COX-1 was clearly detected in the gastric foveolar and glandular epithelium including parietal cells. Patchy cytoplasmic staining for COX-1 was also seen in the inflammatory mononuclear cells and macrophages, myofibroblasts, as well as endothelial cells in the lamina propria. Spotty cytoplasmic staining for COX-1 was seen in gastric cancer cells (Figure 1). Perinuclear and cytoplasmic staining for COX-2 was mainly seen in the foveolar and glandular epithelium, and mild staining in mononuclear inflammatory cells and macrophages in the lamina propria. Strong expression of COX-2 was also found on glandular epithelium of IM and dysplasia. Immunoreactivity of COX-2 protein showed diffuse staining in the cytoplasm of gastric cancer cells (Figure 2). Furthermore, scattered expression for COX-2 was detected in interstitial cells such as vascular endothelial cells and myofibroblasts. Table 2 shows the positive rates of COX-1 and COX-2 expression in the gastric mucosa with various lesions. From CSG to GA, IM, dysplasia and finally to gastric cancer, the expression of COX-2 showed an ascending tendency, whereas COX-1 expression did not change significantly in the gastric mucosa with various lesions.

Table 2 Expression of COX-1 and COX-2 in gastric mucosa with various lesions

Pathological diagnosis	<i>n</i>	COX-1 expression (%)	COX-2 expression (%)
CSG	30	56.6	10.0
GA	28	53.8	35.7 ^a
IM	45	53.3	37.8 ^b
Dysplasia	12	41.7	41.7 ^a
Gastric cancer	23	43.4	69.5 ^{bc}

^a $P < 0.05$; ^b $P < 0.01$ vs CSG; ^c $P < 0.05$ vs GA.

Relationship between *H pylori* infection and COX-2 expression in the gastric mucosa

COX-2 expression was found in 57% (36/63) *H pylori*-infected patients, including one case of CSG, eight cases of GA, twelve cases of IM, four cases of dysplasia, and eleven cases of gastric cancer, with intensity scoring ranged from + to +++ (Table 3). *H pylori*-associated gastritis exhibited strong expression of COX-2 in foveolar and glandular epithelium but with a lower intensity in mononuclear inflammatory cells. On the contrary, only 20% (15/75) of non-infected patients expressed COX-2 protein in the gastric biopsy. The intensity of COX-2 expression in IM and dysplasia was significantly higher in *H pylori*-

Figure 1 Immunostaining of cyclooxygenase-1 in the gastric mucosa with CSG (A), dysplasia (B) and gastric cancer (C) as shown by immunostaining. In the gastric biopsies of cases of CSG, GA, IM and dysplasia, COX-1 immunostaining was detected in the foveolar and glandular epithelium including parietal cells, and in the subepithelial mononuclear inflammatory cells. Spotty cytoplasmic staining for COX-1 was seen in the gastric cancer cells.

Figure 2 Immunostaining of cyclooxygenase-2 in the gastric mucosa with CSG (A), GA (B), IM (C), dysplasia (D) and gastric cancer (E). CSG showing strong expression in foveolar and glandular epithelium and weak expression in mononuclear inflammatory cells, myofibroblasts, and endothelial cells in the lamina propria; GA showing strong expression in the atrophic glands of the gastric mucosa; IM showing strong expression in intestinal epithelium and goblet cells; and gastric cancer showing strong expression in cancer cells.

Table 3 Relationship between *H pylori* infection and COX-1/COX-2 expression in the gastric mucosa with various lesions

Pathological diagnosis			COX-1				COX-2			
			<i>n</i>	–	+	++	+++	–	+	++
CSG	<i>H pylori</i> (+)	11	5	1	3	2	10	0	0	1
	<i>H pylori</i> (-)	19	8	3	4	4	17	1	1	0
GA	<i>H pylori</i> (+)	18	9	2	4	3	10	1	3	4
	<i>H pylori</i> (-)	10	4	2	2	2	8	1	1	0
IM	<i>H pylori</i> (+)	14	6	3	2	3	2	2	4	6 ^b
	<i>H pylori</i> (-)	31	15	5	5	6	26	3	2	0
Dysplasia	<i>H pylori</i> (+)	4	2	0	1	1	0	0	2	2 ^b
	<i>H pylori</i> (-)	8	5	0	1	2	7	0	1	0
Gastric cancer	<i>H pylori</i> (+)	16	9	2	2	3	5	1	3	7
	<i>H pylori</i> (-)	7	4	2	0	1	2	1	2	2

^b $P < 0.01$ vs *H pylori* (–).

positive than in *H pylori*-negative subjects ($P < 0.01$). However, there was no significant difference in COX-2 expression in CSG, GA and gastric cancer patients with or without *H pylori* infection (Table 3).

