K1, C×7*	C>T	1 450	CpG
Frameshift mutations			
C×7*	1 bp ins	847	TCTCaAAAAAGAT
C086*	1 bp ins	941	TCGGaAAAATTCA
K40	1 bp ins	1 454	CCTaAAAAATAAA
22	1 bp ins	1 554	GCAGaAAAAAACTAT
Cx10	1 bp ins	1 935	TTTCCCCaAGTCA
K10	1 bp del	907	TCTgGGTCT
C086*	2 bp del	1 464	AAGAGAGagAGTGG
K39	2 bp del	799	GATtaTGTT
T10	1 bp del	1 416	AGTGGcATTATA

Note: ID means tumor identification; nt stands for neocleotide; '>' for transition or transvertion; each tumor with more than 2 mutations marked by *; del for deletion; ins for insertion; small letter for nucleotide frameshift.

RESULTS

Spectra of APC mutations in HNPCC are listed in Table 1. Screening for truncating APC mutations was carried out using IVSP assay in carcinomas from 19 HNPCC cases. There were altogether 11 mutated cases with 13 mutations confirmed in the study, all of which were only found in the tumor tissues, indicating the somatic nature of mutation. The prevalence of APC mutation in HNPCC was 58%(11/19). Exhibiting mutations consisted of 9 frameshift ones and 4 nonsense, indicating the existence of more frameshift mutations. All of

frameshift mutations were deletion or insertion of 1-2 bp and most of them (7/9) happened at simple nucleotide repeat sequences, particularly within (A)n tracts (5/9). Repeat number (n) of mononucleotide A ranged from 2 to 7. All of four detected point mutations presented C-to-T transitions at CpG sites in the study. Distributions of mutations were uneven and with no hot spot but hot region. Eight (61.5%) of thirteen mutations were located in the segment 3 (codon 1099-1701) and half of them in the mutation cluster region (codon 1286-1513).

DISCUSSION

Colorectal cancer is the fourth leading cause of cancer deaths and tends to increase in China, especially in big cities like Shanghai. The basic mechanism of reducing the mortality remains elusive and poses a big challenge for clinicians and researchers.

HNPCC is one of the most common inherited cancer syndromes, accounting for approximately 4-6% of all CRCs. It is characterized by defective MMR, which results in MSI and manifests hypermutable phenotype[17,18]. In our study, MSI was defined in all but one (T16) of HNPCC cases (data not shown).

In contrast to FAP, HNPCC was usually not associated with LOH of APC allele and therefore not develop extensive polyposis but multiple primary cancers. MMR gene responsible for HNPCC functioned as caretaker and indirectly inhibited the promotion of tumor growth, defective MMR was considered to be primary event because of its occurrence throughout the adenomas in HNPCC[19,20]. It had been reported that CRC with and without MSI involved different genes including APC[21]. APC gene, a FAP causing gene, was proven to be rate-limiting for tumor initiation and functioned as housekeeper of cellular proliferation. APC mutation provided cells with a selective advantage without known effect on the mutation rate, it suggested that both APC and MMR genes played an important role in the early carcinogenesis of familial CRC. Accumulating evidence actually revealed that the sequence of alteration of cancer genes in MMR deficient tumor was somewhat different from non-HNPCC[7,21]. The study was to investigate the mutational features of housekeeping gene APC and its potential arising mechanism in carcinomas with deficiency of caretaking gene MMR, in order to evaluate the role of APC gene alteration in HNPCC.

There were 11(58%) of the 19 HNPCC carcinomas exhibiting APC somatic mutations, which was a bit higher than that (50%) reported in a series of Japanese HNPCC adenomas[22] and somewhat lower than that (67%) in sporadic CRC[4,5]. The result implied that inactivation of APC gene also played an important role in the tumorigenesis of HNPCC. But there was evidence that the frequency of APC gene mutation in HNPCC was likely less than that in non-HNPCC (21% *vs* >70%; $P<0.05$)[23].

Analysis of the spectra of APC mutations revealed that APC frameshift mutations were more frequent than point ones in HNPCC (69.3% *vs* 30.7%; $P<0.05$). As with frameshift mutations, most of them (67%) occurred in the simple repeat sequences (microsatellite) of the APC coding regions, particularly at (A)n tracts (56%), which was consistent with the effect of mismatch repair deficiency on mutations of other target genes containing short repeated sequences in the coding regions[24]. It suggested that MMR deficiency might be one of the important pathway leading to inactivation of its tumor suppressor ability by altering microsatellite of the APC coding regions. Animal studies further supported the notion that APC mutations in Msh6(-/-)Apc1638N mice consisted predominantly of base substitutions (93%) creating stop codons, however, in Msh3(-/-)Msh6(-/-)Apc1638N tumors, a mixture of base substitutions (46%) and frameshifts (54%) was observed, indicating that Msh3 could suppress frameshift mutations of Apc gene in Msh6(-/-)Apc1638N mice[25]. The observation demonstrated that type of APC mutation was closely related

to the function of specific MMR gene while in Mlh1-/- Apc1638N animals, the prevailing mechanism of APC mutation in tumors was altered from allelic loss to intragenic mutation as a result of Mlh1 deficiency, the observed mutations were more frameshifts (73%) than base substitutions (27%), most frameshifts were located within dinucleotide repeats[26]. We therefore hypothesized that defective MMR might precede APC mutation in some HNPCC cases whereas for those frameshifts not showing microsatellite alterations, the initiation mechanism for these tumors was not clear yet and proposed to be similar to that for sporadic CRCs[2,3,5,12], which meant that APC mutation, rather than genomic instability, might be the initiating event in tumorigenesis.

With respect to point mutations of APC gene, they were all non-sense mutations and with pathogenic nature because of the generation of stop cordons. All these mutations in the study presented C-to-T transitions and affected Cog dinucleotides, suggesting that they probably derived from endogenous processes due to spontaneous deaminations of 5-methylcytosine. Further studies were therefore necessary to clarify the origin and relationship between endogenous and exogenous processes of APC mutations in CRC tumorigenesis.

In HNPCC cases without detected APC mutations, it was still of great importance to determine methylated status of APC gene or mutation of other genes like β-catenin, although more sensitive methods needed to be developed or used. Yamamoto reported that DNA methylation of APC was higher in HNPCC than in sporadic CRC with MSI-H (53% vs 35%)[27]. Miyaki observed that a notable frequency of β-catenin gene mutation (43%) was found to occur in HNPCC and detected in tumors without APC mutations[23]. These data suggested that activation of the β-catenin -Tcf signaling pathway, through either β-catenin mutation or silence (methylation) of APC, might aslo contribute to part of HNPCC colorectal carcinogenesis.

In conclusion, inactivation of APC gene played an important role in the tumorigenesis of HNPCC; Most of APC mutations probably derived from endogenous processes including MMR deficiency and presented some mutational features. Defective MMR might occur earlier than APC mutation in some patients with HNPCC.

Abstract

AIM: To observe the adsorbent effect of resin on endotoxin, cytokine, bilirubin in plasma of patients with hepatic failure and to determine the resin perfusion as an artificial liver support system in the treatment of hepatic failure.

METHODS: One thousand milliliters of discarded plasma was collected from each of 6 severe hepatitis patients treated with plasma exchange. The plasma was passed through a resin perfusion equipment for 1-2 h via extracorporeal circulation, and then absorbent indicators of transaminase, bilirubin, blood ammonia, endotoxin and cytokines were examined. In the meantime, study of *in vivo* resin plasma perfusion was performed on 7 severe hepatitis patients to compare the changes of endotoxin and cytokines in blood before and after perfusion.

RESULTS: The levels of total bilirubin, endotoxin, interleukin 1β and TNF-α in plasma were significantly decreased after *in vitro* resin plasma perfusion. The levels of interleukin 1β, TNF-α and endotoxin in blood were also evidently declined after *in vivo* resin plasma perfusion. Nevertheless, no obvious changes in IL-6, creatinine (Cr) and urea nitrogen (UN), blood ammonia and electrolytes were found both *in vitro* and *in vivo*.

CONCLUSION: Bilirubin, endotoxin and cytokines in plasma of patients with hepatic failure can be effectively adsorbed by resin *in vitro*. Most cytokines and endotoxin in plasma can also be effectively removed by resin *in vivo*. It demonstrates that resin perfusion may have good treatment efficacy on hepatic failure and can be expected to slow down the progression of hepatic failure.

INTRODUCTION

In the research field of artificial liver, blood perfusion, blood filtration, plasma exchange techniques and methods are called non-biological artificial liver[1-3]. They are based on the mechanical mechanism of blood purification to remove toxins in body to achieve the treatment goal for hepatic failure[4-11]. New-style resin blood perfusion is mostly used in toxicosis rescue and uremia, etc in clinic, but was rarely reported in the treatment of hepatic failure. Since endotoxin and cytokine play a pivotal role in the pathogenesis of hepatic failure in severe hepatitis[12-16], it has become an important issue whether resin blood perfusion can effectively remove endotoxin and cytokine in body. Therefore, we examined the effect of a non-bioartificial liver with resin plasma perfusion on the plasma endotoxin and cytokine removal in patients with severe hepatitis to determine and assess the curative effect of resin plasma perfusion in the treatment of severe hepatitis.

MATERIALS AND METHODS

Subjects

Thirteen subjects with severe viral hepatitis (female 1, male 12, aged 28 to 57 years with a mean of 41.3 years) were enrolled in this study. All subjects belonged to chronic severe hepatitis caused by HBV infection according to the diagnostic criteria described in the Viral Hepatitis Protection and Cure Guideline established on a national conference. Of these patients, 8 were in middle stage, 5 in final stage, complication of encephalopathy, spontaneous peritonitis and hepatorenal syndrome was found in 11, 5 and 3, respectively.

Experimental protocol in vitro

One thousand milliliters of discarded plasma was collected from each of 6 severe hepatitis patients treated with plasma exchange, and mimic blood perfusion was performed in 3 h. The resin perfusion device (Lizhu Bio-material Company, Zhuhai, China) and tubes were filled with 500 mL of 50 g/L glucose injection, then rinsed with 3 000 mL of normal saline containing 80 mg heparin from bottom to top at 50-100 mL/min. In the mean time, perfusion device was tapped by hand and rotated to exclude bubbles and particles. Plasma perfusion was performed for 1-2 h (average 1.7 h) and the velocity of plasma cycling through the perfusion device was at 80-120 ml/min. Plasma before and after circulation was collected, sealed and stored at -40 ℃. All the procedures, such as plasma collection, perfusion *in vitro* and sample harvesting used aseptic technique, syringe, cycling tubes and frozen tubes were radiated by ^{60}Co to remove pyrogen.

Figure 1 Schematic diagrams of resir perfusion *in vitro*.

Experimental protocol in vivo

Resin plasma perfusion was performed in 7 patients with severe hepatitis. Temporal artery-vein circuit was established by

insertion of femoral and pectoral venous cannulas. The patients were heparinized based on individual conditions. The first dose was 1-1.5 mg/kg, then 0.1 mg/kg each 30 min was added. The patients' blood was introduced to a plasma separator (Fresenius Medical Care, Bad Homblurg, GER) at 100-120 mL/min for separation of plasma from the whole blood. The separated plasma was absorbed by the resin perfusion device, then mixed with separated blood cells, and returned to patients. The perfusion was maintained for 1-2 h (average 1.6 h) (Figure 2). The plasma before and after perfusion was collected and stored as the above methods.

Figure 2 Circuit diagrams of plasma perfusion.

Biochemical estimations and cytokines detection

Plasma aminotransferase, total bilirubin (TB), total bile acid (TBA), electrolyte, UN and Cr were measured using a biochemical autoanalyzer (Hitach Co., Tokyo, Japan). Blood ammonia was measured by a blood ammonia detector (Shiga Co., Tokyo, Japan). Endotoxin was measured by using a limulus test kit according to the manufacturer's instructions (Yihua Medical Technology Co., Shanghai, China). The level of IL-1β and TNF-α was measured by using a radio immunoassay (RIA) kit according to manufacturer's instructions (Department of Radio Immunoassay, PLA General Hospital Technical Development Center). IL-6 level was measured by using an ELISA kit according to manufacturer's instructions (Shengxong Medical Technology Co., Shanghai, China).

Statistical analysis

All results were expressed as mean±SD. Comparisons between the groups and the same group before and after perfusion were analyzed by Student's t test.

RESULTS

Changes in transaminase and bilirubin

After resin perfusion device was used to absorb plasma of the patients with severe hepatitis *in vitro*, transaminase, TB and TBA were all declined with a statistically significant difference in TB, DB and IB before and after resin perfusion (t value was 2.081, 2.048, and 2.086 respectively, $P<0.05$).

Table 1 Comparison of transaminase, TB and TBA before and after *in vitro* resin perfusion (mean±SD)

	Before absorption	After absorption
ALT(IU/L)	74.17±49.68	47.83±22.33
AST(IU/L)	88.83±45.58	58.33±44.64
TB(μmol/L)	518.8±180.27	356.13±162.87[a]
TBA(μmol/L)	157.17±53.53	131.67±34.95

[a]$P<0.05$, *vs* before absorption.

TBA was markedly declined in patients with *in vivo* resin plasma perfusion with a significant difference ($P<0.01$). Nevertheless, transaminase and TB had no marked change before and after absorption (Table 2).

Table 2 Comparison of transaminase, TB, and TBA before and after *in vivo* resin perfusion (mean±SD)

	Before absorption	After absorption
ALT(IU/L)	270.03±355.54	288.38±314.58
AST(IU/L)	252.50±391.51	224.88±356.79
TB(μmol/L)	519.66±209.00	460.80±165.99
TBA(μmol/L)	194.88±47.32	166.75±48.98[b]

[b]$P<0.01$ *vs* before absorption.

Comparison of electrolytes and renal function

The electrolytes – K, Na, Cl, Ca, Mg, and P after absorption had no significant changes compared to those before absorption. UN and Cr were declined after absorption with no statistical significance compared to those before absorption with UN value of 6.79±4.14 mmol/L before absorption and 6.42±3.39 mmol/L after absorption, and Cr value of 135.67±30.77 μmol/L before absorption and 121.85±20.40 μmol/L after absorption.

Blood ammonia

After *in vitro* resin absorption, blood ammonia in plasma was not markedly decreased (98.17±20.60 μmol/L and 91.50±18.84 μmol/L). Similar to the result of *in vitro*, blood ammonia had no significant difference before and after *in vivo* resin plasma perfusion (48.25±8.63 μmol/L and 46.75±9.44 μmol/L).

Level of LPS and cytokines

The level of LPS was markedly decreased after *in vitro* absorption ($t=6.604$, $P<0.01$). The changes in TNF-α and IL-1β had a statistical significance (t was 2.876 and 3.673 respectively, $P<0.05$). IL-6 had no significant change before and after *in vitro* resin absorption (Table 3).

Table 3 Level of LPS and cytokines before and after *in vitro* resin absorption (mean±SD)

	Before absorption	After absorption
LPS (ng/L)	60.35±8.58	32.75±10.14[a]
TNF-α(ng/L)	1.49±1.06	1.04±0.91[b]
IL-1β(ng/L)	2.61±1.42	1.68±0.92[b]
IL-6(ng/L)	100.07±10.99	87.64±12.27

[a]$P<0.05$, [b]$P<0.01$ *vs* before absorption.

The plasma endotoxin was markedly decreased after *in vivo* resin plasma perfusion ($t=5.233$, $P<0.001$). TNF-α and IL-1β also changed significantly (t value was 3.474 and 4.869 respectively, $P<0.01$) with declined levels of 16.3% and 37.1% respectively. IL-6 had no evident change before and after *in vivo* plasma perfusion (Table 4).

Table 4 Level of LPS and cytokines before and after *in vivo* resin absorption (mean±SD)

	Per- perfusion	Post- perfusion
LPS(ng/L)	58.64±11.03	36.13±5.24[a]
TNF-α(ng/L)	2.28±0.89	1.69±0.76[a]
IL-1β(ng/L)	1.98±0.82	1.24±0.88[a]
IL-6(ng/L)	88.41±24.96	84.85±16.55

[a] $P<0.01$ *vs* before absorption.

DISCUSSION

Blood perfusion is a commonly used method for blood purification[17-20]. Activated charcoal representing perfusion equipment is most widely applied in the clinical treatment for drug toxicosis, uremia and liver coma and a good result has been obtained[21,22]. However, the shape of activated charcoal particles is irregular and their mechanical strength is inferior, thus particles are easily broken. If a broken particle directly contacts with blood, it will cause hemolysis and microvessel occlusion. Therefore, activated charcoal must be encapsulated before use. Synthetic resin is another kind of medical absorbent material with macropore high molecular polymers belonging to neutral macropore resin that absorbs substances via Vandar Val gravitation. Its absorbent ability has been found to be characterized by a fast absorbent speed, high mechanical strength, relative absorbent specificity mainly absorbing the substances with a molecular weight of 500- 5 000 Da and showing an outstanding absorbent ability to those toxins which can bind to proteins closely or are highly fat-soluble[23,24].

In the experiment of resin blood perfusion *in vitro*, we found that the resin blood perfusion device was able to effectively absorb transaminase and bilirubin but weakly affect kidney function and blood ammonia, considering that it absorbed medium molecules not small molecules. It illustrated the resin blood perfusion could improve the hepatic function in patients with severe hepatitis. In the meantime, it did not cause electrolyte imbalance and disturbance in the internal environment. Therefore, resin blood perfusion can be used as an artificial liver support system in the treatment of severe hepatitis.

Current studies considered that the pathogenesis of severe hepatitis was the superposition of virus-caused primary immunopathological damage and cytokine-induced secondary damage[25-27]. When liver barrier function was impaired, endotoxaemia would occur. Endotoxins stimulated the mononuclear phagocyte system inside and outside the liver, and thus, enormous cytokines were released. Furthermore, this cytokine-induced secondary hepatocellular damage played an important role in the course of hepatitis. Hereby, cytokine removal was good for alleviating liver damage, reducing leukoplania and thrombocyte aggregates, maintaining internal environmental equilibrium, and sequentially slowing down or even reversing the progression of disease and improving prognosis[28-30].

Along with the development in molecular biology, research of antagonists for various cytokines has been launched, for example, monoclonal antibody, receptor antibody, soluble antibody. However, their clinical application is not ideal. In recent years, more and more researchers have began to use blood purification to remove cytokines[31-33]. At present, it is still disputable whether   blood purification can effectively remove cytokines[34,35]. Some researchers held that leucocytes could be activated by passing through the device during blood perfusion to cause the releasing of cytokines. In addition, it has been found the molecular weight of cytokines is relatively high, and cytokines are mostly bound to proteins in plasma, the half-life of cytokines is short and they are produced and metabolized quickly. Therefore, it would be hard to remove them via blood purification[36].

In this study, after plasma perfusion treatment for severe hepatitis, both TNF-α and IL-1β in plasma were significantly decreased, illustrating that plasma perfusion was an effective method for cytokine removal. The change of IL-6 was not significant, because IL-6 might be produced too fast, or it related to different absorbent efficacy of the perfusion device to various cytokines.

In conclusion, resin can effectively absorb bilirubin, LPS, TNF-α and IL-1β *in vitro*, and LPS, TNF-α and IL-1β can be significantly decreased in resin plasma perfusion *in vivo*, resin perfusion has good curative effects on severe hepatitis with hepatic failure.

Abstract

AIM: To establish a mice model of hepatitis B by using HBV-transgenic mice, and to transfer HBV-specific cytotoxic T lymphocytes (CTL) induced from syngeneic BALB/c mice immunized by a eukaryotic expression vector containing HBV complete genome DNA.

METHODS: HBV DNA was obtained from digested pBR322-2HBV and ligated with the vector pcDNA3. Recombinant pcDNA3-HBV was identified by restriction endonuclease assay and transfected into human hepatoma cell line HepG2 with lipofectin. ELISA was used to detect the expression of HBsAg in culture supernatant, and RT-PCR to determine the existence of HBV PreS1 mRNA. BALB/c mice were immunized with pcDNA3-HBV or pcDNA3 by intramuscular injection. ELISA was used to detect the expression of HBsAb in serum. MTT assay was used to measure non-specific or specific proliferation ability and specific killing activity of spleen lymphocytes. Lymphocytes from immunized mice were transferred into HBV-transgenic mice (2.5×10^7 per mouse). Forty-eight hours later, the level of serum protein and transaminase was detected with biochemical method, liver and kidney were sectioned and stained by HE to observe the pathological changes.

RESULTS: By enzyme digestion with *Eco* RI, *Xho* I and *Hind* III, the recombinant pcDNA3-HBV was verified to contain a single copy of HBV genome, which was inserted in the positive direction. HepG2 cells transfected with the recombinant could stably express PreS1 mRNA and HBsAg. After immunized by pcDNA3-HBV for 4 weeks, HBsAb was detected in the serum of BALB/c mice. The potential of spleen lymphocytes for both non-specific and specific proliferation and the specific killing activity against target cells were enhanced. The transgenic mice in model group had no significant changes in the level of serum protein but had an obvious increase of ALT and AST. The liver had obvious pathological changes, while the kidney had no evident damage.

CONCLUSION: A eukaryotic expression vector pcDNA3-HBV containing HBV complete genome is constructed successfully. HepG2 cells transfected with the recombinant can express PreS1 mRNA and HBsAg stably. Specific cellular immune response can be induced in mice immunized by pcDNA3-HBV. A mice model of acute hepatitis with HBV has been established.

INTRODUCTION

HBV infection is a worldwide problem that affects human health severely[1-3]. No appropriate animal model is available till now because of the strict host specificity of HBV infection. At present, HBV transgenic animals could be obained during embryonic period, which always induce immune tolerance to dominating HBV antigens[4-6]. In addition, it has great difference in biological characteristics between duck hepatitis B virus and HBV. So it is imperative to establish a mice model that can simulate human viral hepatitis B precisely and is convenient for wider applications.

Both clinical researches and animal experiments suggest that the pathological changes are not caused by the virus directly, but are meditated by immunity[7,8]. HBV specific CTL induced by HBV antigens can cause immune damage to the liver to clear the viruses and recruit non-specific inflammatory cells to local infection tissue simultaneously, thus aggravating hepatic injury[9,10]. We planned to induce HBV specific CTL by gene immunity and to establish a mice model of hepatitis B by transferring CTLs to HBV-transgenic mice.

MATERIALS AND METHODS

Animals
SPF BALB/c mice were provided by the Laboratory Animal Center of Shandong University. HBV complete genome (ayw subtype) transgenic BALB/c mice with a high level of HBsAg, HBeAg and with HBV DNA positive in peripheral blood, were purchased from Transgenic Animal Central Laboratory, 458 Hospital of PLA, China.

Cell lines
Hepatocellular carcinoma cell line HepG2 was cultured and conserved in our laboratory. HepG2.2.15 cell line carrying four whole HBV genes can not only express HBsAg and HBeAg but also produce Dane's particles of HBV. SP2/0-HBV is a mouse myeloma cell line with pcDNA3-HBV stably transfected.

Plasmids
pBR322-2HBV was a recombinant plasmid with a double copy of HBV (ayw subtype) inserted into *Eco*RI restriction site of pBR322. Mammal animal cell expression vector pcDNA3 was 5.4 kb in length. It has a CMV early promoter enhancer, multiple cloning sites (MCS) and neomycin resistant gene.

Construction of recombinant pcDNA3-HBV
Alkaline lysis method was used to extract large quantity of

pBR322-2HBV and pcDNA3 DNA respectively. Precipitation with polyethylene glycol was used to purify plasmid DNA, and biometer was used for quantitative analysis. pBR322-2HBV was digested with *Eco*RI and separated by 10 g/L agarose gel electrophoresis. The gel band containing 3.2 kb DNA was cut under UV light. HBV DNA was extracted using a DNA recovery kit. pcDNA3 was also digested by *Eco*RI and a 5.4 kb fragment was recovered with the same method. Ten microliter of HBV DNA and 2 µL of pcDNA3-HBV (mol ratio 3:1) were mixed together with 2 µL of T4 DNA ligase, 2 µL of buffer and 2 µL of sterile water. The mixture was placed overnight at 4 ℃, and then the reaction was terminated. Ten microliter of ligated product was transformed to competent DH5α, which was then transferred to a LB medium plate containing 60 µg/mL of ampicillin and incubated overnight at 37 ℃.

Identification of recombinant pcDNA3-HBV

Antibiotic selection and restriction endonuclease assay were used to screen and identify positive clones. A positive clone was selected randomly and amplified for recombinant plasmid DNA. Then the recombinant DNA was digested by *Eco*RI, *Xho*I and *Hind*III, respectively. The digestion system was 20 µL, including 1 µL DNA, 1 µL endonuclease, 2 µL10×buffer and 16 µL sterile water, and incubated for 3 hours at 37 ℃. The correctness of ligation was further identified by 10 g/L agarose gel electrophoresis.

pcDNA3-HBV transfected to HepG2 cell with lipofectin

HepG2 cells during logarithmic period were digested by trypsinization and diluted to 4×10^5/mL. Then the cells were plated to 24-well plates with 0.5 mL per well (cell count 2×10^5) and cultured for 24 h for transfection next day, when 80-90% of the cells were fused. One µg purified pcDNA3-HBV plasmid DNA was transfected to the prepared HepG2 cells using lipofectin reagent. After transfection, HepG2 cells were screened by G418 resistance and routinely cultured. The culture supernatant was collected periodically to detect HBV antigens. The selected positive clone was named as HepG2.02G.

HbsAg detection

Concentration of HBsAg in culture supernatant of transfected cells was detected by ELISA. Critical value (cutoff) = 2.1×N, in which N is the average OD of negative control, and S is the OD of sample. The sample was positive when S/N ≥ 2.1, otherwise negative.

Extraction of total RNA

HepG2.02G, HepG2.2.15, and HepG2 cells in logarithmic period were harvested, each of 1×10^6 cells, was rinsed by 0.01 mol/L PBS once and centrifuged at 1 000 rpm for 5 min. The precipitate was used for total RNA extraction according to the protocol of TRIZOL kit.

Primer design and synthesis

According to the sequence of HBV S1 (subtype ayw) described by GenBank, primers were designed to amplify HBV PreS1 gene. PCR product would be 625 bp. β-actin served as control, with a PCR product 366 bp in length. The sequences of the primers were: PreS1 forward: 5'-GCTCTAGACACCAAATGCCCCTA-3', reverse: 5'-GCTCTAGAGAATCCCAGAGG-3', β-actin forward: 5'-ACACTGTGCCCATCTACGAGGGC-3', reverse: 5'-ATGATGGAGTTGAAGGTAGTT TCG TGG AT-3'. These oligonucleotide primers were synthesized by Shanghai Sangon Biological Engineering Technology and Service Co. Ltd.

Amplification of PreS1 mRNA

Reverse transcription was performed with 1 µg of total RNA to obtain cDNA as the template. PCR was carried out in 25 µL volume with 1 µL RT-PCR product, 2.5 µL 10×PCR buffer, 0.3 µL Mg^{2+}, 5 nmol/L of dNTP, 3 U *Taq* polymerase and 10 nmol/L of primers (forward and reverse). The reaction conditions were pre-denatured at 94 ℃ for 3 min, 30 cycles (denatured at 94 ℃ for 1 min, annealed at 50 ℃ for 1 min and extended at 72 ℃ for 1 min), followed by a final extension at 72 ℃ for 5 min. Ten microliter of the PCR product then underwent 2% agarose gel electrophoresis at 70 V for 30 min. HepG2 cells were used as negative control, while HepG2.2.15 as positive.

Scheme for mice immunization with pcDNA3-HBV or pcDNA3

The purified pcDNA3-HBV DNA was diluted with sterile NS to the concentration of 1 000 µg/mL and preserved at -20 ℃. Twelve male BALB/c mice were randomly divided into 2 groups, 6 mice each. One was experimental group (Exp), which was injected 50 µL 250 g/L sucrose intramuscularly to both sides of anterior tibial muscle, 50 µL pcDNA3-HBV (100 µL per mouse) was injected at the same site 20 min later. Another was the control group (Ctrl), the same quantity of pcDNA3 was injected as negative control. The immunization was intensified once 2 to 3 wk.

HbsAb detection in serum of mice immunized with pcDNA3-HBV

Blood samples were collected by cutting tails of the mice at wk 2, 4, 8 and 10, respectively. Serum was separated and HBsAb was detected by double-antibody sandwich ELISA.

Measurement of proliferation reaction of spleen lymphocytes of mice immunized by pcDNA3-HBV or pcDNA3

Mice spleen cells were prepared routinely (cell density adjusted to 5×10^6/mL) and plated to 96-well plates (100 µL per well). The supernatant of HepG2.2.15 (containing a high level of HBsAg), PHA (eventual concentration 25 µg/mL) or ConA (eventual concentration 10 µg/mL) was added to 3 wells, respectively. MTT assay was performed after the cells were cultured at 37 ℃ for 68 h. Proliferation rate was calculated as: (OD of stimulatory – OD of non-stimulatory) / OD of non-stimulatory × 100%.

Measurement of specific killing activity of spleen lymphocytes of mice immunized by pcDNA3-HBV or pcDNA3

Mice spleen cells were plated to 96-well plates, mixed with SP2/0-HBV cells (effector/target ratio 50:1). Control groups were designed and each group had 3 wells. MTT assay was performed after the cells were cultured for 72 h. Killing rate of CTLs was calculated as: [1- (OD of effector and target cells - OD of effector cells) / OD of target cells] × 100%.

Establishment of animal model

Transgenic mice were divided into 3 groups (6 mice each): Model, negative control and blank control. Mice in model or negative control group were injected with spleen lymphocytes of mice immunized by pcDNA3-HBV (HBsAb positive) or pcDNA3 respectively. Mice in blank control group were injected with NS, 0.5 mL each mouse. Spleen lymphocytes were adjusted to 5.0×10^7/mL using NS and injected to transgenic mice through caudal vein (2.5×10^7 lymphocytes, 0.5 mL per mouse).

Identification of animal model

After 48 h, the transgenic mice were killed and their venous blood was collected. Serum total protein, albumin, globulin, ALT and AST were detected. Liver and kidney were fixed with 100 g/L formaldehyde, embedded, sliced and stained with HE to observe inflammation and immune-pathological changes with a microscope.

Statistical analysis

All data were shown as mean±SD. Significant levels of differences between values were analyzed using the Chi-square test and Student's *t* test. Statistically significant *P* value was defined as <0.05.

RESULTS

Restriction digestion results of pBR322-2HBV and pcDNA3

Extracted plasmid DNA had a high purity ($OD_{260/280}$=1.6-1.8). After pBR322-2HBV was digested by *Eco*RI, 2 bands were obtained at about 4.3 kb and 3.2 kb in size (Figure 1). pcDNA3 was linear after digestion, and a band at 5.4 kb proved it was completely digested (Figure 2).

**Figure 1** Enzymatic digestion of pBR322-2HBV by EcoRI.

Figure 2 Enzymatic digestion of pcDNA3 by EcoRI.

Identification of recombinant pcDNA3-HBV

A high purity of the extracted 2 kinds of DNA was certified by electrophoresis. The recombinant pcDNA3-HBV was digested by *Eco*RI and the product underwent electrophoresis. Only a band of 5.4 kb indicated that the transformed plasmid was pcDNA3 without exogenous genes, while 2 bands at 5.4 kb and 3.2 kb indicated successful ligation (Figure 3). pcDNA3-HBV was digested by *Hind*III, and the product of 8.6 kb in size indicated that the recombinant pcDNA3-HBV contained a single HBV gene. pcDNA3-HBV was digested by *Xho*I, and the products of 3.1 kb and 5.5 kb showed that HBV was inserted at the correct direction (Figure 4).

Figure 3 Analysis of ligation of HBV and pcDNA3. 1, 3: pcDNA3 vector, 2: pcDNA3-HBV (5.4 kb+3.2 kb), 4: DNA marker (λDNA／*Hind*III).

Figure 4 Digestive identification of recombinant plasmid pcDNA3-HBV. 1: DNA marker (λDNA／*Hind*III), 2: *Xho*I digestion(3.1 kb+5.5 kb), 3: *Hind* III digestion (8.6 kb), 4: *Eco*RI digestion (5.4 kb+3.2 kb).

HBsAg expression in supernatant of HepG2.02G cell culture

HBsAg in supernatant could be detected on day 15, and expressed stably after 40 d (S/N=48).

PreS1 mRNA expression in HepG2.02G

A specific band at 625 bp demonstrated that HBV could efficiently replicate and transcript in human hepatocellular carcinoma cells, as shown in Figure 5.

Figure 5 Expression of preS1 mRNA by RT-PCR. 1: HepG2.2.15 (positive control); 2: β-actin; 3: HepG2.02G; 4: DNA marker (DL2 000); 5: HepG2 (negative control).

HBsAb level in serum of mice immunized by pcDNA3-HBV

pcDNA3-HBV immunized mice had specific immune response at the 4th week (S/N=19). Antibody expression reached the highest level at the 8th week and this level lasted to the 10th week.

Proliferation reaction of spleen lymphocytes of mice immunized by pcDNA3-HBV or pcDNA3

As illustrated in Table 1, the non-specific proliferation ability of spleen lymphocytes of mice immunized by pcDNA3-HBV to both PHA and ConA was enhanced as compared with that of pcDNA3 (*P*<0.05), and the specific proliferation ability to supernatant of HepG2.2.15 was also promoted (*P*<0.01).

Table 1 Spleen lymphocyte proliferation of immunized mice (%)

Group	PHA (25 μg／mL)	ConA (10 μg／mL)	HepG2.2.15 media (1:1)
Exp	52.9±3.7	80.9±8.3	33.8±3.2

[a]*P*<0.05 *vs* Exp, [b]*P*<0.01 *vs* Exp.

Specific killing activity of spleen lymphocytes of mice immunized by pcDNA3-HBV or pcDNA3

MTT assay showed that the killing activity of spleen lymphocytes of mice immunized by pcDNA3 against SP2/0 and SP2/0-HBV had no significant difference (*P*>0.05), but that of mice immunized by pcDNA3-HBV to SP2/0-HBV was

distinctly enhanced as compared to SP2/0 ($P<0.01$). Results are shown in Table 2.

Table 2 Specific killing activity of mice spleen lymphocytes (%, mean±SD)

Group	SP2/0	SP2/0-HBV
Exp	14.3±3.4[1]	51.5±9.8[b]
Ctrl	20.8±4.6[2]	24.5±3.7[3]

[b]$P<0.01$ *vs* 1, 2, 3.

Identification of mice model of hepatitis B

The mice in each group had no significant changes in the level of serum protein compared with the blank control group ($P>0.05$). The serum ALT and AST of transgenic mice in blank and negative control groups were normal (0-40 U/L), while they (ALT 232±14 U/L, AST 315±21 U/L) were much higher in the model group than in the control group ($P<0.01$). The hepatic cords of mice in the blank control group had a radiated structure surrounding the central vein, the hepatic lobule had a clear structure with cells tightly connected. The hepatic cells had large and round nuclei, with obvious nucleoli and abundant symmetrical cytoplasm. There was no inflammatory cell infiltration in the portal area with a clear structure (Figure 6A). Mice in negative control group had sporadical acidophilic changes of hepatic cells, without inflammatory cell infiltration (Figure 6B). In the model group, hepatic cells of transgenic mice had diffuse ballooning degeneration, cytoplasmic loosening, acidophilic changes, appearance of acidophilic body, spotty necrosis of hepatic tissue and obvious infiltration of inflammatory cells in the portal area (Figure 7). However, mice in the model group had no obvious inflammation and structure damage of the kidney.

DISCUSSION

The host variety of HBV infection is limited. At present, the animal models for HBV research included chimpanzee[11], Tupaia Glis[12] and other hepadnaviridae virus infected animals[13]. Although duck hepatitis B virus (DHBV) has been found to be similar to HBV in mechanism of pathogenesis, ducks infected with DHBV did not develop hepatic cirrhosis and hepatocellular carcinoma because DHBV lacks X gene[14]. Mice

Figure 6 Liver structure of mice by HE-staining (×200). A: Liver structure of mice in blank control group, B: Liver structure of mice in negative control group.

Figure 7 Pathological changes of mouse liver with acute hepatitis in model group(HE, ×200). A: Infiltration of inflammationary cells in the portal area, B: Local necrosis as arrow indicated, C: Obvious infiltration of inflammatory cells and eosinophilic changes, D: Cytoplasmic loosening of liver cells.

had low susceptibility to HBV, but HBV could replicate in transgenic mice[15]. Two research groups established the transgenic mice which could produce HBV envelopes or HBsAg particles in 1985[16,17]. A high level of HBsAg in circulatory blood could be detected, but no hepatitis was observed in the transgenic mice. The mechanisms of HBV pathogenesis was not caused by virus directly, but closely related to T lymphocyte activation, as demonstrated both *in vitro* and *in vivo*[18,19]. Ando *et al*[20] induced a fulminant hepatitis mice model by transferring HBsAg-specific CTLs to HBsAg-transgenic mice, in which there was no human hepatitis B virus. To establish a mice model of human viral hepatitis B by using HBV complete genome transgenic mice with virus replication *in vivo*, we constructed a new eukaryotic expression vector containing HBV complete genome and produced HBV-specific CTLs for adoptive transfer by immunizing non-transgenic syngeneic mice with the recombinant.

HBV complete genome DNA was obtained from *Eco*RI digested pBR322-2HBV and ligated with the vector pcDNA3 which was also digested by *Eco*RI, thus constructing the recombinant pcDNA3-HBV. pcDNA3 is a eukaryotic expression vector. MCS contains the restriction sites of *Eco*RI, *Xho*I and *Hind*III. CMV promoter can express efficiently in many kinds of cells. The immunostimulatory sequences (ISS) of pcDNA3 can not only activate B lymphocytes to produce antibodies, but also stimulate lymphocytes to secrete IL-12, IFN-γ and IL-6. IL-12 and IFN-γ could foster Th1 responses and enhance cell-mediated immunity, while IL-6 could further promote B lymphocyte activation and antibody secretion and also enhance cell-mediated immunity as its primary role[21,22]. So this vector is a better alternative for gene immunity. The recombinant was constructed by inserting the HBV complete genome to *Eco*RI sites of pcDNA3, with *Hind*III site upstream of *Eco*RI in MCS of pcDNA3 and no *Hind*III site in HBV genes. A single *Xho*I site was at 180 bp upstream of HBV gene. According to these characteristics, restriction endonuclease assay was used to verify whether pcDNA3-HBV contained a complete HBV gene with correct direction. In order to verify the expression of the recombinant in mammal cells, pcDNA3-HBV was transfected into HepG2 cells with lipofectin. Positive clones were selected by G418 resistance. A high level of HBsAg was detected in culture supernatant and HBV PreS1 mRNA expression was proved by RT-PCR. These results could demonstrate that HBV can stably replicate, transcript and express in transfected host cells.

The molecular mechanisms of hepatic cell death and viral clearance during HBV infection have not been illuminated clearly yet. Studies *in vitro* and *in vivo* indicated that hepatic injury caused by HBV infection was immunity mediated[23-25]. It is considered at present that CTL was the dominate effector molecule during viral clearance, and CTL inducement was the precondition[26-28]. To simulate human hepatitis after natural HBV infection, we chose HBV complete genome transgenic BALB/c mice as the experimental model. Syngeneic BALB/c mice were undertaken gene immunity by a self-constructed HBV complete genome expression vector to induce HBV specific CTLs. Mice models of viral hepatitis B were established after transgenic mice administrated CTLs with different schemes.

There were two reasons to adopt gene immunity method. First, HBV complete genome recombinant of ayw subtype was constructed because of the transgenic mice containing HBV of the same subtype, while the main component of the present gene vaccines was HBsAg with no definite subtype. Second, generally speaking, humoral immunity could be induced by protein antigens, while cell mediated immunity could be induced by gene immunization[29-31]. There were several ways of gene transfer for gene immunity, which would influence

immune effect and even determine the type of immunity. Skeletal muscle has been found to be the exclusive tissue that can efficiently ingest and express foreign genes, especially for plasmid DNA[32,33]. Because of its simpleness and convenience, it has become the dominant method for immunity. After immunized by pcDNA3-HBV once 2-3 wk, HBsAb was detected in the serum of BALB/c mice at the 4th wk. Pretreatment with 250g/L sucrose improved immune effect and induced HBV specific CTLs with a high activity.

The liver would have the most severe pathological changes in viral hepatitis B. The essential changes included degeneration and necrosis of hepatic cells, inflammatory cell infiltration, regeneration of hepatic cells, hyperplasia of fibrous tissue, and increase of serum transaminase[34,35]. HBV specific CTLs produced by immunized mice were transferred into HBV-transgenic mice. Forty-eight hours later, normal serum protein content and a high level of serum AST and ALT were detected both in negative and blank control groups. The liver stained by HE in the model group showed typical pathological changes of acute viral hepatitis B, while no pathological damage was found in the negative control group. The kidney had no pathological changes in all groups. Acute hepatitis model of mice with HBV complete genome has been established successfully by the above research project, which could mimic human hepatitis B much better because of viral replication and HBV antigens expression in the model. This study would provide a new way for anti-HBV drug screening and mechanism investigation of liver injury due to HBV infection.

Abstract

AIM: Quasispecies of hepatitis C virus (HCV) are the foundation for rapid sequence evolution of HCV to evade immune surveillance of hosts. The consensus sequence evolution of a segment of HCV NS3 region, which encompasses putative cytotoxic T cell epitopes, was evaluated.

METHODS: Three male patients, infected with HCV through multiple transfusions, were identified from clinical symptoms and monitored by aminotransferase for 60 months. Blood samples taken at months 0, 32, and 60 were used for viral RNA extraction. A segment of HCV NS3 region was amplified from the RNA extraction by RT-PCR and subjected to subcloning and sequencing. HLA types of these three patients were determined using complement-dependent microlymphocytotoxic assay. CTL epitopes were predicted using MHC binding motifs.

RESULTS: No patient had clinical symptoms or elevation of aspartate/alanine aminotransferase. Two patients showed positive HCV PCR results at all 3 time points. The other one showed a positive HCV PCR result only at month 0. A reported HLA-A2-restricted CTL epitope had no alteration in the HLA-A2-negative carrier over 60 months. In the HLA-A2-positive individuals, all the sequences from 0 month 0 showed an amber mutation on the initial codon of the epitope. Most changes of consensus sequences in the same patient occurred on predicted cytotoxic T cell epitopes.

CONCLUSION: Amber mutation and changes of consensus sequence in HCV NS3 region may be related to viral immune escape.

INTRODUCTION

Hepatitis C virus (HCV) is one of the main pathogens of transfusion-associated hepatitis. After acute transfusion-associated HCV infection, about 70-80% of the patients may progress to chronicity. Although many patients with chronic hepatitis C have no symptoms, cirrhosis may develop in 20% within 10 to 20 years after acute infection. The risk for hepatocellular carcinoma is increased in patients with chronic hepatitis C and almost exclusively in patients with cirrhosis[1-15].

HCV is a linear, single-stranded positive-sense, 9400-nucleotide RNA virus. HCV constitutes its own genus in the family *Flaviviridae*. The HCV genome contains a single large open reading frame that codes for a virus polyprotein of approximately 3000 amino acids. Due to the high mutation rate of RNA dependent RNA polymerase, there are genotype and quasispecies diversity of HCV[16-19]. The high mutation rate may interfere with effective immunity and cause the progression to chronicity[20, 21].

Of the components of adaptive immunity, cytotoxic T cells play an important role in eliminating intracellular infections[22]. They recognize body cells infected with viruses by detecting peptide fragments derived from viruses bound to MHC class I molecules on the infected body cells. Then, they kill the infected cells before viral replications complete. In this study, 3 patients with transfusion-associated hepatitis C were followed-up for 60 mo to evaluate the evolution of cytotoxic T cell epitopes in the HCV NS3 region.

MATERIALS AND METHODS

Patients
Patients C, Z and W, being 43, 48 and 49 years old Chinese males, were infected with HCV through multiple transfusions. They were followed-up for 60 mo after identification. During the follow-up period, no elevation of aspartate/alanine aminotransferase was found. Their peripheral blood was collected at mo 0 (the time of identification), 32 and 60, and stored at -70 ℃. Patients C and Z were positive for HCV RNA. Patient W was positive for HCV RNA only in the blood sample taken at mo 0 and consistently negative after that.

HLA typing
HLA types of the three patients were assessed by using the Tasaki HLA class I dry tissue typing tray (One Lambda, Canoga Park, CA). Briefly, blood samples were drawn and lymphocytes were isolated immediately. After antibody and 2×10^6 lymphocytes were mixed in each well, 1 μL of complement was added into each well to incubate at room temperature for 1 hour. After incubation, the cells were stained with eosin and fixed with formaldehyde. Positive (dead) lymphocytes appeared dark and non-refractiles with eosin dye.

RNA extraction and RT-PCR
Single step guanidine thiocyanate-chloroform method[23] was used to extract HCV RNA from 50 μL of plasma. RNA extracted was reverse-transcribed using random primers. Nested PCR (primers see Table 1) was used to amplify the HCV NS3 region that spanned a reported cytotoxic T cell

epitope (-KLVALGINAV-)[24], which is HLA-A2-restricted. The first round PCR was run for 35 cycles with denaturing at 94 ℃ for 1 min, annealing at 53 ℃ for 1 min, and elongating at 72 ℃ for 1 min. The second round of PCR was run for 35 cycles with denaturing at 94 ℃ for 1 min, annealing at 60 ℃ for 1 min, and elongating at 72 ℃ for 1 min.

Cloning and sequencing of amplified segment of HCV NS3

PCR products were subcloned into M13mp19 phage. For each blood sample, 5 clones were selected and amplified. The single strand DNA produced by the M13mp19 phage was purified by QIAprep Spin 13 kit (Qiagen, Valencia, CA) and sequenced using sequence version 2.0 sequencing kit (USB, Cleveland, OH).

Sequence analysis

DNA sequences were translated and aligned. Consensus sequence was produced for every 5 clones of each blood sample. Cytotoxic T cell epitopes for each consensus sequence were predicted based on the HLA type of the patients and MHC molecule binding motifs[25].

RESULTS

HLA types

Patient C was (A11, 30; B13, -; Bw4, -). Patient Z was [A2, 11; B60 (40), 70; Bw6, -]. Patient W was [A2, 11; B40, 55 (22); Bw6, -].

Nucleotide sequences of HCV

Five clones of NS3 sequences were ascertained for each blood sample. Since all the blood samples of patients C and Z were positive for HCV RNA, 15 sequences were obtained from each one of them. Due to the negative result of HCV RNA in the later 2 blood samples in patient W, only 5 cDNA sequences

were obtained. The GenBank accession numbers for all the sequences are in Table 2. The translated amino acid sequences are aligned in Figure 1.

Table 2 Assigned accession number for each nucleotide sequence of three patients

Sequence variation on reported cytotoxic T cell epitope

Our consensus sequences showed (K/*)LSSLGLNAV (*: stop codon) on the site of the reported HLA-A2-restricted cytotoxic T cell epitope[24]. In patient C, who was not HLA-A2-restricted, all the 15 sequences were KLSSLGLNAV. In patient W, who was HLA-A2-restricted, all the 5 sequences showed a stop codon at the beginning of this peptide (four sequences showed

				ATPPGSITV	32th, 60th mo

*These two peptides fitted the MHC binding motif because proline and glycine residues allowed flexibility which made the peptides accommodate to the motif by kinking in the peptide backbone[40].

*LSSLGLNAV and one sequence showed *LSPLGLNAV). In patient Z, who was also HLA-A2-restricted, all the sequences from 0-mo showed the stop codon at the beginning of the epitope (*LSSLGLNAV), nine sequences from blood samples at mo 32 and 60 showed KLSSLGLNAV, one sequence from blood sample at mo 32 showed KLSSLGLKPV.

Sequence variation on predicted cytotoxic T cell epitopes

Using MHC binding motifs to predict cytotoxic T cell epitopes, we found that most sites which showed changes of consensus sequences between successive blood samples were on the predicted cytotoxic T cell epitopes (Table 3).

DISCUSSION

Due to errors of the RNA-dependent RNA polymerase, RNA genomes had a relatively high mutation rate[25,26]. RNA viruses evolve as complex distributions of mutants termed viral quasispecies. These coexisting mutant genomes always have a consensus or master sequence. Despite the potentially high mutation rate and variability of RNA viruses, changes in the consensus sequence of a viral population would occur only if some selection mechanism acted on the population and caused a shift in the population equilibrium[27]. Immune response of the host can influence the distribution between different viral variants and will consequently cause a change in the consensus

Figure 1 Alignment of HCV amino acid sequences from three patients. Consensus sequences were given for the 5 sequences from the same blood sample.

sequence. A cellular immune-driven selection pressure has been demonstrated by the existence of HCV escape mutants in relation to cytotoxic T cell epitopes[28]. In the HCV-infected human, the NS3 protein seems to be fairly immunogenic. T cell activation in response to NS3 has been detected in a number of studies of patients with acute or chronic HCV infection[24, 29]. It was proposed that a strong *in vitro* T cell reaction to NS3 correlated with clearance of acute HCV infection whereas a less vigorous, or absent, NS3-specific T cell reactivity was observed in those who progressed to chronicity[30]. Thus, in this study, we chose a segment of HCV NS3 region as our focus on sequence evolution.

T lymphocytes recognize their antigens in context of MHC-encoded molecules, a phenomenon called MHC restriction. Our sequence segment encompassed a cytotoxic T cell epitope, which was restricted by HLA-A2 and reported by Rehermann *et al*[24]. In patients with HLA-A2 allele, their viral consensus sequences showed stop codons at the initial part of this epitope. On the contrary, in patients without HLA-A2 allele, their viral consensus sequences did not show the stop codon. Normally, stop codons are generated by random non-sense mutations in RNA virus and they are expected to occur randomly throughout the entire coding region. Viruses with stop codon in the open reading frame have been found to be defective viruses which usually make a small fraction of the RNA virus quasispecies[31,32]. Here, stop codons were unusually concentrated at the beginning of the reported epitope, in the sequences of patients with HLA-A2 allele, suggesting that they are specifically selected by some pressure, probably by cytotoxic T cells. We would suppose that HCV specific and HLA-A2-restricted cytotoxic T cells, which recognize and kill the infected hepatocytes to prevent replication and proliferation of the viruses, were generated in patients W and Z. Under this immune pressure, viral quasispecies in these two patients would have shifted toward a new equilibrium to avoid the immune attack. In patients W and Z, the defective viruses, which did not express the reported cytotoxic T cell epitope, dominated the viral quasispecies at month 0. This may reflect the strong immune pressure at that time. Thirty-two months later, in patient W, the viruses were cleared and the patient was recovered. In patient Z, the viruses were not cleared at month 32 or 60, suggesting that the viral quasispecies escaped from the immune pressure and survived.

Cytotoxic T cells could recognize peptides loaded on the MHC class I molecules[33]. The solution of the crystal structure of MHC class I molecules could reveal peptide-binding groove made up by $\alpha1$ and $\alpha2$ domains of heavy chains[34,35]. Naturally occurring processed peptides have been isolated from purified MHC class I molecules. Analyzing their sequences revealed the presence of simple amino acid sequence motifs that were specific to particular allelic forms of class I molecules[36]. Based on the sequence motifs, we found that most sites, with changes of the consensus sequences, were on the putative cytotoxic T cell epitopes in the corresponding patients, implying the possible underlying immune impetus for sequence evolution.

In summary, by molecular sequencing, the quasispecies nature and sequence evolution of HCV NS3 region can be revealed. By HLA typing and epitope prediction, the non-sense mutation and changes of consensus sequences might be the result of immune pressure. This study has paved the way for further cytotoxicity assay[37] to confirm the possible immune target sites of HCV.

Abstract

AIM: To establish a stable and reliable model of *Helicobacter pylori* infection model in Mongolian gerbils and to observe pathological changes in gastric mucosa in infected animals.

METHODS: Mongolian gerbils were randomly divided into 18 groups; 6 groups were infected with *H pylori* clinical strain Y06 ($n=6$, groups Y), 6 groups were infected with *H pylori* strain NCTC11637 ($n=6$, groups N), and 6 uninfected groups as negative controls ($n=4$, groups C). *H pylori* suspensions at the concentrations of 2×10^8 and 2×10^9 CFU/mL of strain NCTC11637 and strain Y06 were prepared. The animals in three groups N and in three groups Y were orally challenged once with 0.5 mL of the low concentration of the bacterial suspension. The animals in another three groups N and in another three groups Y were orally challenged with 0.5 mL of the high concentration of the bacterial suspension for 3 times at the intervals of 24 h, respectively. For the negative controls, the animals in six groups C were orally given with the same volume of Brucella broth at the corresponding inoculating time. The animals were killed after 2nd, 4th and 6th week after the last challenge and the gastric mucosal specimens were taken for urease test, bacterial isolation, pathological and immunohistochemical examinations.

RESULTS: Positive isolation rates of *H pylori* in the animals of groups Y at the 2nd, 4th and 6th week after one challenge were 0%, 16.7% and 66.7%, while in the animals of groups N were 0%, 0% and 16.7%, respectively. Positive isolation rates of *H pylori* in the animals of groups Y at the 2nd, 4th and 6th week after three challenges were 66.7%, 100% and 100%, while in the animals of groups N were 66.7%, 66.7% and 100%, respectively. In animals with positive isolation of *H pylori*, the bacterium was found to colonized on the surface of gastric mucosal cells and in the gastric pits, and the gastric mucosal lamina propria was infiltrated with inflammatory cells.

CONCLUSION: By using *H pylori* suspension at high concentration of 2×10^9 CFU/mL for multiple times, the orally challenged Mongolian gerbils can be used as a stable and reliable *H pylori* infection model. The 2 strains of *H pylori* can colonize in gastric mucosa of the infected animals and

cause mild inflammation reaction.

INTRODUCTION

Helicobacter pylori, a microaerophilic, spiral and Gram-negative bacillus, is recognized as an important pathogen causing human gastritis and peptic ulcer and a high risk factor for gastric carcinoma[1,2]. In China, chronic gastritis and peptic ulcer are two of the most common digestive diseases, and gastric cancer is one of the malignant tumors with high morbidities[3-34]. An ideal public measure to prevent and control these *H pylori* infection-associated diseases may be a vaccine that could induce strong humoral and cellular immune responses. However, no commercial *H pylori* vaccine is available so far, and the development of *H pylori* vaccine by using genetic engineering techniques is being active[35-39]. A stable and reliable *H pylori* infection animal model would be necessary for evaluating vaccine efficacy and helpful for understanding the pathological mechanism of the organism. Therapeutic drugs for *H pylori* eradication differ from those for many other bacteria such as using metronidazole[40,41]. Therefore, *H pylori* infection animal models would contribute to screen new drugs against *H pylori*. In recent published data, Mongolian gerbils have been considered as ideal animals to establish infection model by using internationally collected *H pylori* strains[42-44]. In this study, we used a clinical *H pylori* isolate named Y06 to establish a stable and reliable infection model in Mongolian gerbils. The colonization sites of *H pylori* and pathological changes in gastric mucosa of the animals were also observed.

MATERIALS AND METHODS

H pylori strains

A clinical strain of *H pylori* named Y06 was isolated from a patient with gastric ulcer. This strain was identified based on their characteristic morphology by Gram staining under microscope, and positive for urease and oxidase activities, further confirmed by slide agglutination test using commercial rabbit antiserum against whole cell of *H pylori* (DAKO). A reference *H pylori* strain, NCTC11637, was used as an infection control. The two strains were subcultured in Columbia agar (bioMérieux) containing 80 mL/L sheep blood under microaerobic conditions containing 100 mL/L CO_2, 50 mL/L O_2 and 850 mL/L N_2.

Animals

Eight-week-old specific pathogen-free male Mongolian gerbils with body mass of 75±5 g were provided by Experimental Animal Center, Zhejiang Academy of Medical Sciences. These gerbils were randomly divided into eighteen groups: six groups infected with the clinical strain Y06 (groups Y, $n=6$ in each group), six groups infected with the reference *H pylori* strain NCTC11637

(groups N, *n*=6 in each group) and six groups as negative controls (groups C, *n*=4 in each group).

Dosages and pathway of inoculation

Bacterial cells grown on the 2 strains on Columbia agar for 3-5 d were collected and diluted to the final concentrations of 2×10^8 CFU/mL and 2×10^9 CFU/mL, respectively, by using Brucella broth (bioMérieux). Each Mongolian gerbils in 3 groups Y and 3 groups N were orally challenged with 0.5 mL of 2×10^8 CFU/mL *H pylori* suspension, while the animals in another 3 groups Y and 3 groups N were attacked with 0.5 mL of 2×10^9 CFU/mL *H pylori* suspension through the same pathway. For the negative controls, the animals in 6 groups C were orally given with 0.5 mL of Brucella broth. Each animal in the groups was given with the different concentrations of *H pylori* suspensions or Brucella broth, respectively, as the described above for 3 times at an interval of 24 h. The animals were deprived of food but offered with water for 12 h before the challenge, and supplied with food and water after 4 h of *H pylori* inoculation.

Isolation and identification of *H pylori*

Six animals in group Y, 6 in group N and 4 animals in group C were killed, respectively, at 2, 4 and 6 wk after the last challenge. Two gastric mucosal specimens at the adjacent position were taken from antrum and corpus, respectively. One of the specimens was used for *H pylori* isolation, and the others were fixed with 40 g/L formaldehyde solution. The colonies on Columbia plates were identified by microscopy after Gram-staining, assays for urease and oxidase activities and slide agglutination test using the commercial *H pylori*-specific antiserum. The bacterium was defined to be *H pylori* if it was Gram-negative with arc shape or "seagull-like", positive for the two enzymes and immune agglutination.

Pathological and immunohistochemical examinations

The gastric mucosal specimens fixed with formaldehyde were pathologically examined after embedding, section and haematoxylin-esosin (HE) staining. *H pylori* in gastric mucosal specimens were detected by the immunohistochemical method using a commercial rabbit anti-*H pylori* antibody and goat anti-rabbit HRP-labeled IgG antibody (Jackson Immunoresearch).

RESULTS

Infection of Mongolian gerbils with *H pylori* strains

The results of *H pylori* isolation from gastric mucosal specimens of Mongolian gerbils are shown in Table 1.

Table 1 The detection results of *H pylori* isolated from gastric mucosa of experimental infected Mongolian gerbils

Group	Detection time (wk)	Infection rate (%) (positive/total cases)	
		1×10^8 CFU (1 challenge)	1×10^9 CFU (3 challenges)
Y	2	0(0/6)	66.7(4/6)
N	2	0(0/6)	66.7(4/6)
C	2	0(0/4)	0(0/4)
Y	4	16.7(1/6)	100(6/6)
N	4	0(0/6)	66.7(4/6)
C	4	0(0/4)	0(0/4)
Y	6	66.7(4/6)	100(6/6)
N	6	16.7(1/6)	100(6/6)
C	6	0(0/4)	0(0/4)

Y, groups infected with strain Y06; N, groups infected with strain NCTC11637; C, negative controls.

Pathological and immunohistochemical findings

In animals with positive *H pylori* isolation, the organisms were found to colonize the surface of gastric mucosa and the gastric pits (Figure 1). In the presence of *H pylori* infection, infiltration of chronic inflammatory cells in the lamina propria and erosions on the surface of gastric mucosa were observed (Figure 2).

Figure 1 The *H pylori* bodies located on the surface of gastric mucosal cells and in gastric pits (×1000).

Figure 2 The infiltrated chronic inflammatory cells in the gastric mucosal lamina propria of the specimens with positive *H pylori* isolation (×400).

DISCUSSION

In previous published data, animals for establishment of *H pylori* infection models included guinea pigs, rats, nude mice, chimpanzee *etc.*[45-48]. These animal models have many disadvantages such as low infection rates, instability, immunodeficiency and high costs. In 1997, Lee *et al* successfully established an animal model infected with a *H pylori* strain named as SS1 in C_{57}BL/6 and BaLb/c mice[48]. This animal model showed a high frequency and stability for *H pylori* infection. However, strain SS1 is a mutant of *H pylori* and its virulence is considerably low. Recently, Mongolian gerbils, which has distinct advantages such as high frequency and stability of infection, large colonization of *H pylori*, longer living suitable for study with long period of time and pathological changes similar to those observed in human with chronic gastritis, have become the predominant animals for preparing *H pylori* infection model[42-44]. In 1999, Chi e*t al* established a stable model of *H pylori* infection in Mongolian gerbils, which was orally pretreated with alcohol[49]. Therefore, Mongolian gerbils are regarded as an ideal animal for *H pylori* infection models.

Previous studies have shown that infection model in Mongolian gerbils by oral challenge once with *H pylori* suspension at the concentration of 1×10^8 CFU of *H pylori* is stable[42-44]. In the present study, *H pylori* was undetectable in the gastric mucosa from Mongolian gerbils at 2 wk after challenge once with 1×10^8 CFU of the bacterium. Furthermore,

the infection rates at 6 wk after one challenge by *H pylori* strain Y06 and strain NCTC11637 were only 66.7% and 16.7%, respectively. On contrast, by using three oral challenges at the dosage of 1×10^9 CFU, *H pylori* colonization rates in the gastric mucosa at 2 and 6 wk after challenge by *H pylori* strain Y06 or strain NCTC11637 were both 66.7% and 100%, respectively, which indicates that multiple challenges with a high concentration of *H pylori* contribute to the increased infection rates.

The infection rates of *H pylori* strain Y06 and strain NCTC11637 in Mongolian gerbils were 100% and 66.7% at 4 wk for 3 challenges using the low concentration of bacterial suspension, and 16.7% and 0% at 4 wk and 66.7% and 16.7% at 6 wk after one challenge using the high concentration. *H pylori* strain Y06, a fresh clinical isolate, seems to be more virulent than strain NCTC11637 and more beneficial for establishing *H pylori* infection model in Mongolian gerbils with a higher infection rate in a shorter period of time.

H pylori was found on the surface of gastric mucosa and in the gastric pits of Mongolian gerbils when infection was established. The observations that there were erosions of mucosal surface and infiltration of chronic inflammatory cells in the lamina propria of gastric mucosa of *H pylori* infected Mongolian gerbils indicates that the two tested *H pylori* strains are able to colonize gastric mucosa of Mongolian gerbils and cause chronic inflammation and gastric erosions.

Abstract

AIM: To investigate effects of non-starch polysaccharides(NSP) enzymes on pancreatic and small intestinal digestive enzyme activities in piglet fed diets containing high amounts of barley.

METHODS: Sixty crossbred piglets averaging 13.5 kg were randomly assigned to two treatment groups with three replications (pens) based on sex and mass. Each group was fed on the diet based on barley with or without added NSP enzymes (0.15%) for a 40-d period. At the end of the experiment the pigs were weighed. Three piglets of each group were chosen and slaughtered. Pancreas, digesta from the distal end of the duodenum and jejunal mucosa were collected for determination. Activities of the digestive enzymes trypsin, chymotrypsin, amylase and lipase were determined in the small intestinal sections as well as in homogenates of pancreatic tissue. Maltase, sucrase, lactase and γ-glutamyl transpeptidase (γ-GT) activities were analyzed in jejunal mucosa.

RESULTS: Supplementation with NSP enzymes improved growth performance of piglets. It showed that NSP enzymes had no effect on digestive enzyme activities in pancreas, but decreased the activities of proteolytic enzyme, trypsin, amylase and lipase in duodenal contents by 57.56%, 76.08%, 69.03% and 40.22%($P<0.05$) compared with control, and increased γ-GT activities in jejunal mucosa by 118.75%($P<0.05$).

CONCLUSION: Supplementation with NSP enzymes in barley based diets could improve piglets' growth performance, decrease activities of proteolytic enzyme, trypsin, amylase and lipase in duodenal contents and increase γ-GT activities in jejunal mucosa.

INTRODUCTION

Barley is one of the major energy sources of swine diets in many parts of the world. But anti-nutritive factors in barley limit its use in feed industry[1]. The predominant anti-nutritive factor is non-starch polysaccharides (NSP), including β-glucan ((1-3), (1-4)-β-D-glucan)[2,3] and arabinoxylan[4]. The β-glucan and pentosan content in whole barley grain was 4.2% and 6.6%, being 1.8% and 1.4% in endosperm[5]. The major nutrients in barley, starch and protein, are enclosed within endosperm cell walls, which consist mainly of mix-linked β-glucan and arabinoxylan[6]. Pigs, especially piglets, do not produce enzymes that can degrade the cell wall and NSP in barley. So β-glucan and arabinoxylan in barley may interfere with digestion and absorption of nutrients[7], even the production of digestive enzymes[8,9].

Studies have shown that mix-linked β-glucan and arabinoxylan are easily hydrolyzed by β-glucanases and xylanases respectively. Addition of cell wall degrading enzymes *in vitro* increased the release of proteins and non-starch carbohydrate in barley[10]. Supplementation of exogenous NSP enzymes to piglet diets can increase the digestibility of barley and pigs' growth[11-13]. This has been attributed mainly to the breakdown of endosperm cell wall components, resulting in more complete digestion of starch and protein in the small intestine. But there is little information on the effect of β-glucanases and xylanases supplementation on digestive enzyme activities in barley-based diets for piglets.

The aim of the present study was to investigate the effect of supplementation of NSP enzymes on pancreatic and small intestine digestive enzyme activities in piglets fed diets containing high amounts of barley.

MATERIALS AND METHODS

Animals, diets and enzyme complex

Sixty crossbred (Duroc×Landrace×Jiaxing) piglets averaging 13.5 kg were randomly assigned to two treatment groups with three replications (pens) based on sex and mass. Each group was fed on one of the two experimental diets for 40 d. As shown in Table 1, pigs received the same basal diet based on barley-soybean meal and NSP enzymes were added to the basal diet respectively at 0% and 0.15% of the diet at the expense of barley. To accustom pigs to the diets, all pigs were allowed access to the basal diet on alternate days for 7 d prior to commencement of the experiment. The diets and water were offered ad libitum throughout the experiment. Pigs were weighed individually and feed consumption per pen was measured weekly. Growth performance results as average daily gain (ADG), average daily feed intake (ADFI), feed gain ratio (FGR) were collected for all pigs for the experimental period. At the end of feeding trial, three pigs from each treatment (one pig per pen) were slaughtered under general anaesthesia. The pigs were then immediately eviscerated to collect intestinal samples. NSP enzymes complex was supplied by Primal Co. Ltd., BIOTEC, Finland, which contained 10 000 U/g β-glucanase (E.C.3.2.1.6) and 80 000 U/g xylanase (E.C.3.2.1.8).

Table 1 Formula and chemical composition of the basal diet

Ingredients (%)	Percentage
Barley	79.0
Soybean meal (dehulled, solvent)	11.0
Fishmeal	4.0
Yeast meal	2.0
Limestone	1.0
Dicalcium phosphate	1.2
Sodium chloride	0.3
L-Lysine-HCl (78%)	0.2
Vitamin-mineral premix[1]	1.3
Analyzed chemical composition (% as feed)	
Digestible energy(Kcal/kg)[2]	2960
Crude protein	18.28
Crude fat	1.70
Crude fiber	5.26
Calcium	1.11
Phosphorus	0.48

[1]The vitamin/mineral premix provided (per kg feed): 2 000 IU vitamin A, 200 IU vitamin D_3, 20 mg vitamin E, 1 mg vitamin K, l mg thiamine, 3 mg riboflavin, 10 mg d-pantothenic acid, 0.5 mg folic acid, 1 mg pyridoxine, 20 mg niacin, 10 μg cobalamin, 500 mg choline chloride, 0.1 mg biotin, 0.2 mg Se, 0.2 mg I, 80 mg Fe, 5 mg Cu, 2 mg Mn, and 80 mg Zn. [2]Digestible energy was based on calculated values.

Sampling procedure

The contents taken from the small intestine were digesta from the distal end of the duodenum to the ileo-cecal junction. Digesta samples were collected by massaging the tract from both ends. The digesta samples were stored immediately at -20 ℃ until use. Enzyme activity analyses of the samples obtained from the small intestine were performed on freeze–dried material, which was extracted with 1 mmol/L HCl (50 mg lyophilized digesta in 1 mL 1 mmol/L HCl) for 1 h at 4 ℃ followed by centrifugation (3 000 r/min). The supernatants were then collected for analysis of protease, trypsin, chymotrypsin, amylase and lipase activities.

The pancreas from slaughtered pigs was homogenized in ice-cold 0.2 mol/L Tris– HCl buffer containing 0.05 mol/L NaCl. The homogenate was centrifuged at 3 000 r/min for 15 min at 4 ℃ and the supernatant was saved. Protease, chymotrypsin, amylase and lipase activities were determined.

Jejunum mucosa was homogenized in 4.0 mL distilled-water and kept at 4 ℃ for 24 h followed by 10 min centrifugation (3 000 r/min). The supernatants were then collected for analysis of maltase, sucrase, lactase and γ-glutamyl transpeptidase (γ-GT) activities.

Digestive enzyme assay

Protease activity was analyzed using the method of Iwamori *et al*(1997)[14] Chymotrypsin (EC 3.4.21.1) was determined according to Erlanger *et al*[15] using glutaryl-1-phenylalanine-p-nitroanilid (GPNA) as substrate. Amylase (EC 3.2.1.1) activity was determined using a kit (No.700) from Sigma Chemical Company (Sigma Chemical Co., St. Louis, MO 63178-9916) and lipase (EC 3.1.1.3) by a pH-stat titration method using tributyrin as substrate according to Erlanson-Albertsson *et al*.[16]. The activities of protease, trypsin, chymotrypsin, amylase, and lipase are expressed as unit (U) which is defined as the amount of enzyme that hydrolyses 1 μmol of substrate per min. Maltase, sucrase, lactase and γ-GT activities were analyzed using the modified method of Dahlqvist[17]. The activities of maltase, sucrase, lactase and

γ-GT are expressed as unit (U) which is defined as the amount of enzyme that hydrolyses 10 μmoL of substrate per min.

Statistical analysis

One way analysis of variance was performed using the General Linear Model (GLM) Procedure of SAS[18]. Differences among means were tested using Duncan's multiple range test. A significant level of 0.05 was used.

RESULTS

Growth performance

Growth performance of pigs fed NSP enzymes is presented in Table 2. As compared to control, supplementation with 1.5 g/L NSP enzymes significantly improved average daily gain (ADG), average daily feed intake (ADFI) and feed conversion ratio (FCR) by 6.22% ($P<0.01$), 2.14% ($P<0.05$) and 3.69% ($P<0.05$) respectively.

Table 2 Growth performance of piglets fed diets based on barley with and without NSP enzymes

	Dietary NSP enzymes level (%)	
	0	0.15
Initial mass(kg)	13.91±0.25	14.01±0.17
Final mass(kg)	33.95±0.38[a]	35.35±0.40[c]
Average daily gain (g)	501.16±16.18 [a]	532.34±6.88[c]
Average daily feed intake (g)	1 224.00±3.62[a]	1 250.15±7.27[c]
Feed/Gain ratio	2.44±0.03[a]	2.35±0.02[c]

Values are presented as mean±SD; $n=30$ for average daily gain (ADG), $n=3$ for average daily feed intake (ADFI) and feed/gain ratio per treatment. Means in a row with different letters differ significantly, $P<0.05$.

Pancreatic digestive enzyme activities

The results of the effects of NSP enzymes on the digestive enzyme activities in the pancreas of piglets are shown in Table 3. Supplementation with 1.5 g/L NSP enzymes had no significant effect on the activities of protease, chymotrypsin, amylase and lipase in pancreas.

Table 3 Effects of NSP enzymes on the digestive enzyme activities (U/g pancreas) in the pancreas of piglets

	Dietary NSP enzymes level (%)	
	0	0.15
Protease	160.50±17.49	188.86±63.93
Chymotrypsin	1.09±0.28	0.99±0.19
Trypsin	32.14±21.96	27.25±6.79
Amylase	3 009.40±157.19	2 957.02±302.35
Lipase	89.08±13.86	92.15±13.86

Values are presented as mean±SD; $n=3$ per treatment.

Duodenal digestive enzyme activities

Effects of NSP enzymes on duodenal digestive activities are presented in Table 4. NSP enzymes affected duodenal digestive activities significantly. Compared with the control, protease, trypsin, amylase and lipase activities were decreased by 57.56%, 76.08%, 69.03% and 40.22%($P<0.05$) respectively.

Jejunal digestive enzyme activities

The activities of digestive enzyme in jejunal mucosa are shown in Table 5. Supplementation with 1.5g/LNSP enzymes had no effect on maltase, sucrase, lactase activities, but increased γ-GT activities by 118.75%($P<0.05$) compared with the control.

Table 4 Effects of NSP enzymes on the digestive enzyme activities (U/mg protein) in the small intestinal contents of piglets

	Dietary NSP enzymes level (%)	
	0	0.15
Protease	60.04±12.86[a]	25.48±4.98[c]
Trypsin	37.21±11.47[a]	8.90±3.72[c]
Amylase	3 600.45±155.68[a]	1 115.16±93.32[c]
Lipase	68.68±11.93[a]	41.06±6.81[c]

Values are presented as mean±SD; n=3 per treatment. Means in a row with different letters differ significantly, $P<0.05$.

Table 5 Effects of NSP enzymes on the digestive enzyme activities (U/mg) in jejunal mucosa of piglets

	Dietary NSP enzymes level (%)	
	0	0.15
Maltase	28.49±6.45	29.89±10.017
Sucrase	8.13±0.62	8.92±2.16
Lactase	1.22±0.75	1.72±0.97
γ-Glutamyl transpeptidase	0.16±0.05[c]	0.35±0.13[a]

Values are presented as mean±SD; n=3 per treatment. Means in a row with different letters differ significantly, $P<0.05$.

DISCUSSION

Numerous researchers have reported increased growth and improved feed conversion ratio as a consequence of NSP enzymes inclusion in animal diets based on barley, especially for poultry[19-22]. Effects of exogenous enzymes on growth performance for swine have been variable. Inborr et al[11] reported that barley-based diets supplementation with NSP enzymes increased average daily gain and feed conversion ratio of weaned piglets significantly ($P<0.05$). Yin et al (2001)[23] showed that β-glucanases and xylanase improved growth performance and feed gain ratio when piglets were fed with barley based diets. Lindberg et al[24] found enzymes (including β-glucanases, xylanases and cellulase) could enhance growth performance especially body mass gain of piglets when fed with diets based on barley. However, negative results were also reported. Baas[25] found there was no effect of β-glucanases on growth performance of finishing swine. But most experiments indicated that NSP had positive effects on growth performance for young pigs. Our study verified this point. Increase of digestibility of nutrients is the main reason for this phenomenon. The inconsistent effects between the experiments may result from different stage of pigs and/or formula of diets used.

Endogenous enzyme is very important for digestibility of nutrients. Increasing gut viscosity due to viscous polysaccharides has been shown to increase the output of pancreatic juice and enzyme activities in rats[9]. However, Mosenthin et al[26] and Zebrowska and Low[27] observed no change in the secretion of enzymes from the exocrine pancreas when feeding pigs on diets containing different levels of dietary fibre. Makkink et al[28] showed that trypsin and chymotrypsin activity depended on dietary protein source. However, in the present experiment the protein source was the same as in all other diets which may explain why no differences in enzyme activities were observed. The activities of the pancreatic enzymes in the present study were not changed with the enzyme supplementation. This indicated that the synthesis of pancreatic enzymes was unaffected by these factors.

The present study also showed that NSP enzymes decreased the activities of protease, chymotrypsin, amylase and lipase significantly in digesta from the distal end of the duodenum.

Almirall et al[29] observed that supplementation with β-glucanases increased trypsin, amylase and lipase obviously in chyme of chicken. Jensen[30] found that when pigs were fed barley based diets supplemented with NSP enzymes, chymotrypsin activity was enhanced sharply. Ikegami et al (1990) reported that soluble NSP could increase the activities of lipase, amylase and chymotrypsin in rat gut[9]. Our results are different from the studies mentioned above, but are consistent with the results reported by Inborr[11]. Inborr found exogenous NSP enzymes decreased the activities of endogenous enzymes and he thought NSP enzymes might provide a situation appropriate for endogenous enzyme action. But this may result from the fact that NSP enzymes degrade β-glucan and arabinoxylan in endosperm cell wall and decrease the viscosity of digesta in small intestine. Viscosity may act as a barrier to prevent contact of digestive enzymes with their substrates, thickening of the unstirred layer of mucosa and prevention of micelle formation required for absorption of lipids[31]. This process makes the endogenous enzymes to approach substrate easily and work more efficiently.

γ-GT is the key enzyme for amino acids absorption. The present study showed that supplementation with NSP enzymes increased γ-GT activities in jejunal mucosa when piglets were fed barley based diets. The results may indicate that NSP enzymes improves digestibility of the nutrients and supplies more substrates for these endogenous enzymes to act on, which then feedback on the secretion of the enzymes.

Abstract

AIM: To study the effects of daidzein on human pancreatic cancer cells *in vitro*.

METHODS: Human estrogen-receptor (ER)-positive pancreatic cancer cells MiaPaCa-2 and ER-negative pancreatic cancer cells PANC-1 were treated by 0.1 µmol/L, 1 µmol/L, 10 µmol/L, 25 µmol/L, 50 µmol/L, 75 µmol/L and 100 µmol/L of daidzein, respectively. Its antiproliferative effect was studied by MTT assay.

RESULTS: Daidzein inhibited the growth of MiaPaCa-2 and PANC-1 cells at the concentrations from 0.1 µmol/L to 100 µmol/L. A dose- and time-dependent manner was found. The IC_{50} of daidzein on MiaPaCa-2 and PANC-1 cells was 45 µmol/L and 75 µmol/L, respectively. After MiaPaCa-2 cells were treated by daidzein for 3 d and at the concentrations more than IC_{50}, the inhibitory manner was identical and the inhibition appeared a saturation phenomenon, but the inhibitory manner of daidzein on PANC-1 cells was different from that of MiaPaCa-2 cells.

CONCLUSION: Daidzein has antiproliferative effects on human estrogen-receptor-positive and negative pancreatic cancer cells, but their mechanisms may be different.

INTRODUCTION

Phytoestrogens are natural compounds, which exhibit estrogen-like activities. They have been thought to have a preventive effect against a wide range of human conditions, including breast cancer, bowel cancer, prostate cancer, colon cancer and other cancers, cardiovascular diseases, brain function, alcohol abuse, osteoporosis and menopausal symptoms[1-4]. There are three main classes of phytoestrogens, namely isoflavones, coumestans, and lignans[5]. They are widely distributed in soybeans, oil seeds, and vegetables. Soy contains a number of isoflavones (such as genistein, genistin, daidzein, and biochanin A), which are found to have potential anticancer properties[6]. Interestingly, phytoestrogens can not only inhibit the growth of estrogen-receptor (ER)-dependent cancer cells, but also the growth of ER-independent cancer cells[7]. The mechanisms of their anticancer effects include induction of apoptosis, alterations of cell cycle distribution, *etc*.[8,9].

The morbidity of pancreatic carcinoma has taken an upward trend all over the world. In Occidental countries, the morbidity of pancreatic carcinoma has increased by 3 to 7 times in nearly thirty years, and pancreatic carcinoma has become one of the ten commonest malignant tumors[10]. Only 15% of patients with pancreatic cancer could undergo resection and the overall 5-year survival rate was about 10%[11]. In recent years, many advances in the diagnosis and treatment (including surgical and adjuvant treatment) of pancreatic cancer have been achieved[12-14].

Estrogen receptor has been found in many cases of pancreatic tumor tissues and antiestrogen therapy has benefit to some patients with pancreatic cancers[15,16]. There is evidence to support the hypothesis that the increased incidence of pancreatic cancer in Western communities might be related to the relatively low dietary content and protective role of naturally occurring plant hormones and related compounds[17]. Generally speaking, treatment of pancreatic cancer is still a serious challenge to us[10]. The key problem is to seek novel diagnostic methods, effective adjunctive therapy and the mechanism of pathogenesis and progression of pancreatic cancer. Pancreatic cancer is often detected in its late stages. As a result, it is very important to develop new potential chemopreventive and anticancer reagents for pancreatic cancer, especially those from nature. The effects of daidzein, one of the rich compounds in Eastern countries' traditional diet, on human pancreatic cancer cells are unclear. In this study, we observed the effects of daidzein on the growth of human pancreatic cancer cells *in vitro*.

MATERIALS AND METHODS

Materials

Daidzein was purchased from Sigma Chemical Co. (St. Louis, MO) and dissolved in dimethylsulfoxide (DMSO). 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) was from Sigma. RPMI-1640 medium was from Life Technologies (Grand Island, NY). Human pancreatic cancer cell lines MiaPaCa-2 and PANC-1 were obtained from Department of General and Gastroenterological Surgery, Osaka Medical College, Takatsuki City, Japan.

Cell culture and treatment

Cells were cultured in plastic flasks or multi-well plates at 37 ℃ in a humidified atmosphere of 50 ml/L CO_2 and 950 ml/L air with RPMI-1640 medium containing 100 ml/L fetal calf serum, 50 000 U/L penicillin and 50 mg/L streptomycin. The medium was changed every other day. Exponentially growing cells were used in experiments. For quantitative assays of proliferation, 1×10^4 MiaPaCa-2 or PANC-1 cells were seeded in 96-well

plates in regular growth medium. Twenty-four hours later, cells were incubated in the medium with test compounds or 1 ml/L DMSO (as control). There were 7 test groups. Their concentrations of daidzein were 0.1 μmol/L, 1 μmol/L, 10 μmol/L, 25 μmol/L, 50 μmol/L, 75 μmol/L and 100 μmol/L, respectively. After cells were treated for 1 d, 2 d, 3 d, 4 d, 5 d and 6 d, the growth of cells was monitored by MTT assay.

MTT assay

Sets of 12 wells were used for each dose and control in this assay. When the growth time reached, 30 μL MTT solution (2 g/L in PBS) was added into each well of a 96-well plate. After cells were treated for 4 h at 37 ℃, the medium was removed and then 150 μL DMSO was added into each well to solubilize formazan. After that, the microplate was shaken on a rotary platform for 10 min. Finally, absorbance was measured at 550 nm with a Wellscan (Labsystems, USA). The inhibitive rate (%)=$((A_{control}-A_{experiment})/A_{control}) \times 100\%$.

Statistics

Statistical analysis was performed using SPSS software 10.0. Student's *t*-test was used to make a statistical comparison between groups. The level of significance was set at $P<0.05$.

RESULTS

Morphologic change of the cells

The effects of daidzein on the growth of pancreatic cancer MiaPaCa-2 and PANC-1 cells were tested over a range of concentrations from 0.1 μmol/L to 100 μmol/L. The changes of configuration and number were observed under a microscope (Figures 1, 2). Both pancreatic cancer cells treated by daidzein grew slower than control (Figures 1, 2). The higher the concentration of daidzein, the less the number of cells.

Inhibitory effect of daidzein on estrogen-receptor-positive pancreatic cancer cells

Estrogen-receptor-positive MiaPaCa-2 cells were treated by various concentrations of daidzein for 1 d to 6 d. At the concentrations from 0.1 μmol/L to 100 μmol/L, especially at 50 μmol/L, 75 μmol/L, and 100 μmol/L, daidzein inhibited the growth of cells ($P<0.01$) in a time-dependent manner (Figure 3). When cells were treated for 3 d, 50% inhibitory rate might be reached. The IC_{50} was 45 μmol/L. At the concentrations of more than IC_{50}, the inhibitory patterns were identical ($P>0.05$, Figure 3).

Figure 3 Inhibitory effects of daidzein on growth of estrogen-receptor-positive pancreatic cancer MiaPaCa-2 cells. 0.1 μmol/L, 1 μmol/L, 10 μmol/L, 25 μmol/L, 50 μmol/L, 75 μmol/L and 100 μmol/L of daidzein were used, respectively.

Inhibitory effect of daidzein on estrogen-receptor-negative pancreatic cancer cells

ER-negative pancreatic cancer PANC-1 cells were treated by daidzein. A dose-dependent effect was observed (Figure 4; 10 μmol/L, 25 μmol/L, 50 μmol/L and 75 μmol/L, $P<0.05$;

Figure 1 Morphologic changes of MiaPaCa-2 cells treated by daidzein. A: Control, B: Cells treated by 10 μmol/L of daidzein for 3 d, C: Cells treated by 75 μmol/L of daidzein for 3 d (×200).

**Figure 2** Morphologic changes of PANC-1 cells treated by daidzein. A: Control, B: Cells treated by 10 μmol/L of daidzein for 3 d, C: Cells treated by 75 μmol/L of daidzein for 3 d (×200).

100 μmol/L, $P<0.01$). When cells were treated for 2 d, 50% inhibitory rate might be observed. The IC_{50} was 80 μmol/L on day 2 and 75 μmol/L on day 3.

Figure 4 Inhibitory effects of daidzein on growth of estrogen-receptor-negative pancreatic cancer PANC-1 cells. 0.1 μmol/L, 1 μmol/L, 10 μmol/L, 25 μmol/L, 50 μmol/L, 75 μmol/L and 100 μmol/L of daidzein were used, respectively.

DISCUSSION

There has been an increase in the incidence of pancreatic cancer recent years[18-21]. The pattern of its increase had some similarities to the high incidence of breast cancer in women and prostate cancer in men in Western communities[17]. Typical Western diets have a low content of natural plant hormones, phytoestrogens, which are beneficial to our health[1-6]. They exerted their anticancer effects by their specific bi-effects, estrogenic and antiestrogenic properties[22-24]. On the one hand, they acted as antiestroges by competing with endogenous estrogens for receptor binding sites, and decrease the promoting effects of high levels of endogenous estrogens[25]. On the other hand, they could inhibit the activities of tyrosine protein kinase, DNA topisomerase, angiogenesis and antioxidant[26-29].

Hormone products were related to the pathological behaviors of several carcinomas (including colorectal carcinoma, gastric carcinoma, pancreatic carcinoma, *etc*.) and might help to predict the prognosis and effectiveness of endocrine therapy for some kinds of carcinomas[30-32]. As to pancreatic carcinoma, there were indications of possible effects of sex hormones[33]. The pancreatic cell lines, MiaPaCa-2 and PANC-1, used in our study were ER positive and negative cells, respectively[34,35]. We found that daidzein inhibited the growth of both ER positive and negative pancreatic cancer cells. However, their inhibitory patterns were different. For ER-positive cells, MiaPaCa-2, when the concentrations of daidzein were higher than the level of IC_{50}, the inhibitory effect would not significantly increase. It indicated that its antiprolifertive effect was exerted by binding to ER and appeared a saturation phenomenon. For PANC-1, an ER-negative cell, the saturation phenomenon was not found and the inhibition was in a dose-dependent manner. Its IC_{50} was higher than that of MiaPaCa-2, indicating that for the chemoprevention of ER-negative pancreatic cancer, high concentrations of daidzein should be used.

The antiestrogen reagent, tamoxifen was a choice of hormonal therapy for pancreatic cancer[16,33]. The favorable response to this therapy and survival of patients were dependent on whether the patients' tumor cells were estrogen receptor positive or not[16]. The presence or absence of estrogen receptors was also important in determining the effects of phytoestrogens on pancreatic cancer cells. A report used four kinds of phytoestrogens to study human pancreatic cancer cells showed that equol and coumestrol had anticarcinogenic effects on human ER positive pancreatic cancer Su86.86 cells. However,

they stimulated the growth of human ER negative pancreatic cancer HPAF-11 cells, genistein stimulated the growth of HPAF-11 cells but had little effect on Su86.86 cells. Another phytoestrogen, biochanin A, inhibited the growth of both Su86.86 cells and HPAF-11 cells[36]. Our results showed that daidzein, another main phytoestrogen, had inhibitory effects on both ER positive and negative pancreatic cancer cells. As phytoestrogens are a large group of compounds, the possibility of gender differences in response to these reagents may be important in determining their ability to act as chemoprotective reagents for pancreatic cancer.

Abstract

AIM: To investigated the effects of intravenous administration of the antioxidant glutathione (GSH) on reperfusion injury following liver transplantation.

METHODS: Livers of male Lewis rats were transplanted after 24 h of hypothermic preservation in University of Wisconsin solution in a syngeneic setting. During a 2-h reperfusion period either saline (controls, $n=8$) or GSH (50 or 100 µmol/(h·kg), $n=5$ each) was continuously administered via the jugular vein.

RESULTS: Two hours after starting reperfusion plasma ALT increased to 1 457±281 U/L (mean±SE) in controls but to only 908±187 U/L ($P<0.05$) in animals treated with 100 µmol GSH/(h·kg). No protection was conveyed by 50 µmol GSH/(h·kg). Cytoprotection was confirmed by morphological findings on electron microscopy: GSH treatment prevented detachment of sinusoidal endothelial cells (SEC) as well as loss of microvilli and mitochondrial swelling of hepatocytes. Accordingly, postischemic bile flow increased 2-fold. Intravital fluorescence microscopy revealed a nearly complete restoration of sinusoidal blood flow and a significant reduction of leukocyte adherence to sinusoids and postsinusoidal venules. Following infusion of 50 µmol and 100 µmol GSH/(h·kg), plasma GSH increased to 65±7 mol/L and 97±18 mol/L, but to only 20±3 mol/L in untreated recipients. Furthermore, plasma glutathione disulfide (GSSG) increased to 7.5±1.0 mol/L in animals treated with 100 µmol/(h·kg) GSH but did not raise levels of untreated controls (1.8±0.5 mol/L) following infusion of 50 µmol GSH/(h·kg) (2.2±0.2 mol/L).

CONCLUSION: Plasma GSH levels above a critical level may act as a "sink" for ROS produced in the hepatic vasculature

during reperfusion of liver grafts. Therefore, GSH can be considered a candidate antioxidant for the prevention of reperfusion injury after liver transplantation, in particular since it has a low toxicity in humans.

INTRODUCTION

A decade after the introduction of the University of Wisconsin (UW) solution for cold preservation of solid organs, hepatic preservation and reperfusion injury is still a serious problem which contributes to primary nonfunction and dysfunction of the liver allograft[1-3]. Years of research in liver preservation have established the superiority of the UW formulation over other solutions. Although hepatocytes and sinusoidal endothelial cells are injured during cold preservation in UW solution they remain alive even after periods of ischemia well beyond the limit of organ viability[2-4]. Hepatocyte and SEC death occurs rapidly on oxygenated reperfusion[2,4] and the extent of SEC death has been shown to be a critical factor influencing graft survival in various animal models[5-7]. However, therapeutic strategies which reduce reperfusion injury to hepatocytes and SEC during liver transplantation remain to be established.