DISCUSSION

Epidemiological studies have shown that long-term use of NSAIDs reduces the risk of colon cancer development by 40%^[22,23] and the risk of esophageal cancer development by up to 90%^[24,25].

In addition, NSAIDs could induce regression of adenomatous polyps in patients with familial adenomatous polyposis^[26,27], as well as in an Apc Min mouse model^[28]. Although the exact mechanisms of NSAIDs on cancer prevention have not been clarified, one possible role of NSAIDs is via the inhibition of COX enzymes, leading to chemopreventive effect. COX exists in two isoforms, of which COX-1 is constitutively expressed in many tissues, including the stomach, and COX-2 showing 61% homology with COX-1 is expressed at low concentrations or is even undetectable in unstimulated cells or tissues, but is readily induced by various stimuli including mitogens, cytokines, growth factors, and tumor promoters in inflammatory and certain cell types, such as fibroblasts, macrophages and endothelial cells^[29,30]. It is well known that COX-2 is strongly expressed in gastric cancer^[17,20]. More than 90% of gastric cancers are adenocarcinomas, which are divided into intestinal and diffuse histological types. Pathogenesis of the intestinal-type gastric cancer has been connected to precursor changes such as GA, IM, and dysplasia. The present study clearly showed that COX-2 protein was expressed not only in gastric cancer cells but also in the glandular epithelium of IM and dysplasia as detected by immunohistochemistry. From CSG, GA to IM and dysplasia and finally to gastric cancer, the expression of COX-2 showed an ascending tendency, whereas COX-1 expression did not change significantly in premalignant and malignant gastric lesions. These results provided evidence that COX-2 might contribute to an early event in gastric carcinogenesis^[31], and suggesting the possibility that the use of selective COX-2 inhibitors may provide a chemopreventive strategy against gastric carcinogenesis.

H. pylori infection is an important risk factor for adenocarcinoma of the distal stomach in humans^[2-5], but the mechanism whereby *H. pylori* infection contributes to gastric carcinogenesis is still hypothetical. Recent studies have shown that *H. pylori* infection induces COX-2 expression in human gastric mucosa^[6-8]. Furthermore, McCarthy *et al.*^[32] showed that COX-2 expression in antral mucosa was reduced but not eliminated in the epithelium after successful eradication of *H. pylori*. Kimura *et al.*^[33] reported that immunoreactivity of COX-2 was observed in all cases of IM even after the cure of *H. pylori* infection. Thus, cure of *H. pylori* infection may decrease the risk of gastric carcinogenesis due to COX-2-related compounds in gastric mucosa but not in those patients with IM. In this study, we demonstrated that COX-2 was expressed in epithelial lining of the stomach in the *H. pylori*-associated gastric carcinogenesis pathway from CSG, to GA and IM and dysplasia, and finally to gastric cancer. The level of COX-2 expression in patients with IM and dysplasia was significantly higher in *H. pylori*-positive than in *H. pylori*-negative subjects. In contrast, COX-1 protein was constitutively expressed in different gastric mucosal lesions with or without *H. pylori* infection. Thus, COX-1 is considered as a housekeeping gene, and prostanoids synthesized via the COX-1 pathway are thought to be responsible for cytoprotection of the stomach, for vasodilatation in the kidney, and for production of a proaggregative prostanoid, thromboxane, by the platelets. In contrast, COX-2 is an inducible immediate-early gene, and its role has been connected to inflammation, reproduction, and carcinogenesis. Although the exact mechanism of COX-2 expression in carcinogenesis is still unclear, some studies have suggested that overexpression of COX-2 is associated with cellular resistance to apoptosis whereas treatment with specific COX-2 inhibitors could suppress cell proliferation and induces apoptosis^[14,34-36]. It has been hypothesized that the alteration of the balance between apoptosis and proliferation of gastric epithelial cells, induced by *H. pylori* infection, contributes to either gastric injury or carcinogenesis of the stomach^[37-39]. Although *H. pylori* could decrease epithelial cell proliferation and induce apoptosis *in vitro*^[40-43], *H. pylori* infection *in vivo* was associated with both increased apoptosis and proliferation^[44-46].