There is substantial evidence that activation of Kupffer cells (KC), the generation of reactive oxygen species (ROS) and disturbance of the hepatic microcirculation contribute to reperfusion injury[8-11]. During the reperfusion, activated KC produce mediators of inflammation, including tumor necrosis factor α, interleukins and chemokines, and release ROS into the sinusoidal space[3,8]. The resulting vascular oxidant stress has been discovered as potential mechanism of vasoconstriction and leukocyte adherence in the liver[12-16]. This may lead to disturbance of the hepatic microcirculation, ultimately resulting in hypoxic cell injury. Furthermore, KC-derived ROS could activate redox-sensitive transcription factors such as nuclear factor (NF)-κB and activator protein-1 (AP-1) in endothelial cells and hepatocytes, thereby activating proinflammatory genes and adding to the hepatic damage[17,18].

Thus, ROS can be considered as signal molecules which trigger several pivotal mechanisms of reperfusion injury. A large number of investigations using antioxidant interventions support this hypothesis[10]. However, the clinical relevance of many antioxidants is limited by side-effects or high cost which may explain the lack of established antioxidative interventions to prevent hepatic reperfusion injury[3]. Therefore, recent studies investigated the therapeutic potential of the endogenous

antioxidant *glutathione (GSH)*, in particular since it has a low toxicity in humans[19]. Furthermore, GSH is able to react spontaneously with nearly all oxidants formed during inflammation, which results in the formation of oxidized glutathione (GSSG)[20-22]. Previous studies demonstrated that GSH released through the GSH transporter of hepatocytes may act as an endogenous defense system against KC – and leukocyte – derived ROS, thus protecting the hepatic vasculature from damage by inflammatory cells[8]. Therefore, interventions increasing plasma GSH levels should confer protection against reperfusion injury. Accordingly, treatment of cold preserved livers with GSH upon reperfusion prevented damage to hepatocytes in the model of isolated rat liver perfusion[23]. These *in vitro* findings suggest that GSH, as a candidate drug, could prevent reperfusion injury of the liver allograft. Consequently, future studies need to be directed toward characterization of the protective potential of GSH treatment *in vivo* which may have important implications for an application in the clinical setting.

Therefore, the purpose of this study was to investigate whether intravenous administration of GSH protects the rat liver against reperfusion injury during liver transplantation. In particular, the aims of the current study are: (1) to investigate effects of intravenously applied GSH on hepatocyte and SEC damage; (2) to examine the effect of GSH treatment on disturbances of the hepatic microcirculation, and (3) to determine the functional significance of changes of the extracellular antioxidant capacity.

MATERIALS AND METHODS

Animals and preparation
Syngeneic, male Lewis rats (donors: 207±12 g; recipients: 276±18 g body mass) were purchased from Charles River Wiga, Sulzfeld, Germany and housed in a temperature- and humidity-controlled room under a constant 12-h light/dark cycle. Animals had free access to water and rat chow (standard diet, Altromin, Germany). All experiments were performed with rats fasted 12 h prior to donor and recipient operations. All studies were performed with the permission of the government authorities and in accordance with the German Legislation on Laboratory Animal Experiments.

Donor and recipient operations were performed under spontaneous ether inhalation. The left carotid artery was cannulated with a polyethylene catheter for continous monitoring of the mean arterial blood pressure and heart rate during the operation. Another catheter was inserted into the jugular vein for substitution of plasma volume and injection of fluorescent compounds as well as for continuous infusion of glutathione during reperfusion. Body temperature was kept between 36.5 ℃ and 37.5 ℃ by means of a heating pad. Donor livers were preserved by retrograde aortal flush with 10 mL UW-solution and stored at 4 ℃ for 24 h. Prior to the implantation procedure, the livers were rinsed with warm Ringer's lactate solution (10 mL) via the portal vein at a hydrostatic pressure of 10 cm H_2O. Orthotopic liver transplantation was performed using a modified cuff technique[24]. Differing from the original technique, grafted livers were rearterialized and simultaneously reperfused through the portal vein and hepatic artery[25]. Portal clamping time was less than 20 min in all experiments.

The common bile duct of the graft was cannulated with a PE-tube and bile was collected in Eppendorf cups. Plasma samples (500 μL) were obtained in the recipient before hepatectomy and 60 and 120 min after reperfusion of the transplanted liver. The volume of the blood drawn was replaced by saline. Five minutes after starting reperfusion, all rats received 0.5 mL of albumin (5%) and 0.5 mL sodium bicarbonate in order to maintain blood pressure and physiological pH. To avoid major fluid loss and drying of the liver, possibly affecting microhemodynamics the abdominal cavity was covered with Saran wrap throughout the operation. After 120 min of reperfusion, experiments were terminated and the liver weight was determined.

Experimental groups
Two intervention groups (*n*=5 each) were compared with the control group (*n*=8). In control animals, saline was infused intravenously (2 mL/h) during reperfusion of the grafted liver, starting 20 min before declamping of the portal vein and hepatic artery. In contrast, intervention groups received GSH via the jugular vein, starting 20 min prior to reperfusion until the end of the two hour reperfusion period (total infusion time 140 min). GSH (Tationil 600®, Roche Pharmaceuticals/Italy) was administered at 50 or 100 μmol/(h· kg) (*n*=5 each) by continuous infusion (2 mL/h) of stock solutions (0.24 mol/L and 0.48 mol/L), using a micro-infusion pump (SP100i, WPI, Aston, UK). Two sham groups underwent laparotomy and intravital microscopy without hepatic ischemia in the absence (*n*=6) or presence of intravenous GSH infusion (100 μmol GSH/(h· kg), *n*=5) for 140 min.

In-vivo fluorescence microscopy (IVM)
In vivo fluorescence microscopic studies were performed 30 min after revascularization under stable hemodynamic conditions, using a modified Leitz-Orthoplan microscope combined with epi-illumination technique[26,27]. For assessment of microvascular liver perfusion and leukocyte-endothelial interaction the left liver lobe was exteriorized on a stage. For visualization of microcirculatory disturbances, sodium fluorescein (1 μmol/kg; Merck AG, Darmstadt, Germany) and rhodamin 6G (0.1 μmol/kg; Merck AG, Darmstadt, Germany) were injected intravenously for fluorescent staining of hepatocytes (negative contrast for plasma) and leukocytes, respectively. Quantification of microhemodynamic parameters was performed offline by frame-to-frame analysis of the videotaped images in a blinded fashion. Lobular perfusion and leukocyte adherence were analyzed by scanning a region of 10 randomly selected acinar areas and postsinusoidal venules, respectively. *Non – perfused sinusoids* were estimated by counting the number of continuously perfused and non - perfused sinusoids and were expressed as the percentage of all sinusoids visible in a pre-defined area. *Permanent adherence* (*sticking*) *of leukocytes to the sinusoidal endothelium* was quantified by counting the number of permanently attached leukocytes (at least for 20 s) within the 3 different segments of sinusoids. *Leukocyte sticking in postsinusoidal venules* was determined by the quantity of leukocytes attached for at least 20 s to the surface of postsinusoidal venules. Furthermore, *temporary adherence of leukocytes* (*rolling*) was assessed as the number of transiently attached leukocytes along the endothelial surface of postsinusoidal venules during an observation period of 20 s.

Determination of Kupffer cell function
KC function was assessed by determination of their particle phagocytosis as described earlier[28,29]. At the end of IVM analysis, plain fluorescent latex beads in isotonic saline solution were injected as bolus (3×10^8/kg) through the carotid catheter (diameter 1.1 μm, Polysciences Inc., Warrington, PA, USA). Phagocytic activity was then analyzed successively during the first 5 min after injection in 10 randomly selected liver lobules in each experiment. Adherence of latex particles was quantified by counting the number of beads moving in sinusoids as a percentage of all beads visible in the field during an observation period of 10 s. Beads in presinusoidal and postsinusoidal venules were not included in analysis.

Analytical methods

Blood samples of 500 μL were collected for determination of total glutathione (sum of GSH and GSSG) and GSSG. For GSSG analysis, an aliqot (200 μL) of blood was mixed immediately with 200 μL of 10 mmol/L N- ethylmaleimide (NEM) in 100 mmol/L phosphate buffer (pH 6.5) containing 17.5 mmol/L EDTA[30]. The remaining blood was centrifuged at full speed for 1 min. An aliquot (100 μL) of plasma was pipetted into 100 μL sulfosalicylic acid (5%) for determination of total glutathione. To separate GSSG from NEM and NEM-GSH adducts, an aliquot of NEM treated plasma was passed through a Sep-PakC$_{18}$ cartridge (Waters, Framingham, MA, USA) followed by 1 mL of 100 mmol/L phosphate buffer (pH 7.5). GSSG in the eluates and total glutathione in acidified plasma samples was determined by an enzymatic test as described previously[31]. GSH plasma concentrations were calculated as the difference between total glutathione and GSSG.

Serum aminotransferases

Serum aminotransferases were used as established markers of hepatic injury. Aspartarte aminotransferase (AST) and alanine aminotransferase (ALT) were measured 2 h after reperfusion using a serum multiple analyzer (Hitachi 917, Roche Germany).

Transmission electron microscopy

At the end of the experiments, perfusion-fixation of hepatic tissue was performed using a 50 g/L glutaraldehyde/40 g/L paraformaldehyde mixture in phosphate buffer (pH 7.4) via the hepatic artery at a constant pressure of approximately 80 mmHg. Specimens were cut from both the right and left liver lobes and blocks were diced into 1 mm cubes. Samples were stored in fixative for 2 to 3 d prior to further processing. Specimens were postfixed with osmium tetroxide, dehydrated in graded alcohol and embedded in Epon 812. Ultrathin sections were cut and contrasted with uranyl acetate and lead citrate for electron microscopy[11].

Statistical analysis

All data are expressed as mean±SE. Statistical differences between groups were calculated using paired or unpaired Student's t test for randomly distributed data and the Mann-Whitney U test for nonparametric data following analysis of variance (ANOVA). Differences were considered significant at $P<0.05$.

RESULTS

Cell injury and liver function after liver transplantation

Injury of parenchymal and non-parenchymal liver cells after liver transplantation was assessed by the release of ALT and AST as well as by electron microscopic analysis at 120 min of reperfusion. Parenchymal cell damage in untreated animals was indicated by a 25- and 40-fold increase of ALT and AST serum levels, respectively, when compared with sham- operated animals (Figure 1). Continuous intravenous administration of 100 μmol GSH/(h· kg) during reperfusion significantly ($P<0.05$) reduced ALT and AST levels by almost 40% whereas infusion of 50 μmol GSH/(h· kg) had no effect (Figure 1).

Transmission electron microphotographs of the untreated liver grafts after 120 min of reperfusion showed alterations of hepatocytes, including cell edema, a substantial loss of microvilli and generalized swelling of mitochondria (Figure 2A,B). Furthermore, non- parenchymal injury was evident by various degrees of SEC–detachment from the perisinusoidal matrix plate or even complete loss of the sinusoidal endothelial lining (Figure 2 A,B). Consequently, the space of Dissé was

enlarged in control livers. In contrast, treatment of animals with 100 μmol/(h· kg) GSH was effective in protecting hepatocytes with only minimal loss of microvilli of normally shaped parenchymal cells and only sporadic mitochondrial swelling. Moreover, GSH prevented SEC detachment, thus resulting in normal spaces of Dissé (Figure 2 C,D).

Function of liver allografts was estimated by recovery of bile flow. Bile flow of sham-operated animals remained constant during the observation period of 150 min and was comparable to bile flow rates of donor livers before ischemia (Figure 3). After transplantation of control livers, bile flow returned to only 45% of baseline values. Intravenous infusion of 50 μmol GSH/(h· kg) had no effect on the postischemic bile flow whereas 100 μmol GSH/(h· kg) significantly ($P<0.05$) increased bile flow during the complete reperfusion period (Figure 3).

Figure 1 ALT (A) and AST (B) plasma levels after liver transplantation. Livers preserved for 24 h in UW solution at +4 ℃ before transplantation. Compared to untreated livers (n=8) administration of 100 μmol GSH∕(h· kg) (n=5), but not of 50 μmol GSH∕(h· kg) (n=5), resulted in a significant decrease of plasma ALT and AST levels at 2 h of reperfusion. Results are mean±SE. [b]$P<0.001$ vs sham- operated animals (n=5); [a]$P<0.05$ vs untreated livers.

Kupffer cell function after liver transplantation

Latex particle phagocytosis by KC reflects their function under various conditions. In agreement with earlier observations, rapid clearance of intra-arterially administered fluorescent latex particles was observed in sham-operated animals. Five minutes after injection only 8.1±2.5% particles were freely movable in the sinusoids. This rate was not influenced by liver transplantation as indicated by 11.2±1.0% of all visible beads, freely movable in the sinusoids of untreated animals. Neither GSH treatment with 50 μmol/(h· kg) nor with 100 μmol/(h· kg) affected phagocytosis of latex particles, resulting in 12.0±1.1% and 10.5±2.0% of beads moving in sinusoids at 5 min upon bolus injection, respectively. Since KC represents approximately 90% of the phagocytic capacity in the liver, these results suggest unaltered KC function after reperfusion of untreated and GSH- treated liver grafts.

Figure 2 Transmission electron microphotographs of untreated and GSH- treated liver allografts. Arrow-heads indicate mitochondrial swelling of hepatocytes in untreated livers (A) which was almost absent in allografts treated with 100 μmol GSH/(h·kg) during reperfusion (C). Arrows demonstrate the loss of hepatocyte microvilli in untreated controls (B) whereas GSH administration preserved microvilli in nearly all hepatocyte membranes (D). As indicated by open arrows detachment of SEC (A) as well as its complete loss (B) was evident in untreated livers. GSH- treatment preserved sinusoidal endothelial lining with a normal space of Dissé (C,D). Letters indicate: H, hepatocyte; KC, Kupffer cell; EC, endothelial cell; S, sinusoidal lumen. Bars represent either 1.7 μm (B) or 2.5 μm (A,C,D).

Figure 3 Effect of GSH treatment on bile flow after liver transplantation. Animals were treated with 50 μmol/(h·kg) GSH (◐, *n*=5) or 100 μmol/(h·kg) GSH (◑, *n*=5) and compared with untreated controls (◓, *n*=8) and a sham- operated group (●, *n*=5). Results are mean±SE. [b]*P*<0.001 *vs* untreated or GSH-treated livers; [d]*P*<0.01 *vs* 100 μmol GSH/(h·kg); [a]*P*<0.05 *vs* untreated controls.

Effect of GSH treatment on the microcirculation of liver allografts

Compared with sham-operated animals, substantial disturbances of the microcirculation were observed in untreated liver allografts (Figure 4). Thirty minutes after starting reperfusion almost 25% of the sinusoids were not perfused. Intravenous infusion of 50 as well as 100 μmol GSH/(h·kg) prevented this no – reflow phenomenon, thereby improving hepatic perfusion (Figure 4 A).

Furthermore, intravital microscopy revealed considerable leukocyte sticking within sinusoids and postsinusoidal venules in untreated liver allografts (Figure 4 B,C). A significant

reduction (*P*<0.001) of stagnant leukocytes in sinusoids was found in both treatment groups (Figure 4 B). Comparable to acinar leukocyte sticking, permanent adherence of leukocytes to postsinusoidal venules was reduced by 57% and 69% (*P*<0.001) when animals received 50 or 100 μmol GSH/(h·kg), respectively (Figure 4 C). Temporary adherence of leukocytes (rolling) in postsinusoidal venules is supposed to be the initiating event in the sequence to permanent adherence to the vascular endothelium. However rolling of leukocytes was slightly increased by GSH treatment (Figure 4E).

Effect of intravenous GSH infusion on plasma GSH and GSSG levels

Sixty minutes after starting reperfusion plasma GSH levels of untreated animals increased 2-fold when compared to sham-operated animals (Figure 5). This was accompanied by a 3-fold increase of plasma GSSG (Figure 5). Infusion of 50 μmol GSH/(h·kg) resulted in a 6-fold increase of plasma GSH whereas GSSG did not exceed levels of untreated controls. In contrast, 100 μmol GSH/(h·kg) elevated plasma GSH as well as GSSG by up to 9-fold above values obtained in the sham-group (Figure 5). Moreover, plasma GSSG increased to significant higher levels when compared with untreated or GSH – treated (50 μmol/(h·kg)) animals. In order to estimate the role of spontaneous oxidation of intravenously applied GSH a second group of sham-operated animals was treated with 100 μmoL GSH/(h·kg). This resulted in marked increase of plasma GSH to 93±10 mol/L which was similar to that observed in liver allografts (97±18 mol/L). However, plasma GSSG increased to only 3.0±0.9 in contrast to 7.5±0.9 mol/L in GSH-treated liver allografts. These findings clearly indicate enhanced oxidation of intravenously applied GSH at the cytoprotective dose of 100 μmol/(h·kg).

Figure 4 Impact of GSH treatment on the hepatic microcirculation after liver transplantation. Data from *in vivo* microscopy were obtained 30 min after starting reperfusion comparing untreated controls (*n*=8) with GSH- treated allografts (50 μmol∕(h· kg) and 100 μmol∕(h· kg); each *n*=5) as well as to a sham group (*n*=5). (A) Acinar perfusion failure is indicated as the percentage of non-perfused sinusoids (no reflow). (B) Leukocyte-adhesion (sticking) to sinusoids and (C) to postsinusoidal venules. (D) Temporary attachment of leukocytes (rolling) to the endothelium of postsinusoidal venules (PSV). Results are mean±SE. [a]*P*<0.05, [d]*P*<0.01 and [b]*P*<0.001 *vs* sham group. [f]*P*<0.001 *vs* control group.

Figure 5 Plasma GSH- and GSSG concentrations following liver transplantation. Compared to sham-operated animals (*n*=5) a significant increase of reduced and oxidized glutathione was determined upon reperfusion of untreated grafts (*n*=8). Intravenous infusion of GSH at rates of 50 μmol∕(h· kg) (*n*=5) and 100 μmol∕(h· kg) (*n*=5) resulted in a dose- dependent in-crease of plasma GSH concentrations. The corresponding GSSG levels showed only a slight increase after administration of 50 μmol GSH∕(h· kg), but increased markedly following infusion of 100 μmol GSH∕(h· kg). Mean±SE. [a]*P*<0.05 *vs* sham; [b]*P*<0.001 and [c]*P*<0.05 *vs* control group; [e]*P*<0.05 *vs* GSH 50 and [f]*P*<0.01 *vs* GSH 50.

DISCUSSION

Recently, we have found that treatment of cold preserved livers with GSH upon reperfusion prevented reperfusion injury in the model of isolated rat liver perfusion[23]. Due to several limitations of this experimental model, such as the absence of plasma antioxidants and the lack of leukocytes[32,33], the potential protective effect of GSH treatment during liver transplantation remained to be defined. We also found that intravenous GSH treatment during liver transplantation prevents reperfusion injury of the liver allograft.

We obtained the following main results: (1) increase of the vascular antioxidant capacity by intravenous infusion of GSH causes a significant reduction of injury to hepatocytes and SEC as well as of (2) microcirculatory disturbances in liver allografts, and (3) Administration of GSH does not affect

KC function but enhances detoxification of KC-derived ROS as indicated by a marked increase of plasma GSSG.

Prevention of reperfusion injury to liver allografts by GSH
Intravenous administration of GSH at a dose of 100 μmol/h/kg during the reperfusion phase of liver transplantation significantly reduced ALT and AST release by approximately 40% indicating the protection of the liver allografts. This contention is supported by distinct signs of parenchymal and non-parenchymal cell injury under electron microscopy already after 2 h of re-establishing blood flow. Untreated livers showed a complete detachment of SEC from the perisinusoidal matrix which in part determines graft viability[4-7]. In contrast, detachment of SEC was dramatically attenuated in GSH-treated livers, indicating preservation of the sinusoidal architecture. Furthermore, GSH treatment markedly reduced mitochondrial swelling and the loss of microvilli in hepatocytes. These cytoprotective effects were accompanied by a marked improvement of postischemic liver function as assessed by a 2.5-fold increase of bile flow. Because postischemic GSH treatment can only protect cells which are not already seriously damaged before the onset of reperfusion, our results clearly demonstrate prevention of reperfusion injury to parenchymal and non-parenchymal liver cells by GSH.

Prevention of reperfusion injury by GSH depended on the GSH dose: 100 μmol/(h· kg) but not 50 mmol/(h· kg) showed protection. Based on steady state GSH plasma concentrations following GSH infusion, a concentration of approximately 100 mol/L appears to be pivotal for cytoprotection. In view of these findings, GSH seems as ideal and presumably safe candidate drug for prevention of reperfusion injury of the liver allograft since plasma GSH levels up to 500 mol/L showed no toxicity in humans[19].

Mechanisms of GSH – mediated protection
Effect on Kupffer cell function There is extensive experimental evidence for KC activation as a central pathomechanism of reperfusion injury of the liver after warm or cold ischemia[8,9]. To assess KC function we used the tool of intravital microscopic

analysis of latex particle phagocytosis[28,29]. In agreement with earlier studies[29] particle phagocytosis was not affected by cold preservation indicating functionally intact Kupffer cells in liver allografts. Furthermore, clearance of latex particles was not affected by postischemic administration of GSH. These results argue against a suppression of KC function as a potential protective mechanism of GSH action. Thus, potential hazards of other protective approaches interfering with vital host-defense function of KC (e.g. calcium channel blocker, KC-depleting agents;[8,34,35]) would be avoided by GSH treatment.

Detoxification of ROS in the hepatic vasculature Intravenous administration of GSH results in the degradation of GSH to its amino acids which are the again available for GSH synthesis in various organs including the liver[36]. However several studies demonstrated no relevant increase of the hepatic GSH content 2 h after starting high-dose GSH infusion[22,23]. These findings suggest that GSH effects are related rather to the increase in the extracellular antioxidant capacity than to influences on intracellular GSH. In line with this interpretation we obtained evidence for an extracellular mechanism of GSH-mediated cytoprotection.

The increase in plasma GSSG observed during reperfusion of untreated and GSH-treated livers was associated with a marked increase in plasma GSH. This parallel increase in GSH and GSSG suggests that GSSG resulted from extracellular oxidation rather than from intrahepatic generation of GSSG[37,38]. Accordingly, previous studies with the blood – free perfused rat liver found only a very small release of GSSG into the perfusate during reperfusion[39]. Furthermore, there was no evidence for a relevant increase of intracellular GSSG formation[8,39]. Thus, plasma GSSG formation observed during reperfusion of liver allografts is likely to take place extracellularly. This could be due to spontaneous as well as reactive oxygen species-related oxidation of GSH. The results of the present study argue against a predominant role for spontaneous GSH oxidation. First, intravenous infusion of 50 μmol GSH/(h· kg) during reperfusion of liver allografts resulted in a several fold increase of plasma GSH whereas plasma GSSG did not exceed the levels of untreated controls. Second, a comparable increase of plasma GSH was observed when sham-operated or transplanted animals were treated with 100 μmol GSH/(h· kg). In contrast, a 2.5-fold higher increase of plasma GSSG was determined in transplanted rats. This difference clearly indicates that spontaneous oxidation of intravenously applied GSH contributes only in part to the increase in plasma GSSG. Based on these findings oxidation of GSH by ROS appears as a major determinant of plasma GSSG formation following liver transplantation. Consequently, the marked increase of plasma GSSG during infusion of the protective GSH dose of 100 μmol/(h· kg) most likely reflects an enhanced detoxification of ROS in the hepatic vasculature.

Activated KC have been identified as potential source of extracellular ROS formation and GSH oxidation during reperfusion after warm hepatic ischemia[8,40]. Accordingly, there was no evidence for plasma GSSG formation during reperfusion of KC-depleted liver allografts[41]. These findings suggest that intravenously applied GSH protects liver allografts against the vascular oxidant stress produced by KC during reperfusion. This interpretation is further substantiated by the observation that externally added GSH and catalase protected leukocyte- free perfused rat livers against oxidant cell injury following selective KC activation[42,43]. In this experimental model cytoprotection was achieved by vascular GSH concentrations of 100 mol/L, but not by 50 mol/L. The same vascular concentrations of GSH were achieved in the present study. Again, protection of liver allografts was only evident at plasma GSH concentrations of approximately 100 mol/L and was associated with a considerable extra-formation of plasma GSSG. These findings suggest that plasma GSH above a critical level may act as a "sink" for ROS produced by KC during reperfusion. This could be due to non-enzymatic reactions between GSH and various ROS which strongly depend on the GSH concentration[29,44,45].

Prevention of microcirculatory perfusion failure and SEC injury GSH of both doses remarkably improved the hepatic microcirculation. In particular, the number of perfused sinusoids increased to that observed in non-ischemic livers indicating prevention of the no-reflow phenomenon. This could be related to the counteraction of ROS-mediated mechanisms of vasoconstriction and leukocyte adherence to sinusoids and postsinusoidal venules[12-16]. In accordance with the proposed stepwise process of leukocyte-endothelial interaction from leukocyte rolling as an initial event to permanent attachment of leukocytes as the second step[46], our results indicate GSH as an inhibitor of the second step: treatment with GSH prevented sticking but slightly increased the rolling of leukocytes. Similar effects can be achieved by the administration of superoxide dismutase[12,13,16], suggesting superoxide anion ($O_2^{-\bullet}$) as the contributing mediator of leukocyte adherence. Therefore, it seems likely that GSH prevents leukocyte adherence through reaction with $O_2^{-\bullet}$ or inhibition of $O_2^{-\bullet}$ - mediated mechanisms of leukocyte adherence. Protection of leukocyte adherence by 50 μmoL GSH/(h· kg) without evidence for additional GSSG formation does not argue against this concept because the reaction of GSH with $O_2^{-\bullet}$ can result in the formation of glutathione sulfonate[44].

However, the antioxidative potential of GSH does not rule out beneficial effects through non-antioxidative properties. Accumulating evidence indicates that detachment of SEC from the perisinusoidal matrix plate represents a critical component of preservation injury and postischemic microcirculatory failure[5,47,48]. It has been proposed that SEC damage occurs independent of ROS formation because several antioxidants failed to prevent SEC injury in the liver allograft[6]. SEC detachment is caused by various matrix metalloproteinases (MMPs) released into the extracellular compartment during cold liver preservation. In the present study attachment of SEC to their matrix was impressively preserved by GSH and could contribute to the improvement of the hepatic microcirculation. Recent experiments demonstrated the inhibition of MMPS by GSH in vitro. These findings suggest that MMPs were possible targets of GSH in liver allografts but this requires further investigations.

In summary, the present study demonstrates a dose-dependent prevention of reperfusion injury in rat liver allografts by postischemic intravenous administration of GSH. Treatment of recipient animals with GSH prevented reperfusion injury to SEC as well as to hepatocytes, markedly improved the hepatic microcirculation and preserved postischemic liver function. GSH-mediated protection of liver allografts was associated with an increased formation of plasma GSSG providing evidence for an accelerated detoxification of ROS by intravenously applied GSH. Therefore, intravenous administration of GSH appears to be a candidate therapy for the prevention of ROS-related reperfusion injury after liver transplantation, in particular since it has a low toxicity in humans and seems cost-effective.

Abstract

AIM: To clarify the protective effect of exogenous adenosine triphosphate (ATP) on hypothermically preserved rat livers.

METHODS: Establishment of continuous hypothermic machine perfusion model, detection of nucleotides in hepatocytes with HPLC, measurement of activities of LDH and AST in the perfusate, observation of histopathological changes in different experiment groups, and autoradiography were carried out to reveal the underlying mechanism of the protective effect of ATP.

RESULTS: The intracellular levels of ATP and EC decreased rapidly after hypothermic preservation in control group, while a higher ATP and EC level, and a slower decreasing rate were observed when ATP-MgCl$_2$ was added to the perfusate ($P<0.01$). As compared with the control group, the activities of LDH and AST in the ATP-MgCl$_2$ group were lower ($P<0.05$). Furthermore, more severe hepatocyte damage and neutrophil infiltration were observed in the control group. Radioactive [α-^{32}P] ATP entered the hypothermically preserved rat hepatocytes.

CONCLUSION: Exogenous ATP has a protective effect on rat livers during hypothermical preservation. However, Mg^{2+} is indispensable, addition of ATP alone produces no protective effect. The underlying mechanism may be that exogenous ATP enters the hypothermically preserved rat liver cells.

INTRODUCTION

Improving the quality of cold stored organs and prolonging the effective preservation time are the pivotal contents in the investigation of hypothermic preservation of transplant grafts. Several investigators have reported that the intracellular level of adenosine triphosphate (ATP) in cold stored organs was closely correlated with the viability of transplant grafts[1-3]. Bowers reported that ATP level in cold stored pretransplant organs was a sensitive parameter for examining the activities of cold stored organs[4]. Therefore, providing direct energy substrate ATP to cold stored organs[5], should be a simple and effective method to sustain the high level of intracellular ATP.

However, thus far, whether exogenous ATP could enter cells or not is controversial[6-9]. Furthermore, there were few reports which elucidated the protective effect of ATP on cold stored transplant grafts. In this study, a continuously hypothermic machine perfusion model of rat liver was applied to reveal the protective effect of ATP on cold stored rat livers and its mechanism.

MATERIALS AND METHODS

Experimental animals
Wistar rats weighing 180-220 g, both male and female, were randomly used..

Experiment groups and protocol
Cold storage study on rat livers The rats mentioned above were divided into 3 groups at random, group A (containing neither ATP nor MgCl$_2$ in the perfusate), group B (containing 5 mmol/L ATP but no MgCl$_2$ in the perfusate), group C (containing either ATP or MgCl$_2$ in the perfusate), respectively. There were 6 rats in each group. The rat liver was weighed immediately after resection by the method described previously[10-12], then these grafts were put into the modified Hoffmann perfusate[13] (0-4 ℃) for 30 min (Table 1). Finally, the livers were preserved in a hypothermic preservation incubator by continuously hypothermic preservation perfusion model (Figure 1). The perfusate temperature was 6-8 ℃[14], perfusion speed was 0.1 mL/(min.g)[14], the total volume of perfusate was 120 mL.
Autoradiography study Six rats were chosen randomly, the livers were resected with the same method. One mCi [α-^{32}P] ATP, 5 mmoL MgCl$_2$, 200 μL and 40 U phenol kinase were added into 1 L perfusate, and the same liver preservation method was applied.

Table 1 Components of perfusate

Composition	Concentration
Hydroxyethyl starch	50 g/L
Calcium gluconate	80 mmol/L
Raffinose	10 mmol/L
KH$_2$PO$_4$	25 mmol/L
Hydroxyethyl piperazine	10 mmol/L
Dexamethasone	12 mg/L
Penicillin	2×10^5 units/L
Insulin	100 units/L
[1]MgCl$_2$	5 mmol/L
[1]ATP	5 mmol/L

The pH value was modulated to 7.35 with NaOH, and the osmotic pressure was 300-320 mOsm/L; [1]Addition of MgCl$_2$ and ATP was dependent on the different groups.

Biochemical detection
Detection of energy status in cold stored rat livers The rat liver samples were used to detect the intracellular ATP, ADP, AMP, TAN and EC at 0, 1, 2, 6, 12, 24 and 36 h after

preservation by HPLC method[15] (TAN=ATP+ADP+AMP, EC=[ATP+0.5ADP]/TAN)[16]. One milliliter of perfusate was taken to detect the LDH and AST activities[17,18] at 6, 12, 24 and 36 h respectively after preservation.

Histological and morphological findings Paraffin sections of HE staining were made after 24 h preservation of the rat livers[19], and observed by a light microscope.

Autoradiography of [a-^{32}P] ATP The rat liver samples were made into paraffin sections of HE staining after 4-h preservation. Moreover, whether ATP entered the cells of cold stored rat livers or not was examined by autoradiography of [α-^{32}P] ATP[20].

Figure 1 Preservation of continuously hypothermic machine perfusion. A: Organ hypothermic preservation box, B: Temperature displayer, C: Perfusion pump, D: Perfusion pump, (Displaying the perfusion pressure). E: Perfusate container, F: Organ preservation container, G: pH displayer, H: Entry of wire, (Being sealed while preservation).

Statistical analysis

The average values were presented as mean±SD, *t*-test was applied and *P*<0.05 was considered to be statistically significant.

RESULTS

Energy status in cold stored rat livers (**mm**ol/g wet liver)

In group A, following the prolongation of preservation time, the ATP and EC levels in rat liver cells were significantly decreased. The ATP and EC levels were also rapidly decreased in group B, there was no statistical difference between these two groups (*P*>0.05). However, the ATP and EC levels were slowly decreased in group C (*P*<0.01, Table 2).

LDH and AST activities in hypothermic preservation perfusate

LDH and AST activities in the perfusate were increased in groups A and B, there was no significant difference between two groups (*P*>0.05). On the other hand, compared with those in groups A and B, the relevant activities were slowly increased in group C (*P*<0.05, Table 3).

Histological and morphological findings after 24-h hypothermic perfusion preservation

In group A (Figure 2), the hepatocytes were obviously swollen, cytosol and part of nucleus were faintly stained. Part of the endothelial cells entered the hepatosinus.

In group B (Figure 3), the hepatocytes were also expanded, cytosol was faintly stained. Some nuclei were strongly stained. Some endothelial cells entering the hypatosinus were also found.

In group C (Figure 4), the hepatocytes were lightly expanded. There was no apparent bubble in cytosol, and the morphology of nucleus was normal. The endothelial cells of hepatosinus were continuous.

Autoradiography of [α-^{32}P] ATP

Numerous silver spots of [α-^{32}P] ATP were found to be limited within the rat hepatocytes, while no silver spots were found in the hepatosinus and central vein (Figure 5). This observation demonstrated that [α-^{32}P] ATP entered the cold stored rat hepatocytes.

DISCUSSION

Protective effects of exogenous ATP on hypothermically preserved rat livers

Up to now, some reports have revealed that ATP-MgCl$_2$ had a protective effect on the therapy of hemorrhagic shock[7,21], but reports revealing the protective effect of ATP-MgCl$_2$ on hypothermically preserved transplant organs were few[22]. The results of this study demonstrated that the intracellular level of ATP in the group containing no ATP-MgCl$_2$ or the group containing ATP alone decreased rapidly after hypothermic preservation. Simultaneously, the release of intracellular enzymes was increased, indicating severe damages of the membrane functions. Moreover, significant swelling of the hypatocytes and obvious infiltration of neutrophils were found histologically. On the contrary, the intracellular ATP level in the group containing ATP-MgCl$_2$ was almost maintained at the normal level for quite a long time, and decreased much slower after hypothermic preservation. Furthermore, because of the protective effect of ATP on cell membranes[23,24], the metabolic function of hepatocytes was restored, and the release of intracellular enzymes (LDH and AST) was significantly inhibited. The histological observations also showed that the swelling of hepatocytes was milder than that in groups B and C. These results suggested that ATP-MgCl$_2$ could directly provide the energy or energy substrates for intracellular Na$^+$-K$^+$ ATPase as well as Ca^{2+}-ATPase to remain the extracellular and intracellular ion balance[25-29], and lighten the intracellular acidosis and cell swelling[21,23]. In addition, ATP-MgCl$_2$ also had effects on the amelioration of microcirculation, restoration of membrane voltage, restoration of normal membrane permeability and improvement of cellular functions[30,31].

Together, ATP showed protective effects on cold stored rat livers, and it might be a synthetical effect of multiple actions.

Mechanism of protective effect of ATP on hypothermically preserved rat livers

ATP had a very strong effect on vascular expansion[7], but our current study demonstrated that exogenous ATP protected cold stored rat livers not through vascular expansion.

If ATP-MgCl$_2$ protected the cold stored rat livers through vascular expansion, then addition of ATP alone to the perfusate should also exhibit a protective effect. But no protective effect was observed by the addition of ATP alone in our study (Data not shown). Moreover, addition of MgCl$_2$ alone to the perfusate also showed no protective effect[21]. Addition of ADP-MgCl$_2$ complex, which has a more effective action of vascular expansion, showed no protective effect as ATP-MgCl$_2$ (Data not shown). An even more important finding was that, ATP-MgCl$_2$ could enter cold stored rat liver cells in our study. This also directly confirmed that exogenous ATP-MgCl$_2$ could protect cold stored rat livers through the intracellular mechanism. By our knowledge, no report has revealed that exogenous ATP could enter hepatocytes through the membrane, and the mechanism is still unclear. We suspect that the possible pathway might be considered as followings. First, as ATP is a large biomolecule, the membrane is impermeable to it under normal status. But the permeability is increased to ATP due to the activation of some membrane carrier proteins by hypothermia and anoxia. Second, ATP enters hepatocytes through the disrupted hepatocyte membrane. In addition, how does ATP play the protective effect after entering the cells is still poorly understood.

Taken together, these results indicate that exogenous ATP-MgCl$_2$ could protect cold stored livers through an intracellular rather than an extracellular mechanism.

Participation of Mg^{2+} in protection of cold stored rat livers by exogenous ATP

As we know, ATP could form chelate with other extracellular bivalent cations (Ca^{2+}, Sr^{2+}, Mg^{2+}, *etc.*). However, addition of ATP-MgCl$_2$ complex could inhibit the dephosphorylation and deamino action of ATP, suppress the extracellular hydrolysis of ATP, and prevent the different dynamic effects by interaction of ATP and other extracellular cations[32]. The other possible reason may be that participation of Mg^{2+} may be required while

ATP goes through the cell membrane. The carrier protein has been found on the intima of mitochondria. The functional mechanism was found to be: ATP-Mg^{2+}_{out}+$HPO_4^{2-}_{in}$<=>ATP-Mg^{2+}_{in}+$HPO_4^{2-}_{out}$[33]. Further investigation is needed to confirm whether there is such a carrier protein on the outside membrane of hepatocytes or not, and whether ATP enters hepatocytes by interaction with Mg^{2+} or not. In addition, there is also the possibility that, as a co-factor of many intracellular functions, Mg^{2+} could participate in a diverse of ATP dependent intracellular actions, such as Na^+-K^+ ATPase, Ca^{2+}-ATPase, and glycolysis[34].

In summary, the results of the current study suggest that exogenous ATP could protect cold stored rat livers by entering hepatocytes. ATP-$MgCl_2$ should be a pivotal component in the hypothermic preservation solution. Further study is required to clarify the protective mechanism of ATP on cold stored organs, which may contribute to the development of hypothermic preservation solution.

Abstract

AIM: To study the alterations of brain-gut peptides following traumatic brain injury (TBI) and to explore the underlying significance of these peptides in the complicated gastrointestinal dysfunction.

METHODS: Rat models of focal traumatic brain injury were established by impact insult method, and divided into 6 groups (6 rats each group) including control group with sham operation and TBI groups at postinjury 3, 12, 24, 72 h, and d 7. Blood and proximal jejunum samples were taken at time point of each group and gross observations of gastrointestinal pathology were recorded simultaneously. The levels of vasoactive intestinal peptide (VIP) in plasma, calcitonin gene-related peptide (CGRP) and cholecystokinin (CCK) in both plasma and jejunum were measured by enzyme immunoassay (EIA). Radioimmunoassay (RIA) was used to determine the levels of VIP in jejunum.

RESULTS: Gastric distension, delayed gastric emptying and intestinal dilatation with a large amount of yellowish effusion and thin edematous wall were found in TBI rats through 12 h and 72 h, which peaked at postinjury 72 h. As compared with that of control group (247.8±29.5 ng/L), plasma VIP levels were significantly decreased at postinjury 3, 12 and 24 h (106.7±34.1 ng/L, 148.7±22.8 ng/L, 132.8±21.6 ng/L, respectively), but significantly increased at 72 h (405.0±29.8 ng/L) and markedly declined on d 7 (130.7±19.3 ng/L). However, Plasma levels CCK and CGRP were significantly increased through 3 h and 7 d following TBI (126-691% increases), with the peak at 72 h. Compared with control (VIP, 13.6±1.4 ng /g; CGRP, 70.6±17.7 ng/g); VIP and CGRP levels in jejunum were significantly increased at 3 h after TBI (VIP, 35.4±5.0 ng/g; CGRP, 103.8±22.1 ng/g), and declined gradually at 12 h and 24 h (VIP, 16.5±1.8 ng/g, 5.5±1.4 ng/g; CGRP, 34.9±9.7 ng/g, 18.5±7.7 ng/g), but were significantly increased again at 72 h (VIP, 48.7±9.5 ng/g; CGRP, 142.1±24.3 ng/g), then declined in various

degrees on d 7 (VIP, 3.8±1.1 ng/g; CGRP, 102.5±18.1 ng/g). The CCK levels in jejunum were found to change in a similar trend as that in plasma with the concentrations of CCK significantly increased following TBI (99-517% increases) and peaked at 72 h.

CONCLUSION: Traumatic brain injury can lead to significant changes of brain-gut peptides in both plasma and small intestine, which may be involved in the pathogenesis of complicated gastrointestinal dysfunction.

INTRODUCTION

Gastrointestinal dysfunction occurs frequently in patients with traumatic brain injury (TBI)[1-3]. More than 50% patients with severe head injuries do not tolerate enteral feedings[4]. This intolerance is manifested by vomiting, abdominal distention, delayed gastric emptying[5,6], esophageal reflux[7] and decreased intestinal peristalsis[8], indicating that gastrointestinal dysfunction is a common phenomenon following TBI. The association of severity of brain injury with the intolerance of enteral feeding suggests a strong link between the central nervous system and the nonfunctioning gut. However, the precise mechanism of gastrointestinal dysfunction following TBI has not been reported to date and remains to be interpreted.

Gastrointestinal motility is mainly regulated by two factors including humoral hormones and nervous transmitters from both central nervous system and peripheral enteric nervous system[9]. Brain-gut peptides possess two functions as mentioned above, *e.g.*, exerting action on gastrointestinal motility via both endocrine hormones and peptidergic transmitters. These peptides also play their roles in modulation of the gastrointestinal motility through central nervous system, which is a part of brain-gut interaction[10]. Recent studies have indicated that some disorders of gastrointestinal motility following sepsis[11-13], trauma[14], surgery[15-17], chronic stress[18] and experimental spleen deficiency[19] are related to brain-gut peptides, such as cholecystokinin (CCK), vasoactive intestinal peptide (VIP), calcitonin gene-related peptide (CGRP), neuropeptide Y (NPY) and substance P (SP), suggesting that brain-gut peptides are important mediators in the regulation of gastrointestinal motility[20-22]. Until now, no study has been made to investigate the relationship between brain-gut peptides and gastrointestinal dysmotility following TBI. Therefore, we hypothesized that TBI could induce marked alterations of

brain-gut peptides in both plasma and gut, which could be involved in the pathogenesis of complicated gastrointestinal dysfunction.

Brain-gut peptides as modulatory mediators appear to be major components of bodily integration and have important regulatory actions on physiological function of gastrointestinal tract. Increasing studies have demonstrated that VIP[14,17,19,23], CCK[12,20,21] and CGRP[11,15,16,24] play important protective role in regulation of blood flow, cell differentiation, immune function and secretion of digestive glands. On the other hand, they have an adverse effect on the gut motility[11-19]. It is also well known that VIP, CCK and CGRP are located in both central nervous system (CNS) and peripheral enteric nervous system, and mainly exert inhibitory action on gut motility[16-21,24]. Several kinds of stress, such as trauma, cold, restraint and pain, can induce the release of these brain-gut peptides from CNS and enteric nerve[14,18], and the alterations of relevant receptors in the gut[19] to induce the gastrointestinal dysmotility. However, it is unknown how these peptides change and what the underlying significance of these changes is in the gastrointestinal dysmotility following TBI. Further insights into the alterations of brain-gut peptides following TBI may provide new therapeutic opportunities for the gastrointestinal dysfunction complicating head trauma. In current study, rat models of TBI were made to measure the alterations of VIP, CCK and CGRP in both plasma and jejunum and to investigate the underlying role of brain-gut peptides in gastrointestinal dysfunction.

MATERIALS AND METHODS

Rat models of TBI

Male Wistar rats, weighing from 220 to 250 g, were purchased from Animal Center of Chinese Academy of Science, Shanghai, China. The rats were fed rodent chow with free access to tap water and housed in temperature- and humidity-controlled animal quarters with 12 h light/dark cycle. All procedures were approved by the Institutional Animal Care Committee.

The rats were randomly divided into six groups (6 rats/ group) including control group with right parietal bone window alone and no brain injury, and TBI groups at h 3, 12, 24 and 72, and day 7, respectively. Following intraperitoneal anesthesia with urethane (1 000 mg/kg), animal head was fixed in the stereotactic device. A right parietal bone window of 5 mm in diameter was made under aseptic conditions with dental drill just behind cranial coronal suture and beside midline. The dura was kept intact. Right parietal brain contusion was adopted from the impact method described by Feeney et al.[25] and severe traumatic brain injury was made by dropping weight with impact diameter of 4 mm, depth of 5 mm and total impact energy of 1 000 g· cm. The control animals were killed for sample collection at 72 h, and TBI group rats were decapitated at corresponding time point. Blood samples were obtained by right ventricle puncture and centrifuged with the plasma stored at -40 ℃ for further analysis. A segment of the jejunum 15 cm distal to Treitz ligament was taken, rinsed and weighed, then were put into a tube with 1 mL saline water. The tube was plunged into vigorous boiling water and boiled for 3 min, and then all layers of jejunum sample and 0.5 mL of 1 mol/L glacial acetic acid were added to a homogenizer to be homogenized for 10 min. The 0.5 mL of 1 mol/L NaOH was mixed with the homogenized sample. After centrifugation at 3 000 r/min for 5 min at low temperature, the supernatant was collected and stored at -40 ℃ until assay of brain-gut peptides.

Assay analysis of VIP, CCK and CGRP in plasma

The concentrations of VIP, CCK and CGRP in plasma samples were measured by enzyme immunoassay (EIA) with commercially available kits according to the manufacturer's instructions. Peptides [VIP (S-80039), CCK (S-80013-B), α-CGRP (S-80011-R)] were purchased from AOR Diagnostics, USA. The minimum detectable concentration for VIP, CCK and α-CGRP was 0.06-0.08 ng/L of sample with intra- and inter-assay variation less than 6% and 15% respectively. There was 25% cross-reaction with β-CGRP.

Assay analysis of VIP, CCK and CGRP in jejunum samples

VIP levels in jejunum were determined by radioimmunoassay (RIA) with the kit purchased from Beijing Huayin Biotechnology Institute, China. The concentrations of CCK and CGRP in all layers of jejunum were measured by EIA as mentioned above. The protein concentration of jejunum samples was determined by using a bicinchoninic acid assay kit with bovine serum albumin as the standard (Pierce Biochemicals, Rockford, IL).

Statistical analysis

Software SPSS 11.0 was used in the statistical analysis. Parameters were expressed as mean±SD, and compared using one-way ANOVA analysis of variance, followed by Tukey test. Statistical significance was determined at $P<0.05$.

RESULTS

Gross observations of gastrointestinal pathology

Gastrointestinal tract was found to be nearly normal in rats of control group and TBI 3 hour group (Figure 1A). In TBI groups at 12, 24 and 72 h postinjury, gastric distention and intestinal dilatation with a large amount of yellowish effusion existing within intestinal cavity were found, and intestinal wall became thinner and edematous (Figures 1B and 1C), suggesting that delayed gastric emptying and paralytic ileus occurred following TBI. The above mentioned pathological changes culminated at 72 h following TBI. On d 7 postinjury, small intestine was found to become thin and slender, suggesting that an atrophy in the gut occurred (Figure 1D).

Figure 1 Gross observation of intestinal pathology was shown as A, B, C and D. A: nearly normal morphology at TBI 3 h; B: intestinal dilation with large amount of yellowish effusion and thin edematous wall at 72 h following TBI; C: gastrointestinal distention at 72 h following TBI, stomach indicated by solid arrow and intestine by blank arrow; D: gastrointestinal atrophy on day 7 following TBI.

Levels of VIP, CCK and CGRP in plasma

As compared with that of control group (247.8±29.5 ng/L), plasma VIP levels were significantly decreased at 3, 12 and 24 h postinjury (106.7±34.1 ng/L, 148.7±22.8 ng/L, 132.8±21.6 ng/L, respectively), but significantly increased at 72 h (405.0±29.8 ng/L) and declined markedly on d 7 (130.7±19.3 ng/L) (Figure 2). However, Plasma levels CCK and CGRP were significantly increased through 3 h and 7 d following TBI (126-691% increases), with the peak at 72 h (Figures 3 and 4).

Figure 2 Alteration of VIP in plasma after TBI. Compared with control, plasma level of VIP was significantly decreased at 3, 12 and 24 h postinjury, but was significantly increased at 72 h, then declined to a low level on d 7 with the value similar to that of groups of 3 h, 12 h and 24 h. [b]$P<0.01$ *vs* control; [d]$P<0.01$ *vs* 3 h, 12 h, 24 h and 7 d.

Figure 3 Alteration of CCK in plasma after TBI. Compared with control, plasma level of CCK was significantly increased postinjury, and peaked at 72 h, then declined to some degree on d 7, but was still significantly higher than that of control. [b]$P<0.01$ *vs* control; [d]$P<0.01$ *vs* 3 h. Mean±SD of 6 animals, control: 2.1±0.3 μg/L, 3 h: 5.8±1.2 μg/L, 12 h: 6.7±0.5 μg/L, 24 h: 8.3±0.7 μg/L, 72 h: 10.8±1.2 μg/L, 7 d: 4.8±0.9 μg/L.

Figure 4 Alteration of CGRP in plasma after TBI. Compared with control, plasma level of CGRP was significantly increased postinjury, and peaked at 72 h, then declined obviously on d 7 with the value still significantly higher than that of control. [b]$P<0.01$ *vs* control; [d]$P<0.01$ *vs* 3 h; [f]$P<0.01$ *vs* 12 h, 24 h and 72 h.

Mean±SD of 6 animals, control: 120.8±47.7 ng/L, 3 h: 323.8±75.9 ng/L, 12 h: 596.7±82.7 ng/L, 24 h: 536.0±77.2 ng/L, 72 h: 955.0±63.0 ng/L, 7 d: 273.3±83.8 ng/L.

Figure 5 Alteration of VIP levels in all layers of jejunum after TBI. Compared with control, the level of VIP was significantly increased at 3 h following TBI, then declined markedly at 12 h and 24 h, and was significantly increased again at 72 h, but was at its lowest level on day 7 postinjury. [b]$P<0.01$ *vs* control; [d]$P<0.01$ *vs* 3 h; [f]$P<0.01$ *vs* 3 h and 12 h.

Figure 6 Alteration of CCK levels in all layers of jejunum after TBI. The level of CCK was significantly increased after TBI as compared with that of control, and peaked at 72 h postinjury, then declined to some degree but was still significantly higher than that of control on d 7. [b]$P<0.01$ *vs* control; [d]$P<0.01$ *vs* 3 h. Mean±SD of 6 animals, control: 46.5±13.9 ng/g, 3 h: 92.6±28.7 ng/g, 12 h: 139.8±24.7 ng/g. 24 h: 178.5±25.8 ng/g, 72 h: 286.8±25.9 ng/g, 7 d: 137.8±27.3 ng/g.

Figure 7 Alteration of CGRP levels in all layers of jejunum after TBI. Compared with control group, the level of CGRP was significantly increased at 3 h, then declined significantly at 12 h and 24 h, and significantly increased again at 72 h postinjury, then declined on d 7, but was still significantly higher than that of control. [a]$P<0.05$ *vs* control; [b]$P<0.01$ *vs* control; [d]$P<0.01$ *vs* 3 h, 12 h, 24 h and 7 d.

Levels of VIP, CCK and CGRP in jejunum

As compared with that of control group (VIP, 13.6±1.4 ng/g;

CGRP, 70.6±17.7 ng/g), VIP and CGRP levels in jejunum were increased significantly at 3 h after TBI (VIP, 35.4±5.0 ng/g; CGRP, 103.8±22.1 ng/g, $P<0.01$), then declined gradually at 12 h and 24 h (VIP, 16.5±1.8 ng/g, 5.5±1.4 ng/g; CGRP, 34.9±9.7 ng/g, 18.5±7.7 ng/g), but were significantly increased again at 72 h postinjury (VIP, 48.7±9.5 ng/g; CGRP, 142.1±24.3 ng/g, $P<0.01$). The VIP level declined to a significantly low level on d 7 (3.8±1.1 ng/g) (Figure 5), otherwise, CGRP declined to the level close to that of TBI 3 h group (102.5±18.1 ng/g) (Figure 7). The CCK levels in jejunum were found to change in a similar trend as that in plasma with the concentrations of CCK significantly increased (99-517% increases) from 3 h to 7 d following TBI and peaked at 72 h (Figure 6).

DISCUSSION

TBI is a critically ill condition resulting in metabolic and immune alterations, inflammatory response and disturbance of gastrointestinal peptides via hypothalamo-pituitary-adrenal axis and brain-gut axis[10,26]. Therefore, TBI can lead to disturbance of peptidergic mediators as a result of systemic stress with the same mechanism as occurred in trauma, sepsis, surgery and burns[11-17]. Brain-gut peptides possess many biological functions such as dilating vessels, improving focal blood flow perfusion, regulating immune action and relaxing smooth muscle of trachea[13,27,28]. The present study shows that brain-gut peptides VIP, CCK and CGRP change significantly following TBI in both plasma and jejunum, behave in different manner and partly adapt to the systemic pathophysiological needs. Our data suggest that levels of CCK in plasma and jejunum tissue change in parallel and increase gradually following TBI, with a maximum at 72 h postinjury. By contrast, VIP and CGRP levels in plasma and in jejunum tissue show non-parallel fluctuations. Nevertheless, concentrations of all neurohormonal mediators peak at 72 h postinjury, which coincides with the maximal morphological alterations occurring in the gut following TBI[29]. High level of VIP, CCK and CGRP in plasma implies a large amount of release of these peptides into circulation from nerve ending due to systemic stress. Decreased VIP and CGRP level in plasma and/or jejunum may be related to the low synthesis, depletion of secretion, more binding to the relevant receptors, reduced tissue perfusion of blood flow and cell edema.

On the other hand, obvious alterations of VIP, CCK and CGRP may play an important role in gastrointestinal dysmotility induced by TBI, mainly because brain-gut peptides involved in the endocrine and enteric nervous systems as well as in the central nervous system are the important factors in the regulation of gastrointestinal motility through pathways of endocrine, paracrine or neurocrine. CCK exerts action mainly via endocrine, otherwise, VIP and CGRP mainly via neurocrine[9]. Mechanic and chemical stimuli which induce peptide release from the epithelial endocrine cells are the earliest step in the initiation of peristaltic activities. The dorsal vagal complex (DVC), located in the medulla of brainstem, constitutes the basic neural circuit of vago-vagal reflex control of gastrointestinal motility[9]. Several gut peptides act on the DVC to modify the vagal cholinergic reflexes directly (VIP and CGRP) or indirectly via the afferent fibers in the peripheral (CCK). The DVC is also a primary site of action of many neuropeptides in mediating gastrointestinal motor activities (TRH and NPY). More and more evidences have shown that there is a complicated bidirectional inter-relationship between nervous system and gastrointestinal tract[30]. Gastrointestinal signals produced during chronic stress and colitis can be transmitted into central nervous system (CNS) and influence the function of the latter. In turn, CNS can modulate the electrical activity of gastrointestinal tract, as occurred in TBI.

VIP is a 28 amino acid neurotransmitter peptide that is widely distributed, particularly in the central and peripheral nervous systems, with a broad spectrum of biological actions mediated by stimulation of parasympathetic nerves coinciding with tissue responses. VIP is one of main inhibitory nervous transmitters located in the gut, which induces relaxation of intestinal smooth muscle and sphincters, dilation of peripheral blood vessels and inhibition of gastric acid secretion. Additionally, *in vivo* studies showed VIP could protect lung, retina, heart, kidney and stomach from the harmful effects of inflammation, ischemia-reperfusion injury and glutamate-induced cell death[27,31]. It also increases survival rate of animals exposed to severe septic and hemorrhagic shock[32]. VIP is a nonadrenergic noncholinergic nervous transmitter, and exerts inhibitory action on gastrointestinal motility through its binding to the relevant receptors located in gastrointestinal tract and subsequent activation of cyclic AMP-dependent protein kinase. VIP neurons occupy 40% of submucosal neurons of rat small intestine[33]. In the intestine, VIP markedly stimulates intestinal secretion of electrolytes and hence of water. The results of this study showed that VIP level in both plasma and jejunum was increased significantly at 72 h following TBI. Increased concentrations of VIP in plasma and jejunum might be responsible for the intestinal dilation and large amounts of intra-intestinal effusion as shown in Figure 1 B and C. From 12 h to 24 h following TBI, VIP concentrations in both plasma and jejunum were decreased significantly due to binding to receptors and low synthesis, which was partially responsible for the acute gastrointestinal mucosal damage induced by ischemia.

CCK is involved in the endocrine cells in the upper small intestine, principally acting to stimulate gallbladder contractions[34] and pancreatic secretion[35], and to delay gastric emptying after meals[26]. Evidence has shown that CCK, stimulated by nutrients, is a physiological mediator which inhibits gastric emptying and subsequently suppresses food intake[26]. CCK mainly reduces the tone of lower esophageal sphincter, inhibits the peristalsis of proximal duodenum and promotes the peristalsis of distal duodenum and jejunum via activation of Ca^{2+}-dependent protein kinase. Previous studies have demonstrated that CCK could increase the mean contractile amplitude of antral circular muscle, motility index of pyloric circular muscle and the resting tension of fundus[21,24,36,37]. Therefore, CCK possesses both excitatory and inhibitory action on contractile activity of different regions of stomach. Since systemic administration of CCK increases vagal afferent activity[27] and this effect is blocked by the disruption of vagal capsaicin-sensitive afferent fibers, it has been suggested that CCK acts on the vagal afferent neurons and induces gastric relaxation[28] and CCK-A receptor mediates this action[30,38]. CCK exerts an inhibitory function on the colonic motility, which is mediated by CCK-A receptors[39]. Besides the effects of CCK on the digestive tract, other biological actions of this peptide have been observed, such as appetite inhibition[40], prevention of LPS-induced decrease of blood pressure and attenuation of LPS-induced increase of proinflammatory cytokines (TNF-α, IL-1β and IL-6) in *vivo*[12]. The current study showed that the levels of CCK in both plasma and jejunum were increased significantly following TBI, suggesting that CCK may play an important role in protection of splanchnic functions. Conversely, increased concentrations of CCK in plasma and jejunum might be highly responsible for the gastric emptying dysfunction[20,41-44] and esophageal reflux which usually occur after head trauma[1,6,7] through the mechanism as mentioned above. Gastric distention was found in rats at 12, 24 and 72 h following TBI, as shown in Figure 1, possibly due to the inhibitory action of persistently high CCK concentrations on the stomach contraction.

CGRP is a 37 amino acid neurotransmitter peptide that is widely distributed in the central and peripheral nervous

systems[11,28,45], particularly in the viscera and vascular adventitia. It can also be synthesized and released by lymphocytes in rats[46]. CGRP in blood mainly comes from the gut and vessels. CGRP may be released extensively from the nerve ending around vessels into circulation through organ stimuli such as endotoxin, inflammatory mediators, stress and intestinal ischemia-reperfusion injury in the rat [11,13,47]. Endotoxemia, inflammatory cytokines and other kinds of stress can also stimulate the synthesis of CGRP in spinal dorsal root ganglia neurons (DRG). Therefore, TBI can also induce the extensive release of CGRP into plasma and synthesis of CGRP in jejunum as demonstrated in this study. CGRP possesses extensive biological functions such as cardiotonic effect, dilating vessels and regulating immune system[11]. It has been previously shown that CGRP is one of the important mediators involved in the pathogenesis of infection, hemorrhage and trauma, and also is one of the mediators for the interactions of neural-immune systems. Recently, the involvement of CGRP in abdominal surgery-induced inhibition of gastric and colonic motility has been reported[15]. The postoperative gastric ileus is mediated by CGRP released from spinal afferent neurons in the celiac and superior mesenteric ganglia as part of an extra-spinal gastrointestinal inhibitory reflex pathways[15,16]. This study demonstrated that the CGRP concentration in plasma was increased persistently after TBI. Increased level of CGRP in plasma following TBI may contribute to the decreased tone of lower esophageal sphincter, delayed gastric emptying and paralytic ileus of small intestine. Decreased concentrations of CGRP in jejunum may be responsible for the ischemic damage of gut mucosa. The mechanism of CGRP inhibiting gastrointestinal motility includes: (1) CGRP is released into local gut tissue or circulation, and then binds to the relevant receptors located on the surface of gastrointestinal smooth muscle to exert inhibitory action; (2) CGRP, acting as a part of inhibitory spinal reflex, is released into local gut induced by all kinds of stress factors to activate spinal afferent nerve fibers, leading to decreased gastrointestinal motility[15]; (3) CGRP can promote the release of substance P which partly mediate postoperative intestinal ileus[17]; (4) CGRP interacts with the receptors on surface of D cells to induce the release of somatostatin, inhibiting gastrointestinal motility; (5) CGRP may slow the transmit of cholinergic nerve fibers of enteric nervous system to inhibit gastrointestinal peristalsis.

It is concluded that the concentrations of VIP, CCK and CGRP in both plasma and jejunum change significantly following TBI. All these data imply that alterations of these peptide concentrations in plasma and gut may be involved in the pathogenesis of gastrointestinal dysfunction after traumatic brain injury. Increased CCK level might be responsible for the delayed gastric emptying, otherwise, VIP and CGRP might be responsible for the paralytic dilation of small intestine and large amounts of intra-intestinal effusion.

Abstract

AIM: To investigate frequency and clinical significance of K-ras mutations in pancreatic diseases and to identify its diagnostic values in pancreatic carcinoma.

METHODS: 117 ductal lesions were identified in the available sections from pancreatic resection specimens of pancreatic ductal adenocarcinoma, comprising 24 pancreatic ductal adenocarcinoma, 19 peritumoral ductal atypical hyperplasia, 58 peritumoral ductal hyperplasia and 19 normal duct at the tumor free resection margin. 24 ductal lesions were got from 24 chronic pancreatitis. DNA was extracted. Codon 12 K-ras mutations were examined using the two-step polymerase chain reaction (PCR) combined with restriction enzyme digestion, followed by nonradioisotopic single-strand conformation polymorphism (SSCP) analysis and by means of automated DNA sequencing.

RESULTS: K-ras mutation rate of the pancreatic carcinoma was 79%(19/24) which was significantly higher than that in the chronic pancreatitis 33%(8/24) (*P*<0.01). It was also found that K-ras mutation rate was progressively increased from normal duct at the tumor free resection margin, peritumoral ductal hyperplasia, peritumoral ductal atypical hyperplasia to pancreatic ductal adenocarcinoma. The mutation pattern of K-ras 12 codon of chronic pancreatitis was GGT→GAT, GGT and CGT, which is identical to that in pancreatic carcinoma.

CONCLUSION: K-ras mutation may play a role in the malignant transformation of pancreatic ductal cell. K-ras mutation was not specific enough to diagnose pancreatic carcinoma.

INTRODUCTION

Despite considerable development in sophisticated imaging techniques and cytological examination, an early diagnosis of pancreatic neoplasm is rare. Furthermore, surgical therapy for pancreatic cancer is frequently not curative, most often as a consequence of this tumor's propensity to metastasize. Only in a minority of cases is the diagnosis made at a very early stage, when curative surgery might significantly ameliorate the 5-year survival rate[1-3]. Therefore, a better understanding of the molecular basis of transformation into malignant tumor may contribute to the establishment of new criteria for diagnosis, prognosis and treatment of human neoplasms. K-ras mutation at codon 12 is one of the most common mutational events in the carcinogenesis of human malignancies[4]. It occurs mainly in mucin-producing adenocarcinomas[5]. The highest incidence of K-ras mutation has been found in ductal adenocarcinoma of the pancreas, in which it ranged from 70% to 100%[6,7]. Because K-ras has been found in very small incidental carcinomas, which were diagnosed only at autopsy[8], as well as in intraductal portions of ductal carcinomas, it is considered as an initial event in carcinoma development. This may make it a good tool for detecting pancreatic carcinomas at an early stage[9,10]. However, Yanagisawa et al.[11] showed that K-ras mutations also occur in hyperplastic ductal lesions in pancreas that do not harbor any malignancy. Therefore the K-ras mutation cannot be used as a marker of pancreatic ductal adenocarcinoma. However, this also suggests that ductal lesions, even without dysplasia, may be the forerunners of ductal adenocarcinoma. This assumption also was fostered by the early observation that some of the described ductal lesions frequently are associated with ductal adenocarcinoma. Several studies generally have confirmed the results of Yanagisawa et al, whereas others failed to detect K-ras mutations in nondysplastic epithelium. To address these issues we analyzed 117 ductal lesions for K-ras mutations.

MATERIALS AND METHODS

Tissue selection

The tissues used in this study were derived from patients who underwent partial duodenopancreatectomy for ductal adenocarcinoma of the pancreas and chronic pancreatitis. The basis for selection was the availability of suitable paraffin blocks (blocks age <5 years). 117 ductal lesions were identified in the available sections from pancreatic resection specimens of 24 pancreatic ductal adenocarcinoma, comprising 24 pancreatic ductal adenocarcinoma, 19 peritumoral ductal atypical hyperplasia, 58 peritumoral ductal hyperplasia and 19 normal duct at the tumor free resection margin. 24 ductal lesions were obtained from 24 patients of chronic pancreatitis. 7 surgical specimens of normal pancreas from patients with widely invasive gastric and colonic carcinoma in whom the tumor had not invaded the pancreas and who did not have pancreatic carcinoma or pancreatitis were examined. Multiple 5- and 10-μm sections were cut from each block and floated onto glass slides. Hematoxylin and eosin staining was performed on 5-μm sections from each paraffin block. The blade was replaced after each block was cut to prevent carryover of DNA between sections. Pancreatic carcinoma cell line Patu-8988 was obtained from Doctor Elsasser Philips of University of Germany.

DNA extraction

A boiling method of DNA extraction was employed similar to

that previously described by Shibata[12]. Tissue sections were deparaffinized and digested with a proteinase K digestion buffer (50 mmol/L Tris-HCL, pH 8.5, with 250 µg/mL proteinase K overnight at 55 ℃). The tissue was then boiled for 10 min and centrifuged. DNA was quantitated using a spectrophotometer.

Enriched PCR amplification

The first PCR- mediated amplifications were performed as described previously with minor modifications[13] and produced a 157-base pair fragment that contain K-ras codon 12. Aliquots of the first PCR product were digested with BstN1 (Biolab) at 60 ℃ for 2 h under the conditions recommended by the supplier. After boiling the mixture for 5 min to inhibit the enzymatic activity, 1/100 volume of the PCR product was subjected to the second PCR under the same conditions but using a different primer set, which flanked internal sequences of 135 bp DNA fragments. The amplified fragments were directly subjected to SSCP. The oligonucleotide primers were purchased from Sangon Co. (Shanghai, China). The sequences of oligonucliotide primers were as follows: 5' ACT GAA TAT AAA CTT GTG GTA GTT GGA CCT 3' (forward primer for first and second PCR); 5' TCA AAG AAT GGT CCT GGA CC 3' (reverse primer for first PCR); 5' TAA TAT GTC GAC TAA AAC AAG ATT TAC CTC 3' (reverse primer for second PCR).

Nonradioisotopic SSCP analysis

Nonradioisotopic SSCP Analyses were performed as described previously, with minor modification[13]. After denaturation at 100 ℃ for 5 min, a 10 µL sample was applied and resolved by 120 g/L polyacrylamide gel electrophoresis at 35 V for 21 h at 4 ℃. The gels were silver-stained. Each sample was analyzed by SSCP repeatedly to confirm its accuracy.

Direct sequencing of the amplified PCR product

For sequencing the deviant homoduplex bands were cut out of the gel, the DNA eluted by soaking in TE, reamplified, and TA cloned in the pUCm-T vector. Sequencing was performed on an ABI PRISM 377 automated sequencer.

Statistical analysis

A statistical analysis was performed using the chisquare test, the Fisher's exact test and Student t test with SPSS.

RESULTS

Detection of K-ras point mutation by nonradioisotopic SSCP analysis and direct sequencing of PCR product

To estimate the sensitivity of this analysis, 1 µg of the DNA extracted from normal peripheral blood lymphocytes and a pancreatic carcinoma cell line were subjected to PCR. Figure 1 shows the electrophoretic profiles of amplified DNA fragments by SSCP. The positive percentage of K-ras mutation of the pancreatic carcinoma was 79%(19/24) which was significantly higher than that in the chronic pancreatitis 33% (8/24) ($P<0.01$). It was also found that K-ras mutation rate was progressively increased from normal duct at the tumor free resection margin, peritumoral ductal hyperplasia, peritumoral ductal atypical hyperplasia to pancreatic ductal adenocarcinoma (Table 1).

The nucleotide sequences of K-ras mutation showed the following transitions: GGT to GAT, GGT to GTT, and GGT to CGT. (Table 2).

Relationship between K-ras gene mutation and location, histological grade and clinical stage of tumors

The diagnostic accuracy of K-ras mutations in pancreatic carcinoma relative to the location, histological grade and clinical stage of the tumor is summarized in Table 3. There are no apparent correlation between the location, histological grade, clinical stage of the tumor and the presence of K-ras gene mutations.

Figure 1 Detection of point mutations of the K-ras oncogene in pancreatic diseases. Lane N, healthy control subject DNA from normal peripheral blood lymphocytes. Lane 8988, pancreatic carcinoma cell line Patu-8988 DNA with confirmed mutant K-ras. Lane 6, patients with pancreatic carcinoma with mutant K-ras. Lane 7, normal pancreatic tissue. Lane 1, 3, 4, patients with chronic pancreatitis with mutant K-ras. Lane 2, 5, patients with chronic pancreatitis with wild type K-ras.

Table 1 Relative frequency of K-ras mutation in ductal lesions with pancreatic diseases

Ductal lesion	n	K-ras (-)	K-ras (+)	Positive percentage (%)
Pancreatic ductal adenocarcinoma	24	5	19	79.2
Peritumoral ductal atypical hyperplasia	19	15	14	73.6
Peritumoral ductal hyperplasia	58	38	20	34.5
Normal duct at the tumor free resection margin	16	16	0	0
Chronic pancreatitis	24	16	8	33.3
Normal pancreas	7	7	0	0

Table 2 K-ras mutation pattern of ductal lesions and the corresponding primary pancreatic carcinoma

Ductal lesion	Nucleotide sequence of K-ras12 codon		
	GAT	GTT	CGT
Pancreatic ductal adenocarcinoma	8	4	7
Peritumoral ductal atypical hyperplasia	7	2	3
Peritumoral ductal hyperplasia	10	3	7
Chronic pancreatitis	4	2	2

Table 3 Relationship between K-ras gene mutation and location, histologicalal grade and clinical stage of pancreatic carcinomas

Pathologic factor	n	Positive rate (%)
Tumor location		
Head	18	55.6
Tail/Corpus	6	66.7
Histological grade		
G1	6	66. 7
G2	10	50
G3	8	62.5
Clinical stage		
I	1	100
II	3	66.7
III	9	66.7
IV	11	45.5

Clinical and morphologic data on 24 patients with chronic pancteatitis

The occurrence of mutations was unrelated to clinical and morphologic indexes. The difference was not statistically significant (Student *t* test) (Table 4).

Table 4 Clinical and morphologic data on 24 patients with chronic pancteatitis

	K-ras positive cases (*n*=8)	K-ras negative cases (*n*=16)
Mean age of patients (yrs)	39.9±15.5(19-68)	51±14.9(23-67)
Gender ratio (M:F)	6:2	10:6
Mean duration of CP (yrs)	6.7±3.2(2-27)	5.7±4.5(3-25)
Mass-CP of pancreatic head	5 cases	10 cases
Weight loss (>10 kg)	3 cases	7 cases
Diabetes (insulin dependent)	4 cases	7 cases
Nicotine(>20 cigarettes/day, >5 yrs)	5 cases	8 cases

CP: chronic pancreatitis.

DISCUSSION

Pancreatic ductal carcinoma is known to have the highest K-ras mutation rate among all tumors. The codon 12 of this gene is affected in 80-100% of the cases. Mutated K-ras also has been found in ductal lesions such as mucinous cell hypertrophy and ductal papillary hyperplasia; therefore these lesions have been regarded as precursor lesions of carcinoma[11]. However, this assumption is based on rather contradictory results, with K-ras mutation rates in ductal lesions ranging from 0-94%[14]. The discrepancies between the results of the various studies are based on the wide range of investigated cases, the selection of lesion types, and PCR employed.

Matsubayashi *et al*[15] analyzed 317 carcinoma-associated ductal lesions, 39% were positive for K-ras mutations. Moskaluk *et al*[14] focused on atypical papillary hyperplasia and found K-ras mutations in 75% of their samples. Both study groups used a detection method (nested PCR-RLFP) with a sensitivity of 5%. But SSCP analysis is one of the simplest and most sensitive methods for detection of mutations based on PCR technology[16-18]. Since its first report, the SSCP analysis has been widely used to detect mutations in genes responsible for various hereditary diseases and somatic mutations of oncogenes. In an earlier study, Lemoine *et al*[19] found no mutations in cases of ductal hyperplasia, but they did find mutation in all severely dysplastic lesions that they regarded as intraductal extensions of the associated ductal adenocarcinoma. It appears that their method, which was based on slot-blot analysis, was not sensitive enough to detect K-ras mutations in nondysplastic ductal lesions.

Chronic pancreatitis, regardless of its etiology, is considered a risk factor for the development of pancreatic ductal adenocarcinoma[20]. The risk seems to increase with the duration of CP. Some histological studies have searched for possible carcinoma precursor lesions in this disease. Cylwik *et al*[21] reported severe dysplasia in 8.6% of 70 resection specimens from patients with CP; advanced fibrosis was associated with dysplasia in 65%. Because of these results, they concluded that surgical removal of the pancreas should be recommended. We cannot confirm these data. We were unable to identify any severe dysplasia carcinoma in situ changes in 24 resection specimens from patients with CP and varying duration of the disease.

K-ras mutation is considered an early event in the tumorigenesis of pancreatic carcinomas. In our study the positive percentage of K-ras mutation of the pancreatic carcinoma was 79%(19/24) which was significantly higher than that in the chronic pancreatitis 33%(8/24) (*P*<0.01). It was also found that K-ras mutation rate was progressively increased from normal duct at the tumor free resection margin, peritumoral ductal hyperplasia, peritumoral ductal atypical hyperplasia to pancreatic ductal adenocarcinoma. It appeared that the locations, histological grade, clinical stage of pancreatic carcinomas were all not related to the presence of K-ras mutations. The occurrence of K-ras mutations was not associated with the duration of CP and also not with mass-CP of pancreatic head. Rivera *et al*[22] reported K-ras mutations in 2 of 11 cases and Yanagisawa *et al*[11] even 62.5% mutations in 10 of 16 lesions from 10 cases. K-ras mutations were not detected by Kubrusly *et al*[23]. Their negative results probably were due to the comparatively insensitive PCR method and the tissues they selected for investigation. To summarize, when sensitive enough methods are applied, K-ras mutation frequently can be detected in nondysplastic ductal epithelium of patients with CP. Berger *et al*.[24] reported a clear correlation between K-ras mutations and the nicotine history of their patients. In our study, the relationship was unclear. Therefore, nicotine seems to be a major factor in the induction of the mutation but does not inevitably induce it.

The relation between CP and pancreatic adenocarcinoma remains difficult to explain. Continuous epithelial regeneration and proliferation are thought to promote carcinogenesis in many organs. In our study, the incidence of the ductal lesions and K-ras mutations did not increase with the duration of CP. It therefore seems that hyperplastic ductal changes and K-ras mutations will not inevitably lead to the development of ductal adenocarcinoma.

Future prospective studies should be performed to get a well documented long term follow-up of K-ras positive cases to elucidate the role of K-ras mutations in pancreatic carcinogenesis in CP patients. In addition, other mutations, such as those of the p16, DPC4, and BRCA2 genes or promoter methylation of tumor suppressor, which evidently play role in a linear tumor progression model of pancreatic carcinoma, also should be looked for in lesions that might be responsible for the presumed pancreatic carcinoma sequence in chronic pancreatitis[25-30].

Abstract

AIM: To evaluate the local expression of CTLA4Ig gene in small bowels and its effect on preventing acute rejection of the small bowel allografts.

METHODS: Groups of Wistar rats underwent heterotopic small bowel transplantation from SD rats. The recipients were randomly divided into experimental group (allografts were transfected with CTLA4Ig gene) and control group (non CTLA4Ig gene transfected). In the experimental group, the donor small bowels were perfused *ex vivo* with CTLA4Ig cDNA packaged with lipofectin vector via intra-superior mesenteric artery before transplantation, and the CTLA4Ig expression in the small bowel grafts post-transplantation was assessed by immunohistology. On d 3, 7 and 10 post-transplantation, the allografts in each group were harvested for the examination of histology and detection of apoptosis.

RESULTS: Small bowel allografts treated with CTLA4Ig cDNA showed abundant CTLA4Ig expression after transplantation. Acute rejection of grade I on d 7 and grade II on d 10 after transplantation was noticed in the control allografts, and a dramatically increased number of apoptotic enterocytes in parallel to the progressive rejection could be recognized. In contrast, the allografts treated with CTLA4Ig cDNA showed nonspecific histological changes and only a few apoptotic enterocytes were found after transplantation.

CONCLUSION: Local CTLA4Ig gene transfection of small bowel allograft is feasible, and the local CTLA4Ig expression in the allograft can prevent acute rejection after transplantation.

INTRODUCTION

CTLA4Ig is a soluble recombinant fusion protein constructed with an extracellular domain of mouse CTLA4 and Fc portion of human IgG. This protein binds to the mouse and rat B7-1/2 molecules, and blocks the co-stimulatory signals from antigen processing cell (APC) to antigen specific T cell. Treatment with CTLA4Ig gene transfection has been shown to prolong graft survival in mouse and rat heart, liver, pancreatic islet, kidney and lung transplantations and to induce donor-specific tolerance in some of these cases[1-7].

There are two methods of gene transduction: systemic administration (*ie.* intravenous injection) and local transfection of allograft. Gene transfer of sequences coding for soluble immunosuppressive molecules into transplanted organs aims to create a local microenvironment directly modulating the activation state of immune cells responsible for graft rejection[8]. Therefore, when compared with systemic administration, local and continuous production of biologically active compounds might increase their bioavailability and allow a more effective treatment. Furthermore, cells not involved in the rejection process could be spared, and side effects or generalized immunosuppression may thus be avoided.

Intragraft expression of CTLA4Ig by gene transfection at the time of transplantation can successfully prolong survival of several grafts[9-12]. Nevertheless, study of CTLA4Ig expression within the small bowel allograft has not been reported. In the present study, we transfected gene by *ex vivo* intra-superior mesenteric artery infusion of mCTLA4Ig cDNA packaged with lipofectin vector before transplantation, evaluated the local expression of CTLA4Ig gene and its effect on preventing acute rejection of small bowel allografts in rats.

MATERIALS AND METHODS

Animals and transplantation
Inbred male SD and Wister rats weighing 250 to 300 g were used as donors and recipients, respectively. All rats were obtained from the Animal Center of Nanjing Medical University.

After fasting for 24 h, donors and recipients were anesthetized with an intraperitoneal injection of pentobarbital (50 mg/kg). The vasculature of the donor small bowel was perfused with 10 mL heparinized saline solution at 4 ℃. A segment of 20 cm small bowel with portal vein and superior mesenteric artery attached to a cuff of aorta were removed. The lumen of the donor small bowel perfused with 20 mL pure saline solution at 4 ℃. The small bowel graft was transplanted with an end - to - side anastomosis of the cuff of aorta and portal vein of the graft to the infrarenal aorta and infrarenal vena cava (Figure 1). After revascularization of the graft, the oral end and the anal end of the small bowel graft were constructed as a stoma respectively through the right abdominal wall of the recipient. All animals had free access to water within 24 h after transplantation. Starting from postoperative d 1, they received standard rat chow.

Experimental groups
Animals were placed into two groups: One group of recipients did not receive treatment (control group, *n*=21), and the other group of recipients received CTLA4Ig gene transfection (experimental group, *n*=21).

Delivery of mCTLA4Ig to small intestine
The plasmid of AAVmCTLA4Ig was a kind gift of Professor I. Anegon (INSERM U437, Nants, France). DOTAP:Chole (*in vivo* GenSHUTTLE, Qbiogene) was used as the vector.

The AAVmCTLA4Ig was mixed with DOTAP:Chole at room temperature for 15 min to create the DNA-lipid complex. The final concentration of DNA in the complex was 0.5 µg/µL. Before cold preservation, the small bowel graft was irrigated with cold saline and then 50 µL lipid (control group) or 50 µL DNA-lipid complex (experimental group) was delivered into the superior mesenteric artery by slow infusion over 5-10 min. After 1.5 h of cold preservation, the superior mesenteric artery of small bowel was reperfused with 5 mL cold saline for 10 min before transplantation.

Figure 1 Heterotopic small bowel transplantation in the rat. The vasculature of the graft has been anastomosed. RSB: recipient' s small bowel. TSB: transplanted small bowel.

Graft histology, apoptosis detection and immunohistology

Three, seven and ten days after transplantation, 7 rats were killed in each group. Samples of the small bowel allografts were obtained. One half was fixed in paraformaldehyde for histology examination and cell apoptosis detection. Another half was preserved in nitrogen liquid for immunohistology.

For histology, sections from paraffin embedded blocks were stained with hematoxylin-eosin (H&E). Kuusanmaki' s protocol[13] served as basis for the grading of acute graft rejection and determination of diagnostic categories.

Apoptosis was detected on sections from paraffin-embedded blocks by the terminal deoxynucleotidyl transferase (TdTase) mediated d-UTP-biotin nick end labeling (TUNEL) technique[14-17]. Apoptosis assay with a detection kit from Bochinger (Mannheim, Germany), conformed to the manufacturer' s protocol strictly except that the sections were finally counterstained with methylgreen (Vector Laboratories). The nuclei of apoptotic cells were stained brown as detected under light microscope, and the number of apoptotic cells was determined by counting labeled enterocytes in 10 randomly chosen high-power fields[18].

Immunohistology was performed in cryostat sections. To detect CTLA4Ig in tissues, sections were subsequently incubated (60 min) with hamster anti-murine CTLA4 mAb (UC-4F10-11, BD Biosciences). Tissues probed with the mAb were then incubated with a biotin-conjugated mouse IgG-absorbed anti-hamster IgG Ab (60 min; G70-204 & G94-56, BD Biosciences), followed by HRP-conjugated streptavidin (45 min; Woburn MA) and DAB substrate, and sections were counterstained with hematoxylin.

Statistical analysis

Data were expressed as mean±SD and Student' s *t* test was used. Significant difference was assumed when $P<0.05$.

RESULTS

Immunohistology

The CTLA4Ig expression of implanted small bowels was detected by immunohistology, and the small bowel grafts transduced with CTLA4Ig showed the presence of abundant labeling in mesenteric vascular walls, muscularis, submucosa and villus. Higher densities of CTLA4Ig were detected in grafts sampled at early time points, and persistent expression of CTLA4Ig was confirmed within 10 d after transplantation (Figure 2: A, B, C). As anticipated, there was no detectable expression of CTLA4Ig in the control small intestines (Figure 2: D).

Figure 2 Presence of CTLA4Ig in the small bowel allografts. CTLA4Ig was stained as the brown granules. A, B, C represent the cryostat sections of CTLA4Ig gene transfected grafts on d 3, 7, 10 after transplantation, respectively. D represent the cryostat sections of non-CTLA4Ig gene transfected grafts, expression of CTLA4Ig was not detected. [original magnification ×200].

Morphological findings

In the control group, on d 3 after transplantation, only nonspecific changes were noted. Focal mesenteric inflammation, mild endothelial vacuolization, and minimal swelling and desquamation of enterocytes were observed in allografts, and a relatively normal villiform mucosal structure was retained. On d 7, a widespread inflammatory infiltrate in the mesentery, with moderate invasion of the intestinal wall,

villous blunting and part of the crypt destruction, was noticed in allografts. In addition, endothelial swelling and proliferation with intimal thickening were found in small mesenteric arteries and arterioles. On d 10, a pronounced mesenteric infiltrate with severe invasion of the intestinal wall was found in allografts. Endothelial proliferation with intimal thickening resulted in luminal obliteration. Furthermore, moderate to extreme enterocystic necrosis could be recognized as erosions and focal ulcerations. However, the allografts treated with CTLA4Ig gene transfection showed nearly normal mucosal structure, slight cell infiltration and minimal swelling and desquamation of enterocytes on d 3, 7 and 10 post-transplantation.

Detection of apoptotic enterocytes by TUNEL

Apoptotic cells were detected mainly in the crypts. On d 3 after transplantation, a small number of labeled enterocytes were observed both in control (5.3±1.5, n=7) and experimental (5.8±1.8, n=7) groups. There was no significant difference in the number of apoptotic enterocytes between the two groups. On d 7, the number of labeled enterocytes increased dramatically (61.7±2.8, n=7) and reached a higher level on d 10 (101±6.1, n=7) in control group after transplantation (Figure 3: A1, B1, C1), whereas an increasing number of labeled nuclei could not be recognized in experimental group on d 7 (3.4±1.0, n=7) and on d 10 (3.6±1.3, n=7) after transplantation (Figure 3: A2, B2, C2). The difference in the number of apoptotic enterocytes in allografts between control and experimental groups on d 7 and 10 was extremely significant ([b]P<0.0005, t=41.2876 on day 7 and [d]P<0.005, t=39.2437 on d 10).

Figure 3 Apoptotic crypt cells in the small bowel allografts. A1, B1, C1 represent the tissue sections of non-CTLA4Ig gene transfected grafts obtained on d 3, 7, 10 after transplantation, respectively. A2, B2, C2 represent the tissue sections of CTLA4Ig gene transfected grafts obtained on d 3, 7, 10 after transplantation, respectively. [original magnification ×400].

DISCUSSION

Small bowel transplantation has emerged as a life-saving therapy for patients with irreversible intestinal failure and is now a routine therapeutic tool at some transplant centers[19,20]. Nevertheless, graft rejection is still the major obstacle to the transplantation[21-23]. Blockade of the B7/CD28 co-stimulation signal by systemic transfer of CTLA4Ig gene through

intravenous infusion of AdCTLA4Ig has been shown to prolong small intestinal graft survival[24]. However, different from heart, liver, kidney and other organs, the small bowel is unique among vascularized organ grafts with rich lymphoid components and large amounts of bacteria, severe infection as well as rejection occurs easier after transplantation. Local CTLA4Ig gene transfection of small bowel allograft could be the ideal therapeutic strategy of anti-rejection. It allows inhibition of the recipient's rejection response, while maintaining the recipient's efficient peripheral immune function (not suppressing the antibacterial response). The local transfection of CTLA4Ig gene has been successfully achieved in rat heart, liver, kidney, islet and lung allografts[9-12], but it has not been studied in the small bowel transplantation. In the present study, we perfused CTLA4Ig cDNA packaged with lipofectin vector via intra-superior mesenteric artery into the small bowels. By immunohistology, there were a large amount of CTLA4Ig expression in the small bowel allografts on days 3, 7 and 10 after transplantation. The result suggests that local CTLA4Ig gene transfection of small bowel allograft is feasible.

In non-CTLA4Ig gene transfected small bowel allografts, a histological change of progressive acute allograft rejection could be recognized. Although the allografts did not show any specific morphological changes on d 3, acute allograft rejection of grade I on d 7 and grade II on d 10 after transplantation was noticed. In contrast, no evidence of acute rejection was observed in CTLA4Ig gene transfected allografts on d 3, 7 and 10 after transplantation. These data indicate that local CTLA4Ig expression in small bowel allografts can prevent acute rejection after transplantation. The protection of local CTLA4Ig expression in small bowel allografts from acute rejection may be because of the inhibition of expansion of alloantigen-induced T cell priming. The local transfection of CTLA4Ig can block B7 ligand expression on the surface of intragraft APCs, and thus blocking B7/CD28 co-stimulatory pathway. In the absence of B7/CD28 co-stimulatory signal, the interaction of T cell with the alloantigen commonly produces T cell anergy[25-29].

Apoptosis is a DNA-dependent cell death mechanism, which occurs under physiological and pathological conditions. In organ transplantation, apoptosis is an important biochemical indicator of allograft rejection[14-17]. In the process of allograft rejection, the target cells damage is mainly mediated by cytotoxic T lymphocytes through the perforin-dependent granule-exocytosis pathway and the Fas/Fas ligand (FasL) pathway[30-32]. Both perforin- and Fas-mediated pathways of cytotoxicity can result in target cell apoptosis. Numerous reports have demonstrated up-regulation of transcripts for perforin, granzyme B, and FasL during allograft rejection[33-36]. In the present study, TUNEL illustrated a few apoptotic enterocytes on d 3 and showed a dramatically increased number of apoptotic enterocytes on d 7 and 10 after transplantation in non-CTLA4Ig gene transfected small bowel allografts. This result demonstrates the existence of acute rejection after transplantation. Nevertheless, in CTLA4Ig gene transfected small bowel allografts, a few apoptotic crypt cells was observed on days 3, but the number of apoptotic enterocytes did not increase on d 7 and 10 after transplantation. It indicates that the apoptosis in small bowel allografts can be prevented by local CTLA4Ig gene transfection, and the cytotoxic roles of infiltrated T lymphocytes and the acute rejection after transplantation can be prevented by CTLA4Ig expression in the allografts. The few apoptosis in allografts on d 3 was likely caused by cold preservasion damage and postischemic reperfusion damage[37-39].

In conclusion, local CTLA4Ig gene transfection of small bowel allograft can be achieved by perfusing CTLA4Ig cDNA packaged with lipofectin vector via intra-superior mesenteric artery into the small bowels, and the local CTLA4Ig expression in the allograft can prevent acute rejection after transplantation.

Abstract

AIM: To investigate the effect of cholesterol (Ch) on the growth and functional protein expression of rabbit bile duct fibroblasts.

METHODS: The cultured bile duct fibroblasts were divided randomly into two groups: the control group and the experiment group (fibroblasts were incubated respectively with 0.6 g/L Ch for 12, 24, 36 and 48 h). The growth and DNA synthesis of bile duct fibroblasts were measured by the means of ^{3}H-TdR incorporation. The total protein content of fibroblast was measured by BSA protein assay reagent kit, then the expression of α-actin was analyzed semi-quantitatively by Western blot.

RESULTS: After treatment with 0.6 g/L Ch for 12, 24, 36 and 48 h, the values of ^{3}H-TdR incorporation of bile duct fibroblasts were respectively 3.1±0.39, 3.8±0.37, 4.6±0.48 and 5.2±0.56 mBq/cell, and the values of the corresponding control groups were 3.0±0.33, 3.2±0.39, 3.7±0.49 and 4.3±0.43 mBq/cell. After comparing the values of experiment groups and their corresponding control groups, it was found that the ^{3}H-TdR incorporation of bile duct fibroblasts after treatment with 0.6 g/L Ch for 24, 36 and 48 h were significantly increased ($P<0.05$, $P<0.01$, $P<0.01$), while the ^{3}H-TdR incorporation of 12-h group was not different statistically from its control group. Ch had no obvious effect on the total protein content of fibroblasts. After incubated with 0.6 g/L Ch for 12, 24, 36 and 48 h, the total protein content of each experiment group was not altered markedly compared with its corresponding control group. The values of experiment groups were 0.246±0.051, 0.280±0.049, 0.263±0.044 and 0.275±0.056 ng/cell, and those of corresponding control groups were 0.253±0.048, 0.270±0.042, 0.258±0.050 and 0.270±0.045 ng/cell. Western blot analysis revealed that the α-actin expression in fibroblasts affected by Ch for 12 and 24 h was not markedly changed compared with their corresponding control groups ($P>0.05$), the values of total gray scale of 12- and 24-h groups were 1 748±185 and 1 756±173, respectively. But after stimulation with Ch for 36 h, the total gray scale of fibroblasts (1 923±204) was significantly higher than that of control group (1 734±197). When the time of Ch treatment was lengthened to 48 h, the α-actin expression was markedly elevated, the total gray scale was 2 189±231 ($P<0.01$ vs control group).

CONCLUSION: Moderately concentrated Ch can promote the proliferation of bile duct fibroblasts at early stage. With the prolongation of Ch treatment, the α-actin expression of fibroblasts was also increased, but the hypertrophy of fibroblasts was not observed.

INTRODUCTION

The disorder of cholesterol metabolism is an important cause of biliary diseases. Previous studies suggest that cholesterol can change the motility of cholecyst[1,2] and decrease gallbladder contraction[3-7] in the patients with cholesterol calculus and in the animals with hypercholesterolemia. Weak contraction of gallbladder may be a reason of cholesterol calculus[8-12]. Researchers consider that cholesterol metabolism disorder has an effect on the structure and function of bile duct and sphincter of bile duct (SBD)[13-16]. We have found that cholesterol liposome (CL) affected not only the configuration and quantity of cytoskeleton in rabbit SBD smooth muscle cells, but also the proliferation of cells[17,18]. There are many fibroblasts in biliary system except that SBD is formed mainly with smooth muscle cells[19-22]. In our previous experiment, we observed that middle concentration Ch could accelerate the proliferation of bile duct fibroblasts and result in the changes of phenotype[23,24]. Fibroblasts displayed some characteristics of myofibroblasts or smooth muscle cells[23,24]. In order to lucubrate the reactivity of bile duct fibroblasts to Ch and the role of fibroblasts on the configuration variation of bile duct and SBD, the effects of Ch on bile duct fibroblasts at different time point were studied and the relation between the effects of Ch and time was analyzed in this study.

MATERIALS AND METHODS

Materials

New Zealand rabbits aged 1 month were provided by the Animal Center of the Fourth Military Medical University. Trysin (Gibco, Paisley, Renfrewshire, UK), Dulbecco' s modified eagles medium (DMEM) (Gibco, Paisley, Renfrewshire, UK), fetal calf serum (Qinghu Institute of Foetus Bovine Utilization in Jinhua Zhejiang), water soluble cholesterol (Sigma, St. Louis, USA), antibody of vimentin, α-actin and desmin (DakoCytomation, Glostrup, Denmark), ABC immunohistochemical kit (Shaanxi Biotech. Co., Xi' an, China), IMT-2 inverted biological microscope (Olympus

Corporation, Japan), YJ-875 ltra-clean operating boar (Suhang Experimental Animal Technology Development Co), LD4-2 centrifugal machine (Beijing Medical Centrifugal Machine Factory), and BCA protein assay reagent kit (Pierce Chemical Company, Rockford, USA) were commercially obtained.

Dispensing of main reagent

Ch was diluted to 0.6 g/L with DMEM before experiment. DMEM was dispensed according to the description. Fetal calf serum was inactivated for 30 min at 56 ℃, and was stored at -20 ℃. Trypsin was made into 2.5 g/L solution with PBS (0.01 mol/L, pH 7.4) and stored at 4 ℃. TBST was prepared by mixing 10 mL of Tri-Cl, 8.78 g of NaCl, 500 μL of Tueen-20, and adding distilled water up to 1L.

Primary culture of rabbit bile duct fibroblasts

Bile ducts of New Zealand rabbits were dissociated by the means of aseptic technique and broken by shears. The tissue was digested to become single cell suspension by trypsin (1.25 g/L). Cells were washed and resuspended with DMEM (containing 100 mL/L fetal calf serum) and incubated at room temperature for 75-90 min. Then the cells were collected and transferred into culture bottles. The cells of 2nd-4th passages were used for experiments.

Identification of rabbit bile duct fibroblasts

Three glass cover slips (18 mm×18 mm) were placed into 6 cm diameter culture dishes, and then cell suspension was added and incubated at room temperature for 48 h. The slips covered with cells were washed twice with PBS (pH 7.4). Some slips were fixed by cold acetone for 15 min at 4 ℃ and used for HE staining, another three slips were fixed by citromint (40 g/L) for immunohistochemical ABC staining to exam vimentin and desmin expression.

[³H] Thymidine incorporation

Bile duct fibroblasts were planted in 96-well plates. Sub-confluent cells were cultured without serum for 24 h, then treated respectively by 0.6 g/L Ch for 12, 24, 36 and 48 h and pulsed with 18.5 kBq of [³H] thymidine for 4 h. The control group cells were incubated with DMEM containing 20 mL/L fetal calf serum instead of Ch. The radioactivity of each group was counted by Beckman LS6500 counter.

Assay of total protein content

The cells of each group were trypsinized and counted. Cells were centrifugated at 1 000 r/min for 5 min at 4 ℃, washed twice with ice-cold PBS and lysed in ice –cold lysis buffer for 30-60 min. The lysates were centrifugated at 12 000 g for 5 min at 4 ℃ and supernatant was transferred into new Eppendorf tubes. The standard curve was drawn according to the description of BCA protein assay reagent kit, and then the total protein content per cell was measured and converted.

Western blot analysis

Loading buffer was added to each lysate, which was subsequently boiled for 10 min. Equal amounts (10 μg) of cell extracts were separated by 100 g/L SDS-PAGE and transferred to nitrocellulose membrane. The membrane was blocked for one h at room temperature in 50 g/L skim milk and probed with α-actin antibody for one h. The membrane was washed three times with PBS-T and incubated for one h with secondary antibody. After washing the membrane with PBS-T for several times, the protein reactive to the primary antibody were visualized by electrochemiluminescence (ECL) detection, and semi-quantitatively analyzed by Kodak digital science 1D software.

Statistical analyses

Results were presented as mean±SD. Significance was determined by Student' s t test or one-way ANOVA. $P<0.05$ was considered statistically significant.

RESULTS

Cultured rabbit bile duct fibroblasts

Under phase-contrast microscope, the cultured rabbit bile duct fibroblasts showed shuttle-shaped or multiangular. Their cytoplasm was clear and nucleus was large and ellipse, and their nucleoli were obvious. The isolated bile duct fibroblasts were free of smooth muscle cell contamination because they presented positive staining with vimentin and negative staining with desmin by the means of immunocytochemical ABC staining.

³H-TdR incorporation of bile duct fibroblasts

Following incubation with 0.6 g/L Ch for 12, 24, 36 and 48 h, the values of ³H-TdR incorporation of bile duct fibroblasts were respectively 3.1±0.39, 3.8±0.37, 4.6±0.48 and 5.2±0.56 mBq/cell, and those of the corresponding control groups were 3.0±0.33, 3.2±0.39, 3.7±0.49 and 4.3±0.43 mBq/cell. After comparing the values of experiment groups and their corresponding control groups, we found that the ³H-TdR incorporation of bile duct fibroblasts after treatment with 0.6 g/L Ch for 24, 36 and 48 h were significantly increased ($P<0.05$, $P<0.01$, $P<0.01$), while the ³H-TdR incorporation of the 12 h group was not statistically significant as compared with the control group (Figure 1).

Figure 1 Effects of cholesterol on the H³-TdR incorporation of bile duct fibroblasts.

Total protein content of bile duct fibroblasts

Ch has little effect on the total protein content of fibroblasts. After being incubated with 0.6 g/L Ch for 12, 24, 36 and 48 h, the total protein content of each experiment group was not altered markedly compared with its corresponding control group. The values of experiment groups were 0.246±0.051, 0.280±0.049, 0.263±0.044 and 0.275±0.056 ng/cell, and those of corresponding control groups were 0.253±0.048, 0.270±0.042, 0.258±0.050 and 0.270±0.045 ng/cell (Figure 2).

a-actin expression of bile duct fibroblasts

Western blot analysis revealed that the α-actin expression of fibroblasts affected by Ch for 12 h and 24 h was not markedly changed compared with their corresponding control groups, the values of total gray scale of the 12 h and 24 h groups were 1 748±185 and 1 756±173 respectively, but after stimulation with Ch for 36 h, the total gray scale of fibroblasts (1 923±204) was significantly higher than that of control group (1 734±197). When the time of Ch treatment was lengthened to 48 h, the α-actin expression was markedly elevated, and the total gray

scale was 2 189±231 (*P*<0.01 *vs* control group) (Figure 3, Table 1).

DISCUSSION

Fibroblasts are derived from mesenchymal cell of embryo period. During the process of wound healing, fibroblasts can proliferate greatly by mitoses, and also synthesize and excrete collagen fibers and matrix components[25-29]. With the stimulation of trauma and other agents, some mature fibroblasts could change into infantile fibroblasts and their function could be recovered[30,31]. Cardiac fibroblasts are able to secret biological active substances, which facilitate the growth of myocardial cells[32,33], suggesting that cardiac fibroblasts must play an important role in the normal growth of heart and its pathologic remodeling[34,35]. Hypoxia could, mediated by pulmonary arterial endothelial cells (PAECs), induce phenotype alteration of human embryonic lung fibroblasts, transforming to smooth muscle cell-like cells, suggesting that the transformation of human embryonic lung fibroblasts might be one of the reasons for nonmuscular lung arteriole to become muscular arteriole[36-38]. Silent fibroblasts in the border of wound can differentiate to contraction phenotype and have the special expression of α-SM actin. The cells are considered as myofibroblasts which can cause contraction of granulation tissue[39,40]. It is thus clear that fibroblasts can take part in many kinds of physiological and pathologic responses and they have important effects on the occurrence and development of diseases.

Biliary system is the unique passage of bile ejection,

especially its terminal sphincter, SBD. Biliary system can modulate bile ejection and maintain normal pressure of biliary system[41,42]. The coordination of its anatomic structure and function makes it not only prevent regurgitation of duodenal fluid but also modulate and stabilize the pressure of bile duct[42-44]. So the structural remodeling of biliary system, especially the structural change and dysfunction of SBD, might be one of basic reasons of biliary system diseases occurrence. There are a lot of fibroblasts in bile duct system. In previous study, we have found that the middle concentration Ch can promote the proliferation of bile duct fibroblasts and make them present some phenotypic characteristics of muscle cell[23,24]. But at present, it is still unclear what are the exact effects of cholesterol on bile duct fibroblasts and how fibroblasts are revolved in remodeling of biliary system, especially what roles fibroblasts play in the remodeling of SBD. In order to lucubrate the problem, we observed the effects of Ch on the proliferation and functional protein expression of bile duct fibroblasts at different times and analyzed the relation between the effects of Ch and time.

³H-TdR, prosoma of DNA synthesis, can incorporate into DNA synthesis. So the radioactivity intensity of cells can reflect DNA metabolism and proliferation of cells. It has been demonstrated that middle concentration Ch can accelerate the proliferation of bile duct fibroblasts[23]. But the relation between Ch effects and time is still unknown. In the present study, our focal point is to observe how the Ch effects on fibroblasts alter with the changes of incubation time. Our results show that the DNA synthesis and proliferation of bile duct fibroblasts are elevated after incubated with moderately concentrated Ch for 24 h, and the effect becomes more significant gradually with the elongation of Ch treatment.

In the research of cardiovascular disease, it has been found that the proliferation and hypertrophy of cardiac fibroblasts participate in the cardiac remodeling[34,35]. In the process of estrogen-induced uterine enlargement, there are not only the hyperplasia of uterine smooth muscle cell and epithelial cell but also augmentation of size of cells. Chronic enteritis is linked with hypertrophy of intestinal smooth muscle cells[45-47]. From the phenomena mentioned above, we conjecture whether Ch can not only accelerate the proliferation of bile duct fibroblasts but also cause hypertrophy of fibroblasts. According to our result, the total protein content of bile duct fibroblasts was not altered after fibroblasts were treated with Ch, indicating that Ch might not significantly facilitate the hypertrophy of bile duct fibroblasts although it could promote the proliferation of fibroblasts greatly.

In our previous experiment, we detected that middle concentration Ch could increase α-actin expression of bile duct fibroblasts, and we also observed that bile duct fibroblasts showed some characteristics of muscle cells, which suggested that Ch might lead to the phenotypic variation of fibroblasts[24]. In present study, we aim to observe the time effects of Ch on fibroblasts by the means of Western blot. It has been demonstrated that α-actin expression in bile duct fibroblasts begins to increase after incubated with Ch for 36 h, and the effect becomes more significant after 48 h. From the results above, we can easily find that the proliferation of bile duct fibroblasts is enhanced after Ch treatment for 24 h, however, it is not until Ch incubation for 36 h that the α-actin expression in bile duct fibroblasts begins to ascend. It indicates that the short-term effects of Ch are mainly to promote the proliferation of bile duct fibroblasts, and by the prolongation of Ch treatment time, Ch can also alter the functional protein expression of fibroblasts. Ch has no obvious effect on the total protein content of bile duct fibroblasts, nevertheless, it can enhance α-actin expression in fibroblasts. It suggests that Ch can only result in the changes of some special protein

expression instead of causing the hypertrophy of bile duct fibroblasts. The protein, α-actin, is an important functional protein existing in myofibroblasts and smooth muscle cells[48,49]. So we can realize that Ch accelerates the proliferation of bile duct fibroblasts, and what is most important is that Ch can induce bile duct fibroblasts to possess some phenotypic characteristics of muscle cell.

By studying the anatomy of SBD, people found that the length of SBD is 5-15 mm without accordant result and the data fluctuates in a wide range. It has not been lucubrated whether it is only attributed to the congenital diversity of individual or it is the result of SBD remodeling induced by some postnatal factors. Wei et al.[21] have found that gallbladder-derived abdominal pain after cholecystectomy, recurrent bile calculus and cholangiectasis have significant correlation with too lengthy of SBD ($\geq$10 mm). It has also been manifested that most of the patients whose SBD length exceeds 10 mm are often accompanied by SBD motor dysfunction[50]. Combining our present outcome, we suspect that some postnatal factors may result in constitution alteration of SBD, including the changes of length. The proliferation of fibroblasts, especially their phenotype transformation, may play an important role during the constitution changes of bile duct and SBD.

In conclusion, cholesterol does activate bile duct fibroblasts at the early stage, facilitating the proliferation of fibroblasts, and it can also induce the phenotype transformation of fibroblasts following the elongation of Ch treatment time. The alteration of fibroblasts might participate in the configuration remodeling of biliary system, especially the reconstitution of SBD. Gradually the function of bile duct system becomes abnormal and ultimately biliary system diseases occur. But the change in vivo is affected by multiple factors and is a multistage procedure. In vitro experiments can not absolutely reflect the conditions in vivo. So our experiment provides a clue to research the occurrence, development and treatment of biliary system diseases, but the certain role of bile duct fibroblasts and the certain mechanisms are still open to be elucidated.

Abstract

AIM: Primary biliary cirrhosis (PBC) is a chronic, cholestatic disease of autoimmune etiology, the histology of which shows a destruction of the intrahepatic bile duct and portal inflammation. Ursodeoxycholic acid (UDCA) is now used as a first-line drug for asymptomatic PBC (aPBC) because it is reported that UDCA decreases mortality and prolongs the time of liver transplantation. However, only 20-30% of patients respond fully to UDCA. Recently, lipoprotein-lowering agents have been found to be effective for PBC. The aim of this study was to examine the safety and efficacy of fenofibrate, a member of the fibrate class of hypolipidemic and anti-inflammatory agent via peroxysome proliferatory-activated receptor α, in patients with aPBC.

METHODS: Fenofibrate was administered for twelve weeks in nine patients with aPBC who failed to respond to UDCA. UDCA was used along with fenofibrate during the study. The data from aPBC patients were analyzed to assess the biochemical effect of fenofibrate during the study.

RESULTS: The serum levels of alkaline phosphatase (ALP) (285±114.8 IU/L) and immunoglobulin M (IgM) (255.8±85.9 mg/dl) significantly decreased to 186.9±76.2 IU/L and 192.9±67.5 mg/dL respectively, after fenofibrate treatment in patients with aPBC ($P<0.05$). Moreover, the titer of antimitochondrial antibody (AMA) also decreased in 4 of 9 patients with aPBC. No adverse reactions were observed in any patients.

CONCLUSION: Fenofibrate appears to be significantly effective in treating patients with aPBC who respond incompletely to UDCA alone. Although the mechanism of fenofibrate on aPBC has not yet been fully clarified, combination therapy using fenofibrate and UDCA might be related to the anti-immunological effects, such as the suppression of AMA production as well as its anti-inflammatory effect.

INTRODUCTION

Primary biliary cirrhosis (PBC) is a chronic, cholestatic liver disease characterized by inflammation and progressive destruction of interlobular bile ducts, eventually leading to cholestasis, biliary cirrhosis and finally hepatic failure. The etiology of PBC is attributed to autoimmunity mainly due to the association with autoantibodies such as antimitochondrial antibodies (AMA), which present in 95% of PBC patients, and an increased level of immunoglobulin M (IgM). Regarding this therapy, orthotopic liver transplantation is selected for PBC patients with liver failure and intractable pruritus, while ursodeoxycholic acid (UDCA) has been widely used as a first-line drug for asymptomatic PBC (aPBC) to slow the disease progression[1-3]. Although the biochemical data of the liver functions tend to normalize in 20-30% of patients with aPBC who are administered UDCA, the rest of the patients often progress to cirrhosis[4,5]. Therefore, there is a need for a more effective treatment[6].

PBC is often associated with lipoprotein abnormalities such as an elevation of serum cholesterol concentration[7]. Recently, several studies focusing on lipoprotein-lowering drugs for PBC have been reported[8-15]. Simvastatin, an HMG-CoA reductase inhibitor, was proven to be useful as a modulator of cholestasis and an immune response in PBC[8]. Bezafibrate, a hypolipidemic agent, was also effective in PBC patients who failed to respond to UDCA[9-15]. The mechanism of action of bezafibrate is believed to be the anti-inflammatory effects via peroxysome proliferator-activated receptor α (PPARα), a member of the nuclear hormone receptor superfamily, and the expression of multiple drug resistance gene-3, both of which ameliorate hepatobiliary inflammation in PBC[11,16-18]. Fenofibrate is a member of fibrate class agents as bezafibrate and works as a ligand of PPARα, showing a potent triglyceride-lowering effect. Fenofibrate treatment for PBC has been addressed in very few studies[19], including our previous abstracts which we presented at conferences[20,21]. The effect of fenofibrate on PBC therefore has to be clarified and is currently being evaluated.

For this purpose, we studied the efficacy of fenofibrate on nine patients with aPBC who responded insufficiently to monotherapy of UDCA.

MATERIALS AND METHODS

Patients and regimen

Nine patients with aPBC consisting of 2 males and 7 females were included in the prospective study. Ages were 50.3±11.7 (mean±SD) yr ranging from 34 to 69 yr, and mean body mass 57.9±5.6 (mean±SD) kg ranging from 50.0 to 64.6 kg. They were diagnosed to have aPBC according to laboratory and/or histological findings. All patients were negative both for anti-hepatitis C virus antibody and for hepatitis B surface antigen. All 9 patients with aPBC exhibited a poor therapeutic response to UDCA of 600 mg/d for 6 mo or more. Fenofibrate of 100 mg/d was administered for 4 patients (less than 60 kg in body mass) and of 150 mg for 5 patients (60 kg or more in body mass) for at least 12 wk. The study was approved by the local ethics committee, and informed consent was obtained from each patient included in the study.

Laboratory examination

During the study, any changes in dietary therapy were prohibited. In order to determine the drug compliance and safety, all patients were required to visit the hospital every 2 wk, and the serum blood chemistry including apolipoprotein was examined every 4 wk. Serum concentrations of total bilirubin, immunoglobulins G and M (IgG, IgM) as well as aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase (ALP) and gamma-glutamyltransferase (γGTP) were determined before the fenofibrate treatment as well after the treatment of 12 wk by routine laboratory procedures. AMA titers were measured using indirect immunofluorescence based on stomach/kidney frozen sections. Blood was sampled early in the morning during fasting, and a medical laboratory (SRL Co., Tokyo) centrally controlled the measurements up to 12 wk after the start of administration.

Statistical analysis

Differences in the means and proportions were evaluated by Chi-square test and Student's *t*-test. Baseline variables were assessed in the study, including AST, ALT, ALP, γGTP, apolipoproteins, IgG, IgM and AMA titers. *P* value less than 0.05 was considered statistically significant.

RESULTS

Effect of fenofibrate on laboratory findings for hepatobiliary system and serum lipids

Table 1 and Figure 1 show the enzymatic changes in the hepatobiliary system identified up to 12 wk after the start of the combination therapy of fenofibrate and UDCA. The mean ALP value of 285.0 IU/L prior to fenofibrate therapy decreased to 186.9 IU/L at wk 12 after the initiation of the therapy, thus showing a statistically significant difference. The serum γ-GTP concentration also decreased after 12 wk of fenofibrate and UDCA treatment compared to that at initiation, although the difference was not statistically significant. The serum concentrations of AST and ALT did not change statistically regarding those obtained prior to and after 12 wk of treatment. The serum concentration of IgM of 255.8 mg/dL prior to the treatment was significantly reduced to 192.9 mg/dL at wk 12, whereas the concentration of IgG did not decrease. Regarding the titer of AMA, a reduction was identified in 4 of the 9 patients based on that obtained prior to and after 12 wk of treatment. As shown in Figure 2, the AMA titer of 320 decreased to 40, 320 to 80, 80 to 20 and 40 to 20 in 4 of 9 patients, respectively. The titers of AMA in the rest 5 patients remained unchanged. The serum levels of ALP of 571 IU/L and IgM of 236 mg/dL decreased to 306 IU/L and 154 mg/dL, respectively, in a patient whose AMA titer decreased from more than 320 to 40. Likewise, those of 276 and 159 decreased to 285 and 102 in a patient whose AMA titer decreased from more than 320 to 80, those of 215 and 375 decreased to 107 and 241 in a patient whose AMA titer decreased from 80 to 20, and those of 191 and 240 decreased to 114 and 180 in a patient whose AMA titer decreased from 80 to 20, respectively. Interestingly, all the four cases who showed a reduction of the AMA titer were females.

Table 2 shows the changes in serum lipids and apoprotein levels in all 9 patients. The concentrations of apo A-II (median value: 31.6 mg/dL) and apo C-II (median value: 3.9 mg/dL) increased statistically to 44.1 mg/dL and 4.5 mg/dL during fenofibrate therapy (*P*<0.005), respectively. The concentrations of total cholesterol (TC), triglyceride (TG), low density lipoprotein-cholesterol (LDL-C) and Apo B lipoprotein tended to decrease while the high density lipoprotein-cholesterol (HDL-C), apo A-I and apo E levels tended to increase. However, the difference was not statistically significant.

Table 1 Change in concentrations of laboratory data (mean±SD)

Laboratory Variable	Before therapy	4 wk	8 wk	12 wk
AST (IU/L)	29.9±8.1	50.0±36.3	46.6±24.9	46.9±28.3
ALT(IU/L)	31.1±13.2	48.6±35.2	57.0±38.9	48.4±42.5
ALP (IU/L)	285.0±114.8	238.5±88.4	200.6±76.7[a]	186.9±76.2[a]
γ-GTP(IU/L)	149.6±143.0	147.0±178.6	128.8±128.1	125.2±110.3
LDH (IU/l)	311.2±46.7	318.4±44.8	320.1±59.9	324.6±59.2
TB (mg/dl)	0.7±0.7	0.4±0.2	0.6±0.4	0.6±0.5
IgG (mg/dl)	1 431.4±285.3	-	-	1 415.0±316.1
IgM (mg/dl)	255.8±85.9	-	-	192.9±67.5[a]

[a]*P*<0.05 (baseline-matched *t*-test) *vs* the serum concentrations prior to the treatment.

Figure 1 Change in the serum alkaline phosphatase levels during fenofibrate treatment.

Figure 2 Change in antimitochondria antibody titers before and after fenofibrate treatment.

Table 2 Change in concentrations of serum lipids and apoproteins

Varuables	Before	4 wk	8 wk	12 wk
TC (mg/dL)	206.3±26.5	186.3±22.9	189.9±27.7[a]	192.1±30.1
TG (mg/dL)	126.0±50.1	119.5±76.2	102.8±52.3	103.6±53.0
HDL-C (mg/dL)	63.6±11.3	63.8±14.0	68.8±12.6	69.3±13.1
LDL-C (mg/dL)	115.7±22.1	99.3±29.3	105.6±28.0	105.2±25.1
Apo A-I (mg/dL)	159.0±17.9	154.7±19.4	158.3±17.9	172.1±24.3
Apo A-II (mg/dL)	31.6±6.5	39.5±7.0[a]	40.7±4.6[a]	44.1±4.9[a]
Apo B (mg/dL)	95.1±22.9	84.1±31.4	81.0±26.5	84.1±23.1
Apo C- II (mg/dL)	3.9±1.7	4.6±2.0[a]	4.2±1.6	4.5±1.5[a]
Apo C-III (mg/dL)	9.7±3.8	9.5±4.2	8.9±2.9	9.8±3.6
Apo E (mg/dL)	4.3±1.0	4.3±0.8	4.4±0.8	4.6±0.9

TC: total cholesterol, TG: triglyceride, HDL-C: HDL-cholesterol, LDL-C: LDL-cholesterol, Apo: apoprotein. [a]*P*<0.05 (baseline-matched *t*-test) *vs* the serum concentrations prior to the treatment.

Rate of change of each variable between AMA-reduced group and AMA-unchanged group

The rate of change of each variable between the AMA-reduced group and the AMA-unchanged group was compared before and after the combination therapy of fenofibrate and UDCA. As shown in Table 3, the IgM concentrations dropped to 35.4±0.6% in the AMA-reduced group and 7.1±11.8% in the AMA-unchanged group, showing a statistically significance between the two groups. Interestingly, however, the values of ALP, γGTP and apo A-II dropped at a similar rate in two groups.

Table 3 Rate of change in the valuables between AMA-reduced group and AMA-unchanged group

Factors	AMA-reduced group	AMA-unchanged group	t-test
ALT (IU/L)	61.6±124.8[1]	52.0±109.2	0.905
ALP (IU/L)	-33.4±24.8	-33.8±16.0	0.978
γ-GTP (IU/L)	-2.8±73.4	-5.3±39.8	0.950
IgM (mg/dL)	-35.4±0.6	-7.1±11.8	0.010
Apo A-II (mg/dL)	52.0±17.3	37.4±38.6	0.573
Apo C-II (mg/dL)	29.5±13.8	10.6±10.1	0.089

[1]Changing rate (%) (mean±SD).

Adverse effects

In all the nine patients, no subjective symptoms such as systemic malaise, anoxia, were observed. No deterioration of the liver function tests was identified in any cases as shown in Table 1. The blood urea nitrogen and creatinine levels did not change either after fenofibrate administration.

DISCUSSION

Primary biliary cirrhosis presents as a chronic cholestatic disease involving predominantly middle-aged women with a very frequent association with AMA. In addition, PBC has been found to be often associated with other autoimmune diseases[22-27]. Therefore, PBC is thought to be an autoimmune disease and most therapies have thus been directed at altering the immune response. So far, the use of corcicosteroid, azathioprine, cyclosporine[28], D-penicillamine[29], methotrexate[30,31], colchicines[31,32] has been studied for patients with PBC.

However, none of these drugs appeared to offer any significant benefits while they tended to induce adverse effects such as osteoporosis, or pulmonary toxicity[24]. Recently UDCA appeared to be a drug which most effectively treated patients with PBC[1-3] through cytoprotective and choleretic effects and alterations in the bile pool by competition for uptake by ileal bile acid receptors. However, a considerable number of patients with PBC still clinically respond insufficiently to UDCA alone, and now a new problem has emerged concerning which agent should be used for these patients.

Several clinical studies on lipoprotein-lowering agents such as simvastatin[8] and bezafibrate[9-15] for PBC patients who failed to respond to UDCA have so far been conducted, and the results have been found to be of value. In addition, fenofibrate, a member of such fibrate class agents as bezafibrate, has recently been found to be an expected agent for PBC because of its stronger activity of an anti-inflammatory effect via PPARα[33], and more potentiality in reducing TG and LDL-C levels[34] than that of bezafibrate. Early attempts of the apoprotein-lowering agents focused on treating concomitant conditions of hypertriglycemia or hypercholesterolemia. Therefore, we conducted a study on the efficacy of fenofibrate in nine patients with aPBC.

Indeed, serum concentrations of TC and TG decreased and the concentration of HDL-C increased in all the 9 patients with aPBC, however, these changes were not statistically significant. As for apoprotein, apo AII and apo C II, which are major protein constituents of HDL, were significantly increased in the study. As a result, lipoprotein, an indicator for the risk of developing atherosclerotic disease was improved after fenofibrate treatment in PBC patients in our study[7,35].

Fenofibrate has been shown to regulate the expression of various kinds of lipids and proteins, and cell proliferation through the activation of PPARα[36,37]. However, apart from the lipoprotein-lowering effect, its pleiotropic effects have recently received much attention ranging from inhibited production of interleukin (IL)-1, IL-6, IL-1- and IL-6-induced prostaglandin E2 as well as cyclooxygenase (COX)-2 expression to the induction of apo A-II through the inhibition of the nuclear factor (NF)-κB signalling by activation of PPARα[38,39]. Furthermore, fenofibrate could inhibit the expression of intercellular adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1, which play a role in the adhesion of monocytes through apo A-II induction or NF-κB inhibition

Figure 3 Possible mechanisms of action for fibrates on PBC.

[40]. These findings suggest that fenofibrate can inhibit not only the lipid metabolism but also the inflammatory reaction through PPARα. It is therefore likely that the PPARα activation-mediated anti-inflammatory effects of fenofibrate, such as the inhibited expression of NF-κB, IL-1, IL-6, COX-2 and prostaglandin E2 might contribute to an improvement of PBC. Apo A-II could inhibit the expression of such adhesion molecules as ICAM-1 and VCAM-1 which are believed to be progression factors in cases of PBC, because adhesion molecules induce lymphocytes into epithelial cells of hepatobiliary ducts. From another point of view, as reported by Iwasaki *et al*[11], improvement of PBC might also occur because the canalicular phospholipid translocator, encoded by multi-drug resistant gene-3 (MDR3) expressed by bezafibrate administration, was exclusively present on the canalicular membrane, increases the secretion of biliary phospholipids and inactivating hydrophobic bile acid by micellization to protect hepatocytes and epithelial cells of bile ducts[18] (Figure 3). Thus, MDR3 messenger RNA and the canalicular phospholipid translocator (MDR3-P glycoprotein) of fibrates are strictly PPARα dependent. Although the different sensitivities to PPARα between fenofibrate and bezafibrate have not yet been clarified, a possible reason is that fenofibrate could selectively act on PPARα only, while bezafibrate could act on PPARα, γ as well as δ[33].

The emerging question is whether fenofibrate's anti-immunological effect is truly mediated via PPARα or its receptor-independent anti-inflammatory effects. Our results demonstrated that fenofibrate did not only improve dyslipoproteinemia but also significantly reduce serum ALP and IgM levels. It was of great interest that a reduction of AMA titer was also observed in 4 of 9 patients. The immunological response of PBC patients to fenofibrate therapy thus raises another question, namely, how is the AMA production regulated by PPARα in PBC? Is the AMA production interrelated in the inflammation or lipid synthesis? Kurihara *et al* reported 5 cases of aPBC who responded to the combination therapy of bezafibrate and UDCA[9], however, the AMA titer remained unchanged in all cases. Nevertheless, there was a reduction of IgM as well as ALP, γGTP and TC. Similarly, Iwasaki *et al* described that IgM decreased significantly, but the AMA titers were not affected in all 5 PBC patients treated with bezafibrate[11]. In contrast, Fukuo *et al* showed 6 cases of aPBC who responded to bezafibrate with a decreased AMA titer[10]. Nakai *et al* did not analyze the AMA titer among 23 patients with PBC treated with a combination therapy of bezafibrate and UDCA, while they confirmed a decrease in the IgM concentration[12]. Although no relationship between IgM concentration and AMA titer was observed in these papers, our study demonstrated that IgM concentration closely correlated with the reduction of AMA titer, whereas the decrease of ALP and γ-GTP levels was not correlated with the AMA reduction. Interestingly, immunoglobulins, the secretary products of stimulated B lymphocytes, were characteristically elevated, with a distinct focus on IgM in PBC. One possibility to explain the reduction of IgM by fenofibrate treatment for PBC is that the decreased production of prostaglandin E2 via PPARα suppressed the Th2 lymphocytes that induce B cells, thus leading to the reduced production of immunoglobulin[41]. However, our study showed that fenofibrate treatment for PBC resulted in a decrease in IgM level, while IgG level was unchanged. Fenofibrate may also possess an additional or synergistic potential for lowering IgM levels as observed in the ALP and γGTP levels. The exact cause of hyperglobulinemia in PBC, however, remains to be elucidated.

Regarding the adverse effect of fenofibrate, diabetes arteriosclerosis intervention study (DAIS) showed that micronized fenofibrate at 200 mg (equivalent to 300 mg of the standard formulation) was administered for 3 yr to type 2 diabetic patients in order to observe its inhibitory effect on the progression of coronary arterial stenosis. As a result, no difference in the safety between fenofibrate and placebo was observed[42]. In addition, studies of human first-generation cultured cells and HepG2 cells suggested that serum aminotransferase levels were transiently elevated and then normalized or returned to pretreatment levels[43]. The increase in the aminotransferase level after treatment with fenofibrate was not considered to be clinically significant. As fenofibrate could activate the aminotransferase gene expression, thus leading to a mild and transient elevation of aminotransferase through mechanisms of PPARα involving increased levels of reactive oxygen species and intracellular glutathion deplesion, thus leading to mitochondrial dysfunction and perturbation of intracellular Ca^{++} homeostasis and also to cell death[43,44]. A dosage of 100 mg or 150 mg per day of fenofibrate in the 9 patients studied, which is half the commonly administered dose, was thus administered to poor responders to UDCA, and a blood examination was performed every 2 wk. No adverse effect was observed either clinically or biochemically in all the 9 patients in our study.

Administration of fenofibrate in combination with UDCA was safe and useful for patients with aPBC. This finding confirms our belief that fenofirate's beneficial effects are mediated only through its lipoprotein-lowering effect. The mechanism underlying the long term efficacy of fenfibrate for symptomatic PBC remains to be elucidated[15]. The expansive array of ligands, target genes, and metabolic processes regulated by nuclear receptors such as PPARα, β, γ within hepatocytes, and ever-changing internal milieu, has made a completely comprehensive regulatory scheme virtually impossible to depict graphically[44]. Nuclear receptors-regulated gene products may create or disable a protein ligand or regulate the import or export of another nuclear receptor, which might be related to the production of IgM or AMA. There are likely many more mechanisms of action for fenofibrate on PBC still awaiting further discovery.

In conclusion, fenofibrate can be well tolerated by all patients with aPBC, while it has no remarkable side effects. This agent is beneficial for the treatment of aPBC. However, further studies are needed to elucidate the effect of fenofibrate on PBC and to determine its long-term biochemical and histological efficacy.

Abstract

AIM: There is still no accepted conclusion regarding the clinical features and related risk factors of patients with fatty liver. The large-scale clinical studies have not carried out yet in Guangzhou area. The aim of the present study was to investigate the clinical features and related risk factors of patients with fatty liver in Guangzhou area.

METHODS: A total of 413 cases with fatty liver were enrolled in the study from January 1998 to May 2002. Retrospective case-control study was used to evaluate the clinical features and related risk factors of fatty liver with logistic regression.

RESULTS: Obesity (*OR*: 21.204), alcohol abuse (*OR*: 18.601), type 2 diabetes mellitus (*OR*: 4.461), serum triglyceride (TG) (*OR*: 3.916), serum low-density lipoprotein cholesterol (LDL-C) (*OR*: 1.840) and fasting plasma glucose (FPG) (*OR*: 1.535) were positively correlated to the formation of the fatty liver. The levels of serum alanine aminotransferase (ALT) and gamma-glutamyltransferase (GGT) increased mildly in the patients with fatty liver and were often less than 2-fold of the normal limit. The higher abnormalities of aspartate aminotransferase (AST) levels (42.9%) with AST/ALT more than 2(17.9%) were found in patients with alcoholic fatty liver (AFL) than those with nonalcoholic fatty liver (NAFL) (16.9% and 5.0% respectively). The elevation of serum TG, cholesterol (CHOL), LDL-C was more common in patients with NAFL than with AFL.

CONCLUSION: Obesity, alcohol abuse, type 2 diabetes mellitus and hyperlipidemia may be independent risk factors of fatty liver. The mildly abnormal hepatic functions can be found in patients with fatty liver. More obvious damages of liver function with AST/ALT usually more than 2 were noted in patients with AFL.

INTRODUCTION

Fatty liver is a condition of hepatic steatosis caused by many risk factors and may progress to liver fibrosis and cirrhosis. Generally, the diagnosis of fatty liver should be based on the history, clinical manifestation, laboratory investigation and medical imaging. Liver biopsy should be taken if necessary. After to know the possible related risk factors of fatty liver existed in the history, the abnormal degree of the biochemical and imaging features can provide a clue for early diagnosis. Although the related risk factors and laboratory features have already been reported, there is still no well-accepted conclusion[1-3]. The large-scale clinical studies have not carried yet in Guangzhou area, southern China[4].

Retrospective case-control study was used to analyze fatty liver. The age, gender, obesity, type 2 diabetes mellitus, hyperlipidemia, alcohol abuse, smoking, and history of drugs or toxins and so on were recorded to evaluate the effects of these variables on fatty liver and investigate the related risk factors. The liver function and other serum biochemical levels were compared to find out the difference of laboratory abnormalities, so that they could provide a scientific foundation for the diagnosis, prevention and treatment of fatty liver.

MATERIALS AND METHODS

Clinical data
The data of 413 cases of fatty liver in this hospital from January 1998 to May 2002 were collected. Fatty liver was diagnosed according as the standard by Chinese Association of Medicine and Sherlock[5-7] The 200 cases without fatty liver during the same period were selected randomly as control. Age, gender, serum lipids, fasting plasma glucose (FPG), obesity (body mass index, BMI$\geqslant$25), alcohol abuse, smoking, type 2 diabetes mellitus, history of drugs and toxins, hepatitis virus infection (HCV and HBV), pregnancy, jejuno-ileal bypass surgery and total parenteral nutrition were recorded in fatty liver group and non fatty liver group respectively.

The laboratory data of serum triglyceride (TG), cholesterol (CHOL), high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C), apolipoprotein AI (Apo AI), apolipoprotein B (Apo B), uric acid (UA), aspartate aminotransferase (AST), alanine aminotransferase (ALT), the ratio of AST/ALT, albulin (ALB), globin (GLB), ratio of A/G, gamma-glutamyltransferase (GGT) and total bilirubin were collected in two groups respectively. The serum biochemical indexes were examined by an autoanalyzer based on a standard protocol.

Statistical analysis
All data analysis was performed with EXCEL 97 and SPSS 10.0 /PC statistical package. A *P* value less than 0.05 (2-tailed) was considered to be statistically significant. The frequency was compared using Chi-squared (χ^2) test. The univariate and multivariate stepwise logistic regression was used to select the independent variables. Data with normal distribution were expressed as mean±SD. The differences between groups were analyzed for statistical significance using Student's *t* test. Data

with abnormal distribution were expressed as median and interquartile range.

RESULTS

General condition

Among 413 fatty liver cases, the gender ratio (M/F) was 1.02:1. The age ranged from 8 to 83 years. The median age was 57 years. No significant differences in age and gender were found between the fatty liver group and non-fatty liver group. The possible causes of fatty liver are showed in Table 1.

Table 1 Possible causes of fatty liver and its comparison with non-fatty liver group (%)

Factors	Fatty liver group (n=413)	Non-fatty liver group (n=200)
Alcohol abuse	51(12.4)[b]	7(3.5)
Obesity	244(59.1)[b]	17(8.5)
Type 2 diabetes mellitus	206(49.9)[b]	15(7.5)
Hyperlipidemia	276(66.8)[b]	63(31.5)
Hypertriglyceridemia	92(22.3)[b]	17(8.5)
Hypercholesterolemia	64(15.5)	35(17.5)
Mixed Hyperlipidemia	120(29.1)[b]	11(5.5)
HBV infection	50(12.1)	31(15.5)
HCV infection	34(8.2)	10(5.0)
History of drugs and toxins	6(1.5)	2(1.0)

[b]$P<0.001$, vs Non-fatty liver group.

Analysis of independent risk factors of patients with fatty liver

Analysis of univariate logistic regression was performed among 20 variables, such as age, gender, obesity, alcohol abuse, smoking, type 2 diabetes mellitus, TG, CHOL, HDL-C, LDL-C, Apo AI, Apo B, FPG, HCV and HBV infection, history of drugs and toxins, pregnancy, jejuno-ileal bypass surgery and total parenteral nutrition. TG, CHOL, HDL-C, LDL-C, Apo B, FPG, obesity, alcohol abuse, smoking, type2 diabetes mellitus were positively correlated to fatty liver respectively (odds rate, $OR>1$, $P<0.05$), while Apo AI was negatively correlated to it ($OR<1$, $P<0.05$). Multivariate stepwise logistic regression was used to select the variables independently associated with fatty liver. Obesity, alcohol abuse, type 2 diabetes mellitus, TG, LDL-C and FPG were entered the model of logistic regression as the independent risk factors of fatty liver. In contrast, Apo B was negatively correlated to it (Table 2).

Table 2 Multivariate stepwise logistic regression

Variables	β	SE	OR	95%CI	P-value
Obesity	3.054	0.354	21.204	10.539-42.429	0.000
Alcohol abuse	2.923	0.509	18.601	6.585-50.432	0.000
Type 2 diabetes mellitus	1.495	0.354	4.461	2.228-8.952	0.022
TG	1.365	0.268	3.916	2.316-6.621	0.000
LDL-C	0.610	0.184	1.840	1.283-2.640	0.001
FPG	0.429	0.094	1.535	1.278-1.846	0.000
Apo B	-1.590	0.530	0.204	0.072-0.576	0.003

β: partial regression coefficient; SE: standard error of partial regression coefficient; OR: odds ratio; CI: confidence interval.

Abnormal liver function in patients with fatty liver

Using χ^2 test, the abnormal frequencies of ALT, AST/ALT and GGT showed significant differences between the patients with and without fatty liver (Table 3).

Comparison of serum biochemical features between alcoholic fatty liver (AFL) group and nonalcoholic fatty liver (NAFL) group

The abnormal frenquencies of serum TG, CHOL, LDL-C and ApoB were higher in NAFL group than those in AFL group. The proportion of HDL-C≤1.0, AST≥40 and AST/ALT≥2 were higher in patients with AFL than with NAFL (Table 4).

Table 3 Abnormal liver function in the patients with fatty liver and non-fatty liver (%)

Liver function	Fatty liver group (n=413)	Non-fatty liver group (n=200)
AST (≥40 U)	85(20.6)	38(19.0)
(40-80 U)	65(15.7)	26(13.0)
(≥80 U)	20(4.8)	12(6.0)
ALT (≥40 U)	129(31.2)[a]	37(18.5)
(40-80 U)	84(20.3)[a]	26(13.0)
(≥80 U)	45(10.9)[a]	11(5.5)
AST/ALT (<1)	161(39.0)[a]	28(14.0)
(≥2)	23(5.6)[a]	54(27.0)
ALB (≤35 g/L)	16(3.9)	15(7.5)
GLB (≥30 g/L)	42(10.2)	29(14.5)
A/G (≤1.5)	84(20.3)	47(23.5)
GGT (≥50 U/L)	145(35.1)[a]	46(23.0)
TBIL (≥17.1 μmol/L)	75(18.2)	39(19.5)

[a]$P<0.05$, vs Non-fatty liver group.

Table 4 Comparison of laboratory abnormalities among AFL, NAFL and control groups (%)

Biochemical Index	AFL group (n=28)	NAFL group (n=301)	Control group (n=163)
TG (≥1.7 mmol/L)	2(7.1)[a]	169(56.2)[c]	27(17.7)
CHOL (≥5.2 mmol/L)	2(7.1)[a]	148(49.2)[c]	35(22.9)
HDL-C (≤1.0 mmol/L)	9(32.1)[a]	35(11.6)	27(17.7)
LDL-C (≥2.6 mmol/L)	12(42.9)[a]	214(71.1)	97(63.4)
Apo AI (≤1.2 mmol/L)	13(46.4)	118(39.2)	45(29.4)

A/G (≤1.5)	7(25.0)	64(21.3)	31(20.3)
GGT (≥50 U/L)	10(35.7)	95(31.6)[e]	30(19.6)
TBIL (≥17.1 μmol/L)	6(21.4)	50(16.6)	30(19.6)

[a]$P<0.05$, vs NAFL group; [c]$P<0.05$, vs control group; [e]$P<0.05$, vs control group.

DISCUSSION

In recent years, the prevalence of fatty liver is constantly increasing along with the improvement of life-style, the change of dietetic structure, the aged population and the application of new diagnostic technique. The incidence of fatty liver in 3432 Japanese adults thorough medical examination was 21.8%[2]. In China, fatty liver affected 10.2% of cadres in Nanjing[8] with 11.4% of male and 6.8% of female. There were no data to show the prevalence of fatty liver in the southern China. Because of distinct life-style and climate feature in Guangzhou, the pattern

of fatty liver could be different from other area. Among 413 patients with fatty liver, the gender ratio (M/F) was 1.02:1. The age ranged widely. The median age was 57 years.

Fatty liver may be an independent disease, but more generally, it is a lesion of the liver in certain systemic diseases. Fatty liver may be caused by many diseases and risk factors, and can progress from mild steatohepatitis to severe fibrosis and cirrhosis[9]. The etiological prevention is very important because of the lack of effective therapy. Although the etiology of hepatic steatosis is explored extensively, the complicated and multi-factor pathogenesis make it remain poorly understood. The possible related risk factors include: alcohol abuse, diabetes mellitus, obesity, hyperlipidemia, drugs and toxins, hepatitis virus infection (especially HCV), rapid weight loss, jejuno-ileal bypass surgery, total parenteral nutrition, pregnancy and so on[10-16].

413 patients with fatty liver were diagnosed mainly according to the history, clinical manifestations, laboratory and ultrasound examination. Liver biopsy was the best method of diagnosing fatty liver. But it was difficult to carry out in large sample of populations. This was the possible limitations of the study.

Our data from 413 patients with fatty liver showed that obesity, alcohol abuse, type 2 diabetes mellitus, hyperlipidemia and elevation of fasting plasma were independent risk factors confirmed by a multivariate logistic analysis. These correlations were similar to the researches at home and abroad[3,4]. It suggested that the pathogenesis of fatty liver in southern China might have a similar pattern to other area in China and abroad.

Obesity was easily accompanied with fatty liver[17]. The percentage of the obese patients with fatty liver (59.1%) was significantly higher than controls (8.5%). Obesity is a very common phenomenon in the developed countries. 60-100% patients of non-alcoholic steatohepatitis (NASH) were proved to have obesity[18]. This situation was also found in developing country, especially in China. According to the data in 11 provinces/autonomous regions/municipalities of China from July 1995 to July 1997, the prevalence rate of overweight and obesity among 42 751 Chinese adults aged 20-74 years were 21.51% and 2.92% respectively[19]. There were about 200-300 million of overweight and 30-40 million of obese populations in China. With the odds ratio of 21.204, obesity was a predictor of fatty liver. The practice of prevention for overweight and obesity was very important for control of fatty liver.

Alcohol liver disease was the major medical complications of alcohol abuse. Alcohol abuse was one of the major causes of fatty liver and cirrhosis in the Western countries. At least 80% of heavy drinkers developed fatty liver, 10-35% of alcoholic hepatitis, and approximately 10% cirrhosis[20]. Alcohol drinkers were not as common in southern China as in northern China[19]. Based on our data, there were only 12.4% patients with alcohol abuse and 6.8% of them with alcoholic fatty liver among 413 patients with fatty liver according to diagnostic standard of China in 2002. But, the proportion of alcoholic abuse was still higher in patients with fatty liver than those without fatty liver. Alcoholic abuse contributed to a risk factor of fatty liver.

Type 2 diabetes mellitus usually accompanied insulin resistance[12,21]. Both peripheral and hepatic insulin resistance were present in almost all patients with nonalcoholic fatty liver disease, irrespective of the coexistence of related risk factors[21]. Above findings, together with the associated hyperlipidemia, obesity, hypertension and herperurisemia, were considered as the manifestations of the metabolic syndrome that was associated with insulin resistance[22,23]. In this study, either type 2 diabetes or elevation of fasting plasma glucose was related to fatty liver. It suggested that insulin resistance might be a risk factor of fatty liver.

The role of serum lipids in fatty liver remained controversial[16,24]. Some researches showed that the effects of hyperlipidemia on fatty liver were complicated and difficult to be disassociated with obesity and type 2 diabetes mellitus. Among the 413 patients with fatty liver, the total incidence of hyperlipidemia was 66.8%, which consisted of 22.3% of hypertriglyceridemia, 15.5% of hypercholesterolemia and 29.1% of mixed hyperlipidemia. TG and LDL-C were independent risk factors and ApoB was a protective factor confirmed by multivariate logistic analysis. TG and LDL-C stimulated the proliferation and collagen synthesis of hepatic stellate (HSC) and increased deposition of extracellular matrix (ECM) in the liver by means of lipid peroxidation[25,26]. This process was relative to hepatic fibrosis and effected prognosis of patients with fatty liver.

The correlation between hepatitis virus infection (especially HCV) and hepatic steatosis was found[27]. Although the incidence of chronic HBV and HCV infection in China remained the highest proportion in the world, there was no significant difference in the incidence of HBV or HCV infection between patients with and without fatty liver. The infection of HBV and HCV was excluded from the model of multivariate stepwise logistic regression.

The clinical and laboratory features varied greatly with different causes and degree of hepatic steatosis in patients with fatty liver[28]. The elevation of serum TG, CHOL and LDL-C was more common in patients with NAFL than those with AFL. Most patients with fatty liver had no obvious symptoms and signs of liver disease at the time of diagnosis. But a higher proportion of patients with cryptogenic cirrhosis shared many of the clinical and demographic features of patients with fatty liver. NASH played an under-recognized role in many patients with cryptogenic cirrhosis[29]. Mild elevation usually less than 2 folds of the normal limit of serum ALT and GGT was showed in this investigation. The mitochondria was the most likely source of the reactive oxygen species (ROS) leading to lipid peroxidation in patients with fatty liver[30]. AST, a mitochondrial enzyme, was more easily affected by ethanol[31]. Among the abnormal hepatic functions, the higher AST levels with AST/ALT more than 2 were found in those with AFL. The increases of serum lipids and AST/ALT ratio might be useful in differentiating NAFL from AFL.

Abstract

AIM: To detect the origin of hepatocellular carcinoma (HCC) recurring and attempt to propose a new recurrent mechanism.

METHODS: Orthotopic liver allotransplantation was performed on male rats with HCC- induced by diethylnitrosamine using female donors. Metastatic tumors in transplanted livers were obtained. A DNA probe that exhibits specificity for the rat Y chromosome was generated by using a set of primers specific to murine *sry* gene. *In situ* hybridization (ISH) for Y chromosome was used to detected the origin of HCC recurring. Male HCC tissue was designed to be positive control. ISH on female tissue and using non-labeled with DIG probe was thought to be negative control.

RESULTS: Positive marks were seen through ISH for Y chromosome in recurrent tumor tissue and positive control. No signal was detected in both negative controls.

CONCLUSION: Recurrent HCC after liver transplantation originated from disseminated tumor cells in recipients. Extrahepatic cells homing into liver may be a new HCC recurrence mechanism. Likewise, it implicates that this mechanism is responsible for HCC recurring after hepatectomy.

INTRODUCTION

The poor outcomes of patients with hepatocellular carcinoma (HCC) are mainly resulted from high postoperative recurrence rate with 65% after radical resection versus 58% after liver transplantation[1,2]. Over the past decades, many investigations using clinicopathological and molecular biological methods have showed that there existed two HCC recurrent mechanisms of intrahepatic metastasis (IM) and multicentric occurrence (MO)[3-5]. However, the both mechanisms are very reluctant to elucidate the HCC recurrence following liver transplantation in rigidly selected patients. Therefore, we refer a hypothesis that recurrent HCC in transplanted liver is likely to originate from extrahepatic tumor cells in recipient if de novo

carcinogenesis is excluded. Likewise, disseminated tumor cells possibly go back to remnant liver after hepatectomy.

We have established an animal model of liver transplantation for HCC in rats. Male rat liver with HCC induced by diethylnitrosamine (DENA) was replaced by allograft from normal syngenic female animal. Recurrent tumors from male recipient of female liver were analyzed using *in situ* hybridization (ISH) for the Y chromosome to indicate cells origins. On the basis of our investigation and other supportive literatures, we make an attempt to propose a new possible mechanism of HCC recurrence.

MATERIALS AND METHODS

Orthotopic liver transplantation (OLT) for HCC-induced in gender discordant rats

Ninety-eight inbred seven-week-old male SD rats, weight ranged from 100 g to 120 g, were purchased from PEAK Company in Shanghai with the approval of Shanghai Animal Committee. HCC was induced by oral administrantion of 100 ppm DENA (Sigma Company, USA) water solution. OLT for HCC was performed according to Kamada cuff techniques[6] on male rats with HCC and donor livers were from normal syngenic female SD rats with weight ranged from 250 g to 300 g. No immunosuppressant was postoperatively administered. Explanted livers were examined pathologically. The recurrent tumors in the transplants may be explored through laparatomy before the recipients' death. Harvested specimens were preserved at -70 ℃.

Using ISH to detect the Y chromosomes in recurrent HCC cells[7,8]

Male rat genomic DNA was purified from 300 µL blood sample using Wizard Genomic DNA Purification Kit (Promega). *sry* gene specific primer, of which the sequences are 5'-CAGAGATCAGCAAGCAGCTG-3' and 5'-TGCAGCTCTACTCCAGTCTTG-3', was synthesized by Shenggong Biochemical Incorporation in Shanghai. 0.1 µg of the genomic DNA as template, *sry* gene was amplified by PCR. The reaction was comprised of 35 cycles of 5 min at 94 ℃, 0.5 min at 60 ℃, 1 min at 72 ℃. PCR products were analyzed on 15 g/L agarose gel and then purified with QIAquick Gel Extraction Kit (Qiagen). Target gene was labeled according to the instruction of DIG High Prime DNA Labeling and Detection Starter Kit II (Roche).

Male SD rat HCC tissue confirmed by pathology was designed to be positive control. ISH on female SD rat liver tissue and using non-labeled with DIG probe was thought to be negative control. ISH efficacy would be verified by the both controls.

Frozen tissue sections (5 µm in thickness) were fixed on the slides treated by 40g/L polyformaldehyde. Slides were washed in PBS (PH7.4) for 5 min (2 times), 3g/L Triton X-100/PBS for 10 min, and PBS (PH7.4) for 5 min (2 times). Tissue was digested with pepsin 2 µg/mL for 15 min at 37 ℃, and then washed in PBS for 5 min and rinsed in 4×sodium saline citrate (SSC) for 2 min at room temperature. Slides were

denatured with 50% formamide in 2×SSC for 15 min at room temperature, then dehydrated and air dried. Probe for Y chromosome (10 ng/μL) was denatured for 5 min at 75 ℃, added to the denatured tissue, coverslipped and incubated in a humid chamber overnight at 42 ℃. Slides were then washed in 2×SSC for 10 min (2 times), 1×SSC for 10 for min (2 times), 0.1×SSC 10 for min (3 times), and in buffer1 (Tris-HCl, PH7.5, 100 mmol/L; NaCl 150 mmol/L) for 5 min. Anti-DiG-Ap (1:500 dilution) was added to tissues and incubated for 2 h at 43 ℃. Slides were washed in buffer1 for 5 min (2 times) and buffer 2 (Tris-HCl, PH9.5, 100 mmol/L; NaCl 100 mmol/L, MgCl$_2$ 50 mmol/L) for 10 min. And then slides were transferred to NBT/BCIP solution to be stained for more than 2 h, and rinsed with distilled water. Tissue sections were mounted and evaluated by light microscopy.

RESULTS

HCC recurrence was found in 6 transplants from 98 transplanted rats. Of them, 3 grafts were discarded because the recipients have been dead when laparotomy. Thirteen lesions were obtained in other three available transplants, confirmed to HCC by pathological examination. These specimens were preserved at -70 ℃ as a bank for further utilization.

HCC cells carrying a positive reaction product (blue staining) were seen in control male rats. No signal was detected in the controls of female liver and system using non-labeled probe. Control trials showed that the *sry* gene specific probe was efficient.

Positive staining was seen in frozen sections of the 3 recurrent transplants. Typically, the probe was successfully hybridized with target gene on tumor cells, whereas failed to on para-tumor tissues. The capsule, aimed at by arrow, definitely parts the recurrent tumor from the recipient liver parenchyma under 10×10 magnification (Figure 1).

Figure 1 The blue blots under the purple background indicated Y chromosomes in these nuclei of recurrent tumor cells with 10×10 magnification microscope. The capsule definitely parted the recurrent tumor tissue from the recipient liver parenchyma. No positive signals were found out in the para-tumor tissue.

DISCUSSION

Liver transplantation for HCC in rats provides an excellent animal model to carcinogenesis investigation[9]. Intrahepatic tumors and underlying lesions are removed completely, and then some interventional trials could be executed etiologically. In our experiments, no immunosuppressants were administered because rejective reaction was weak in allotransplantation on syngenic SD rats. The promotion of immunosuppressants to tumor growth can be excluded. However, it remains indefinite that induction of HCC existed in recipients after the withdrawal of DENA[10]. There were two possible mechanisms of tumor recurring with the inclusion of disseminated tumor cells homing

into implanted liver and sequential contribution of DENA. Therefore, a marker is a key to discriminate between the two possibilities.

Cellular markers have been obtained through varieties of strategies such as transgenic animal, retroviral transduction. But these strategies are very complicated and low efficient. Discordant gender transplants offer the benefit of having 100% of the cells marked, as opposed to retroviral transduction, where at best only 5-10% of the cells are marked[11]. In our experience, Y chromosome, uniquely existed in male cell, was initially acted as a marker with which male and female tissues were differentiated. Y chromosome-specific probe was successfully hybridized with *sry* gene of which multiple copies facilitated this hybridization[7]. This i*n situ* hybridization system was proved to be reliable by positive and negative control we designed. Our results therefore indicated that the origin of recurrent HCC in female liver was from disseminated tumor cells in male recipient. We personally define this phenomenon that extrahepatic tumor cells go back to liver as "homing".

Other studies could support the homing hypothesis we proposed. (1). Alpha-fetoprotein (AFP) messenger RNA (mRNA) has been proposed as a marker of HCC cells disseminated into the circulation. Multiple molecular methods, such as nested and semi-quantitative retro-transcription polymerase chains reaction (RT-PCR), have been utilized to detect AFP mRNA in order to confirm the presence of hematogenous HCC cells. This marker expression in peripheral blood of patients with HCC indicates the existence of tumor cells, although it remains controversial that AFP mRNA is taken as an evidence of HCC recurrence[12-14]. (2). The homing of both lymphocytes and malignant hematic cells has been acknowledged[15,16]. Involved adhesion molecules that mediate their migration also contribute to invasiveness of liver cancer[16]. (3). Metastasis is the result of multiple sequential steps and is a highly organized, nonrandom, and organ-selective process[17]. A group of biological molecules is collectively responsible for determining whether tumor cells can progress from a single malignant cell to a metastatic disease[17]. But metastatic cells eventually colonize a particular organ that provides an optimal microenvironment[18,19]. It therefore is warranted that transplanted liver or regenerating liver after resection may be a particularly fertile ground for extrahepatic HCC cells to proliferate.

Figure 2 It is acknowledged that there exist two HCC recurring mechanisms of intrahepatic metastasis through portal venous system and multicentric occurrence from cirrhotic nodules. These extrahepatic cells homing into liver may be a

new mechanism after liver transplantation. Likewise, it implicates that this mechanism is responsible for HCC recurrence after hepatectomy.

On the basis of this experiment, we concluded that recurrent HCC after liver transplantation originated from the disseminated tumor cells. These extrahepatic cells homing into liver may be a new HCC recurrence mechanism. Likewise, it implicates that this new mechanism is responsible for HCC recurrence after hepatectomy besides MO and IM (Figure 2). But our experiment, to some extent, was to describe a homing phenomenon. Its real mechanism needs to be further investigated by molecular biology.

Abstract

AIM: Whether operative procedure is a risk factor influencing recurrence following resection of carcinoma in the head of pancreas or not remains controversies. In this text we compared the recurrence rate of two operative procedure: the Whipple procedure and extended radical operation, and inquired into the factors influencing recurrence after radical resection.

METHODS: From January 1995 to December 1998, 35 cases of carcinoma of pancreas underwent the Whipple operadure, 21 patients received the Extended radical operation. All patients were followed up for more than 3 years. Prognostic factors included operative procedure, size of tumor, lymph node, interstitial invasion.

RESULTS: Deaths duo to recurrence within 3 years after operation were studied. The death rate was 51.4% in the Whipple procedure and 42.9% in the Extended radical operative procedure. There was a significant difference between the two groups. Recurrence occurred in 75% patients with tumor large than 4 cm, in 87.5% patients with lymph node involvement, and in 50% patients with the presence of interstitial invasion.

CONCLUSION: Tumor exceeding 4 cm, lymph node involvement, and presence of interstitial invasion are high risk factors of recurrence after Whipple's procedure and extended radical operation.

INTRODUCTION

Recurrence of pancreatic cancer is common after operation. Intraabdominal recurrence ranged 38% to 86%[1-3]. Factors influencing recurrence in some studies included lymph node metastasis[4,5], tumor size[5,6], and tumor in surgical resection[5-7]. In the present study we retrospectively analysis 56 patients with carcinoma located in pancreatic head after operation in our department of surgery, The aim was to find the factors influencing recurrence following surgical resection for patients with pancreatic cancer hoping to improve the therapeutic results of carcinoma in the head of pancreas.

MATERIALS AND METHODS

Materials

Fifty six curative surgical resections were performed for pancreatic cancer in our department of surgery between January 1995 and December 1998. The patients did not receive any anticancer therapy before or after surgery.

Methods

Our radical procedures employed for carcinoma of pancreas was the Whipple operation in 35 cases, male/female ratio was 2.2:1(24/11), patients with an average of age were (57.3±4.6) years. According to the General Rules for Cancer of the Pancreas (4th edition, 1996), lymphatic clearance was limited to the regional lymph nodes immediately adjacent to the pancreatic head (D1-). In the pancreas, the line of resection was on the left border of the superior mesenteric vein. Extended radical operation (D2+) was performed in the other 21 cases, the male/female ratio was 2.5:1(15/6) with an average of age 58.9±5.1 years (Figure 1A and B). On the basis of n1 and n2 group and neighboring connective tissue clearance, the n3 group lymph nodes and soft tissues were properly cleared, nerve-plexus dissection around the retroperitoneum in 13 cases. Resection and reconstruction of the portal -vein system were performed in 6 cases, the line of resection of the pancreas was 1-2 cm outside the left border of the aorta.

The resected specimens were fixed in 40g/L formaldehyde solution, and sliced into 5 μm sections. Histologic sections were stained with hematoxylin and eoxin. We measure the maximum size of the tumor, metastasis in lymph nodes, and determined whether tumors extended directly beyond the posterior confines of the pancreas. The maximum tumor sizes were classified into four grades: $0 < t1 \leqslant 2$ cm, $2.0 < t2 \leqslant 4.0$ cm (t2), $4.0 < t3 \leqslant 6.0$ cm, and $t4 > 6.0$ cm. The lymph node involvement were gradeded into n0, n1, n2, and n3 accoding to the General Rules for Pancreatic Cancer Study (4th edition, 1996) proposed by the Japanese Pancreatic Society. The primary group included N_{06}: infrapyloric, N_{08}: anterosuperior nodes along the common hepatic artery, $N_{012inferior}$: inferior nodes along the proper hepatic artery, along the bile duct, and along the posterior to the portal vein, N_{013}: posterior surface of the head of pancreas, N_{01}: origins of the superior mesenteric artery, the inferior pancreaticoduodenal artery, and the middle colic artery along the first jejunal branch, and the the superior mesenteric vein, N_{017}: on the anterior surface of the head of pancreas. The second group included (N2): N_{09}: around the celiac artery, N_{011}: along the splenic artery, $N_{012superior}$: superior nodes along the proper hepatic artery, the bile duct, superrior to the portal vein, around the cystic duct, N_{016}: paraabdominal aorta. The third group (N3) included N_{03}: lessur curvature, N_{04}: greater curvature, N_{05}: suprapyloric, N_{07}: left gastric artery. Retroperitoneal invasion was classified into two grades Rp (+) and Rp(-) on the basis of whether the tumors extended directly beyond the posterior confines of the pancreas.

After surgery, all patients were followed up by serial determinations of plasma carcinoembryonic antigen (CEA), CA19-9, ultrasonograms and computed tomograms (CT) to determine whether and where cancer recurrence developed. The mode of clinical recurrence was classified into four types: hepatic metastasis (H), retroperitoneal recurrence (R), peritoneal dissemination (P), and distant metastasis (M). Retroperitoneal recurrence was divided into two subtypes: (1) local retroperitoneal recurrence was defined as infiltration of nerves, lymphatic vessels, and connective soft tissue, and (2) lymph node metastasis (LN).

The cumulative recurrence rate was analysed by using a χ^2 test. *P* value less than 0.05 was considered statistically significant.

RESULTS

No operative death occurred within 1 mo after excision. The follow-up period was more than 3 years for all patients of the two groups. In D1- group, 6 cases were lost to be followed, 7 cases died of other disesses unrelated to cancer within three years, the remaining 22 patients died of recurrence, of which 18 patients was dead within 3 years. In D2+ group, 2 patients were lost to be followed, 3 patients died of other diseases within

3 years, the remaining 9 patients died of recurrence within 3 years. The 3 years cumulative rate of death duo to recurrence was 51.4% in D1- group and 42.9% in D2+ group, there was a significant difference between the 2 groups (*P*<0.05). The histopathological backgrounds in patients who died of recurrence are showed in Table 1.

Recurrent styles
In D1- group at least more than 2 recurrent sites could be found. Eighteen patients had retroperitoneal recurrence, among them 7 patients were complicated with peritoneal dissemination, 2 patients were complicated with liver metastasis, and 1 patient was complicated with extroabdomen metastasis. In D2+ group, the major recurrent styles of were as fellows: hepatic metastasis alone or in combination with retroperitoneal recurrence (*n*=5), peritoneal dissemination alone or combined with abdomen lymph node enlargement (*n*=4), or combined with other organ out of abdomen cavity metastasis (*n*=1).

Histopathological diagnosis
The distribution of cases was histopathologically (Figure 2) based on 3 factors: maxinum tumor size, lymph node involvement, and interstitial invasion (Table 2).

**Figure 1** A: Ranges of lymphatic and neighboring connective tissure dissection n1, n2, and part of n3 group nodes were cleared with neighboring connective tissue, B: lymph node dissection around aorta, inferior vein,resection and reconstruction portal vein.

Figure 2 A: peritoneal dissemination, B: nerve invasion, C: cancer thrombus in lymphatic vessel, D: portal venious wall invasion. (HE original magnification×200).

Table 1 Histopathological findings in patients died of Recurrence

Operative procedure (No.of patients)	Maximum size				Nodal involvement				Interstitial invasion	
	t1	t2	t3	t4	n0	n1	n2	n3	Ii (-)	Ii (+)
D1$^-$	1/5	7/16	10/14	-	3/9	15/26	-	-	6/13	12/22
D2+	0/4	3/9	3/5	3/3	0/6	2/7	4/5	3/3	1/5	8/16

Table 2 Comparision of tumor Size, nodal involvement and interstitial invasion between two groups

Operative procedure (No.of patients)	Maximum size				Nodal involvement				Interstitial invasion	
	t1	t2	t3	t4	n0	n1	n2	n3	Ii (-)	Ii (+)
D1$^-$	5	16	14	-	9	26			13	22
D2+	4	9	5	3	6	7	5*	3**	2	19

*5 is positive also in n1, **3 is also positive in n1,and n2.

In D2$^+$ group, tumors were less than 2 cm in diameter (4 cases), one case had lymph-node metastasis, and 2 lymph node vessels and perineural invasion respectively. In t2 group, 77.8%(7/9) of cases was associated with lymph-vessel invasion. Perineural invasion was present in 88.9%(8/9) of the tumor, and loose connective tissue invasion occurred in 55.6%(5/9). Tumors larger than 4.1 cm were all associated with lymph-vessel, perineural, and loose connective tissue invasion. Metastatic rate of lymph node was 69.2% (n=15). Lymph node metastatic rate was 69.2% (n=15). Rates of histologically proved metastasis to individual lymph nodes observed in our series were as follows: N1: N_{06}: 23.8%(n=5), N_{08}: 14.4%(n=3), $N_{012inferior}$: 33.3%(n=7), N_{013}:33.3%(n=7), N_{014}:28.6%(n=6), N_{017}:33.3%(n=7); N2: N_{09}:14.4%(n=3), N_{011}:19.1%(n=4), $N_{012superior}$23.8%(n=5), N_{016}:23.8%(n=5); N3: N_{03}:0%, N_{04}:0%, N_{05}:14.4%(n=3), N_{07}: 13.3%(n=2). In tumors with negative lymph nodes, 5/6 had lymph-vessel invasion, and 4/6 had perineural invasion. The tumors with nodal involvement were all associated with lymph-vessel, perineural, and loose connective tissue invasion.

DISCUSSION

Argument existed about whether operative procedure on the risk factors influencing recurrence or not[8-11]. Factors that influence the recurrent rate after resection were the absence of lymph node involvement[12,13], and retroperitoneal invasion[14], and microscopic curative resection[12,14]. Such a procedure is also called Ro surgery. In our current study we confirmed that D2$^+$ procedure could decrease recurrence in compassion with D1$^-$. In D2$^+$ group we found there exists wide extension of nodal involvement,and 'interstitial invasion' required careful dissection. D1$^-$ procedure only provided simple lymphadenectomy limited to the region of the head of pancreas without resection of surrounding connective tissues, and dissection of the second and tertiary group lymph node was inadequate for the purpose of lymphatic clearance. Theoretically D2$^+$ procedure could achieve a microscopic curative resection[15,16]. Macroscopic curative resection has been proven to be microscopic noncurative resection by precise serial section analysis. Even the patients with microscopic curative resection had a surgical margin of only a few millimeters away from tumor[17], that could not assure avodance of future metastasis. Only in those with small (t1/t2), noninvasive lesions or slight retroperitoneal invasion, could D2$^+$ actually decrease recurrence. In those with t3/t4 tumors, even after extended lymphatic and soft tissue dissection that goes beyond the regional lymph-node stations, D2$^+$ procedure still has a higher recurrence.

The rate of recurrence in patients with t1 and t2 tumors generally was lower than that in those with t3 and t4 tumors

after D2$^+$ procedure. The collective recurrence rate in t3 and t4 tumors was 75%(6 of 8). Tumors larger than 4.1 cm were all associated with lymph-vessel and perineural invasions. Therefore, our conclusion is that the larger the tumor the more extensive infiltration within interstitial invasion and nodal involvement, or the higher the recurrent risk, this is in accord with that reported in the literature[18-21].

In comparision with D1$^-$, D2$^+$ procedure decreased recurrence in no and n1 group. There was a close relation between lymph node involvement and 'interstitial invasion'. Positive lymph node was often accompanied by lymph vessels invasion. Even if in pNo stage, lymph vessels invasion was present in 64% of the cases[19]. Lymph vessel invasion might imply lymphatic metastasis before cancer cells flowed into lymph nodes. If nodal involvement was found in n1 region, microinvasion had already occurred in the n2 region[22]. If n2 and n3 groups were invaded , the chance of distant recurrence was much increased.

Our study confirmed that pancreatic cancer tended to be accompanied by 'interstitial invasion' and positive of 'interstitial invasion' was a factor influencing recurrence. The so-called 'interstitial invasion' includes lymph vessel, nerves, and loose connective tissue invasions. The recurrence rate in patients with or without 'interstitial invasion' was 50% and 20%, respectively. The significance of nerve invasion has been annotated by other researchers[23-25]. Peritoneal dissemination after excision could not be treated by surgery alone, bcause cancer cells either as single cells or cell clumps were randomely allocated on the large area of loose connective tissue of the peritonum[26]. About 40% of patients had small distant metastases. Such metastases were typical 1-2 mm nodules located on the surface of the peritoneum[27]. So far as peritoneal dissemination concerned, there is no effective treatment. Even extensive lymph node dissection and resection of surrounding connective tissues and major vessels combined with radiotherapy and chemotherapy could not assure avoidance of recurrence up to now[28-30].

In summary, the long term survival following resection depends on decrease of recurrence. Therefore rationally standardized operative procedure with due to attention to factors of recurrence may help improve the long term survival of pancreatic cancer patients.

Abstract

AIM: To evaluate the efficacy and safety of lamivudine treatment of chronic hepatitis B disease in pregnancy.

METHODS: The study group was comprised of 38 chronic HBV patients who were diagnosed pregnant during lamivudine treatment and voluntary to continue the same therapy. The control group was from documented patient data in the literatures. We compared the following parameters with those of a control group: anti-HBV efficacy, complications of pregnancy (abortion, preterm birth, neonatal asphyxia, fetal death, and congenital anomaly), incidence of HBV-positive babies and developmental anomalies in pregnant women treated with lamivudine.

RESULTS: The blocking rate of lamivudine treatment was significantly higher than that of active vaccine immunization for babies with double-positive (HBsAg/HBeAg) mothers with 30-30-10 μg doses of vaccine (74.07%) and with 30-20-10 μg (64.87%). The natural vertical HBV transmission from mother to infant of "double-positive" mothers was 100% (10/10). No pregnancy complication was noted during the observation period, but in the control group the incidences of pregnancy complication were 16.67% (abortion), 43.02%(preterm), 15.62% (neonatal asphyxia), and 4.49% (fetal death), 10.0% (congenital anomaly). No HBV-positive newborn was detected and no developmental anomaly was found in the study group.

CONCLUSION: Lamivudine is helpful to prevent maternal-infant HBV transmission and may reduce the complications of HBV-infected pregnant patients.

INTRODUCTION

Throughout the world, over 300 million people have chronic hepatitis B virus (HBV) infection, and more than 75 percent of those affected are of Asian origin[1]. Chronic HBV infection causes cirrhosis, liver cancer, and death[2,3]. The disease is endemic in Africa and Asia, where the virus is transmitted from mother to newborn or between close contacts in early childhood[4-6].

Chronically infected persons with viral replication are at the highest risk for progressive liver disease[7]. In China, chronic HBV infection is a common clinical occurrence in pregnancy as well as a potentially serious condition[8]. In pregnant patients the complications of HBV occurr more frequently and with a higher mortality[9]. Also vertical transmission of HBV to the infant is common[4,5]. Perinatal transmission of HBV is the most important cause of chronic HBV infection and remains one serious problem despite passive immunization (hepatitis B immune globulin at birth) and active immunization (hepatitis B vaccination according to the standard 3-dose schedule). In different studies high maternal HBV DNA levels were associated with a vaccination breakthrough[10,11]. Recently nucleoside analogues have been used to prevent mother-to-infant transmission of HIV-1[12]. In that setting, lamivudine given during the last weeks of pregnancy in HIV-1 and HBV positive women appeared to be safe[12-15]. Following a similar rationale, there was a clinical trial about the use of lamivudine, a potent inhibitor of HBV replication, in pregnant women with high HBV viral loads in highly endemic countries[16].

However, few data are available regarding the efficacy and safety of lamivudine treatment for chronic HBV from the early phase of pregnancy. Pharmaceutical inserts regarding lamivudine indicate it is of "uncertain safety" during pregnancy. In this retrospective analysis, we evaluated 38 cases of chronic HBV pregnant patients treated with lamivudine from the early phase of pregnancy for pregnancy-related complications and congentital anomalies.

MATERIALS AND METHODS

Patients

Forty-two chronic HBV-infected women were found to be pregnant during lamivudine treatment and presented to the physician between 2-3 mo of gestation. Then they were enrolled in the study. During the study, one patient chose to terminate her pregnancy, two stopped lamivudine therapy, and one was lost to follow-up. Thus the final study consisted of 38 pregnant patients who continued lamivudine therapy. The pretreatment diagnosis of HBV was based on National Prevention and Treatment Profiles of Viral Hepatitis (2000)[17] criteria with the following criteria: detectable HBsAg and HBeAg/HBeAb in serum, detectable serum HBV DNA, and elevated alanine aminotransferase (ALT) levels (more than 3-4 times normal level). Patients were excluded if they had hepatitis C or D infection. Patients had not received any other antiviral drugs in the preceding 6 mo. All patients were warned about that studies in rabbits had demonstrated lamivudine to result in fetal demise. However, it was also explained that the dosages used in animal studies were nearly 60 times higher than those used in humans (private communication).

Currently there is a clinical trial in Asia evaluating lamivudine use perinatally in mothers with high HBV viral

loads with the goal to reduce vertical HBV transmission to the infants[13]. The patients who earlier stopped lamivudine often experienced significant clinical deterioration. Thus overall we felt it appropriate to consider continuing lamivudine therapy. HBV infection in pregnant women was more serious than in non-pregnant women[9]. All the above were informed to any pregnant patients with HBV infection. Decision was made by patient herself on whether to terminate lamivudine treatment or not.

The data of complications of HBV hepatitis and HBV-positive babies were based on Prevention and Treatment of Viral Hepatitis study edited by Gao[19]. Lamivudine safety profile was obtained from international studies[13-15,18].

Regimen and parameters

Pregnant women with chronic HBV infection were treated with lamivudine. The dosage, course, efficacy evaluation, follow-up, measures to deal with resistant mutation were based on the Guideline for Lamivudine Clinical Use (2000)[20] and Expert Consensus on Lamivudine Clinical Use (2001)[21]. Complications of pregnancy included abortion, preterm birth, neonatal asphyxia, fetal death, and congenital anomaly[19]. Regular ultrasonic examination was carried out to monitor the safety of the fetus. All newborns were given the standard passive-active immunization or actively immunized at birth. Twelve babies were tested of HVB DNA (PCR), HBsAg, HBeAg, anti-HBs, anti-HBe, anti-HBc at birth before HBIg administration (T_0) and at the 6th mo (T_6) and the 12th mo (T_{12}) after birth. The percentage of HBV-positive babies was calculated. The health status and development of babies were assessed by the local children healthcare institution. All children were followed-up and documented.

RESULTS

Antiviral efficacy

HBV-DNA was converted to negative in 35 patients (92.11%) of the study group. HBeAg was converted to negative in 12 patients (31.58%). The rate of HBeAg seroconversion (loss of HBeAg or development of antibody to HBeAg) was 26.32% (10/38). The normalization rate of ALT was 73.68% (28/38). The rate of resistant mutation was 11.43% (4/35). Lamivudine efficacy was similar to other reports in the international medical literatures[13-15]. ALT normalization may have been confounded by hepatic injury of pregnancy. Thus the complete efficacy of lamivudine was difficult to assess.

Incidence of HBV-positive baby (Table 1)

Twelve maternal-baby pairs were evaluated for HBV markers (HBsAg, HBeAg, anti-HBs, and anti-HBe,anti-HBc) before and after delivery. All 12 mothers were double positive (HBsAg/HBeAg) before lamivudine treatment. Although the HBV-DNA parameters of all 12 mothers were converted to negative prepartum, 8 mothers remained HBeAg-positive, 1 HBeAg negative, and 3 reached seroconversion. Of the 8 mothers who were HBeAg-positive at childbirth, 3 babies were HBsAg-positive at birth (T_0), but turned negative at T_6 and T_{12} postpartum. The other babies were all HBsAg- negative during 12 months of follow-up. Thus after one year, 100% of the babies were HBsAg-negative. But in control group, the blocking rates of active vaccine immunization for babies with double-positive (HBsAg/HBeAg) mothers were 74.07% with 30-30-10 μg doses of vaccine and 64.87% with 30-20-10 μg. The natural vertical HBV transmission from mother (double-positive) to infant was 100% (10/10)[19]. The prevention of HBV maternal-infant transmission was very significant in lamivudine-treated mothers.

Table 1 Blocking of maternal transmission in HBsAg and HBeAg double-positive mothers[19]

	n	HBsAg(+)			HBV-DNA(+)	Blocking rate
		T_0	T_6	T_{12}		
Lamivudine treatment	12	3	0	0	0	100.00
Vaccine 30-30-10 μg	81		21	21	21	74.07
Vaccine 30-20-10 μg	37		13	13	13	64.87
Natural transmission	10		10	10	10	0.00

Complications of pregnancy (Table 2)

The infants of lamivudine-treated mothers were delivered at full term without any complication. The incidence of pregnancy complication was lower in the study group than in the control group of pregnant mothers with chronic HBV[19].

Table 2 Complications of pregnancy in different groups [19]

	Abortion (%)	Preterm (%)	Neonatal asphyxia (%)	Fetal death (%)	Congenital anomaly (%)
Lamivudin	0/38	0/38	0/38	0/38	0/38
Control	16.67	43.02	15.62	4.49	10
	(1/6)	(37/86)	(14/89)	(4/89)	(1/10)

Control of viral hepatitis activity (Table 3)

Although three out of 38 patients in the study group did not convert to HBV-DNA-negative within one year, ALT normalized in all three patients. Ten patients in the study group converted to HBV-DNA-negative, but their ALT remained abnormal. They were included in the pregnancy liver injury group. Six patients were HBeAg-negative, and four patients had seroconversion for HBeAb. A resistant HBV mutant emerged in four cases though their ALT remained normal. Thus overall hepatitis activity was controlled in all the study patients (100%). In the two patients who quitted lamivudine after the consultation, active hepatitis recurred within 6 months. Honkoop *et al* reported that the incidence of "lamivudine withdrawal hepatitis" was 17% (7/41)[22]. Hepatitis activity was better controlled in lamivudine treatment group than in the group who quitted lamivudine therapy (Table 3).

Table 3 Control of hepatitis activity[22]

	n	Active hepatitis (%)
Lamivudine treatment during pregnancy	38	0 (0.00)
Stop lamivudine while pregnant	2	2 (100.00)
Stop lamivudine	41	7 (17.07)

Infant development and health

Community maternal-child health clinics failed to detect any unfavorable outcome related to the infant' s health and development.

DISCUSSION

It has been well-known that the pregnant women chronically infected with HBV have more complications and a higher mortality during pregnancy[5,8,9]. Lamivudine has been found to be an effective treatment strategy for chronic HBV[15]. However, its use is not recommended during pregnancy especially during the first trimester because animal studies have demonstrated lethal effects on the rabbit fetus (private communication). In our study 38 pregnant women with chronic HBV infection continued lamivudine therapy during the entire pregnancy. Their decision to continue its therapy was voluntary

after informed consent. They were all provided with information about the drug benefits and risks. Our results indicated lamivudine therapy not only provided a protective effect against maternal-infant HBV transmission, but decreased the likelihood of active HBV infection in the mother. Further complications were minimal compared with the control group. These results should be presented to a mother contemplating continuation of lamivudine therapy during pregnancy.

Pregnancy complications are likely caused by the activity of hepatitis B virus in mothers with chronic HBV infections. The rate of vertical maternal-infant HBV transmission was 90-100% in mothers who were double positive for both HBsAg and HBeAg[19]. It is probable that such a high transmisson rate has been led by the high viral load[10,11]. The data in our study indicated lamivudine was able to neutralize hepatitis activity and reduction in the viral load might result in fewer pregnancy complications and prevent maternal-infant HBV transmission. This benefit may well outweigh the risk of lamivudine's early toxic effects on the infant during the first trimester. Lamivudine has been found belonging to the L-form enantiomorph nucleotide analogue which is negatively selective for the human nucleotide[15]. Toxicity was detected only at very high dosages of 1 000 times higher than the recommended human dosages. The dosage used in animals was 60 times greater than that used in human (private communication). Thus currently recommended lamivudine dosages for human may represent little risk to the pregnant mother.

However, there are several concerns about our current study. First, our study was not designed as a randomized-placebo-controlled study, thus any improvement in the study group could be due to such confounding factors as "self-selection" bias, or observer bias. Second, the study group was small and thus might lack power to distinguish a true difference between the treated group and the control group. However, we do consider the study to be of value in raising the question of benefit of lamivudine treatment of chronic HBV in pregnancy. Further studies, especially larger well-designed placebo-controlled studies are needed to confirm a true beneficial effect of lamivudine therapy for chronic HBV infection in pregnancy.

Abstract

AIM: To evaluate the reliability of the *Helicobacter pylori* stool antigen test, ImmunoCard STAT HpSA, for detecting *H pylori* infection.

METHODS: Stool specimens were collected from 53 patients who received upper endoscopy examination due to gastrointestinal symptoms. ImmunoCard STAT HpSA was used to detect *H pylori* stool antigens. *H pylori* infection was detected based on three different tests: the urease test, Warthin-Starry staining and culture. *H pylori* status was defined as positive when both the urease test and histology or culture alone was positive.

RESULTS: Sensitivity, specificity, positive predictive and negative predictive values and the total accuracy of ImmunoCard STAT HpSA for the diagnosis of *H pylori* infection were 92.6% (25/27), 88.5% (23/26), 89.3% (25/28), 92% (23/25) and 90.6% (48/53), respectively.

CONCLUSION: The stool antigen test, ImmunoCard STAT HpSA, is a simple noninvasive and accurate test for the diagnosis of *H pylori* infection.

Li YH, Guo H, Zhang PB, Zhao XY, Da SP. Clinical value of *Helicobacter pylori* stool antigen test, ImmunoCard STAT HpSA, for detecting *H pylori* infection. *World J Gastroenterol* 2004; 10(6): 913-914

INTRODUCTION

Helicobacter pylori infection is a major cause of chronic gastritis and peptic ulcer, and is associated with gastric cancer and gastric MALT lymphoma[1-4]. There are several methods of diagnosing *H pylori* infection including invasive procedures using mucosa biopsies taken during endoscopy (mainly culture, histology and the rapid urease test) and noninvasive procedures (mainly ^{13}C or ^{14}C urea breath tests (UBTs) and serological tests). But invasive procedures suffer from biopsies and endoscopy, and the UBTs require expensive equipment or is harmful to patients. Because *H pylori* antibody titers fall very slowly even after successful eradication, tests lack of specificity and sensitivity[5-9]. Recently, the *H pylori* stool antigen (HpSA) test has been put in the market as another noninvasive technique[10-13], but has rarely validated in China[14]. The aim of this study is to evaluate the

clinical value of a new test, ImmunoCard STAT HpSA, for the diagnosis of *H pylori* infection.

MATERIALS AND METHODS

Patients
A total of 56 patients (33 males and 23 females, average age 43.7years old) participated in this study. Chronic gastritis and peptic ulcer were endoscopically diagnosed in 47 and 9 patients, respectively. Patients treated with antibiotics, bismuth, or proton pump inhibitors within 4 weeks preceding the study were excluded.

Methods
Invasive tests using mucosal biopsies including culture, histology (Warthin-Starry staining) and the rapid urease test (RUT) were used to establish the "gold standard", in order to evaluate the accuracy of the new stool antigen test, ImmunoCard STAT HpSA.

Mucosal biopsies for detecting Hp
During upper endoscopy, three gastric biopsies were taken. One biopsy was used for RUT and the remaining two were used for Warthin-Starry staining and culture. The gold standard for the presence of *H pylori* infection was defined when both RUT and Warthin-Starry staining or culture alone was positive. The absence of *H pylori* infection required all three tests to be negative.

ImmunoCard STAT HpSA
On the same day of endoscopy, patients collected stool into an air tight container. The stool assay was performed using the same test series of the ImmunoCard STAT HpSA (Meridian Diagnostics, Inc, USA). A small portion (5-6 mm diameter) of stool specimen was transferred into the sample diluent vial using the applicator stick, vortexed for 15 s, and then 4 drops were dispensed into the round window at the lower end of the device. The results were read 5 min later. Positive and negative results were judged as recommended by the manufactures. The endoscopy-based tests and HpSA test were carried out by different people with double blind procedures.

Statistical analysis
Sensitivity, specificity, PPV, NPV and accuracy of the kit were calculated according to the gold standard.

RESULTS

Altogether, 53 patients were enrolled and tested by ImmunoCard STAT HpSA and the endoscopy-based tests. *H pylori* infection was present in 27 patients as determined by the gold standard. The HpSA test produced positive and negative results in 28 and 25 patients, resepctively. Compared with the gold standard, the HpSA was inaccurate in five patients (three false positive, and two false negative), giving a sensitivity, specificity, positive predictive and negative predictive values and total accuracy of the ImmunoCard STAT HpSA of 92.6%(25/27), 88.5%(23/26), 89.3% (25/28), 92% (23/25) and 90.6%(48/53), respectively (Table 1).