These differences between the *in vivo* and *in vitro* results suggest that *in vivo* factors including inflammatory cells, extracellular matrix proteins, cytokines, and adhesion molecules may also contribute to epithelial cell turnover. On the other hand, COX-2 expression has been reported to correlate with invasion of the lymphatic vessels, lymph node metastasis, and advanced tumor stage in gastric cancer^[47,48].

In conclusion, COX-2 overexpression plays an important role in the initiation of gastric carcinogenesis. The use of selective COX-2 inhibitors may provide a chemopreventive strategy against gastric carcinogenesis.

Abstract

AIM: To investigate the protective effect of lansoprazole on ischemia and reperfusion (I/R)-induced rat intestinal mucosal injury *in vivo*.

METHODS: Intestinal damage was induced by clamping both the superior mesenteric artery and the celiac trunk for 30 min followed by reperfusion in male Sprague-Dawley rats. Lansoprazole was given to rats intraperitoneally 1 h before vascular clamping.

RESULTS: Both the intraluminal hemoglobin and protein levels, as indices of mucosal damage, significantly increased in I/R-groups compared with those of sham-operation groups. These increases in intraluminal hemoglobin and protein levels were significantly inhibited by the treatment with lansoprazole at a dose of 1 mg/kg. Small intestine exposed to I/R resulted in mucosal inflammation that was characterized by significant increases in thiobarbituric acid-reactive substances (TBARS), tissue-associated myeloperoxidase activity (MPO), and mucosal content of rat cytokine-induced neutrophil chemoattractant-1 (CINC-1). These increases in TBARS, MPO activities and CINC-1 content in the intestinal mucosa after I/R were all inhibited by pretreatment with lansoprazole at a dose of 1 mg/kg. Furthermore, the CINC-1 mRNA expression was increased during intestinal I/R, and this increase in mRNA expression was inhibited by treatment with lansoprazole.

CONCLUSION: Lansoprazole inhibits lipid peroxidation and reduces development of intestinal mucosal inflammation induced by I/R in rats, suggesting that lansoprazole may have a therapeutic potential for I/R injury.

INTRODUCTION

Reactive oxygen species such as superoxide radicals, hydrogen peroxide, and hydroxyl radicals, have been implicated in the pathogenesis of ischemia-reperfusion (I/R) injury in a variety of organs, including the brain^[1], large intestine^[2], and heart^[3]. Intestinal I/R is an especially grave condition resulted from acute mesenteric ischemia, small bowel transplantation, abdominal aortic aneurysm, hemorrhagic, traumatic, or septic shock, and severe burns^[4,5]. I/R injury of the small intestine is characterized by a number of microvascular and mucosal alterations, including endothelial cell swelling, capillary plugging, prolonged reduction in intestinal blood flow, and mucosal barrier dysfunction^[6-8]. Previous studies have demonstrated that neutrophils are critically involved in I/R injury. This hypothesis based on experiments shows that neutrophil depletion^[9,10] and inhibition of neutrophil-endothelial cell interactions^[11] could protect against injury after I/R.

Proton-pump inhibitors (PPIs)^[12] such as omeprazole and lansoprazole are extensively used for therapeutic control of acid-related disorders, including gastroesophageal reflux disease and peptic-ulcer diseases caused by stress, nonsteroidal anti-inflammatory drugs and *Helicobacter pylori* infection^[13-16]. PPIs are strong antisecretory agents that act on gastric (H⁺/K⁺) ATPase of parietal cells^[17]. Recently, it has been suggested that PPIs inhibit neutrophil functions such as chemotaxis, superoxide production and degradation^[18]. We have already reported that PPIs can attenuate neutrophil adherence to endothelial cells via inhibition of the expression of adhesion molecules^[19]. These results have indicated that PPIs have anti-inflammatory effects and can inhibit acid secretion.

The present study was to evaluate anti-inflammatory effects of lansoprazole, which has dramatically influenced the management of acid-peptic disorders in recent years, using I/R-induced rat intestinal mucosal injury model unrelated to acid secretion.