Table 1 Performance of the ImmunoCard STAT HpSA test in the detection of *H pylori* infection, according to the biopsy-based gold standard

| ImmunoCard STAT HpSA | Gold standard | | Total |
	Positive	Negative	
Positive	25	3	28
Negative	2	23	25
Total	27	26	53

DISCUSSION

A variety of highly sensitive and specific tests are available to diagnose *H pylori* infection. Invasive tests using mucosal biopsies taken during endoscopy might lead to cross infection. In addition, some patients refuse to undergo endoscopy, especially after eradication therapy, due to its invasive nature. Fortunately, there are several noninvasive tests including ¹³C or ¹⁴C urea breath tests (UBT) and serological tests. The UBT tests are currently provn to have high sensitivity and specificity, and considered to be the optimal test for monitoring *H pylori* eradication therapy. However, ¹³C-UBT needs special equipment and is expensive, and ¹⁴C-UBT requires a radioactive isotope, and cannot be used for children and pregnant women. As a result, UBTs are not widely available. Therefore, it is necessary to find a new, easy, cheaper and accurate noninvasive test.

Gastric epithelial cells renew once in one to three days, and are output in feces with *H pylori*, which can be detected by polyclonal capture anti-*H pylori* antibodies. The HpSA was reported in America Gastroenterology Week in 1997, and put in the market by Meridian Company in the same year, with the name Premier Platinum HpSA. Premier Platinum HpSA is a microplate enzyme-immunoassay for the qualitative detection of *H pylori* antigens in human stool, and was approved by FDA to be used in clinic in 1998. The HpSA test has been widely evaluated around the world, with a weighted mean sensitivity and specificity of 90-98%, respectively[13,15,16]. The HpSA test is a cheap and useful method for the diagnosis of *H pylori* infection before and after eradication therapy[17,18]. It is an accurate test in all age groups of children too[19]. However, Peitz *et al* reported that the diagnostic accuracy, in particular the sensitivity, of the HpSA stool test was reduced by upper gastrointestinal bleeding, and a negative test result should be confirmed by a further diagnostic method[20,21]. Although the HpSA test seems to be less accurate than the UBT, both UBT and stool antigen tests are reliable noninvasive tests for monitoring the efficacy of *H pylori* eradication therapy.

A novel easier stool antigen test named ImmunoCard STAT HpSA has recently been put in the market by Meridian Company. This test was first reported to have an sensitivity of 96.1% and specificity of 90.6% at Gastrointestinal Pathology and *Helicobacter* Conference in 2002 in Athens, but and have not been reported since. In the present study, we conclude that the ImmunoCard STAT HpSA test has a diagnostic value comparable to the gold standard in detecting *H pylori*. The sensitivity and specificity of the ImmunoCard STAT HpSA for the diagnosis of *H pylori* infection were 92.6% and 88.5%, respectively, with an accuracy of 90.6%. Because it is easy and convenient to perform, the ImmunoCard STAT HpSA could be used at many situations, especially for children, pregnant women, old people and others who are not suitable for endoscopy. The ImmunoCard STAT HpSA is an ideal test for the diagnosis of *H pylori* infection in clinical practice.

Abstract

AIM: To evaluate hepatic reserve function by investigating the change of functional hepatic flow and total hepatic flow in cirrhotic patients with portal hypertension.

METHODS: HPLC method was employed for the determination of concentration of D-sorbitol in human plasma and urine. The functional hepatic flow (FHF) and total hepatic flow (THF) were determined by means of modified hepatic clearance of D-sorbitol combined with duplex doppler color sonography in 20 patients with cirrhosis and 10 healthy volunteers.

RESULTS: FHF, evaluated by means of the D-sorbitol clearance, was significantly reduced in patients with cirrhosis in comparison to controls (764.74±167.91 vs 1 195.04±242.97 mL/min, $P<0.01$). While THF was significantly increased in patients with cirrhosis in comparison to controls (1 605.23±279.99 vs 1 256.12±198.34 mL/min, $P<0.01$). Portal blood flow and hepatic artery flow all were increased in cirrhosis compared to controls ($P<0.05$ and $P<0.01$). D-sorbitol total clearance was significantly reduced in cirrhosis compared to control ($P<0.01$), while D-sorbitol renal clearance was significantly increased in cirrhosis ($P<0.05$). In controls FHF was similar to THF (1 195.05±242.97 vs 1 256.12±198.34 mL/min, $P=0.636$), while FHF was significantly reduced compared with THF in cirrhosis (764.74±167.91 vs 1 605.23±279.99 mL/min, $P<0.01$).

CONCLUSION: Our method that combined modified hepatic clearance of D-sorbitol with duplex doppler color sonography is effective in the measurement of FHF and THF. FHF can be used to estimate hepatic reserve function.

INTRODUCTION

The management of portal hypertension in patients with liver cirrhosis is still a therapeutic challenge[1]. Liver failure and variceal bleeding are the chiefly causes that lead to death in cirrhosis. Now surgical devascularization and shunting play an important role in treatment of portal hypertension. Though operation is useful in controlling variceal bleeding, the mortality of operation is very high. Some cirrhotic patients can not bear the strike of operation and anaesthesia because of inadequate hepatic reserve function. So the evaluation of hepatic reserve function preoperatively is very important, in addition to proper perioperative management. At present the evaluation of clinical severity of cirrhosis is mostly based on the Child-Pugh score. However, such an approach can not directly provide reliable quantitative evaluations of the integrity and functional reserve of the hepatic parenchyma because the parameters are not very specific and test sensitivity is sometimes too low to detect mild liver alteration[2]. Recently several studies[3-10] have considered that hepatic clearance of D-sorbitol was a valid procedure in determination of FHF, by which hepatic reserve function could be estimated. The aim of this study was to measure THF and FHF of control subjects and patients with cirrhosis by means of duplex doppler color sonography combined with modified hepatic clearance of D-sorbitol and then to evaluate the hepatic reserve function.

MATERIALS AND METHODS

Patients

This study was carried out on 20 patients with cirrhosis and portal hypertension. The diagnosis of cirrhosis was established by liver biopsy intraoperatively. Fourteen patients with cirrhosis were males and six were females. They ranged in age from 35 to 73 years. The etiology of the disease was virus-related in 19 cases and drug-induced in the remaining one. The exclusion criteria were: patients with a variceal bleeding in the previous four weeks; those on portal-pressure-lowering drugs; those with portal and splenic vein thrombosis; those with severe ascites.

Ten subjects that without any clinical or laboratory evidence of liver disease served as controls. They were matched with the patients with cirrhosis for sex, age and body surface area. All patients gave their informed consent before participation in this study, which was performed according to the Helsinki Declaration.

Measurement of THF

Duplex doppler measurements of the portal vein and common hepatic artery were obtained using a real-time electronic sector scanner and a pulsed doppler unit.

All the patients and controls were kept fasting overnight prior to the procedure. They were examined in the supine position and were asked to hold their breath during the doppler recording. The portal vein was scanned longitudinally, and the sample volume was positioned in the middle of the portal trunk. The hepatic artery measurements were taken where a straight stretch ran parallel to the portal vein, some centimeters away from the coeliac axis. Care was taken to maintain the angle at below 55º. Portal vein and hepatic artery flow were determined by multiplying the mean blood velocity (V mean) by the sectional area (πr^2). Total hepatic flow was calculated as the sum of portal flow and hepatic artery flow.

Measurement of FHF

All tests were carried out at rest after an overnight fast. The sterile pyrogen-free 5% water solution of D-sorbitol (Fluka,

US) was intravenously infused at a constant rate of 50 mg/min. The steady-state regimen would be achieved after 2-h of continuous infusion[11]. Three blood samples were taken from peripheral vein at about 15-min intervals between 135 and 165 min after the start of the infusion. Urine samples were spontaneously collected for a 1-h period between 120 and 180 min during the infusion. FHF was determined on the basis of the hepatic clearance of SOR, as previously described by Molino[8].

Analyses

Blood and urine samples were centrifuged at 2 500 r/min for 15 min and the supernatants were stored at -40 ℃ until analysis. All samples were thawed before concentration measurement, then deproteinized by means of super-filter.

HPLC method was employed for the determination of concentration of D-sorbitol in human plasma and urine. The HPLC system (Waters) consisted of a pump, an injector and a fluorescence-detection (4210). The extracts of samples were chromatographed on a CORGEL-87P column that was kept at 85 ℃ and monitored by fluorescence-detection. The mobile phase was H_2O at a flow-rate of 1.0 mL/min. All data were treated according to the formula described by Molino[8].

Statistical analysis

All the data are expressed as mean±SD The statistical analyses were performed by means of two-sample t-test and paired t-test.

RESULTS

The results are shown in the Table 1. All the tests were performed on 20 patients with cirrhosis and 10 healthy controls and all subjects tolerated the procedure without complications or side effects. As expected, FHF, evaluated by means of the D-sorbitol clearance, was significantly reduced in patients with cirrhosis in comparison to controls (764.74±167.91 vs 1 195.05±242.97 mL/min, $P<0.01$). While THF was significantly increased in patients with cirrhosis in comparison to controls (1 605.23±279.99 vs 1 256.12±198.34 mL/min, $P<0.01$).

Portal blood flow and hepatic artery flow were increased in cirrhosis compared to controls ($P<0.05$ and $P<0.01$). D-sorbitol total clearance was significantly reduced in cirrhosis compared to control, while D-sorbitol renal clearance was significantly increased in cirrhosis ($P<0.01$).

In controls FHF and THF were similar (1 195.05±242.97 vs 1 256.12±198.34 mL/min, $P=0.636$), while FHF was significantly reduced compared to THF in cirrhosis (764.74±167.91 vs 1 605.23±279.99 mL/min, $P<0.01$).

DISCUSSION

Liver cirrhosis is the final pathologic and clinical expression of a wide variety of chronic liver diseases. The commonest causes of cirrhosis are chronic hepatitis B or C virus infection (nearly 90% of the total cases of cirrhosis in China). Pathophysiologically, the clinical manifestation of liver cirrhosis arises from the occurrence of two major events: hepatocellular insufficiency and portal hypertension[12]. In cirrhosis, portal hypertension develops as a result of an increased sinusoidal or post-sinusoidal portal resistance to blood flow, due to the loss of normal hepatic architecture and collagenization of the space of Disse[13,14]. The major pathophysiologic consequences of portal hypertension include portal-systemic collaterals formation, ascites and splenomegaly. The gastric and esophageal varices constitute the major cause of life-threatening digestive tract bleeding in cirrhosis. Now surgical devascularization and shunting play an important role in management of the complications of portal hypertension. Though operation is effective in controlling bleeding, the mortality of operation is still higher as some patients can not bear the strike of operation and anaesthesia due to inadequate hepatic reserve function. Recently some study discovered that the patients whose liver volume was decreased by 40% and the hepatic clearance of D-sorbitol was below 600 mL/min would have a higher incidence of postoperative complication[15]. Therefore it is of much importance to evaluate the hepatic reserve function preoperatively for the selection of operation approaches and the timing of operation.

FHF may be defined as the blood perfusing the liver that makes contact with functioning hepatocytes. The most widely used procedures to assess FHF are based on the clearance technique. But the test compound must not be eliminated by any organ other than the liver, must not re-enter the circulation once it has been eliminated, and has relatively high hepatic intrinsic clearance. To date, no compound has fulfilled these requirements completely. D-sorbitol, a naturally occurring polyol with prevailing hepatic metabolism, is almost completely extracted by the liver during the first-pass, and extrahepatic elimination is negligible[16]. Reproducible first-order kinetics and flow-depended principle were demonstrated for D-sorbitol in previous studies[2,10,11,17]. D-sorbitol had an exceptionally high extraction ratio in the normal liver (approaching 100%)[16,17], even in the presence of a severely impaired liver function, so we might consider that hepatic clearance of D-sorbitol very closely approximates total hepatic flow. While in cirrhosis, the hepatic clearance of D-sorbitol is less than total hepatic flow due to intrahepatic shunting. The

Table 1 Results of Duplex doppler and D-sorbitol clearance in 20 patients with liver cirrhosis and 10 healthy controls

	Controls	Cirrhosis	P
Portal blood flow (mL/min)	960.35±220.86	1 181.10±279.79	<0.05
Hepatic artery flow (mL/min)	295.77±82.59	424.13±116.89	<0.01
Total hepatic flow (THF) (mL/min)	1 256.12±198.34	1 605.23±279.99	<0.01
THF per kg b.w. (mL/min)	20.14±3.51	25.12±4.40	<0.01
D-sorbitol concentration in blood (mg/dl)	4.15±0.81	6.05±1.22	<0.01
D-sorbitol total clearance (mL/min)	1 246.72±242.59	857.22±167.61	<0.01
D-sorbitol urinary elimination rate (mg/min)	2.16±1.0	5.58±2.76	<0.01
D-sorbitol renal clearance (mL/min)	51.67±19.96	92.48±48.66	<0.05
Functional hepatic flow(FHF) (mL/min)	1 195.05±242.97	764.74±167.91	<0.01
FHF per kg b.w. (mL/min)	19.18±4.28	12.07±2.40	<0.01

The data are expressed as mean±SD.

difference between THF and FHF can be assumed to be a parameter reflecting intrahepatic shunting.

Generally THF was measured by means of the hepatic extraction of D-sorbitol and indocyanine green, according to the Fick's principle[4,10]. But the procedure, which needs hepatic vein catheterization is invasive and difficult to popularize. In addition, direct measurements of total hepatic flow through the hepatic artery and the portal vein have been achieved with electromagnetic flow probes or laser doppler flow meter[18]. But the technique is applicable only during surgical procedures, which severely limits its usefulness. Recently the technique of duplex doppler color sonography has been gaining increasing popularity in the measurement of hepatic blood flow and found to be a safe, reproducible, noninvasive and fairly accurate method[19-22].

There are still large variabilities in determination of FHF and THF by means of hepatic clearance of D-sorbitol and duplex doppler color sonography because of limitation of techniques and operations. To the former, the measurement of concentration of D-sorbitol is difficult. A small error of D-sorbitol concentration will lead to a large variability of final outcome. The concentration of D-sorbitol in plasma and urine used to be determined by an enzymatic-spectrophotometic method. It needs an enzymatic oxidation and deoxidization reaction since there is no absorption of ultraviolet for D-sorbitol. The concentration of D-sorbitol is determined indirectly following the measurement of fluorescence intensity of NADH1 that produced in reaction. While the attenuation of fluorescence and the incompleteness of reaction will result in certainty errors. To minimize these errors, we first established the method that measured the concentration of D-sorbitol by the use of HPLC and made the standard concentration curve. The data obtained in our study are in agreement with previous observations[2,3,9]. Moreover, there is smaller standard error than that of other studies due to absence of extremely big or small data. In the latter, the errors stem from uncertainty in the measurement of blood velocity, vessel caliber and the possible non-circular shape of the cross-sectional area of the vessel. To minimize these errors, the examination was always performed by the same investigator, who had more than 5 years' experience in doppler examination of deep vessels and was unaware of the clinical diagnosis of the subject, and following strict guidelines during the operation.

The results of our study showed that THF was similar to FHF in controls (1 256.12±198.34 *vs* 1 195.05±242.97 mL/min, *P*=0.636), which support the measurement of FHF and THF by non-invasive techniques. However, since D-sorbitol hepatic extraction was never completed, the FHF slightly underestimated THF in controls. In cirrhosis, the FHF was significantly decreased, while doppler-assessed THF was increased, indicating that a part of the portal flow was diverted through intrahepatic shunts or a substantial impairment of the functional integrity of hepatocytes[23]. In this case simultaneous assessment of these two non-invasive parameters could be useful to quantify functional shunting in cirrhosis. As expected, portal vein and hepatic artery blood flow were increased in cirrhosis in comparison to controls respectively, suggesting a hyperkinetic systemic circulation with a high cardiac output and decreased total peripheral vascular resistance. Though the THF was preserved or increased, the FHF was still reduced. This is thought to be due to reduced FHF and a compensatory increase in THF to maintain hepatic perfusion. In addition, we measured the FHF and THF in six patients with liver cirrhosis before and after transjugular intrahepatic portosystemic shunt (TIPS). We discovered that the THF measured one week after TIPS was more than that of before TIPS, while FHF was reduced significantly in all subjects. It may be considered that the reduction of portal vein pressure and increase in

portosystemic shunting caused by TIPS are associated with the reduction of hepatic perfusion, which can partly explain the high incidence of hepatic encephalopathy in patients with liver cirrhosis[24-26].

Abstract

AIM: To study clinical characteristics and management of patients with early severe acute pancreatitis (ESAP).

METHODS: Data of 297 patients with severe acute pancreatitis (SAP) admitted to our hospital within 72 h after onset of symptoms from January 1991 to June 2003 were reviewed for the occurrence and development of early severe acute pancreatitis (ESAP). ESAP was defined as presence of organ dysfunction within 72 h after onset of symptoms. Sixty-nine patients had ESAP, 228 patients without organ dysfunction within 72 h after onset of symptoms had SAP. The clinical characteristics, incidence of organ dysfunction during hospitalization and prognosis between ESAP and SAP were compared.

RESULTS: Impairment degree of pancreas (Balthazar CT class) in ESAP was more serious than that in SAP (5.31±0.68 vs 3.68±0.29, $P<0.01$). ESAP had a higher mortality than SAP (43.4% vs 2.6%, $P<0.01$), and a higher incidence of hypoxemia (85.5% vs 25%, $P<0.01$), pancreas infection (15.9% vs 7.5%, $P<0.05$), abdominal compartment syndrome (ACS) (78.3% vs 23.2%, $P<0.01$) and multiple organ dysfunction syndrome (MODS)(78.3% vs 10.1%, $P<0.01$). In multiple logistic regression analysis, the main predisposing factors to ESAP were higher APACHE II score, Balthazar CT class, MODS and hypoxemia.

CONCLUSION: ESAP is characterised by MODS, severe pathological changes of pancreas, early hypoxemia and abdominal compartment syndrome. Given the poor prognosis of ESAP, these patients should be treated in specialized intensive care units with special measures such as close supervision, fluid resuscitation, improvement of hypoxemia, reduction of pancreatic secretion, elimination of inflammatory mediators, prevention and treatment of pancreatic infections.

INTRODUCTION

Despite considerable improvement in the treatment of severe acute pancreatitis (SAP), the mortality of the disease still ranges between 15-25%[1-3]. Multiple organ dysfunction syndrome (MODS)[4-7], the extent of necrotic pancreatic parenchyma and the presence of bacterial infection have been identified as major determinants for death[8,9]. A number of such patients developed pancreatitis-associated intractable organ failure during the early course of SAP, and no effective treatment methods were available, the mortality was up to 40-60%[3,10,11]. For the purpose of assessing the clinical course and management of these specific severe pancreatitis, we defined these severe acute pancreatitis with presence of organ dysfunction within 72 h after onset of symptoms as early severe acute pancreatitis (ESAP)[12]. In this paper, we analyzed the clinical features of 69 cases of ESAP and discussed the key of ESAP management.

MATERIALS AND METHODS

Clinical data

From January 1991 to June 2003, a total of 297 patients with SAP were treated in our hospital, including 140 males and 157 females (average age 58.53, from 15 to 79 years). Among them 69 cases were with organ dysfunction within 72 h after onset of symptoms, and 228 cases without organ dysfunction.

SAP and organ dysfunction definitions were adopted from the Atlanta Classification System for SAP[13]. All patients received standardized intensive care treatment as the following: (1) Supportive care including maintaining circulation volume, nutritional supplements, prophylactic antibiotics for pancreatic infection, oxygen supplementation, and mechanical ventilation, as well as monitoring for respiratory, cardiovascular and renal insufficiency and correcting them early. (2) To ' rest the pancreas' by fasting with nasogastric drainage to remove gastric secretions and by using anticholinergic agents or H_2-blocking agents and somatostatin to inhibit pancreatic secretion. (3) Multiple measures were taken early for accelerating the recovery of gastrointestinal function. (4) Infectious necrosis of pancreas was identified by dynamic contrast-enhanced CT. (5) Oddi's sphincterotomy and nasobile drainage were performed for biliary pancreatitis accompanied by bile duct obstruction. (6) Surgical treatment (necrosectomy with drainage and continuous postoperative lavage of the lesser sac) was performed if infected pancreatic necrosis was identified or if the patient did not respond to maximal intensive care treatment over a period of more than 72 h.

Patients were divided into two sub-groups: ESAP with organ dysfunction and SAP without organ dysfunction within 72 h after onset of symptoms. APACHEII score, Balthazar CT class, number of organ dysfunction and rate of pancreatic infection in both groups were analyzed retrospectively.

Statistical analysis

Measurement data was expressed as mean±SD, the difference between the groups was analyzed with Student's t test. Quantitative data was analyzed with Chi-square test. To identify the risk factors for ESAP, multiple logistic regression analysis with backward elimination was used. The level of significance was $P<0.05$.

RESULTS

ESAP characteristic

Data of 297 SAP are given in Table 1. The mean time between onset of symptoms and hospital admission was 25.64 h. Mortality of ESAP was higher than that of SAP, early death rate (within 1 wk) was 53.3%(16/30) in ESAP and 33.3%(2/6) in SAP respectively. Pulmonary failure was the most frequent organ dysfunction in ESAP. Compared with SAP group, the different types of organ dysfunction were observed more frequently in the ESAP group. The hospital course of patients with ESAP was characterized by a high incidence of progressive MODS (Table 2).

Table 1 Comparison of clinical characteristics between ESAP and SAP

Factor	ESAP group	SAP group
Age (year)	58.95±5.51[a]	60.12±5.16
Sex (M/F)	38/31[a]	102/126
Hours between onset and admission	24.72±5.21[a]	26.04±4.03
APACHE II at admission	16.6±0.72[b]	9.4±0.45
Impairment degree of pancreas (Balthazar CT class)	5.31±0.68[b]	3.68±0.29
Hypoxemia (%)	59(85.5)[b]	57(25)
ACS (%)	54(78.3)[b]	53(23.2)
Fever (T>38.5 °C)(%)	38(55.1)[b]	55(24.1)
Pancreas infection (%)	11(15.9)[a]	17(7.5)
Other infections (%)	40(57.9)[b]	41(17.9)
Non-effective after 48 h ICU treatment (%)	42(60.8)[b]	27(11.8)
Surgical treatment (%)	18(26.1)[b]	15(6.5)
Death (%)	30(43.4)[b]	6(2.6)
Death within 3 d	7	1
Death within 1 wk	16	2
Death after 1 wk	14	4
Mean hospitalization (d)	44.72±42.15[1]	21.26±23.66

Features of victim in ESAP

Table 3 shows the features of death cases of ESAP. Multiple logistic regression analysis with backward elimination revealed that hypoxemia, higher APACHE II score, MODS and the extent of pancreatic necrosis were high risks for ESAP death.

DISCUSSION

With the advance in SAP study over the years, that the occurrence of early organ dysfunction is correlated with cascade response which gives rise to inflammatory mediators such as cytokine has been recognized gradually[14-16]. The effect of cytokine on the early stage of SAP should be emphasized. In fact, ESAP, a special critical type of SAP, is manifested as sharp changes during the early stage of SAP of non-stable vital signs and early organ dysfunction. Isenmann and Beger reported a group of SAP cases admitted to hospital within 72 h after onset of abdominal pain with organ dysfunction, which was defined as ESAP, and the mortality rate was up to 42%[12]. According to Mckay's data[11], 40% of all death occurred within 3 d in SAP. In our data, the mortality rate was 23.3% (7/30) in ESAP group within 3 d and 53.3%(16/30) within 1 week. This indicated that ESAP was the higher risk group of acute pancreatitis death. Therefore it is very important to understand the characteristics of ESAP, which were mainly summarized as: a short disease course with progressive multiple organ dysfunction; early hypoxemia; a higher incidence of abdominal compartment syndrome; a higher incidence of infected pancreatic necrosis; and higher CT score of pancreatic changes. ESAP is a critical type of SAP with a high early mortality rate and poor prognosis. High-risk factors of mortality in ESAP group are early hypoxemia and multiple organs dysfunction.

Because there is an extremely high risk of progressive MODS, as well as an extremely high mortality rate in ESAP, ESAP patients should receive maximal intensive care treatment for organ dysfunction. First of all, our data showed that hypoxemia occurred in 85.5% ESAP. For correcting hypoxemia, all patients were given positive end-expiratory pressure (PEEP) early. Respirator respiration through tracheal intubation should be used if hypoxemia can not be improved after 4-6 h. The principle of respirator use is ' to use early and to stop early', the oxygen concentration should be lower than 40%. The most important change of respiration system is ARDS. Pulmonary infection may be present due to ARDS, and even pulmonary infection may become the main reason for deterioration in ESAP. Monitoring of occurrence and progression of ARDS should be emphasized. Secondly, abdominal compartment syndrome (ACS) will be established if intra-abdominal pressure is higher than 15 mmHg (2kPa) with low cardiac output and progressive oliguria, and hypoxia occurred even if the airway peak value is normal or higher. Our result showed that higher pressure of abdominal cavity was presented in 78.3% ESAP. Higher pressure of abdominal cavity may damage the function of lung, heart, kidney and liver, inducing or exacerbating organ dysfunction. Abdominal decompression is the only way treating ACS. ACS can be divided into two types: one is present as ascites, peritoneal lavage or drainage can not only reduce the higher intra-abdominal pressure by using laparoscope but can also reduce systemic inflammation by diluting and draining abdominal exudates which contained pancreatic juice and cytokines. Another type of ACS is the result of enteroparalysis and gastrointestinal (GI) pneumatosis. Recovery of GI function is very important. We usually use purgative agents such as magnesium sulfate or Dahuang decoction (TCM) for accelerating GI function. These agents can promote GI peristalsis, decrease the intra-abdominal pressure, combat bacteria infection, protect the barrier function of GI tract, decrease translocation of bacterial and endotoxin and accelerate

the ascites absorption. Also, magnesium sulfate can reduce the opportunity of bacterial infection by promoting bile excretion and pancreatic juice excretion. Additionally, Pixiao can draw ascites out of peritoneal cavity. Our results indicated that the earlier the ACS was relived, the better the prognosis was. Thirdly, most ESAP cases had systemic inflammatory response syndrome (SIRS), which is the result of interaction of multiple inflammatory cytokines and has no specific therapeutic treatment modality. Hemofiltration has the effect of stabilizing hemodynamic and homeostasis, cleaning excess inflammatory factors such as cytokines, improving the function of heart, lung and kidney, and reducing the degree of illness[17-20]. We treated 25 ESAP patients with SIRS by hemofiltration at the early stage and obtained satisfactory (Data not shown). Fourthly, our data showed that the prognosis of early non-organ dysfuncion group was satisfactory based on the same treatment principle and the mortality rate was just 2.6%. In the absence of evidence for pancreatic necrosis, SAP should be treated by non-surgical treatment if the condition is stable[21-25]. Owing to the unstable condition in ESAP, the mortality rate may increase because of operation[26]. Surgical treatment would be considered when: (1) Higher intra-abdominal pressure is not resolved or ascites is increased after 8-12 h' therapy. (2) Dynamic CT examination indicates the evidence of severe pancreatic lesion or inflammatory necrosis. As conventional operation may make patient's condition worse at this stage, we proposed the method with minimal interruptions on body function such as peritoneal lavage under laparoscope, posterior peritoneal or paracolici sulci drainage to avoid systemic circulation or metabolism disturbances. The emphasis of surgery is peritoneal drainage and relief of intraabdominal pressure. Our data indicated that the outcome was better than simple conservation group and the mortality rate was reduced. Fifthly, prophylactic antibiotic was used early. All patients were given antibiotics once SAP was diagnosed. Antibiotics which can pass the blood-pancreas barrier and have effect on normal gut bacteria were first of choice. In general, Tienam or third generation cephalosporin with flagyl was applied. Sometimes, antibiotic was given by using arterial catheterization so that the pancreas could encounter higher drug concentration. Sixthly, low molecular weight heparin and Alprostadil can improve the microcirculation in pancreas[27,28]. We usually used these agents early. Lastly, nutritional support should be applied under the circumstance of stable systemic condition[29,30]. In general, we used parenteral nutrition (PN) at early stage. Enteral nutrition (EN) was used through jejunum once gut function recovered. EN can maintain gut mucosa barrier function, prevent or reverse the damage of gut mucosa barrier.

As our knowledge about the pathogenesis of systemic complications of ESAP is limited, patients with early organ dysfunction still remain a serious problem. The mechanism of ESAP and effective therapy still pose a challenge for future study.

Abstract

AIM: To assess the clinical significance of the D-dimer levels and the relationship between plasma D-dimer levels and clinicopathologic parameters in operable colorectal cancer patients.

METHODS: The plasma levels of D-dimer were measured pre- and postoperatively in 35 patients with colorectal cancer, and 30 healthy subjects served as controls by the method of quantitative enzyme-linked immunosorbent assay (ELISA).

RESULTS: The mean preoperative plasma levels of D-dimer in the patients with colorectal cancer (1.06±0.24 mg/L) were significantly higher than those of controls (0.33±0.12 mg/L, $P<0.01$). The D-dimer levels were remarkably elevated on the 1st day after operation (1.22±0.55 mg/L, $P<0.01$). On the 3rd day the level of D-dimer began to stepwise descend and on the 14th day nearly returned to control level. The preoperative levels of D-dimer were significantly correlated with the lymph node metastasis and Dukes stage but had no association with tumor location and the degree of differentiation. A stepwise increase in the mean D-dimer levels was found with increase of the tumor stage.

CONCLUSION: Hypercoagulation and higher fibrinolytic activities occur in patients with colorectal cancer. The operative trauma could enhance the fibrinolysis in the patients with colorectal cancer. The measurement of preoperative D-dimer levels is considered to be useful for predicting lymph node metastasis and stage of colorectal cancer.

INTRODUCTION

Activation of coagulation and fibrinolysis is known to be frequently associated with malignancy, although the mechanism involved has not been fully clarified. The extent of such activation has been reported to correlate with tumor stage and prognosis in some malignancies, including colorectal cancer[1-3]. D-dimer is a stable end-product of fibrin degradation and levels of D-dimer are elevated by enhanced fibrin formation and fibrinolysis. It is a marker of hypercoagulable stage. D-dimer levels are elevated in the plasma of various solid tumor patients[4,5]. The present study was to assess the clinical significance of the D-dimer levels and the relationship between plasma D-dimer levels and clinicopathologic findings in pre and post operative patients with colorectal cancer.

MATERIALS AND METHODS

Patients
Thirty-five patients with colorectal cancer were investigated. There were 21 males and 14 females, with a median age of 52 years, ranging from 32 to 75 years. Patients with cerebro, cardiovascular and diabetes were excluded. Meanwhile, 30 healthy subjects served as controls (17 males and 13 females, median age 56 years, ranging from 33 to 86 years).

Measurement of plasma D-dimer
Five milliliter of whole blood was drawn from antecubital vein of patients on the day prior to operation and on the 1st, 3rd, 7th, 14th postoperative days, using 3.8g sodium citrate collection tube. All samples were centrifuged within 4 h of veinpuncture, the plasma components were pipetted off and placed in plastic tubes. Centrifuged plasma was stored at -80 ℃ until assay. Meanwhile 30 samples of healthy subjects served as controls. Plasma D-dimer levels were determined by quantitative enzyme-linked immunosorbent assay (ELISA).

Statistical analysis
Statistical analysis of mean value of D-dimer levels was made by Student's *t* test and Student Newman-keuls's test. $P<0.05$ was considered to be significant.

RESULTS

Relationship between plasma D-dimer levels and clinicopathologic parameters
The D-dimer levels of colorectal cancer patients with positive lymph nodes were significantly higher than that of negative lymph nodes (0.94±0.26 *vs* 1.15±0.12, $P<0.01$, Table 1). A stepwise increase in the mean D-dimer levels was found with the increase of tumor clinical stage. There was no association between D-dimer levels and tumor location or degree of the differentiation.

Pre- and postoperative plasma D-dimer levels in colorectal cancer patients
The mean plasma levels of D-dimer in the patients with colorectal cancer were significantly higher than that of the controls ($P<0.01$, Table 1). It was also observed that D-dimer levels were remarkably elevated on the 1st day after the operation ($P<0.01$). On the 3rd day after operation the D-dimer levels began to stepwise descend and on the 14th day almost returned to control ($P>0.05$).

Table 1 Relationship between plasma D-dimer levels (mean±SD) and clinicopathology variables

	Course (d)	Clinicopathology		n	D-dimer (mg/L)
Preoperation				35	1.06±0.24[b]
		Location	Colon	14	1.11±0.16
			Rectum	21	1.03±0.25
		Differentiation	Well	13	1.01±0.28
			Moderate	16	1.02±0.31
			Poor	6	1.08±0.14
		Lymph node	Negative	15	0.94±0.26
		Metastasis	Positive	20	1.15±0.12[a]
		Dukes stage	A + B	15	0.94±0.26

Control				30	0.33±0.12

[b]$P<0.01$ *vs* control; [a]$P<0.05$ *vs* negative; [c]$P<0.05$, [d]$P<0.01$ *vs* Dukes A+B; [e]$P<0.05$, [f]$P<0.01$ *vs* preoperation.

DISCUSSION

Both experimental and clinical data have shown that coagulation disorders are common in patients with cancer although clinical symptoms may occur rarely. Recent reports showed hypercoagulable state in cancer patients and the plasma D-dimer levels were increased in these patients[4,5]. The process of metastasis involves multiple tumor-host interactions. To survive, metastatic cancer cells must leave the primary tumor, migrate into the lymphovascular system and establish a new blood supply at their metastatic site[6-8]. Fibrin remodeling is almost certainly involved in all steps of metastasis and has been proved to play a crucial role in new vessel formation[9-11]. Our study showed that the preoperative D-dimer levels were higher and correlated with the tumor lymph node metastasis. It confirmed that unregulated fibrinolytic activities in colorectal cancer and increased levels of fibrinolytic activities in metastasis of colorectal cancer. The reason may be that cancer cells appear to be capable of both thrombin formation and induction of fibrin degradation because cancer cells tend to adhere to, aggregate, necrose, which could induce monocytes and endothelioid cells to release many clotting factors[12,13]. Studies suggested that higher D-dimer levels could induce the secretion of interleukin-l, urokinase-type plasminogen activator (u-PA) and plasminogen activator inhibitor-2 in a human promonocytic leukemia cell line. u-PA is the predictive marker in many malignant tumors and may play an important role in the invasive cancer[14-16]. The prethrombotic state (depicted by a prolongation of PT and increase of D-dimer) is confirmed to be an aggravating condition in cancers. Studies suggesting an attempt to reverse possible haemostatic abnormalities with the use of anticoagulants have been justified. Thus anticoagulant treatment may have a positive influence on colorectal cancer therapy.

    We found that D-dimer levels were remarkably elevated on the 1st day after the operation. On the 3rd day after operation the D-dimer levels began to stepwise descend and on the 14th day returned to control. The remarkable increase in D-dimer levels occurring in patients indicated that patients undergoing surgery were at high risks for the occurrence of a thromboembolic event. Thus D-dimer could be used for estimating individual risk of thromboembolism and prophylactic treatment in these patients. Oya *et al* had obtained the same results. In addition,

we found the D-dimer levels of colorectal cancer patients with positive lymph nodes were significantly higher than that of negative lymph nodes. A stepwise increase in the mean D-dimer levels was found with the increase of tumor clinical stage. The measurement of preoperative D-dimer levels is considered to be useful for predicting lymph node metastasis and clinical stage of colorectal cancer.

Abstract

DC-SIGN, a dendritic Cell-specific adhesion receptor and a type II transmembrane mannose-binding C-type lectin, is very important in the function of DC, both in mediating naive T cell interactions through ICAM-3 and as a rolling receptor that mediates the DC-specific ICAM-2-dependent migration processes. It can be used by viral and bacterial pathogens including Human Immunodeficiency Virus (HIV), HCV, Ebola Virus, CMV and Mycobacterium tuberculosis to facilitate infection. Both DC-SIGN and DC-SIGNR can act either in *cis*, by concentrating virus on target cells, or in *trans*, by transmission of bound virus to a target cell expressing appropropriate entry receptors. Recent work showed that DC-SIGN are high-affinity binding receptors for HCV. Besides playing a role in entry into DC, HCV E2 interaction with DC-SIGN might also be detrimental for the interaction of DC with T cells during antigen presentation. The clinical strategies that target DC-SIGN may be successful in restricting HCV dissemination and pathogenesis as well as directing the migration of DCs to manipulate appropriate immune responses in autoimmunity and tumorigenic situations.

INTRODUCTION

Dendritic cells and Langerhans cells are specialized for the recognition of pathogens and have a pivotal role in the control of immunity[1-7]. Recently, several C-type lectin and lectin-like receptors (DC-SIGN and DC-SIGNR) have been characterized that they are expressed abundantly on the surface of these professional antigen-presenting cells, which not only serve as antigen receptors but also regulate the migration of dendritic cells and their interaction with lymphocytes. DC-SIGN was originally defined as an intercellular adhesion molecule-3 (ICAM-3) receptor supporting DC-mediated T-cell proliferation and binding and presentation of HIV-1 virions through gp120. DC-SIGNR or L-SIGN is a homologue of DC-SIGN and expressed in lymph nodes and by liver sinusoidal endothelial cells. L-SIGN has the same ligand-binding specificities as DC-SIGN, but is not produced by DCs or LCs. Furthermore, a series of DC-SIGN-like transcripts are predicted to encode other membrane-associated and soluble isoforms. The DC-

SIGN and L-SIGN genes, map to chromosome 19p13 adjacent to the type II C-type lectins CD23 (Fc$_E$ receptor II) and activation marker CD69. DC-SIGN and L-SIGN can bind mannose residues of viral glycoproteins through a C-terminal carbohydrate recognition domain (CRD)[8].

Hepatitis C virus (HCV) is the major causative agent of non-A, non-B hepatitis throughout the world with more than 170 million people infected. The majority of infected patients are unable to clear the virus and many develop chronic liver disease, cirrhosis and hepatocellular carcinoma. Replication of the HCV genome could be demonstrated *in vivo* and *in vitro* in liver hepatocytes and hematopoietic cells including dendritic cells and B cells. However, the molecular mechanism by which the virus targets to these sites of replication, notably in the liver, is not known. Regarding the interaction with DC-SIGN it has been shown that this lectin facilitates virus entry into DC in *cis* by enhancing attachment of HCV, as well as HIV, Ebola Virus, Cytomegalovirus, and Dengue Virus to the cell, thereby increasing the likelihood of interaction with specific entry receptors[9-17].

TROJAN HORSES: DUAL ROLES FOR DC-SIGN

DCs from different anatomical sites express distinct arrays of alternative HIV receptors. Some of these subsets could represent good gatekeepers, whereas others may be "Trojan horses" that carry HIV into the lymph node[18]. Our understanding of the role of DC-SIGN has become more complicated with the discovery of other functions. First, DC-SIGN binds ICAM-2, an integrin expressed on the endothelia of blood vessels and high endothelial vessels. DC-SIGN–ICAM-2 interactions help mediate tethering and transendothelial migration of DCs and may be critical for permitting DCs or their precursors to migrate towards inflammation in peripheral tissue or to enter lymph nodes[19-22]. Second, DC-SIGN initiates interactions with naï ve T cells through contact with a third ligand, ICAM-3, which is believed to stabilize DC-T cell membrane contacts and enable efficient T cell receptor engagement. Finally, DC-SIGN can internalize soluble antigen ligands, resulting in processing and presentation of antigenic peptides to T cells[23-27].

All of the above functions are consistent with a general model in which DCs in mucosa encounter HIV-1, internalize particles *via* DC-SIGN and become "Trojan horses", traveling to lymph nodes to release infectious particles into the midst of activated T cells. The concept that DC-SIGN is the primary receptor mediating this sequence of events came mostly from studies of DCs derived *in vitro* from monocytes. To address this problem, Turville *et al*[28] isolated resident DC subsets from skin, tonsils and blood and analyzed DC-SIGN expression and the gp120 binding capacity of these cell types directly *ex vivo*. Their results showed DC-SIGN has been detected on immature DCs in the lamina propria of mucosal tissues as well as on macrophages in decidua and placenta. DC-SIGN supports tethering and rolling of DC-SIGN–positive cells on the vascular ligand ICAM-2 under shear flow. The DC-SIGN-ICAM-2 interaction regulates chemokine induced transmigration of DCs across both resting and activated endothelium. Thus, DC-SIGN is central to the unusual trafficking capacity of DCs, further supported by the expression of DC-SIGN on precursors in blood and on immature and mature DCs in both peripheral

and lymphoid tissues. DC-SIGN- and DC-SIGNR-gp120 interactions represent a potential target for anti-HIV therapy aimed at disrupting the DC-virus interaction at primary sites of infection, in order to lower the efficiency of T cell infection. Lastly, these studies[29-31] suggest that the interaction of DC-SIGN and DC-SIGNR with endogenous ligands may not be restricted to ICAMs that have been studied to date, but may include other cell surface or soluble glycoproteins with appropriately displayed high mannose oligosaccharides. The mechanism of DC SIGN-mediated *trans*-infection is not completely understood, but it involves the internalization of HIV particles into an early endosome, where they appear to undergo pH-dependent changes that make them more infectious. When DCs contact CD4+ T cells, virus is released and T cells become infected. Evidence is accumulating that DC-SIGN may also facilitate infection in *cis*. *Cis* infection occurs when virus directly infects the DC-SIGN–expressing cell. Because DC-SIGN also binds HIV-2 and SIV, it has been dubbed the "universal receptor" for primate lentiviruses. All of the above functions are consistent with a general model in which DCs in mucosa encounter HIV-1, internalize particles *via* DC-SIGN and become "Trojan horses", traveling to lymph nodes to release infectious particles into the midst of activated T cells. Another example is *M. tuberculosis*. Dendritic cells (DCs) are important mediators of immune responses against *M. tuberculosis*. The interaction of mycobacteria with DC-SIGN also results in production of IL-10, which can modify the immune response, and might promote survival of mycobacteria. These results[11] indicate that M. tuberculosis infects DCs and interferes with DC-mediated immune responses by targeting DC-SIGN. So, DC-SIGN is a Trojan horse for *M. tuberculosis* as has been shown previously for HIV-1.

DC-SIGN also binds HIV gp120 to facilitate HIV transmission from DCs to T cells. Engering *et al*[32] showed DC-SIGN underwent rapid ligand-specific internalization to deliver its cargo to the acidic late endosome-lysosome compartments, where subsequent antigen-processing and presentation to T cells could occur. Internalization of soluble DC-SIGN ligands triggered antigen-specific T cell activation[33,34]. Importantly, such ligand internalization points to a mechanism by which HIV may cloak itself for delivery to T cell–rich areas in peripheral lymphoid tissues. There was high expression of DC-SIGN on MDDCs and in gp120 binding assays, DC-SIGN mediated all gp120 binding on MDDC. Recently Pohlmann *et al*[35] discovered DC-SIGNR, which can also act as a similar HIV 'trans-infection,' receptor in a 293T transfectant background. Furthermore, DC-SIGNR is expressed predominantly in the liver and lymph node tissue and MDDCs do not appear to express this receptor at high levels, suggesting it has a less important role in HIV binding. Therefore in addition to DC-SIGN, CD4, MMR, and as yet unknown trypsin resistant DC-SIGN and, possibly, DC-SIGNR, on DCs seems likely to have the capacity to bind gp120. This work supports intraepithelial DC as the first target for HIV but the original SIV tracking work suggested deeper tissue DC within the lamina propria were the first to be infected. Trauma during sexual transmission or genital ulceration would favour the latter. These data suggest that skin and probably other tissue DCs bind gp120 and/or HIV via both DC-SIGN and CD4/CCR5. HIV gp120 saccharide-DC-SIGN binding may provide constant high affinity virion binding to DC for any HIV strain, facilitating subsequent CD4/chemokine receptor binding and fusion. Therefore DC-SIGN may enhance DC infection and mucosal transmission. Furthermore mucosal DCs may provide the selection event which results in the predominance of R5 isolates[36].

Two papers in <<Immunity>> show that the HIV-1 protein Nef up-regulates DC-SIGN expression on DCs and that binding of DC-SIGN mediates internalization of virus particles into a non-lysosomal compartment, which enhances infectivity. The study from Sol-Foulon *et al*[37] examined the role of HIV-1 Nef in viral infectivity. DC-SIGN was found to be upregulated at the surface of infected cells. Up-regulation was dependent on Nef, given that DCs infected with Nef-deficient virus showed DC-SIGN staining patterns similar to uninfected cells. Two putative internalization signals - a tyrosine-based motif and a dileucine motif - are located in the cytoplasmic tail of DC-SIGN. The role of these motifs was examined using DC-SIGN-negative HeLa cells transfected with plasmids encoding DC-SIGN or Nef, or both. HeLa cells expressing wild-type DC-SIGN had very little surface expression but a high rate of endocytosis. By contrast, dileucine mutants of DC-SIGN showed high levels of surface expression with little or no internalization. Co-transfection with wild-type DC-SIGN and Nef resulted in stable expression of DC-SIGN at the plasma membrane. These results show that Nef up-regulates DC-SIGN surface expression by preventing internalization, which enhances the ability of DCs to form clusters with lymphocytes and facilitates viral transmission. The study from Baribaud *et al*[36] focused on the role of DC-SIGN in internalization and infectivity of HIV-1. DC-SIGN was shown to mediate the internalization of gp120 in a monocyte cell line transduced with a DC-SIGN-encoding virus. Fluorescence confocal microscopy showed that whole viral particles could be internalized by human DCs. After 45 min, most of the viral particles were localized in a non-lysosomal compartment, and these could be transmitted to a second target cell. Low pH in this compartment was important for maintenance of infectivity, given that neutralization of pH abolished the ability of DC-SIGN-positive cells to enhance infection of T cells. Although several questions - such as how HIV returns to the cell surface and what regulates this process - remain to be answered, this new work has implications for our understanding of HIV pathogenesis. Finally, DC-SIGN is up-regulated on monocytes exposed to inflammatory cytokines or undergoing differentiation into DCs, which suggests that expression on cells can be modulated by the microenvironment[38-41]. More definitive experiments will be required to determine actual amounts of expression in the blood and lymph nodes of both healthy and HIV-infected subjects. They suggest that DC-SIGN-mediated *cis*-infection of DCs could play a key role in viral dissemination[42-46]. This diversity may pose additional challenges for those who wish to block HIV infection by targeting DC-SIGN.

BINDING RECEPTORS FOR HCV

HCV is a small, enveloped, plus-strand RNA virus belonging to the family flaviviridae and genus hepacivirus. The HCV RNA genome is 9 600 nucleotides in length and encodes a single polyprotein that is post-translationally cleaved into up to 10 polypeptides including three structural proteins (core, E1 and E2), located at the N-terminus, and five nonstructural proteins. Shortly after translocation into the endoplasmic reticulum (ER), oligosaccharidetransferase catalyzes addition of Glc3Man9GlcNAc2 complexes at up to 6 (E1) and 11 (E2) Nglycosylation sites. Glucose residues are removed by glucosidases I and II and correctly folded proteins are released from ER chaperones calnexin and calreticulin. The transmembrane domains of E1 and E2 are responsible for both heterodimerization and retention of the glycoproteins in a high mannose EndoH sensitive glycoform in the ER. By analogy to other flaviviruses it is assumed that HCV capsids bud from the cytoplasm into the ER and that enveloped particles follow the secretion pathway through the Golgi. However, attempts to produce secreted HCV particles *in vitro* have not been successful so far and it is not known if E1 and E2 on mature

infectious virions possess a high-mannose, complex or mixed glycosylation.

Since the genomic sequence of HCV was determined, significant progress has been made towards understanding the functions of the HCV-encoded proteins, despite the lack of an efficient in-vitro replication system or convenient small-animal model. The identity of the receptor for HCV remains elusive, however. Several receptors have been proposed that could play a role in HCV entry into hepatocytes. Low-density lipoprotein receptor, CD81 and GAGs may all act as receptors for HCV, either sequentially or by different viral quasispecies The low density lipoprotein (LDL) receptor (LDLR) has been shown to mediate HCV internalization via binding to virus associated LDL particles. A second putative HCV receptor, the tetraspanin CD81, has been identified as a high affinity binding receptor for soluble recombinant E2 from HCV genotype 1a. CD81 and LDLR are expressed in most cell types and thus not likely account for the hepatic tropism of the virus. Recent work using pseudotypic VSV bearing E1 or E2 chimeric molecules showed that entry of the E1 pseudotype can be inhibited by recombinant LDLr, whereas the E2 pseudotype is more sensitive to inhibition by recombinant CD81 or heparin. These results suggest that E1 and E2 may be responsible for interactions with different cellular molecules. It is also conceivable that additional, yet unidentified, cellular proteins are involved in viral binding and entry. Intriguingly, the reports of HCV-RNA associated with PBMC suggest that HCV infection may not be restricted to hepatocytes. Thus, separate reservoirs of virus may exist, and HCV may use different receptors to access these different cell types. The lack of an efficient cell culture model has precluded functional confirmation of these receptor candidates at the level of virus entry. Recently Lozach *et al*[9] found that DC-SIGN and L-SIGN are two novel HCV envelope binding receptors and the HCV envelope glycoprotein E2 binds DC-SIGN and L-SIGN through high-mannose N-glycans. Competing ligands such as mannan and an antibody directed against the carbohydrate recognition domains (CRD) abrogated binding. The highest affinity is seen for plasma membrane expressed DC-SIGN and L-SIGN. These results indicate that several high-mannose N-glycans in a structurally defined cluster on E2 bind to several subunits of the oligomeric lectin CRD. Its localization on the endothelium lining hepatic sinusoids makes it an interesting candidate for the capture of HCV. Productive infection of endothelial cells by HCV has not been demonstrated, but L-SIGN could be responsible for the transmission of bound virus to neighbouring hepatocytes. This kind of mechanism of *trans*-enhancement has been demonstrated more than a decade ago for HIV transmission from DC to T cells and can be attributed to DC-SIGN. In the case of HCV, it is tempting to speculate that subsequent to interaction with L-SIGN on endothelial cells, the virus could be transmitted to hepatocytes where it uses a specific receptor for entry. In conclusion,the results show that HCV envelope glycoprotein E2 strongly binds to oligomeric C-type lectins in a high-mannose *N*-glycan dependent fashion. High affinity interaction of viral glycoproteins with lectins might represent a strategy by which enveloped viruses target to the site of replication and represents an interesting novel target for antiviral drug development.

In another, Pohlmann *et al*[47] found that soluble versions of the hepatitis C virus (HCV) E2 glycoprotein and retrovirus pseudotypes expressing chimeric forms of both HCV E1 and E2 glycoproteins bound efficiently to DC-SIGN and DC-SIGNR expressed on cell lines and primary human endothelial cells but not to other C-type lectins tested. Soluble E2 bound to immature and mature human monocyte-derived dendritic cells (MDDCs). Binding of E2 to immature MDDCs was dependent on DC-SIGN interactions, while binding to mature MDDCs was partly independent of DC-SIGN, suggesting that other cell surface molecules may mediate HCV glycoprotein interactions. HCV interactions with DC-SIGN and DC-SIGNR may contribute to the establishment or persistence of infection both by the capture and delivery of virus to the liver and by modulating dendritic cell function[48].

QUESTIONS TO BE ANSWERED

DC-SIGN and DC-SIGNR are two closely related membrane-associated C-type lectins that bind human immunodeficiency virus (HIV) envelope glycoprotein with high affinity. Binding of HIV to cells expressing DC-SIGN or DC-SIGNR can enhance the efficiency of infection of cells coexpressing the specific HIV receptors[49-51]. DC-SIGN is expressed on some dendritic cells, while DC-SIGNR is localized to certain endothelial cell populations, including hepatic sinusoidal endothelial cells. The pattern of cellular expression of DC-SIGN is somewhat controversial. The term "DC-specific" DC-SIGN is also expressed on brain microvascular endothelial cells, certain tissue macrophages, can be induced on monocyte-derived macrophages under certain conditions and can even be found on rare CD14+ cells, resembling monocytes in blood[52-55]. Pathogenic microbes have evolved means to bypass these sentinels[56-67]. For example, human immunodeficiency virus binds to DC-SIGN and hides directly beneath the cell surface until the DC encounters a T cell, that which the virus can then infect. The measles virus seems to induce death and/or fusion of the DC, thereby preventing immune responses. Wu *et al*[68] demonstrated that Dengue virus (DV), an RNA virus with a peculiar pathogenesis, preferentially targets DCs. They have demonstrated that immature monocyte-derived DCs, generated *in vitro*, were 10-fold more permissive for DV infection than either monocytes or macrophages. Several avenues are now open for investigation. How does the infection affect DCs function and the ensuing T-cell responses? Although the authors did not explore the effects of DV on DCs, a block in LC function could explain the lack of cytotoxic T-lymphocyte immunity in response to Dengue infection. Would the targeting of different DC subsets explain why some patients develop protective immunity whereas others develop non-protective responses? Indeed, targeting of interstitial DCs could skew the immune responses toward the production of DV-specific antibodies, which may result in enhanced viral load through increased entry into macrophages. Another important question is which of the DC-specific molecules DV uses as a receptor for entry. Answering this could provide a target for the design of an anti-DV compound. Furthermore, receptor polymorphisms might explain why some patients mount protective immunity whereas others do not. Finally, would the targeting of appropriate DC subset permit us to develop a successful vaccine? All these questions represent exciting areas of experimentation and are likely to keep the DC experts busy and DC researchers eager to follow their work[69-71].

Abstract

There are two main functions of gastrointestinal tract, digestion and absorption, and barrier function. The latter has an important defensive effect, which keeps the body away from the invading and damaging of bacteria and endotoxin. It maintains the systemic homeostasis. Intestinal dysfunction would happen when body suffers from diseases or harmful stimulations. The lesser dysfunction of GI tract manifests only disorder of digestion and absorption, whereas the more serious intestinal disorders would harm the intestinal protective mechanism, or intestinal barrier function, and bacterial/endotoxin translocation, of intestinal failure (IF) would ensue. This review disscussed the theory of the intestinal failure, aiming at attracting recognition and valuable comments by clinicians.

INTRODUCTION

It is traditionally considered that the gut is quiescent in diseases. That is why the GI tract is not paid much attention and protected like other organs as heart, lungs and kidneys by ICU doctors. It is considered that the metabolism of the body takes place mainly in liver. Because of the advancements in research and surgical technology, issues in gastrointestinal metabolism, nourishment, anatomy, physiology and the like have been further understood. It is very important for functions of GI tract when body suffers from hunger and stress. It bears not only digesting and absorbing nutrients, but also supplying and modulating systemic immunity. Moreover, the GI tract can prevent germs and toxin from entering into the body (so-called barrier function). Capability in GI tract sometimes determines the recovery or deterioration of a disease. It is of traditional nutrition support that makes the intestinal mucous membrane in hunger and that would aggravate the intestinal dysfunction, or accelerate the occurrence of the intestinal failure. The further study and recognition of gut physiological function and pathophysiology hence, is of initial importance to gastroenterologists[1-3].

RECOGNTION OF GI TRACT FUNCTION

There are unusual structures for GI tract: villus, microvillus, crypt and tight junction. Small holes (about 0.4-0.7 nm in radius) bestrew the epithelial surface of the GI tract. The epithelial cells of small intestine is one of the tissues that most rapidly grow and metabolise in the body. It renews in 2-5 d for a cycle. The circular folds, villi and microvilli expand the absorptive area of small intestine to hundreds times of its primary area, reaching to 600 m$^{2[4-6]}$. Modern technology reveals that GI tract has following actions or functions except for digestion and absorption.

Gut is the primary one of four bacterial reservoirs in the body
There is a homeostasis between intestinal epithelium, total system and the flora in the bowel. Bacteria generally divide once every 20 min, but they only reproduce 4 to 5 generations within the bowel lumen. Once the balance destroyed, intestinal failure follows, bacteria translocation and morbidity would ensue. The upper GI tract and proximal jejunum are considered aseptic in general, because the number of bacteria in these sites is smaller or approximately equals to $10^{3[7-11]}$. Table 1 lists the normal flora in the bowel[7].

Table 1 Normal Flora in Humans' GI Tract

	Stomach	Jejunum	Ileum	Feces
Total bacterial count Aerobic facultative or anaerobic bacteria	0-10^3	0-10^5	10^3-10^7	10^{10}-10^{12}
Enterobacteria	0-10^2	0-10^3	10^2-10^6	10^4-10^{10}
Streptococci	0-10^3	0-10^4	10^2-10^6	10^5-10^{10}
Staphylococci	0-10^2	0-10^3	10^2-10^5	10^4-10^7
Lactobacilli	0-10^3	0-10^4	10^2-10^5	10^6-10^{10}
Fungi	0-10^2	0-10^2	10^2-10^3	10^2-10^6
Anaerobic bacteria	0	0	0	0
Bacteroids	Rare	0-10^2	10^3-10^7	10^{10}-10^{12}
Bifidobacteria	Rare	0-10^3	10^3-10^5	10^8-10^{12}
Gram-positive cocci^1	Rare	0-10^3	10^2-10^5	10^8-10^{11}
Clostridia	Rare	Rare	10^2-10^4	10^6-10^{11}
Eubacteria	Rare	Rare	Rare	10^9-10^{12}

^{1}Includes peptostreptococcus and peptococcus.

Secretion and absorption of digestive juice
Secretions of gastrointestinal fluid during 24 h vary in different site or segments. They are: saliva, 500 mL, gastric juice, 1 000-2 000 mL, bile, 800 mL and pancreatic juice, 700 mL daily. Chyme in upper segment of jejunum (200 cm lower from duodenum-jujenal flexure) can be diluted into 5 to 8 times more than that of ingested amount. That is why stoma in proximal jujenum and the higher intestinal fistula could cause severely lose of water, electrolytes and nutriments[1].

Immunological Functions
GI tract is the largest immune organ in the body. The mucosal immune system is made up of gut-associated lymphoid tissue (GALT), which contains 10^{10} cells/m and accounts for 80% of the total body immunocytes[12].

Absorption function of different intestinal segments
Stomach and duodenum do not nearly absorb any nutrients.

The upper jejunum (a segment in 200 cm long distal from Treitz's ligment), absorbs carbohydrates, protein and most of water soluble vitamins, whereas the fat absorption needs a longer segment of jejunum. The ending segment of ileum contributes to absorption of vitB12 and re-absorption of bile-salts for circulation of intestine-liver. Right half of colon is in charge of absorption water and inorganic salts; and left half of colon, in charge of storage and excreting feces. Adaptation and compensation happens in structure and function of the rest small intestines and colons after resection of most parts of small intestine[1].

A specific mechanism for nutrients absorption

Nutriments that all the organs and tissues needed in the body are supplied solely by arteries, but the intestinal mucous epithelia has a completely different mode of nutrient uptake. It receives 30% of nutrients from the artery and takes in the other 70% from the contents within the lumen directly. That is why total parenteral nutrition (TPN) could result in an atrophy of intestinal mucosa[10,11].

INTESTINAL BARRIER FUNCTION

Conception of gut barrier and bacterial/endotoxin translocation

In normal situations the GI tract can only absorb the needed nutrients selectively. It is the largest reservoir of germs in the body and contains about 10^{12} of bacteria, occupying about 1/3 of dry weight of feces[7]. Such an astronomical figures of bacteria produces a great quantity of toxin, which was not taken in by the intestine because of presence of the mucosal barrier function and hence no sickness was resulted by the toxin. Generally, the intestinal mucosa barrier is consisted of three parts: mechanical, biological and immnune barriers. Any etiological factors that impair these barriers would cause bacterial/endotoxin translocation (a phenomenon that bacteria/endotoxin gets across the gut barrier and enter into blood and other aseptic tissues)[13,14].

Mechanical Barrier

It consist of closed-lining intestinal epithelial cells[5,6]. Many harmful factors and diseases could destroy this structure, such as intestinal obstruction, haemorrhagic and necrotic enteritis, chemotherapy, radiotherapy, using some medicines (for example, anti-inflammatory drugs of non-steroids) for a longer time and shock[11,15].

Structure of intestinal mechanical barrier

It is constituted by intestinal epithelial cells and the tight-junction between enterocytes[5,6]. The enterocyte apical membrane is interspersed with water-filled pores (<0.8 nm in radius), which permit the permeation of non-lipid polar molecules. The tight junction between enterocytes constitutes only a small proportion (<5%) of the total surface area of the intestinal epithelium, which is about 0.95 nm in radius and permits transition of larger molecules. The dual saccharides test for measuring intestinal permeability is devised according to this structure[5].

Immune barrier

It is composed of intra-epithelial secreting IgA, intra-mucosal lymphocytes, Payer's nodules and mesenteric lymph nodes. It is also called the GALT[12]. Any factors that destroy the body's immunity, such as protein malnutrition, leukemia, systemic chemotherapy and HIV infection, would damage the barrier[9,16].

Biological barrier

It is made up of normal inhabitant flora in GI tract, and hence the colonization resistance comes into being[7,17]. It is an effect of the flora that prevents the external or harmful bacteria from colonizing in the bowel because of the intrinsic flora holding the surface of intestinal mucosa. The colonization resistance would be destroyed by the alterations of inhabitant bacteria in the bowel. These diseases are bacterial enteritis, ileus (bacterial overbreeding), antibiotic enteritis (double infection), and so on[1,18].

Micro-ecological equilibrium

There is a micro-ecological balance between bacteria in bowel with intestinal mucosal epithelia and the body system (the intestinal flora would colonizes for a postnatal infant in a few days). Any alterations in each of these three aspects would impair the balance and lead to sickness. Such cases are the impairment of systemic immunity (damage of immune barrier), destruction of intestinal mucosal structure (damage of mechanical barrier), and overgrowth of bacteria in the bowel (damage of biological barrier)[1,17].

GASTROINTESTINAL TRACT IS A CENTRAL ORGAN FOR SURGICAL STRESS

Developments in different disciplines since the middle of last century have led to our current understanding and treatment of intestinal failure. This owes to the advances in 3 aspects: First, the application to both normal subjects and those with intestinal resection of new laboratory techniques, has advanced understanding of small intestinal function; Second, the scope of surgical treatments has extended to more complex operations on the intestine so that intestinal failure occurs more frequently and is often more severe; Third, clinical necessity has stimulated the application of innovative techniques to treat the condition in the short- or long-term[1].

Clinical phenomena

(1) No matter what the cause is for critically-illed patients, infection would happen during the course of disease, and is one of the main causes of death. The mostly infected bacteria are normal intestinal flora. (2) Although isolated in aseptic wards for patients with transplantation of bone marrow, leukemia, and severe burns, they still had a high morbidity of infection. The pathogens cultured were mainly those of normal intestinal inhabitants. (3) Treatments with intravenous antibiotics and selected digestive decontamination therapy to these patients could markedly reduce the morbidity of infection. (4) Treatment with antibiotics excessively would cause a "double infection"[1,18].

Animal experiments

(1) Enterocytes and colon cells proliferate rapidly (the enterocyte renew once in 5-7 d), and cover a broad area of intestinal inner surface. So metabolism and energy need for them are high. Windmueller *et al*.[19] investigated the metabolism of mucosal epithelia with an isolated, vascularly perfused preparation of rat intestine. They discovered that small intestine extracted large amounts of glutamine as energy fuel when fed enterally miscellaneous nutriments quantitatively. The mucosal enterocyte converts most of the glutamine into metabolites of ammonia, alanine, citrulline. The epithelium metabolize the ketones (β-hydroxybutyrate, acetoacetate and acetone) as fuel, and colon combust short chain fatty acids. (2) It has been discovered through immunologic research that there are a great deal of intraepithelial lymphocytes, Peyer's nodules, secreted IgAs, lymphatic follicles and mesenteric lymph nodes (named as GALT- Gut associated lymphatic tissue) in gut. When stimulated by stresses, an intense immunologic responses in them would happen[1,12]. (3) Phenomena revealed by experiments that phagocytosis of intestinal mucous epithelium and bacteria gain

access to blood stream and other tissues across the epithelia (so-called bacterial translocation) explain the existence of mucosal barrier of the gut[18,20]. (4) Animals with intestines resected had a better resistance to trauma and strike than that of not resected when given equal parenteral nutrition. They had lived for a longer time and had a low morbidity of infection (such as Hammer-Hodges test that blocks the upper mesenteric artery temporarily so as to induce a lethal endotoxin shock in rabbits)[21]. (5) Spicific pathogen-free and gnotobiotic animals tolerate well to harmful stimulations and have lower morbidity of infection than that of ordinary animals.

Based on researches and advances we mentioned above, especially developments in medical sciences of last century, Wilmore[17] suggested in 1988 that ' gut is a central organ after surgical stress' . The main contents of the hypothesis are as follows: The breakage of gut barrier occurs in patients after injury, multiorgan system failure, or severe burns and in persons with cancer after undergoing chemotherapy or bone marrow transplantation, which results in the entrance of bacteria and endotoxin into the blood stream and other tissues across the mucous epithelium from the gut. The cytokines produced by the reticular- endothelial system when body suffers from invasions of bacteria and endotoxin would stimulate pituitary-adrenal gland axis, and hence stress responses ensue. There are active metabolic effects for GI tract, especially when stimulated by stresses.

CONCEPTS OF INTESTINAL FAILURE

Historical retrospect

In the beginning of last century, Dr. Metchnikoff, the father of hypothesis of phagocytosis suggested that the entrance of microbes and associated toxin from the bowel into the body was an important cause of early death[1]. In 1970' s, the theory of multiple organs failure for death was put forward, underlying the facts that many critical-ill patients die of organs failure. But the concept have not given the course of evolving and transforming of a disease, whereas it just told a clinical phenomenon of a terminal patient[22]. This is less helpful to treatments for patients by doctors. The studies in animal experiment and clinical investigation on physiology and pathophysiology of gastrointestinal tract have been increasingly reported since 1980s[20,23-26]. The concept of multi-organs dysfunction syndrome (MODS) and systemic inflammatory response syndrome (SIRS) were raised since 1990s, and recognition in essence of inflammation, infestation and of the gut functions, and re-defining on them was made at the same time[27-29]. All these have established a steady foundation for hypothesis of intestinal failure, which is a magnitude in gastroenterology, critical care medicine and infection-immunology etc[1].

Definition of intestinal failure

The term ' intestinal failure' was first used by Irving and colleagues in the title of a paper published in 1980[30]. The following year, a book chapter by Flamming and Remington[1] gave the first definition as a ' reduction in functioning gut mass below the minimal amount necessary for adequate digestion and absorption of nutrients' . Now the viewpoint is further advanced. It widens the concept that ' reduced gastrointestinal absorption to the extent that macronutrient and/or fluid supplements are required' , which includes the need for enteral or parenteral supplements to maintain a normal nutritional state. Mulnutrition and/or dehydration would happen if supplements are not given or compensation does not work during the time[31]. Comparative to description on functional failure of heart, lungs, brain and kidneys, it is no doubtful that the concept emphasized the equal importance of GI tract as other vital organs during the course of diseases.

CLASSIFICATION AND TREATMENTS OF INTESTINAL FAILURE[1]

Staging of intestinal failure

Acute intestinal failure It is divided into reversible (in 6 mo) and causative surgical factors (such as percutaneous fistula, ileus), and those of internal medicine (such as chemotherapy or enteritis caused by acute radioactive injury, or infectious enteritis including HIV infection).

Chronic intestinal failure It results from following diseases: gastrointestinal resections (such as short bowel syndrome and gastrectomy), intestinal bypass operations (such as surgery for obesity treatment), and dysfunction of small intestine (such as pseudo-ileus, chronic enteritis - Crohn' s and radioactive, microvilus atrophic or autoimmune enteropathy). Total or subtotal gastrectomy with a remnant of gastrointestinal disorders often needs nutrients complements and also belongs to intestinal failure.

Grading of intestinal failure

The severity of intestinal failure can be graded as follows according to the method by which macronutrients/fluid are given.

Severe intestinal failure Parenteral nutrition and/or parenteral saline are required because health cannot be sustained by exposing the small bowel mucosa to more, continuous or altered nutrients and/or electrolytes.

Moderate intestinal failure An enteral tube is used for the administration of macronutrients and/or a glucose/saline solution.

Mild intestinal failure Dietary adjustments, oral nutrients and/or a glucose/saline solution (or sodium chloride supplements) are needed.

A patient may change, due to compensatory mechanisms, from severe to mild IF with time. For example, a patient who has had a massive small intestinal resection, and in whom intestinal adaptation has occurred, may with careful dietary advice and appropriate drug therapy be able to stop parenteral nutrition (such as the intestinal rehabilitation therapy in short bowel syndrome).

COMMON DISEASES UNDERLYING IF

Acute IF

The usual conditions that cause an IF are as follows: (1) inflammatory diseases: in their attacks of Crohn' s disease and ulcerous colonitis, especially in cases with surgical complications; (2) peptic ulcer; (3) pancreatitis; (4) mesenteric vascular disease; (5) malignancy; (6) external intestinal fistula; (7) cases receiving chemotherapy and transplantation of bone marrow; (8) AIDs; (9) others: such as acute ileus, gastric paralysis, inflammatory intestinal obstruction, severe intestinal infections (for example, shigellosis, cholera), external abdominal trauma (blunt or sharp and viscera rupture).

Chronic IF

(1) pseudo-intestinal obstruction; (2) radioactive enteritis; (3) post-gastrectomy; (4) short bowel syndrome; (5) post-surgery for obesity; (6) others: such as constipation resulting from various etiological factors.

The concept of IF presented above involves miscellaneous diseases and it seems confused because of that the meaning of the word ' failure' is different in Chinese from the English original word. It describes a broad functional status of an organ from dysfunction to complete loss of function in English meaning, whereas the word ' failure' denotes the function of an organ being severely injured or complete lost in Chinese. The gut has two functions: digestion and absorption, and barrier function. Therefore, we comprehend that the IF contains two implications: gastrointestinal dysfunction when there is only disorder of

digestion and absorption, whereas it would be named as IF when there is a disorder of barrier function. The former presents a less sick situation clinically and recovers easily, and the latter is complicated by critical illness or manifestations of severe enteropathy and has a high morbidity and mortality because of bacterial/endotoxin translocation. The suggested classification seems more reasonable, practical and directive.

EPILOGUE

Theory of IF is a great advancement in clinical medicine, especially in gastroenterology. It comes from developments and researches in the disciplines of critical care medicine, immunology in infection, clinical nutrition support and others. It also profits from developments in modern surgical technology and its clinical application. The IF theory has a significant guiding role to gastroenterologists. We should pay attention to the capability of GI tract in diseases and do not neglect protecting the barrier function of GI tract in clinical practice.

Abstract
AIM: To investigate the immune function of dendritic cells from both peripheral blood and operated tissues of esophageal carcinoma patients in order to find the relationship between the immune function of dendritic cells and the pathogenesis of esophageal carcinoma.

METHODS: The expression of CD83, CD80, and CD86 on the surface of dendritic cells cultured from the peripheral blood of patients was detected compared with that from health donors using flow cytometry. The ability of dendritic cells to induce T lymphocyte proliferation was evaluated by a liquid scintillation counter. The expression of CD80, CD86, CD83, and S-100 proteins was assessed in esophageal carcinoma tissues using immunohistochemical method.

RESULTS: Compared with those from healthy donors, dendirtic cells cultured from the peripheral blood of patients expressed lower CD80 and CD86. Furthermore, the ability of dendritic cells in patients to induce T lymphocyte proliferation was significantly lower than that of the control group. Compared with the control group, the positive expression ratio and frequencies of CD80, CD86, and S-100 in esophageal carcinoma tissues were significantly down regulated. The expression of CD83 was up-regulated in the pericancerous tissues, but no expression was found in the cancerous nodules.

CONCLUSION: The impaired immune function and the decreased number of dendirtic cells cause pathogenesis and progression of esophageal carcinoma.

INTRODUCTION
Esophageal carcinoma (EC) is one of the top ten frequently occurred malignant cancers, particularly common in China. Our palace - Chaoshan area, located in the Eastern Guangdong, China, is one of the areas of high-incidence EC with morbidity of 197.82/10⁵ and 81.32/10⁵ world-standardized populations for males and females, respectively[1,2]. Squamous cell carcinoma has been the more common cell-type of EC, accounting for almost 90%. Now the therapy including surgery, chemotherapy, radiation, or a combination for EC is only to palliate the symptoms. However, a 5-year survival rate in patients with esophageal carcinoma is less than 10%[3]. Novel treatment options of EC are urgently needed. Indeed, tumor immunotherapy has evolved specifically to offer several attractive potential advantages. It is strictly autologous with very few side effects. Additionally, once the immune response has started, its efficacy is independent on the localization, type, and proliferative state of tumor cells[4,5].

The aim of tumor immunotherapy is to activate our own immune system to fight the existing tumor. The majority of experimental systems clearly demonstrate that tumor cells are largely defended by $CD4^+$, $CD8^+$ T lymphocytes, or NK cells[6-8]. Lymphocyte T and possibly NK cells, however, require to be activated by antigen-presenting cells (APCs). The dendritic cells (DCs) are one of the most potent APCs *in vivo* and play crucial roles in the enhancement or regulation of cell-mediated immune reactions[9-11]. Since DCs strongly express various costimulatory and/or adhesion molecules, they can activate even naive T cells in a primary response. The DCs-based approach has been used to establish treatments for several malignant diseases, including B cell lymphoma and melanoma[12-14]. However, the immune functions of DCs are occasionally suppressed under some tumor-bearing states. Thus, the functions of DCs must be assessed in relation to the disease status to further apply DCs as an immunotherapeutic tool. In this study, we detected the expression of CD83, CD80, and CD86 molecules on the surface of DCs cultured from the peripheral blood of patients and healthy donors, and the ability to induce T lymphocyte proliferation. Furthermore immunohistochemical method was used to assess the expression of CD80, CD86, CD83, and S-100 proteins in esophageal carcinoma tissues to find the relationships between the immune function of DCs and the pathogenesis and progression of esophageal carcinoma.

MATERIALS AND METHODS
Materials
Ten Patients with EC were enrolled in this study. All patients were diagnosed by clinical criteria and confirmed by appropriate histological findings (hematoxylin and eosin staining). To assess the DC function of EC patients, 10 age-matched healthy individuals were assigned as controls.

Methods
Esophageal tissue specimens Esophageal tissue specimens were obtained during operation. All patients attended the Second Affiliated Hospital of Shantou University Medical College (Shantou, China) between 2001 and 2002. All samples were fixed in 40 g/L buffered formaldehate, embedded in paraffin, and cut into 5 μm section. Thirty patients with esophageal carcinoma (aged 58-76 yr) were diagnosed by clinical criteria

and confirmed by appropriate histological findings (hematoxylin and eosin staining). We took specimens from the esophageal carcinoma tissue (ECT), pericancerous tissue (PCT), and tissue far away from the esophageal carcinoma tissues about 8 cm as the normal esophageal tissue (NET). At the time of surgery, all patients were free from any other tumor therapy.

Generation of DCs from peripheral blood mononuclear cells
The DCs were generated from peripheral blood mononuclear cells (PBMNC) according to the methods described by Zhu *et al.*[15-19]. The PBMNC were collected from venous blood by Ficoll-Hypaque density-gradient centrifugation. After the PBMNC were suspended in DCs culture medium (RPMI 1640 supplemented with 100 mL/L fetal calf serum, 50 U/mL penicillin, 2 mmol/L L-glutamine, and 50 μmol/L 2-mercaptoethanol), they were placed at 10 mL polystyrene culture plates and stored at 37 ℃ for 2 h. After incubation, nonadherent cells were removed by gently pipetting with warm RPMI 1640. Adherent cells were supplied with DCs medium containing 800 U/mL of recombinant human GM-CSF and 500 U/mL of recombinant human IL-4, and cultured for 7 d at 37 ℃ under 50 mL/L CO$_2$. Cells were referred fresh medium containing 800 U/mL of GM-CSF and 500 U/mL of IL-4 every 2 d. After 7 d, the cultures developed an adherent monolayer and clusters of DCs colonies (Figure 1). The DCs yield was defined as the percentage of the obtained DCs numbers to the PBMNC numbers used as the source.

**Figure 1** Typical appearance of DC cultures on 7 d.

Figure 2 Transmission electron microscopy (×8000).

Electron microscopy
The nonadherent cells were aspirated, washed in PBS, pelleted, and fixed for 30 min in 30 g/L glutaraldehyde in 0.1 mol/L phosphate buffer (pH 7.35). After washing, the cells were postfixed for 1 h in 10 g/L buffered osmium teroxide, washed once in phosphate buffer and 3 times in water, and stained with 5 mL/L aqueous uranyl acetate for 1 h. After dehydration through a series of ethanol dilutions, the cells were pelleted, and embedded in 1:1 Poly/Bed. Thin sections were cut with Diatome diamond knife, mounted 200 mesh nickel guides, and poststained with 50 mL/L methanolic uranyl acetate. Samples were viewed on a Philips 400 transmission electron microscope (Figure 2).

Mixed lymphocyte reaction
To evaluate the allostimulatroy capacity of DCs, mixed lymphocyte reaction (MLR) was performed. To compare the function between DCs from EC patients (EC-DCs) and those from donors (N-DCs), allogeneic lymphocytes were obtained from the same healthy volunteer. The PBMNC were suspended in DC culture medium and incubated at 37 ℃ under 50 mL/L CO$_2$ for 1 h, non-adherent cells were gathered as T cells (TCs). After DCs were treated with 50 μg/mL of mitomycin C for 45 min at 37 ℃, they were suspended in DC medium and placed at 1×10^2-2×10^4/well on 96-well flat-bottom culture plates. The TCs were mixed with DCs at 2×10^5/well and cultured for 96 h at 37 ℃, 50 mL/L CO$_2$. During the last 16 h of incubation, pulse labeling was done with 2.0 μCi/well of [^{3}H] thymidine (MSI, Beijing, China). Assays were performed in triplicate. On day 4, the cells were harvested, and the amounts of [^{3}H] thymidine incorporated to responder cells were counted with a beta counter. The ratio of MLR was determined by the ratios of cpm between EC-DC and N-DC in the presence of the same reagents at a TCs/DCs ratio of 10 to 1.

Flow cytometric analysis
After 7 d of culture, DCs were harvested, and their surface molecule expression was analyzed using FACS (Becton Dickinson Immunocytometry Systems, San Jose, CA). In each step of the staining, 5×10^4 cells were stored with specific antibodies (Abs) for 30 min at 4 ℃ in 50 μL of PBS containing 20 mL/L of bovine serum albumin and 1 mL/L of sodium azide. For the staining of mouse monoclonal anti-human CD80, CD83, or CD86 (PharMingen, San Diego, CA), fluorescein isothiocyanate (FITC)-conjugated goat monoclonal anti-mouse IgG was used according to the procedure of indirect immunofluorescence staining. Isotypic Ab (purified mouse IgG) was substituted for specific Abs to obtain a negative control. After staining, all cells were fixed with 10 mL/L paraformaldehyde (Sigma), and analyzed with the FACStarP1 (Becton Dickinson) using a single argon laser. For the comparison of CD83 and costimulators, the mean fluorescence intensity of stained DCs (MFIs) and that of controls (MFIc) was measured using a Consort 30 software program (Becton Dickinson). The degree of surface molecule expression was estimated as the ratio of MFIs to MFIc (MFIs/MFIc) and expressed as the net fluorescence intensity (NFI). All samples were assayed in duplicate.

Immunohistochemical staining of CD80, CD86, and S100 proteins Immunohistochemical staining was performed. Rabbit anti-human monoclonal antibodies to CD80, CD86 and S100 proteins (PharMingen International) were used as primary antibodies (Ab1). The antigen-Ab1 complex was then incubated with biotinylated secondary antibody followed by horseradish peroxidase-avidin. Staining procedure was done according to the introduction of the agent box, SP method. A known sample from a patient with breast cancer was used as a positive control, and the staining for negative controls was followed the method described above, except for incubation with PBS instead of the primary antibody. Colorization was performed by diaminobenzidine (DAB)-hydrogen peroxide as a chromogen.

Immunohistochemical staining of CD83 The staining of CD83 was performed with some modifications, according to a previously described method[19]. Formalin-fixed, paraffin-embedded specimens were washed three times in PBS and treated with pepsin (5 mg/mL in 0.01 mol/L HCl, Zhongshan, Beijing, China) for 20 min at 37 ℃ before staining for CD83. The specimens were then treated with normal goat serum for 20 min to block non-specific binding. The monoclonal antibody with appropriate dilution was then added. Tissue sections were treated with 0.3 mL/L methanol-hydrogen peroxide to inactivate endogenous peroxidase. The sections then were reincubated

with biotinylated goat anti-mouse immunoglobulin at room temperature for 1 h. After a wash in PBS, sections were soaked in alkaline phosphatase-conjugated streptavidin, washed, and New Fuchsin was used as a chromogen. A known sample from patients with primary biliary cirrhosis was used as a positive control. The staining of negative controls was performed using PBS instead of primary antibody.

Enumeration of positive staining cells The numbers of CD80-, CD86-, S100-, and CD83-positive cells in the whole specimen were determined. The prevalence of CD80, CD86, and S100 protein-positive cells were shown as the ratio of a total 100 infiltrating cells. The prevalence of CD83 positive cells was shown as total numbers of cells/specimen.

Statistical analysis

The data were expressed as mean±SD. The statistical analyses were done by unpaired and paired t-tests, when indicated. Mann-Whitney's U-test and the Wilcoxon rank-sum test were also used when unpaired and paired t-tests were not indicated, respectively. P-values less than 0.05 were considered to indicate statistical significance. Statistical calculations were performed using the SPSS 10.0 statistical program.

RESULTS

Phenotypic analysis of DC

After 7 d of culture under GM-CSF and IL-4, the cells from patients or volunteers exhibited DC morphology with veiled process and dendrites. Through the observation from transmission electron microscopy, the cell surface was irregular but lacked the discrete microvilli and ruffles (Figures 1, 2). The cells were free polysomes and ribosomes, and lysosomes were scanty. These results showed that the generated cells from both patients and donors were morphological and compatible with DCs. The expression of CD80 and CD86 in EC patients was weaker than that in volunteers, but no the expression of CD83 was not different between EC patients and volunteers (Table 1 and Figure 3). The yield of DCs was not different between patients and donors (5±3% vs 5±1%).

Low mixed lymphocyte reaction in DCs generated from EC patients

In MLRs, the degree of T cell proliferation from EC-DCs was significantly lower than that from N-DCs. The reduced allogeneic response from EC-DCs was confirmed with the comparison of the cpm at a TCs/DCs ratio of 10 to 1 with large numbers of subjects (P<0.01) (Table 1). Since the responders were identical in each series of the comparisons, the difference in TCs proliferation mainly depended on the DCs difference.

Table 1 Antigen presentation and ability to induce T lymphocyte proliferation on DCs in peripheral blood from donors and EC patients (%, mean±SD)

Group	CD80	CD86	CD83	MLR (cpm)
Donor	61.41±7.47	37.28±6.75	5.18±1.59	20 000±3 000
Patient	41.76±7.35[b]	29.68±7.32[b]	4.44±1.17	10 000±2 000[b]

[b]P<0.01 vs donor group.

Lower expression of CD80 and CD86 in EC patients

The expression of CD80 and CD86 could be detected in the nucleus and cytoplasm but not on the cell membrane for all the specimens. The expression of CD80 and CD86 in the nucleus was found randomly. The expression in the cytoplasm was located in the necrotic area and around with infiltrated lymphocytes (Figure 4A, B, C, D). The prevalence of positive expression of CD80 and CD86 was lower in ECT than that in NET (P<0.01), but there was no significant difference between PCT and NET (Table 2).

Table 2 Positive staining of CD80, CD86, and S100 proteins in esophageal tissues

Group	Tissue	n	Prevalence	Frequency (%)
CD80	ECT	30	8 (26.7%)[b]	24.37±4.87[b]
CD80	NET	30	18 (60%)	46.25±14.04
CD86	ECT	30	12 (40%)	20.37±4.89[a]
CD86	NET	30	13 (43.3%)	26.87±5.89

Table 3 Expression of CD83 in esophageal tissues

Group	n	Prevalence (%)	Frequency (%)
ECT	30	10 (33.3)[a]	7.82±6.69[a]
PCT	30	18 (60)	23.34±19.7

[a]$P<0.05$ *vs* PCT group. ECT: esophageal carcinoma tissue, PCT: pericancerous tissue.

Lower expression of S-100 in EC patients

The S100 protein-positive cells were diffusely detected in infiltrating cells of esophageal mucous membrane and epithelium tissues. In ECT, they were localized in cancer cells and cancer nodules; only little could be detected in the tissues away from cancer tissues (Figure 4E, F). Contrast to NET, ECT expressed lower S100-positive cells ($P<0.05$) (Table 2).

Expression of CD83-positive cells

The CD83-positve cells were detected in infiltrating cells in PCT. The NET did not show any positive staining for CD83. In ECT, CD83-positive cells could only be dispersedly detected surround cancer nodules, but there were no CD83-positive

activated DCs in cancer nodules (Figure 5A, B, C). Contrast to PCT, ECT expressed lower CD83-positive cells ($P < 0.05$) (Table 3).

DISCUSSION

To activate naive T cells, DCs can uptake, process, and present antigens via their MHC molecules. In addition, T cell activation requires engagement of costimulatory receptors on the T cells. The DCs are at the center of the developing tumor-specific immune response, and are involved both in the initiation of tumor-specific immunity and the generation of immune effector functions. Many observations have suggested that DCs in tumors are functionally impaired[19-24].

In this study, we compared the functions of DCs generated from EC patients with those from healthy volunteers. Our results showed that the allogeneic MLR from EC-DCs was lower than that from N-DCs. With regard to the APC dysfunction in EC-DCs, the decreased expression of costimulators might be involved. Among the examined costimulators, lower expression of CD80 and CD86 was found in EC-DCs. The importance of the CD80/CD86-CD28 system in T cell responses has been well demonstrated[10,20,21,29].

The CD80 and CD86, members of the immunoglobulin super gene family, are encoded by separate genes and provide costimulatory function for APC-dependent T-cell activation both *in vivo* and *in vitro*[25-28]. A previous study reported that most tumor tissues, like those from the nonhematopoietic origin, did not express costimulatory molecules, which would render T cells unresponsive for the specific antigens[20]. Recent studies demonstrated that B7 expression of tumor cells resulted in increased tumor immunogenicity, enhanced generation of allogeneic and antilogous tumor reactive CTL. The decrease, abrogation or loss of CD80 and CD86 were detected both from EC-DCs and specimens from EC patients in this study, which might have profound implications for the down-regulation of the immune system and for enhancing the progression of esophageal carcinoma.

Furthermore, both the expression of CD80 and CD86 in EC sections could only be detected in the nucleus and cytoplasm but not on the cell membrane, suggesting the impaired transmembrane transfusion of CD80 and CD86 molecules. This interesting phenomena was similar to the B7 molecule expression in renal carcinoma and hepatocarcinoma[29,30].

The lower frequency of S100-positive cells in EC indicated the less DCs during esophageal cacinogenesis. However, the S100 protein family contains 21 members, and so far the physiological implication of its function is confusing[19]. Therefore, the significance of positive S100 protein is not clearly known.

Because CD83-positive DCs could not be detected in most of the normal esophagus, their existence in the tissues from EC patients indicated the maturation and activation of immature DCs. Alternatively, it was also possible that the activated CD83-positive DCs infiltrated into the esophagus in EC patients through the circulation in spite of having almost similar frequencies of CD83-positive DCs in peripheral blood form both healthy donors and EC patients. Most strikingly, all CD83-positive DCs were localized in the pericancerous tissues, and there were no CD83-positive DCs in any cancer nodules.

What is the significance of absence of activated DCs in cancer nodules form patients with EC? Activated DCs present the antigenic epitope to T cells and induce its activation, which are the most strong inducers for IL-12 and specific cytotoxic T lymphocytes during carcinogenesis[31,32]. In the absence of activated DCs in cancer nodules, normal immune surveillance against EC may be hampered due to defective production of tumor -specific lymphocytes. Again, tumor-specific lymphocytes would not be able to function and survive in the absence of activated DCs.

In summary, the impaired immune functions of DCs in patients with EC, including lower amount of DCs, decreased expression of CD80/86, minimally activated DCs, and complete absence of activated DCs in cancer nodules, are correlated to the pathogenesis and progression of EC.

Abstract

AIM: To analyse the role of genetic susceptibility and environmental factors in the process of esophageal cancer (EC) formation in Xi' an, China.

METHODS: A hospital based case-control study, combined with molecular epidemiological method, was carried out. A total of 127 EC cases and 101 controls were interviewed with questionnaires containing demographic items, habit of tobacco smoking, alcohol drinking, and family history of EC. Polymorphism of CYP1A1 and GSTM1 of 127 EC cases and 101 controls were detected by PCR method. The interactions between genetic susceptibility and environmental factors were also discussed.

RESULTS: Tobacco smoking, alcohol drinking and a family history of EC were risk factors for EC with an OR of 2.04 (95% CI 1.15-3.60), 3.45(95% CI 1.74-6.91), 3.14 (95% CI 1.28-7.94), respectively. Individuals carrying CYP1A1 *Val/Val* genotype compared to those with CYP1A1 *Ile/Ile* genotype had an increased risk for EC (OR 3.35, 95% CI 1.49-7.61). GSTM1 deletion genotype was a risk factor for EC (OR1.81, 95% CI 1.03-3.18). Gene-environment interaction analysis showed that CYP1A1 *Val/Val* genotype, GSTM1 deletion genotype had synergetic interactions with tobacco smoking, alcohol drinking and family history of EC.

CONCLUSION: Tobacco smoking, alcohol drinking and a family history of EC are risk factors for EC. CYP1A1 *Val/Val* and GSTM1 deletion genotypes are genetic susceptibility biomarkers for EC. There are synergic interactions between genetic susceptibility and environmental factors.

INTRODUCTION

China is a country with high incidence and mortality rate of EC. Risks for EC vary in different countries or different places[1-6].

Studies have shown that tobacco smoking, alcohol drinking[7-13], nutrition factors (fruit and vegetable consumption), life style, virus infection, heredity or exposure to nitro amines, fungi or AFB1 may be involved in the process of EC[1,3,14-24]. In China, the risks for EC were different among areas with different incidences[1-5,17,19,25,26]. The mortality rate of EC is about 24 per 100 000 in Xi' an, and it ranks first of all cancer mortalities. Previous studies showed that tobacco smoking and a family history of EC were risk factors for EC in Xi' an[2,27,28].