MATERIALS AND METHODS

Experimental animals

Male Sprague-Dawley (SD) rats weighing 190-210 g were obtained from Keiri Co. Ltd. (Osaka, Japan). The rats were housed in stainless steel cages with wire bottoms and maintained on a 12-h light and dark cycle, with the temperature and relative humidity of the animal room controlled at 21-23 °C and 55-65%, respectively. The rats were not fed for 18 h prior to the experiments, but allowed free access to water. All experimental procedures described below were approved by the Animal Care Committee of the Kyoto Prefectural University of Medicine (Kyoto, Japan).

Preparation of rats for intestinal ischemia-reperfusion

Intestinal ischemia was induced for 30 min by applying a small clamp to the superior mesenteric artery after ligating the celiac artery in rats given intraperitoneal urethane anesthesia (1 000 mg/kg). Reoxygenation was produced by removal of the clamp. Sixty minutes after reperfusion, the rats were killed by exsanguinations via the abdominal aorta under urethane anesthesia (1 000 mg/kg). 2-[[[3-methyl-4-(2,2,2-trifluoroethoxy)-2-pyridyl] methyl] sulfinyl] benzimidazole (Lansoprazole), a gift from Takeda Chemical Industries Ltd. Japan, was diluted with physiological saline at a dose of 0.3–1 mg/kg after dissolved in dimethylsulfoxide, and was given to rats intraperitoneally 1 h before the vascular clamping. In the control groups, rats received an equivalent volume of the vehicle.

Assessment of intestinal mucosal injury induced by ischemia-reperfusion

To estimate the severity of the intestinal mucosal damage by I/R, leakage of intraluminal protein and intraluminal hemoglobin levels were measured as mg/cm intestine.

The concentrations of thiobarbituric acid-reactive substances (TBARS) in the intestinal mucosa, an index of lipid peroxidation, were measured by the method of Ohkawa *et al.*^[20]. In brief, the small intestine was opened by a longitudinal incision, and the intestinal mucosa was scraped off using two glass slides. Mucosal tissue was then homogenized with 10 mmol/L potassium phosphate buffer (pH 7.8) containing 30 mmol/L KCl in a Teflon Potter-Elvehjem homogenizer. The levels of TBARS in the mucosal homogenates were expressed as nmol of malondialdehyde per gram of wet weight using 1,1,3,3-tetramethoxypropane as the standard.

Myeloperoxidase (MPO) activity in the intestinal mucosa, an index of polymorphonuclear leukocyte accumulation, were determined by a modification of the method of Grisham *et al.*^[21]. Two milliliters of mucosal homogenate was centrifuged at 20 000 *g* for 15 min at 4 °C to pellet the insoluble cellular debris. The pellet was then rehomogenized in an equivalent volume of 0.05 mol/L potassium phosphate buffer (pH 5.4) containing 5 g/L hexadecyltrimethylammonium bromide. Samples were centrifuged at 20 000 *g* for 15 min at 4 °C, and the supernatants were saved. MPO activity was assessed by measuring the H₂O₂-dependent oxidation of 3,3',5,5'-tetramethylbenzidine. One unit of enzyme activity was defined as the amount of MPO that caused a change in the absorbance of 1.0/min at 655 nm and 25 °C.

The content of cytokine-induced neutrophil chemoattractant-1 (CINC-1) in the intestinal mucosal homogenates was determined by enzyme-linked immunosorbent assay (ELISA) using a kit (Immuno Biological Laboratories, Gunma, Japan) according to the manufacturer's instructions. The absorbance of each well was read at 490 nm by a microplate reader (MPR-A4i; Tosoh, Tokyo, Japan).

The expression of intestinal CINC-1 was determined using the RT-PCR method. Samples of intestinal tissue for mRNA isolation were prepared from the whole intestine. Total RNA was isolated using the acid-guanidium-phenol-chloroform (AGPC) method with ISOGEN (NIPPON GENE). The concentration of RNA was determined by the absorbance at

260 nm in relation to that at 280 nm. The RNA was stored at -70 °C until used for RT-PCR. One microliter of RT-PCR products was added to 3 mmol/L of each primer, CINC-1 and β -actin (for internal standard purpose), and a solution of 0.5 U of *Taq* DNA polymerase (Takara Biochemicals) in a final volume of 50 L. The primers had the following sequences: for CINC-1, sense 5'-ACAGTGGCAGGGATTCACCTT-3', and antisense 5'-CTAGCA CAGTGGTTGACACT-3'; for β -actin, sense 5'-TCCTGTGG CATCCATGAAACT-3', and antisense 5'-GAAGCATTTGCGG TGCACGAT-3'. The mixture was subjected to 30 cycles (1 min at 94 °C, 1 min at 54 °C, 1 min at 72 °C) of amplification. Then the reaction products were separated by electrophoresis on 25 g/L agarose gel and stained with ethidium bromide.