Environmental risks and genetic susceptibility may play the main role in the process of EC[2,27-37]. Susceptibility and environmental carcinogens exposure are indispensable factors for EC[25,28,37]. To explore the bio-basis of genetic susceptibility to EC in Xi' an, we carried out a hospital based case- control study to analyze the role of tobacco smoking, alcohol drinking, family history of cancer, family history of EC, CYP1A1, and GSTM1 gene polymorphism in the process of EC, and possible susceptibility –environmental risk interaction.

MATERIALS AND METHODS

Selection of patients and controls

Cases of esophageal cancer (confirmed by pathological diagnosis) came from inpatients of Tangdu Hospital, during Dec 1999 to May 2000. Controls were randomly selected from non-cancer inpatients from different wards of the same hospital during the same period. Both cases and controls were confined to Xi' an area residents.

Data collection

Trained interviewers using a structured questionnaire interviewed cases and controls in the hospital. The questionnaire contained information of residence, occupation, tobacco smoking habit, alcohol intake, family history of EC, *etc.* Tobacco smoking was defined as smoking at least one cigarette per day and persisting for more than one year. Alcohol intake was defined as drinking at least twice a week with more than 50 gram every time and persisting for more than one year. Totally 127 cases (male 97, female 30) and 101(male 78, female 23) controls were included. Blood samples were also collected for extraction of DNA genome. All blood samples were stored at -70 ℃ before DNA extraction.

Detection of polymorphism of CYP1A1 and GSTM1 by PCR methods

DNA genomes were extracted from blood clots by proteinase K digestion, hydroxybenzene, and chloroform method. Polymerase chain reaction (PCR) was used to identify their CYP1A1 and GSTM1 polymorphisms.

Primers for GSTM1(P1: 5' -GTA CCC TAC TTG ATT GAT GGG-3' ; P2: 5' -CTG GAT TGT AGC AGA TCA TGC-3') and CYP1A1 (P3: 5' -CGG AAG TGT ATC GGT GAG ACC **A** -3' , P4: 5' -CGG AAG TGT ATC GGT GAG ACC **G** -3' ; P5: 5' -GTA GAC AGA GTC TAG GCC TCA-3') were synthesized by Shengong Bio-technology Company of Shanghai. PCR condition for GSTM1: 50 μL solution containing 10×buffer 5 μL, Mg²⁺ 2 μL, P1,P2 1 μL, template

DNA1.5 μL, dDNTPs 1 μL and *Taq* DNA polymerase 3u. PCR consisted of denaturation first at 94 ℃ for 10 min, followed by addition of *Taq* DNA polymerase, and then at 94 ℃ for 1 min, at 60 ℃ for 1 min, at 72 ℃ for 1 min with 30 cycles. After 20 g/L agar was used for electrophoresis, PCR products were observed under violet light. GSTM1 genotype was characterized by 273 bp fragment, while GSTM1 deletion genotype had no fragment.

Two pairs of primers were used to detect the polymorphism of CYP1A1 (7th exon). For each DNA sample two sets of PCR were carried out using P3, P5 (marked as tube A) and P4, P5 (marked as tube B) respectively. PCR conditions for tube A and tube B were the same: 50 μL solution containing 10×buffer 5 μL, Mg^{2+} 2 μL, P3, P5 (or P4, P5) 1 μL, template DNA1.5 μL, dNTPs 1 μL and *Taq* DNA polymerase 3u. PCR was carried out at 94 ℃ for 10 min, followed by at 94 ℃ for 1 min, at 55 ℃ for 1 min, at 72 ℃ for 1 min, for a total of 35 cycles, at last extension at 72 ℃ for 10 min. After 20 g/L agar was used for electrophoresis, PCR products were observed under the violet light. If only tube A had the specific fragment (200 bp), the DNA was regarded as CYP1A1 *Ile/Ile* genotype (pure wild genotype). If only tube B had the positive fragment, CYP1A1*Val/Val* genotype (pure mutation) was considered, and CYP1A1 *Ile/Val* genotype was identified when both tube A and tube B had the fragment.

Quality control
DNA extraction and PCR were conducted in different times and places. The genotypes of DNA samples were identified blindly. Controls were set up within every PCR operation as blank control (without DNA template), positive control and negative control and when any one of these controls failed, PCR needed to be re-conducted.

Statistical analysis
Data were checked and input into the computer. The values of chi-square, odds ratio (OR) and OR 95% CI (confidence interval) were calculated. And interactions between genetic susceptibility-environmental factors were also estimated.

RESULTS
Test of comparability between cases and controls showed that the age and gender in cases and controls were comparable.

Risk factors for EC
Tobacco smoking, alcohol drinking, a family history of EC, *GSTM1* deletion genotype and *CYP1A1* genotype (*Val/Val*) were risk factors of EC (Table 1).

Analysis of genetic susceptibility-environmental factor interaction
GSTM1 deletion genotype had synergic interactions with tobacco smoking, alcohol drinking and family history of EC (Tables 2,3,4).

CYP1A1 *Val/Val* genotype had synergic interactions with tobacco smoking, alcohol drinking, and family history of esophageal cancer (Tables 5, 6, 7).

DISCUSSION

Under similar environmental carcinogens exposure, different individuals respond to environmental exposures differently. The different liability to cancer was called genetic susceptibility to cancer. Genetic susceptibility can affect in every step of carcinogenesis, including modifying the effect of environmental carcinogens[29,38-44]. Oncogenes and tumor suppressor genes can also affect individual's susceptibility to cancer[34-36,45]. Cancer susceptibility genes include type I, type II metabolism enzyme genes, DNA repair gene and those affecting cell proliferation rate. In recent years the evidence has been accumulated to support the hypothesis that cancer susceptibility genes may be of importance in determining individual susceptibility to cancer[43,46-59].

EC is a multi-factor determined disease, including environmental risk factors and genetic factors. In recent years, more and more researchers considered environmental and genetic susceptibility factors and their interactions in evaluating the risks of cancer[2,18,53,60-63]. Investigations showed the mortality rate of EC in Shanxi province was not decreased during the latest 20 years, and risk factors for EC in Xi'an city were discussed in several researches[2,27,28,33]. In the present hospital based case-control study, it was revealed that tobacco smoking was a risk factor, and also had interactions with GSTM1deletion genotype and CYP1A1 *Val/Val* genotype.

Aroma hydrocarbons (AHs) in tobacco smoking are pro-carcinogens. They need to be activated to reactive electrophilic forms by type I metabolic enzymes (CYP450s), then initiate cell carcinogenesis. On the other hand, the reactive electrophilic forms of carcinogen can be detoxified and excreted by type II

metabolic enzymes such as GSTM1. Although theoretically the increase of activity of type I metabolic enzymes and/or decrease of activity of type II metabolic enzymes can increase the risk for cancer, there were different results in different studies[43,44,47,50-52,64-69]. Our results showed that individuals carrying GSTM1 deletion genotype or/and CYP1A1 *Val/Val* genotype had increased risks for EC.

P450 CYP1A1 gene product metabolizes pro-carcinogens. There are three kinds of polymorphism of CYP1A1: *Msp*I site, 7th exon (Ile-Val) and AA polymorphism. CYP1A1 Ile-Val polymorphism is caused by a base difference (A or G) at 4 889 of 7th exon. The transition of A to G results changing of amino acid from isoleucine to valine at 462[14], thus forming three kinds of genotypes: homozygote wild genotype (*Ile/Ile*), mutation genotype (*Val/Val*) and heterozygote *Ile/Val* genotype. Researches showed CYP1A1 *Val/Val* genotype had a higher ability to activate pro-carcinogen than CYP1A1 *Ile/Ile* genotype. PAH-DNA adducts in leukocytes were higher in heavy smoking population with CYP1A1 *Val/Val* genotype than those with CYP1A1 *Ilel/Val or Ile/Ile* genotype.

The associations between CYP1A1 genotype and susceptibility to cancers were varied[39-42,47,70]. Data from Guangdong province of China showed that *MspI* C correlated with lung cancer susceptibility in no-smoking populations[65]. In studies in Shanghai and Haerbin, no significant relationship was discovered between CYP1A1 (*Ile-Val*) polymorphism and lung cancer susceptibility in non-smoking female patients[64]. CYP1A1 *Val/Val* genotype in white population only appeared about 3.2-5%, while in Japanese it was about 19.8%, in Chinese

22.3%. Our study showed that CYP1A1 *Val/Val* genotype was a genetic susceptibility risk factor for EC (OR 3.35, 95% CI 1.49-7.61). CYP1A1 *Val/Val* genotype had synergic interactions with tobacco smoking, alcohol drinking, and a family history of esophageal cancer.

GSTM1 can detoxify a number of reactive electrophilic compound substances, including the carcinogens PAHs. In individuals with GSTM1 deletion genotype, the ability of detoxifying the carcinogens decreased. Individuals with GSTM1 deletion could have increased risk of cancers[29,53,56]. In China there were similar researches on GSTM1 deletion genotype and the risks of lung cancer (OR=2.56)[66], and stomach cancer (OR 1.90, 95%CI 1.01-3.56)[67]. It was reported that in Henan province, a high incidence area of EC in China, GSTM1 deletion genotype did not show significant relation with EC susceptibility[25]. Results in our study indicated GSTM1 deletion genotype was a genetic susceptibility risk factor for EC (OR1.81, 95% CI 1.03-3.18), which interacted synergistically with tobacco smoking, alcohol drinking and family history of esophageal cancer.

In summary, we found that tobacco smoking, alcohol drinking, and a family history of EC were risk factors for EC in Xi'an area. CYP1A1 *Val/Val* genotype, GSTM1 deletion genotype were genetic susceptibility risk factors for EC. Gene-environment interaction analysis showed that CYP1A1 *Val/Val* genotype, GSTM1 deletion genotype synergetically interacted with tobacco smoking, alcohol intake, and family history of EC. Gene-gene interaction analysis did not show synergistic interaction between CYP1A1 mutation genotype and GSTM1 deletion genotype, although individuals carrying these two genotypes had increased risks for EC.

Abstract

AIM: To investigate the effects of vitamin E succinate (VES) on the expression of Fas and PCNA proteins as well as its clinical significance in human gastric carcinoma, and to explore the mechanism of VES-induced inhibition of gastric carcinoma cell growth.

METHODS: Immunohistochemical methods were used to detect Fas and PCNA expression both in human gastric cancer SGC-7901 cells treated with VES at different doses and in human gastric carcinoma tissues.

RESULTS: After the SGC-7901 cells were treated with VES at 5, 10, 20 mg/L for 48 h, the positive rates of Fas expression were 16%, 27% and 48%, respectively, significantly increased compared to that of control group ($P < 0.05$); while the positive rates of PCNA expression in groups treated with different doses of VES were 20%, 18% and 7%, respectively, which were significantly decreased compared to that of the control group ($P < 0.05$). In human gastric carcinoma tissues, the Fas positive expression rate was 42.4%(25/59), which declined with the decrease in the degree of tumor differentiation ($P < 0.05$) and with the existence of lymph node metastasis ($P < 0.001$). While the PCNA positive expression rate was 91.5%(54/59), no relationship was observed between PCNA expression and clinicopathologic parameters.

CONCLUSION: VES inhibited the growth of gastric cancer cells by inducing Fas expression and inhibiting PCNA expression. It is, therefore, considered that the expression of Fas and PCNA genes, through tumor cell apoptosis and proliferation, respectively, may be useful as a clinical predictive index in the application of VES to gastric carcinoma therapy, where as Fas may be of more value than PCNA.

INTRODUCTION

RRR-α-tocopheryl succinate (vitamin E succinate, VES), a derivative of natural vitamin E, has been shown to be a potent growth inhibitor of many kinds of cancer cell types such as human monocytic leukemia cell[1], murine Bl6 melanoma cell[2,3], human prostate cancer cell[4], human breast cancer cell[5,6] and murine EL-4 thymic lymphoma cell[7,8]. Characterization of cellular processes involved in VES antiproliferative effects have shown that VES inhibits tumor cell growth by a variety of mechanisms, including cell cycle blockage[9,10], DNA synthesis arrest[11], induction of differentiation[12-14], and triggering of apoptosis[15-19]. Meanwhile, VES is also noteworthy because of its non-toxic and non-inhibitory effects on normal cell types[20], indicating that VES can be used as a chemopreventive/ chemotherapeutic agent against tumors.

Gastric cancer is one of the most common malignant tumors in China[21-29]. Our previous studies found that VES could inhibit human gastric cancer SGC-7901 cell growth by blocking cell cycle, arresting DNA synthesis and triggering apoptosis[30-32]. In addition, our *in vivo* research demonstrated that VES inhibited benzo (a) pyrene (B (a) P)-induced forestomach carcinogenesis in female mice[33]. In this study, the expression of Fas and PCNA both in SGC-7901 cells treated with VES and in human gastric carcinoma tissues was investigated further for its clinical significance. It may provide reference indices for VES application in clinical therapy.

MATERIALS AND METHODS

Cell culture and treatment

Human gastric cancer cell lines SGC-7901 were maintained in RPMI 1640 medium supplemented with 100 mL/L fetal calf serum (FCS), 100 kU/L penicillin, 100 mg/L streptomycin and 2 mmol/L L-glutamine, incubated in a humidified atmosphere containing 50 mL/L CO_2 at 37 ℃. The SGC-7901 cells were collected after incubation for 48 h in the presence of VES at 5, 10 and 20 mg/L and of ethanol at 1 mL/L as the control group (VES was dissolved in absolute ethanol and diluted in RPMI 1640 complete condition media correspondingly to a final concentration of VES and 1 mL/L ethanol). The cells were then fixed in 40 g/L formaldehyde and embedded in paraffin.

Clinical materials

Fifty-nine paraffin-embedded specimens of gastric cancer were obtained from the pathological laboratory of the First Affiliated Hospital of Harbin Medical University. These specimens were from resections of gastric cancer in this hospital from 1991 to 2001. Of these, 35 were from males, and 24 from females and the age of the patients varied from 31 to 77 years. These specimens had been histologically classified in which 7 were highly to moderately differentiated adenocarcinomas, 52 were poorly differentiated. Thirty-three tumors had invaded the serosa by histology, and 22 cases had local lymph node metastasis.

Reagents and methods

VES was purchased from Sigma Co. Ltd. RPMI 1640 medium was obtained from Gibco BRL. Antibodies against either PCNA or Fas and SP immunohistochemical reagent kit were purchased from Beijing Zhongshan Biotechnology Co. Ltd.

Serial sections of 4 μm thick were sliced from each of the

cell and clinical tissue blocks. These were deparaffinized and rehydrated, and immersed in 30 mL/L H_2O_2 for 10 min to remove the endogenous peroxidase activity. The sections were further incubated with 100 mL/L normal goat serum for 1 h to reduce nonspecific binding. They were, then, incubated with either primary Fas or PCNA antibody at 4 ℃ for 12-16 h. All sections were washed in phosphate buffer solution (PBS) (0.01 mol/L, pH7.2). Afterwards, they were sequentially incubated with biotin conjugated secondary antibody, and avidin biotin enzyme reagent. Staining was done by first immersing the slides in 3, 3' -diaminobenzidine tetrahydrochloride (DAB). All slides were counterstained with haematoxylin/methyl-green, dehydrated and mounted. PBS substituted for the primary antibody was used as the negative control. For the slides initially incubated with primary Fas antibody, if the proportion of positively stained cells was more than 10%, it was considered as a Fas positive sample. For the slides initially incubated with primary PCNA antibody, if the proportion of positively stained cells as more than 50%, it was considered as a PCNA positive sample.

Statistics

The data of Fas and PCNA expression were analyzed by t-test. Correlations between Fas and PCNA expression and clinicopathologic parameters were examined using c^2 test. $P<0.05$ was considered to be statistically significant.

RESULTS

The effect of VES on Fas expression in SGC-7901 cells

The Fas positive expression appeared as brown granules located in the membrane and cytoplasm, and the cell nucleus appeared green after counterstaining with methyl green (Figure 1). After the SGC-7901 cells were treated with VES at 5, 10, 20 mg/L and ethanol at 1 mL/L for 48 h, the Fas positive rates were 16%, 27%, 48% and 10%, respectively (Figure 3). The positive rates for the VES treated groups at different doses were significantly increased compared to that of the control group ($P<0.05$), with an evident dose-effect relationship.

Figure 1 Effects of VES on the expression of Fas protein in SGC-7901 cells. A: control group (×200), B: 20 mg/L VES treated for 48 h (×200).

Effects of VES on PCNA expression in SGC-7901 cells

In contrast to Fas positive expression, the positive PCNA brown stained granules were in the nucleus, while the negative cell nucleus appeared blue after counterstaining with hematoxylin (Figure 2). PCNA positive expression rates, when the cells were treated with VES at 5, 10, 20 mg/L for 48 h were 20%,18% and 7%, respectively (Figure 3), and in the control group 28%. The positive rates of the cells treated with VES at different doses were significantly decreased compared to that of the control group ($P<0.05$), with an evident dose-effect relationship.

Figure 2 Effects of VES on the expression of PCNA protein in SGC-7901 cells. A: control group (×200), B: 20 mg/L VES treated for 48 h (×200).

Figure 3 Effects of VES on the expression of Fas and PCNA proteins at different doses.

Expression of Fas in clinical pathological tissues of gastric carcinoma

As shown in Figure 4A, the expression of Fas protein in normal gastric tissues was stronger, for there were many brown stained granules in the membrane and cytoplasm of both glandular and interstitial cells. In the gastric carcinoma tissues, the Fas expression was decreased (Figure 4B) or even negative, the Fas positive rate was only 42.4%(25/59).

Expression of PCNA in clinical pathological tissue of gastric carcinoma

There were brown stained granules located in the nuclei of

PCNA positive cells, while the negative cell nucleus appeared blue after counterstaining with hematoxylin (Figure 5). The positive expression rate of PCNA in normal gastric tissues was not high; the stained cell rate was 49.6%. The stained cell rate in gastric carcinoma tissues was between 33-99%, and the PCNA positive rate was 91.5%(54/59).

Figure 4 Expression of Fas protein in human normal gastric tissues and gastric carcinoma tissues. A: normal gastric tissue (×200), B: gastric carcinoma tissue (×200).

Figure 5 Expression of PCNA protein in human normal gastric tissues and gastric carcinoma tissues. A: normal gastric tissue (×200), B: gastric carcinoma tissue (×200).

Correlation of clinicopathological parameters with expression of Fas and PCNA in gastric carcinoma tissues

As shown in Table 1, the rates of Fas and PCNA protein expression were not correlated with either the patient's age or sex ($P>0.05$). The immunoreactivity of Fas was significantly associated with tumor differentiation and lymph node metastasis. Among the 59 cases of gastric carcinoma, Fas positive expression rate in the 7 well-differentiated tissues (85.7%) was obviously higher than that in the 52 cases that were poorly differentiated tissues (36.5%)($P<0.05$). The Fas positive expression rate in the group with lymph node metastasis was 13.6%(3/11), lower than in that without lymph node metastasis ($P<0.01$). PCNA positive expression was not associated with clinicopathologic parameters ($P>0.05$).

Table 1 Correlation of clinical pathological parameters with expression of Fas and PCNA in clinical gastric carcinoma tissues

Pathologic parameters	n	Fas expression		PCNA expression	
		+	(%)	+	(%)
Age (yr)					
≤45	11	4	(36.3)	11	(100)
>45	48	21	(43.7)	43	(89.5)

[a]$P<0.05$, [b]$P<0.01$.

DISCUSSION

The mechanisms of VES-induced inhibition of tumor cell growth have been a topic of great interest. Turley *et al*[34] observed that the expression of Fas, a cell surface receptor, was increased after treatment of breast cancer cells with VES. They also observed that VES-induced apoptosis in breast cancer cells was inhibited when using Fas neutralizing antibody or transfecting Fas antisense oligonucleotides to cancer cells. Since then, other studies have shown that Fas-mediated apoptosis may be another important pathway by which VES inhibits tumor cell growth[35-37].

Fas/APO-1, a 45 ku type I transmembrane protein, belongs to the nerve growth factor (NGF)/tumor necrosis factor (TNF) receptor superfamily. As a member of the five death domain-containing receptors, Fas initiates a signal-transduction cascade leading to programmed cell death[38-46]. In recent studies, Fas protein expression has been identified in various organs. It was reported that Fas antigen expression could be related to lymph node status and clinical stages in cancer patients. The rate of Fas antigen expression was significantly higher in gastric carcinoma tissues without lymph node metastasis than in those with lymph node metastasis, and also higher in clinical stages I and II than in clinical stages III and IV of gastric carcinoma. Moreover, the prognosis of patients with negative expression of Fas was worse[47,48]. In this study, we determined the Fas expression both in SGC-7901 cells treated with VES and in human gastric carcinoma tissues. The data showed that after 48 h of VES treatment, the expression of Fas protein was evidently increased with a marked dose-dependent relationship compared to that of the control group, indicating that Fas signal

pathway was involved in VES-triggered apoptosis. In addition, the expression of Fas protein in gastric carcinoma tissue was depressed with the decrease of tumor differentiation degree and with the existence of lymph node metastasis. These results are in accordance with the reports mentioned earlier. It suggested that Fas protein expression may be one of indices to predict prognosis of patients with gastric carcinoma, thus establishing a theoretical foundation for using Fas protein expression to assess the effect and prognosis of VES application in clinic therapy.

PCNA functions as a cofactor for DNA polymerase δ. It is associated with DNA repair in both S phase and DNA synthesis phase. As an index of cellular proliferative status, PCNA was determined in various lesions. The overexpression of PCNA with high frequency was usually used as a reliable marker for assessment of tumor progression, premalignant evolution and clinical prognosis of patients with various malignancies[49-59]. Our in vitro results showed that VES at different doses could decrease the PCNA expression in SGC-7901 cells to different degrees, indicating that the inhibition of the growth of human gastric carcinoma by VES might be associated with its depression of PCNA protein, decrease in DNA-polymerase δ activity and interference of DNA synthesis. Additionally, the expression of PCNA in clinical gastric carcinoma tissue was higher than that in normal gastric tissues, but we failed to demonstrate the correlation between PCNA expression and clinicopathological parameters in gastric carcinoma in this study, which was conflicted with the reports about PCNA expression in gastric carcinoma[60,61] and the reports that PCNA could be an effective indicator of prognosis for tumor. Based on the in vitro results that VES has effects on PCNA expression in gastric carcinoma cells in our study and the reports we have mentioned, we presumed that the conflicting results in our study might be related to fewer cases we have collected, such as only seven cases of highly-moderately differentiated carcinoma.

With the progress of tumor research, it has been realized that the tumorigenesis is a result of imbalance between cell proliferation and apoptosis. On the one hand, cells proliferate massively; on the other hand, cellular apoptosis is inhibited. Fas and PCNA are the two genes closely related to apoptosis and proliferation. Our study indicates that both of them play important roles in the inhibitory effects of VES on gastric carcinoma cells in vitro. But for evaluating the effect of VES on gastric carcinoma tissue, Fas, as an effective predicting index for VES application to gastric carcinoma therapy may be of more value than PCNA.

Abstract

AIM: To study the synergistic effects of calmodulin (CaM) antagonist O-4-ethoxyl-butyl-berbamine (EBB) and pegylated liposomal doxorubicin (PLD) on hepatoma-22 (H_{22}) *in vivo*.

METHODS: Hepatoma model was established in 50 Balb/c mice by inoculating H_{22} cells (2.5×10^6) subcutaneously into the right backs of the mice. These mice were divided into 5 groups, and treated with saline only, PLD only, doxorubicin (Dox) only, PLD plus EBB and Dox plus EBB, respectively. In the treatment groups, mice were given 5 intravenous of PLD or Dox on days 0, 3, 6, 9 and 12. The first dosage of PLD or Dox was 4.5 mg/kg, the other 4 injections was 1 mg/kg. EBB (5 mg/kg) was coadministered with PLD or Dox in the corresponding groups. The effect of drugs on the life spans of hepatoma-bearing mice and tumor response to the drugs were recorded. Dox levels in the hepatoma cells were measured by a fluorescence assay. Light microscopy was performed to determine the histopathological changes in the major organs of these tumor-bearing mice. The MTT method was used to analyze the effect of Dox or PLD alone, Dox in combination with EBB, or PLD in combination with EBB on the growth of H_{22} cells in an *in vitro* experiment.

RESULTS: EBB (5 mg/kg) significantly augmented the antitumor activity of Dox or PLD, remarkably prolonged the median survival time. The median survival time was 18.2 d for control group, but 89.2 d for PLD+EBB group and 70.1 d for Dox+EBB group, respectively. However, Dox alone did not show any remarkable antitumor activity, and the median survival time was just 29.7 d. Addition of EBB to Dox or PLD significantly increased the level of Dox in H_{22} cells *in vivo*. Moreover, EBB diminished liver toxicity of Dox and PLD. *In vitro*, EBB reduced the IC50 value of Dox or PLD on H_{22} cells from 0.050±0.006 mg/L and 0.054±0.004 mg/L to 0.012±0.002 mg/L and 0.013±0.002 mg/L, respectively (*P*<0.01).

CONCLUSION: EBB and liposomization could improve the therapeutic efficacy of Dox in liver cancer, while decreasing its liver toxicity.

INTRODUCTION

O-4-ethoxyl-butyl-berbamine (EBB)[1,2], a new derivative of bisbenzylisoquinoline, is one of the most powerful and specific calmodulin (CaM) antagonist with almost no cytotoxicity on normal cells. Its IC_{50} value is 100 times lower than that of tetrandrine and in the same grade with R2457. Previous studies have shown that EBB has a strong inhibitory effect on the proliferation of hepatoma cells, and can prolong the life span of tumor-bearing mice. EBB augments the antitumor activity of 5-FU[2], restores abnormal CaM content in major organs of tumor-bearing mice[3] and improves their immunofunction[4]. Therefore, EBB may have a synergistic effect with chemotherapeutic drugs and alleviate their organ toxicity clinically.

Doxorubicin (Dox) is a widely used anti-tumor agent. However, systemic treatment with Dox is complicated by its dose limiting toxicity, even at relatively low concentrations, as well as its rapid plasma clearance and distribution to non-relevant tissues[5-10]. Pegylated liposomal doxorubicin (PLD) not only increases concentration of Dox in tumor and thus enhances its antitumor activity, but also has lower toxicity to the cardiac muscle compared with Dox alone[7,11-15]. In this study, we adopted two strategies to enhance the anti-tumor activity and lower the cytotoxicity of Dox: Dox was administrated in liposome form and in combination with EBB.

MATERIALS AND METHODS

Reagents

EBB was kindly provided by Dr. Xu YH (Institute of Molecular Biology, Nankai University, China). Hydrogenated egg phosphatidylcholine (HEPC) was kindly supplied by Lipod (Ludwigshaven, Germany). Polyethylene glycol-distearoyl phosphatidyethanolamine (PEG-DSPE) was purchased from Pharmachemie (Haarlem, the Netherlands). PLD (stabilized long circulating liposomes, Dox-HEPC-SLL) with an average diameter of 80 nm was prepared as described earlier[16].

Animals and tumor model

Age- and sex-matched Balb/c mice (weighting 18-22 g) from the Animal Breeding Center of Peking University (Beijing, China) were used. H_{22} cells in 0.2 mL (2.5×10^6) were inoculated subcutaneously into the right backs of the mice. Tumor became apparent about 7 d after the inoculation, and the mice died approximately 18 d later without treatment.

Treatment protocol

On d 7 after inoculation, tumor-bearing mice were randomly divided into 5 groups. Control group received only saline. PLD or Dox group received 4.5 mg/kg PLD or Dox *i.v.* on the first

day, followed by 4 dosages of 1 mg/kg PLD or Dox in 3-d intervals. PLD+EBB or Dox+EBB group was treated in the same way, except that EBB (5 mg/kg, toxicity-free dosage)[2] was coadministered. All these dosages could be well tolerated by mice (Dr. Yang SG, unpublished observations).

Assessment of tumor response

Tumor growth was recorded before and after the treatment by caliper measurements, and tumor size was calculated using the formula $0.4 \times (A^2 \times B)$ (where B represents the largest diameter and A the diameter perpendicular to B). Tumor response was also assessed by the life span of mice.

Tumor response rate was assessed on d 0 and 10 after commence of the treatment as follows: progressive disease (PD) = increase in tumor size above 25%, no change (NC) = tumor size equal to that at the beginning of treatment (at a range of -25% and + 25%), partial remission (PR) = decrease in tumor size between -25% and -90%, and complete remission (CR) = decrease in tumor size between -90% and -100%.

Drug levels in tumor tissue[17]

Seven days after inoculation, Dox (10 mg/kg) or PLD (equal to 10 mg/kg Dox) alone, or each of them in combination with EBB (5 mg/kg) was injected *i.v.* After 1, 18, and 36 h, the mice were anesthetized with pentobarbital. Tumors were excised immediately after being perfused with saline. Tissues were homogenized and subjected to acidic isopropanol extraction, and Dox level was measured by a Perkin-Elmer Model MPF44 spectrofluorometer using an excitation wave at 490 nm and the emission wave at 590 nm. Fluorescence intensity was translated to μg or ng of Dox equivalents using a standard curve of Dox.

Histological examinations

One of the major objectives of these studies was to assess whether the treatment with Dox or PLD in combination with EBB would result in any significant alleviation of their tissue damages. Light microscopy was performed to determine the histological changes in organs from tumor-bearing mice treated with saline and drugs. Mice were sacrificed by cervical dislocation on d 20. The liver, spleen, kidney, lung, and heart were moved and fixed in formalin solution and cut into 4 μm thick sections. The tissue sections were hematoxylin-eosin stained and accessed by conventional histological criteria.

Determination of anti-tumor activity in vitro

H_{22} cells were cultured at the concentration of 1×10^7 cells/L in 24-well plates in RPMI1640 culture medium containing 100 mL/L heat-inactivated fetal calf serum, 100 U penicillin, and 1 000 U streptomycin at 37 ℃, 50 mL/L CO_2. Dox (0.01-0.20 mg/L) or PLD (0.01-0.20 mg/L) alone, Dox (0.01-0.20 mg/L) + EBB (1.17 mg/L, the IC50)[2], or PLD (0.01-0.20 mg/L) + EBB (1.17 mg/L, the IC50) were added. Cells were harvested 72 h later, and 50 μL of MTT regent was added to each well followed by 4 h incubation at room temperature. Absorbance was measured at 540 nm. Four replicate experiments were performed, and IC50 values were calculated.

Statistical analysis

SPSS9.0 for Windows 98 statistic software was used for data analysis. A *P*-value less than 0.05 was considered statistically significant.

RESULTS

Antitumor activity of DOX or PLD in combination with EBB

Intravenous administration of 5 injections of Dox or PLD in combination with EBB (5 mg/kg) strongly inhibited the growth of tumor, and resulted in tumor regression in some mice. The median survival time was 89.2 d in PLD+EBB group and 70.1 d in Dox+EBB group, respectively, significantly longer than that of control group (18.2 d) and Dox group (29.7 d) (Figure 1, Table 1).

Figure 1 Antitumor activity of Dox or PLD alone or in combination with EBB in mice with hepatoma.

Table 1 Tumor response and survival time of hepatoma-bearing mice after systemic treatment with Dox or PLD alone or in combination with EBB

Group	Tumor response[1]					Mean survival time (d)
	PD	NC	PR	CR	(PR+CR)%	
Dox (n=10)	10				0	29.7±8.2[a]
Dox+EBB (n=10)	5	2	3		30	70.1±8.3[ac]
PLD (n=10)	6	2	2		20	67.2±9.1[ac]
PLD+EBB (n=12)	2	1	6	3	75	89.2±13.2[aeg]
Controls (n=8)	8				0	18.2±2.7

[1]Tumor response was scored on d 0 and d 10 after start of treatment. [a]$P<0.05$ compared with control group; [c]$P<0.05$ compared with Dox alone; [e]$P<0.05$ compared with Dox+EBB; [g]$P<0.05$ compared with PLD alone.

Drug concentrations in tumor tissues

The Dox levels in subcutaneous hepatoma were significantly increased by EBB in both Dox+EBB and PLD+EBB groups ($P<0.01$) (Figure 2).

Figure 2 Dox concentrations in tumor tissues from mice after *i.v.* injection of Dox (10 mg/kg) or PLD (equal to 10 mg/kg Dox) in combination with EBB (5 mg/kg).

Histopathological changes

Severe histological changes were found in the liver of Dox group as compared to both Dox+EBB and PLD+EBB groups. Briefly, compared with control mice (Figure 3A), Dox-treated mice showed diffuse fatty degeneration and necrotic changes

Figure 3 Histopathological changes in livers of tumor-bearing mice treated with saline (A), Dox (B), Dox+EBB (C), PLD (D) or PLD+EBB (E). (Original magnification, ×200).

in the liver (Figure 3B). Livers from Dox+EBB-treated and PLD-treated mice showed similar change, but all were milder than Dox-treated mice (Figure 3C, D). Livers from PLD+EBB-treated mice showed very mild or even undetetable changes (Figure 3E). Severe histological damage was observed in the spleens from all drug-treated mice (data not shown). However, there were no significant abnormalities in the hearts, lungs, and kidneys from all animals (data not shown).

Synergetic effect of EBB with Dox or PLD in vitro
The *in vitro* experiment confirmed that EBB (1.17 mg/L, the IC50) augmented the cytotoxicity of Dox and PLD, and reduced the IC_{50} of Dox or PLD on H_{22} cells from 0.050 ± 0.006 mg/L and 0.054 ± 0.004 mg/L to 0.0120 ± 0.002 mg/L and 0.0130 ± 0.002 mg/L, respectively ($P<0.01$, Figure 4).

Figure 4 IC_{50} value of Dox or PLD alone or in combination with EBB.

DISCUSSION

Liposomes are attractive drug carriers for intravenous use because of their biocompatibility and versatility of formulation. As witnessed by publications, liposomes can be used for the delivery of cytotoxic drugs, antifungal agents, and biological response modifiers in humans. Phase I and some Phase II studies with liposomal doxorubicin have been reported. However,

the rapid and dominant uptake of these liposomes by the reticuloendothelial system affects its distribution in tumor[18-20]. We have previously reported that encapsulation of Dox in long-circulating, pegylated liposomes could dramatically improve its mean residence time in serum[16]. In the present study, we demonstrated the ability of sonicated liposomes to deliver DOX into H_{22} cells. This may account for the increased antitumor effect of liposome-entrapped Dox observed in the model of hepatoma.

CaM is a ubiquitous calcium-binding protein that is responsible for many intracellular actions of calcium[21-30]. Lot of evidences suggest that CaM not only plays an important role in the proliferation of normal cells, but also is related to hepatoma growth[2,31]. In fact, an increased concentration of CaM has been demonstrated in malignant tissues and transformed cell lines[32,33], and the correlation between inhibition of cell growth and antagonism of CaM has been observed[21,34]. EBB, one of the strongest and most specific CaM antagonists with almost no cytotoxicity on normal cells, could decrease the amount of CaM in hepatoma cells and block the proliferation of hepatoma cells at G_2/M phase[2].

In the present study, we demonstrated for the first time that EBB could strongly enhance the antitumor activity of liposomal doxorubicin. *In vitro*, EBB reduced the IC_{50} value of both Dox and PLD in inhibiting H_{22} cells. *In vivo*, EBB enhanced accumulation of Dox in tumor tissue. There are at least three possible mechanisms underlying these effects. First, EBB could significantly enhance intracellular accumulation of Dox. Secondly, EBB could decrease the CaM content in cytoplasm, resulting in the inhibition of hepatoma cell growth[2]. The third is that EBB upregulated the expression of wild-type p53 gene[2], which is an antioncogene.

In terms of histological damage in the livers of the tumor-bearing mice, the present study showed that the changes were milder in mice treated with Dox+EBB and PLD+EBB than in mice treated with Dox or PLD alone. Unfortunately, severe histological damage was observed in the spleens of all experimental animals treated with drugs (data not shown). The reasons for these remain to be further investigated.

In conclusion, although Dox is extremely toxic when used

systemically, encapsulation of Dox in pegylated liposomes allows effective treatment of hepatoma when used in combination with EBB without potential hazards. In our model, administration of PLD resulted in a better tumor response compared with free Dox, and addition of EBB to PLD regimen resulted in a strongly enhanced synergistic tumor response. Therefore, in combination with EBB, the dosage of PLD can be reduced without loss of its antitumor activity, but with a decrease in cytotoxity.

Abstract

AIM: To investigate the cellular effects of hybrid polar compound hexamethylene bisacetamide (HMBA) on the growth and apoptosis of human hepatocellular carcinoma cells and to provide the molecular mechanism for potential application of HMBA in the treatment of liver cancer.

METHODS: Effects of HMBA on the growth of human hepatocellular carcinoma SMMC-7721 cells were assayed by MTT chronometry. Apoptosis induced by HMBA was detected by phase-contrast microscopy, flow cytometry, propidium iodide staining and immunocytochemical analysis.

RESULTS: The growth of SMMC-7721 cells was significantly inhibited by HMBA, and the growth inhibitory rate was 51.1%, 62.6%, 68.7% and 73.9% respectively after treatment with 5.0, 7.5, 10.0 and 12.5 mmol/L of HMBA. In the cells treated with 10 mmol/L of HMBA for 72 h, the population of cells at sub-G_1 phase significantly increased, and the apoptotic bodies and condensed nuclei were detected. Moreover, treatment of SMMC-7721 cells with 10 mmol/L of HMBA down-regulated the expression of Bcl-2 anti-apoptotic protein, while slightly up-regulated the level of pro-apoptotic protein Bax.

CONCLUSION: Treatment with 10.0 mmol/L of HMBA can significantly inhibit the growth and induce apoptosis of human hepatocellular carcinoma SMMC-7721 cells by decreasing the ratio of Bcl-2 to Bax.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignancies worldwide and accounts for as many as one million deaths annually[1]. HCC is a leading cause for cancer-related deaths of adults in Asia and sub-Saharan[2,3]. In China, the mortality rate of HCC ranks first in rural areas and second in cities[4,5].The main environmental risk factors identified to be closely associated with hepatocellular carcinoma incidences are hepatitis B virus (HBV) and hepatitis C virus (HCV) infections, which account for more than 80% of HCC cases worldwide. Other agents that also play an important role in HCC development include aflatoxin B1 (AFB1) exposure, heavy alcohol consumption and cigarette smoking[3,6]. However, the cellular and molecular mechanism underlying HCC development remains poorly understood. HCC is still one of the worst malignant diseases without an effective treatment. Therefore, it is critical to search for novel chemotheraputic agents that can inhibit the growth or induce the apoptosis of hepatocellular carcinoma cells.

Hybrid polar compounds are potent inducers of cell differentiation for a wide variety of tumor cells[7]. Hexamethylene bisacetamide (HMBA), a prototype of hybrid polar compounds, has been used to induce terminal differentiation in a number of leukemic and solid tumor cell lines[8-12]. In the previous reports[13,14], we have shown that HMBA at a low concentration induced differentiation of human hepatocellular carcinoma SMMC-7721 cells, a cell line that has been previously used as an appropriate cell model *in vitro* to study the cellular mechanism of HCC development[15-22]. However, whether HMBA at a higher concentration can induce apoptosis of hepatocellular carcinoma cells has not been determined yet. Here we reported the effects of HMBA on the growth and apoptosis of human hepatocellular carcinoma SMMC-7721 cells. We revealed that treatment with 10.0 mmol/L of HMBA significantly inhibited the growth and induced apoptosis of SMMC-7721 cells by down-regulating the Bcl-2/Bax ratio.

MATERIALS AND METHODS

Materials

Hexamethylene bisacetamide (HMBA), [3-(4,5)-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT), dimethyl sulphoxide (DMSO) and propidium iodide (PI) were purchased from Sigma. DMEM was obtained from Invitrogen Inc. Fetal bovine serum was supplied by Si-Ji-Qing Biotechnology Co. (Hangzhou, China). Mouse anti-human Bcl-2 and Bax monoclonal antibodies were obtained from Santa Cruz Biotechnology. SP detection kit and DAB kit were purchased from Beijing Zhongshan Biotechnology Co.

Cell culture

SMMC-7721 cell line was obtained from the Institute of Biochemistry and Cell Biology, Shanghai Institute of Biological Sciences, Chinese Academy of Sciences. Cells were maintained in DMEM supplemented with 100 mL/L heat-inactivated fetal

bovine serum, 100 units/mL of penicillin and 100 mg/L of streptomycin at 37 ℃ with 50 mL/L CO$_2$ in atmosphere.

MTT assay

SMMC-7721 cells were seeded in 96-well plates at a density of 7×10^3 cells/well. After 24 h, the cells were treated with different concentrations of HMBA for different times. One hundred μL MTT (250 mg/mL) was added to the cells per well. The plate was incubated for 4 h at 37 ℃ until purple formazan crystal developed. Then MTT-containing medium was removed and 200 μL DMSO solution (containing 900 mL/L DMSO and 100 mL/L 0.1 mol/L of glycine-NaOH) was added to each well and incubated at room temperature for 30 min. The absorbance at 570 nm was read and four wells were examined with an ELISA plate reader (Bio-Rad) for each treatment.

Phase-contrast microscopy

SMMC-7721 cells and the cells treated with 10 mmol/L of HMBA for 72 h on 6-well plates were examined under phase-contrast microscopy (Leica DM IRB).

Flow cytometry assay and fluorescence microscopy

SMMC-7721 cells untreated and treated with 10 mmol/L of HMBA for 72 h were assayed for DNA content using the propidium iodide staining method and subsequent flow cytometry analysis. Briefly, the cells (generally 2×10^6) were collected, rinsed in PBS, resuspended and fixed in 70% ethanol at 4 ℃ overnight. The fixed cells were pelleted, resuspended in PBS, and incubated in 100 mg/L of RNase A at 37 ℃ for 30 min and in 50 mg/L of propidium iodide at 4 ℃ for 30 min in the dark. Cell cycle distribution at different phase was analyzed with FACScan flow cytometry (Becton Dickinson). More than 10 000 events were acquired for analysis. The nuclear morphology of the stained cells was also observed under fluorescence microscope (Leica DM IRB).

Immunocytochemical analysis

SMMC-7721 cells untreated and treated with 10 mmol/L of HMBA were cultured on coverslips in a 6-well plate. After 72 h, the cells growing on coverslips were fixed with cold acetone for 10 min, rinsed twice in PBS for 10 min. Endogenous peroxidases were inactivated by immersing the sections in 3% hydrogen peroxide for 10 min, washed with distilled water and PBS for 15 min, blocked with 100 mL/L normal goat serum for 10 min to reduce the non-specific binding, and incubated with monoclonal mouse anti-human Bcl-2, Bax antibodies (1:200) at 4 ℃ overnight. After incubation, the cells on coverslips were incubated with biotinylated anti-mouse IgG at 37 ℃ for 10 min, rinsed twice in PBS for 15 min, and then incubated in streptavidin-peroxidase at 37 ℃ for 10 min. The chromogenic reaction was developed with diaminobenzidine (DAB). Negative controls were incubated in the absence of primary antibodies.

Statistical analysis

Data of MTT assay were expressed as mean±SD. Difference between means was analyzed using Student's *t*–test, $P<0.05$ was considered statistically significant.

RESULTS

Effects of HMBA on growth of SMMC-7721 cells

To address whether HMBA affected the growth of hepatocellular carcinoma cells, SMMC-7721 cells were treated with different concentrations of HMBA and then examined by MTT dye reduction assay. As is shown in Table 1, HMBA significantly inhibited the growth of hepatocellular carcinoma cells at concentrations of 5.0, 7.5, 10.0 and 12.5 mmol/L, and the growth inhibitory rate on SMMC-7721 cells at the 72 h was 51.1%, 62.6%, 68.7% and 73.9%, respectively ($P<0.05$).

Figure 1 Detection of cell morphology by phase-contrast microscopy (×200). A: SMMC-7721 cells, B: SMMC-7721 cells treated with 10 mmol/L of HMBA for 72 h.

Apoptosis of SMMC-7721 cells indueed by HMBA

In the previous reports, we have revealed that treatment with 5 mmol/L of HMBA induced differentiation of SMMC-7721. In this study, we found that treatment with 10 mmol/L of HMBA caused more dramatic changes of cellular morphology of SMMC-7721 cells (Figure 1). To test whether HMBA-mediated growth inhibition and morphological alteration of hepatocellular carcinoma cells were associated with the induction of apoptosis,

Table 1 Growth inhibition of SMMC-7721 cells by HMBA

Concentrition (mmol/L)	24 h treatment		48 h treatment		72 h treatment	
	A_{570}	I R (%)	A_{570}	I R (%)	A_{570}	I R (%)
0	0.201±0.029	/	0.409±0.064	/	0.788±0.037	/
5.0	0.155±0.009	22.9	0.238±0.031	41.8	0.385±0.033	51.1

I R: Inhibitory rate.

Figure 2 Detection of apoptotic morphology in SMMC-7721 cells treated with 10 mmol/L of HMBA for 72 h (×400). SMMC-7721 cells displayed fragmented nuclei and apoptotic bodies (B, C) after treatment with 10 mmol/L of HMBA for 72 h, while the untreated cells did not show these apoptotic characteristics (A).

Figure 3 Immunocytochemical analysis of Bcl-2 and Bax expression in SMMC-7721 cells treated with 10 mmol/L of HMBA for 72 h (×200). A: The high level of Bcl-2 protein in SMMC-7721 cells, B: The decreased level of Bcl-2 protein in the cells treated with 10 mmol/L of HMBA, C: The low level of Bax protein in SMMC-7721 cells, D: The slightly increased level of Bax protein in the cells treated with 10 mmol/L of HMBA.

SMMC-7721 cells were cultured in the presence of 10 mmol/L of HMBA for 72 h, stained with propidium iodide and then cellular morphology was examined. A significant population of cells treated with 10 mmol/L of HMBA displayed the features of apoptosis, such as fragmented nuclei and apoptotic bodies (Figure 2). In addition, in the untreated control cells, only 2.74% cells were found in sub-G_1 phase, but in the cells treated with 10 mmol/L of HMBA for 24, 48 and 72 h, 5.49%, 7.31% and 21.6% cells were found in sub-G_1 phase respectively, indicating that HMBA treatment at a high concentration could significantly induce apoptosis of SMMC-7721 hepatocellular carcinoma cells.

Effects of HMBA on expression of Bcl-2 and Bax in SMMC-7721 cells

To elucidate the mechanism by which HMBA induces apoptotic cell death of SMMC-7721 cells, we analyzed the expression of two critical apoptosis-associated proteins, Bcl-2 and Bax, which are known to regulate the cell death/survival in opposite manners. As is shown in Figure 3, Bcl-2 protein level was significantly decreased while Bax protein level was slightly increased in the cells treated with 10 mmol/L of HMBA for 72 h. This result suggested that HMBA could induce apoptosis of SMMC-7721 cells by down-regulating the ratio of Bcl-2 to Bax.

DISCUSSION

Dysregulations of cell proliferation, differentiation and apoptosis are hallmarks of cancer cells[23]. It is possible that these malignant features could be altered by many differentiation inducers such as hybrid polar compound HMBA. Considerable progress has been made toward elucidating the mechanism by which HMBA induces terminal differentiation of cancer cells. In recent year, some reports showed that HMBA induced apoptosis on a number of cancer cells[24-28], which appeared characteristics of cell shrinkage, chromatin condensation, DNA fragmentation and membrane blebbing[29,30].

In the present study, we investigated the cellular effects of HMBA on the growth and apoptosis of human hepatocellular carcinoma SMMC-7721 cells. Our data demonstrated that HMBA could effectively inhibit the growth of SMMC-7721 cells in a dose- and time-dependent manner. A significant

portion of the cells treated with 10 mmol/L of HMBA for 72 h displayed the classical hallmarks of apoptosis with typical condensed nuclei and apoptotic bodies. In addition, as was shown in the previous reports[13,14], HMBA at 5 mmol/L concentration could arrest most of SMMC-7721 cells in G_0/G_1 phase and induce differentiation but not apoptosis. Our present results indicated that HMBA at 10 mmol/L concentration could not only inhibit cell proliferation and induce cell terminal differentiation, but also significantly induce apoptosis in human hepatocellular carcinoma SMMC-7721 cells.

To investigate the mechanism by which HMBA induces cellular apoptosis, we studied the effects of HMBA on apoptotic regulatory proteins in SMMC-7721 cells. Numerous molecular entities have been shown to regulate the apoptosis. Among these, the Bcl-2 family of proteins is well known for its regulatory role during apoptosis, and the interaction between anti-apoptotic and pro-apoptotic members of the family, such as between Bcl-2 and Bax, seemed to be crucial for regulation of this process[31-33]. Bcl-2, originally described as a proto-oncogene, is known as a cell death inhibitor that is regulated by its interaction with pro-apoptotic factors such as Bax family. Bax, one of the pro-apoptotic proteins, could counteract the anti-apoptotic effects of Bcl-2 by forming a heterodimer with Bcl-2[34]. In fact, the ratio of Bcl-2 to Bax, rather than the levels of individual proteins, has been considered to be critical in determining the survival or death of cells[35-38]. A number of studies have revealed that apoptosis induced by many agents is mediated through a decrease of the Bcl-2/Bax ratio[39-43]. Our results also showed that HMBA could reduce the ratio of Bcl-2 to Bax, indicating that the decreased ratio of Bcl-2 to Bax caused by HMBA treatment might trigger apoptosis of SMMC-7721 cells.

In conclusion, HMBA as a potent inducer can effectively inhibit the proliferation of human hepatocellular carcinoma cells at a low concentration and induce cellular apoptosis at a higher concentration. HMBA induces cell apoptosis of human hepatocellular carcinoma cells by decreasing the ratio of Bcl-2 to Bax.

Abstract

AIM: To investigate the effects of hepatitis B virus x gene and its protein product HBxAg on apoptosis in hepatocyte line HL-7702.

METHODS: The reconstituted plasmid pcDNA3-x was established through recombination DNA technique; pcDNA3-X was transfected into HL-7702 cells by lipid-mediated trasfection. Positive clones were screened by G418, and HL-7702/HBx cells were analysed by the RT-PCR to confirm the steady expression of X gene in HL-7702 cells. The apoptosis rate in HL-7702 cells was determined by flow cytometry, TUNEL technology, electronic microscope. At the mean time, pcDNA3-X was transfected transiently into HL-7702 cells, and total RNA from HL-7702 cells was extracted 24, 48, 72, 96 and 120 h after the transient transfection, and semi-quantitative analysis was performed by RT-PCR to detect the expression of HBV X gene. Furthermore, apoptosis rate in HL-7702 cells was determined by flow cytometry analysis at the different times.

RESULTS: RT-PCR analysis showed that HBV X gene could be expressed stably in HL-7702 cells. Both flow cytometry and TUNEL technology revealed that the apoptosis rates of HL-7702/HBx cells were much higher than those of HL-7702/pcDNA3 and HL-7702 cells. Furthermore, the apoptotic phenomena and apoptotic body were observed in HL-7702/HBx cells under electronic microscope, but not in HL-7702/pcDNA3 and HL-7702 cells. In the experiment of transient transfection, RT-PCR reveals that X gene was expressed most at 72 h after transfection; and the apoptosis rate reached the highest at the same time. After that, the apoptosis rate was reduced with the decrease of the X gene expression.

CONCLUSION: HBV X gene and X protein can promote the apoptosis in hepatocyte. And there exist a quantity-effect relationship between the X gene expression and apoptosis rate in hepatocyte.

INTRODUCTION

Chronic Hepatitis B virus (HBV) infection is associated with a high incidence of liver disease, including hepatitis and hepatocellular carcinoma (HCC)[1-3]. Based on epidemiologic studies involving chronic HBV infection, it is estimated that the relative risk of developing HCC for HBV carriers may be 100- to 200-fold higher than that for non-carriers[4].

HBV genome has four open reading frames (ORFs), including envelope genes coding region (*pre-s1*, *pre-s2* and *s* gene coding region), precore (*pc*) gene and core (*c*) gene coding region, polymerase (*p*) gene coding region, X gene coding region. X gene is the smallest open reading frame of HBV. X gene codes for a 16.5-ku protein (X protein, HBx), which is made of 154 amino acids. HBx is a multifunctional viral regulator that modulates transcription, cell responses to genotoxic stress, protein degradation, and signaling pathways[5]. Besides, it may affect DNA repair, cell cycle control, and apoptosis[6-9].

To explore the effection of HBV X gene and its protein product on apoptosis, we transfected X gene into hepatocyte line HL-7702, and observed its role on cell apoptosis by flow cytometry, TUNEL technology and electronic microscope.

MATERIALS AND METHODS

Biological and chemical materials

Restriction *end* onucleases, T4 DNA ligase, reverse transcription system, G418 and Transfast transfection reagent were obtained from Promega Biotech (USA). Vector PUCmT was purchased from Shanhai Sangon Co. (China). RNA isolation kit was from Jingmei Biotech Co. (China). TUNEL reagent was obtained from Beijing Zhongshan Co. (China). The plasmid PcDNA3 was from Invitrogen Co. (USA).

Construction of HBx expression vector

The HBV X DNA fragment was amplified by polymerase chain reaction (PCR) using the HBV carrier's serum as a template. The sequences of primers for the PCR were as follows: 5'-ATGCAAGCTTATGGCTGCTAGGCTGTACTG-3' and 5'-TGCGAATTCTTAGGCAGAGGTGAAAAAGTTG-3'. The PCR was carried out as follows: pre-denaturation at 95 ℃ for 5 min, 30 amplification cycles (denaturation at 94 ℃ for 45 s, annealing at 61 ℃ for 35 s, and extension at 72 ℃ for l min). After the PCR product was added an A-tailing, it was connected with vector pUCmT to construct the middle vector pUCmT-X. According to the sequencing result of pUCmT, the positive clone was selected to extract plasmid. Then the plasmid was digested with *Eco*R I and *Hin*d III and ligated into pcDNA3 to establish the reconstituted plasmid pcDNA3-X, which was confirmed by restriction *end* onucleases digestion and direct DNA sequencing.

Steady expression of HBx and apoptosis ananlysis

Cell culture and DNA transfection HL-7702 cells were cultured in RPMI 1640 supplemented with 200 mL/L FBS. The cells in logarithmic glowth were separately transfected with pcDNA3-X and pcDNA3 plasmids, by lipid-mediated trasfection using Transfast transfection reagent with a total of 2 μg of DNA per well in a 6-well plate. G418 was added to

select the resistant clones after 48 h. After 2-wk selection, positive clones that were named HL-7702/HBx and HL-7702/pcDNA3 were isolated and further expanded.

RT-PCR analysis Total RNA was extracted separately from the cells of each group (HL-7702/HBx, HL-7702/pcDNA3, HL-7702) with RNA isolatione kit, and RT-PCR was carried out. Using 5 µL of RT product as template, X gene and β-actin were amplified together by PCR. The sequence of X gene primers for RT-PCR were as described above. The primers of β-actin were: 5'- GGCATCGTGATGGACTCCG-3' and 5' - GCTGGAAGGTGGACAGCGA-3' . PCR was carried out as follows: Pre-denaturation for 5 min at 95 ℃; 32 amplification cycles (denaturation at 94 ℃ for 35 s, annealing at 65 ℃ for 35 s, and extension at 72 ℃ for l min).

Flow cytometric analysis The cells of three groups were harvested with trypsin, resuspended in PBS (1×10^6 cells/mL), and analyzed for cell apoptosis rate by flow cytometry.

TUNEL technology The cells of three groups were separately seeded into the wells of 96-well plate. When cells nearly full confluent, they were fixed for 1 h at 37 ℃. Tunel assay was performed following the manufacturer' s instructions. Finally, the cells were analyzed under a microscope. The apoptosis cells which had blue-black nucleus were counted among 3 000 cells.

Electronic microscope observation A total of 1×10^6 cells of HL-7702/HBx or HL-7702/PcDNA3 or HL-7702 were digested, centrifuged, fixed and analyzed for cell apoptosis under an electronic microscope.

Instantaneous expression of HBx and apoptosis ananlysis
Instantaneous transfection HL-7702 cells were cultured in RPMI 1640 supplemented with 200 mL/L FBS. The cells in logarithmic glowth were separately transfected with pcDNA3-X and pcDNA3 plasmids with Transfast transfection reagent with a total of 2 µg of DNA per well in a 6-well plate.

RT-PCR semi-quantitative analysis At the time of 24, 48, 72, 96, 120 h of post-transfection, RNA from the cells of 3 groups were separately extracted and transcribed reversely to cDNA. The RT reaction contained 2.5 µg RNA, 2 µL of 10×buffer, 4 µL of MgCl2, 2 µL of dNTP (10 mmol/L), 0.5 µL of RNasin, 0.6 µL AMV (24 U/µL). A 20 µL total RT reaction

volume was obtained by adding sterile water, and RT was carried out at 42 ℃ for 1 h and 95 ℃ for 5 min. Then using 5 µL RT product as template, X gene and β-actin were amplified together by PCR as described above. The semi-quantitative analysis for the expression of HBV X gene was performed through the luminosity contrast between X gene and β-actin at the different time under ultraviolet ray. This experiment was repeated under the same conditions 3 times.

Flow cytometric analysis At the 5 different times, the cells of 3 groups were harvested by trypsinization, resuspended in PBS (1×10^6 cells/mL), and analyzed for cell apoptosis by flow cytometry.

RESULTS

pcDNA3-X vector construction
A 465 bp HBV X gene was amplificated from HBV genomic DNA and subcloned into the expression vector pcDNA3, with which the pcDNA3-X was constructed. The sequence of X gene in the plasmid was coincident with that reported before as identified by restriction endonucleases digestion (Figure 1) and confined by DNA direct sequencing (Figure 2).

Figure 1 The reconstituted plasmid pcDNA3-X confirmed by restriction endonucleases digestion. Lane 1: 1 Kb DNA ladder; Lane 2: digestion product of pcDNA3-X; Lane 3: digestion product of pcDNA3.

Steady expression of HBx gene in HL-7702 cells
After pcDNA3-X plasmids were transfected into HL-7702

Figure 2 The direct sequencing result of pcDNA3-X (HBV X gene was inserted from 10th bp to 474th bp).

cells, the cells were isolated by G418 selection. HBV X mRNA was detected in HL-7702/HBx cells by RT-PCR which suggested that pcDNA3-X plasmids were expressed steadily in eukaryotic cells (Figure 3).

Figure 3 Detection of HBV X gene expression in transfected HL-7702 cells by RT-PCR. 1: 100 bp DNA ladder; 2: HL-7702/HBx cells; 3: HL-7702/PcDNA3 cells; 4: HL-7702 cells.

Effects of HBx steady expression on cell apoptosis

Flow cytometric analysis The apoptosis rate of HL-7702/HBx cells was 23%, while no apoptosis of cells was found in the HL-7702/pcDNA3 and HL-7702 cells (Figure 4).

TUNEL analysis Of 3000 HL-7702/HBx cells counted, 589 cells underwent apoptotic cell death, while in the HL-7702/pcDNA3 and HL-7702 cells only 36 and 29 cells underwent apoptotic cell death, respectively. Apoptosis was significantly increased in HL-7702/HBx cells compared with the other two groups (using SAS software, χ^2 test: *P1, P2*<0.01, Figure 5).

Figure 4 Flow cytometric analysis of apoptosis of HL-7702 cells. A: HL-7702/HBx cells; B: HL-7702/pcDNA3 cells; C: HL-7702 cells.

Figure 5 TUNEL analysis of apoptosis of HL-7702 cells. A: HL-7702/HBx cells (×400). The cells showing blue-dark nuclear staining were apoptotic cells. B: HL-7702/PcDNA3 cells (×400), no apoptotic cells were seen.

Figure 6 Cell apoptosis observed under electronic microscope. A: HL-7702/pcDNA3 cells (×4 800). B: Typical apoptosis were found in HL-7702/HBx cells (×6 000). C: apoptotic body was found in HL-7702/HBx cells (×4 800). D: assemblage of heterochromatin and edema of mitochondria were found in HL-7702/HBx cells (×4 800).

Figure 7 Semi-quantitative analysis of instantaneous expression of X gene by RT-PCR. Lane 1: 100 bp ladder; Lane 2: 24 h after transfection; Lane 3: 48 h after transfection; Lane 4: 72 h after transfection; Lane 5: 96 h after transfection; Lane 6: 120 h after transfection.

Electronic microscope analysis Under electronic microscope, typical apoptosis phenomena were found in HL-7702/HBx cells: the outward appearance of cells look like plum blossom; the membrane existed entirely; stainable feature concentrate into blocks and break down; the decreased density of cytoplasm; endoplasmic reticulum looked like bubbles (Figure 6B). And apoptotic body (Figure 6C), assemblage of heterochromatin and edema of mitochondria (Figure 6D) were found in some apoptotic cells, While none of apoptotic phenomena were observed in the HL-7702/PcDNA3 and HL-7702 cells (Figure 6A).

Effects of HBx instantanous expression on cell apoptosis
RT-PCR semi-quantitative analysis The result of RT-PCR can be seen in Figure 7. The luminosity contrasts between X gene and β-actin at the different times is described in Table 1. The results suggest that HBV X gene was expressed the first day after transfection, and most strongly expressed 72 h after transfection. After that, the expression of HBV X gene decreased with time.

Table 1 The luminosity contrasts between X gene and β-actin at the different times

The time after transfection(h)	First time	Second time	Third time	Average
24	1.3234	1.2823	1.3333	1.3130
48	1.2396	1.3433	1.3568	1.3132
72	1.5884	1.6212	1.6345	1.6147
96	1.2814	1.3612	1.3245	1.3224
120	1.3224	1.3041	1.3012	1.3092

Flow cytometric analysis As shown in Figure 8A-E, the apoptosis phenomena were observed the first day after transfection, and reach the highest at 72 h, then dropped again.
The link between apoptosis rate and X gene expression A two-axis broken line graph was drawn in order to determine the association between HBV X gene expression and cell apoptosis rate (Figure 9).

Figure 9 A two-axis broken line graph. The abscissa represents the days after transfection, and the two axis of ordinate are the relative figure of X gene expression and apoptosis rate: 1: X gene expression; 2: apoptosis rate.

Figure 8 Flow cytometric analysis of apoptosis of HL-7702 after transient transfected with HBV X gene. A: 24 h after transfection (the apoptosis rate is 7.17%); B: 48 h after transfection (the apoptosis rate is 7.40%); C: 72 h after transfection (the apoptosis rate is 14.13%); D: 96 h after transfection (the apoptosis rate is 12.77%); E: 120 h after transfection (the apoptosis rate is 12.11%).

DISCUSSION

The HBx protein is a small polypeptide encoded by mammalian hepadnaviruses that is essential for viral infectivity and is thought to play a role in development of hepatocellular carcinoma during chronic hepatitis B virus infection[10]. It is known to be a transactivator of transcriptional elements that regulates the expression of a variety of genes associated with the growth, differentiation, survival and the apoptosis of cells. However, the role of the hepatitis B virus protein HBx in liver cell proliferation and apoptosis remains controversial. A number of studies have revealed that HBx protein exerts dual activity on cell apoptosis[11].

On one hand, HBx protein can block apoptosis through the following ways: (1) upregulates the activity of NF-kappa B[12] and activates NF-kappa B to translocate into nuclei of hepatocellular carcinoma cells[13,14]; (2) upregulates the expression of FasL in hepatoma cells, which contribute to tumor escape from immune surveillance of the body[15,16]; (3) abrogates Bcl-2-mediated protection against Fas apoptosis in the liver[17]; (4) decreases the expression of Bid[18]; (5) inhibits caspase 3 activity[19]; (6) inhibits transforming growth factor beta-induced apoptosis through the activation of phosphatidylinositol 3-kinase pathway[20].

On the other hand, increasing evidence here suggested that HBx may exert a proapoptotic effect on hepatocytes and in the liver of HBx transgenic mice[9,21-31]. HBx protein has been shown to induce or sensitize cells to apoptotic killing by proapoptotic stimuli, such as etoposide and tumor necrosis factor α[24,25,32,33]. Terradillos *et al* reported that HBx induced apoptosis in a p53-independent manner[23], but Chirillo *et al* reported p53-dependent apoptotic killing of cells by HBx[26]. However, a recent study could not substantiate that HBx has any detectable effect on p53 activity or location[34]. In addition, HBx can also lead to several activities, including stimulation of Ras, activition of Src kinases, transcriptional activation of myc genes, constitutive activation of JNKs, and loss of cell cycle checkpoint controls, thereby leading to cell apoptosis[9]. Moreover, HBx could interact with mitochondria, cause loss of mitochondrial membrane potential[35] and mitochondrial aggregation at the nuclear periphery[31], leading to cell death.

The dual activity of HBx protein on cell death suggests that the expression of HBx gene and its physiological role in viral pathogenesis are not simple and might be tightly regulated[11]. It seems that HBx may have evolved strategies to block and/or induce apoptosis depending on the cellular environment[24] and infection stage. Thus, HBx protein may play an opposite role in the different cellular environments and different infection stages.

Here, we constructed the HL-7702/HBx cells which could espress HBV X gene steadily and found that X gene able to promote cell apoptosis. In addition, a dose-dependent apoptotic function of HBx was demonstrated in transient transfections of liver cell lines. There existed quantity-effect relationship between the X gene expression and apoptosis rate, suggesting that the more X gene expression, the higher apoptosis rate in liver cells.

However, the precise role of HBx-mediated apoptosis is still unkown. It has been proposed that induction of apoptosis by HBx can actually facilitate propagation of viral infection by permitting efficient particle release from cells while minimizing the antiviral inflammatory response[9]. Alternatively, it is also possible that stimulation of apoptosis by HBx might promote release of hepatocyte growth factors, enhancing regenerative responses and increasing the level of uninfected hepatocytes for new infection, ultimately leading to liver cell transformation[9,12,24]. And the apoptotic effects of HBx by naturally occurring mutations might render the hepatocytes susceptible to uncontrolled growth and contribute to multistep hepatocarcinogenesis associated with HBV-infection. Further study is required to explore the mechanisms and roles of HBx-mediated apoptosis.

Abstract

AIM: To investigate the specific value of resistance index (RI) in color Doppler ultrasonography in the diagnosis of focal hepatic lesions.

METHODS: Eight hundred patients with 893 hepatic solid lesions were studied with color Doppler flow imaging (CDFI) and pulsed Doppler, including 644 malignant cases (596 primary malignant liver tumors, and 48 metastatic liver tumors), 156 benign cases. All were confirmed by operation and pathology.

RESULTS: The detection rate of arterial flow in malignant tumors was 92%, and 52% in benign lesions. Doppler spectrum analysis showed that the resistance index in primary malignant tumors was 0.75 ± 0.12, 0.73 ± 0.09 in metastatic tumors, and was below 0.6 in benign lesions. The difference was significant ($P<0.001$). This difference was related with its histopathologic structure.

CONCLUSION: The arterial flow with RI$\geqslant$0.6 identified by CDFI within the liver lesion can be regarded as a criterion of malignant tumors, RI<0.6 can be regarded as benign disorders. RI is useful in differential diagnosis of liver neoplasms.

INTRODUCTION

Extensive use of high resolution ultrasonography has led to the detection of a large number of small focal lesions in general practice. However, differential diagnosis of benign and malignant liver lesions may be difficult, even with clinical, biochemical data, and imaging techniques[1,2]. Color Doppler flow imaging can provide information on blood flow, which is useful in the differential diagnosis of liver tumors[3]. Our study was to develop a standard protocol of color Doppler ultrasound for liver tumor vascularization and to assess resistance index (RI) in the differential diagnosis of liver lesions.

MATERIALS AND METHODS

Materials

From 1992 to 2001, 800 patients with 893 hepatic solid lesions were studied (643 males, 157 females), their age ranged from 14-101 years (mean 50 years). The lesions included 644

malignancies (596 primary malignant liver tumors, and 48 metastatic liver tumors) and 156 benignancies. Primary malignant liver tumors included 564 hepatocellular carcinomas, 7 cholangiocarcinomas, and 12 mixed hepatocellular cholangiocarcinomas, 13 others. The benign lesions included 62 hepatic cavernous hemangiomas, 36 focal nodular hyperplasiae, 14 hepatic angiomyolipomas, 11 inflammatory pesudotumors of liver, 11 cirrhotic nodules, 5 hepatic tuberculosis, 3 hepatic adenomas, 3 liver abscesses, 2 liver lipomas, 9 others. The lesion size ranged from 6-180 mm in diameter. The histological distribution and tumor size are shown in Table 1.

Table 1 Histopathological type and tumor size distribution of liver tumors

Histological type	Size (mm)			
	n (lesions)	<30	30-60	>60
Primary malignant tumor	596(651)	232	255	164
Metastatic tumor	48(57)	15	25	17
Hemangioma	62(86)	25	33	28
Fucal nodual hyperplasia	36(36)	19	16	1
Inflammatory pseudotumor	11(11)	6	5	
Angiomyolipoma	14(17)	3	10	4
Cirrhotic nodules	11(11)	9	2	
Tuberculosis	5(6)	4	2	
Adenoma	3(4)	1		3
Abscess	3(3)	1	2	
Lipoma	2(2)	1		1
Others	9(9)	2	5	2
Total	800(893)	316	357	220

Methods

For ultrasonic evaluation of hepatic lesions, high-resolution ultrasonography equipment Acuson 128/XP10.USA.) with a 3.5MHz vector transducer was used. To minimize the splanchnic vasomotor influences, all patients were fasted overnight before sonographic evaluation. After the morphological characteristics of the lesions were assessed by B mode, Color Doppler ultrasound was used to determine the distribution, intra-and/or peritumoral vessels, and pulsed Doppler was used to point the interested lesions. Echogenicity and vascularity of the lesions were determined by using a magnification mode (Res) that not only provided simple geometric magnification but also improved the spatial resolution in the area of interest.

To visualize the blood flow, standard color Doppler sonography was used for each lesion, and pulsed Doppler was optimized to detect the low flow components by diminishing pulse repetition frequencies, usually down to 500Hz and adapting frequency filters. The color gain was manipulated until noise began to exceed the homogeneous single color background of color Doppler scans. Within the lesions, pulsed Doppler samples were assessed whenever possible on the basis of pulsatile flow. Vascularity could be arterial or venous. At least three measurements of resistance index (RI) of intratumoral and peritumoral arterial blood flow would be the last mean value. Only those showing the highest SPV values obtained with pulsed Doppler were taken into account. For statistical analysis, one-way ANOVA and χ^2 test were used.

RESULTS

The 893 lesions were manifested as hyperechoic, hypoechoic or isoechoic masses with distinct or indistinct margins. In the real time ulrtasonography, intra-and/or perilesional blood flow signals presented as pulsed or continuous activity, slow blood flow showed a single color, and fast flow showed mixed color signals. The pulsating wave of arterial flow in malignant tumors, appeared as linear color signals or branching, whereas in benign tumors, a constant spectrum of venous flow was shown as dots or patches.

Intratumoral and peritumoral arterial flow signals were obtained in 92% of the malignant tumors, and in 52% of benign lesions ($P<0.01$). The detection rate of intratumoral and peritumoral arterial flow was 92.3% in primary malignant liver tumors, 87.7% in metastatic liver tumors, and 33.7% in hemangiomas. The detection rates of intratumoral and peritumoral arterial flow in different lesions are shown in Figure 1. The detection rates of intratumoral and peritumoral arterial flow signals in malignant tumors, including primary or metastatic tumors were much higher than those in benign tumors, except angiomyolipomas and focal nodular hyperplasiae. Then RI was more helpful in differentiating the lesions having more arterial flow signals.

Figure 1 Detection rates of arterial blood flow in different types of liver tumors. PLT-primary liver tumor, MLT-metastatic liver tumor, HCH-hepatic cavernous hemangioma, IPL-inflammatory pseudotumor of liver, LCN-liver cirrhotic node, AML-angiomyolipoma, FNH-focal nodular hyperplasia.

The average value of RI in primary malignant liver tumors was 0.75±0.12 and 0.73±0.09 in metastatic tumors (the difference was not statistically significant, and so was it in different histologic types). It was significantly higher than that in benign ones. RI of hemangiomas was 0.55±0.08. The values of RI in different histological lesions are shown in Table 2. There were significant differences between malignant and benign tumors.

In our study we also found that the detection rates of intratumoral and/or peritumoral arterial flow signals and the value of RI in spectral analysis tended to be related to the tumor size, as arterial flow was easily detected in ≥2 cm lesions. The higher RI was mainly observed in smaller malignant tumors, but it decreased in larger tumors. The detection rates of arterial flow and the value of RI of vascular primary liver tumor (PLT) stratified by tumor size are shown in Table 3.

In our series, there were 50 lesions of PLT with no arterial flow signals. Most of them were hyperechoic masses, the size of 28 lesions was smaller than 30 mm. In 19 cases the position of the lesions was deeply located in the right posterial lobe. Eleven lesions near the diaphragm were interfered with the lung gas. Ten cases were in the left lateral lobe, 4 cases in the left medium lobe, 3 cases near the inferior vena cava (IVC), with interference of the heart beat. One case was necrosis, 2 cases were unable to control breath.

Table 2 RI in different histopathological lesions (mean±SD)

Histopathological type	RI range	RI means
Primary malignant tumor	0.34-1.0	0.75±0.12[b]
Metastatic tumor	0.57-1.0	0.73±0.09[b]
Hemangioma	0.45-0.77	0.55±0.08
Fucal nodual hyperplasia	0.41-0.79	0.58±0.10
Angiomyolipoma	0.38-0.71	0.52±0.14
Cirrhotic nodules	0.57-0.59	0.58±0.01
Inflammatory pseudotumor	0.49-0.55	0.54±0.05

[b]$P<0.001$ *vs* different groups.

Table 3 Detection rates of arterial flow and RI in primary liver malignant tumors, stratified by tumor size (mean±SD)

Diameter	<30(mm)	30-60(mm)	>60(mm)	P
Detection rates (%)	87.93[b] (204/232)	93.3[b] (238/255)	97[b] (159/164)	<0.01
RI	0.77±0.12[a]	0.76±0.11[a]	0.71±0.12[a]	<0.05

[a]$P<0.05$, *vs* RI diffrent datum groups, [b]$P<0.01$ *vs* different rate groups.

DISCUSSION

The type of blood flow signal (arterial or venous) and its distribution detected by color and pulsed Doppler is more helpful in differential diagnosis. Our study showed that the presence of both intra-and peritumoral arterial flow was strongly suggestive of malignancy, whereas the presence of intratumoral venous flow was remarkably suggestive of benignancy[4-7]. Intratumoral and peritumoral arterial flow signals were obtained in 92% of malignant tumors, but only in 52% of benign lesions. In the present study, with improvement of the equipment, we also found some arterial flow in some of the benign lesions, such as focal nodular hyperplasia (FNH) and angiomyolipoma (AML). How to differentiate them from malignant tumors remains a question. In our study, RI was more useful, combination of the type of signals and RI could significantly increase the accuracy of diagnosis. In 1997, Gonzalez-Anon et al[8] evaluated these aspects and the distribution of tumoral vessels, and concluded that the type of signals (arterial or venous) and its distribution detected by color and pulsed Doppler was more helpful than the assessment of quantitative spectral parameters obtained by pulsed Doppler. Some researchers attempted to characterize tumors by quantitative spectral criteria only, and found that systolic peak velocity (SPV) was above 70 cm/s in 12 hepatocarcinomas in their series, the velocities differed significantly from those found in metastases and hemangiomas. Numata et al[9] found that the mean of SPV in hepatocarcinomas was significantly higher than that of metastases, and hemangiomas. They also correlated the findings by Doppler angiography and hepatic pathology in both experimental animals and human beings, the high velocities of systolic peak was related with the presence of arterial venous shunts and the low resistant spectra were associated with vascular channels in the absence of muscle layer[10]. Since then, many attempts have been made to assess the usefulness of Doppler in the study of liver tumors[11]. Someda, et al[12] found that the arteries supplying HCCs had lower PI and higher PSV. Some investigators found a remarkable overlap between the spectral values of metastases and primary carcinomas. Kamalov et al[13] studied 128 lesions of primary and metastatic liver tumors, and found that the velocity and RI had no significance in differential diagnosis of tumors. In our experience, the value of SPV could usually be affected by the Doppler angle, but in most cases, the course

of tumor vessels could not be determined. So the mean of SPV varied greatly, and high SPV usually presented in larger tumors, and was not significant in the differentiation of small lesions. RI (resistance index=(Vsp-Ved)/Vsp) presents the resistance of distal vessels. It is not influenced by the Doppler angle. In 1991, Xu *et al* and Wang *et al* studied the value of RI in differentiation of liver tumors, and concluded that RI>0.5 was usually observed in malignant tumors, and RI<0.5 was found in the hemangiomas[14,15]. In our further study, the statistical analysis of 800 patients also showed that RI in malignant tumors was significantly higher than that in benign tumors. The average value of RI in primary liver malignant tumors was 0.75±0.12, and 0.73±0.09 in metastatic tumors. They were much higher than that of benignancies. Pulsed Doppler spectrum analysis showed that the lesions without any signal during diastole or with diastolic reversal spectrum were all malignant. The mean value of RI in hemangiomas was 0.55±0.08. Furthermore, the larger the tumor size was, the more the arterial flow could be visualized. The detection rates of intratumoral and/or peritumoral arterial flow signals and the value of RI in spectral analysis tended to be related to the tumor size. High RI was mainly observed in smaller malignant nodules, but it decreased in larger malignant tumors. It is conceivable that several factors are involved such as histological pattern, pseudocapsular growth type, and absence of necrotic areas. These would contribute to the increase of vascular impedance in small tumors. Some angioarchitectural features may also contribute to the explanation of the peculiar hemodynamic pattern observed. The nodule comprises exclusively arterial tumoral vessels, and hepatocytes are arranged in trabeculae of varying thickness that may compress the interposed vascular space, producing multiple "stenoses". Furthermore, the presence of pesudocapsules and cirrhotic parenchymas that usually surround HCCs might affect the venous outflow by compression of peritumoral portal branches. But in larger tumors (diameter>6 cm) with formation of A-V shunt and destruction of pseudocapsules, the value of RI tended to be lower.

In our series, combination of color Doppler flow imaging and RI was more helpful in differentiating malignant from benign tumors. Some of FNH, AML usually had more arterial flow just like malignant tumors, but they showed peculiar angioarchitectural features. FNH was characterized pathologically by cholangiolar proliferation associated with hyperplastic hepatocytes, blood vessels and fibrosis. AML was characterized pathologically by vessels with a thick muscle layer, showing more arterial flow signals like "blood ball". They often showed high peak velocity and low impedance, RI was usually <0.6. In the other aspect, RI was more useful to differentiate some benign lesions with less blood flow such as inflammatory pseudotumors of liver and cirrhotic nodules. Inflammatory pseudotumors of liver had no blood flow or less peritumor flow signals with RI<0.6. Cirrhotic nodules usually had venous intratumoral flow or less peritumor flow with RI<0.6.

The factors affecting RI in the diagnosis of liver lesions include: (1) sensitivity of the equipment. The difference in findings of flow is presumably due to the sensitivity of the equipment used for Doppler frequency shifts. Thus even lower and finer blood flows can probably be visualized if newer instruments are developed. (2) Management of the equipment. To visualize blood flow, pulsed Doppler is optimized to detect even low flow components by deminishing pulse repetition frequencies, usually down to 500Hz and adapting frequency filters. (3) Color imaging of blood flow is insufficient when the tumor is located deep within in the liver. (4) Tumor size. It is difficult to visualize when tumor size is less than 2 cm with deep location or near the diaphragm. (5) Cirrhotic parenchyma of the liver usually causes acoustic attenuation. (6) The angle of Doppler can affect the sensitivity of CDFI.

We should notice that the lesion without blood flow signals is presumably due to the angioarchitectural features or the above factors. In our series, most of malignant tumors without blood flow were usually smaller than 3 cm, and deeply located in the right posterial lobe of the liver or near the diaphragm, or located in the left lateral lobe with interference of the lung gas and the heart beating.

In conclusion, the type of flow signals (arterial and/or venous) and its distribution in CDFI and pulsed Doppler are helpful in differentiating benign from malignant lesions. The presence of intratumoral venous flow is strongly suggestive of benign tumors. When intra-and/or peritumoral arterial blood flow is found, RI<0.6 would strongly suggest a benign tumor. Simultaneous occurrence of both intra-and peritumoral arterial flow and RI≥0.6 would strongly suggest malignancies. So that combined studies of the type of intra-and peritumoral flow signals in CDFI and the parameter of RI would be more helpful in differential diagnosis of benign and malignant liver tumors.

Abstract

AIM: Interactions between hepatitis B virus (HBV) and other viral hepatitis infections are well known, whether the newly discovered SEN virus (SENV) has any effect on lamivudine antiHBV activity is unclear. Our aim was to clarify the effect on treatment outcome of coinfection with SEN virus in patients with hepatitis B during lamivudine therapy.

METHODS: Nested polymerase chain reaction (PCR) amplification was used to detect SENV-D and SENV-H strains in serum from 45 patients with chronic hepatitis B treated with lamivudine 100 mg daily for 12 mo. HBV DNA load was detected with fluorescence quantitative PCR (FQ-PCR) and YMDD (tyrosine, methionine, aspartate, aspartate) motif mutation of HBV DNA was investigated with cDNA microarray.

RESULTS: SENV DNA was detected in 5 of 45(11.1%) cases after 12 mo they received lamivudine treatment. SENV-D and SENV-H were 4.4% and 6.7% respectively. HBV DNA failed to respond to lamivudine therapy in 4 of 5 SENV coinfected patients while only 10 of 40 patients became SENV positive and the difference was statistically significant. Response of ALT and HBeAg to lamivudine had no significant difference between coinfection patients and single HBV infection ones.

CONCLUSION: Coinfection with SEN virus in chronic hepatitis B patients may adversely affect the outcome of lamivudine treatment.

INTRODUCTION

A new DNA virus with approximately 3 800 nucleotides, referred to as SEN virus (SENV), has been isolated in blood of a human immunodeficiency virus (HIV)-infected injection drug user (IDU)[1,2]. Phylogenetic analysis showed that 8 strains of SENV were members of the circoviridae family, a group of small, single-strand, nonenveloped circular DNA virus that includes TT virus (TTV), TUS01, SANBAN and YONBAN[3-6]. Although structurally similar to TTV, SENV has less than 55% sequence homology and less than 37% amino acid homology with the TTV prototype[2]. A strong association between two SENV variants (SENV-D and SENV-H) infections and transfusion-associated non-A to E hepatitis has been reported[7]. SENV-D and SENV-H have been extensively studied, they were found to be present in approximately 2% of Americans and 20% of Japanese blood donors, and could be readily transmitted by blood transfusion and other common parenteral routes[8]. However, the association of SENV infection with liver cell damage remains controversial[9]. Furthermore, several recent studies have shown that persons with SENV-D/H infection alone or coinfected with HBV or HCV had no evidence of liver disease[10-14].

Chronic liver diseases are common in China, most of them can be attributed to infection with hepatitis B virus (HBV) or hepatitis C virus (HCV)[15-21]. Although GB virus and TT virus (TTV) have been claimed to be prevalent in chronic liver disease patients in our previous study and other researches, most studies have indicated that neither virus causes liver diseases[22-25]. Taking advantage of the frequency of SENV-D/H coinfection in cases of chronic hepatitis and transient elevations of alanine aminotransferase observed in babies following transmission of SENV from mothers[8,26], the preliminary observation of clinical relevance of SENV infection alone or in combination with HBV or HCV infection needs to be independently confirmed in larger numbers of patients and in different areas.

A research letter appeared in Lancet by Basil Rigas and colleagues suggests that coinfection with SEN virus in hepatitis C patients (HC) may adversely affect the outcome of antiviral therapy with interferon and ribavirin[27]. On the contrary, another result indicated coinfection with SENV did not affect the clinicalpathological features of chronic hepatitis C and response to combination therapy[28]. These conflicting interpretations may reflect the difference in patient selection and sample size. Since coinfection of hepatitis B virus (HBV) and SEN virus is common[10,26], the precise role of SEN virus in chronic hepatitis B patients remains to be determined. Our aim was to provide the initial the evidence whether SENV coinfection affected the outcome of lamivudine therapy in patients with hepatitis B.

MATERIALS AND METHODS

Subjects

From Sept 2001 to July 2002, serum samples were obtained from 45 patients treated with lamivudine 100 mg daily in Hubei province. All patients were excluded infection of hepatitis viruses A, C, D, E, and TTV, HGV, HIV. These serum samples were stored at -70 ℃. Hepatitis B virus infection was confirmed by enzyme-linked immunosorbent assay (ELISA, second-generation). Commercially available ELISAs were used for immunoglobulin M (IgM) antibodies to hepatitis A virus, hepatitis B surface antigen (HBsAg) and e antigen (HBeAg), antibodies to hepatitis B core antigen (HBcAb) and e antigen

(HBeAb), hepatitis D virus, hepatitis E virus TTV, HGV and HIV. Serum HBV DNA levels was quantified using the hepatitis virus B nucleic acid amplification fluorescence Kit according to manufactures instructions (DA AN Gene Co. Ltd, Zhongshan University). The detection limit of this assay is 10^3 copies/ml[29].

Detection of SEN-V DNA by polymerase chain reaction

DNA was extracted from 50 µL of serum using Acupure DNA/RNA kit (Inc Biotronics, USA). PCR amplification was performed using primers specific for ORF1 region. Two common external primers were used. They were sense primer: 5'-TACCCCAACGACCAACTACGC-3', antisense primer: 5'-GTTTGTGGTGAGCAGAACGGAA-3'. Inner primers for SENV-D were sense primer: 5'-TAAGCAGCCCTAACAC TCATCCA-3', antisense primer: 5'-CAGTTGACCGCAAAG TTACAAG-3'. Inner primers for SENV-H were sense primer: 5'-ATACTTTGGCTGCACCTTCTG-3', antisense primer: 5'-CCAACTGACTAGGGGAACCTTA-3'. The first-round PCR amplification was carried out in a volume of 30 µL including 3 µL of DNA extraction product, 1×PCR buffer (Promega), 1.5 mmol/L $MgCl_2$, 100 pmoles of each sense and antisense external primers, 20 mmol/L each dNTP and 1U Taq DNA polymerase (Promega). PCR was performed for 30 cycles at 94 ℃ for 45 s, at 55 ℃ for 45 s, at 72 ℃ for 50 s. Two microliter of the first PCR product was subjected to a second amplification for 30 cycles under the same condition as for the first PCR, using sense and antisense inner primers. The amplified products were visualized by 20 g/L agarose gel electrophoresis and ethidium bromide stained. The amplified DNA was directly sequenced by the BigDye terminator kit (Bioasia Biotehnology Ltd) using the ABI 377 sequencer.

DNA microarray analysis

HBV YMDD mutation chip was provided by Shanghai Institute of Microsystem and Information Technology and Ruixin Biotehnology Ltd. The probes on the chip were labeled with digoxingenin-dUTP for color detection with NBT/BCIP. HBV DNA extracted from 50 µL of serum was amplified with PCR. The PCR products were denatured respectively in a 95 ℃ bath for 5 min, then added on the chip. They were hybridized in a sealed chamber at 42 ℃ for 30 min and washed in turn with solutions of 2×SSC + 2 g/L SDS, 0.1×SSC + 2 g/L SDS and 1 g/L SSC for 10 min each, then dried at room temperature. The hybridization was detected with anti-digoxingenin-AP Fab fragments and visualized with the colorimetric substrate NBT/BCIP.

Data statistics

Data were analyzed by Fisher's exact test, χ^2 test with Yate's correction, or Student's *t* test. A *P* value <0.05 was considered statistically significant.

RESULTS

Prevalence of SENV-DNA

SENV DNA was detected in 5 of 45 patients (11.1%) with chronic hepatitis B after 12 mo they received lamivudine treatment. Of the 5 patients with SENV coinfection, 2 (4.4%) were infected with SENV-D and 3 (6.7%) with SENV-H.

Association of SENV with severity of liver disease

Of the 45 patients received lamivudine treatment 100 mg daily, 1 had abnormal serum alanine transaminase (ALT) (>45 IU/L) among 5 cases of SENV infection and 8 had no SENV infection among 40 cases of SENV infection. The ALT level between patients with and without SENV coinfection was

not statistically significant (42.0±19.9 U/L *vs* 39.2±35.8 U/L, *t*=0.174, *P*=0.863) (Table 1).

Table 1 Association of SENV with severity of liver disease

	Normal ALT (*n*)	Abnormal ALT (*n*)	Total
SENV DNA P	4	1	5
SENV DNA N	32	8	40

Abbreviations: *P*, positive; *N*, negative.

Association of SENV with HBeAg response to lamivudine treatment

None of the 5 patients coinfected with SENV had HBeAg seroconversion or HBeAg loss, and 4 of 40 patients without SENV coinfection had HBeAg seroconversion or HbeAg loss. There was no significant difference between patients with SENV infection and those without SENV coinfection in HBeAg seroconversion (χ^2=0.549, *P*=0.459).

Table 2 Association of SENV with HBeAg response to lamivudine treatment

	HBeAg *P* (*n*)	HBeAg *N* (*n*)	Total
SENV-DNA P	5	0	5
SENV-DNA N	36	4	40

Abbreviations: *P*, positive; *N*, negative.

Association of SENV with HBV DNA response to lamivudine treatment

Only one of the 5 patients coinfected with SENV responded to lamivudine treatment in terms of HBV DNA, while 30 of the 40 patients infected with HBV alone responded to the treatment of lamivudine. The difference was statistically significant (χ^2=3.97, *P*=0.046). Although the baseline mean of serum HBV DNA level in the patients coinfected with SENV was higher than that in those without SENV infection (5.50±0.47 *vs* 4.98±0.75), the difference was not statistically significant(*t*=1.246, *P*=0.236).

Table 3 Effect of lamivudine treatment on patients with SENV coinfection

	HBV DNA positive patients (*n*)	Mean Log$_{10}$ HBV DNA (copies/mL)	HBV DNA negative patients(*n*)
SENV DNA Positive	4	5.50±0.47	1
SENV DNA Negative	10	4.98±0.75	30

Abbreviations: *P*, positive; *N*, negative.

Table 4 Clinical features of 5 patients with SENV infection

Patient	Sex (M/F)	Age (yr)	ALT (IU/L)	HBeAg	HBV DNA	YMDD motif
SENV-D1	M	24	25	P	P	YMDD
SENV-D2	M	34	96	P	P	YIDD
SENV-H1	M	27	38	P	P	YMDD
SENV-H2	M	29	17	P	N	
SENV-H3	M	19	29	P	P	YVDD

Abbreviations: *P*, positive; *N*, negative; *M*, male.

Clinical features of 5 patients with SENV infection

Of the 14 HBV DNA positive patients, 2 had YMDD mutation in 4 patients with SENV coinfection and 5 had YMDD

mutation in 10 patients with HBV infection alone. One was YIDD mutant and the other was YVDD mutant in 4 coinfected patients, 3 were YVDD mutants and 2 were YIDD mutants in 10 HBV infected alone patients. Lamivudine resistant mutation (YMDD mutate to YIDD or YVDD) had no significant difference in SENV coinfected group and HBV infected alone group (χ^2=0.35, P=0.72).

DISCUSSION

Recent studies indicated that SENV-D/H infections occurred more often in high-risk groups (54-90 %), patients with chronic hepatitis B (41%), HBV-related hepatocellular carcinoma (HCC) (54%), chronic hepatitis C (67%), and HCV-related HCC (76%) than in healthy adults (15%)[10]. Although most subjects with SENV-D/H infection alone had no hepatitis or mild hepatitis[13,30-32], an association of SENV-D/H with transfusion-associated hepatitis has been reported[7]. Whether SENV-D/H serves as causative agents of non-A and non-E hepatitis remains controversial[7,12,30].

Coinfection with HBV and hepatitis D virus has been reported to be associated with severe and rapidly progressive liver diseases[33]. The clinical manifestations of patients with HBV/HCV coinfection seemed mild and occult. Additionally, it was shown that HBV could inhibit HCV replication, but no evidence that HCV could suppress HBV replication was found in the data[34]. In contrast, another study showed that acute superinfection in patients with chronic hepatitis might increase the risk of severe hepatitis, suggesting that HBV as a newcomer might suppress pre-existing HCV[35]. Together with the earlier observation that acute HCV superinfection suppressed pre-existing HBV, it seemed that the time or sequence of infection was a factor influencing the outcome of viral interactions. Newly published issue indicated that infections with HCV plus other hepatitis viruses might exacerbate the pathological lesion of the liver[36]. Interactions between two specific viruses need to be determined. Our data showed the ALT level (42.0±19.9 U/L vs 39.2±35.8 U/L) between patients with or without SENV coinfection was not statistically significant, so did HBeAg response to lamivudine antiviral treatment. These data suggested that SENV had limited or no hepatic pathogenicity, which was consistenting with the previous observation that the vast majority of SENV-infected hemodialysis patients did not develop hepatitis[37].

The clinical relevance of SENV infection alone or in combination with HBV remains controversial. Whether SENV affects other virus replication needs to be determined. In our study, the baseline mean of serum HBV DNA level in the patients coinfected with SENV was higher than that in those without SENV infection (5.50±0.47 vs 4.98±0.75), the difference was not statistically significant. However, the lamivudine antiviral response rate of HBV DNA was lower in patients coinfected with SENV infection than those without (20% vs 75%), and the result indicated that coinfection with SEN virus in chronic hepatitis B patients might adversely affect the outcome of lamivudine treatment. In patients with chronic hepatitis C infection after interferon plus ribavirin therapy in another study, serum HCV level in patients coinfected with SENV was not significantly lower than that in patients without SENV infection, but HCV genotype 2a was more often found among patients with HCV and SENV coinfection than among those with HCV infection alone, suggesting that there was a specific link between SENV and HCV genotype 2a[28].

Recent registration of lamivudine, a dideoxycytidine analogue that inhibits HBV reverse transcriptases, has provided new perspectives for the treatment of chronic HBV infection[38,39]. Mutation of methionine to valine or isoleucine at the YMDD motif of HBV reverse transcriptase has been shown to be responsible for lamivudine resistance in HBV[40,41]. HBV precore stop mutant was increased in the first stage following acute superinfeciton of HCV and then decreased in the later stage[42]. The observation raised the possibility of a limit relation of HBV mutant to coinfected virus in different stages of coinfection. Whether YMDD mutant has an association with SENV coinfection is unknown. No significant association was observed between SENV and HBV YMDD mutations during lamivudine treatment in our present study.

Coinfection with SENV might adversely affect the outcome of lamivudine treatment. It is not surprising that infection of the liver with more than one virus might render it resistant to antiviral therapy. Indeed, coinfection with HBV, either HDV or HIV, could predicts the unfavourable outcome of antiviral treatment compared with those infected with HBV only[43], but TTV coinfection did not influence the outcome of long- term lamivudine therapy on hepatitis B[44], so did interferon therapy on chronic hepatitis B or C[45]. Thus, further studies need to address this important and interesting issue.

In summary, coinfection with SENV in chronic hepatitis B in Wuhan area might adversely affect the outcome of lamivudine treatment. SENV should be detected when HBV DNA fails to respond to lamivudine treatment for HBV infected patients.

Abstract

AIM: To study the sequential changes of serum ferritin levels in lamivudine-treated patients with chronic viral hepatitis B and the clinical implications.

METHODS: Thirty-eight patients with chronic viral hepatitis B were prospectively studied during their treatment with lamivudine. Each patient received 100 mg oral lamivudine daily for 12 mo, and was observed and tested for blood biochemistry and hepatitis B virus (HBV) DNA levels and serum ferritin levels at baseline and at 3, 6 and 12 mo during the treatment. Serum HBV DNA levels were quantitatively determined using fluorescent quantitative polymerase chain reaction (FQ-PCR), and serum ferritin levels were measured by radioimmunoassay. The sequential changes of serum ferritin levels and their relationships with virological, serological and biochemical responses in the patients were analyzed.

RESULTS: All the patients had a baseline HBV DNA level higher than 1×10^7 copies/L as determined by FQ-PCR and positive HBsAg and HBeAg and abnormal ALT levels. At the end of the 12-mo treatment, 19 of the 38(50.00%) patients had undetectable serum HBV DNA levels by FQ-PCR, and 12(31.58%) became negative for serum HBeAg and 10(26.32%) had seroconversion from HBeAg to HBeAb. Nineteen out of the 38(50.00%) patients had biochemically normal ALT levels after 12-mo lamivudine treatment. Sequential determination showed that lamivudine treatment significantly reduced ferritin levels in chronic hepatitis B patients. When the patients were divided into different groups according to their post-treatment virological, serological and biochemical responses for analysis of the sequential changes of ferritin levels, it was found that the decrease of ferritin levels in HBV DNA-negative group was significantly more obvious than that in HBV DNA-positive group at 6 mo during the treatment (P=0.013). Consecutive comparisons showed that ferritin levels at 3 mo of treatment were obviously decreased as compared with the baseline levels (P<0.05) in HBeAg-negative group, and the decrease of serum ferritin levels in patients with normalized ALT was more significant than that in patients with abnormal ALT at the end of the 12-mo treatment (P=0.048).

CONCLUSION: Lamivudine treatment can reduce the serum

ferritin levels in chronic viral hepatitis B patients and decreases of ferritin levels can be more significant in patients exhibiting virological, serological and biochemical responses, indicating that dynamic observation of serum ferritin levels in patients with chronic viral hepatitis B during lamivudine treatment might be helpful for monitoring and predicting patients' responses to the therapy.

INTRODUCTION

Hepatitis B virus (HBV) is one of the major causes of liver diseases worldwide, which may progress into cirrhosis and hepatocellular carcinoma[1-5]. It is thus important to implement anti-viral therapy against chronic hepatitis B to minimize the liver damage[6]. Studies suggest that around half of all patients with chronic HBV infection respond to a 6- to 12-mo course of interferon (IFN) therapy, which may induce the elimination of serum hepatitis B viral DNA (HBV DNA) and hepatitis B e antigen (HBeAg), as well as normalization of serum alanine aminotransferase (ALT) activity. However, the response rate is still low and relapse occurs in about half of the responders[6-12]. Lamivudine has become a recent interest in the treatment of chronic viral hepatitis B[13-20] and it is suggested that high levels of pretreatment ALT and low levels of HBV DNA are predictive of response[8,21-23]. However, other predictors of response to lamivudine therapy are unclear. Studies indicated that serum ferritin levels could be used to assess the degree of hepatocyte lesion in chronic viral hepatitis B[24-31], but the role of serum ferritin determination in the treatment of viral hepatitis B with lamivudine remains uncertain. We therefore conducted the present study to investigate the possible role of sequential determination of serum ferritin levels in patients treated with lamivudine to explore the clinical implications.

MATERIALS AND METHODS

Patients and treatment
We prospectively studied 38 chronic hepatitis B patients with a complete clinical record, including 28 male and 10 female patients aged between 13 and 59 years (mean 29.32±10.97 years), and none of the patients received interferon or other anti-viral therapy 6 mo before this study. Chronic hepatitis B was defined as positive hepatitis B surface antigen (HBsAg), positive HBeAg, detectable HBV DNA and abnormal serum ALT levels (normal <40 IU/L) for more than 6 mo. All patients had at least three documented occasions of serum ALT levels higher than the upper normal limit measured at intervals of one mo, within 6 mo prior to the enrollment. Alcoholics and intravenous drug users or homosexual persons and patients

with use of hepatotoxic drugs, herbal medicine or immuno-suppressive therapy within the past 6 mo were excluded, and none of the patients had decompensated liver function, cirrhosis, chronic renal failure, clotting abnormalities, hemophiliacs, serious neurological disorders, obesity, chronic viral hepatitis C or delta, human immunodeficiency virus (HIV) infection, autoimmune disease (anti-nuclear antibody titer >1:40), and/or inheritable disorders such as hemochromatosis, alpha-1-antitrypsin deficiency or Wilson's disease. All patients with peripheral white blood cells <4 000 per mm^3 and platelet < 80 000 per mm^3 were also excluded. Serum HBV DNA levels were quantitatively determined using hepatitis B virus fluorescence polymerase chain reaction (FQ-PCR) diagnostic kit manufactured by Daan Gene Corporation Limited of Zhongshan University (Shenzhen, China) according to the instruction. The lowest detectable HBV DNA level of FQ-PCR was 10^4 copies/mL. Serum ferritin levels were determined using a commercially available radioimmunoassay kit manufactured by China Atomic Energy Research Institute (Beijing, China). The reference values for normal serum ferritin level are 20-140 μg/L and 16-132 μg/L for male and female, respectively.

All patients received 100 mg oral lamivudine daily for 12 mo, and were observed and tested for blood biochemistry, HBV DNA levels, serological markers of HBV infection and serum ferritin levels at baseline and at 3, 6 and 12 mo during the treatment. Absence of serum HBV DNA and HBeAg, HBeAg seroconversion to HBeAb and normalization of serum ALT levels were assessed for the efficacy of treatment. Informed consent was obtained from all the patients before treatment.

Statistical analysis

Data in the text and tables are expressed as mean±SD and were analyzed with SPSS software. Statistical analysis was performed using two-tailed Fisher's exact test, two-tailed Student's *t* test and Chi-square test where appropriate. A *P* value less than 0.05 was considered statistically significant.

RESULTS

Sequential changes of serum ferritin levels during treatment

All of the 38 patients completed the 12-mo treatment. When all the patients were analyzed for the changes of serum ferritin levels, it was shown that their serum ferritin levels gradually decreased as lamivudine treatment prolonged (Figure 1). Serum ALT and aspartate aminotransferase (AST) levels declined in correlation with the serum ferritin levels. Serum ferritin levels were significantly decreased within 6 mo of lamivudine treatment (baseline *vs* mo 3, *P*=0.018; mo 3 *vs* mo 6, *P*=0.027) and stabilized thereafter (mo 6 *vs* mo 12, *P*=0.593).

Figure 1 Sequential changes and comparisons of serum ferritin levels (μg/L) at different time points during lamivudine treatment.

Relationships between sequential changes of serum ferritin levels and virological responses to treatment

At the end of 12-mo treatment, 19 of the 38(50.00%) patients had undetectable serum HBV DNA levels and another half of the patients still had detectable HBV DNA by FQ-PCR. The ferritin levels and their sequential changes were analyzed between these two groups. The ages (28.58±11.47 years *vs* 30.05±10.71 years) and HBV DNA levels at baseline [(6.3±8.6)×10^8 copies/mL *vs* (7.1±6.1)×10^8 copies/mL] between two groups had no statistical difference. The mean baseline ALT and AST levels in the HBV DNA-negative group (141.68±105.99 IU/L and 101.00±71.85 IU/L, respectively) were higher than those in HBV DNA-positive group (99.94±73.00 IU/L and 63.80±37.99 IU/L, respectively), but not statistically different (*P*=0.166 and *P*=0.054, respectively) between two groups. The mean baseline ferritin levels between two groups were not statistically different (Table 1). After initiation of lamivudine treatment, serum ferritin levels were decreased in both HBV DNA-negative and -positive groups, but the decrease in the former group was more apparent, with a statistically significant difference at mo 6 (*P*=0.013, Table 1). Interestingly, the percentage of female patients was higher in HBV DNA-negative group than in HBV DNA-positive group (10/19 *vs* 0/19, *P*<0.01).

In HBV DNA-negative group, consecutive comparisons of the ferritin levels within this group showed that the mean ferritin level at mo 3 of treatment was significantly decreased as compared with the baseline level (*P*<0.01), and the level at mo 6 was not obviously decreased compared with that at mo 3 (*P*=0.140), as with the comparison between the level at mo 12 and at mo 6 (*P*=0.866). In HBV DNA-positive group, consecutive comparisons showed no significant decreases in ferritin levels when compared in the same way as in HBV DNA-negative group (*P*= 0.825, *P*=0.110 and *P*=0.349, respectively, Table 1).

Relationships between sequential changes of serum ferritin levels and serological responses to treatment

Of the 38 patients, 12(31.58%) were negative for serum HBeAg and 26 positive for serum HBeAg at the end of the 12-mo treatment. The ferritin levels and their changes were analyzed between these two groups. The gender (female/total, 4/12 *vs* 6/26), ages (28.33±12.67 years *vs* 29.77±10.33 years), baseline ALT (116.25±70.58 *vs* 122.92±101.88 IU/L), AST (91.92±59.13 *vs* 78.00±60.67 IU/L), ferritin (Table 2) and HBV DNA levels [(8.85±9.83)×10^8 copies/mL *vs* (5.67±5.92)×10^8 copies/mL] between two groups had no statistical difference. The comparisons of serum ferritin levels between the 2 groups showed no significant difference at any time point (Table 2).

Consecutive comparisons of ferritin levels within the two groups showed that, in HBeAg-negative group, ferritin level at mo 3 of treatment was obviously decreased as compared with the baseline levels (*P*<0.05), and the levels at mo 6 and 12 of treatment were not significantly decreased when compared with the level at month 3 (*P*=0.261) and mo 6 (*P*=0.373), respectively. In HBeAg-positive group, ferritin levels were not obviously decreased when compared in the same way as in HBeAg-negative group (*P*=0.228, *P*=0.051 and *P*=0.834, respectively, Table 2).

Of the 38 patients treated, 10(26.32%) had a seroconversion from HBeAg to HBeAb while 28 had not at the end of 12-mo treatment. The ferritin levels and their changes were also analyzed between these 2 groups of patients. The ages (29.77±10.33 years *vs* 28.33±12.67 years), ratio of female patients (3/10 *vs* 7/28) and baseline ALT(116.10±76.55 *vs* 122.50±98.43 IU/L), AST(96.50±64.12 *vs* 77.36±58.49 IU/L), ferritin (Table 3) and HBV DNA levels [(10.2±1.03)×10^8 copies/mL *vs* (5.52±5.77)×10^8 copies/mL] between the 2

groups were comparable. Statistically, no significant differences in serum ferritin levels between two groups were found at any time points although the decreases of ferritin levels in HBeAb-positive group after the initiation of treatment were more apparent than those in HBeAb-negative group (Table 3).

In HBeAb-positive group, consecutive comparisons of the ferritin levels showed that ferritin level at mo 3 of treatment was not obviously decreased as compared with the baseline level (P=0.077), and the levels at mo 6 and 12 of treatment were not obviously decreased compared with those at mo 3 (P=0.303) and 6 (P=0.370), respectively. In HBeAb-negative group, consecutive comparisons showed that the ferritin level at mo 6 was statistically decreased when compared with that at mo 3 (P= 0.041), while the ferritin levels at mo 3 and mo 12 of treatment were not decreased as compared with those at baseline (P=0.121) and mo 6 (P=0.836), respectively (Table 3).

Relationships between sequential changes of serum ferritin levels and biochemical responses to treatment

Nineteen out of the 38(50.00%) patients had biochemically normal ALT levels and another half of the patients still had elevated ALT levels at mo 12 of treatment. The ferritin levels and their changes were analyzed between these 2 groups of patients. The ages (29.16±11.71 years *vs* 29.47±10.49 years), ratio of female patients (5/19 *vs* 5/19) and baseline ALT (139.58±112.45 *vs* 102.05±63.98 IU/L), AST (94.58±77.00 *vs* 70.21±33.07 IU/L), and ferritin (Table 4) and HBV DNA levels [(7.34±9.12)×10^8 copies/mL *vs* (6.14±5.31)×10^8 copies/mL]

between two groups were comparable. It was shown that the decrease of serum ferritin levels in patients with normalized ALT was more significant than that in those with abnormal ALT at mo 12 of treatment (P=0.048, Table 4).

In both groups, consecutive comparisons showed that the ferritin levels at mo 3, 6 and 12 of treatment were not significantly decreased when compared with those at baseline, mo 3 and 6 (P=0.120, P=0.145 and P=0.108 in patients with normalized ALT and P=0.062, P=0.088 and P=0.720 in those with still elevated ALT), respectively, although the ferritin levels at mo 12 were significantly decreased compared with the baseline levels in both groups (P=0.008 and P=0.020, respectively. Table 4).

DISCUSSION

Elimination of HBeAg could significantly improve the clinical outcome and survival in chronic hepatitis B patients[5-7]. A 6- to 12-mo course of IFN therapy could induce the elimination of serum HBV DNA and HBeAg, as well as normalization of serum ALT activity in about half of patients with chronic HBV infection at the end of treatment[6-8]. The usage of immune modulators, as the currently available thymosin-α1, seemed effective in part of patients[32,33]. However, the response rate was still low and relapse occurred in a high proportion of responders. Lamivudine has been increasingly administered to chronic viral hepatitis B patients in recent years and had a reportedly response with HBeAg seroconversion in about (15-30)% of patients after 1 to 2 years of therapy[13-20].

In this study, 19 of the 38 patients (50.00%) had undetectable serum HBV DNA levels after the 12-mo treatment, suggesting the potent inhibition of HBV replication in patients with chronic hepatitis B. In 12 of the 38(31.58%) patients, their serum HBeAg became negative and 10(26.32%) had HBeAg seroconversion to HBeAb at the end of treatment, indicating that lamivudine treatment can enhance the elimination of HBeAg and its seroconvertion to HBeAb in chronic hepatitis B patients through the inhibition of HBV replication. Biochemically, 19(50.00%) of the 38 patients had normalized ALT levels after lamivudine treatment, indicating that lamivudine treatment can also improve the biochemical abnormalities in the patients. The HBeAg seroconversion rate in the patients in this study was in accordance with other reports[13-20]. It can be obviously seen from our results and other reports that the response rate is still not satisfactory and further studies on new regimens, including lamivudine in combination with IFN and other agents, are needed[23,34-41].

The relationship between iron metabolism and liver diseases has long been a focus of study. More than two decades ago, it was found that a high serum ferritin level prior to HBV infection might increase the likelihood of persistent infection[24]. Correlations between an increase of both AST and ALT and a higher level of ferritin in patients with chronic hepatitis C and B and alcoholic hepatitis were also documented by previous observations[31]. Furthermore, Serum ferritin was significantly higher in cirrhotic patients in comparison to patients with chronic viral hepatitis and highly elevated ferritin levels were observed in hepatocellular carcinoma (HCC) patients[25-31]. Clinical observations also indicated that desferrioxamine infusion to achieve a normal serum ferritin level could enhance the likelihood of response by a chronic hepatitis B patient to IFN therapy[42].

The precise mechanisms associated with elevated ferritin levels in chronic hepatitis and other acute and chronic liver diseases have not been fully clarified. Firstly, it is implicated that HBV might infect the liver cells and then actively replicate with the propensity for increasing ferritin synthesis, resulting in increased liver iron storage[24,25]. The iron overload may enhance the hepatocyte damage induced by HBV. Secondly, serum AST activities correlated with serum ferritin levels in patients with liver disease and the severer the hepatocyte damage is, the higher the serum ferritin and serum iron are, which seems more obvious in fulminant hepatitis and liver cirrhosis. It is therefore suggested that ferritin and iron levels would increase in serum because of their release from hepatocellular storage in association with necrosis[29-31]. Thirdly, it was also indicated that tumor cells might produce ferritin[27], and lastly, iron-induced oxidative stress, in addition to iron storage and hepatocyte damage, has been believed to be another cause of increased serum ferritin levels in chronic liver diseases[43]. Our observations on the sequential changes of serum ferritin levels showed that the antiviral treatment with lamivudine could reduce the ferritin levels in patients with chronic hepatitis B and the decrease in HBV DNA-negative group at the end of 12-mo treatment could be more profound than that in HBV DNA-positive group, supporting the notion that virus replication could stimulate ferritin synthesis[24,25]. Our sequential determination also showed that the ferritin level in patients with normalized ALT at the end of treatment decreased more apparently than that in patients with abnormal ALT, and the decrease in ferritin levels paralleled that in ALT and AST levels, indicating that the improvement of necroinflammatory damage of hepatocytes also contributes to the decline of ferritin levels. In addition, the virological response in patients was associated with early decrease of ferritin levels while the biochemical response appeared to be associated with relatively gradual decreases of ferritin levels, indicating that the early decrease of ferritin levels might result mainly from the inhibition of HBV replication in hepatocytes and the reduction of ferritin synthesis while the subsequent changes might result from the improvement of necroinflammatory damage of liver tissues and the reduction of ferritin release from hepatocytes.

Many factors may affect the response to antiviral treatment for chronic hepatitis B and it was indicated that serum ferritin levels could be used for predicting the response to IFN treatment in patients with chronic hepatitis B. Interferon-α treatment of chronic hepatitis B showed that ferritin levels correlated well with the type of IFN response, as the serum ferritin level increased, the response rate to IFN declined. Serum ferritin level appeared to influence the type of IFN response achieved[8]. Observations in children with chronic hepatitis B found that in the group of patients with detectable seroconversion in the HBe system resulting from interferon-α therapy, lower serum levels of iron and ferritin could be present[44]. Therefore, to detect serum markers of iron metabolism was believed to be helpful for evaluating the curative effect and prognosis of hepatitis B[30]. So far, although it is suggested that higher levels of pretreatment ALT and lower levels of pretreatment HBV DNA levels were predictors of response[21-23], no data are currently available to address the value of serum ferritin detection in patients with chronic hepatitis B treated with lamivudine.

Our observation was focused mainly on serum ferritin levels with regard to their sequential changes and their relationships with the virological, serological and biochemical responses to lamivudine treatment in chronic hepatitis B patients. We found that lamivudine treatment could reduce serum ferritin levels in chronic hepatitis B patients and the effect was more significant during the first 6 mo of treatment. As the ages, gender, baseline ALT, AST and HBV DNA levels between the groups were comparable, our determination and analysis showed that statistically significant decreases of ferritin levels occurred in virologically and biochemically responding groups but not in nonresponding groups although female patients appeared to be more likely to have viral response. The decreases of ferritin levels in serologically responding groups (elimination of HBeAg and HBeAg seroconversion to HBeAb) were also more obvious than those in serologically nonresponding groups although they were not statistically significant between the two groups. Furthermore, we found that the decreases of serum ferritin levels paralleled the declines of serum ALT and AST levels during lamivudine treatment. Therefore, it indicates that sequential determination of serum ferritin levels, rather than only the detection of pretherapy ferritin levels, in chronic hepatitis B patients treated with lamivudine is helpful for monitoring and predicting the responses to treatment.

Contrary to other observations[22,23], we did not observe any statistical differences in the baseline ALT, AST and HBV DNA levels between any responding and nonresponding groups although, generally speaking, pretherapy ALT and AST levels in responding groups appeared to be higher than those in nonresponding groups. As the number of patients we observed in this study was relatively small, large-scale observations on the response predicting and monitoring factors in relation to lamivudine treatment are needed.

In conclusion, lamivudine treatment for patients with chronic hepatitis B can decrease serum ferritin levels, and the decreases are more profound in virologically and biochemically responsive patients. It is suggested that sequential determination of serum ferritin levels, rather than only the baseline ferritin levels, in patients with chronic hepatitis B may be useful for monitoring and predicting the virological and biochemical responses to the treatment of lamivudine.

Abstract

AIM: To clone *ureB* gene from a clinical isolate of *Helicobacter pylori* and construct a prokaryotic expression system of the gene and identify immunity of the expressed recombinant protein.

METHODS: *ureB* gene from a clinical *H pylori* strain Y06 was amplified by the high fidelity polymerase chain reaction technique. The target DNA fragment amplified from *ureB* gene was sequenced after T-A cloning. Prokaryotic recombinant expression vector pET32a inserted with *ureB* gene (pET32a-ureB) was constructed. The expression of recombinant UreB protein (rUreB) in *E. coli* BL21DE3 induced by isopropylthio-β-D-galactoside (IPTG) at different concentrations was examined by SDS-PAGE. Western blot using commercial antibodies against whole cell of *H pylori* and an immunodiffusion assay using a self-prepared rabbit anti-rUreB antibody were applied to determine immunity of the target recombinant protein. ELISA was used to detect the antibody against rUreB in sera of 125 *H pylori* infected patients and to examine rUreB expression in 109 *H pylori* isolates.

RESULTS: In comparison with the reported corresponding sequences, the nucleotide sequence homology of the cloned *ureB* gene was from 96.88-97.82% while the homology of its putative amino acid sequence was as high as 99.65-99.82%. The rUreB output expressed by pET32a-ureB-BL21DE3 was approximate 30% of the total bacterial proteins. rUreB specifically combined with the commercial antibodies against whole cell of *H pylori* and strongly induced rabbits to produce antibody with a 1:8 immunodiffusion titer after the animals were immunized with the recombinant protein. Serum samples from all *H pylori* infected patients were positive for UreB antibody and UreB expression were detectable in all tested *H pylori* isolates.

CONCLUSION: A prokaryotic expression system with high expression efficiency of *H pylori ureB* gene was successfully established. The expressed rUreB showed qualified immunoreactivity and antigenicity. High frequencies of UreB

expression in different *H pylori* isolates and specific antibody against *UreB* in sera of *H pylori* infected patients indicate that *UreB* is an excellent antigen candidate for developing *H pylori* vaccine.

INTRODUCTION

In China, chronic gastritis and peptic ulcer are two most common gastric diseases, and gastric cancer is one of the malignant tumors with high mortalities and morbidities[1-34]. *Helicobacter pylori*, a microaerophilic, spiral and Gram-negative bacterium, is recognized as a human-specific gastric pathogen that colonizes the stomachs of at least half of the world's populations[35]. Most infected individuals are asymptomatic. However, in some subjects, *H pylori* infection causes acute/chronic gastritis or peptic ulceration. Furthermore, the infection is also a high risk factor for the development of gastric adenocarcinoma, mucosa-associated lymphoid tissue (MALT) lymphoma and primary gastric non-Hodgkin's lymphoma[36-43]. Recently, direct evidence that *H pylori* causes gastric carcinoma in an animal model has been reported[44-46]. Immunization against the bacterium represents a cost-effective strategy to prevent *H pylori*-associated peptic ulcer disease and to reduce the incidence of global gastric cancer[47]. The selection of antigenic targets is critical in the design of *H pylori* vaccine. So far, no vaccine preventing *H pylori* infection was commercially available. Almost all *H pylori* strains produce a special urease decomposing urea and forming ammonia, which is harmful to gastric mucosa. Moreover, a high pH value is benefit for organisms to colonize the stomach. Urease is composed of 4 subunits, A, B, C and D. The subunit B (UreB), a peptide with 569 amino acid residuals encoded by *ureB* gene, has been demonstrated to show the strongest antigenicity and protection among all known *H pylori* proteins[48-50]. Furthermore, almost all *H pylori* isolates have *ureB* gene and express UreB protein, and their nucleotide and putative amino acid sequence homologies are as high as approximate 95%[51-53]. These data strongly indicate that UreB is a potential antigen candidate for *H pylori* vaccine. In this study, a recombinant prokaryotic vector responsible for the recombinant UreB protein (rUreB) expression was constructed. Immunogenicity and immunoreactivity of rUreB were further examined. Furthermore, rUreB was used as an antigen in ELISA to detect specific antibody in sera from *H pylori* infected patients, and rabbit anti-rUreB serum was prepared to examine the UreB expression in different *H pylori* isolates. The results of this study will supply further experimental foundation for the development of *H pylori* vaccine.

MATERIALS AND METHODS

Materials

A clinical strain of *H pylori*, provisionally named Y06, which was well-characterized by the Department of Medical Microbiology and Parasitology, College of Medical Science, Zhejing University, was used in this study. A plasmid pET32a (Novagen, Madison, USA) and *E. coli* BL21 DE3 (Novagen, Madison, USA) were used as the expression vector and host cell, respectively. Primers for polymerase chain reaction (PCR) amplification were synthezed by BioAsia (Shanghai, China). A Taq-plus high fidelity PCR kit and restriction endonucleases were purchased from TaKaRa (Dalian, China). The T-A Cloning kit and sequencing service were provided by BBST (Shanghai, China). DAKO (Glostrup, Denmark) and Jackson ImmunoResearch (West Grove, USA) supplied rabbit antiserum against whole cell of *H pylori,* HRP-labeling sheep anti-rabbit IgG and anti- human IgG antibodies, respectively. Agents for *H pylori* isolation and identification were purchased from bioMérieux (Marcy I' Etoile, France). Overall, 126 patients (86 males and 40 females; age range: from 6-78 yr; mean age: 40.5 yr) who were referred for upper endoscopy from 4 different hospitals in Hangzhou during the period between December 2001 and June 2002 and had *H pylori* isolated from gastric mucosa were included in the study. All patients gave a written informed content. Of the 126 patients, 68 were endoscopically diagnosed as having chronic gastritis (CG, 48 superficial, 10 active and 10 atrophic gastritis), and 58 as having peptic ulcer disease (PUD, 12 gastric, 40 duodenal, and 6 gastric and duodenal ulcer). None of the patients had taken nonsteroidal anti-inflammatory drugs, antacids and antibiotics during the 2-wk before seeking medical advice. At the same time, serum specimens were also collected from these patients.

Isolation and identification of H pylori

Each gastric biopsy taken during endoscopy was homogenized with a tissue grinder and then inoculated on Columbia agar plates supplemented with 80 mL/L sheep blood, 5 g/L cyclodextrin, 5 mg/L trimethoprim, 10 mg/L vancomycin, 2.5 mg/L amphotericin B and 2 500 U/L cefsoludin. The plates were incubated at 37 ℃ under microaerobic conditions (50 mL/LO2, 100 mL/LCO2 and 850 mL/LN2) for 3 to 5 d. A bacterial isolate was identified as *H pylori* according to typical Gram stain morphology, biochemical tests positive for urease and oxidase, and agglutination with the commercial rabbit antibodies against whole cell of *H pylori.* One of the isolated strains, named as Y06 that had typical characteristics of *H pylori,* was selected for further experiments.

Preparation of DNA template

Genomic DNA of *H pylori* strain Y06 was prepared by the routine phenol-chloroform method and DNase-free RNase treatment. The obtained DNA was dissolved in TE buffer, and its concentration and purity were determined by ultraviolet spectrophotometry[54].

Polymerase Chain Reaction

Primers were designed to amplify the whole sequence of *ureB* gene from strain Y06 based on the published sequences and reading frames[51-53]. The sequences of *ureB* sense primer with an endonuclease site of EcoRV and antisense primer with an endonuclease site of *Xho*I were 5'-GGAGATATCATGATTAGCAGAAAAG AATATGTTTC-3' and5'-GGACTCGAGCTAGAAAATGCTAAAGAGTTGTGC-3', respectively. Total volume per PCR was 100 μL containing 2.5 mol/L each dNTP, 250 nmol/L each of the 2 primers, 15 mol/L MgCl2, 3.0 U Taq-plus polymerase, 100 ng DNA template and 1×PCR buffer (pH8.3). The parameters for PCR were 94 ℃ for 5 min, ×1; 94 ℃ for 30 s, 56 ℃ for 30 s, 72 ℃ for 120 s, ×10; 94 ℃ for 30 s, 56 ℃ for 30 s, 72 ℃ for 130 s (10 s addition for each of the following cycles), ×20; and then 72 ℃ for 12 min, ×1. The results of PCR were observed under UV light after electrophoresis in 10 g/L agarose, pre-stained with ethidium bromide. The expected size of target amplification fragment was 1 704 bp.

Cloning and sequencing

The target amplification DNA fragment from *ureB* gene was cloned into pUCm-T vector (pUCm-T-ureB) by using the T-A Cloning kit according to the manufacturer's instruction. The recombinant plasmid was amplified in *E. coli* strain DH5α and then extracted by Sambrook's method[54]. A professional company (BBST) was responsible for nucleotide sequence analysis of the inserted fragment. Two *E. coli* DH5α strains containing pUCm-T-ureB and expression vector pET32a, respectively, were subcultured in LB medium. Then the plasmids were extracted[54] and digested with *Eco*RV and *Xho*I, respectively. The *ureB* target fragments and pET32a were recovered for ligation. The recombinant expression vector pET32a-*ureB* was transformed into *E. coli* BL21DE3, which was named as pET32a- ureB-BL21DE3. The target *ureB* gene fragment inserted in pET32a plasmid was sequenced again.

Expression and identification of the fusion protein

pET32a-ureB-BL21DE3 was rotatively cultured in LB medium at 37 ℃ and induced by isopropylthio-β-D-galactoside (IPTG) at different concentrations of 1.0, 0.5 and 0.1 mmol/L. The supernatant and precipitate were separated by centrifugation after the bacterial pallet was ultrasonically broken (300 V, 5 s×3). The molecular mass and output of rUreB were measured by SDS-PAGE. The expressed rUreB was collected by Ni-NTA affinity chromatography. The commercial rabbit antiserum against whole cell of *H pylori* and HRP-labeling sheep anti-rabbit IgG were used as the first and second antibodies, respectively, to determine the immunoreactivity of rUreB by Western blot. Rabbits were immunized with rUreB to prepare the antiserum, and an immunodiffusion assay was applied to determine the antigenicity of rUreB.

ELISA

By using rUreB as antigen at the coated concentration of 20 μg/mL, a patient serum sample (1:400 dilution) as the first antibody and HRP-labeling sheep anti-human IgG (1:4 000 dilution) as the second antibody, the specific antibody against UreB in sera from the 126 patients infected with *H pylori* were detected by ELISA. The result of ELISA for a patient's serum sample was considered as positive if the *A* value at 490 nm (A_{490}) was over the mean plus 3 SD of 6 negative serum samples[55]. UreB expression in *H pylori* isolates was examined by ELISA using the ultrasonic supernatant of each isolate (50 μg/mL) as a coated protein antigen, the self-prepared rabbit anti-rUreB serum (1:2 000 dilution) as the first antibody and HRP-labeling sheep anti-rabbit IgG (1:3 000 dilution) as the second antibody. The result of ELISA for a *H pylori* ultrasonic supernatant sample was considered as positive if its A_{490} value was over the mean plus 3 SD of 6 ultrasonic supernatant samples at the same protein concentration of *E. coli* ATCC 25922[55].

Data analysis

The nucleotide sequences of the cloned *ureB* gene inserted in the two recombinant plasmid vectors were compared for homology with the 3 published *ureB* gene sequences (NC000915, M60398, X57132, AB032429)[51-53] by using a molecular biological analysis soft ware.

RESULTS

PCR

The target fragment of *ureB* gene with the expected size amplified from DNA template of *H pylori* stain Y06 is shown in Figure 1.

Figure 1 The target fragment of *ureB* gene amplified from *H pylori* strain Y06 DNA. Lane 1, 1 kb DNA marker (BBST); lanes 2 and 3, the target amplification fragment of *ureB* gene from genomic DNA of *H pylori* strain Y06; lane 4: blank control.

Nucleotide sequence analysis

The nucleotide sequences of *ureB* gene in *pUCm-T-ureB* and *pET32a-ureB* were completely same. The homologies of the nucleotide and putative amino acid sequences of the cloned ureB gene compared with the published *ure*B gene sequences[51-53] were from 96.88% to 97.82% and from 99.65% to 99.82%, respectively (Figures 2 and 3).

Expression of the target fusion protein

IPTG at concentrations of 1.0, 0.5 and 0.1 mmol/L efficiently induced the expression of rUreB in the pET32a-ureB-BL21DE3 system. The product of rUreB was mainly presented in ultrasonic precipitates and the output was approximate 30% of the total bacterial proteins (Figure 4).

Immunoreactivity and antigenicity of rUreB

The commercial rabbit antibodies against the whole cell of *H pylori* combined with rUreB as confirmed by Western blot (Figure 5), and the titer demonstrated by immunodiffusion assay between rUreB and self-prepared rabbit anti-rUeB serum was 1:8.

ELISA

Since the mean±SD of A_{490} values of the 6 negative serum

samples was 0.173 ± 0.025, the positive reference value for the specific antibody detection in patients' sera was 0.248. According to the reference value, 100% (125/125, one serum sample was contaminated) of the tested patients' serum samples were positive for antibody against rUreB with an A_{490} value range of 0.27-1.97. Since the mean$\pm$SD of A_{490} of the 6 negative bacterial controls was 0.170 ± 0.026, the positive reference value was 0.248 for UreB detection in *H pylori* isolates. According to the reference value, 100% (109/109, the other 17 isolates could not be revived from -70 ℃) of the tested *H pylori* isolates were positive for rUreB epitopes with an A_{490} value range of 0.47-1.93.

DISCUSSION

Amoxciilin and metronidazole, used as routinely therapeutic antibiotics in a triple therapy, effectively eradicate *H pylori* infection *in vivo*[56-58]. However, there are problems such as side effects, emergence of drug resistance and re-infection after withdrawal of antibiotics, *etc*. It is generally considered that inoculation with *H pylori* vaccine is of value in prevention and control of *H pylori* infection. Previous studies have demonstrated that inoculation with sonic-broken *H pylori* resist the challenge of live *H pylori* and even eliminate existing infection of *H pylori* in animal models. But high nutrition requirements, poor growth after several passages, easy contamination during cultivation and difficulty in bacterial conservation make whole cell vaccine of *H pylori* impracticable. Genetic engineering vaccine seems to be a possible pathway for developing *H pylori* vaccine. UreB, used as a candidate antigen for *H pylori* genetic engineering vaccine, has advantages of high sequence conservation, a high frequency of distribution and large expression in different isolates, strong

antigenicity due to its big molecular mass, granular structure and exposure on the surface of bacteria[59,60].

In the present study, a prokaryotic expression system of rUreB was constructed. In comparison with the three published *ureB* gene sequences[51-53], high homologies of 96.88-97.82% and 99.65-99.82% of the nucleotide and putative amino acid sequences of the cloned *ureB* gene from the *H pylori* strain Y06, respectively, were found, whereas homologies were 96.78-97.83% and 99.82-100%, respectively, among the *ureB* genes from the 3 *H pylori* strains. These data indicate that the mutation level of *ureB* gene from different *H pylori* strains is considerably low.

The results of SDS-PAGE performed in this study demonstrate that the constructed prokaryotic expression system pET32a-ureB-BL21DE3 efficiently produces rUreB even at the concentration of IPTG as low as 0.1 mmol/L. rUreB mainly is presented in the form of dissoluble inclusion body and appears in the supernatant of culture only in a small amount. The output of rUreB is relatively high (approximately 30% of the total bacterial proteins), which is beneficial to industrial production.

Western blot assay performed in this study confirms that the commercial rabbit antiserum against whole cell of *H pylori* recognizes and combines to rUreB, indicating a high immunoreactivity of the recombinant protein. The immunodiffusion assay also demonstrates that rUreB efficiently induces rabbit to produce specific antibody with a higher titer, exhibiting a favorable antigenicity of the recombinant protein.

The findings by ELISA that all the tested *H pylori* isolates expressed UreB and all the tested sera from *H pylori* infected patients were positive for UreB-specific antibody indicate the universal existence of UreB in *H pylori* strains and a high frequency of UreB-specific antibody in human, which supports application of rUreB as an antigen for the development of *H pylori* vaccine.

Abstract

AIM: To construct a recombinant prokaryotic expression vector inserted with *Helicobacter pylori vacA* gene and identify the immunity of the expressed recombinant protein, and to determine prevalence of *vacA*-carrying/VacA expressing *H pylori* isolates and seroprevalence of specific ant-VacA antibody in *H pylori* infected patients.

METHODS: Polymerase chain reaction technique was used to amplify complete *vacA* gene of *H pylori* strain NCTC11637 and to detect *vacA* gene in 109 *H pylori* isolates. The amplification product of the complete *vacA* gene was sequenced after T-A cloning. A recombinant expression vector inserted with a complete *vacA* gene fragment, named as *pET32a-vacA*, was constructed. Expression of the target recombinant protein VacA (rVacA) was examined by SDS-PAGE. Western blot using commercial antibodies against whole cell of *H pylori* and an immunodiffusion assay using self-prepared rabbit anti-rVacA antibody were applied to determine immunoreaction and antigenicity of rVacA. Two ELISA methods were established to detect VacA expression in *H pylori* isolates and the specific anti-VacA antibody in sera from 125 patients infected with *H pylori.*

RESULTS: In comparison with the reported corresponding sequences, homologies of nucleotide and putative amino acid sequences of the cloned *vacA* gene were 99.82% and 100%, respectively. The constructed recombinant prokaryotic expression system efficiently produced rVacA. rVacA was able to combine with the commercial antibodies against whole cell of *H pylori* and to induce the immunized rabbit to produce specific antibody with an immunodiffusion titer of 1:4. All tested *H pylori* isolates carried *vacA* gene, but only 66.1% expressed VacA protein. Of the serum samples tested, 42.4% were positive for specific anti-VacA antibody.

CONCLUSION: A prokaryotic expression system of *H pylori vacA* gene was successfully constructed. The expressed rVacA can be used to detect specific anti-VacA antibody in human and to prepare antiserum in animals. The high frequency of *vacA* gene in *H pylori* isolates, but with a low frequency of VacA expression and specific anti-VacA antibody

in *H pylori* infected patients implies that VacA is not an ideal antigen for *H pylori* vaccine.

INTRODUCTION

In China, gastritis and peptic ulcer are two most prevalent gastric diseases, and gastric cancer is one of the malignant tumors with high morbidities[1-34]. *Helicobacter pylori* is recognized as a human-specific gastric pathogen that colonizes the stomachs of at least half of the world's populations[35]. Most infected individuals are asymptomatic. However, in some subjects, the infection causes acute/chronic gastritis or peptic ulceration, and plays an important role in the development of gastric adenocarcinoma, mucosa-associated lymphoid tissue (MALT) lymphoma and primary gastric non-Hodgkin's lymphoma[36-43].

Vacuolating cytotoxin, an important pathogenic factor of *H pylori*, is able to cause vacuolar degeneration in epithelial cells such as HeLa and RK-13 cell lines[44-46]. The gene of vacuolating cytotoxin has 3 864-3 888 bp in size containing a region for a signal peptide at the amino-end, a fragment with approximate 2 241 bp (*vacA*) and a region for a peptide at the cariboxyl-end[47]. The signal and C-end peptides are left in inner and outer membranes of *H pylori* during secreting the cytotoxin[48]. VacA, responsible for the toxicity of vacuolating cytotoxin, is excreted out of the bacterium[49]. In some of the previous studies, VacA was demonstrated as a fine antigen for *H pylori* vaccine[50,51]. However, it has been reported that almost all *H pylori* strains carry *vacA* gene but VacA is detectable only in 50-60% of the strains[52]. For a fine practical strategy of genetic engineering vaccine development, an antigen candidate must satisfy the requirements including exposure on the surface of bacterial body, universal distribution in different strains and strong antigenicity to induce a specific antibody. So it is a critical subject to determine VacA expression in different *H pylori* strains and the prevalence of specific anti-VacA antibody in infected individuals from various geographical areas. In this study, a recombinant expression plasmid containing complete *vacA* gene was constructed. By using ELISA, VacA expression in different *H pylori* isolates and seroprevalence of anti-VacA specific antibody from *H pylori* infected patients were determined.

MATERIALS AND METHODS

Materials

H pylori strain NCTC11637 was kept in our laboratory. Primers for polymerase chain reaction (PCR) amplification were synthezed by BioAsia (Shanghai, China). Taq-plus high fidelity

PCR kit and restriction endonucleases were purchased from TaKaRa (Dalian, China). The T-A Cloning kit and sequencing service were provided by BBST (Shanghai, China). A plasmid *pET32a* as an expression vector and *E. coli* BL21 DE3 as a host cell were provided by Novagen (Novagen, Madison, USA). Rabbit antiserum against whole cell of *H pylori*, HRP-labeling sheep antisera against rabbit IgG and against human IgG were purchased from DAKO (Glostrup, Denmark) and Jackson ImmunoResearch (West Grove, USA), respectively. Overall, 156 patients who were referred for upper endoscopy at four hospitals in Hangzhou during November 2001 to February 2003 due to various gastroduodenal diseases and who had a positive urease test on gastric biopsy specimens and serum samples collected, were included in the study. Reagents used in isolation and identification of *H pylori* were purchased from bioMérieux (Marcy I' Etoile, France).

Isolation and identification of H pylori

Each biopsy specimen was homogenized with a tissue grinder and then inoculated on Columbia agar plates supplemented with 80 mL/L sheep blood, 5 g/L cyclodextrin, 5 mg/L trimethoprim, 10 mg/L vancomycin, 2.5 mg/L amphotericin B and 2 500 U/L cefsoludin. The plates were incubated at 37 ℃ under microaerobic conditions (50 mL/L O_2, 100 mL/L CO_2 and 850 mL/L N_2) for 3 to 5 d. A bacterial isolate was identified as *H pylori* according to typical Gram staining morphology, biochemical tests positive for urease and oxidase, and slide agglutination with the commercial rabbit antibodies against whole cell of *H pylori*. A total of 126(80.1%) *H pylori* strains isolated from the 156 specimens were well-characterized.

Preparation of DNA template

Genomic DNA from each *H pylori* strain was extracted by the conventional phenol-chloroform method and DNase-free RNase treatment. The obtained DNA was dissolved in TE buffer. Concentration and purity of the DNA preparations were determined by ultraviolet spectrophotometry[53].

Polymerase chain reaction

Primers were designed to amplify complete *vacA* gene from *H pylori* strain NCTC11637 based on the published data (GenBank accession No.: AF049653)[54]. The sequences of sense primer with an endonuclease site of *Eco*R I and antisense primer with an endonuclease site of *Xho* I were 5' -GAGGAATTCATGGAAATACAACAAACACACCGC-3' and 5' -GGACTCGAGTTAATTGGTACCTGTAGAA ACATTACC-3' , respectively. The total volume per PCR was 100 μL containing 2.5 mol/L each dNTP, 250 nmol/L each of the 2 primers, 15 mol/L $MgCl_2$, 3.0 U Taq-plus polymerase, 100 ng DNA template and 1×PCR buffer (pH8.3). The parameters for PCR were 94 ℃ for 5 min, ×1; 94 ℃ for 30 s, 58 ℃ for 30 s, 72 ℃ for 120 s, ×10; 94 ℃ for 30 s, 58 ℃ for 30 s, 72 ℃ for 135 s (15 s addition for the each of the following cycles), ×15; and then 72 ℃ for 15 min, ×1.

The sequences of primers for detecting *vacA* gene in *H pylori* isolates were 5' -TCAATATCAACAAGCTC-3' (sense), and 5' -CCGCATGCTTTAATGTC-3' (antisense)[55]. The reagents and the concentrations, reaction volume and PCR parameters were the same as those for amplifying complete *vacA* gene, except primer difference, annealing temperature at 52 ℃, extensive time for 60 s and 35 cycles.

The results of PCR were visualized under UV light after electrophoresis in 10 g/L agarose pre-stained with ethidium bromide. The expected sizes of the target amplification fragments with whole length of *vacA* gene for cloning and partial length of *vacA* gene for detection were 2 241 bp and 787 bp, respectively.

Cloning and sequencing

The target amplification fragment of complete *vacA* gene from *H pylori* strain NCTC11637 was cloned into plasmid vector *pUCm*-T (*pUCm*-T-*vacA*) by using the T-A Cloning kit according to the manufacturer' s instruction. The recombinant plasmid was amplified in *E. coli* DH5α and then extracted by Sambrook' s method[53]. A professional company (BBST) was responsible for nucleotide sequence analysis of the inserted fragment. Two plasmids, *pUCm*-T-*vacA* and *pET32a*, in 2 different strains of *E. coli* DH5α after amplified in LB medium were extracted and then digested with *Eco*RI and *Xho* I, respectively[53]. The target fragments of *vacA* gene and *pET32a* were recovered and then ligased. The recombinant expression vector *pET32a*-*vacA* was transformed into *E. coli* BL21DE3, and the expression system was named as *pET32a*-*vacA*-*E. coliBL21DE3*. *vacA* gene inserted in *pET32a* plasmid was sequenced again.

Expression and identification of the target recombinant protein

pET32a-*vacA*-*E. coliBL21DE3* was rotatively cultured in LB medium at 37 ℃ and induced by isopropylthio-β-D-galactoside (IPTG) at different concentrations of 1.0, 0.5 and 0.1 mmol/L Supernatant and precipitate of the culture after incubation were separated by centrifugation and then the bacterial pallet was ultrasonically broken (300 V, 5 s×3). SDS-PAGE was used to measure the molecular weight and output of rVacA, and Ni-NTA affinity chromatography was applied to collect the recombinant protein. The commercial rabbit antiserum against whole cell of *H pylori* and HRP-labeling sheep antiserum against rabbit IgG were respectively used as the first and second antibodies to determine the immunoreactivity of rVacA by Western blot. Rabbits were immunized with rVacA to prepare the antiserum. An immunodiffusion assay was performed to determine antigenicity of rVacA.

ELISA

By using rVacA as the coated antigen at concentration of 20 μg/mL, a patient serum sample (1:200 dilution) as the first antibody and HRP-labeling sheep antibody against human IgG (1:4 000 dilution) as the second antibody, antibody against VacA in sera of the 126 *H pylori* infected patients were detected. The result of ELISA for a patient' s serum sample was considered as positive if the value of optical density at 490 nm (A_{490}) was over the mean plus 3 SD of five different negative serum samples[56]. VacA expression in clinical isolates of *H pylori* was examined by using the ultrasonic supernatant of each isolate (50 μg/mL) as the coated antigen, the self-prepared rabbit anti-rVacA serum (1:2 000 dilution) as the first antibody and HRP-labeling sheep antibody against rabbit IgG (1:4 000 dilution) as the second antibody. The result of ELISA for a *H pylori* ultrasonic supernatant sample was considered as positive if its OD_{490} value was over the mean plus 3 SD of five separated *E. coli* ATCC 25922 ultrasonic supernatant samples at the same protein concentration[56].

Data analysis

The nucleotide and putative amino acid sequences of the cloned *vacA* gene were compared for homology with the published corresponding sequences (GenBank accession No. AF049653)[54].

RESULTS

PCR

All tested *H pylori* isolates (109/109) were positive for *vacA* gene. The target amplification products with whole length of *vacA* gene from *H pylori* strain NCTC11637 and with partial

fragment of *vacA* gene from *H pylori* isolate were shown in Figure 1, respectively.

Figure 1 The target amplification products with whole length of *vacA* gene from *H pylori* strain NCTC11637 and partial fragment of *vacA* gene from a *H pylori* isolate. Lane 1, DNA marker; lane 2, an amplification fragment of complete *vacA* gene from *H pylori* strain NCTC11637; lane 4, an amplification fragment of partial *vacA* gene from a *H pylori* isolate; and lanes 3 and 5, blank controls.

Nucleotide sequence analysis

The nucleotide sequences of *vacA* gene in *pUCm*-T-*vacA* and *pET32a-vacA* were completely same. The nucleotide and putative amino acid sequences of the cloned *vacA* gene (Figure 2) showed 99.82% and 100% homologies, respectively, compared with the published sequence from *H pylori* strain NCTC11637 *vacA* gene (GenBank accession No.: AF049653)[54].

Expression of the target recombinant protein

IPTG at concentrations of 1.0, 0.5 and 0.1 mmol/L efficiently induced the expression of rVacA in the *pET32a-vacA-E. coli BL21DE3* system. The expressed rVacA was mainly presented in ultrasonic precipitates, and the output was approximate 15% of the total bacterial proteins (Figure 3).

Figure 3 Expression of rVacA induced by IPTG at different concentrations. Lane 1, the protein marker; lanes 2-4, IPTG at 1.0, 0.5, 0.1 mmol/L respectively; lanes 5 and 6, bacterial precipitate and supernatant with IPTG at 0.5 mmol/L, respectively; and lane 7, the negative control.

Immunoreactivity and antigenicity of rVacA

The commercial rabbit antibodies against whole cell of *H pylori* combined with rVacA as confirmed by Western blot (Figure 4). The titer demonstrated by immunodiffusion assay between rVacA and rabbit anti-rVacA serum was 1:4.

Figure 4 Western blot result of rabbit antibody against whole cell of *H pylori* and rVacA. Lane 1, rVacA expressed by *pET32a-vacA-E.coliBL21DE3*; and lane 2: negative control of *E.coliBL21DE3*.

Figure 2 Nucleotide and putative amino acid sequences of *vacA* gene from *H pylori* strain NCTC 11637. Note: Underlined areas indicate the position of primers; C, T, C and A are replaced by t, c, g and g in the nucleotide sequence from strain NCTC 11637, respectively, but the encoded amino acid residuals are not altered (are the changes correct?). "*" means stop codon.

ELISA

Since the mean±SD of A_{490} values of the five negative serum samples was 0.275±0.111 in the detection of specific antibodies in patients' sera, the positive reference value was 0.625. According to the reference value, 42.4% (53/125, one serum sample was contaminated) of the tested patients' serum samples were positive for antibody against rVacA with an A_{490} value range from 0.63-1.21. Since the mean±SD of A_{490} values of the five negative bacterial controls was 0.098±0.036 in the detection of VacA expression in *H pylori* isolates, the positive reference value was 0.205. According to the reference value, 66.1% (72/109, other 17 isolates could not be revived from -70 ℃) of the tested *H pylori* isolates were positive for the epitope of rVacA with an A_{490} value range from 0.27-1.73.

DISCUSSION

Amoxciilin and metronidazole, used as routine therapeutic antibiotics in triple therapies, efficiently eradicate *H pylori* infection *in vivo*[57-59]. However, there are problems such as side effects, emergence of drug resistance and re-infection after withdrawal of the antibiotics, *etc*. It is generally considered that *H pylori* vaccination is the optimal strategy for the prevention and control of *H pylori* infection.

VacA, confirmed as a unique *H pylori* exotoxin with strong antigenicity[47,48], has been considered to be an antigen candidate in *H pylori* vaccine[50,51]. However, the low prevalence (50-60%) of VacA expression in *H pylori* strains and rare data on specific antibody inducement after *H pylori* infection in human make this consideration difficult to test. Therefore, we constructed a prokaryotic expression system of *H pylori vacA* gene, used rVacA to detect anti-VacA antibody in *H pylori* infected patients and prepared rabbit anti-rVacA serum to determine VacA expression in *H pylori* isolates, in order to determine the potential of VacA as an antigen in *H pylori* vaccine development.

The present study demonstrated high homologies (99.82% and 100%) of the nucleotide and putative amino acid sequences of the cloned *vacA* gene compared with the reported (GenBank accession No.: AF049653)[54] and efficient expression of *pET32a-vacA-E. coliBL21DE3*, indicating the successful establishment of a prokaryotic expression system of this target gene. The high specificity, immunoreactivity and strong antigenicity of rVacA exhibited in this study are beneficial to establish ELISAs to detect VacA-specific antibody in *H pylori* infected patients and VacA expression in *H pylori* isolates.

All tested *H pylori* isolates were positive for *vacA* gene by PCR. However, expression of VacA, not like those of UreB and HpaA in our previous studies[60], was detectable only in 66.1% of the tested *H pylori* isolates. The lower positive detection rate (42.4%) for VacA-specific antibody in sera of *H pylori* infected patients was also found. The fact that the prevalence of VacA expression is lower than that of *vacA* gene in *H pylori* strains suggests possible mutation of the gene[44], and the even lower seroprevalence of specific anti-VacA antibody in infected patients is probably due to the defect of signal peptide in the protein[61].

In conclusion, a prokaryotic expression system of *H pylori vacA* gene was successfully constructed. The expressed rVacA can be used to detect specific anti-VacA antibody in human and to prepare antiserum in animals. However, the evidence obtained from this study indicates a poor potential for VacA as an antigen in the development of *H pylori* vaccine. In addition, detection of specific anti-VacA antibody is not a reliable diagnostic indicator as to whether an individual is infected by *H pylori*.

Abstract

AIM: To evaluate the association of pre-treatment ^{13}C-urea breath test (UBT) results with *H pylori* density and efficacy of eradication therapy in patients with active duodenal ulcers.

METHODS: One hundred and seventeen consecutive outpatients with active duodenal ulcer and *H pylori* infection were recruited. *H pylori* density was histologically graded according to the Sydney system. Each patient received lansoprazole (30 mg b.i.d.), clarithromycin (500 mg b.i.d.) and amoxicillin (1 g b.i.d.) for 1 week. According to pre-treatment UBT values, patients were allocated into low (<16‰), intermediate (16-35‰), and high (>35‰) UBT groups.

RESULTS: A significant correlation was found between pre-treatment UBT results and *H pylori* density ($P<0.001$). *H pylori* eradication rates were 94.9%, 94.4% and 81.6% in the low, intermediate and high UBT groups, respectively (per protocol analysis, $P=0.11$). When patients were assigned into two groups (UBT results ≤35‰ and >35‰), the eradication rates were 94.7% and 81.6%, respectively ($P=0.04$).

CONCLUSION: The intragastric bacterial load of *H pylori* can be evaluated by UBT, and high pre-treatment UBT results can predict an adverse outcome of eradication therapy.

INTRODUCTION

Helicobacter pylori can be identified in 90-95% of patients with duodenal ulcers and 60-80% of patients with gastric ulcers[1]. Eradication of *H pylori* infection was reported to be able to change the natural history of peptic ulcer disease[2-4]. Nowadays, *H pylori* has been regarded as the main cause of chronic gastritis and peptic ulcer[5, 6].

Eradication therapy for *H pylori* has developed rapidly in recent years. The global trend has now shifted to proton pump inhibitor (PPI)– based triple therapy (a PPI and two different antimicrobial agents)[7], which can assure rapid symptom relief, improve ulcer healing, and reduce ulcer recurrence[8,9]. However, treatment failure still occurs in some cases with this advanced PPI-based triple therapy. Patient compliance and antibiotic resistance are currently regarded as the major causes of eradication failure[10]. In addition, several papers have also revealed that high pre-treatment ^{13}C-urea breath test (UBT) results, suggestive of a high intragastric bacterial load, were an independent predictor of treatment failure[10-12]. A high antral density of *H pylori* may be related to low eradication rate and increased rate of ulcer recurrence[12-14]. The intragastric bacterial load could be another factor affecting the success of eradication therapy.

UBT is the noninvasive method of choice to determine *H pylori* status. It is easy to perform and reliable, with a high sensitivity and specificity[15]. Furthermore, some authors have found that the results of UBT could be employed to semi-quantitatively assess both the intragastric bacterial load and the severity of gastritis[12,16]. Therefore, we conducted this study to investigate the association of UBT results with *H pylori* density in the stomach and the efficacy of eradication therapy in patients with active duodenal ulcers.

MATERIALS AND METHODS

Patient recruitment

From January 2 000 to December 2 002, consecutive outpatients with endoscopically verified active duodenal ulcers (5 mm in diameter or larger) at Cathay General Hospital were enrolled for this study. All panendoscopic examinations were performed and interpreted by the same group of experienced endoscopists. We only selected patients with a positive diagnosis of *H pylori* infection proven by both histological examinations and UBT. To avoid interference in evaluating the status of *H pylori*, the following patients were initially excluded before endoscopy: those who had ingested bismuth, antibiotics, anti-secretory medication, or PPI during the 4 wk prior to beginning the study; those who used non-steroidal anti-inflammatory drug; those who were pregnant or immuno-compromised; and those who had a history of gastric surgery or a previous attempt to eradicate *H pylori*. Patients with coexisting gastric ulcers or gastric cancer were also excluded. All procedures were performed after obtaining informed consent from the patients.

The enrolled patients were all treated with the same regimen of 30 mg lansoprazole b.i.d. plus 500 mg clarithromycin b.i.d. and 1 g amoxicillin b.i.d. for the first 7 d and followed by 30 mg lansoprazole once daily for an additional 3 wk. After the completion of such therapy, neither PPI or anti-secretory H_2-blocker was used; only oral antacids were taken for symptomatic relief when necessary. The second endoscopic examination was scheduled 4 wk after the completion of therapy.

If the patient refused the second endoscopy, we arranged follow-up UBT only.

Histology

During the first endoscopic examination, three biopsies were taken from the gastric antrum (one near the incisura and the other two on the greater and lesser curvature, 2 cm within the pyloric ring)[17]. On the follow-up endoscopic examination, two additional specimens were taken from the greater curvature of the gastric body due to the possibility of patchy distribution of *H pylori* after eradication therapy. We used an Olympus GIF-XQ 200 endoscope; the biopsy forceps were the FB 25-K type. Specimens were stained with hematoxylin-eosin and with a modified Giemsa stain. Then they were examined by an experienced histopathologist unaware of the patients' clinical diagnoses for the existence of *H pylori*. The version of the visual analogue scale in the updated Sydney system was used to grade the density of *H pylori* (4 grades: normal, no bacteria; mild, focally few bacteria; moderate, more bacteria in several areas; and marked, abundance of bacteria in most glands)[18]. If the density varied, the highest grade of density in the specimens was selected.

Urea breath test (UBT)

UBTs were performed before the start of therapy (right away after the first endoscopy) and on two separate occasions, at 4 and 8 wk after the completion of therapy, respectively. The ^{13}C-urea used was 100 mg of 99% ^{13}C-labelled urea produced by the Institute of Nuclear Energy Research, Taiwan. Patients drank 100 mL of fresh milk as the test meal. The procedure was modified from the European standard protocol for the detection of *H pylori*[19,20]. We chose 3 per mL for the cut-off level of the rise in the delta value of $^{13}CO_2$ at 15 min after the ingestion of ^{13}C-urea. UBT was defined as positive when $\triangle \delta\ ^{13}CO_2$ was above this value. By using this cut-off, the sensitivity and specificity of UBT are 97% and 95%, respectively[20]. According to the pre-treatment UBT value, patients were allocated into low (<16‰), intermediate (16-35‰), and high (>35‰) UBT groups[12].

Eradication of *H pylori* infection was defined as negative results on both UBT and histology tests at 4 wk after the completion of therapy or negative results on two UBTs at both 4 and 8 wk after the completion of therapy[21].

Statistical analysis

The qualitative data of patients were evaluated using chi-square or Fisher's exact test. ANOVA test was applied for the quantitative data. The relationship between the UBT results and *H pylori* density was assessed by Spearman's rank correlation test. The Kruskal-Wallis test was applied to detect the significant difference in UBT values among patients with different levels of *H pylori* density. Fisher's exact test was used to compare the eradication rates of *H pylori* infection in different UBT groups. The 95% confidence intervals (CI) were calculated. A *P* value of less than 0.05 was considered significant.

RESULTS

One hundred and twenty-three patients were initially considered eligible for the study, but 6 patients were later excluded due to negative results for *H pylori*. We thus enrolled 117 patients who fulfilled the inclusion criteria (intention-to-treat). Among them, 4 patients did not complete the study adequately because of not taking drugs regularly (2 cases) or taking disallowed medications (two cases). Therefore, a total of 113 patients were included for the per protocol analysis. Table 1 shows the

demographic and other baseline characteristics of the patients according to the levels of UBT results. None of the differences in variables was statistically significant.

Correlation between H pylori density and UBT results

Levels of *H pylori* density, as assessed histologically, were compared with the UBT results in Figure 1. The median (P_{75}-P_{25}) UBT value in each group was 9.6 (13.2), 17.9 (26.9) and 33.2 (25.4), respectively (*P*<0.001). A significant correlation was found between the UBT result and *H pylori* density (r_s=0.47).

Figure 1 Relationship between UBT result and *Helicobacter pylori* density. *P*<0.001.

Table 2 Correlation between UBT results and eradication rates of *H pylori* infection

UBT result (‰)	Eradication rate (95% CI)
Low (<16) *n*=39	94.9 (81.4-99.1%)
Intermediate (16-35) *n*=36	94.4 (79.9-99.0%)
Low+ Intermediate (*n*=75)	94.7 (86.2-98.3%)
High (>35) *n*=38	81.6 (65.1-91.7%)[1,2]

[1], comparison among low, intermediate and high UBT groups (three groups); *P*=0.11; [2], comparison between low+intermediate and high UBT groups (two groups), *P*=0.04.

Eradication rates of H pylori infection and UBT results

The overall eradication rates were 87.2% (95% CI: 79.5-92.4%) in the intention-to-treat analysis and 90.3% (95% CI: 82.9-94.8%) in the per protocol analysis. Table 2 shows the eradication rates in the three UBT groups. Although there was a downward

trend in the eradication rate with an increase in the UBT results, the difference was not statistically significant (*P*=0.11). However, when the UBT results were allocated into only two groups (≤35% and >35%), the difference in the eradication rates between the 2 groups became statistically significant (*P*=0.04) (Table 2). The higher UBT group had less eradication efficacy.

DISCUSSION

H pylori is now known to play the leading role in the pathogenesis of duodenal ulcer. Many reports have shown that eradication of *H pylori* not only aids ulcer healing but also prevents ulcer recurrence[22]. Eradication of *H pylori* can cure duodenal ulcer disease, and has become a standard therapy for duodenal ulcer patients[2,3,13].

The short-term (7 d) triple therapies including a PPI and two antibiotics (clarithromycin, and amoxicillin or a nitroimidazole compound) are currently considered as the firstline anti-*H pylori* regimens[7]. Despite the high efficacy, treatment failure occurs in a proportion of patients, varying from 10% to 25%, in the first attempt to eradicate *H pylori*[10]. Patient compliance and antibiotic resistance are regarded as the key factors affecting the outcome of treatment[10,12]. However, several reports have also revealed that patients with higher intragastric *H pylori* loads had reduced eradication rates. This association was found in both bismuth- and PPI-based triple therapies[10,12-14]. Thus, pre-treatment bacterial density has been used by some authors to predict the success of *H pylori* eradication in patients with duodenal ulcers[13,14,23]. The relationship between the eradication efficacy and intragastric bacterial load supports the importance of bacterial density as a factor in the treatment of *H pylori* infection[10,12-14].

UBT is the most useful noninvasive test for *H pylori*. The bacterium produces a powerful urease, which is the basis of UBT[24]. Since the numerical results of UBT are a function of the total urease activity within the stomach, they might be a quantitative index of the density of gastric *H pylori* colonization. Many studies have reported inconsistent conclusions about the relationship between the UBT results and those of histology-based semi-quantitative measures of bacterial infection. Such inconsistencies may have arisen from inter-observer differences or inaccuracies in the estimation of bacterial density[25]. Thus, UBT is best considered a qualitative test by some authors' opinions[15]. However, in a recent study, Kobayashi *et al*[26] used a sensitive real-time (TaqMan) polymerase chain reaction to estimate numbers of *H pylori* genomes in biopsy samples, and found that the numerical results of *H pylori* density correlated significantly with the values of UBT. So, they concluded the information from UBT was useful not only in identifying *H pylori* infection but also in indirectly assessing of the numbers of *H pylori* in the stomach. In our study, UBT results correlated with the density of *H pylori* in the stomach as well, although the number of cases was relatively small.

Higher intragastric bacterial loads, as semi-quantitatively assessed by UBT, are associated with lower eradication rats[12-14]. Adopting the same cut-off value of δ UBT used by Perri *et al.*[12], that is, >35% as an index of a high *H pylori* load, we confirmed the existence of an inverse relationship between successful eradication and intragastric bacterial load. Although we did not find a correlation between eradication efficacy and the UBT results when we allocated the patients into three UBT groups, statistically significant correlation was revealed when patients' UBT results were divided at 35% into 2 groups.

High UBT values may reflect high urease activity and indicate a high intragastric bacterial load. As observed in other infectious diseases, the bacterial load could be important in determining the outcome of eradication treatment[11]. There are other factors than the number of *H pylori* which influence the

UBT results, including gastric emptying time, area of contact between the bacteria and the urea in the stomach, and differences in urease activity among *H pylori* strains[15]. Levels of *H pylori* too low to be detected by histology are usually associated with a negative UBT. High urease activity implies a high density of *H pylori*. Between the two extremes, some authors have considered that the actual test results can tell the clinicians little except that the infection is present[15]. When we wanted to use the results of UBT as a predictor of the efficacy of eradication therapy of *H pylori* infection, we had to set a high cut-off level to obtain statistical significance. Our result is consistent with previous reports which also revealed that high pre-treatment UBT results could be an independent predictor of eradication failure[10-12].

Recognition of predictors for eradication therapy is helpful in clinical practice. Since high UBT results adversely influence the efficacy of eradication therapy, patients with high intragastric bacterial loads may benefit from an extension of treatment duration from 1 to 2 wk[10]. Prolonging the duration of the standard triple therapy has been proposed to overcome the unfavorable effect caused by high *H pylori* density and proven to be effective[10,12].

Most patients (113/117 cases, 96.6%) in this study had good drug compliance. However, bacterial culture and drug sensitivity test to assess the effect of antibiotic resistance were not performed. Thus, we cannot demonstrate the influence of drug resistance on eradication therapy. The culturing and susceptibility testing of *H pylori* are time-consuming, and they are not performed routinely in most countries[27]. Our study may therefore provide an easy and practical option to disclose the pre-treatment predictor of eradication therapy when information on drug sensitivity is not available.

In conclusion, our findings reveal that the UBT results correlate with *H pylori* density in the stomach, and that high pre-treatment UBT results might adversely affect the success of eradication therapy in patients with active duodenal ulcers. Identifying patients with high bacterial loads before treatment and thus making adjustment in therapeutic regimens may further improve the efficacy of eradication therapy.

Abstract

AIM: To analyze the characterization of T-cell receptor-γ (TCR-γ) gene rearrangement in the gastrointestinal lymphomas and evaluate the value of PCR-SSCP analysis in gastrointestinal lymphomas investigation.

METHODS: TCR-γ gene rearrangement segments of gastrointestinal lymphomas were cloned and sequenced. Single clone plasmid and mixed clone plsamids were subsequently submitted to PCR-SSCP analysis to investigate the relationship between the number of amplified clones and band patterns of the amplified products. The PCR products of TCR-γ gene rearrangement of 40 gastrointestinal lymphomas were electrophoresed on agarose gels and the positive cases on agarose gels were studied by SSCP analysis.

RESULTS: The sequencing showed that TCR-γ gene rearrangement of the gastrointestinal lymphomas included functional gene and pseudogene with extensive variety in the junctional regions. In SSCP analysis, the number of the single-stranded bands was about two times of the number of amplified clones, and double-stranded band became broad with the increased number of the amplified clones. Thirteen of the 25 B-cell gastrointestinal lymphomas and 14 of the 15 gastrointestinal T-cell lymphomas were positive detected on agarose gel electrophoresis. Of the positive cases detected by SSCP analysis, 3 B-cell lymphomas and 13 T-cell lymphomas showed positive bands. The other cases showed only smears. The rearranged pattern included 13 monoallelic gene rearrangements and 3 biallelic or oligoclonal gene rearrangements.

CONCLUSION: The pattern of TCR-γ gene rearrangement in gastrointestinal lymphomas are similar to that of the nodular lymphomas. PCR-SSCP analysis for TCR-γ gene rearrangement can be applied both for adjuvant diagnosis of gastrointestinal lymphomas and analysis of the gene rearrangement pattern. The ratio of TCR-γ gene rearrangements occurred in T-cell gastrointestinal lymphomas is significantly higher than that in B-cell gastrointestinal lymphomas. The gene rearrangement pattern involves monoallelic and biallelic (or oligoclonal) gene rearrangement.

INTRODUCTION

Primary gastrointestinal lymphomas are the most common extranodal lymphomas and are almost exclusively of non-Hodgkin types[1-3]. These lymphomas are biologically different from their nodal counterparts. Distinguishing the two phenotypes is of importance as the survival rates are different between T-cell and B-cell gastrointestinal lymphomas[4-6]. As cytological features of gastrointestinal lymphomas are usually not specific, the combination with clinical, histological, immunophenotypic and molecular genetic studies is necessary to characterize these neoplasms[7].

T-cell receptor (TCR) gene rearrangement provides a convenient genetic marker for demonstrating clonality in T-cell malignant neoplasm. Among the four TCR gene types, the TCR-γ gene rearrangement occurs in the early stage of cell differentiation and the rearrangement retains in both α β and γ δ phenotypic T cells along with the cell differentiation[8]. Analysis of TCR-γ gene rearrangement is of practical value in determining the clonality of T-cell populations and for diagnosis T-cell malignant neoplasms[9-11]. But the junctional diversity in TCR-γ gene rearrangement is limited compared with the other TCR or IgH gene rearrangement because of the fewer inserted nucleotides during the rearrangement, this lead the PCR products of TCR-γ gene rearrangement amplified by a consensus primers pair to be similar in length. The similarity may result in false clonal bands, when analyzed by standard gel electrophoresis methods that separate DNA molecules based solely on size[12,13]. A high- resolution for the amplified products of TCRγ gene rearrangement is required.

Single-strand conformational polymorphism analysis (SSCP) separates different DNA molecules based on their single-strand secondary structure conformations under certain electrophoretic condition. DNA molecules with different conformations migrate different rates on polyacrylamide gel and therefore can be separated from each other[14]. Besides gene point mutation analysis, SSCP analysis is also suitable for TCR-γ gene rearrangement study[15].

In this study, we expected to analyze the characteristics of TCR-γ gene rearrangement and evaluate the practicability of PCR-SSCP for TCR-γ gene rearrangement in the diagnosis and analysis of gastrointestinal lymphomas.

MATERIALS AND METHODS

Clinical specimen

Specimens of the gastrointestinal lymphoma were obtained by biopsy and surgical resection between January 1997 to October 2002 in the department of pathology of the Nangfang Hospital of the Frist Military Medical University, the First Municipal Hospital of Guangzhou and the No. 157 Hospital of The People's

Liberation Army. Of the 40 patients, 9 had tumors located within stomach, 1 in duodenum, 1 in jejunum, 10 in ileum, 11 in ascending colon, 2 in transverse colon, 5 in descending colon and 1 in rectum. All cases were regarded gastrointestinal lymphomas because of absence of disease in other organs. The specimens were fixed in buffered formalin, embedded in paraffin and stained with haematoxylin-eosin (HE). Lineage was confirmed by staining with CD20 and CD79a for B-cells, and CD45RO and CD3 for T-cells. The 40 cases were retrospectively diagnosed according to the new WHO classification[16]. Twenty-five of the 40 cases were confirmed B-cell lymphomas and 15 cases were confirmed T-cell lymphomas. A reactive lymph node and Jurkat cell line were considered as negative and positive control, respectively.

DNA extraction

The 7 μm thickness sections were cut with disposable blades, collected on glass slides,deparaffinized with xylene, washed with ethanol, and rehydrated in deionized water. The moist tissues of 0.5 cm×0.5 cm containing abundant malignant cells (according to HE) were scraped off the glass slides with a sterile blade, and collected in Eppendorf tube. Jurkat cells were collected and rinsed twice in PBS. A total of 50 μL digesting buffer containing 10 mmol/L Tris, 1 mmol/L EDTA, 10 g/L Tween 20, and 200 mg/mL proteinase K were added to the tubes. The digestion was performed at 37 ℃ for 16 h. Samples were then heated at 96 ℃ for 10 min to inactivate the enzyme, centrifuged, and the supernatant was used as template for PCR amplification.

PCR and agarose gel electrophoresis

The primers design was based on those used by Benhattar et al.[13], spanning the rearranged V γ 1-8 and J1/2 region with the expected products ranging from 160 to 190 bp in length. The sequences of the primers were: TVG sense, 5' AGGGTTGTGTTGGAATCAGG3' , and J1/2 antisense, 5' CCTGTGACAACAAGTGTTGT3' . PCR amplification was performed in GeneAmp PCR system 9600 (Perkin Elmer, Norwalk, CT). The reaction mixture (30 μL) contained PCR buffer (50 mmol/L KCl, 10 mmol/L Tris-HCl, pH 8.3), 200 mmol/L each of dNTP, 1.5 mmol/L MgCl$_2$, 0.5 mmol/L of each primer, and 1.25 U of AmpliTaq (Perkin Elmer). A total of 300 ng of samples and cell line DNA (or 20 ng of plasmids) were used as templates, respectively. The PCR amplification cycles were designed to a decreasing annealing temperature similar to a touch-down PCR[17]: 5 cycles consist of 94 ℃ for 45 s, 60 ℃ for 45 s, 72 ℃ for 30 s; the next 5 cycles consisted of 94 ℃ for 45 s, 56 ℃ for 45 s, 72 ℃ for 30 s; and the last 25 cycles consisted of 94 ℃ for 45 s, 56 ℃ for 45 s, 72 ℃ for 30 s. The reaction mixture was first incubated at 95 ℃ for 5 min to denature double-stranded DNA. Finally, an additional incubation for 10 min at 72 ℃ was performed to ensure full extension of the products. In all experiments, monoclonal (Jurkat cell lines) and polyclonal (reactive lymph node) controls were run in parallel with the test samples. Products were analyzed by electrophoresis on 20 g/L agarose gels stained with ethidium bromide, visualized and photographed on an UV transilluminator. SSCP analysis was performed only if a single band of the expected size was detected on the gel. DNA from each sample was amplified at least twice.

Cloning, sequencing and PCR amplifying for the plasmids inserted with TCRg gene rearranged segment

A total of 100 μL PCR products of TCR-γ gene rearrangement from five T-cell gastrointestinal lymphomas was separately purified and ligated into pGEM-T Easy cloning vector (Promega Corporation, 2 800 Woods Hollow Road Madison WI 53711-

5399 USA). The recombinant vector DNA was then transformed into Escherichia coli JM109. The transformed bacteria solution was spread on selective LB-agar plate with X-gal, IPTG and ampicillin. After overnight incubation at 37 ℃, 2 to 3 white colonies (with DNA inserts in the plasmid) from each plate were selected randomly and cultured in LB medium containing ampicillin for 12 h at 37 ℃. Plasmid DNA was isolated from each culture following a standard protocol[18] and dissolved in double distilled deionized water. Deoxyribonucleic acid sequencing of cloned PCR products was performed following the standard protocol[19] involving the universal forward-sequencing primer M13 for pGEM-T vector. The concentration of the plasmids were adjusted to 20 ng/μL. According to the sequencing results, 2, 3 and 4 plasmids with different inserted PCR products were mixed, respectively. Single and mixed plasmids were submitted as templates to PCR.

SSCP analysis

SSCP analysis was performed according to the Signoretti et al.[15] with some alternation. Briefly, 6 μL of PCR products were mixed 1:1 with denaturing loading buffer (containing 95 g/L formamide, 0.5 g/L bromophenol blue, 2.5 g/L xylene cyanol and 20 mmol/L EDTA). The mixture was heated to 95 ℃ for 10 min, quickly chilled on ice for 1 min, and loaded on 120 g/L nondenaturing polyacrylamide (29:1 acrylamide/biasacrylamide) gel in Tris-borate- EDTA (1×TBE) buffer. The gel was electrophoresed at 120 (12 v/cm) volts for approximately 4 to 6 h at room temperature and subsequently stained with silver and photographed.

Statistical analysis

Comparisons between the 2 groups were performed by the chi-square test using SPSS 10.0 statistical software (SPSS Company, Chicago, Illinois, USA). P values < 0.05 in two-tailed were considered statistically significant.

RESULTS

Agarose gel electrophoresis analysis

PCR amplification for the TCR-γ rearranged gene showed single band of 160-190 bp in 93% (14/15) T-cell and 52% (13/25) B-cell gastrointestinal lymphomas on agarose gel electrophoresis. The positive rate was significantly higher in T-cell lymphomas (P<0.05) than that in B-cell lymphomas. Both the reactive lymph node and the Jurkat cell line showed single band (Figure 1).

Analysis of the TCR-g gene rearrangement by sequencing

Sequence of the clones were identified to the particular V γ (1-8) segment by internet (http://www.ncbi.nlm.nih.gov/BLAST/Blast.cgi) assisted comparison with published TCR-γ sequence (gi 28436398 ref NG_001336.2. Homo sapiens T cell receptor gamma locus (TRG@) on chromosome 7, Length=140728). The sequenced V γ segments were assigned to the member of the V γ (1-8) family that, by comparison, showed the highest degree of homology (95% to 100%). Most of the V γ (1-8) -J γ 1/2 combinations had the functional V γ genes: V3, V4, V5, V8. Of the 14 sequenced cases, only one case was pseudogene V γ 7. In the VJ junctional N regions, the deleted nucleotides ranged from 2 to 23 nucleotides with an average length of 9.38±6.42 bp, and the size of the inserted nucleotides ranged from 3 to 13 bp (average length, 7.38±2.98 bp). The TCR γ junctional regions showed considerable diversity with no two clones showing the same sequence. The size of the PCR products amplified by this primers combination ranged between 160-190 bp. The letters with delete lines represent the deleted nucleotides and capital letters represent the inserted nucleotides during the rearrangement.

PCR-SSCP analysis of plasmids inserted with TCR-**g** gene rearranged segments

During SSCP analysis and gel electrophoresis, the PCR products of plasmids inserted with TCR-γ gene rearranged segments showed discrete bands in all lanes, except lane 7 (Figure 2) with faint band, which might be due to the insufficient DNA product in lane 7. The fastest migrating band was double-stranded DNA, located in the zone ranging from 160-190 bp. Running above the double-stranded DNA were single-stranded bands. PCR products of one cloned plasmid showed two single-stranded bands. The bands patterns of different clones were different (Figure 1 lane 5, 6 and 8). PCR products of 2 mixed cloned plasmids showed one double-stranded band and 3 to 4 sigle-stranded bands (Figure 2 lane1, 2, 3 and 4). PCR Products of 3 to 4 plasmids mixed together showed one broad double-stranded band and 6 to 8 single-stranded bands (Figure 3). Some faint single-stranded bands presented in the lanes were disregarded or interpreted with caution. Based on the results of these studies, two single-stranded bands (sometimes only one) represented the monoallelic gene rearrangement, and those with more than two single-stranded bands might be the biallelic or oligoclonal gene rearrangement.

Figure 3 PCR-SSCP analysis of mixed plasmids inserted with TCR-γ gene rearranged segments. Lanes 1-4: PCR products of 3 mixed plasmids showed one double-stranded band and about five to six single-stranded bands; Lanes 5-8: PCR product of 4 mixed plasmids showed one double-stranded band and about six to eight single-stranded bands. The double-stranded bands were broader than that in the single or double plasmids amplified products.

Figure 1 Agarose gel electrophoresis of the PCR products of TCR-γ gene rearrangement. M: DNA marker; Lane 1: reactive lymph node; lane 2: Jurkat cell line; lanes 3-8: gastrointestinal lymphomas.

Figure 4 PCR-SSCP analysis of some gastrointestinal lymphomas. M: DNA marker; Lane 1: Jurkat cell line; lane 2: reactive lymph node; lanes 3-8: B-cell gastrointestinal lymphomas. Lane 5 had 4 single-stranded bands and lane 1, 7, 8 had one or two single-stranded bands. The other samples showed only smears with no predominant band.

Figure 2 PCR-SSCP analysis of the plasmids inserted with TCR-γ gene rearranged segments. M: DNA marker; Lanes 1-4: two mixed plasmids amplified products showed one double-stranded band and three to four single-stranded bands; lanes 5-8: single plasmid PCR products showed one double-stranded band and two single-stranded bands (except lane 7).

Figure 5 PCR-SSCP analysis of some T-cell gastrointestinal lymphomas. M: DNA marker; Lane 7 presented four single-stranded bands, and the others had one or two single-stranded bands. Four of the 8 samples were absence of the double-stranded bands probably due to insufficient PCR products.

PCR-SSCP analysis of the gastrointestinal lymphomas

Of the 29 samples submitted to SSCP analysis, 17 showed one or more discrete bands, including the Jurkat cell line, 3/13 B-cell gastrointestinal lymphomas (Figure 4) and 13/14 T-cell gastrointestinal lymphomas (Figure 5) confirmed by the HE and immunohistochemistry. The positive rate was significantly higher in T-cell lymphomas than that in B-cell lymphomas ($P<0.01$). Less than half of the cases only showed the single-stranded bands, but not double-stranded bands. This might be due to insufficient quantity of PCR products. According to the numbers of the single-stranded bands of the 17 positive cases, 13 cases were monoallelic gene rearrangement, and 4 cases might be biallelic or oligoclonal gene rearrangements. The other 10 samples and reactive lymph node which were positive on the agarose gel electrophoresis yielded only smears with no obvious band. This patterns was the characteristic of rearranged TCR-γ V-J fragments amplified from polyclonal T-cell populations without a predominant.

DISCUSSION

Most T-cells express the α β T-cell phenotype and only a small population expresses γ δ TCR. The lineage is determined by the gene rearrangement and protein expression. γ-chain gene rearrangement generally takes place in the α β T-cell but not express a functional γ δ receptor[12]. In addition, a fraction of B cells undergoes TCR-γ gene rearrangement, especially immature B cells (illegitimated gene rearrangement)[20,21]. Furthermore, a T-cell lymphoma may aberrantly express the B-cell phenotype[22]. In this study, the illegitimate TCR-γ gene rearrangement in B-cell gastrointestinal lymphomas was investigated, which showed about 12% (3/25) positive result. TCR-gamma gene rearrangement involves the recombination between one of the V region (V γ 1-8, V γ9, V γ 10, V γ 11) and one of the J regions (J γ 1/2, J γ P1/2, J γ P)[8]. In this study, we used only V γ 1-8 and J γ 1/2 consensus primers set to analyze the most common VJ gamma recombination. It is likely that using additional V and J region primers would have further increased the yield of positive results, but our study showed that this consensus primers combination seemed to be sufficient for the diagnosis of T-cell gastrointestinal lymphomas.

Cloning and sequencing are the precise but time and labour-consuming methods in the study of clonal gene rearrangement. Because of the admixture of reactive T-cells, at least 8 to 10 clones from each patient must be sequenced for the purpose of diagnosis, to confirm whether there are any two clones showing the same sequence[21]. In this study, we intended to know the general aspects of the TCR-γ gene rearrangement in gastrointestinal lymphomas and to obtain the clonal rearranged gene segments. So, only 2 to 3 clones from each patient were sequenced, which were obviously inadequate for clonality judgement. The sequencing result showed that the TCR-γ junctional region (N region) presented considerable diversity with no two clones showing the same sequence. The junctional region differed in both sequence and size with the deleted and inserted nucleotides. The PCR products obtained by the consensus V γ_{1-8}/J$_{1/2}$ primers ranged from 160 to 190 base pairs. All these characteristics were similar to that of nodal lymphomas[23]. The narrow size of the PCR products between different clones did not provide a means for distinguishing between monoclonal and polyclonal TCR junction by the conventional agarose gel electrophoresis[13].

PCR-SSCP has been introduced to detect DNA mutation because it can resolve DNA molecules differing as litter as a single base pairs substitution. The high sensitivity of PCR-SSCP makes it fit to tell apart the clonal from polyclonal gene rearrangement, and its simplicity makes it a good candidate for application in clinical laboratory tests[15]. In the present study,

we would like to study whether the different band numbers observed on SSCP gel tell the different rearranged patterns apart in gastrointestinal lymphomas. The PCR products of single clone and mixed clones submitted to PCR-SSCP analysis showed that a consistent relationship existed between the number of single-stranded bands twice the numbers of clones amplified, which suggested that the number of single-stranded bands might estimate whether the samples were monoallelic or biallelic (oligoclonal) gene rearrangements. Two single-stranded bands (sometimes only one band) could definitely be regarded as monoallelic gene rearrangement. Three to four bands could be regarded as a clonal T-cell population with biallic gene rearrangements or two clonal T-cells populations both with monoallelic gene rearrangements. Those with more than four single-stranded bands were most probably oligoclonal gene rearrangements[24]. Owing to the high sensitivity and resolution of PCR-SSCP, multiple single-stranded bands must be interpreted with caution, and the PCR-SSCP analysis conditions must be optimized individually for a special pair of primers. The condition for the V γ_{1-8}/J$_{1/2}$ primers we used was optimized thoroughly before introducing to the study of gastrointestinal lymphomas.

Gastrointestinal lymphomas differ from their nodal counterpart in many aspects and are more likely to be misdiagnosed before surgical resections[25]. The histological and cytological features may be more complex, with most having pleomorphic small, medium, large or anaplastic cell cytologic features and generally with a mixture of reactive cells. The immunophenotype is especially important for gastrointestinal lymphomas, as the prognosis for T-cell gastrointestinal lymphomas is poorer than that for B-cell type and more incline to perforation[3]. It should be emphasized that gastrointestinal lymphomas must be defined by a combination of factors as not a single parameter is entirely specific.

The sensitivity and validity of TCR-γ gene rearrangement investigated by PCR-SSCP were compared with conventional histology and immunohistology. Of the 40 gastrointestinal lymphomas, 13 of the 15 T-cell lymphomas and 3 of the 25 B-cell lymphomas showed positive results. The high consistency indicates that PCR-SSCP analysis for the TCR-γ gene rearrangement study is an additional powerful tool for the diagnosis of T-cell gastrointestinal lymphomas.