Statistical analysis

All values were expressed as mean \pm SE. The data were compared by one-way analysis of variance (ANOVA) followed by Dunnett's multiple comparison test. All analyses were performed using the Stat View 5.0-J program (Abacus Concepts Inc. Berkeley, CA). $P < 0.05$ was considered statistically significant.

RESULTS

Intraluminal protein and hemoglobin levels of the small intestine

Intraluminal hemoglobin and protein levels, the reflections of intestinal mucosal injury, were significantly increased above basal levels after 60 min of reperfusion. These increases in intraluminal protein and hemoglobin levels induced by I/R were significantly decreased by lansoprazole treatment at a dose of 1 mg/kg (Table 1).

TBARS in the intestinal mucosa

TBARS in the intestinal mucosa, an index of lipid peroxidation, significantly increased 60 min after reperfusion (13.0 \pm 2.5 nmol/100 g wet wt). These levels were significantly decreased to 7.98 \pm 1.98 nmol/100 g wet wt after lansoprazole treatment at a dose of 1 mg/kg (Figure 1A).

MPO activity in the intestinal mucosa

The I/R group showed a significant increase in mucosal MPO activity (0.167 \pm 0.046 mU/mg wet wt) compared with the sham-operation group (0.014 \pm 0.001 mU/mg wet wt). However, this increase in MPO activity significantly decreased to 0.028 \pm 0.008 mU/mg wet wt after lansoprazole treatment at a dose of 1 mg/kg (Figure 1B).

Inflammatory cytokine in the intestinal mucosa

The content of mucosal CINC-1 in the I/R groups was significantly increased compared with the levels in sham-operated groups. This increase in the levels of inflammatory cytokines was significantly inhibited by lansoprazole at a dose of 1 mg/kg (Figure 1C).

Intestinal expression of CINC-1 mRNA during ischemia-reperfusion

The expression of CINC-1 mRNA in the intestinal mucosa was up-regulated by I/R injury. This increase in the expression of CINC-1 mRNA was also inhibited by lansoprazole at a dose of 1 mg/kg (Figure 2).

Table 1 Effect of lansoprazole on intraluminal hemoglobin and protein levels in small intestine of I/R-induced rats (mean \pm SE)

	Sham-operation (Normal)	Ischemia-reperfusion (Control)	Lansoprazole (mg/kg)	
			0.3	1
Intraluminal hemoglobin (mg/cm)	0.000043 \pm 0.000002	0.0043 \pm 0.0006 ^a	0.0035 \pm 0.0007	0.0010 \pm 0.0004 ^c
Intraluminal protein (mg/cm)	0.065 \pm 0.012	0.172 \pm 0.016 ^a	0.156 \pm 0.022	0.087 \pm 0.010 ^c

^a $P < 0.05$ vs normal; ^c $P < 0.05$ vs control.

DISCUSSION

Our results clearly showed that lansoprazole had a protective effect against reperfusion-induced intestinal mucosal injury in rats. In addition, increases in TBARS contents, MPO activity and CINC-1 contents were inhibited by the treatment of lansoprazole. In I/R-induced tissue injury, oxygen radicals have been suggested to be generated via several mechanisms, including the xanthine/xanthine oxidase reaction^[22], NADPH oxidase and myeloperoxidase of activated leukocytes migrating into the previously ischemic area^[23], and mitochondrial respiratory system^[24]. We have already reported that oxygen-derived free radicals and lipid peroxidation played a role in the formation of gastrointestinal mucosal damage induced by I/R^[25,26]. Furthermore, it is well known that neutrophils that adhere to post-capillary venules and subsequently emigrate into the interstitium are implicated in the I/R-related tissue injury^[27,28]. Activated neutrophils release a variety of cytotoxic substances, including proteases, collagenases, cytokines, leukotrienes, and cationic proteins, thereby causing tissue damage. In addition, adhered and aggregated neutrophils can physically disturb capillary flow and induce a non-reflow phenomenon.