Furthermore, the gene rearrangement pattern, which may be a prognostic factor, can be revealed by PCR-SSCP[26]. Our study showed that 23.5% (4/17) of the positive cases were biallelic or oligoclonal gene rearrangements. PCR-SSCP gives reproducible band migration patterns for the same DNA molecules, therefore, this technique potentially can be used to compare multifocal lesion from a single patient or to compare a recurrent lesion with a primary one in a patient previously diagnosed with T-cell gastrointestinal lymphomas[27].

Abstract

AIM: To study the mechanism and effect of nuclear factor-κB (NF-κB) activation and inflammatory response on the extended cold-preserved graft injury after orthotopic liver transplantation (OLT).

METHODS: OLT was performed in rats with varying time of cold ischemia grafts (6, 18 and 24 h in University Wisconsin solution at 4 ℃). We determined the time of NF-κB activation and expression of tumor necrosis factor-α (TNF-α), cytokine-inducible neutrophil chemoattractant (CINC), and intercellular adhesion molecule-1 (ICAM-1) within 6 h after reperfusion. Serum alarming aminotransferase (ALT), neutrophil sequestration, circulating neutrophil CD11b and L- selectin expression were also evaluated.

RESULTS: The accumulation of neutrophils in the graft was significantly increased in the 18 h and 24 h cold-ischemia groups within 0.5 h after reperfusion, compared with the 6 h group. But the strongly activated neutrophils was slightly increased at 2 h after reperfusion and remained at high levels 4 h after reperfusion, which was synchronized with the common situation of recipients after transplantation. Prolonged cold-preservation did not affect neutrophil accumulation and activation. NF-κB activation preceded the expression of TNF-α, CINC, and ICAM-1 in the liver, which was significantly increased with prolonged cold preservation. In prolonged cold preserved grafts, prominently elevated NF-κB activation occurred at 0.5 h and 1 h, compared with that at 2 h after reperfusion, which was consistent with greatly increased intrahepatic TNF-α response.

CONCLUSION: NF-κB activation is correlated with the expression of TNF-α, CINC, and ICAM-1 *in vivo* in OLT rats. Extended cold preservation of grafts might up-regulate TNF-α, CINC, and ICAM-1 expression in the grafts, most probably through elevated NF-κB activation, and might contribute to neutrophil infiltration in the grafts after reperfusion. Elevated NF-κB activity is harmful to inflammatory response in the grafts, and inhibited NF-κB activity might protect against early graft injury after liver transplantation.

INTRODUCTION

Liver transplantation has become an accepted therapy for end-stage liver diseases, but poor immediate graft function presents a persistent problem and contributes to mortality rates[1-5]. The clinical incidence of primary graft nonfunction is strongly dependent on the duration of cold ischemia storage[6]. It has become increasingly evident that reperfusion after ischemia is responsible for the majority of tissue injuries in liver transplantation[5-7]. In addition, recent evidence confirms that liver ischemia-reperfusion injury is a result of the activation of inflammatory mediators in the early phase of reperfusion[8-11].

Nuclear factor-κB (NF-κB) regulates the expression of many genes in which early response products are critical for the development of acute inflammation[12-14]. But NF-κB appears to have both beneficial and harmful effects on liver transplantation[15]. It promotes liver regeneration and prevents apoptosis[23-25], but may also contribute to the inflammatory response to ischemia/reperfusion. NF-κB acts on target genes for proinflammatory cytokines, chemokines, and cell adhesion molecules, thus mediating inflammatory responses. In addition, products of the genes regulated by NF-κB often cause the activation of NF-κB, which creates a positive feedback loop that may amplify and perpetuate local inflammatory responses[14]. But the exact role of NF-κB activity in liver transplantation would depend on the regeneration and apoptosis or ischemia/reperfusion injury, which is the main factor leading to hepatocyte injury after transplantation. However, no definitive evidence has been found for the role of NF-κB activation and inflammatory response after liver transplantation, especially in relation to cold-ischemia time.

In the current study, we investigated the importance of NF-κB in a survival rat model of orthotopic liver transplantation. We determined the time of NF-κB activation after OLT in relation to the expression of tumor necrosis factor (TNF-α), intercellular adhesion molecule (ICAM-1), and cytokine-induced neutrophil chemoattractant (CINC), as well as the recruitment and activation of neutrophils in the grafted livers, with varying cold ischemia time after liver transplantation, to determine whether prolonged cold ischemia time promoted NF-κB activation and inflammatory response in the grafts after reperfusion.

MATERIALS AND METHODS

Experimental protocol

Male Wistar rats weighing 200-250 g were purchased from the Animal Experimental Center, Nanjing Military Command. Animals were allocated randomly to 3 groups (*n*=30 in each

group) according to the cold ischemia time for 6 h, 18 h, and 24 h. Liver harvesting and orthotopic transplantation were performed using the method described by kamada and Calne[16] with minor modifications[17], and the hepatic artery was not reconstructed. The portal vein clamping time in the recipient varied from 18 to 20 min, implantation surgery required less than 50 min, all the procedures took about 60 min. No significant difference was seen in portal clamping time between groups. For the survival study, 8 rats in each group were examined. Animals that survived more than 7 d were considered survivors. The recipients were sacrificed at 0 h, 0.5 h, 1 h, 2 h, 4 h, and 6 h after reperfusion. Blood samples were collected from subhepatic vena cava to determine the serum levels of asparate aminotransferase (ALT) and neutrophil activity at indicated time point. The median lobe of the liver was carefully excised at the designated time point and stored at -80 ℃ for analysis.

NF-*k*B activity evaluation

Nuclear extracts were prepared using a nuclear extract kit (Active Motif) and p65/relA subunit of NF-κB was determined using a TransAM NF-κB p65 kit (Active Motif) according to the manufacturer's protocols. The concentration of p65/relA subunit in liver tissue homogenates was standardized as the total nuclear protein content in each specimen measured by the Pierce BCA protein assay reagent (Jiancheng, Nanjing, China). NF-κB activity was expressed as p65/relA subunit ug/mg total nuclear protein.

Measurement of TNF-*a*, CINC and ICAM-1

Hepatic levels of TNF-α, CINC and ICAM-1 were determined as previously described[18]. In brief, the medial hepatic lobe was weighed and then homogenized in 5 mL of 0.1 mol/L phosphate buffer (pH 7.4) containing 0.5 g/L of sodium azide at 4 ℃. Homogenate was first centrifuged at 2 000 *g* for 10 min to remove solid tissue debris. Supernatant was assayed using a rat ELISA system (Amersham, Buckinghamshire, UK). Concentration of antigens in liver tissue homogenates was standardized as the total protein content in each specimen measured by the Pierce BCA protein assay reagent. The results were expressed as pg/mg total protein.

Intrahepatic neutrophil accumulation assessment

Activity of MPO, an enzyme stored in the azurophilic granules of neutrophils, has been used as a well-established marker to determine tissue neutrophil sequestration[19]. Frozen lungs were thawed and extracted for MPO, following the homogenization and sonication procedure as described in manufacturer's protocols (Jiancheng, Nanjing, China). MPO activity in the supernatant was measured and calculated from the absorbance (at 460 nm) changes resulting from decomposition of H_2O_2 in the presence of o-dianisidine and was expressed as units per milligram wet weight of tissue. To control intravascular leukocytosis, we calculated the ratio of MPO activity in tissue to WBC count in peripheral blood, and expressed it as MPO/WBC.

Circulating neutrophil activity analysis

Heparinized blood samples from each animal collected at each time point were prepared for flow cytometric analysis[20]. For CD11b and L-selectin determination, 50 μL of samples was incubated with 10 μL of PE-labeled mouse anti-rat L-selectin antibody (Camarillo, CA) and 10 μL of FITC-labeled mouse anti-rat CD11b antibody (Camarillo, CA) for 15 min, then 1 mL of FACS lysing solution (Becton Dickinson, San Jose, CA) was added 10 min, and then centrifuged at 1 500 *g* for 5 min. The cell pellets were washed, then resuspended in 500 μL of PBS. The cells were read on a Becton-Dickinson FACS Calibur.

Statistical analysis

The data were expressed as mean±SD. Statistical analysis was performed using analysis of variance on SPSS software (version 11.0 for windows), evaluated by ANOVA, and followed by S-N-K multiple comparisons. A *P* value less than 0.05 was considered statistically significant.

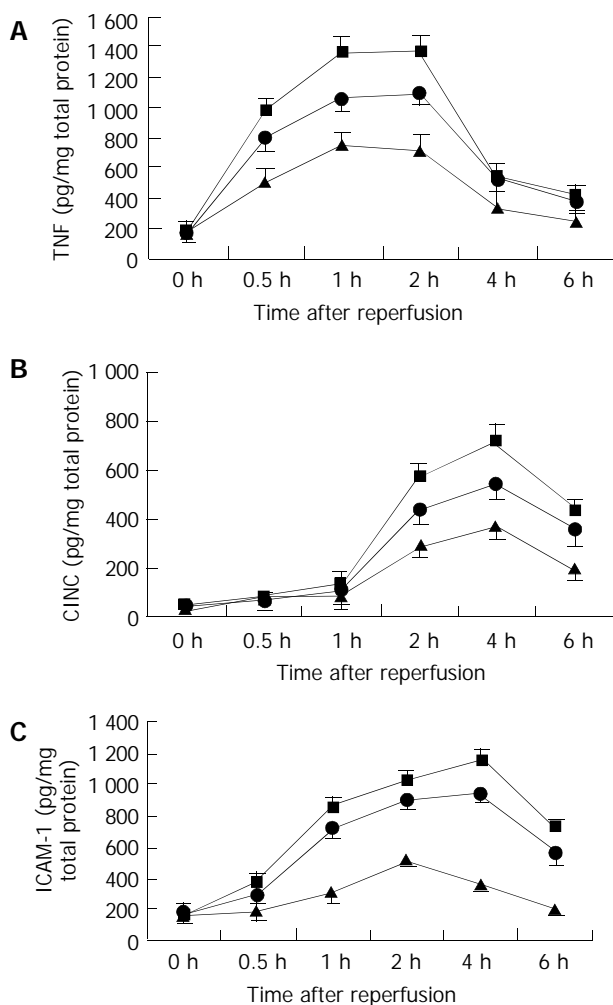
RESULTS

Survival study

All recipients recovered from anesthesia within 15 min, no survivor died within 24 h after reperfusion and experienced massive ascites at the time of death in the absence of technical complication. Thus, the cause of death after reperfusion was considered to be the primary graft nonfunction (PGNF). In all groups, their conditions rapidly deteriorated within 2 h to 4 h after surgery. In the 6 h cold-ischemia group, the general situation was much better, all recipients survived (100%) for more than 7 d. In the 18 h cold-ischemia group, 5 of 8 recipients survived (62.5%) for more than 7 d. In the 24 h cold-ischemia group, no recipient survived (0%) for more than 7 d.

Evaluation of postransplantation liver function time

Serum ALT levels increased at 0.5 h after reperfusion, and remained greatly elevated throughout 6 h reperfusion, increased significantly in the 18 h and 24 h cold-preserved groups, as compared with those in the 6 h group during 6 hours' observation (Figure 1).

**Figure 1** Changes in serum ALT levels after reperfusion. Serum ALT levels significantly increased in the 24 h (closed square) and 18 h (closed circle) cold-preserved groups, compared with the 6 h group (closed triangle) within 0.5 h after reperfusion (*P*<0.05, respectively). Results are mean±SD for each time point in each group (*n*=6).


NF-*k*B activation time

The time of NF-κB activity in liver tissue was established by evaluating p65/relA subunit in nuclear extracts from the whole liver obtained at various time points. In three groups, the activity of NF-κB in the preserved grafts increased slightly at 0.5 h after reperfusion, increased markedly at 2 h after reperfusion and decreased by 4 h (Figure 2). P65/relA subunit significantly increased with prolonged cold preservation, especially at 0.5 h and 1 h after reperfusion. In the 24 h cold-preserved group, p65/relA subunit increased to 3.2 fold of that in the 6 h cold-preserved group at 0.5 h after reperfusion. In the 24 h cold-preserved group, p65/relA subunit increased to 1.7 fold of that in the 6 h cold-preserved group at 2 h after reperfusion. Furthermore, prolonged cold preservation had no effect on p65/relA subunit at 0 h time point, but changed p65/relA subunit level at 6 h after reperfusion, though it had no significant difference (Figure 2).

Inflammatory mediator expression time

We determined the time of OLT-induced TNF-α, CINC, and

ICAM-1 expression in the same tissues as used for NF-κBp65 transcription factor assay. Increases of TNF-α expression were maximal at 1 to 2 h after reperfusion, whereas CINC expression reached the peak at 4 h, and ICAM-1 expression peaked at 2 to 4 h (Figure 3). CINC and ICAM-1 were preceded by NF-κB activation (peaked at 2 h after reperfusion). CINC and ICAM-1 expression, especially TNF-α, were significantly increased in the 18 h and 24 h cold-preserved groups compared with the 6 h cold-ischemia group. Prolonged cold preservation did not affect the time of inflammatory mediator response after OLT.

ICAM-1 levels. TNF-α levels significantly increased in the 24 h and 18 h groups 0.5 h after reperfusion, compared with the 6 h group (P<0.05, respectively). CINC levels significantly increased in the 24 h and 18 h groups 2 h after reperfusion, compared with the 6 h group (P<0.05, respectively). ICAM-1 levels significantly increased in the 24 h and 18 h cold-preserved groups 1 h after reperfusion, compared with the 6 h group (P<0.05, respectively). Results are mean±SD for each time point in each group (n=6). 6 h group–closed triangle, 24 h group–closed square, and 18 h group–closed circle.

Figure 2 Changes in p65/relA subunit levels after reperfusion. P65/relA subunit levels significantly increased in the 24 h (closed square) and 18 h (closed circle) cold-preserved groups, compared with the 6 h group (closed triangle) at 0.5 h, 1 h, and 2 h after reperfusion (P<0.05, respectively). Results are mean±SD for each time point in each group (n=6).

Figure 4 Changes in accumulation of neutrophils in the graft after reperfusion, as assessed by MPO/WBC. MPO/WBC in the 24 h (closed square) and 18 h (closed circle) cold-preserved groups increased significantly, compared with the 6 h group (closed triangle) within 0.5 h after reperfusion (P<0.05, respectively). Results are mean±SD for each time point in each group (n=6).

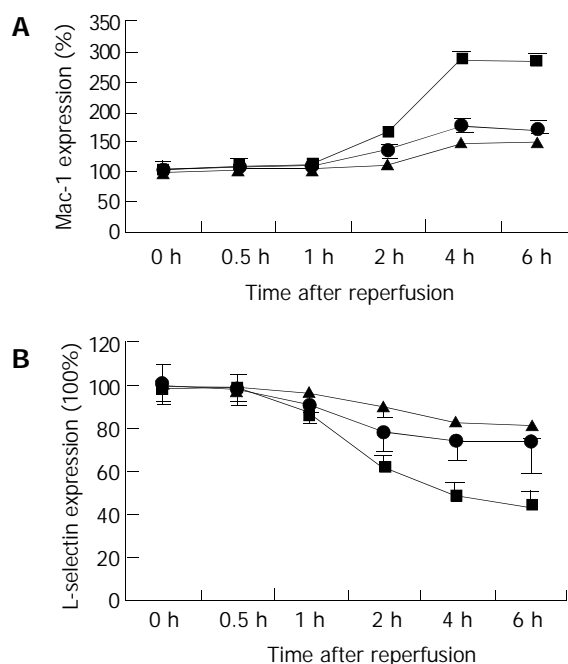


Figure 5 Changes in circulating neutrophil activity in the recipients after reperfusion, as assessed by CD11b and L-selectin expression. A: CD11b expression, B: L-selectin expression. CD11b expression elevated significantly in the 24 h (closed square) and 18 h (closed circle) groups, compared with the 6 h group (closed triangle) 2 h after reperfusion (P<0.05, respectively). L- selectin shed significantly in the 24 h (closed square) and 18 h (closed circle) groups, compared with the 6 h group (closed triangle) 1 h after reperfusion (P<0.05, respectively). Results are the mean±SD for each time point in each group (n=6).

Figure 3 Changes in intrahepatic inflammatory mediator responses after reperfusion. A: TNF-α levels, B: CINC levels, C:

Neutrophils sequestration time in graft
We utilized the MPO biochemical assay to measure tissue

neutrophil infiltration over the course of reperfusion. In all recipients, MPO/WBC was significantly elevated within 30 min of reperfusion and remained at significantly elevated level 4 h after of reperfusion (Figure 4). Prolonged cold preservation promoted neutrophil accumulation.

Time of circulating neutrophil activity after reperfusion

Increased surface expression of Mac-1 (CD11b/CD18) is important to neutrophil adherence to parenchyma cells. CD11b content of circulating neutrophils was quantitatively evaluated by flow cytometric analysis at selected time points after the onset reperfusion (Figure 5). In the 24 h cold-preserved group, expression of Mac-1 at the control time point (0 h) showed low levels of CD11b (mean fluorescence intensity was 76.75 ± 19.15), which reached 131% at 2 h, and above the baseline levels of 227% at 4 h, and remained constantly elevated 6 h after reperfusion. Flow cytometric analysis of circulating neutrophils indicated that prolonged cold ischemia had no effect on the time of its CD11b expression, but increased the expression level. In the 6 h cold-preserved group, expression of Mac-1 reached 147% of baseline at 4 h after reperfusion. At the same time, L-selectin was shed, resulting in 41% loss of the adhesion molecules at 4 h in the 24 h cold-preserved group.

DISCUSSION

Graft injury after reperfusion has been one of the critical problems to be overcome in the field of organ transplantation[1-7]. During recent years, many cellular and molecular events mediating graft inflammatory injury after OLT have been clarified[8-11]. NF-κB has been found to be an amplifying and perpetuating mechanism that can exaggerate the disease-specific inflammatory process through the coordinated activation of many inflammatory genes[13,14,22]. However, there has not been definitive evidence of what a role it played in NF-κB activation and inflammatory response in relation to graft injury and cold-preservation time after liver transplantation.

In this study, we extended our investigation on the pathogenesis of neutrophilic graft inflammation following rat orthotopic liver transplantation to assess the potential contribution of the transcription factor NF-κB. Since transcription factors determine cellular phenotype by specifying protein production, it is particularly interesting to relate changes in activation of transcription factors such as NF-κB, to the expression of specific proteins and evolution of biological relevant end points[23]. We studied the expression of TNF-α, ICAM-1, and CINC because of their critical roles in the reperfusion-induced inflammatory response. In the rat model of orthotopic liver transplantation, we have shown a link between NF-κB activation, intrahepatic TNF-α, CINC and ICAM-1 expression, neutrophilic inflammation, and graft injury. We further demonstrated that reperfusion-induced NF-κB activation *in vivo* preceded the expression of TNF-α, CINC, and ICAM-1. In addition, we have shown that prolonged cold preservation would promote NF-κB activation and inflammatory response in the graft. These observations support the hypothesis that elevated inflammatory response in the extended cold-preserved liver might be involved in NF-κB activation and contribute to subsequent neutrophil-mediated tissue injury after liver transplantation.

In this study, the expression of CINC and ICAM-1 in the graft was at a detectable level even in nonreperfusion rats (0 h time point), suggesting that CINC and ICAM-1proteins might be constitutively expressed in the liver. However, after cold ischemia/reperfusion, intrahepatic CINC and ICAM-1 increased with the duration of cold-ischemia. In contrast, intrahepatic TNF-α was not detectable before reperfusion,

implicating that TNF-α was an inducible chemokine in the liver. However, a significant increase of prominent up-regulation of intrahepatic TNF-α was found in the 24 h cold-preserved group, which was synchronized with early elevated NF-κB activity. It is well known that Kupffer cells were primed for the release of TNF-α during cold-preservation, and then activated at the time of reperfusion[26,28,29]. In addition, it has been previously reported that TNF-α producing activity of Kuffer cells increases with the duration of cold-ischemia *in vitro*[27]. That is, the presence of primed Kupffer cells during the extended cold preservation might result in overresponse to early NF-κB activity and excessive production of TNF-α in the initial phase of reperfusion.

In a rat model of warm hepatic ischemia, Jaeschke *et al.*, observed a biphasic pattern of reperfusion injury[27-29]. During the initial hour after reperfusion, Kupffer cells became activated and were the predominant source of oxygen free radicals. Up to 24 h thereafter, increased hepatic accumulation of neutrophils occurred in parallel to the progression of reperfusion injury[30]. In this study, neutrophils were sequestered earlier than warm ischemia, and increased significantly with prolonged cold-preservation. Neutrophil accumulation in the graft occurred within 0.5 h after reperfusion in the 24 h cold-preserved group, but early neutrophil accumulation was not synchronized with neutrophil activation, indicated by the high CD11b and low L-selectin expression. It was consistant with other studies that there was no rolling in sinusoids, and consequently selectin did not affect neutrophil accumulation in sinusoids[30], and furthermore, antibodies against β_2-integrins had no effect on the initial neutrophil sequestration[31-33]. In addition, previous studies have shown that CD11b and L-selectin expressions were important to neutrophil-mediated tissue injury[20,34]. It implied that in a rat model of OLT, neutrophil-induced graft injury occurred within 2 h after reperfusion in the 18 h and 24 h groups, but graft injury at 0.5 h and 1 h was not neutrophil-dependent.

In summary, in the present study, we have demonstrated that NF-κB activation correlated with the expression of TNF-α, CINC, and ICAM-1 *in vivo* in the OLT model. Extended cold preservation might up-regulate TNF-α, CINC, and ICAM-1 expression in the graft, most probably through elevated NF-κB activation, and might contribute to neutrophil recruitment in sinusoids and subsequent neutrophil-mediated graft injury after liver transplantation. Thus, this chain reaction might play an important role in the development of early graft dysfunction after liver transplantation. We believe that elevated NF-κB activity is harmful to prolonged cold preservation, and inhibiting early NF-κB activity might protect against early graft injury after liver transplantation.

Abstract

AIM: To investigate the effects of rhubarb on severe acute pancreatitis (SAP) in rats.

METHODS: Severe acute pancreatitis was induced by two intraperitoneal injections of cerulein (40 µg/kg body weight) plus 5-h restraint water-immersion stress. Rhubarb (75-150 mg/kg) was orally fed before the first cerulein injection. The degree of pancreatic edema, serum amylase level, local pancreatic blood flow (PBF), and histological alterations were investigated. The effects of rhubarb on pancreatic exocrine secretion in this model were evaluated by comparing with those of somatostatin.

RESULTS: In the Cerulein+Stress group, severe edema and diffuse hemorrhage in the pancreas were observed, the pancreatic wet weight (11.60±0.61 g/Kg) and serum amylase (458 490±43 100 U/L) were markedly increased ($P<0.01$ vs control). In the rhubarb (150 mg/kg) treated rats, necrosis and polymorphonuclear neutrophil (PMN) infiltration in the pancreas were significantly reduced ($P<0.01$), and a marked decrease (50%) in serum amylase levels was also observed ($P<0.01$). PBF dropped to 38% (93±5 mL/min per 100 g) of the control in the Cerulein+Stress group and partly recovered in the Cerulein+Stress+Rhubarb 150 mg group (135±12 mL/min per 100 g) ($P<0.01$). The pancreatic exocrine function was impaired in the SAP rats. The amylase levels of pancreatic juice were reduced in the rats treated with rhubarb or somatostatin, comparing with that of untreated SAP group. The bicarbonate concentration of pancreatic juice was markedly elevated only in the rhubarb-treated group ($P<0.01$).

CONCLUSION: Rhubarb can exert protective effects on SAP, probably by inhibiting the inflammation of pancreas, improving pancreatic microcirculation, and altering exocrine secretion.

INTRODUCTION

Acute pancreatitis is a commonly occurring disease with self-limited course and uneventful recovery. But it can present as a severe form with significant morbidity and mortality. Up to now, the pathogenesis of acute pancreatitis still remains poorly understood and the treatment still remains nonspecific and primarily supportive. Rhubarb, a traditional Chinese herbal medicine, has been widely used in China for the treatment of many diseases. It has also been shown to have a good curative effect on acute pancreatitis in recent years[1,2]. However, fewer experimental data are available to reveal its possible mechanisms. In the present study, we investigated the effects of rhubarb on severe acute pancreatitis (SAP) in rats, and tried to elucidate the possible mechanisms of its clinically well-known therapeutic effect.

MATERIALS AND METHODS

Materials

Cerulein was purchased from BACHEM Co., Ltd. (Switzerland). The tablets of rhubarb were kindly provided by professor Dong-Hai Jiao (Shanghai Xiangshan Chinese Medicine Hospital), which is the ethanol extract from crude rhubarb. The main chemical constituents of rhubarb tablets include emodin, aloe-emodin, rhein, d-catechin, and gallic acid. Sandostatin (somatostatin) is purchased from Novartis Pharma (Switzerland) and Secretin from Eisai Co., Ltd. (Japan). Male Sprague-Dawley rats (provided by the animal center of PUMC Hospital) weighing 350-450 g were used in these studies. They were fed standard laboratory chow and tap water *ad libitum* and housed in cages in a temperature-(22±2 ℃) and humidity-(55±5%) controlled room, with a 12-h light cycle before experimentation.

Protocol I: effects of rhubarb on SAP

Animal models and experimental design SAP was induced by two intraperitoneal injections (*ip*) of cerulein (40 µg/kg body weight) at 1-hr interval and then the rats were immersed in 22 ℃ water to the level of the xiphoid in restraint cages for 5 h[3] (stress). Rhubarb (75 or 150 mg/kg body weight) was orally administered (*po*) twice, 2 and 15 h before the first cerulein injection. The doses of rhubarb were selected according to our preliminary study. Experiments were performed 5 h after the first cerulein injection because previous data had shown that at that time cerulein-induced pancreatitis in the pancreas were the most severe[4]. The time course of cerulein-induced pancreatitis had been confirmed in our early study[5].

Thirty-four rats were randomly divided into five groups and treated as shown below: Control group: normal saline (NS) *po*+*ip*, without stress (*n*=6); Rhubarb group: rhubarb (150 mg/kg) *po*+NS *ip*, without stress (*n*=6); Cerulein+Stress group: NS *po*+cerulean *ip*, with stress (*n*=9); Cerulein+Stress+Rhubarb 75 mg group: rhubarb 75 mg/kg *po*+cerulein *ip*, with stress (*n*=6); Cerulein+Stress+Rhubarb 150 mg group: rhubarb 150 mg/kg *po*+cerulein *ip*, with stress (*n*=7).
Microcirculation in pancreas Local Pancreatic blood flow (PBF) was measured with a hydrogen gas clearance technique prior to sacrifice[6,7]. All animals were anesthetized with an

intraperitoneal pentobarbital injection (40 mg/kg body weight). Body temperature was monitored by a rectal thermometer and kept at 36-37 ℃ with a heating lamp over the abdomen. The pancreas was exposed by laparotomy and then a urethane-coated platinum electrode, 80 μm in diameter with a 0.5 mm portion uncoated at its tip, was inserted into the pancreatic duct through an opening at proximal end of the duct and its tip was kept at 2.5 cm away from the duodenum. The incision was covered with a piece of wet gauze to avoid the loss of body warmth and fluid. The rats were then ventilated with 10% hydrogen in air through a nasal tube. Platinum catalyzes the oxidation of gaseous hydrogen to hydrogen ions. The process is accompanied by a release of electrons, which can be measured as current. For measuring the changing rate of the tissue hydrogen concentration, the blood flow can be determined and calculated by using the following formula: blood flow (mL/min/100 g pancreas)=100 (É.) 0.693/$T_{1/2}$. PBF value was directly provided using a MHG-Dl (Unique Medical Co., Tokyo, Japan) with a built-in computer.

Serum amylase level and pancreatic wet weight After measuring PBF, a blood sample was collected from the vena cava to determine serum amylase level by Phadebas amylase test[8]. After decapitation, the pancreas was quickly removed, trimmed of fat and lymph nodes, and weighed to determine the severity of pancreatic edema, expressed as grams pancreatic wet weight per kilogram body weight.

Histologic examination A portion of the pancreatic tail from each rat was fixed in 40 g/L neutral-buffered formaldehyde, embedded in paraffin, and stained with hematoxylin and eosin. A blinded pathologist evaluated morphologic changes microscopically. Interstitia1 edema was scored as 0=absent, 1=expanded interlobular septa, 2=expanded intralobular septa, and 3= separated individual acini. Hemorrhage was evaluated as percentage involvement of the total pancreas: 0=absent, 1=1-10%, 2=11-50%, 3=more than 50%. Vacuo1ization and parenchymal necrosis were scored as percentage involvement of the examined area: 0=absent, 1=1-10%, 2=11-25%, 3=26-50%, and 4=more than 50%. Polymorphonuclear neutrophil (PMN) infiltration was scored as 0=absent, 1=less than 20 PMNs per intermediate-power field (IPF) (at×200 magnification), 2=20-50 PMNs per IPF, 3=more than 50 PMNs per IPF.

Protocol II: effects of rhubarb on pancreatic exocrine secretion in rats with SAP

Animal models and experimental design SAP was induced as mentioned in protocol I. Rhubarb (150 mg/kg) was orally administered twice at 2 and 15 h before the first cerulein injection. Sandostatin was subcutaneous injected (*sc*) from the leg three times at 30 min before, 1 h and 2.5 h after the first cerulein injection at a dose of 15 μg/kg 0.1 mL.

Thirty-six rats were randomly divided into six groups: Control group: NS *po+sc+ip*, without stress (*n*=6); Rhubarb group: rhubarb (150 mg/kg) *po*+NS *sc+ip*, without stress (*n*=6); Sandostatin group: NS *po*+sandostatin *sc*+NS *ip*, without stress

(*n*=6); Cerulein+Stress group: NS *po+sc*+cerulein *ip*, with stress (*n*=6); Cerulein+Stress+Rhubarb 150 mg group: rhubarb (150 mg/kg) *po*+NS *sc*+cerulein *ip*, with stress (*n*=6); Cerulein+Stress +Sandostatin group: NS *po*+sandostatin *sc*+cerulein *ip*, with stress (*n*=6).

Surgical Procedures Five hours after the initiation of the experiment, the rats were anesthetized and intravenously injected cerulein (0.25 μg/kg) and secretin (5 U/kg) respectively from the tail vein. A laparotomy was then performed through a midline incision, and the duodenal loop was identified. The main pancreatic duct was ligated proximal to the duodenal, and polyethylene tube (PE10) was inserted into the duct for draining pancreatic juice[9]. Pancreatic juice was collected for 30 min. The protein content of pancreatic juice was quantitated by Follin's method. Amylase was assessed by Phadebas test and bicarbonate concentration by blood gas analyzer (ABL510, Denmark).

Statistics

All data were expressed as mean±SD. For continuous data, statistical analysis of data was accomplished by Student's *t*-test and analysis of variance (ANOVA). Histologic data were expressed as range of the scores and mean±SD and compared by means of nonparametric tests: the Mann-Whitney for two groups and the Kruskal-Wallis for multiple groups. *P*<0.05 was considered statistically significant.

RESULTS

Part I: protective effects of rhubarb on cerulein+stress -induced SAP in rats

Severe edema and diffused hemorrhage in the pancreas were observed macroscopically in the Cerulein+Stress group. Upon microscopic examination, edema, hemorrhage, focal acinar necrosis, conspicuous vacuo1ization, and PMN infiltration in the pancreas were observed also in the Cerulein+Stress group. In the Cerulein+Stress+Rhubarb (75 or 150 mg/kg) groups, the severities of pancreatitis were alleviated with reduced scores of histology (*P*<0.01, *P*<0.05). There was no significant change in edema between the groups (Table1).

The data of pancreatic wet weight, serum amylase level, and PBF were shown in Table 2. There were no significant changes in the rats treated with rhubarb alone compared with the controls. The pancreatic wet weight and serum amylase level markedly increased in the Cerulein+Stress group. With the addition of rhubarb (150 mg/kg) to SAP model, a slight decrease in pancreatic wet weight from 11.60±0.61 g/kg to 10.65±0.77 g/kg (*P*>0.05) and an obvious reduction of 50% in serum amylase (*P*<0.01) was observed. PBF was 242±17 mL/min/100 g before the treatment. In the Cerulein+Stress group, it dropped to 93±5 mL/min/100 g (38% of the normal value) and partially recovered in the Cerulein+Stress+Rhubarb 150 mg group (135±12 mL/min per 100 g, 60% of the normal value, *P*<0.01*vs* the SAP group).

Table 1 Effect of rhubarb on morphologic alterations in pancreas in rats with sever acute pancreatitis

Group	n	Edema	Hemorrhage	Vacuolization	Necrosis	PMN infiltration
Control	6	0	0	0	0	0
Rhubarb	6	0	0	0	0	0
Cerulein+Stress	9	2-3 (2.8±0.2)	2-3 (2.8±0.2)	2-3 (2.7±0.2)	2-3 (2.5±0.2)	2-3 (2.2±0.2)
Cerulein+Stress+Rhubarb 75 mg	6	3 (3.0±0)	1 (1.0±0)	2-3 (2.2±0.2)	1-2 (1.4±0.2)	1-2 (1.6±0.2)
Cerulein+Stress+Rhubarb 150 mg	7	2-3 (2.8±0.2)	1-2 (1.0±0.3)[a]	1-3 (1.8±0.3)[a]	1-2 (1.2±0.2)[b]	1-2 (1.8±0.2)[b]

Values are expressed as the range of the scores, with the mean±SD. The nonparametric test (Kruskal-Wallis method) showed [a]*P*<0.05, [b]*P*<0.01 *vs* Cn+St group; and no significant difference in edema.

Table 2 Effect of rhubarb on the changes of pancreatic wet weight, serum amylase activity, pancreatic blood flow

Group	n	Pancreatic wet weight (g/kg)	Serum amylase activity (U/L)	Pancreatic blood flow (mL/min/100 g)
Control	6	3.29±0.12	81 360±2 200	242±17
Rhubarb	6	3.34±0.14	85 370±2 910	238±18

Part II: the effects of rhubarb on pancreatic exocrine function in cerulein+stress -induced SAP

After pretreatment with rhubarb or somatostatin, total volume, amylase activity, protein content, and bicarbonate concentration of pancreatic juice in both Rhubarb group and Sandostatin group did not differ significantly from the controls (Table 3). Amylase activity in Cerulein+Stress group declined to 44%. In addition, the volume and protein output reduced significantly compared with that of the control group. No significant improvement was found in the volume and protein content of pancreatic juice in the Cerulein+Stress+Rhubarb group and the Cerulein+Stress+Sandostatin group compared with Cerulein+Stress group, whereas the amylase activity of pancreatic juice in the Cerulein+Stress+Rhubarb group and the Cerulein+Stress+Sandostatin group significantly decreased than that of the Cerulein+Stress group ($P<0.01$), and were 2.4% and 2.7% of the control respectively. Interestingly, the bicarbonate concentration of Cerulein+Stress+Rhubarb group increased to 403±69 mmol/L, which was three times of the control. This phenomenon could not be seen in Cerulein+Stress+Sandostatin group.

DISCUSSION

Severe acute pancreatitis still has a comparatively high mortality due to the systemic inflammatory response syndrome leading to multiple organ failure. Molecular and pathophysiologic investigations have allowed us to get more information about the events in the initiation and the natural course of acute pancreatitis, and subsequently to know more about how to deal with it. Despite considerable experimental efforts, the complexity in the evolution of acute pancreatitis is still far from being completely understood.

Since studies of acute human pancreatitis has many limitations due to its rapid and severe clinical course, so innovative therapeutic concepts should first be clarified in animal experiments. The cerulein model of experimental acute pancreatitis has become popular for the analysis of intracellular events in the early phase of pancreatitis. The major limitation of this non-invasive model is that it can only produce a mild, self-limited disorder. In order to establish a non-traumatic, easy to induce

and reproducible experimental model of clinical relevance, some researchers had modified the animal treatment protocols. It was revealed that early microcirculatory changes, included the increased permeability of endothelial lining and an accumulation of extravasated fluid in the perilobular space, would be more severe if cold stress was added to cerulein induced pancreatitis[10]. Recently, Ding *et al*.[11] had established a mouse model of severe acute pancreatitis by co-injection of cerulein and lipopolyasccharide, which could produce the same pathological characteristics as those of severe acute pancreatitis in human. In our work, we have used a rat model, in which cerulein-induced mild acute pancreatitis could develop into severe acute pancreatitis under water-immersion stress[12]. Cerulein can cause blocking of zymogen secretion, co-localization of zymogens and lysosome, and digestive enzyme activation. Water-immersion stress can stimulate sympathetic nerve system. In this model, multiple vasoconstrictive factors are released, which contribute to a reduction of pancreatic blood perfusion and tissue hypoxia or anoxia with the consequence of damages of microvascular endothelium. Moreover, an enhanced release of cytokines in turn precipitates the microcirculatory disorders. Our study had shown that cerulein plus water-immersion model evolved a highly reproducible form of pancreatitis that was characterized by hyperamylasemia, pancreatic hemorrhage and reduction of pancreatic blood flow.

The significance of disorders of the microcirculation with the consequence of tissue hypoxia or anoxia has been under consideration in the pathogenesis of acute pancreatitis for several decades[13-15]. The hypothesis that the pathogenesis of acute pancreatitis involves ischemia - reperfusion-associated events has attracted new attention[16,17]. The decreased pancreatic capillary blood flow, reduced functional capillary density, and irregular intermittent perfusion were observed in the specimens of cerulein-induced experimental acute pancreatitis[18]. In addition, experimental studies have indicated that synthesis and release of pro-inflammatory cytokines such as TNFα, IL-1β[19], and platelet activating factor (PAF)[20,21], were responsible for local injury and systemic dispersion of the inflammation in the development of pancreatitis. There also had strong evidence that oxygen free radicals were closely associated with the severity of acute pancreatitis[22,23]. Elucidation

of these mechanisms may lead to the possibility of specific therapies aimed at reducing microcirculatory disorders, interrupting the inflammatory process, and therefore preventing tissue injury in acute pancreatitis. Unfortunately, there is still no specific compound for treatment of severe acute pancreatitis other than supportive critical care today.

Rhubarb, a Chinese herbal medicine, has a very broad spectrum of biological activities and pharmacological functions. Rhubarb is used as a laxative, antiphlogistic, and-homeostatic in the treatment of constipation, diarrhea, jaundice, and gastro-intestinal hemorrhage, etc. Clinical studies have shown that rhubarb could improve the prognosis of patients with systemic inflammatory reaction syndrome (SIRS) by its antagonizing effect against inflammatory cytokines and complements[24]. As reported by Chen et al., rhubarb could reduce the leakage of oxygen radicals from the mitochondria of intestinal mucosa, exert protective effect on barrier of intestinal mucosa, and improve the gastrointestinal blood perfusion in shocked rats[25-28]. It has also been shown that rhubarb was effective in alleviating the severity of early phase of acute pancreatitis, and preventing further complications at later stages[2]. The sites of action could be related to its inhibition of pancreatic enzymic activities[29]. In experimental pancreatitis the therapy of Tong Xia purgative method, in which rhubarb was the main compound, could alleviate the degree of lung injury mediated by TNF[30]. Taken together, Chinese herbs have many pharmacological substances and therefore have multiple therapeutic effects on acute pancreatitis. This study has shown that administration of rhubarb resulted in a marked reduction of serum amylase activity, significant amelioration in the severity of SAP, and improvement of microcirculatory disturbances in pancreas. Rhubarb may play an important role in the regulation of local blood flow of pancreas by eliminating the oxygen free radicals, as well as inhibiting the release of cytokines.

Few studies have characterized the alteration in pancreatic exocrine function after the induction of experimental pancreatitis. Niederau et al.[31] evaluated basal and stimulated pancreatic secretion in vivo and in vitro in four different models of acute pancreatitis. They found that a secretory blockade during pancreatitis was strikingly similar in all models, in particular the pancreatic secretory response to CCK. This secretory blockade might at least partly explain the failure to treat acute pancreatitis effectively by inhibition of secretion. Our preliminary experiment also showed a nearly complete blockade of pancreatic exocrine secretion in rats with SAP (data was not shown). We successfully obtained the pancreatic juice sample by co-injection with CCK analog and secretin at physiological dosage. This study demonstrated a significant reduction of the volume, amylase activity, and protein content of pancreatic juice in rats with SAP. After treatment with rhubarb, bicarbonate output was distinctively increased, which has yet unknown significance. Like secretin, rhubarb might stimulate flow of bicarbonate- and electrolyte-rich ductular secretion via cAMP, and then exert a protective effect on acute pancreatitis[32], which requires further study.

Our present study showed that rhubarb with its natural complexity and typical prescription in combination exerted protective effects on SAP in rats, probably through improvement of pancreatic microcirculation, amelioration of inflammation, inhibition of pancreatic enzyme, and partial alteration of pancreatic exocrine.

Abstract

AIM: To study the method of cryopreserving porcine hepatocytes and gel collagen culture measure after its cryopreservation.

METHODS: Hepatocytes, isolated from Chinese experimental suckling mini-pigs by two-step perfusion with collagenase using an extra corporeal perfusion apparatus, were cryopreserved with 50 mL/L to 200 mL/L DMSO in liquid nitrogen for 4 mo, then thawed and seeded in 1 or between 2 layers of gel collagen. The expression of porcine albumin message RNA, cellular morphology and content of aspartate aminotransferase (AST) and urea nitrogen (UN) were examined during culture in gel.

RESULTS: Viability of 150 mL/L DMSO group thawed hepatocytes was (83±4)%, but after purification, its viability was (90±5)%, attachment efficiency was (86±7)%, the viability of thawed hepatocytes was near to fresh cells. When the thawed hepatocytes were cultivated in gel collagen with culture medium adding epidermal growth factor, the hepatocytes grew in various administrative levels in mixed collagen gel, and bunchy in the sandwich configuration cultures. For up to 10 days' culture, the typical cellular morphological characteristics of cultivated hepatocytes could be observed. The leakage of AST was lower during culture in gel than that in common culture. At the same time, the UN synthesized by cells cultivated in mixed gel collagen was higher than that in other groups.

CONCLUSION: Storage in liquid nitrogen can long keep hepatocytes' activities, the concentration of 150 mL/L DMSO is fit for porcine hepatocytes' cryopreservation. Thawed hepatocytes can be cultivated with collagenous matrix, which provides an environment that more closely resembles that *in vivo* and maintain the expression of certain liver-specific function of hepatocytes.

INTRODUCTION

Bioartificial liver support systems (BALSS), which employ freshly isolated primary hepatocytes, present severe logistic difficulties in the continuous supply of hepatocytes[1-3]. Stored frozen hepatocytes that are thawed as required would solve this problem. Now, storing hepatocytes in liquid nitrogen was an important method to keep its biological abilities, suitable preserving measure can offer high vigorous hepatocytes for several researches. With the further development of related subjects, long-term preservation methods and active architecture of hepatocytes were needed badly to meet the immediate requirement of bioartificial liver and correlated researches[4-7]. Cryopreservation of hepatocytes is essential for the emergent treatment of acute liver failure. Morsiani *et al* reported the clinical use of such thawed cells. These clinical reports certainly reflect the progress made to date in the isolation and handling of hepatocytes, and it is hoped this will lead to a wider use of cellular therapies in liver diseases[8-13].

In order to find a suitable cryopreservation and culture measure, hepatocytes from newly born Chinese experimental mini-pigs were cryopreserved in -196 ℃ for 4 mo, then thawed hepatocytes were cultivated with mixed gel or sandwich gel collagen, and their morphology and biological functions were compared. So this study was to develop a cryopreservation protocol for long-time preparation of porcine hepatocytes, and to determine an optimal purification procedure and culture methods for thawed hepatocytes. At last it could provide important experimental data for the research of bioartificial liver and hepatocytes transplantation.

MATERIALS AND METHODS

Isolation of porcine hepatocytes

Pig hepatocytes were harvested from newly born Chinese experimental mini-pigs (Experimental Animal Center, Third Military Medical University) using the two-step collagenase perfusion method that was modified from the original methods developed by Seglen *et al*[4,20-22]. Briefly, the animals were anesthetized with barbital (30 mg/kg, b.w, intraperitoneally) and their livers were removed. The liver was first perfused *in vitro* via the portal vein with warmed (37 ℃) Ca^{2+} and Mg^{2+} free Hanks balanced salt solution at a flow rate of 20-30 mL/min for 10-15 mL/min, and then perfused with 0.5 g/L collagenase (Sigma, Type IV) in the same solution supplemented with 5 mM $CaCl_2$ and 50 mM HEPES. The reperfusion with collagenase solution lasted 20 min at a rate of 20 mL/min at 37 ℃. After 10 min of incubation (37 ℃) with gentle shaking, the cells suspension was filtered and centrifuged at 50 g, 3 min for 3 times. The viability of the isolated liver cells was determined using standard trypan blue exclusion, ranged from 89% to 98%[14-18].

Cryopreservation of porcine hepatocytes

Isolated hepatocytes were slowly resuspended and gently mixed at 5×10^9 cells/L concentration in different cyropreserving solution which consists of 200 mL/L fetal bovine serum (FBS) and 50 mL/L, 100 mL/L, 150 mL/L or 200 mL/L dimethyl sulphoxide (DMSO, Sigma, America), then placed hepatocytes in 1 mL freezing tube (AXYGEN, America), tagged and put into isopropanol. The concrete freezing procedure was: put in room temperature for 15 min; 4 ℃ for 20 min; -20 ℃ for 30 min;

and stayed overnight at -80 ℃, at last, liquid nitrogen for long-term preservation[7,19-23].

Thawing and removal of DMSO

Four months later, the vials were removed from liquid nitrogen and rapidly thawed by immersion in a 37 ℃ water bath. Immediately after thawing, dimethyl sulfoxide was removed by successive dilutions in 50 mL tubes, 20 mL of Leibowitz-15 medium containing 100 mL/L FBS was gently added to 1.0 mL of cell suspension at 3 min of intervals. The cells were washed three times by centrifugation for 3 minutes at 30 g and 4 ℃ to remove cryoprotectant. Then hepatocytes pellet was resuspended in L-15 medium with 100 mL/L FBS. Cell viability was estimated by trypan blue dye exclusion. 1×10^6 thawed hepatocytes were centrifuged at 1 000 rpm for 10 min, the supernatants of medium discarded, pellet cells fixed by 30 mL/L glutaral and 10 mL/L OsO_4etc, and hepatocytes' ultrastructure was observed through transmission electron microscope[24,25].

Percoll purification of thawed hepatocytes

Working Percoll solution I was prepared by adding 1 part of 10 concentrated D-phosphate-buffered saline into 9 parts of Percoll. Then working Percoll solution II was consisted of 30 mL working Percoll solution I and phosphate-buffered saline. Hepatocytes purification was made by a procedure: to 10 mL of cell suspension, 25 mL of working Percoll solution II were added. The cells pellet was collected by centrifugation at 500 g during 3 min, resuspended, and purified hepatocytes were washed 3 times by centrifugation for 3 min at 30 g and 4 ℃.

Common, mixed collagen gel and sandwich configuration culture of thawed hepatocytes

Then hepatocytes were inoculated at 10^6 cell/ bottle in L-15 medium added by 100 mL/L FBS, 10 μl/L glucagons, 200 U/L insulin and 20 ng/L epidermal growth factor (Sigma), as a control group and the medium was changed every day. The morphologies of hepatocytes were observed under inverted microscope, supernatants of culture cells was stored at -20 ℃ for examination. Viability of cells was determined using standard trypan blue exclusion measure.

The collagen solution was prepared just before its use by mixing three parts of collagen type VII (Sigma) in one part of 4×Dulbecco's modified Eagle's medium (Gibco, America) without bicarbonate (pH 7.4), adjusting its pH to 7.20 with 1N NaOH. One million cells were mixed with 2 mL collagen solution and incubated in T-flasks (25cm²) at 37 ℃. When the mixed collagen matrix was fixed in an hour, the gel was washed slowly and medium was added, and hepatocytes were incubated at 37 ℃ with 100 mL/L CO_2 900 mL/L humidity. The methods of culture and observation were the same to the control group[26,27].

When thawed hepatocytes were cultivated in sandwich configuration, the collagen solution was prepared just as before, then T-flasks were coated with it and incubated one hour at 37 ℃. One million cells were cultivated with L-15 medium. Nonattached hepatocytes were washed after one hour; second layer of collagen solution was spread to sandwich the hepatocytes after 24 h. Thirty minutes later, sandwich configuration hepatocytes were formed[28-30], and the methods of culture and observation were just performed as before.

Expression of porcine hepatocytes albumin message RNA

When hepatocytes were cultivated for one week, its total RNA were distilled by Tripure isolated reagent (the gel cultured hepatocytes were digested with 0.5 g/L pancreatin before distilled). The sequences of primers are designed in Table 1. "House-keeping gene" glyceraldehydes-3-phosphate dehydrogenase (G3PDH) gene was kept as inner standard[31].

Table 1 Nucleotide sequences of primers and band sizes

Primers		Sequences (5'-3')	Band sizes
mRNA	sense	CTTATTCCAGGGGTCTGTTTC	324 bp
	antisense	TCGTTTCTCTCAGGCTCTTCT	
G3PDH	sense	CATCATCCCTGCTTCTACCC	160 bp
	antisense	CCTGCTTCACCACTTTCTTG	

RNA was reverse transcribed using a one-step RT-PCR kit (Promga, America). For RT-PCR amplification, the standard RT-PCR program of one cycle of 48 ℃ for 45 min and 94 ℃ for 4 min, 35 cycles of 95 ℃ for 1 min, 55 ℃ for 1 min, and 72 ℃ for 1 min and one cycle of 72 ℃ for 7 min were applied. The products of RT-PCR were electrophoresised on 15 g/L agarose gel, and figures were gained on Gel-Doc™2000 (BIO-RAD, America). The densities of these straps were scanned, and the odds of every group's band/ corresponding G3PDH strap were seen as the expression of objective gene.

Aspartate aminotransferase (AST) and urea nitrogen (UN)

The level of AST and UN, in culture supernatants of the control group, mixed gel and sandwich configuration, were detected with biological analysis meter (HITACH. Japan)[32].

Data statistics

The data was analysed by the duplication measurement analysis of variance or one-way analysis of variance on SPSS 11.0 software. Results were expressed on mean±standard deviation (mean±SD).

RESULTS

Survival rate and attaching efficiency of hepatocytes

Fresh isolated and cryopreserved/purified hepatocytes were assessed for viability and function by trypan blue dye exclusion. The yield of cells was 1.5 to 5×10^9 cells/liver. Cell viability was (91±4)%, and attachment efficiency of viable hepatocytes after 24 h culture was (89±5)%. After cryopreservtion, the viabilities of 50 mL/L, 100 mL/L, 150 mL/L and 200 mL/L DMSO group of hepatocytes were in Table 2. However, when the 150 mL/L DMSO group thawed hepatocytes were purified by Percoll, its viability was (90±5)%, attachment efficiency was (86±7)%. The viability of thawed hepatocytes were near to fresh cells.

Table 2 Viability and 24 hours attaching efficiency of thawed hepatocytes (%)

Viability/group (mL/L)	50 DMSO	100 DMSO	150 DMSO	200 DMSO
Viability	51±3	71±4ᵃ	83±4ᶜ	79±5ᶜ
Attaching efficiency	32±6	70±5ᵃ	81±5ᶜ	77±6ᵃ

$n=5$, ᵃ$P<0.05$ *vs* 50 mL/L or 100 mL/L DMSO group, ᶜ$P<0.05$ *vs* 50 mL/L DMSO group.

In this table, we can see the viability of 100 mL/L DMSO group cells were much better than that of 50 mL/L and 100 mL/L DMSO groups ($P<0.05$), but there was no significant difference between the group of 150 mL/L DMSO and 200 mL/L DMSO ($P>0.05$).

Morphology of thawed hepatocytes

The ultrastructure of thawed hepatocytes in 150 mL/L DMSO group were kept well, number of mitochondria was normal, with slight swellen cristae, rough endoplasmic reticulum decreased, smooth endoplasmic reticulum and golgi apparatus increased,

chromatin in cell nucleus distributed normal (Figure 1A).

Thawed hepatocytes of 150 mL/L DMSO group attached to dishes within 4 h (Figure 1B). After 24 hours' culture, cells appeared polygonal, containing granular cytoplasm with one or two centrally located nuclei. Seven days later, they were more flattened and appeared bigger than 24 h cultured hepatocytes. Morphology and ultrastructure of other groups' hepatocytes were abnormal, thus the hepatocytes of 150 mL/L group were provided for gel collagen culture.

Figure 1 A: The thawed hepatocytes' ultrastructure after 4 mo cryopreservation, (TEM, ×4000), B: The morphology of thawed hepatocytes after 4 h culture (PCM, ×200).

Figure 2 A: Morphology of thawed hepatocytes cultivated in mixed gel for 4 h (PCM, ×200), B: Morphology of hepatocytes cultivated in sandwich configuration for 24 h (PCM, ×200).

Morphology of mixed gelled cultivated pig hepatocytes

The hepatocytes kept their biological characters well after 150 mL/L DMSO cryopreservation. When the thawed hepatocytes were mixed in gel collagen and cultivated with medium adding epidermal growth factor, the hepatocytes grow in various administrative levels in collagen gel. For up to 7 days' culture, the typical cellular morphological characteristics of hepatocytes could be observed (Figure 2A).

Morphology of sandwich culture pig hepatocytes

Hepatocytes, cultivated for four hours in first layer gel, turned from pellet to polygon. When second layer gel collagen was added, hepatocytes cultured in collagen sandwich configuration had a cuboid, compact, bunchy, and well-defined shape with a classical cobblestone appearance. In the seven-days' culture period, the hepatocytes maintained their typical morphological characteristics under phase contract microscope (Figure 2B).

Expression of albumin mRNA on thawed porcine hepatocytes

When the control group mixed gel collagen and sandwich configuration porcine hepatocytes were cultivated for seven days, they all kept expression of albumin message RNA using RT-PCR, but the level of mixed gel collagen group was higher than that of other group ($P<0.05$), (Figure 3 and Table 3).

Figure 3 Expression of porcine albumin mRNA on culture hepatocytes after RT-PCR. M: DNA markers; lanes 1, 2 and 3 are control groups, mixed gel collagen and sandwich configuration.

Table 3 Change of albumin mRNA expression in culture pig hepatocytes (mean±SD)

Band density/group	Mixed gel group	Sandwich group	Control group
Mean rate of density	0.44±0.041[a]	0.353±0.021[c]	0.261±0.02

$n=3$, [a]$P<0.05$ *vs* group of control or sandwich; [c]$P<0.05$ *vs* control group.

Release of AST

The level of AST in common culture hepatocytes supernatant was very lower on day 1 to day 3, and ascended to the peak on day 7, which was marked higher than the group of mixed gel collagen or sandwich collagen ($P<0.05$). The contents of AST in the group of gel collagen on culture 24 to 48 h were high, but they dropped at day 3 and kept at a lower level ($P>0.05$), (Figure 4).

UN in culture supernatant

The levels of urea nitrogen synthesized by hepatocytes in three groups were different and changed. The content in common culture group decreased on day 5, and was lower than that of other groups on culture period ($P<0.05$). Mixed gel group's level was higher than that of the sandwich, but they had no marked difference. ($P>0.05$), (Figure 5).
**Figure 4** Content of AST on hepatocytes culture medium.

Figure 5 Content of urea nitrogen on hepatocytes culture medium.

DISCUSSION

Hepatocytes cryopreserved in liquid nitrogen were thought as only efficient measure to keep its ability currently[33-36]. Shortage of hepatocytes necessitates the development of improved cryopreservation techniques for long-term storage of hepatocytes to make best use of available hepatocytes. The ultimate goal of any improved cryopreservation protocol is to minimize sudden intracellular formation of ice crystals that could result in ultrastructural damage, and thus maintains cell viability, attachment, and metabolic activity on thawing. Storage time of cryopreserved hepatocytes at temperatures -196 ℃ may play an important role in the quality of thawed cells. Most of the available protocols use dimethyl sulfoxide in the cryopreservation medium[19,37-39].

Successful cryopreservation of porcine hepatocytes would ensure the accessibility of cells for laboratory use, permit the standardisation of experiments, save lives of animals and lead to continuous supply of hepatocytes in BALSS treatment[28,31]. Therefore, we sought the optimal procedure for cryopreservation of porcine hepatocytes for both laboratory and clinical purposes in this study. The protocol for cryopreservation of hepatocytes included the concentration of 150 mL/L DMSO, 200 mL/L fetal bovine serum and rapid thawing followed by slow dilution of DMSO to avoid osmotic shock. After 4 mo cryopreservation, the thawed cells were shown to have a reasonable level of cell viability, compared to freshly isolated hepatocytes. So the storage condition was proved to be suitable for long-time cryopreservation of pig hepatocytes. Our purification method using D-PBS and Percoll achieved a high cell recovery rate with satisfactory viability and function at high cell concentrations (5×10^9 cell/L), facilitating purification of hepatocytes in large quantities. We conclude that frozen/thawed/purified cells can possess satisfactory viability and function. Large-scale cryopreservation of porcine hepatocytes may provide an efficient alternative to freshly isolated porcine hepatocytes[19,40-42].

Proper cryopreservation measure can maintain porcine hepatocytes' abilities for a long time. However, if the thawed hepatocytes were cultivated in unfit conditions, it would not meet the need of application in clinic and basic research. Therefore, the culture pattern of thawed hepatocytes also appeared very important. Traditional cell culture measure, which was common monolayer attaching incubation, was hard to simulate the circulation that hepatocytes grew *in vivo*, and were not suitable for BLASS[43]. Collagen was a kind of matrix in common use to fix hepatocytes. Liver cells *in vivo* assume three-dimension configuration in a liver lobule, and there are complicated contacts among hepatocytes, liver non-parenchyma cells and cell matrix. Matrix is an important part of affecting hepatocytes function. Many researches showed that collagenous matrix could provides an environment that more closely resembles that *in vivo* and allows to maintain the expression of certain liver-specific function of hepatocytes[44-47]. In this study, the hepatocytes keep their biological characters well after storage in liquid nitrogen for 4 mo. When the thawed hepatocytes were cultivated in gelled collagen with culture medium added by epidermal growth factor, the cells grow in various administrative levels in mixed collagen gel, and bunchy in the collagen sandwich cultures. For up to 10 days' cultures, the typical cellular polygonal morphological characteristics of culture hepatocytes could be observed, and the bound between hepatocytes appear brightly and clearly; the leakage of aspartate aminotransferase was less and the level of urea nitrogen synthesized by hepatocytes was higher. Through sandwich culture can hold hepatocytes synthesizing and metabolizing abilities, the cultivated hepatocytes was also at monolayer attaching state, and do not have normal three-dimension construction *in vivo*, so it needs to be further ameliorated[26,29,43].

In conclusion, through the study of many important factors in hypothermic preservation, we can optimize the hypothermic preservation protocols or cultivated conditions, and established a hepatocytes storage room. That will be helpful for the development of BAL and hepatocytes transplantation[9,40,48].

Abstract

AIM: To assess the effects of somatostatin on proliferation and apoptosis of activated rat hepatic stellate cells (HSCs).

METHODS: HSCs isolated from the livers of adult Sprague-Dawley rats (weighing 400-500 g) by *in situ* perfusion and purified by single-step density gradient centrifugation with Nycodenz, became activated after 10 days' cultivation. Then the apoptotic rate of HSCs treated with different doses of somatostatin for 72 h, was assayed by acridine orange/ethidium bromide fluorescent staining, terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling, transmission electron microscopy and flow cytometry, while the proliferation of HSCs was measured by MTT assay. Furthermore, the mechanisms of somatostatin were investigated by cytodynamic analysis.

RESULTS: Somatostatin at the concentration of 10^{-6}-10^{-9} mol/L could decrease the proliferative rate, and promote the apoptosis of activated rat HSCs in a dose-dependent way. Its action was most significant when the concentration reached 10^{-6} mol/L or 10^{-7} mol/L ($P<0.05$-0.01). An obvious cell-cycle arrest (G_0/G_1 arrest) was the important way for somatostatin to exert its action.

CONCLUSION: Antiproliferative and proapoptotic effects of low-dose somatostatin on activated rat HSCs can be obtained. These findings reveal its potential antifibrotic action.

INTRODUCTION

Hepatic stellate cells (HSCs), critical mesenchymal cells in producing hepatic fibrosis and hepatic cirrhosis[1-9], have been the major target of antifibrotic treatment for a long time, although success has been seldom achieved. Fortunately, progress in the research on inducing apoptosis of activated HSCs, together with inhibition of their proliferation, may provide us with a promising solution to fibrogenesis caused by different kinds of chronic hepatic diseases.

Recent researches have revealed the apoptosis-inductive and proliferation-inhibitory effects of somatostatin on various cells. Furthermore, somatostatin also has an inhibitory effect on the secretion of some cytokines such as epidermal growth factor (EGF), transforming growth factor-α (TGF-α) and the like, which are essential for the activation of HSCs. Thus we attempted to investigate the effect of somatostatin on proliferation and apoptosis of HSCs and their possible therapeutic potential in hepatic fibrosis.

MATERIALS AND METHODS

Isolation, culture and identification of rat HSCs

Adult male Sprague-Dawley rats (400-500 g) were employed in the experiment. After anesthesia, *in situ* serial infusions were performed via the portal vein with D-Hank's solution and perfusion medium (Hank's medium containing 0.5 g/L collagenase IV and 1 g/L pronase E). Then the liver was broken into pieces and redigested with collagenase IV and DNase. Finally, HSCs were separated from the cell suspension by single-step density gradient centrifugation with 180 g/L Nycodenz (Sigma,USA). After cultured in Dulbecco's modified Eagle medium (DMEM) (Gibco, USA) containing 200 mL/L calf serum (Shishen, China), penicillin (100 IU/mL) and streptomycin (100 mg/mL), HSCs were inoculated into culture flasks and maintained at 37 ℃ in an atmosphere of 50 mL/L CO_2.

The percentage of freshly isolated living HSCs was up to 95% as defined by trypan blue staining (Sigma, USA), while their purity was over 90% when assessed by light microscopic appearance and their characteristic autofluorescence, which reflected the droplet of vitamin A in cytoplasm (at 325-328 nm). Immunocytochemical staining of desmin (Boster, China) and α-smooth muscle actin (α-SMA) (Boster, China), as well as myofibroblast-like phenotype showed the overall activation of almost all HSCs on the 10th day.

Determination of proliferation of activated HSCs

Exponentially growing activated first-passage-HSCs seeded in 96 well plates at 1×10^4 cells per well, were divided into six groups at random, namely the control group and five somatostatin-treatment groups of 10^{-6} mol/L, 10^{-7} mol/L, 10^{-8} mol/L, 10^{-9} mol/L and 10^{-10} mol/L. Six duplicate wells were arranged in each group. They were incubated at 37 ℃ in 50 mL/L CO_2 for five d, and then the following steps were taken. (a) Twenty micoliters of MTT (5 mg/mL) was added to each well and incubated for four h. (b) The supernatant was aspirated and discarded. (c) One hundred microliters of DMSO was dropped into each well and the plate was agitated for a few min. (d) The optical density (OD) was analysed on an ELISA reader at a test wavelength of 490 nm and a reference wavelength of 620 nm. The inhibition rate (IR) of cell proliferation was calculated according to the following equation. IR=[1-(OD of somatostatin well/OD of control well)]×100%.

Apoptotic analysis of activated HSCs

Activated first-passage HSCs during their logarithmic growth

period were inoculated on the surface of L-polylysine-covered-glass slides in six well plates. According to the same grouping method in the proliferation test, all these wells were divided into six groups for each item of experiment. The apoptotic rates of activated HSCs treated with different concentrations of somatostatin for 72 h, were measured by acridine orange (AO)/ethidium bromide (EB) fluorescent staining, terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL), transmission electron microscopy and flow cytometry, respectively.

Firstly, HSC suspension was prepared via trypsinized method and modulated to a density of 0.5×10^6 cells/mL. Then it was mixed with AO/EB solution (PBS medium containing 0.1 mg/mL AO and 0.1 mg/mL EB) at a proportion of 25:1. Apoptotic cells among 300 randomly selected HSCs were distinguished under high power fluorescent microscope.

Secondly, HSCs fixed with 40 g/L polyformaldehyde were processed in accordance with the instructions of the TUNEL kit (Boster, China): (a) treatment by 30 mL/L H_2O_2 and pronase K successively, (b) reaction with the reactive mixture consisting of 1 μL of TdT, 1 μL of digoxin-labeled dUTP, 18 μL of signal buffer and 20 μL of signal medium, in a wet box at 37 ℃ overnight, (c) incubation with blocking medium, anti-digoxin-biotin and SABC sequentially, (d) exposure to DAB for coloration. Thereafter, twenty high power fields under the microscope in each glass slide were chosen at random and positive cells with brown nuclei were counted. Apoptosis Index (AI)=(apoptotic cells/total cells)×100%.

Thirdly, the following steps were taken for the digested HSCs: namely to rinse with PBS, to fix with cold ethanol at -20 ℃, to incubate with 100 μL 10 g/L RNase at 37 ℃ for 15 min, and to stain with propidium iodide (PI) for 30 min in darkness. Then the apoptotic rate and cell cycle could be obtained by flow cytometry.

Finally, HSCs in culture flask were fixed in 20 g/L glutaraldehyde, centrifuged, embedded in glass and sliced in series. HSC ultrastructure was observed by transmission electron microscopy.

Statistical analysis

Results were expressed as mean±SD. One way ANOVA and t test were applied for data analysis. P values less than 0.05 were considered statistically significant.

RESULTS

Effects of somatostatin on HSC proliferation

Data taken from colorimetric MTT assays showed that somatostatin (10^{-6} mol/L-10^{-9} mol/L) could significantly inhibit the proliferation of activated HSCs in a dose-dependent way (Table 1). As compared with the control group, the inhibitory rates of somatostatin treatment groups rose up to 30.53% and 15.81% when the concentrations of somatostatin reached 10^{-6} mol/L and 10^{-7} mol/L, respectively. But no obvious effect was found in 10^{-10} mol/L somatostatin treatment group.

Table 1 Effects of somatostatin on HSC proliferation (mean±SD)

| SST concentration (mol/L)	ODs	Inhibitory rates (%)
10^{-6}	0.19±0.03[b]	30.53
10^{-7}	0.23±0.02[b]	15.81
10^{-8}	0.25±0.03	7.77
10^{-9}	0.26±0.03	4.48
10^{-10}	0.27±0.04	0
0	0.27±0.04	0

[b]$P<0.01$ *vs* control group.

Figure 1 Effect of somatostatin on apoptosis of HSCs. A: Apoptosis rate of somatostatin-treated HSCs (fluorescent staining), B: Apoptosis of 10^{-6}M somatostatin-treated HSCs demonstrated by TUNEL (×400), C: Apoptosis could not be detected in normal HSCs by TUNEL (×400), D: Apoptosis of 10^{-6}M somatostatin-treated HSCs demonstrated by transmission electron microscopy (×8000). E: Apoptosis could not be detected in normal HSCs by transmission electron microscopy (× 8000).

Apoptosis of HSCs examined by fluorescent staining

After 72 h' treatment, round-shaped HSCs with shrunk nuclei and conglomerated granules became visible in all somatostatin treatment groups. These HSCs underwent early apoptosis and displayed stronger green fluorescence. The experimental results showed that the higher the concentration of somatostatin, the stronger its proapoptotic action (Figure 1). The apoptosis-inductive effect of somatostatin reached its maximum at the concentration of 10^{-6} mol/L-10^{-7} mol/L ($P<0.05$).

Apoptosis of HSC examined by flow cytometry

As detected by flow cytometry, somatostatin of different concentrations could dose-dependently promote apoptosis of activated HSCs. In 10^{-6} mol/L and 10^{-7} mol/L somatostatin treatment groups, the apoptotic rate was significantly higher than that in the control group ($P<0.01$) (Table 2).

Table 2 Effects of somatostatin on HSC apoptosis (mean±SD)

Somatostatin concentration (mol/L)	Apoptosis rate (%)
10^{-6}	16.54±4.59[b]
10^{-7}	6.06±1.79[b]
10^{-8}	2.81±0.72
10^{-9}	2.25±0.98
10^{-10}	1.55±0.64
0	1.53±1.19

[b]$P<0.01$ *vs* control group.

Analysis of cytodynamics demonstrated that somatostatin could increase the percentage of HSCs in G_0/G_1 phase, and reduce it in S phase. However, there seemed to be no alternation in G_2/M phase. Experimental findings also made it clear that the percentage of somatostatin-treated HSCs was 93.14±6.69% (10^{-6} mol/L) and 90.65±8.03% (10^{-7} mol/L) in G_0/G_1 phase, and 78.48±4.43% in control group respectively. Meanwhile, the percentage of somatostatin treated HSCs were 1.75±0.44% (10^{-6} mol/L), 3.87±0.91% (10^{-7} mol/L) in S phase, and 12.50±2.89% in control group, respectively. The difference between somatostatin treatment groups and control group was statistically significant ($P<0.01$-0.05).

Apoptosis of HSC examined by TUNEL

The number of early apoptotic HSCs characterized by pyknosis of nuclear chromatin and condensation of cytoplasm, increased with somatostatin treatment in a dose-dependent manner (Figure 1). The apoptotic rates of different somatostatin treatment groups were 14.65±3.86% (10^{-6} mol/L), 5.97±1.04% (10^{-7} mol/L), 2.30±0.62% (10^{-8} mol/L), 2.02±0.81% (10^{-9} mol/L) and 1.65±0.88% (10^{-10} mol/L), respectively. Statistical difference was found in the rates between two somatostatin treatment groups (10^{-6} mol/L, 10^{-7} mol/L) and the control group ($P<0.01$).

Apoptosis of HSC examined by transmission electron microscopy

Typical apoptotic HSCs could be identified under transmission electron microscope after treatment of somatostatin for 72 h. They were characterized by shrinkage of cells with vacuoles in cytoplasm, swelling of mitochondria, dilated endoplasmic reticulum, irregular nuclei and pyknosis and conglomeration of chromatin ranging along inside of the nuclear membrane (Figure 1).

DISCUSSION

Somatostatin, an important peptide for inhibiting cellular proliferation and differentiation, could slow down the growth of various kinds of cells by blocking the synthesis and/or secretion of many important cytokines and hormones[10-14]. On the other hand, extensive physiological effects of somatostatin and its analogues are mainly mediated by five subtypes of somatostatin receptors (SSTR), including $SSTR_1$, $SSTR_2$ ($SSTR_{2a}$ and $SSTR_{2b}$), $SSTR_3$, $SSTR_4$ and $SSTR_5$. According to our knowledge, somatostatin-14 may be the main endogenous molecular form, although somatostatin-20, somatostatin-25 and somatostatin-28 also exist in the human body.

In recent years, researches have revealed the involvement of somatostatin and its receptors in the differentiation of HSC, *i.e.*, somatostatin-containing nerve fibers inside the liver lobule are in close contact with sinusoidal endothelium as well as HSC[15]. In 2001 Reynaert *et al*[16] demonstrated that HSCs expressed $SSTR_1$, $SSTR_2$ and $SSTR_3$ during their activation. Therefore, it is reasonable to deduce that somatostatin may play a negative regulatory role in the activation of HSCs via paracrine route. Except for its actions through SSTRs, somatostatin exerts inhibitory effect on the secretion of mitogens, including insulin-like growth factor (IGF), EGF and TGF-α, which are essential for the continuous activation of HSCs. In addition, somatostatin can even reverse the action of EGF on EGFR. So somatostatin may be quite a potent antifibrotic agent for liver cirrhosis.

Being consistent with the hypothesis, somatostatin shows an obvious inhibitory effect on the proliferation of activated HSCs in a dose-dependent way. Its pharmacological action is most significant when its concentration reaches 10^{-6} mol/L or 10^{-7} mol/L. Once somatostatin binds to SSTRs on HSCs, the occurrence of cytostatic effect is due to: (a) inhibition of adenylate cyclase activity through $G_{i\alpha1}$, leading to a decrease in cAMP level in cells; (b) active induction of K^+ channel via $G_{i\alpha3}$, whereas blockage of the voltage-operated Ca^{2+} channel through $G_{o\alpha}$ so as to reduce intracellular Ca^{2+} concentration; (c) inhibition of mitogen-activated protein kinase (MAPK)-dependent signal transduction pathway on the basis of protein tyrosine phosphatase (PTP) activation and amino-dephosphorylation-induced deactivation of tyrosine kinase. Then the expression of *c-fos*, *c-jun* and *c-myc* was reduced significantly[17,18]. As for the action of somatostatin on cytodynamics, G_0/G_1 arrest was observed in our study, which was in accordance with the result of Sharma *et al*[19]. Cell-cycle-arrest may reflect the main mechanism of somatostatin.

In vivo and *in vitro* studies have illustrated that activated HSCs can be eliminated by different ways such as spontaneous apoptosis, stimulation of some membrane receptors, incubation with proapoptotic compounds[20-28]. Activation of $SSTR_3$ by somatostatin may be relevant to this process. Binding of $SSTR_3$ and its natural or synthetic ligands can trigger intracellular acidification, and cause a selective activation of cation-insensitive acidic endonuclease through PTP. Then DNA fragmentation caused by acidic endonuclease stimulates the overexpression of bax and wild-type p53, resulting in apoptosis of HSCs. Additionally, dephosphorylation of serine in wild-type p53 has been found to be another pathway towards apoptosis[29,30]. Our study has proved biochemically and ultrastructurally for the first time that somatostatin can dose-dependently promote the apoptosis of first-passage activated HSCs by fluorescent staining, TUNEL, flow cytometry and transmission electron microscopy. Furthermore, a significantly increased apoptosis rate could be obtained with low concentrations (10^{-6} mol/L-10^{-7} mol/L) of somatostatin.

In conclusion, somatostatin at a low dose may exert antiproliferative and proapoptotic actions on activated HSCs. This result may provide a basis for utilizing somatostatin and even its analogues to protect people from hepatic fibrosis and to treat those suffering from it. However, the underlying mechanisms need to be further studied.

Abstract

AIM: To investigate the significance of protein kinase C (PKC), P44/42 mitogen-activated protein kinase (MAPKs) and heat shock protein (HSP)70 signal transduction during hepatocyte ischemic preconditioning.

METHODS: In this study we used an *in vitro* ischemic preconditioning (IP) model for hepatocytes and an *in vivo* model for rat liver to investigate the significance of protein kinase C (PKC), P44/42 mitogen-activated protein kinase (P44/42 MAPKs) and heat shock protein 70 (HSP70) signal transduction in IP. Through a normal liver cell hypoxic preconditioning (HP) model in which cultured normal liver cells were subjected to 3 cycles of 5 min of incubation under hypoxic conditions followed by 5 min of reoxygenation and subsequently exposed to hypoxia and reoxygenation for 6 h and 9 h respectively. PKC inhibitor, activator and MEK inhibitor were utilized to analyze the phosphorylation of PKC, the expression of P44/42 MAPKs and HSP70. Viability and cellular ultrastructure were also observed. By using rat liver as an *in vivo* model of liver preconditioning (3 cycles of 10-min occlusion and 10-min reperfusion), *in vivo* phosphorylation of PKC and P44/42MAPKs, HSP70 expression were further analyzed. AST/ALT concentration, cellular structure and ultrastruture were also observed. All the data were statistically analyzed.

RESULTS: Similar results were obtained in both *in vivo* and *in vitro* IP models. Compared with the control without IP (or HP), the phosphorylation of PKC and P44/42 MAPKs and the expression of HSP70 were obviously increased in IP (or HP) treated model in which cytoprotection could be found. The effects of preconditioning were mimicked by stimulating PKC with 4β phorobol-12-myristate13-acetate (PMA). Conversely, inhibiting PKC with chelerythrine abolished the protection given by preconditioning. PD98059, inhibitor of MEK (the upstream kinase of P44/42MAPKs), also reverted the cytoprotection exerted by preconditioning.

CONCLUSION: The results demonstrate that preconditioning induces a rapid activation of P44/42MAPKs and PKC activation plays a pivotal role in the activation of P44/42 MAPKs pathway

that participates in the preservation of liver cells. HSP expression is regulated by signals in PKC dependent P44/42 MAPKs pathway.

INTRODUCTION

The term ischemic preconditioning (IP) was first coined by Murry *et al*. to describe a phenomenon where brief periods of sublethal ischemia protected the heart against infarction caused by a subsequently more prolonged period of coronary artery occlusion[1]. Preconditioning occurs in 2 phases: an early phase, also known as acute preconditioning, in which protection lasts up to 1-2 h following preconditioning, and a second phase, known as the second window of protection, in which protection reappears 24-72 h following preconditioning. Although a variety of mediators and effectors have been proposed to be essential for conferring preconditioning, including the adenosine receptor[2], protein kanase C[3], and the ATP-sensitive K^+channel[4]. The importance of PKC to ischemic preconditioning has been shown in a variety of studies in whole heart and isolated ventricular cardiocytes[5]. Whereas it is widely accepted that PKC plays a pivotal role in ischemic preconditioning, the relevant downstream signaling molecules remain a topic of intense investigation and controversy.

Over the last few years, a number of studies in both whole hearts and isolated cardiomyocytes have described the activation of members of the MAPK family of signaling proteins during ischemica and ischemic reperfusion[6,7]. All of the MAPKs are proline-directed, serine/threonine-protein kinases are activated by dual phosphorylation on tyrosine and threonine residues by upstream kinases. The family consists of 3 members, extracellular signal-regulated kinases 1 and 2 (ERK1/2; P44/42MAPKs), c-jun NH2-terminal kinases 1 and 2 (JNK1/2), P38MAPKs and ERK5/BMK1 (big mitogen-activated protein kinase, BMK1) which was found recently. ERK1/2 is predominantly activated by growth factors, and JNKs and P38MAPKs are generally activated by stresses such as ultraviolet light, inflammatory cytokines, heat shock, and ischemic reperfusion. Recent evidence implicates PKC is in the activation of 2 members of this kinase family, *i.e*, the P44 and P42MAPKs[8]. But whether PKC-dependent activation of P44/42 MAPKs in signal transduction pathways during hepatocyte ischemic preconditioning contributes to cytoprotective effect is largely unknown. Thus, in the present investigation we tested it by using an *in vitro* IP model for hepatocytes and an *in vivo* model for rat liver. Similar results were obtained both *in vivo* and *in vitro* IP models. The phosphorylation of PKC and P44/42 MAPKs was obviously increased in IP treated. The effects of

preconditioning were mimicked by stimulating PKC with 4β phorobol-12-myristate13-acetate (PMA). Conversely, inhibiting PKC with chelerythrine abolished the protection given by preconditioning. PD98059, an inhibitor of MEK (the upstream kinase of P44/42MAPKs), also reverted the cytoprotection exerted by preconditioning. This suggests that preconditioning induces a rapid activation of P44/42MAPKs and PKC activation plays a pivotal role in the activation of P44/42 MAPKs pathway that participates in the preservation of liver cells.

Although it has been reported that IP conveys protective signals to hepatocytes, few studies have been published on intracellular protective mechanism. It remains to be elucidated whether PKC-dependent P44/42MAPKs pathways are involved in the regulation of protective proteins, such as heat shock protein (HSP70). Some substantial literature describes the induction of HSP70 by ischemia[9], the potential role of HSP70 in ischemic preconditioning[10], and an inverse correlation between expression of HSP70 induced by ischemic or thermal preconditioning and infart size in animal models[11]. In addition, enhanced expression of HSP70 conveys a cytoprotective effect in cultured cells, including cardiac myocytes subjected to simulated ischemia[12,13]. Specifically, overexpression of HSP70 in transgenic mice improves myocardial function[14,15], preserves metabolic functional recovery, and reduces infart size after ischemic preconditioning. Several recent studies suggest that PKC, a ubiquitous intracellular mediator, may play a role in mediating the protective effects of ischemic preconditioning while the activators such as PMA mimic the protective effect via phosphorylation of unknown effector protein. PKC plays a crucial role in the signal transduction for the activation of many cellular functions. Many transcription factors are known to be activated by various PKC subtypes[16]. These include heat shock protein transcription factors (HSF). The synthesis of HSPs is mediated by the activation of heat shock gene transcription which is mediated by the binding of HSF to the heat shock element in the promoter region of HS genes. The gene knockout model of HSF1 *in vitro* demonstrated the essentisl requirement of this regulatory pathway in cellular protection[17]. But whether P44/42 MAPKs signal pathways during hepatocyte ischemic preconditioning mediate the synthesis of protective protein (HSP70) remains elusive and represents an unresolved problem. In this study, we observed that HSP70 expression was increased in IP treated models, while it was inhibited by PKC inhibitor chelerythrine, the cytoprotective effect was reduced, but the activator of PKC (PMA) could induce the activation of PKC, HSP70 expression and cytoprotection apparently. Thus the data presented here suggested that PKC could regulate HSP70 expression directly or indirectly. While MEK inhibitor PD-98059 abolished the activation of P44 and P42 MAPKs. The synthesis of HSP70 was reduced and the protective effect of preconditioning was blocked. We propose that activation of P44 and P42 MAPKs correlates with the regulation of HSP70 expression.

MATERIALS AND METHODS

In vivo model
Nine to twelve-week male Sprague-Dawley rats weighing 220-230 g were obtained from the Animal Center of the First Military Medical University. Chelerythrine chloride (CHE) was purchased from Calbiochem Co. Phorobol 12-myristate 13-acetate (PMA) was obtained from Gibco/BRL Co. PD98059 was purchased from Sigma. All other chemicals in this study were of analytical reagent quality.

Grouping and experimental protocol Male Sprague-Dawley rats were fasted with free access to water 18 h before experiment. Animals were randomly divided into one of the 6 subgroups (6 rats in each group) and subjected to the following experimental

protocals. According to the method of Kobayashi *et al.*[18], the model of rat local ischemic reperfusion was established. (1) Group C (control): The abdomen was opened by a midline incision and the liver hilus was exposed, but not occluded. (2) Group IR (ischemic reperfusion): All vessels (hepatic artery, portal vein, and bile duct) to the left and median liver lobes were occluded for 40 min with a vascular clamp. Thereafter the clamp was removed and blood flow was reperfused for 3 h. Since blood vessels to the remaining parts of the liver were not occluded with this method, portal stasis could be avoided, which was of special relevance for circulatory stability in rats. The abdominal walls were closed during reperfusion. (3) Group IP (ischemic precondition): To induce ischemic preconditioning, mice underwent a sequence of three 10-min liver hilus occlusions separated by 10-min of reperfusion prior to the 40-min occlusion and 3 h reperfusion. (4) Group PMA (IR +PMA): PMA (4 µg/kg[19]) total volume 5 mL was slowly injected through dorsal veins of penis for 10 min, beginning 10 min before the start of ischemic rerperfusion. (5) Group CHE (IP + chelerythrine chloride): Total volume of 5 mL chelerythrine chloride (5 mg/kg[20]) was slowly injected through dorsal veins of penis for 10 min, 10 min before the start of ischemic preconditioning. (6) Group PD (IP + PD98059): Total volume of 5 mL PD98059 (5 mg/kg[20]) was slowly injected through dorsal veins of penis over 10 min, 10 min before the start of ischemic preconditioning. The dose of PD98059 was shown to effectively block the activation of p44/p42MAPKs[21].

Measurement of serum ALT and AST Three hours after the last reperfusion, the abdoman of each group was re-opened. Blood samples of infrahepatic vena cava were obtained and centrifuged to get serum in order to detect the concentration of ALT and AST.

PKC activity assay The rats were euthanized 3 h after the last reperfusion. 0.3 cm×0.3 cm×0.3 cm tissue samples from left liver lobe were rapidly removed. PKC activity assay kit was used. The tissue in 5 mL of cold extraction buffer was homogenized using a cold homogenizer then the lysate was centrifuged for 5 min at 4 ℃, 14 000 *g* in a microcentrifuge and the supernatant was saved. The supernatant was passed over an 1-mL column of DEAE cellulose that was pre-equilibrated in extraction buffer and the column was washed with 5 mL of extraction buffer. The PKC-containing fraction was eluted using 5 mL of extraction buffer containing 200 mmol/L NaCl. Then enzyme sample, PKC coactivation buffer, PKC activation buffer, PKC biotinylated peptide substrate, and [γ-32P]ATP were mixed gently and incubated at 30 ℃ for 5 min. All samples were spotted on SAM2 membrane, and the washing and rinsing steps were followed. The SAM2 membrane was dried and placed into individual scintillation vials added with scintillation fluid and analysed using a phosphorimaging system.

Western blotting analysis of P44/42 MAPKs The rats were euthanized 3 h after the last reperfusion (a time point at which marked activation of P44/42 MAPKs begins[21]). 0.3 cm×0.3 cm×0.3 cm tissue samples from left liver lobe were rapidly removed. P44/42 MAPKs test kit (New England Biolabs) was utilized.

Western blotting analysis of HSP70 The rats were euthanized 3 h after the last reperfusion and tissue samples were obtained as described above. When extracted from hepatocytes, protein samples were separated on 100 g/L SDS-polyacrylamide gel and transferred to nitrocellulose membranes. After membrances were transferred, they were blocked for 1 h with 50 mL/L nonfat milk in Tris-buffered saline. Membranes were incubated with murine monoclonal antibody to HSP70 overnight at 4 ℃, washed 3 times for 5 min in TBST before addition of goat anti-mouse-HRP conjugated secondary antibody for 1 h at room temperature. Membranes were washed 3 times for 5 min with TBS, and peroxidase activity on the nitrocellulose sheet was visualized on X-ray film by means of the ECL Western blotting

detection system.

Changes of cellular structure and ultrastructur The rats were euthanized 3 h after the last reperfusion. 0.3 cm×0.3 cm×0.3 cm tissue samples from left liver lobe were also removed in order to observe the cellular structure and ultrastructure.

In vitro model

Liver cell line L02 was obtained from Shanghai Institute of Cell, (Academy of Medical Sciences of China). The necessary reagents and test kits were similar to *in vivo* setting.

Grouping and experimental protocol Cell viability, estimated at the beginning of the experiments, ranged between 90% to 95%. Hepatocytes were suspended in Krebs-Henseleit-Hepes (KHH)[22] buffer containing 118 mmol/L NaCl, 4.7 mmol/L KCl, 1.2 mmol/L KH2PO4, 1.3 mmol/L CaCl2, 25 mmol/L NaHCO3, and 20 mmol/L Hepes at pH7.4. Hypoxic preconditioning was obtained by 3 cycles of 5 min of incubation at 37 ℃ in KHH buffer equilibrated with 900 mL/L N_2, 80 mL/L CO_2, 20 mL/L H_2 followed up by 5 min of reoxygenation obtained by fluxing the incubation flasks with 950 mL/L O_2, 50 mL/L CO_2 gas mixture. After reoxyenation, the cells were transferred in deoxygenated KHH buffer and further incubated at 37 ℃ in sealed bottles in a 900 mL/L N_2, 80 mL/L CO_2, 20 mL/L H_2 atmosphere for 6 h followed up by reoxygenation for 9 h. Nonpreconditioned cells were incubated in KHH buffer until the beginning of hypoxic treatment. Cells were randomly divided into one of the 6 subgroups and subjected to the following experimental protocals. (1) Group C (control): Untreated hepatocytes were incubated in 950 mL/L O_2, 50 mL/L CO_2 atmosphere. (2) Group HR (Hypoxia reoxygenation,HR): Untreated hepatocytes were incubated in 900 mL/L N_2, 80 mL/L CO_2, 20 mL/L H_2 atmosphere for 6 h followed up by reoxygenation for 9 h. (3) Group IP (hypoxic precondition, HP): preconditioned cells were incubated at 37 ℃ in sealed bottles in a 900 mL/L N_2, 80 mL/L CO_2, 20 mL/L H_2 atmosphere for 6 h followed up by reoxygenation for 9 h. (4) Group PMA (HR + PMA): Hepatocytes suspended in KHH medium were preincubated for 10 min at 37 ℃ with 150 nmol/L PMA[23] and then subjected to hypoxic incubation for 6 h in sealed flasks in a 900 mL/L N_2, 80 mL/L CO_2, 20 mL/L H_2 atmosphere followed up by reoxygenation for 9 h. (5) Group CHE (HP + chelerythrine chloride): Hepatocytes suspended in KHH medium were pretreated with 50 mmol/L[24] chelerythrine for 10 min before preconditioning. (6) Group PD (HP + PD98059): Hepatocytes were pretreated with 50 mmol/L[21] PD98059 for 10 min before preconditioning.

Determination of cell viability Treated with the methods above, the cells of each group were incubated in KHH buffer containing 20 uL (4,5-dimethylthioazol-2-yl)-2,5-diphenyl-tetrazolium bromide (MTT) for 4 h at 37 ℃ in room air containing 50 mL/L CO_2. During this incubation tetrazolium component of the dye was reduced, in metabolically active cells, to a formazan dye. Thereafter the reaction was terminated by addition of 100 μL solubilization solution (ethanol) and the absorbance of the lysate was recorded at 570 nm using an ELISA reader.

PKC activity assay The protocol was the same as the above.

Western blotting analysis of P44/42 MAPKs The protocol was the same as the above.

Western blotting analysis of HSP70 The protocol was the same as the above.

Changes of cellular ultrastructure Having been treated with the methods above, the cellular ultrastructure of each group was observed.

Statistical analysis

Data were presented as mean±SD. Statistical comparisons were made by analysis of variance. When significant differences were observed, SNK-*q* test was used for multiple comparions. Statistical significance was inferred at *P*<0.05.

RESULTS

Cytoprotective effects on hepatocytes induced by PC

The serum concentration of ALT and AST was increased and the cell viability was decreased significantly in group IR (HR) (*P*<0.01) compared with the control group. In contrast, compared with group IR (HR), the serum concentration of ALT and AST was reduced and the cell viability was increased markedly in group IP (HP) (*P*<0.01) (Tables 1, 3). In group C, cells had no apparent degeneration and necrosis where Kupffer cells did not proliferate markedly and the structure of portal area was not changed. Organellae were intact and mitochondria were lined up in order. In group IR, cells of lobules of liver were swollen and had hydropic degeneration where Kupffer cells proliferated significantly and had active phagocytosis. The spotty necrosis could be easily found. Portal area was enlarged and infiltrated with mononuclear cells. Hepatocytes were swollen and endothelial cells had malformation with mitochondria ballooned. Matrix was reduced, densely and floccularly degenerated. Bar was decreased and disarranged (Figures 3A, 6A). In group IP heptocytes were slightly swollen and had no degeneration with no proliferation of Kupffer cells. Portal area was normal. Organellae were not swollen apparently with some neutrophils and lymphocytes infiltrated. Mitochondria were well distributed (Figures 3B, 6B). This indicated that PC could elicit the cytoprotective effects on hepatocytes subjected to a subsequent lethal ischemia reperfusion or hypoxia reoxygenation.