Little is known about the protective mechanism of lansoprazole against I/R injury. However, there have been some reports about the anti-inflammatory action of PPIs. We have shown that the expression of adhesion molecules on neutrophils and endothelial cells elicited by *H. pylori* extract and IL-1 was inhibited by lansoprazole and omeprazole at clinical relevant doses^[19]. Other reports have also revealed that PPIs could prevent the neutrophil-endothelial cell adhesion reaction^[29,30]. Recently, some reports regarding the anti-oxidative effects of PPIs have also appeared. Suzuki *et al.*^[31] reported that PPIs inhibited the production of oxygen-derived free radicals from neutrophils activated by

chemotactic peptides or opsonized zymosan. Other studies have concluded that PPIs block stress-induced increased reactive oxygen intermediates and associated lipid peroxidation and protein oxidation, indicating that its antioxidant properties play a major role in preventing oxidative damage^[32-34].

Lansoprazole has been widely used in the treatment of acid-related diseases including reflux esophagitis. This drug is thought to be transformed into two active species which inhibit acid secretion by (H⁺, K⁺)-ATPase within the parietal cell canaliculi. However, acid secretion was not directly involved in the pathogenesis of I/R-induced intestinal injury model we used. In the present study, lansoprazole was found to prevent lipid peroxidation and to reduce the development of intestinal mucosal inflammation via inhibition of the production of inflammatory cytokines such as CINC-1. These results suggest that lansoprazole may protect against I/R injury via an anti-inflammatory effect but not inhibition of acid secretion.

It was previously reported that CINC levels were increased during small intestinal I/R injury, and that CINC-1 was related with the extent of mucosal damage^[35]. It was reported that CINC could be produced by many types of cells, including macrophages, monocytes, and endothelial cells^[36]. In the present study, lansoprazole inhibited both CINC-1 protein and mRNA in the small intestine after I/R injury. These results suggest that lansoprazole may prevent CINC-1 production by scavenging active oxygen species that are related to signal transduction for the promotion of CINC-1 synthesis. Further study needs to be done to determine the molecular mechanisms involved in the inhibition of CINC-1 production by lansoprazole.

In conclusion, lansoprazole protects against acid-unrelated intestinal injury induced by I/R via inhibition of neutrophil-dependent inflammation. We suggest that lansoprazole has potential as a new therapeutic agent for reperfusion injury.

Abstract

AIM: To investigate the different effects of mesenchymal stem cells (MSCs) and hematopoietic stem cells (HSCs) on hepatic differentiation.

METHODS: MSCs from rat bone marrow were isolated and cultured by standard methods. HSCs from rat bone marrow were isolated and purified by magnetic activated cell sorting. Both cell subsets were induced. Morphology, RT-PCR and immunocytochemistry were used to identify the hepatic differentiation grade.

RESULTS: MSCs exhibited round in shape after differentiation, instead of fibroblast-like morphology before differentiation. Albumin mRNA and protein were expressed positively in MSCs, without detection of alpha-fetoprotein (AFP). HSCs were polygonal in shape after differentiation. The expression of albumin signal decreased and AFP signal increased. The expression of CK18 was continuous in MSCs and HSCs both before and after induction.

CONCLUSION: Both MSCs and HSCs have hepatic differentiation capabilities. However, their capabilities are not the same. MSCs can differentiate into mature hepatocyte-like cells, never expressing early hepatic specific genes, while Thy-1.1⁺ cells are inclined to differentiate into hepatic stem cell-like cells, with an increasing AFP expression and a decreasing albumin signal. CK18 mRNA is positive in Thy-1.1⁺ cells and MSCs, negative in Thy-1.1⁻ cells. It seems that CK18 has some relationship with Thy-1.1 antigen, and CK18 may be a predictive marker of hepatic differentiation capability.

INTRODUCTION

In recent years, liver related stem cells have become a hot spot of research. One of the important findings is that liver stem cells might be derived from bone marrow. Petersen *et al.*^[1] first identified this phenomenon in rat model of liver injury. Later

many researchers have reported similar *in vivo* and *in vitro* findings^[2-8]. Bone marrow cells have been hypothesized as the third recruitment source in liver regeneration besides hepatocytes and endogenous liver stem cells^[9].

Among bone marrow cells, there are two subsets, hematopoietic stem cells (HSCs) and mesenchymal stem cells (MSCs). Hepatic oval cells^[10], well known endogenous liver stem cells, can express CD34^[11], c-kit^[12, 13], Thy-1^[14] and flt-3 receptor mRNA^[15], all of which are markers of HSCs. So HSCs are regarded as the exact source of hepatocytes. However, some studies have found that non-hematopoietic subsets (CD45⁻ subsets) also play such a role^[7]. In this paper, we isolated two subsets of stem cells from rat bone marrow. One was MSCs, isolated and cultured by standard methods, the other was Thy-1.1⁺ cells, isolated and purified by magnetic activated cell sorting (MACS), which were recognized as HSCs of rats. We imitated the circumstances of liver development to define the different capacities of hepatic differentiation of the two subsets *in vitro*.

MATERIALS AND METHODS

Animals

Male Sprague-Dawley (SD) rats at 6-7 wk of age were obtained from Charles River China. All animal experiments were performed in accordance with the animal guidelines of Peking University Health Science Center.

Isolation and culture of MSCs from rat bone marrow

Rat bone marrow was harvested from rat femurs and tibias, and collected into Dulbecco's modified Eagle's medium (DMEM), filtered (40 µm), and centrifuged at 300 r/min to pellet cells. After rinsed in PBS, bone marrow cells were loaded onto 5 mL 57% Percoll (1.073 g/mL in 0.01 mol/L PBS) and centrifuged at 400 r/min for 30 min. Mononuclear cells were collected at the Percoll interface, rinsed twice in PBS, and seeded at $2 \times 10^5/\text{cm}^2$ in 600 g/L low glucose DMEM (DMEM-LG, Sigma-Aldrich), 400 g/L MCDB-201 (Sigma-Aldrich), with 100 mL/L fetal bovine serum (FBS; Hyclone, USA) and 1 000 U/mL rat leukemia inhibitory factor (rLIF; Chemicon, USA). Non-adherent cells were removed after 24 h and culture media were replaced every 3 d. After about 7 d, isolated colonies of MSCs were apparent. Then the cells were trypsinized and replated at $8\,000/\text{cm}^2$, and the cells from passage 3 were used for differentiation protocol.

Differentiation protocols

MSCs from passage 3 were seeded at $2 \times 10^4/\text{cm}^2$ on 10 ng/mL fibronectin (FN, Sigma-Aldrich, USA) in culture medium as above. After 12 h, media were removed and cells were cultured in 600 g/L DMEM-LG, 400 g/L MCDB-201 supplemented with 50 mL/L FBS, 10^{-6} mol/L dexamethasone (Dex, Sigma-Aldrich, USA), 10 ng/mL epithelial growth factor (EGF, R&D, USA), $1 \times$ insulin/transferrin/selenium (ITS, Sigma-Aldrich, USA). In some experiments, inducing growth factors were added into culture medium (20 ng/mL acid fibroblast growth factors, aFGF; 10 ng/mL basic fibroblast growth factors, bFGF; and 20 ng/mL hepatocyte growth factor, HGF). aFGF, bFGF, and HGF were all from R&D System Inc, USA.

Isolation, culture and differentiation of Thy-1.1⁺ stem cells from rat marrow

After Percoll gradient centrifugation, bone marrow mononuclear cells were collected, then incubated with mouse anti-rat Thy-1.1 monoclonal antibody (Serotech, UK) at 4 °C for 30 min. Unbound antibodies were removed by washing twice. Secondary marking was done by incubation with rat-anti-mouse IgG bound magnetic microbeads (MiltenyiBiotec, Germany). The positive cells were absorbed in magnetic field by Mini-MACS columns (MiltenyiBiotec, Germany). The column was removed from the magnetic field and the Thy-1.1⁺ cells were washed out.

Thy-1.1⁺ cells were cultured in differentiation media, 600 g/L DMEM-LG, 400 g/L MCDB-201 supplemented with 150 mL/L FBS, 10⁻⁶ mol/L Dex, 10 ng/mL EGF, 1×ITS, 20 ng/mL aFGF, 10 ng/mL bFGF, and 20 ng/mL HGF. After about 7-10 d, apparent colonies of Thy-1.1⁺ cells appeared.