Effect of ischemic PC or hypoxic PC on PKC activity

Several studies performed in the heart implicated the activation of PKC as one of the key events in the development of ischemic PC[25,26]. Similar results were obtained both *in vivo* and *in vitro* IP models. Compared with group IR (HR), the phosphorylation of PKC was obviously increased in group IP (HP) (Tables 2, 4) and the cytoprotective effect developed during ischemic PC (Tables 1, 3; Figures 3B, 6B). PMA, a well known activator of PKC, decreased cell killing by ischemia reperfusion or hypoxia reoxygenation (Tables 1, 3; Figures 3C, 6C). Conversely, PKC inhibitor chelerythine reverted the effect of preconditioning on hepatocytes. Chelerythrine also abolished the protection against the damage caused by ischemia reperfusion or hypoxia

reoxygenation (Tables 1, 3; Figures 3D, 6D), suggesting that PKC might play a pivotal role in ischemic PC or hypoxic PC.

Figure 1 Expression of P44 and P42 MAPKs in rat liver.

Effect of ischemic PC or hypoxic PC on MAPK activity

Both *in vivo* and *in vitro* IP models, our results showed that hepatocyte lysates exhibited the sharp signal at 60 ku as detected by Western immunoblotting. Compared with group IR (HR), the expression of P44 and P42 MAPKs was markedly increased in group IP (HP) (Figures 1, 4), and the cytoprotective effect developed during ischemic PC (Tables 1, 3; Figures 3B, 6B). This result implied that the activation of P44 and P42 MAPKs was associated with the cytoprotection. The effect was abolished by the MEK inhibiter PD-98059. Compared with group IP (HP), the serum concentration of ALT and AST was increased and the cell viability was decreased significantly in group IP+PD ($P<0.01$). We observed that hepatocytes were swollen with mitochondria ballooned and Kupffer cells proliferated. The spotty necrosis was found. Portal area was slightly enlarged and a few mononuclear cells infiltrated (Figures 3E, 6E). The results indicateed that P44 and P42 MAPKs as a major signal transduction molecule played an important role in cytoprotection during hepatocyte ischemic PC or hypoxic PC. To determine whether activation of P44/42 MAPKs during ischemic PC or hypoxic PC was dependent on PKC activation, we measured P44/42 MAPKs activity undergoing PC after pretreatment with chelerythrine (group IP or HP + CHE). Previous studies demonstrated that chelerythrine completely blocked the translocation of PKC and development of late PC in conscious rabbit model (39 rabbits). In the present study, we found that

chelerythrine completely blocked the activation of P44/42 MAPKs and cytoprotection, and the changes in serum concentration of ALT and AST, cell viability, cellular structure and ultrastructure were similar to those in group IR (HR)(Tables 1, 3; Figures 3D, 6D). PMA, an activator of PKC resulted in increased P44/42 MAPKs activity and mimiced the cytoprotection. The changes in serum concentration of ALT and AST, cell viability, cellular structure and ultrastructure were similar to those in group IP (HP) (Tables 1, 3; Figures 3C, 6C). These data demonstrated that the activation of P44 and P42 MAPKs during ischemic PC or hypoxic PC occurred via a PKC-dependent pathway.

Figure 2 Expression of HSP70 in rat liver.

Effect of ischemic PC or hypoxic PC on HSP70 expression

The expression of HSP70 exhibited a sharp signal at 70 ku as detected by Western immunoblotting. Compared with group IR (HR), the expression of HSP70 was apparently increased in group IP (HP) (Figures 2, 5). In addition, IP conveyed a cytoprotective effect on hepatocytes suffering ischemia reperfusion or hypoxia reoxygenation (Tables1, 3; Figures 3B, 6B). While PKC inhibitor chelerythrine and MEK inhibitor PD-98059 inhibited the protein expression, and the cytoprotective effect was reduced (Tables1, 3; Figures 2, 5, 3D, 6D, 3E, 6E), but the activator of PKC (PMA) could induce HSP70 expression and cytoprotection apparently (Tables 1, 3; Figures 2, 5, 3C, 6C). Thus the data presented here suggested that expression of HSP70 had a cytoprotective effect on hepatocytes and PKC could regulate HSP70 expression directly or indirectly.

DISCUSSION

Ischemic preconditioning refers to the resistance to ischemic injury acquired by tissues following one or more brief periods of ischemia followed by reperfusion. Ischemic preconditioning was first described in myocardium, but has been shown in several other organs, including the brain, skeletal muscles, and small intestine[27-30]. Recent studies have shown that the same phenomenon could also be observed in the liver[31]. Particularly, a 10-min interruption of liver blood supply in anesthetized rats followed by 10 min of reperfusion reduced the release of transaminases during a subsequent 90-min period of ischemia and 90 min of reperfusion[32]. A similar effect has also been observed in steatotic liver after heat shock preconditioning[33]. Furthermore, ischemic preconditioning before cold preservation of rat liver grafts increased the survival rate of rats receiving transplanted livers[34]. The use of isolated hepatocyte suspensions has confirmed that the hepatoprotective action of liver preconditioning observed *in vivo* could be reproduced *in vitro*. In accordance with the *in vivo* experiment, hepatocyte preconditioning developed after a transient hypoxia lasting more than 5 min and not exceeding 10 min and reduced the cytotoxicity during a subsequently prolonged hypoxic incubation by about 40%. But the signal pathway that mediated the development of hepatocyte ischemic preconditioning or hypoxic preconditioning was also largely unknown[35,36]. PKC-dependent activation of P44/42 MAPKs and HSP70 in signal transduction pathways during hepatocyte ischemic preconditioning or hypoxic preconditioning has not been reported.

There were several major findings in this study. First, ischemic PC or hypoxic PC had cytoprotective effects on hepatocytes subjected to a subsequent lethal ischemia reperfusion or hypoxia reoxygenation. Second, PKC appeared to play a pivotal role during hepatocyte ischemic PC. Third, the ischemic PC or hypoxic PC inducing activation of P44/42 MAPKs was completely abolished by the PKC inhibitor chelerythrine, indicating that the activation of P44/42 MAPKs is downstream of, and dependent on, PKC activation, and that P44/42 MAPKs may play a role in PKC mediated ischemic PC or hypoxic PC. Finally, protective proteins, such as HSP70, were induced by PC and regulated by signals in PKC dependent P44/42 MAPKs pathway.

The protective effect of ischemic preconditioning in myocardium involved the interstitial accumulation of endogenous mediators among which adenosine played a major role[25]. Large quantities of adenosine were released within seconds from the beginning of myocardial ischemia. By interacting mainly with adenosine A1 receptors, adenosine mediated mycardiocyte protection through the activation of a signaling pathway involving Gi-proteins, phospholypase C, diacylglyccerol and PKC[25]. Indeed, inhibiting PKC with polymyxin B, calphostin C, or chelerythrine could abolish the protective effect of myocaardialk ischemic preconditioning, whereas the stimulation of PKC by PMA or by diacylglyccerol analogues significantly reduced the infart size[26]. The role of PKC was further supported by membrane translocation of the deta and epsilon PKC isoforms in isolated rat hearts exposed to preconditioning[37]. We have observed that the cytoprotection exereted by preconditioning in the *in vivo* and *in vitro* setting was abolished by inhibiting PKC with chelerythrine. Moreover, PKC stimulation by PMA could reduce cell killing by ischemia reperfusion or hypoxia reoxygenation, mimicking the effect of preconditioning. This indicates that PKC activation might be involved in the signaling pathway responsible for the development of preconditioning in hepatocytes. Such a conclusion was consistent with a number of reports indicating that PKC stimulation was critical for the development of preconditioning in isolated rat, rabbit, and human myocardiocytes[38,39].

Previous studies have addressed the effect of ischemia on MAPK in *in vitro* models of global ischemia (isolated rat heart) and have yielded conflicting results. Maulik *et al.*[40] showed

that 4 cycles of 5-min ischemia/10-min reperfusion caused a significant increase in total MAPK phosphorylation activity and in the activity of MAPK-activated protein kinase 2. Knight and Buxton[41] reported that a single episode of ischemia ⩽10 min followed by 15 min of reperfusion had no effect on total MAPK phosphorylation activity, a 15-min period of ischemia in itself had no effect but was associated with increased MAPK activity after 5-min rerperfusion. The reason for these discrepancies is unclear. Maulik *et al*.[40] Knight and Buxton[41] determined total MAPK activity using a phosphorylation assay. To a certain extent, P38 MAPKs activity, or P44/42 MAPKs activity was not individually assessed. Saurin *et al*[42]. reported that sustained P38 activation occurred during lethally simulated ischemia in cultured rat neonatal cardiocytes. This activation could be attenuated by cardioprotective treatments such as preconditioning and over expression of active PKC-δ[42]. Ping *et al*.[43] demonstrated that P44/42 MAPKs were activated during preconditioning stimuli in both isolated rabbit cardiomyocytes and rabbit hearts. In the present study we examined P44/42 MAPKs and found that P44/42 MAPKs were activated during hepatocyte preconditioning stimuli in both *in vivo* and *in vitro* models. Furthermore, activition of P44/42 MAPKs was PKC dependent. Previous studies suggested that PKC activated MAPKs in neonatal cardiac cells[44] and isolated hearts[45]. Virtuslly no information is available whether PKC activates MAPKs during hepatocyte ischemic preconditioning *in vivo*. If so, whether, in the setting of ischemic PC, mobilization of PKC occurs in parallel to MAPK activation or is a distal event. The results both *in vivo* and *in vitro* models showed that P44/42 MAPKs expression was markedly increased and the cytoprotective effect developed during ischemic PC, implying that the activation of P44 and P42 MAPKs was associated with the cytoprotection. The effect was abolished by the MEK inhibiter PD-98059, indicating that P44/42 MAPKs as a major signal transduction molecule played an important role in cytoprotection during hepatocyte ischemic preconditioning or hypoxic preconditioning. The PC-induced activation of P44 and P42 MAPKs was completely abolished by the PKC inhibitor chelerythrine, and PMA, an activator of PKC resulted in increased P44/42 MAPKs activity and mimicked the cytoprotection. These data demomstrate three important points: (1) PKC plays an obligatory role in the stimulation of P44/42 MAPKs during ischemic PC; (2) PKC activation precedes MAPK activation in the cascade that leads to PC ; (3) P44/42 MAPKs may play an important role in PKC-mediated ischemic PC. Because PKC activation was required for PC to develop[46,47], P44/P42 MAPKs might be downstream phosphorylation targets of PKC and the PKC-induced signaling pathways that mediate ischemic PC or hypoxic PC.

Ping *et al*.[43] indicated that PKC-dependent activation of P44/P42 MAPKs during hepatocyte preconditioning in both isolated rabbit cardiomyocytes and rabbit hearts produced a marked reduction in infarct size and the serum level of LDH, which had cardioprotective effects. Their results were coincident with what we presented. In preconditioned isolated rat hepatocytes, Carini *et al*.[35] observed that interfering with P44 and P42 MAPKs activition using MEK inhibition PD98509 did not affect cytoprotection, whereas SB203580, a specific inhibition of P38 MAPKs completely abolished the effects of preconditioning. So they proposed that P44 and P42 MAPKs in signal transduction pathway was not responsible for the development of liver ischemic preconditioning. Their results were diff was from ours. The possible reasons might be as follows. (1) The experimental environment different *in vitro* Ip model for hepatocyte and *in vivo* model for rat liver. *In vitro* experiment imitated the ischemia *in vivo* merely by depriving of the oxygen and blood serum, but it could not be mimicked completely. Ischemic preconditioning *in vivo* could be affected

by body temperature, homeostasis, anesthesia and some other factors. But in our experiment, both in the *in vivo* and *in vitro* setting, we got the same result. (2) By passing compensatory activation, cross talking existed in intracelluar signal transduction pathways[48], while P44 and P42 MAPKs signal transduction pathway was inhibited, which continued to convey the signals and induced the expression of cytoprotective proteins, such as P38MAPKs signal transduction pathway[49]. (3) Different methods were used in ischemic preconditioning. Fryer *et al*.[50] reported that mutiple-cycle-induced IPC could activate more pathways than a single-cycle IPC stimulus and that this difference could be attributable to the recruitment of another PKC-independent signal transduction pathway. The major signal pathway eliciting the cytoprotection would change while using different IP method. Our results were in agreement with those results of Ping' s group[43] obtained in the rabbit heart also via repetitive IPC, but Carini *et al*.[35] drew the different conclusion using a single IPC. (4) Dose and timing dependence. The activation of intracellular signal molecule was time dependent, and the reverse feedback regulation occurred at a time point. P44/42 MAPKs activity increased as early as 6 h following precondition, and peaked at 48 h. Preincubation with PD98059 (a selective MEK inhibitor) was associated with a dose-dependent inhibition which was statistically significant for concentrations higher than 10 μmol/L, and maximal at 100 μmol/L, and near-complete inhibition of activation of P44 and P42 MAPKs was observed with 50 μmol/L PD98059[21]. Referring to the time point of activation of P44/42 MAPKs and the dosage of PD98059, eventually we got the similar results[43]. Carini *et al*.[35] got various results by using different dosages of PD98059 (20 μmol/L) to treat hepatocytes and detect the effect of inhibition at different time points (after exposure to 90 min of hypoxia).

HSP is one of the most highly conserved proteins in existence, and has been found in every organism[51]. These proteins are known to protect cells from the toxic effects of heat and other stresses and were synthesized quickly and intensely in response to stressors[52]. Exactly how HSPs protect cells is unclear, however, everal explanations have been offered. These include the renaturation of damaged proteins or facilitation of the folding and targeting of newly synthesized proteins to organellae[52]. HSPs may also maintain newly synthesized proteins in a translocational configuration (linear or unfolded). Induction of heat shock protein has been shown to subsequently protect cells in signal transduction pathways in liver ischemic preconditioning[53], but few studies have been published on intracellular protective mechanism. Whether PKC dependent P44/42 MAPKs pathways are involved in the regulation of protective proteins, such as HSP70 is largely unknown. Some substantial literature described the induction of HSP70 by ischemia[21], the potential role of HSP70 in ischemic preconditioning[24], and an inverse correlation between expression of HSP70 induced by ischemic or thermal preconditioning and infart size in animal models[25,26]. In addition, enhanced expression of HSP70 conveyed a cytoprotective effect in cultured cells, including cardiac myocytes subjected to simulated ischemia[29,30]. Specifically, overexpression of HSP70 in transgenic mice could improve myocardial function[32,33], preserve metabolic functional recovery, and reduce infart size after ischemic preconditioning. Several recent studies suggested that PKC might play a role in mediating the protective effects of ischemic preconditioning while the activators such as PMA mimicked the protective effect via phosphorylation of unknown effector protein. PKC played a crucial role in the signal transduction for the activation of many cellular functions. Many transcription factors have been known to be activated by various PKC subtypes[36]. These include heat shock protein transcription factors (HSF). The synthesis of HSPs is mediated by the activation of heat shock gene transcription which is mediated by

the binding of HSF to the heat shock element in the promoter region of HS genes. The gene knockout model of HSF1 *in vitro* demonstrated the essentisl requirement of this regulatory pathway in cellular protection[37]. But whether P44/42 MAPKs signal pathways during hepatocyte ischemic preconditioning mediates the synthesis of HSP70 remains elusive and represents an unsolved problem. In this study, expression of HSP70 exhibited a sharp signal at 70 ku as detected by Western immunoblotting in both *in vivo* and *in vitro* models. HSP70 expression was increased in IP (HP) treated models which provided cytoprotective effect on hepatocytes suffering from ischemia reperfusion or hypoxia reoxygenation. While PKC inhibitor chelerythrine and MEK inhibitor PD-98059 inhibited the protein expression. The cytoprotective effect was reduced, but the activator of PKC (PMA) could induce HSP70 expression and cytoprotection apparently. Thus, HSP70 was recognized as molecular chaperones and could protect cells under the hazardous conditions such as ischemia reperfusion or hypoxia reoxygenation. It was induced by PC and regulated by signals in PKC dependent P44/42 MAPKs pathway.

In summary, PKC-dependent activation of P44/42 MAPKs and HSP70 in signal transduction pathways during hepatocyte ischemic preconditioning is an important part of endogenous protective mechanisms. PKC is upstream of P44/42 MAPKs, and PKC regulates the activation of P44 and P42 MAPKs positively. HSP expression is regulated by signals in P44/42 MAPKs pathway, but this passway is just one of the most important signal transduction pathways during liver ischemic preconditioning. PKC–dependent activation of MAPKs family such as p38MAPK, JNK and ERK5 can regulate HSP70 expression and deserve further study.

Abstract

AIM: To investigate the protective effect of ketamine on the endotoxin-induced proinflammatory cytokines and NF-kappa B activation in the intestine.

METHODS: Adult male Wistar rats were randomly divided into 6 groups: (a) normal saline control, (b) challenged with endotoxin (5 mg/kg) and treated by saline, (c) challenged with endotoxin (5 mg/kg) and treated by ketamine (0.5 mg/kg), (d) challenged with endotoxin (5 mg/kg) and treated by ketamine (5 mg/kg), (e) challenged with endotoxin (5 mg/kg) and treated by ketamine (50 mg/kg), and (f) saline injected and treated by ketamine (50 mg/kg). After 1, 4 or 6 h, TNF-α and IL-6 mRNA were investigated in the tissues of the intestine (jejunum) by RT-PCR. TNF-α and IL-6 were measured by ELISA. We used electrophoretic mobility shift assay (EMSA) to investigate NF-kappa B activity in the intestine.

RESULTS: NF-kappa B activity, the expression of TNF-α and IL-6 were enhanced in the intestine by endotoxin. Ketamine at a dose of 0.5 mg/kg could suppress endotoxin-induced TNF-α mRNA and protein elevation and inhibit NF-kappa B activation in the intestine. However the least dosage of ketamine to inhibit IL-6 was 5 mg/kg in our experiment.

CONCLUSION: Ketamine can suppress endotoxin-induced production of proinflammatory cytokines such as TNF-α and IL-6 production in the intestine. This suppressive effect may act through inhibiting NF-kappa B.

INTRODUCTION

Gram-negative bacteria caused sepsis remains an important cause of morbidity and mortality in septic and endotoxemic patients. Lipopolysaccharide (LPS), or endotoxin, a major component of the outer surface of Gram-negative bacteria, is a potent activator of cells of the immune and inflammatory systems, including macrophages, monocytes and endothelial cells[1], and contributes to the systemic changes seen in septic shock[1-4]. The endotoxic shock syndrome is characterized by systemic inflammation, multiple organ damage, circulatory collapse and death[1,2].

The important role of the intestinal mucosa in the inflammatory and metabolic responses to sepsis, severe injury and other critical illnesses has been increasingly recognized during the last decade. Thus, there is evidence that the gut mucosa becomes the site for production of various inflammatory cytokines[5,6] and other yet unidentified substances that may influence not only the mucosa itself but also the function and integrity of remote organs and tissues[7,8]. Indeed, the gut mucosa has been proposed to be the "motor" of multiple organ failure in critical illness[9]. Besides, sepsis and severe injury are also associated with loss of mucosal integrity, resulting in increased permeability and bacterial translocation. These changes may accelerate the development of multiple organ failure[10].

Ketamine, an intravenous anesthetic, has been advocated for anesthesia in septic or severely ill patients because of its cardiovascular stimulating effects[11,12]. And several previous studies reported that ketamine could suppress LPS-induced tumor necrosis factor alpha (TNF-α) production in the serum and reduced mortality in carrageenan-sensitized endotoxin shock mice[13,14]. However, few studies were undertaken to investigate the protective effect of ketamine on the inflammatory response in the intestine during septic shock *in vivo*. Since local produced cytokines were regarded as the contributing factors in tissue damage during sepsis[15-17]. And nuclear factor kappa B (NF-kappa B) was verified to be an inducible transcription factor that was required for the transcription of some proinflammatory cytokines such as TNF-α, interleukin 6 and interleukin 8 (IL-6 and IL-8)[18]. Our previous study indicated that ketamine could inhibit endotoxin induced NF-kappa B and TNF-α *in vitro*[19]. Therefore, this study was to investigate whether ketamine could suppress endotoxin-induced NF-kappa B activation and proinflammatory cytokines in the intestine *in vivo* in order to define a possible mechanism of the anti-inflammatory effect of ketamine.

MATERIALS AND METHODS

Animals and treatment

Adult male Wistar rats (250-300 g body mass) used in this experiment were purchased from Shanghai Animal Center, Shanghai, China. The rats were exposed each day to 12 h of light and darkness respectively. The experimental protocol followed the institution's criteria for the care and use of laboratory animals in research. Further, all animals received humane care in compliance with Institutional Animal Care Committee.

Experimental protocol

The Wistar rat endotoxemia model was established by injection with a dose of LPS (5 mg/kg, *Escherichia coli* O111: B4) (Sigma Chemical Co., USA) via the tail vein. Then all animals were immediately treated with different doses of ketamine

(0.5, 5, 50 mg/kg) or normal saline (10 mL/kg) intraperitoneally (ip). Endotoxin and ketamine were diluted with normal saline at different concentrations so as to inject them into the rats at the same volume (10 mL/kg). After 1, 4 or 6 h, animals were killed, and tissues from the intestine was removed and kept in liquid nitrogen for later use. We used six rats in every time point of each group.

Electrophoretic mobility shift assay (EMSA)
Nuclear extracts of the intestine tissue was prepared by hypotonic lysis followed by high salt extraction[20-22]. EMSA was performed using a commercial kit (Gel Shift Assay System; Promega, Madison, WI) as previously described. The NF-kappa B oligonucleotide probe, (5'-AGTTGAGGGGACT TTCCCAGGC-3'), was end-labeled with [γ-^{32}P] ATP (Free Biotech, Beijing, China) with T4-polynucleotide kinase. Nuclear protein (80 μg) was preincubated in 9 μL of a binding buffer, consisting of 10 mmol/L Tris-Cl, pH 7.5, 1 mmol/L MgCl$_2$, 50 mmol/L NaCl, 0.5 mmol/L EDTA, 0.5 mmol/L DTT, 40 mL/L glycerol, and 0.05 g/L of poly-(deoxyinosinic deoxycytidylic acid) for 15 min at room temperature. After addition of the 1 μL ^{32}P-labeled oligonuleotide probe, the incubation was continued for 30 min at room temperature. Reaction was stopped by adding 1 μL of gel loading buffer, and the mixture was subjected to non-denaturing 40 g/L polyacrylamide gel electrophoresis in 0.5×TBE buffer. The gel was vacuum-dried and exposed to X-ray film (Fuji Hyperfilm) at -70 ℃.

Reverse-transcription polymerase chain reaction (RT-PCR)
Total RNA was extracted with TriPure Isolation Reagent (Roche Molecular Biochemicals, Switzerland) and quantified by absorption at 260 nm. Reverse-transcription (RT) was implemented using Reverse Transcription System (Promega, WI, USA) according to the protocol. We used glyceraldehyde-3-phosphate dehydrogenase (GAPDH) as normalization control. The sequences of the primers were: TNF-α (sense) CACCACGCTCTTCTGTCTACTGAAC, (antisense) CCGGACTCCGTGATGTCTAAGTACT; IL-6 (sense) GACTGATGTTGTTGACAGCCACTGC, (antisense) TAGCC ACTCCTTCTGTGACTCTAACT; GAPDH (sense) CACGGCAAGTTCAATGGCACA, (antisense) GAATTGTGAGGGAGAGTGCTC. A total volume of 100 μL reaction contained 2 μL of RT product, 1.5 mmol/L MgCl2, 2.5 U Taq DNA polymerase, 100 μmol/LdNTP, 0.1 μmol/L primer and 1×Taq DNA polymerase magnesium-free buffer (Promega, WI, USA). Then the reaction mixture was overlaid with two drops of mineral oil (Sigma Chemical Co., USA) and incubated in thermocycler (MiniCycler PTC 150, MJ Research Inc, USA) programmed to pre-denature at 95 ℃ for 2 min, denatured at 95 ℃ for 1 min, annealed at 60 ℃ for 1 min and extended at 72 ℃ for 2 min for a total of 30 cycles. The last cycle was followed by a final incubation at 72 ℃ for 5 min and cooled to 4 ℃. The polymerase chain reaction products were 546 bp (TNF-α), 509 bp (IL-6) and 970 bp (GAPDH) respectively. Then they were electrophoresed on a 15 g/L agarose gel stained with ethidium bromide. The gel was captured as a digital image and analyzed using Scion Image software (Maryland, USA). Values in each sample were normalized with GAPDH control.

Enzyme-linked immunoadsordent assay (ELISA)
TNF-α and IL-6 in the intestine were measured using commercially available enzyme-linked immunoassay kits (Diaclone USA for TNF-α; Biosource USA for IL-6) according to the test protocol. Values were expressed as pg per milligram protein (pg/mg prot).

Statistics and presentation of data
Data were expressed as mean±SE. Statistical significance was determined by one-way ANOVA using SPSS 10.0. A value of $P<0.05$ was considered significant.

RESULTS

NF-kappa B activation in the intestine
EMSA experiments were performed to examine the effect of ketamine on the activation of NF-kappa B induced by endotoxin. As shown in Figure 1, NF-kappa B activation in the intestine was increased after endotoxin challenge as compared with unstimulated group. The activity of NF-kappa B was in a time dependant manner after endotoxin injection. Ketamine inhibited NF-kappa B activation at three (0.5, 5, and 50 mg/kg) dosing levels ($P<0.05$, as compared with endotoxin group) (Figure 1).

Figure 1 Activation of NF-kappa B in the intestine. Normal saline treatment (Lane 1). 1, 4, 6 h after endotoxin challenge (Lane 2, 3, 4), endotoxin plus ketamine (0.5, 5, 50 mg·kg^{-1}) (Lane 5, 6, 7), ketamine only (50 mg·kg^{-1}) (Lane 8) [a]$P<0.05$ *vs* Lane 1; [b]$P<0.01$ *vs* Lane 1; [d]$P<0.01$ *vs* Lane 2.

Figure 2 Expression of TNF-α in the intestine. Normal saline treatment (Lane 1). 1, 4, 6 h after endotoxin challenge (Lane 2, 3, 4), endotoxin plus ketamine (0.5, 5, 50 mg·kg^{-1}.) (Lane 5, 6, 7), ketamine only (50 mg·kg^{-1}) (Lane 8); [b]$P<0.01$ *vs* Lane 1; [d]$P <0.01$ *vs* Lane 2.

TNF-a mRNA expression by endotoxin challenge and the protective effect of ketamine
TNF-α sustained a baseline level in normal rats. Endotoxin caused a transient elevation of TNF-α *mRNA* in the intestine. This activity increased with time reaching a maximum 1 h

after sepsis. Ketamine was administered intraperitoneally soon after endotoxin challenge. TNF-α gene expression was analyzed 1 h later since TNF-α could reach the maximum level about 1 h later. Ketamine suppressed TNF-α expression in a dose dependent manner. We found that ketamine at a dose of 0.5 mg/kg could suppress TNF-α expression significantly. This dosage was far below clinical anesthetic level (Figure 2).

Figure 3 Expression of IL-6 in the intestine. Normal saline treatment (Lane 1). 1, 4, 6 h after endotoxin only (Lane 2, 3, 4), endotoxin plus ketamine (0.5, 5, 50 mg/kg) (Lane 5, 6, 7), ketamine only (50 mg/kg) (Lane 8); [b]$P<0.01$ vs Lane 1; [c]$P<0.05$ vs Lane 3.

Figure 4 Protective effect of ketamine on the TNF-α production in the intestine. All of the values were obtained 1 h after sepsis. Lane 1 normal saline; Lane 2 endotoxin (5 mg/kg); Lane 3 endotoxin (5 mg/kg) plus ketamine (0.5 mg/kg); Lane 4 endotoxin (5 mg/kg) plus ketamine (5 mg/kg); Lane 5 endotoxin (5 mg/kg) plus ketamine (50 mg/kg); Lane 6 ketamine only (50 mg/kg) [b]$P<0.01$ vs Lane 2.

Figure 5 Protective effect of ketamine on the IL-6 production in the intestine. All of the values were obtained 4 h after sepsis. Lane 1 normal saline; Lane 2 endotoxin (5 mg/kg); Lane 3 endotoxin (5 mg/kg) plus ketamine (0.5 mg/kg); Lane 4 endotoxin (5 mg/kg) plus ketamine (5 mg/kg); Lane 5 endotoxin (5 mg/kg) plus ketamine (50 mg/kg); Lane 6 ketamine only (50 mg/kg) [b]$P<0.01$ vs Lane 2.

IL-6 expression in intestine by endotoxin challenge and the protective effect of ketamine

The IL-6 expression of the small intestine is shown in Figure 3. Endotoxin also enhanced IL-6 expression in the intestine. However the peak time was 4 h after endotoxin challenge. We observed the protective effect of ketamine at this peak time. Ketamine suppressed IL-6 expression in a dose dependent manner. Unlike TNF-α, the minimal dosage at which ketamine could suppress IL-6 significantly was 5 mg/kg. This was within clinical anesthetic range (Figure 3).

Effect of ketamine on TNF-*a* and IL-6 production in intestine homogenates after endotoxin stimulation

Ketamine suppressed endotoxin-induced TNF-α and IL-6 production in a dose dependent manner. Ketamine beyond the concentration of 0.5 mg/kg could inhibit TNF-α production, however the minimal dosage at which ketamine suppressed IL-6 significantly was 5 mg/kg. This was within clinical anesthetic range (Figures 4 and 5).

DISCUSSION

Our laboratory and others have demonstrated that ketamine could suppress endotoxin-induced some proinflammatory cytokines in vitro[23]. However it is to be determined in complex in vivo studies. We assessed the cytokines and transcriptional factor NF-kappa B in the intestine because of the important status of the intestine in sepsis or systemic inflammation reaction syndrome (SIRS). The intestine was not only the passive organs injured by sepsis but participation in the pathogenesis of SIRS[5,6].

TNF-α is regarded as the most important proinflammatory cytokine, which is released early after an inflammatory stimulus[24]. And IL-6, which is elevated after TNF-α, contributes to both morbidity and mortality in conditions of "uncontrolled" inflammation[25]. Among the cytokines produced in the intestinal mucosa during inflammation, TNF-α and IL-6 are particularly important because of its multiple biological effects both in the intestine and in other organs and tissues. In this study, we demonstrated that ketamine suppressed both endotoxin-induced TNF-α and IL-6 expression and production in the intestine. TNF-α was the first cytokine expressed after endotoxin stimulation and later IL-6, which was consistent with several previous reports[24,25]. Studies had demonstrated that ketamine could suppress endotoxin-induced cytokines in vitro. However, proinflammatory cytokines just like TNF-α and IL-6 were not merely stimulated by endotoxin in vivo. Therefore, our experimental protocol was more physiological and closer to clinical condition.

NF-kappa B is associated in the cytoplasm with its inhibitory subunit, inhibitory kappa B (IκB), which prevents NF-kappa B from translocating into the nucleus. Endotoxin can induce the phosphorylation and degradation of IκB. Many effector genes including those encoding cytokines (TNF-α and IL-6) are in turn regulated by NF-kappa B[26]. To determine whether ketamine could inhibit NF-kappa B activation, we did EMSA to detect NF-kappa B activity in the intestine. We found a constitutive activation of NF-kappa B in intestine. Endotoxin could enhance NF-kappa B activation in the intestine and it was most significant 1 h later. Although we had previously demonstrated that ketamine could inhibit NF-kappa B activation in peripheral blood mononuclear cell (PBMC) after endotoxin challenge in vitro. It was to be studied whether ketamine had this effect in vivo. In our experiment, we found ketamine could inhibit NF-kappa B activation. However it was not in a dose dependent manner. We did not found any NF-kappa B activity changes in the group administered ketamine

(50 mg/kg) only, which excluded ketamine itself had any effect on NF-kappa B activity.

As the rats were not anesthetized during the whole experiment, we did not monitor the arterial pressure and pulse rate to confirm septic shock. Because the drug studied in our investigation was ketamine, just an anesthetic drug. To exclude any other anesthetic drug disturbance, we had to give up that monitoring. However, this septic model was successfully used in many other researches[27-29]. In addition, we did find that the rats were dispirited with piloerection and diarrhea, which indicated the septic shock indirectly.

The dosage of ketamine used in this study was from 0.5 to 50 mg/kg, which covered the clinical range. Roytblat *et al*.[30] reported that a single dose of ketamine 0.25 mg/kg administered before cardiopulmonary bypass suppressed the increase in serum IL-6 during and after coronary artery bypass surgery. However, other studies demonstrated such a small dose of ketamine did not suppress IL-6 production[25]. The reason was not clear. In this study, only ketamine reaching a dose of 5 mg/kg could suppress IL-6 production in the intestine. There were perhaps some differences between human being and animals or between *in vitro* and *in vivo* studies. We found 0.5 mg/kg ketamine suppressed TNF-α production, which was in accordance with those *in vitro* studies[25].

In conclusion, we demonstrated that ketamine could suppress endotoxin-induced TNF-α and IL-6 expression and production in the intestine. And this suppressive effect might act through inhibiting NF-kappa B. Further study is required to elucidate the mechanism of ketamine action.

Abstract

AIM: To investigate the protective effects of gastric pentadecapeptide BPC 157 on acute and chronic gastric ulcers in rats and to compare the results in therapy of human gastric ulcers by different administration methods.

METHODS: Gastric pentadecapeptide BPC 157 was administered (initial single or continuous administration) into rats either intragastrically or intramuscularly before (induced acute gastric ulcer) or after (induced chronic gastric ulcer) the applications of inducing agents, and each animal was sacrificed to observe the protective effects of BPC 157 on gastric ulcers.

RESULTS: Both intramuscular (im) and intragastric (ig) administration of BPC 157 could apparently reduce the ulcer area and accelerate the healing of induced ulcer in different models and the effect of im administered BPC 157 was better than that of ig. The rats treated with higher dosages (400 ng/kg, 800 ng/kg) of BPC 157 (im and ig) showed significantly less lesion ($P<0.01$ vs excipient or saline control), the inhibition ratio of ulcer formation varied between 45.7% and 65.6%, from all measurements except 400 ng/kg BPC 157 in pylorus ligation induced model ($P<0.05$), in which the inhibition rate was 54.2%. When im administered (800 ng/kg BPC 157) in three models, the inhibition ratio of ulcer formation was 65.5%, 65.6% and 59.9%, respectively, which was better than that of famotidine (its inhibition rate was 60.8%, 57.2% and 34.3%, respectively). Continuous application of BPC 157 (in chronic acetate induced gastric ulcer) could accelerate rebuilding of glandular epithelium and formation of granulation tissue ($P<0.05$ at 200 ng/kg and $P<0.01$ at 400 ng/kg and 800 ng/kg vs excipient or saline control).

CONCLUSION: Both im and ig administered gastric pentadecapeptide BPC 157 can apparently ameliorate acute gastric ulcer in rats and antagonize the protracted effect of acetate challenge on chronic ulcer. The effect of im administration of BPC 157 is better than that of ig, and the effective dosage of the former is lower than that of the latter.

INTRODUCTION

Pentadecapeptide BPC 157 (M_r 1 419), with the sequence Gly-Glu-Pro-Pro-Pro-Gly-Lys-Pro-Ala-Asp-Asp-Ala-Gly-Leu-Val, a 15-amino acid fragment of body protection compound (BPC) peptide in gastric juice[1,2], is thought to be essential for BPC' s activity and has been fully characterized and investigated. Although the detailed mechanism is poorly understood, BPC 157 appears to be beneficial to almost all organ systems in many species when very low dosages (mostly mg/kg and ng/kg) are used. It has many functions such as attenuating liver, lung, colon and gastric lesions[3-13], displaying anti-anxiety and antidepressant effects[14,15], improving angiogenesis and wound healing[8,16,17], reversing MPTP-motor abnormalities in Parkinson' s disease models[11], having mucosal protective and anti-inflammatory effects[10,18,19], particularly affecting dopamine systems[20], and persistent activity[6,21]. All these findings showed that BPC 157 could be a useful prototype of a new class of drugs and organ protective agents.

In this present we studied the protective effects of synthesized BPC 157 on acute and chronic gastric ulcers and also discussed the differences resulted from different administration methods.

MATERIALS AND METHODS

Materials

BPC 157 was synthesized and purified in our laboratory. Famotidine (Lot No. 970422) was provided by Changzhou Xinhua Industry General Company. Indomethacin was purchased from Lanzhou Pharmaceutical Factory. CIMAS8 true color image analyzer was from Beijing University of Aeronautics & Astronautics. WV-CP410 color camera was produced by Panasonic Electrical Company Limited.

Animals

A total of 330 male Wistar rats, weighing 200-240 g, were used for 3 different gastric ulcer models, namely indomethacin induced model, pylorus ligation induced model and acetate induced model. In each model, rats were randomly divided into 11 groups, of which 6 for intramuscular (im) administration and 5 for intragastric (ig) administration, 10 rats for each group.

Methods

Gastric pentadecapeptide BPC 157 was ig or im administered (1 mL/kg) at three different dosages (200, 400 and 800 ng/kg) in each model. Saline, excipient (mannitol) and famotidine were used as saline control, excipient control and positive control, respectively.

In model 1, the rats were fasted but with free access to water for 24 h, and then BPC 157 was given. Sixty minutes later

ulcer was induced by injection of indomethacin (33 mg/kg body mass). The rats were sacrificed 12 h later and both pylorus and cardia were ligated, followed by injection of 10 mL formaldehyde (40 g/L) into the stomach. Thirty minutes later, the stomach was cut and spread out and the area of the ulcer was measured.

In model 2, the rats were fasted for 54 h with free access to water before administrations of BPC 157. Famotidine and saline were given and pylorus ligation was performed by surgical procedure 60 min later. The rats were fasted for an additional period of 18 h and sacrificed and treated as in model 1.

In model 3 (chronic gastric ulcer model), the stomach was exposed under anesthesia followed by injection of 50 μL acetate (300 mL/L) under the chorion after the rats were fasted with free access to water for 24 h. After injection of acetate, the rats were immediately treated with BPC 157 twice daily for 12 d. Twelve hours following the last treatment, the rats were sacrificed and the ulcer area, glandular epithelium rebuilding and granulation tissue thickness were investigated. The reepithelialization was reflected by the diameter of remnant ulcer and the thickness of granulation tissue was measured every 500 μm.

RESULTS

Effects of BPC 157 on indomethacin induced gastric ulcer

BPC 157 could apparently inhibit the progression of indomethacin induced gastric ulcer. When im administered (400 ng/kg and 800 ng/kg), the protective effect of BPC 157 (the gastric ulcer area was 7.22 mm^2) was better than that of famotidine (the ulcer area 8.20 mm^2). While im and ig application had different effects, the former was better than the latter. The effective ($P<0.01$ *vs* excipient control or saline control) dosage was different; im administration of 200 ng/kg BPC 157 was as effective as ig administration of 400 ng/kg of BPC 157 (Table 1, Figure 1).

Table 1 Effect of BPC 157 on indomethacin induced gastric ulcer formation (*n*=10)

Administration	Agents	Dosage (ng/kg)	Ulcer (mm²)	Inhibition ratio(%)
im	Saline control	-	19.22±2.95	-
	Excipient control	-	20.90±7.55	-
	Famotidine	40 000	8.20±4.68	60.8[b]
	BPC 157	200	9.71±5.00	53.5[b]
	BPC 157	400	7.22±4.01	65.5[b]
	BPC 157	800	7.22±4.64	65.5[b]
ig	Saline control	-	20.18±8.50	-
	Famotidine	40 000	8.28±3.45	58.9[b]
	BPC 157	200	13.56±6.79	32.8
	BPC 157	400	9.92±2.62	50.8[b]
	BPC 157	800	9.75±5.25	51.7[b]

[b]$P<0.01$ *vs* excipient control or saline control.

Effects of BPC 157 on pylorus ligation induced gastric ulcer

The effect of BPC 157 on pylorus ligation induced gastric ulcer was similar to that on indomethacin induced ulcer. When BPC 157 was im administered, it was effective ($P<0.01$ *vs* excipient control) even at dosage of 200 ng/kg and the effects at dosages of 400 ng/kg and 800 ng/kg were better than that of famotidine. When BPC 157 was ig administered, the higher dosages showed significant effect compared with saline control ($P<0.05$) and the lower dosage did not ($P>0.05$) (Table 2, Figure 1).

Effects of BPC 157 on acetate induced gastric ulcer

In chronic acetate induced animal model, the lower dosage was effective ($P<0.05$), and the higher dosages showed significant effects ($P<0.01$) when compared with excipient control (im) or saline control (ig) (Table 3, Figure1).

Table 2 Effect of BPC 157 on pylorus ligation induced gastric ulcer formation (*n*=10)

Administration	Agents	Dosage (ng/kg)	Ulcer (mm²)	Inhibition ratio(%)
im	Saline control	-	131.2±58.1	-

[a]$P<0.05$, [b]$P<0.01$ *vs* excipient control (im) or saline control (ig).

BPC 157's effect on rebuilding of glandular epithelium and granulation tissue formation in chronic acetate induced gastric ulcer was also investigated. Table 4 shows that BPC 157, im and ig administered, had significant protective effects compared with controls ($P<0.05$), and the effect of BPC 157 on the thickness of granulation tissue was more significant than that of famotidine ($P<0.01$). The ulcer in rats treated at 800 ng/kg dosage of BPC 157 was almost healed and the granulation tissue became thick. In the control, putrescence and exudation were apparent, the ulcerous gap was large and the granulation tissue was very thin (Figure 2).

Table 4 Effects of BPC 157 on rebuilding of glandular epithelium and formation of granulation tissue in acetate induced chronic gastric ulcer (*n*=10)

Administration	Agent	Dosage (ng/kg)	Diameter of remnant ulcer (μm)	Thickness of granulation tissue (μm)

DISCUSSION

Gastric pentadecapeptide BPC 157 is a widely studied molecule bearing cyto/organo- protective effects in many organs and can be administered in various ways. In the present study, we investigated the protective effects of chemically synthesized and purified BPC 157 on acute and chronic gastric ulcers in rats. The application way of the agent was also considered.

Generally, in acute and chronic induced gastric ulcers, im and ig administered gastric pentadecapeptide BPC 157 can prominently attenuate the syndrome in rats. When BPC 157 was im administered, the protective effect reached a statistical significance at a low dose (200 ng/kg) and the effect was better than that of famotidine, the positive control, at a higher dose (400 ng/kg or 800 ng/kg). When BPC 157 was ig administered, the effect was less than that when it was im administered, but better than that of saline controls. In the control, the ulcer area

was larger. What was more, the synthesized BPC 157 had a high bioactivity especially in pylorus ligation induced animal model. The effective dosage of famotidine (40 mg/kg) was 50 times that (800 ng/kg) of BPC 157. In acetate induced chronic gastric ulcer model, both famotidine and BPC 157 could apparently antagonize protracted acetate challenge by accelerating rebuilding of glandular epithelium and formation of granulation tissue. Although the protective effect of famotidine was as good as certain dosages of BPC 157, granulation tissue formation was far less than that of BPC 157, so BPC 157 may act at least to some extent in a different way from famotidine.

Although the function of BPC 157 has been fully elucidated, the detailed mechanism of BPC 157 is still poorly understood. Sikiric *et al*. found that gastric pentadecapeptide BPC 157 attenuated chronic amphetamine disturbances and the effect was present throughout the observation period at a statistically

significant level. So they believed that BPC 157 had a modulatory effect on dopamine system[20]. In a haloperidol-induced gastric lesion model, both dopamine agonists (*i.e.*, bromocriptine, amantadine) and gastric pentadecapeptide BPC 157 could antagonize these lesions, but other antiulcer agents (atropine, pirenzepine, misoprostol, pantoprazole, lansoprazole, cimetidine and ranitidine) were not as effective[10]. Besides, a particular interaction of BPC 157 with central dopamine system was also shown in other experimental models (*i.e.*, protection of stress ulcers). Likewise, a considerable number of evidence for interaction of gastric peptides with dopamine system has been found in gastric mucosal protection studies.

However, Sikiric *et al.* found that although the dopaminomimetics (bromocriptine, apomophine and amphetamine) could apparently attenuate the otherwise consistent haloperidol or reserpine-gastric lesions when they were co-administered, their beneficial effects were absent in rats injured by haloperidol in combination with reserpine. On the other hand, BPC 157 was also effective. This result showed that BPC 157 might not act directly through dopamine system, but through a corresponding system parallel to dopamine system, and it might still function despite the extensive inhibition of endogenous dopamine system activity[22]. Considering the indicated GABA (gamma-amino butyric acid)/dopamine system interactions, besides an anti-anxiety effect[14], BPC 157 might act through GABA. Jelovac[23] found that BPC 157 acted in favor of the natural homeostasis of the GABA receptor complex and of the GABAergic transmission, thus having a mechanism at least partly different from those involving diazepam tolerance/withdrawal.

With respect to the prolonged activity of BPC 157 and its surprisingly high activity (at ng level), it can be reasonably speculated that pentadecapeptide BPC 157 was most likely to act through the regulation of central nervous system (CNS) or some beneficial factors[24-28], and then might activate a cascade network, but not directly act on the target tissue or cells. It was reported that the disordered ratio of G/D cells, which can secrete gastrointestinal hormones gastrin and somatostatin, could lead to gastrointestinal dysfunction in acetic acid induced gastric ulcer model[29]. Maybe BPC 157 can antagonize the agents induced damage by modulating the number of G and D cells and maintaining the stable circumstances of stomach.

Although the mechanism of gastric ulcer has been studied for many years, the therapy of human gastric ulcer is still a hard nut to crack. Many substances have been investigated for the therapy of gastric ulcer, but few of them were found to be effective, some were bi-directional[30]. It is well known that human gastric ulcer is characterized by relapse and difficulty in prevention. So, emphasis of treatment of peptic ulcer should be put on preventing relapse. Wang *et al.*[31] found that traditional Chinese medicine Danshen (*Salvia miltiorrhiza*) was effective in promoting ulcer healing and preventing recurrence by strengthening gastric mucosal barrier and promoting gastric mucosal cell proliferation along the edge of the ulcer. The effect of BPC 157 on preventing gastric ulcer recurrence is under investigation.

In conclusion, BPC 157 is a potentially useful peptide and can be used in the treatment of human gastric ulcer. It may have other uses because of its multiple activity. Further studies on its mechanism are needed before we can benefit from this pentadecapeptide.

Abstract

AIM: To study the reversing effect of Ginkgo biloba extract (GbE) on established liver fibrosis in rats.

METHODS: Following confirmation of CCl4-induced liver fibrosis, GbE or saline was administrated to the rats for 4 weeks. The remaining rats received neither CCl4 nor GbE as normal control. The four groups were compared in terms of serum enzymes, tissue damage, expression of αSMA and tissue inhibitor-1 of metalloproteinase (TIMP-1) and metalloproteinase-1 (MMP-1).

RESULTS: Compared with saline-treated group, liver fibrosis rats treated with GbE had decreased serum total bilirubin ($P<0.01$) and aminotransferase levels ($P<0.01$) and increased levels of serum albumin ($P<0.01$). Microscopic studies revealed that the livers of rats receiving GbE showed allieviation in fibrosis ($P<0.05$) as well as expression of αSMA ($P<0.01$). The liver collagen and reticulum contents were lower in rats treated with GbE than saline-treated group ($P<0.01$). RT-PCR revealed that the level of TIMP-1 decreased while the level of MMP-1 increased in GbE group.

CONCLUSION: Administration of GbE improved CCl4–induced liver fibrosis. It is possibly attributed to its effect of inhibiting the expression of TIMP-1 and promoting the apoptosis of hepatic stellate cells.

INTRODUCTION

Hepatic fibrosis represents the response of the liver to diverse chronic insults such as parasitic disease, chronic viral infection (hepatitis B and C), immunologic attack (autoimmune hepatitis), hereditary metal overload, toxic damage, *etc.* Because of the worldwide prevalence of these insults, liver fibrosis is common and is associated with significant morbidity and mortality[1-3]. Ginkgo biloba extract (GbE) is an extract from green leaves of the Ginkgo biloba tree. GbE has been shown to have an SOD-like activity and a hydroxyl radical scavening activity[4-10]. We have demonstrated that GbE concomitant administration to rats subjected to CCl4-induced liver fibrosis resulted in a reliable hepatoprotection against liver damage, as well as a curtailing process in the progression to liver fibrosis[11]. Therefore, the aim of this study was to further evaluate the beneficial action of GbE in reversing a well-established liver fibrosis after 8 wk of administration.

MATERIALS AND METHODS

Animals and treatment

Twenty-four 2-month-old male inbred Wistar rats were purchased from the Experimental Animal Center of Wuhan University of Medical Science. Six normal rats were treated with neither CCl4 nor GbE (group N). GbE was provided by Wuhan Wushi Pharmaceutical Company, China. (No 21003). GbE contains two groups of major components: flavonoid (>24%) and terpenoids (>6%). The GbE and double-distilled water were mixed to 0.1 mg/mL suspension and subjected to full vibration. Carbon tetrachloride (CCl4) and liquid paraffin were purchased from Sigma Corporation, USA. CCl4 was injected intraperitoneally at 0.15 mL per rat (diluted 1:1 in liquid paraffin) twice weekly for 8 wk to produce liver fibrosis. After completing the CCl4 treatment, 3 d after withdrawal of the hepatotoxin, six rats were anaesthetized with ether (group C). One blood sample was taken and the plasma stored until analysis. After this, the animals were exsanguinated and the liver was quickly washed *in situ* with ice-cold isotonic saline, removed, weighed, and divided into two portions, one for histological study (immunohistochemical staining, HE, Gorden-Sweet and Masson staining), the other was immediately frozen in liquid nitrogen. Following establishment of CCl4-induced liver fibrosis, GbE (200 mg/kg per day given orally daily with gavage) or saline was administrated for 4 wk (group E and group Z, respectively). Three days after the last GbE administration, animals (groups N, E and Z) were anaesthetized with ether and kept at a constant temperature of 37.0 ± 0.5℃. One blood sample was taken, centrifugated (3 000 rpm for 10 min), and the plasma stored until analysis. After this, the animals were exsanguinated and the liver was quickly washed *in situ* with ice-cold isotonic saline, removed, weighed, and divided into two portions, one was for histological study, the other immediately frozen in liquid nitrogen. Serum levels of TBIL, albumin and the activities of ALT and AST were determined by routine laboratory methods.

Animals were kept on standard rat chow with free access to tap water and received humane care in accordance with the animal care provisions, maintained in temperature- and humidity-controlled animal quarters under a 12 h light-dark cycle. The rats were weighed daily.

Histopathological examination

Liver tissue sections were fixed in 4 g/L formaldehyde saline and processed in paraffin wax. Sections from blocks were stained with hematoxylin-eosin (HE), reticulum (Gordon-Sweet staining) and Massaon's Trihrome. Qualitative and quantitative histological analyses were performed blindly under a light microscope and computer image analysis system. The image intensity level was kept the same throughout the study. To quantify hepatic fibrosis, we used the Knodell index, scoring as the following: 0, absence of fibrosis; 1, portal fibrous; 2, fibrous portal expansion; 3, bridging fibrosis (portal-portal or portal-central linkage); 4, cirrhosis. For each sample the

collagenous deposits at centrilobular field of the hepatic acinus, and at surrounding terminal hepatic veins were deserved at 100× magnification. In order to avoid possible bias due to the sampling of the individual fields, for every specimen, we analyzed at least 5 fields each containing a centrilobular vein. The microscopic examinations were performed in a blind fashion. Actin, smooth muscle Ab-1 was from NeoMarkers and immunohistochemical streptavidin/ peroxidase (SP) kit from Zhongshan Corporation. Immunohistochemistry of αSMA was performed using an indirect SP technique. At least 5 fields each containing a centrilobular vein were observed and the areas of positive hepatocytes were quantitated at 400×.

RT-PCR

Total RNA was extracted using Trizol (Biostar Biologic Technology Co. Ltd. USA.) according to the manufacturer's directions. Then total RNA was reverse by transcribed into cDNA. PCR was performed using the following primer pairs: β-actin: sense 5' -ATC ATG TTT GAG ACC TTC AAC ACC-3' , antisense 5' -CAT GGT GGT GCC GCC AGA CAG-3' ; TIMP-1[12]: sense 5' -ACA GCT TTC TGC AAC TCG-3' , antisense 5' -CTA TAG GTC TTT ACG AAG GCC-3' . MMP-1[12]: sense 5' -AGC TTG GCC ACT CGC TCG GTC TG-3' , antisense 5' -GTC TCG GGA TGC ATG CTC GTA TGC-3' . The amplified products were electrophoresed on a 12 g/L agarose gel containing 0.5 µg/mL ethidium bromide, and visualised under UV light.

RESULTS

Body, liver and spleen weight

Irritability, aggression, and weight loss were present predominantly in group C rats. Liver and body weight (LW and BW) of rats are presented in Table 1. No changes in body weight were observed in the rats of group Z and group E regardless of the treatment. Animals in group C showed an evident hepato- and splenomegaly. GbE (group E) blocked the hepatosplenomegaly more significantly than saline (group Z).
Table 1 Rat liver weight (LW), body weight (BW) and spleen weight (SW)

	BW (g)	LW (g)	LW/BW(%)	SW(g)	SW/BW (%)
C	297.0±39.6[d]	14.6±3.0	4.9±0.7[c]	1.5±0.2	0.5±0.06[d]
E	343.3±25.7[b]	9.6±4.2[bc]	2.8±0.4[bc]	1.0±0.1[bd]	0.3±0.03[bd]
Z	351.1±21.6[b]	13.2±3.3	3.7±0.4[a]	1.4±0.1	0.4±0.04[b]
N	358.3±72.2[a]	11.4±0.5[ac]	3.2±0.1[ad]	0.7±0.1[bd]	0.2±0.02[bd]

[a]$P<0.05$, [b]$P<0.01$ vs C group; [c]$P<0.05$, [d]$P<0.01$ vs Z group.

Histopathology

The morphology of the rat livers was assessed by light microscopy and is presented in Table 2 and Figure 1. αSMA positive staining of immunohistochemistry was localized in the cytoplasm and membrane. Chronic administration of CCl₄ for 8 weeks induced liver fibrosis. The liver exhibited a marked increase in ECM content and displayed bundles of collagen surrounding the lobules, which resulted in large fibrous septa and distorted tissue architecture. These septa were populated by αSMA-positive cells. The liver damage varied from one area to another, and ranged from moderate fibrosis to cirrhosis. The degree of liver fibrosis was classified according to five stages in the development of fibrosis and the difference between group Z and E, group E and C was statistically significant (group Z vs group E, $q=6.00$, $P<0.01$; group E vs group C, $q=9.46$, $P<0.01$; group Z vs group N, $q=6.74$, $P<0.01$; group N vs group C, $q=50.19$, $P<0.01$; but group Z vs group C, $q=2.29$, $P>0.05$). In group Z, liver collagenous and reticulum proteins as well as expression of αSMA decreased. Microscopic studies revealed that the livers of rats receiving GbE showed decreases in fibrosis and the expression of αSMA was only surrounding blood vessels.
Figure 1 Histology of liver of normal rats (N) and rats treated with CCl_4 for 8 weeks (C) and then treated with saline (Z) or GbE (E) for 4 weeks. The samples were stained with HE (1), Masson (2), Reticulum staining (3) and immunohistochemistry of αSMA (4). (1)-(3) 100×, (4) 200×.

Table 2 Rat liver histopathology

	Liver fibrosis					Collagen (%)	Reticulum (%)	αSMA(+) (%)
	0	I	II	III	IV			
C	0	0	0	3	3	11.4±1.2[d]	12.4±0.9[d]	4.8±2.1[c]

Liver function

Table 3 shows the serum parameters in the four groups of rats. Serum ALT, AST and TBIL concentrations in group C were all 1.3-fold more than that in group Z, and there was a more significant decrease in GbE group. GbE produced improvement both in markers of hepatocellular damage (AST and ALT) and in parameters that indicate synthetic activity (albumin). All the differences were statistically significant compared with group Z.

Table 3 Liver function parameters

	ALT (U/L)	AST (U/L)	Albumin (g/L)	TBIL (mg/L)
C	188.8±52.8	267.8±45.4[c]	22.2±1.7[d]	9.3±1.1[d]
E	80.8±15.2[bd]	108.1±23.4[bd]	35.8±3.2[bd]	5.6±0.9[bd]
Z	143.1±35.0	211.6±53.1[a]	28.7±1.9[b]	7.0±0.8[b]
N	43.4±7.7[bd]	101.3±22.2[bd]	36.3±1.3[bd]	5.3±0.8[bd]

Expression of TIMP-1 and MMP-1

Remarkable TIMP-1 mRNA expression was observed in group C and TIMP-1 mRNA expression decreased in group Z. In groups E and N, RT-PCR analysis revealed very slight TIMP-1 mRNA expression (Figure 2). In groups C, Z and N, the expressions of MMP-1 were all slight while the expression in group E was remarkable.

Figure 2 RT-PCR. M, 2 000 bp DNA marker, A. β-actin (556 bp), B. TIMP-1 (218 bp), C. MMP-1 (365 bp).

DISCUSSION

Incidence of liver fibrosis is growing as a result of the widespread occurrence of chronic hepatitis (predominantly type C). Cameron and Krunaratne first reported the reversibility of hepatic fibrosis after removal of the toxic agent CCl_4 in the CCl_4-induced liver fibrosis model. Since then, fibrolysis after the removal of the causative agents has been observed in experimental models of fibrosis of various types[13-20]. The reversibility of hepatic fibrosis has also been observed in alcoholic liver disease by clinicians. In this study, 4 wk after CCl_4 withdrawal, significant decreases in liver and spleen size as well as liver fibrosis state were recorded in the liver fibrosis rats treated with saline. But liver fibrosis is a complex process, and current therapies targeting at arresting or reversing liver fibrosis are largely ineffective and some has unacceptable

side effects in long-term therapy[21-29]. For example, glucocorticosteroids, which have been shown to inhibit collagen synthesis in culture and in animal models, rarely suppressed fibrogenesis or prevented progression to liver fibrosis[30]. In addition, long-term administration of glucocorticoids may cause serious adverse side effects, which that prevent their use as a general treatment of liver fibrosis. D-penicillamine, which blocks intra- and interchain crosslinking in the newly formed collagen molecules, was found to be ineffective on preventing the progression of hepatic fibrosis and was associated with a high incidence of serious side effects. Medicinally useful plants have made a significant contribution to current medical practice and traditional Chinese herbs are well known for their cheap prices and negligible side effects[31-41]. GbE is a well-known and inexpensive herb that has been used to improve blood circulation without ill effects for centuries in traditional Chinese medicine. GbE contains two groups of major components: flavonoid glycosides and terpenoids. Furthermore, it has been recently reported that GbE has the property of inactivating oxo-ferryl radical species, which are more efficient oxidative agents than classical hydroxyl radicals[3-8]. Li et al.[41] demonstrated that procollagen II peptide, laminin, SOD and MDA were significantly decreased after GbE treatment in patients with chronic hepatitis B. In our previous study, the biochemical and histological protocol demonstrated that GbE[12], administrated at a safe dosage with minimal side effects, effectively prevented both the biochemical and histological changes associated with liver fibrosis in CCl_4-injured rats.

The CCl_4-treated rat is frequently used as an experimental model to study hepatic fibrosis. CCl_4 treatment generates free radicals that trigger a cascade of events resulting in hepatic fibrosis. In this study, when treated with CCl_4 twice weekly for 8 wk, the liver exhibited a marked increase in ECM content and displayed bundles of collagen surrounding the lobules leading to large fibrous septa and distorted tissue architecture. These septa were populated by αSMA-positive cells. All of these are characteristics of advanced fibrosis. In liver fibrosis rats, there was also evident liver dysfunction, as reflected by significantly decreased serum albumin and increased bilirubin contents. In addition, serum levels of ALT and AST were elevated.

When these animals received GbE, hepatomegaly was absent. A primary consideration in the assessment of the efficacy of a potential therapeutic agent for hepatic fibrosis is its effect on liver histology. Those livers from disease control (group C) had a high degree of fibrosis. Group Z had some improvement in histological scores compared to group C. GbE administration to liver fibrosis rats apparently accelerated the reversion of liver fibrosis and lowered the high levels of serum ALT and AST activity, indicating that GbE was also effective on reversing liver cirrhosis.

Hepatic fibrosis, regardless of the cause, is characterized by an increase in extracellular matrix (ECM) constituents. There is now overwhelming evidence suggesting that the hepatic stellate cells (HSC), lying in the space of Disse beneath the endothelial cell layer, are the principal cells involved in hepatic fibrogenesis. Thus, to prevent or reverse liver fibrosis depends greatly on controlling of HSC[42-46]. These cells are usually quiescent, with a low proliferation rate. On activation, probably because of hepatocyte injury, they differentiate into myofibroblast-like cells, with a high proliferative capacity. It has been shown that activated HSCs constitute the source of various collagenases that are necessary for the ECM remodeling. In group C, large fibrous septa were populated by αSMA-positive cells. GbE given orally promoted the apoptosis of most of the HSC and only traces of αSMA-positive cells were detected. It suggests that GbE could enhance the apoptosis of HSC.

Matrix degradation occurs predominantly as a consequence of the action of a family of enzymes called matrix metalloproteinases (MMPs), and the expression of these enzymes are in turn inhibited by a family of TIMPs[47-53]. To explore the way in which this herb results in a significant reduction in fibrosis, we investigated the effect of GbE treatment on the expression of genes known to have a role in hepatic fibrosis such as TIMP-1 and MMP-1 by reverse transcription-polymerase chain reaction (RT-PCR). In group Z, there was a rapid and significant decrease in the expression level of TIMP-1. We also systematically evaluated the mechanism of action of GbE at the molecular level by analyzing TIMP-1 transcript expression. GbE treatment was associated with an increased collagenolytic activity and a prompt normalization of liver levels of TIMP-1 and also caused a more marked reduction in the expression level of TIMP-1 transcript than group Z while increased the level of MMP-1. A lower expression of TIMP-1 indicated decreased hepatic fibrogenesis and might be an effect correlated with enhanced apoptosis in activated myofibroblast-like stellate cells. The expression levels of TIMP-1 in groups Z and E were lower than that in group C.

In summary, our results indicate that treatment with GbE after the establishment of CCl4-induced hepatic fibrosis significantly reduces and even reverses the fibrosis in rats. This effect is related to an increased removal of deposited collagen, enhanced collagenolytic activity due to decreased TIMP-1 levels and enhanced apoptosis of HSC.

Abstract

AIM: To investigate whether octreotide can inhibit the growth of human gallbladder cancer cells *in vitro* and to elucidate the antineoplastic mechanism of octreotide in gallbladder cancer.

METHODS: A human gallbladder cancer cell line, GBC-SD, was cultured *in vitro*. The antiproliferative effects of octreotide were examined by means of an MTT assay and a colony forming ability assay. Morphological variation was investigated under scanning electron microscopy and transmission electron microscopy. Cell cycle analysis and apoptosis rate was evaluated by flow cytometry (FCM) after staining by propidium iodide. DNA fragmentation was assayed by agarose gel electrophoresis. Immunohistochemical staining was performed to evaluate the expressions of mutant-type *p*53 and *bcl-2*.

RESULTS: The growth curve and colony forming ability assay showed significant inhibition of octreotide to the proliferation of GBC-SD cells in culture in a time- and dose-dependent manner. After exposure to octreotide, GBC-SD cells showed typically apoptotic characteristics, including morphological changes of chromatin condensation, vacuolar degeneration, nucleus fragmentation and apoptotic body formation. In FCM profile apoptotic cells showed increased sub-G_1 peaks in the octreotide group, significantly higher than the control group ($P=0.013$). There was also an augmentation in the cell proportion of G_0/G_1 phase ($P=0.015$), while the proportion of S phase and G_2/M phase remained unchanged ($P=0.057$ and $P=0.280$, respectively). DNA agarose gel electrophoresis displayed a ladder after exposure to 1 000 nmol/L octreotide. After being treated with octreotide, the expressions of both mutant-type *p53* and *bcl-2* decreased considering the percentage of positive cells ($P<0.05$).

CONCLUSION: Octreotide has a negative action to the proliferation of GBC-SD cells, and the mechanism may be related to cytostatic and cytotoxic effects. The reduction of mutant-type *p53* and *bcl-2* expressions may be associated with the apoptosis induced by octreotide.

INTRODUCTION

Gallbladder cancer is the commonest tumor of the biliary system[1]. Because of the absence of characteristic early symptoms, the majority of cases are diagnosed at a late stage when most patients already have occult or overt metastasis. As most gallbladder cancers are unresectable, the prognosis is dismal with the median survival time hardly exceeding 6-mo and 5-yr survival less than 5%. Due to the limited efficacy and considerable toxicity of conventional chemotherapy, novel cytotoxic agents and innovative noncytotoxic approaches are being developed. Amongst the various agents, our attention was being directed to somatostatin. Somatostatin and its analogs (SSTA) such as octreotide[2] inhibit tumor cell growth *in vitro* and *in vivo*[3,4]. Their effects are mediated by a family of G-protein-coupled receptors (SSTR$_{1-5}$) that can couple to diverse signal transduction pathways such as inhibition of adenylate cyclase and guanylate cyclase, modulation of ionic conductance channels, and protein dephosphorylation. There are both 'direct' mechanisms that are sequellae of binding of SSTA to somatostatin receptors present on neoplastic cells and 'indirect' mechanisms related to effects of SSTA on the host[3] including antiangiogenetic effect[5] and inhibited secretion of tumor trophic factors or hormones such as insulin-like growth factor[6]. Various tumors are inhibited by octreotide, but little is known about whether octreotide has any antineoplastic effects on human gallbladder cancers[7].

MATERIALS AND METHODS

Materials

Octreotide was a generous gift from Jiuyuan Gene Engineering Co. (Hangzhou, China). RPMI 1640 medium was obtained from Gibco. Newborn bovine serum was supplied by Sijiqing Biotechnology Co. (Hangzhou, China). MTT and propidium iodide (PI) were from Sigma. DNA Extract kit was from Dingguo Biotechnology Co. (Beijing, China). Mouse anti-human P53 and Bcl-2 monoclonal antibodies were purchased from Santa Cruz. ABC kit was provided by Vector.

Methods

Cell culture Human gallbladder cancer line GBC-SD (obtained from Doctor Bo Liu in Department of Hepato-biliary Surgery, General Hospital of PLA) was cultured in RPMI 1640, supplemented with 100 mL/L heat-inactivated newborn bovine serum, 100 U/mL penicillin and 100 µg/mL streptomycin in a humidified atmosphere of 50 mL/L CO_2 at 37 ℃.

MTT assay Equal numbers of cells were seeded into 96-well tissue culture plates. One day later, the cells were treated at different concentrations of octreotide. Cell viability was determined in 5 wells for each drug concentration using MMT assay 12, 24, 36, 48, 60 h later. Optical density was measured at 570 and 630 nm using a microplate reader. Growth curve was made according to the optical density.

Colony-forming ability after drug exposure Aliquots of about 1 000 dispersed cells were seeded into Petri dishes in triplicates and treated with octreotide of different concentrations 24 h later. Colonies consisting of more than 50 cells were scored

and the colony-forming rate was compared with that of untreated controls six days later.

Scanning electron microscopy (SEM) Cells grown on a small coverslip were prefixed with 25 mL/L glutaraldehyde, treated with OTO method, dehydrated in graded ethanol, critical point dried with CO_2 and gold coated. The specimens were examined with a JSM-T300 scanning electron microscope.

Transmission electron microscopy (TEM) Cell cultures to be analyzed by transmission electron microscopy were fixed in 25 mL/L glutaraldehyde in phosphate buffer and post fixed in 10 g/L osmium tetraoxide, dehydrated in graded ethanol, embedded in an Epon 812 mixture, and sectioned on an ultramicrotome. After being stained with uranyl acetate and lead citrate, they were observed in a HITACHI H-800 electron microscope.

Agarose gel electrophoresis of DNA Cells treated with octreotide at 1 000 nmol/L for 72 h were collected, and DNA was extracted and analyzed in 10 g/L agarose gel for 1.5 h. After being stained with ethidium bromide solution for 10 to 15 min, the gel was viewed on a long wave UV transilluminator.

Flow cytometry assay (FCM) The cells subjected to treatment with octreotide were harvested, rinsed with PBS, resuspended and fixed in 700 mL/L ethanol at 4 ℃ overnight. The fixed cells were centrifuged, resuspended in 100 mg/L RNase A at 37 ℃ for 30 min and stained with PI at 4 ℃ for 30 min. FACS flow cytometer fluorescence intensity was measured by FACScan FCM and the DNA content in cells was analyzed by Modfit software. For each sample, 20 000 cells were measured.

Immunohistochemical analysis GBC-SD cells treated with octreotide for 24 h on coverslips were fixed with cold acetone for 5 min, rinsed in PBS for 5 min. Immunohistochemical staining proceeded according to kit instructions. Blank control, negative control (PBS substituting for primary antibodies) and positive control (parafin section of human gastric cancer) were set up at the same time. Cells from at least 10 randomly selected fields (×400) were counted. The percentage of positive cells was calculated as (Number of positive cells/Total number in the same visual field)×100%.

Statistics

Data were analyzed employing the paired two-tailed Student t test and nonparameter analysis, and significance was assumed at $P<0.05$.

RESULTS

Effects of octreotide on the proliferation of GBC-SD cells

The growth curve (Figure 1) and colony forming ability assay (Table 1) showed significant inhibition of octreotide to the proliferation of GBC-SD cells in culture, inducing time- and dose-dependent effects.

Figure 1 The inhibitory effect of octreotide on growth curve of GBC-SD. Each value was the mean of 5 duplicate wells.

Table 1 The inhibitory effect of octreotide on colony forming ability of GBC-SD (mean±SD,%)

Effects of octreotide on the apoptosis and cell cycle of GBC-SD cells

After exposure to octreotide, some GBC-SD cells showed typically apoptotic morphology, including chromatin condensation, vacuolar degeneration, nucleus fragmentation and formation of apoptotic body, which could be seen under SEM and TEM (Figure 2 and Figure 3).

DNA of cells undergoing apoptosis usually displays a ladder in agarose gel electrophoresis. In the present study, a DNA ladder was characteristically identified in cells treated with 1 000 nmol/L of octreotide for 72 h as shown in Figure 4.

Usually, a reduced content in apoptotic cells under PI staining displays a ' sub-G_1' peak in FCM profile and apoptotic cells can be quantified in this way. As demonstrated in Table 2, GBC-SD cells exposed to octreotide showed increased sub-G_1 peaks, significantly higher than those of the control group ($P=0.013$). Compared with the control group, there was also an augmentation in the cell proportion of G_0/G_1 phase ($P=0.015$), while the proportion of S phase and G_2/M phase remained unchanged ($P=0.057$ and $P=0.280$, respectively). This indicated that octreotide could arrest the GBC-SD cells at G_0/G_1 phase.

Table 3 Effects of octreotide on the *p53* and *bcl-2* expression of GBC-SD cells (mean±SD,%)

Group	Percentage of P53 protein positive	Percentage of Bcl-2 protein positive
Control	50.09±4.64	87.12±7.40
Octreotide 1 000 nmol/L	44.12±5.30[a]	80.46±5.45[a]

[a]$P<0.05$ *vs* the control group ($n=10$).

Effects of octreotide on P53, Bcl-2 protein levels in GBC-SD cells

After being treated with octreotide, the expressions of both mutant-type *p53* and *bcl-2* decreased considering the percentage of positive cells ($P<0.05$), as demonstrated in Table 3.

DISCUSSION

Somatostatin and SSTA show antineoplastic activity in a variety of experimental models *in vivo* and *in vitro*[3,4]. There is considerable evidence for antineoplastic activity of SSTA for neoplasms of breast, prostate, pancreas, colon, stomach, liver, and other common solid tumors for which current treatments are inadequate[8-18]. Some clinical trials employed octreotide in the treatment of human advanced tumors, showing increased survival, favorable toxicity profiles and improved life quality[19,20]. Recent studies described some aspects of the molecular mechanisms underlying this antineoplastic activity[21]. These researches suggest somatostatin and SSTA as drug candidates in oncology.

In this research we observed the effect of octreotide on the growth of GBC-SD cells in culture through two methods. Growth curve reflected group proliferative ability, while colony-forming assay reflected individual proliferative ability. Both methods showed significant inhibition of octreotide to the proliferation of GBC-SD cells, inducing time- and dose-dependent effects.

Over the past decade, a variety of studies revealed that somatostatin and SSTA mediated their action through both indirect and direct effects[3]. In our *in vitro* experiments, only direct effect was concerned, including cytostatic and cytotoxic effects.

After exposure to octreotide, FCM demonstrated an increased number of GBC-SD cells at G_0/G_1 phase. In cholangiocarcinoma cells, the G_0/G_1 cycle arrest was also induced[22]. This effect was attributed to the inhibition of signal transduction of some tumor trophic factors or hormones such as insulin and epidermal growth factor, which initiated tyrosine kinase pathway, activated the kinase cascade, increased the expression of cyclin, and promoted the cell cycle from G_1 to S phase[23]. Some researches found octreotide activated SSTR on the membrane, down-regulated cyclin and up-regulated cyclin-dependent kinase inhibitor, thus leading to the inhibition of the mitogenic signal initiated by tyrosine kinase receptor family. Researchers reported specific phosphotyrosine phosphotases were required for maintaining high inhibitory levels of cyclin-dependent kinase inhibitor p27[Kip1] and inactivating complex of cyclin E and cyclin dependent kinase 2[23-26]. Another research reported octreotide-induced growth arrest was mediated by inhibition of phosphatidylinositol 3-kinase pathway and by enhanced expressions of p21[Cip] and p27[Kip1] [27].

A variety of findings indicated that apoptosis could be induced in cancer cells by octreotide, which was implicated in its antineoplastic mechanism[8,28]. In GBC-SD, spontaneous apoptosis was observed, showing an apoptosis rate varying from 0.21% to 0.69% in the control group and apoptosis could be induced by octreotide, displaying typical morphological changes, DNA ladder, and elevated sub-G_1 peaks in FCM profiles. Octreotide-inducing apoptosis was reported to be associated with tyrosine proteinphosphotase pathway, intracellular acidification, activation of endonuclease and modulation of some genes such as wide-type *p53*, *bax* and *bcl-2*[28-31]. Sharma *et al* reported only SSTR3 mediated apoptosis, depending on the expression of wide-type *p53*[29]. Recent studies demonstrated SSTR2 mediated apoptosis in human pancreatic cancer cells and HL60 cells expressing mutated *p53*[32,33]. These results indicate that somatostatin can induce apoptosis by *p53*-dependent and *p53*-independent mechanisms[26].

Two main signaling pathways initiate the apoptotic program in mammalian cells. The cell-extrinsic pathway triggers apoptosis in response to activation by their respective ligand of the tumor necrosis factor (TNF) family of death receptors, while the cell-intrinsic pathway triggers apoptosis in response to DNA damage, loss of survival factors, or other types of cell distress. Guillermet and colleagues reported SSTR2 affected both pathways[32].

By means of immunohistochemical staining, we found high expressions of mutant-type *p53* and *bcl-2* in GBC-SD cells. In the process of octreotide-inducing apoptosis, expressions of both genes decreased. This suggests the down-regulation of both genes may be related to octreotide-inducing apoptosis.

In conclusion, we demonstrate that octreotide could inhibit proliferation *in vitro* in human gallbladder cancer cells, and speculate that cycle arrest and apoptotic induction might be involved in the mechanism.

Abstract

AIM: To investigate effects of pioglitazone on rat hepatic fibrosis and to explore its mechanism.

METHODS: Rat hepatic fibrosis was induced by carbon tetrachloride (CCl_4). Forty Sprague-Dawley rats were divided randomly into 4 groups: control, model, and two treatment (PI, PII) groups. Except for rats in control group, all rats were given subcutaneous injection of 400 mL/L CCl_4, twice a wk for 8 wk. Rats in PI and PII groups were also treated with pioglitazone of 3 mg/kg, daily via gastrogavage beginning on the 1st day and at the end of the 2nd week, administration of CCl_4 respectively. Liver functions (ALT, AST), serum fibrotic markers (HA, LN, PCIII) and hepatic hydroxyproline (HP) concentration were determined respectively. Histochemical staining of formalin-fixed liver sections with HE, Masson-Trichrome, and immunohistochemical staining for α-smooth muscle actin (α-SMA) were performed. Modified Knodell and Chevallier semi-quantitative scoring system (SSS) was used to evaluate necroinflammatory activity and fibrosis degree.

RESULTS: Compared with model group, pioglitazone significantly reduced the serum levels of ALT, AST , HA, LN and PCIII ($P < 0.05$ or < 0.01). The HP concentrations in PI (210.90 ± 24.07 µg/g), and PII (257.36 ± 30.55 µg/g) groups were also lower than those in model group (317.80 ± 36.44 µg/g) ($P < 0.01$). Histologic examination showed that PI and PII groups had milder hepatocellular degeneration, necrosis and infiltration of inflammatory cells, and thinner or less fibrotic septa than did model group. The scores for necroinflammation in PI (2.80 ± 1.03), and PII (3.00 ± 1.05) groups were significantly reduced as compared with model group (4.88 ± 2.30) ($P < 0.05$ or < 0.01); the fibrosis scores in PI (3.40 ± 1.65), and PII (4.60 ± 1.35) groups were also markedly lower than those in model group (7.00 ± 3.21) ($P < 0.05$ or < 0.01). Immunohistochemical staining showed that expression of α-SMA in PI and PII groups was ameliorated dramatically compared with model group.

CONCLUSION: PPARγ agonist pioglitazone greatly retards the progression of rat hepatic fibrosis induced by CCl_4 through inhibition of HSC activation and amelioration of hepatocyte necroinflammation in rats.

INTRODUCTION

Hepatic fibrosis is a common response to chronic liver injury of variable origins (*e.g.* viral, alcoholic, metabolic), which can lead to cirrhosis and ultimately, endstage liver failure and increased risk for hepatocellular carcinoma[1-3]. It seems to be irreversible once liver cirrhosis has been developed[4]. Therefore therapeutic intervention in the progression of hepatic fibrosis in the early stage plays an important role in the prevention of liver cirrhosis. However, until now no satisfactory antifibrotic agent is available.

Peroxisome proliferator-activated receptors (PPARs) are the members of a nuclear receptor superfamily, three isotypes of which have been identified: α, β (also called δ and NUC1) and γ. PPARγ plays a pivotal role in the differentiation of adipocyte and metabolism of glucose and fatty acid[5]. Some studies showed that PPARγ is implicated in inducing differentiation or apoptosis of various human malignant cells [6]. Agonists of PPARγ include 15-deoxy-$\triangle$ [12, 14]-PGJ_2 (15 d- PGJ_2) and thiazolidinediones (TZDs), such as troglitazone, rosiglitazone, and pioglitazone, *etc*. TZDs are synthetic compounds with a high affinity to PPARγ and a new class of oral antidiabetic drugs that act by improving insulin sensitivity. Rosiglitazone and pioglitazone have no obvious adverse effects and have been used in clinic[7-10]. Recently, pioglitazone was reported to be able to prevent early-phase hepatic fibrogenesis induced by carbon tetrachloride (CCl_4) for 72 h[11]. Galli A *et al*. also demonstrated that oral administration of TZD (rosiglitazone and pioglitazone) can reduce extracellular matrix (ECM) deposition in both toxic and cholestatic models of liver fibrosis[12]. In the present study, we investigated the effects of pioglitazone on rat hepatic fibrosis induced by CCl_4, and explored its mechanism.

MATERIALS AND METHODS

Animals

Forty adult male Sprague-Dawley rats, weighing 200-250 g, were purchased from Experimental Animal Department of Xiangya Medical School, Zhongnan University, Hunan Province. Rats were randomly divided into 4 groups including normal control, model and two treatment (PI, PII) groups. Except for control group, all rats were given subcutaneous injection of 400 mL/L CCl_4 (dissolved in castor oil) 3 mL/kg twice weekly for 8 wk, with the first dosage doubled. The control group received injection of castor oil vehicle of the same dosage twice weekly. Rats in PI and PII groups were also given pioglitazone (Beijing Taiyang Pharm. Co., Ltd.) of 3 mg/kg daily via gastrogavage beginning on the 1st day and at the end of the 2nd week, administration of CCl_4 respectively. Once per week, the animals were weighed and the dosages of CCl_4 and pioglitazone were adjusted. At the end of the 8-wk experimental period, all rats were sacrificed by bleeding from femoral arteries and veins. Blood and livers were collected for further examinations.

Serum assays

Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were measured by using a Hitachi Automatic Biochemical Analyzer. Serum fibrotic markers, such as hyaluronic acid (HA), laminin (LN) and type III procollagen (PCIII) were determined by a radioimmunological assay using a commercial kit (Shanghai Navy Medical Institute, China).

Hydroxyproline (HP) determination

Liver tissue (approximately 200 mg) was homogenized into powder and hydrolyzed in 5 mL of 6 mol/L HCl. Hepatic HP concentrations were measured according to manual description (Jiancheng Medical Institute, Nanjing, China).

Histopathological examination

Liver tissues were fixed in 40 g/L formaldehyde, embedded in paraffin and stained with hematoxylin-eosin (HE) and Masson' s trichrome. Modified Knodell and Chevallier semi-quantitative scoring system (SSS)[13] was used to evaluate necroinflammatory activity and fibrosis degree by an independent pathologist blindly.

a-Smooth muscle actin (a-SMA) immunohistochemical staining

Liver tissue sections were deparaffinized in xylene and rehydrated in alcohol gradually. Then the sections were incubated with a primary monoclonal mouse anti-α-SMA antibody (Boster, Wuhan, China) and a secondary biotin-conjugated goat anti-mouse IgG respectively. The positive stains were shown as a brown colour with a SABC technique.

Statistical analysis

Data were presented as mean±SD unless otherwise indicated. One-way analysis of variance (ANOVA) with LSD post-hoc comparison was used to test for differences in means of variables between groups. A P value <0.05 was considered statistically significant. All data were analyzed by SPSS10.0 software.

RESULTS

Histopathological alterations

At the end of the experiment, 2 rats in model group were dead because of infection at the site of injection, another 2 developed ascites. In treatment groups, no death or ascites occurred.

Control livers showed normal lobular architecture with central veins and radiating hepatic cords with irregular sinusoids, and a normal distribution of collagen with a variable amount in portal tracts and a thin rim around central veins (Figure 1). Livers in model group showed disorderly hepatocyte cords, severe fatty degeneration, spotty or focal necrosis and infiltration of inflammatory cells (Figure 2A), and collagen deposition extending from central veins or portal tracts, with thick or thin fibrotic septa and even pseudolobuli formation (Figure 2B). Treatment with pioglitazone in PI, PII groups resulted in apparent amelioration of hepatocyte degeneration, necrosis and infiltration of inflammatory cells (Figure 3), and marked reduction in collagen deposition with no obvious pseudolobuli formation (Figuer 4). Scores of liver necroinflammation and fibrosis are shown in Table 1.

Effects of pioglitazone on liver functions and serum fibrotic markers

Serum ALT and AST levels in model group were significantly increased as compared with control group. But treatment with pioglitazone reduced the ALT, AST levels markedly compared

with model group and the effects in PI group were more obvious than those in PII group (Table 2). Serum levels of HA, LN and PCIII, the surrogate markers of liver fibrogenesis, were significantly higher in model group than those in control group. These markers were lowered markedly in treatment groups compared with model group (Table 3).

Table 1 Effects of pioglitazone on liver inflammation and fibrosis scores(mean±SD)

Group	n	Necroinflammatory scores	Fibosis scores

[a]P<0.05, [b]P<0.01 *vs* model group; [d]P<0.001 *vs* control group.

Effects of pioglitazone on liver HP contents

Liver HP concentrations in model group (317.80±36.44 µg/g) were significantly increased as compared with control group (170.96±29.34 µg/g) (P<0.001). Treatment with pioglitazone in PI (210.90±24.07 µg/g), and PII (257.36±30.55 µg/g) groups decreased HP concentrations markedly compared with model group.

Figure 2 A: Liver tissue from model group showed disorderly hepatocyte cords, severe fatty degeneration, spotty or focal necrosis and infiltration of inflammatory cells. HE × 200. B: Liver tissue from model group showed collagen deposition extending from central veins or portal tracts, with thick or thin fibrotic septa and pseudolobuli formation. Masson × 200.

Figure 3 Liver tissue from PII group showed apparent amelioration of hepatocyte degeneration, necrosis and infiltration of inflammatory cells. HE × 200.

Figure 4 Liver tissue from PII group showed marked reduction in collagen deposition with no obvious pseudolobuli formation. Masson × 100.

a-SMA immunohistochemical changes

α-SMA is a marker of hepatic stellate cells (HSC) activation. In control livers, α-SMA was mainly expressed in vascular walls; but in model group, apart from vascular walls, α-SMA was strongly expressed in areas of centrilobular and periportal fibrotic bands. Compared with model group, treatment with pioglitazone dramatically reduced the expression of α-SMA in the livers. Besides the expression in vascular walls as in control group, there were only few mesenchymal cells expressing α-SMA around blood vessels in treatment groups.

DISCUSSION

Hepatic fibrosis is a reparative response to various chronic liver damage and activated hepatic stellate cells (HSCs) play a pivotal role in its pathogenesis[14]. An abundance of evidence indicated that inhibition of HSCs activation may delay or reverse the progression of hepatic fibrosis[15-17]. Recently, HSCs were reported to express PPARγ which might be important in control of their activation state. Inhibition or inactivation of PPARγ in HSCs may predispose to hepatic fibrosis. Miyahara et al. reported that PPARγ mRNA level and its binding to PPAR-responsive element (PPRE) are reduced in HSCs from cholestatic liver fibrosis rats. Treatment of cultured-activated HSC with ligands for PPARγ (15dPGJ$_2$ or BRL49653) inhibits DNA synthesis[18]. Transfection experiments with a reporter gene ([PPRE]$_3$-tk-luciferase) also demonstrated a progressive reduction of PPAR transcriptional activity during plastic-induced HSC transdifferentiation. But cotransfection with human PPARγ expression vector restored the reporter gene expression and inhibited cell proliferation in a dose-dependent manner in cultured HSCs[19]. PPARγ agonists also can inhibit HSC proliferation and chemotaxis induced by platelet-derived growth factors (PDGF), the effects of which are associated with inhibition of cell cycle progression beyond the G$_1$ phase[19,20]. A latest study reported that curcumin, a potent antioxidant, inhibits proliferation of activated HSCs in cultures, which is involved in its induction of PPAR-gamma activation[21]. HSCs are the main sources of excessive ECM production and deposition[22]. Apart from inhibiting HSC proliferation and activation, PPARγ ligands can inhibit collagen or fibronectin synthesis induced by transforming growth factor (TGF)-β1 in HSC[12,18]. Our experiments showed that α-SMA expression, a marker of activated HSC[23], was reduced significantly in pioglitazone treatment groups compared with model group. The results demonstrated that pioglitazone could inhibit HSC proliferation and activation. Treatment with pioglitazone also resulted in significant decrease in levels of serum fibrotic markers and hepatic HP concentrations compared with model group. The antifibrotic effects were further confirmed by Masson's trichrome collagen staining, which showed that collagen deposition of liver tissues in treatment groups was markedly reduced as compared with model group and was associated with lower scores of fibrosis. Our results demonstrated that pioglitazone could also reduce ECM deposition in hepatic fibrosis rats induced by CCl$_4$. In PII group, pioglitazone was administered beginning at the end of the 2nd week of model establishment, at which time main microscopic changes in livers were hepatocellular degeneration, necrosis and slight collagen deposition[24]. Studies showed that HSCs are activated and proliferate stably at the end of the 2nd week of model establishment[25]. Our experiments found that pioglitazone administered beginning at that time could also inhibit the activated HSC proliferation and prevent the progression of hepatic fibrosis in rats.

Hepatic fibrogenesis is often associated with hepatocellular necrosis and inflammation accompanied by repair processes[26,27]. Kupffer cells were shown to be a critical mediator of the inflammatory and fibrogenic responses during CCl$_4$-mediated

liver damages[28]. Treatment with GdCl$_3$ or glycine that inactivated Kupffer cells, resulted in attenuation of CCl$_4$-induced hepatic fibrosis[29], which proves that suppression of necroinflammation may be an effective antifibrotic treatment. Many studies showed that PPARγ plays regulatory roles in inflammation and immunity[30-32]. PPARγ ligands can inhibit the activation of inflammatory response genes by antagonizing the AP-1, NF-kB and STAT signaling pathways[33] and reduce proinflammatory cytokines (TNF-α, IL-1, IL-6, etc.) in various cell types (eg. macrophages)[34]. Anti-inflammatory activities of some NSAIDs are associated with inhibition of cytokines production through PPARγ activation[34]. There are increasing reports suggesting that PPARγ ligands can be used for treatment of chronic inflammatory diseases such as inflammatory bowel disease[35], rheumatoid arthritis[36] etc. Our experiments showed that treatment with pioglitazone in PI, PII groups ameliorated hepatocyte degeneration, necrosis and infiltration of inflammatory cells and reduced the scores of necroinflammation significantly compared with model group. Liver functions (ALT, AST) were also improved apparently. These results demonstrated that PPARγ agonists also had anti-inflammatory effects, and subsequently retarded the progression of hepatic fibrosis in rats.

Thiazolidinediones are a new class of oral antidiabetic agents that sensitize insulin action and have no risk of hypoglycemic occurrence[37]. Currently two TZDs, rosiglitazone and pioglitazone, have been approved by U.S. Food and Drug Administration (FDA) for treatment of type 2 diabetes. A wealth of clinical studies indicated that rosiglitazone and pioglitazone have no hepatotoxicity[7-10]. Our experiments also showed that after administration with pioglitazone for 6 or 8 wk, no rats were observed to have hepatotoxicity; moreover, their liver functions (ALT, AST) were improved greatly compared with model rats.

In conclusion, pioglitazone, a PPARγ ligand, greatly retards the progression of experimental hepatic fibrosis through inhibition of HSC activation and amelioration of hepatocyte necroinflammation in rats. Therefore, it is a potential new antifibrotic drug for clinical application.