Flow cytometry determination of cell-surface antigen

The cells were resuspended in washing buffer (10 mL/L bovine serum, 2 g/L sodium azide in PBS), and stained on ice according to the manufacturer's recommendations with the monoclonal antibodies as follows: R-PE conjugated mouse anti-rat-Thy1.1 (Pharmingen, USA), FITC conjugated mouse anti-rat-CD45 (HarlanSera-Lab, UK), PE conjugated mouse anti-rat-CD34 (Santa Cruz, USA). After washed three times with washing buffer, the stained cells were resuspended in 300 µL fixation buffer (20 g/L formaldehyde in PBS) and run on a flow cytometer (FACS Calibur, BectonDi-ckinson, USA). The results were analyzed by CellQuest software (BD, USA).

Reverse transcription-polymerase chain reaction (RT-PCR)

Total RNA was extracted by using TRIzol (Invitrogen, USA) according to the manufacturer's instructions and quantified by UV spectroscopy. To prepare RNA for PCR analysis, 2 µg total RNA was converted to the cDNA using SuperScript II reverse transcriptase (Invitrogen, USA) with oligo (dT) (Promega, USA) and random hexamer primers (Promega, USA). PCR was performed by using *Taq* DNA polymerase (Gibco BRL, USA). For each gene, the DNA primers were originated from different exons to ensure that the PCR products represented the specific mRNA species and not genomic DNA. All PCR experiments were performed using

a GeneAmp PCR system 2 400 (Perkin-Elmer, USA).

The following specific oligonucleotide primers were used: albumin (5'-AAGGCACCCCGATTACTCCG-3' (sense), 5'-TGCGAAGTCACCCATCACCG-3' (antisense)), AFP (5'-AGGCTGTACTCATCATTAAGT-3' (sense), 5'-ATATTGTCC TGGCATTTCG-3' (antisense)), CK18 (5'-GGACCTCAGCAAG ATCATGGC-3' (sense), 5'-CCACGATCTTACGGGTAGTTG-3' (antisense)), β-actin (5'-AGAGGGAAATCGTGCCTGAC-3' (sense), 5'-AGGAGCCAGGCAGTAATC-3' (anti-sense)).

Amplification reactions were carried out for 35 cycles (25 cycles for β-actin) at 94 °C for 1 min, 58 °C for 1 min, and at 72 °C for 1 min for albumin; at 94 °C for 45 s, at 51 °C for 45 s and at 72 °C for 45 s for AFP; at 94 °C for 1 min, at 60 °C for 1 min and at 72 °C for 1 min for CK18 and at 94 °C for 30 s, at 55 °C for 45 s, and at 72 °C for 45 s for β-actin. The reaction products were subjected to 12 g/L agarose gel electrophoresis and visualized by ethidium bromide staining. The reaction products were 649 bp (albumin), 484 bp (AFP), 515 bp (CK18), and 353 bp (β-actin), respectively. Housekeeping gene β-actin was used as an internal control. Adult liver tissue or newborn rat liver tissue was used as a positive control.

Immunocytochemistry

Cell cultures were washed with PBS twice and fixed with 95% alcohol/acetic acid (99:1) for 10 min at room temperature, then permeabilized with 2 g/L Triton X-100 for 10 min. After washed, cells were incubated overnight at 4 °C with primary antibodies, including mouse anti-human CK18 (Sigma, USA), mouse anti-human albumin (Dako, Denmark) and goat anti-human AFP (SantaCruz, USA). Subsequently, the cells were washed with PBS three times and incubated with fluorescence labeled second antibody, FITC labeled goat anti-mouse IgG1 and rhodamine labeled donkey anti-goat IgG at 37 °C for 1 h. After washed with PBS, cells were mounted with glycerol-PBS (9:1). The cells were visualized and photomicrographed by a fluorescence microscope (Olympus Provis AX80, Japan).

RESULTS

Cell yield and shape of MSC and Thy-1.1⁺ cells before and after differentiation

The number of mononuclear cells by 57% Percoll gradient centrifugation was about 6.44×10⁷ per rat. After MACS

Figure 1 A-D Cell morphology before and after differentiation (Original magnification, 200×). A: Fibroblast-like MSC before differentiation, B: Round MSC after differentiation, C: Freshly isolated Thy1.1⁺ cells, D: Thy1.1⁺ cells 10 d after differentiation.

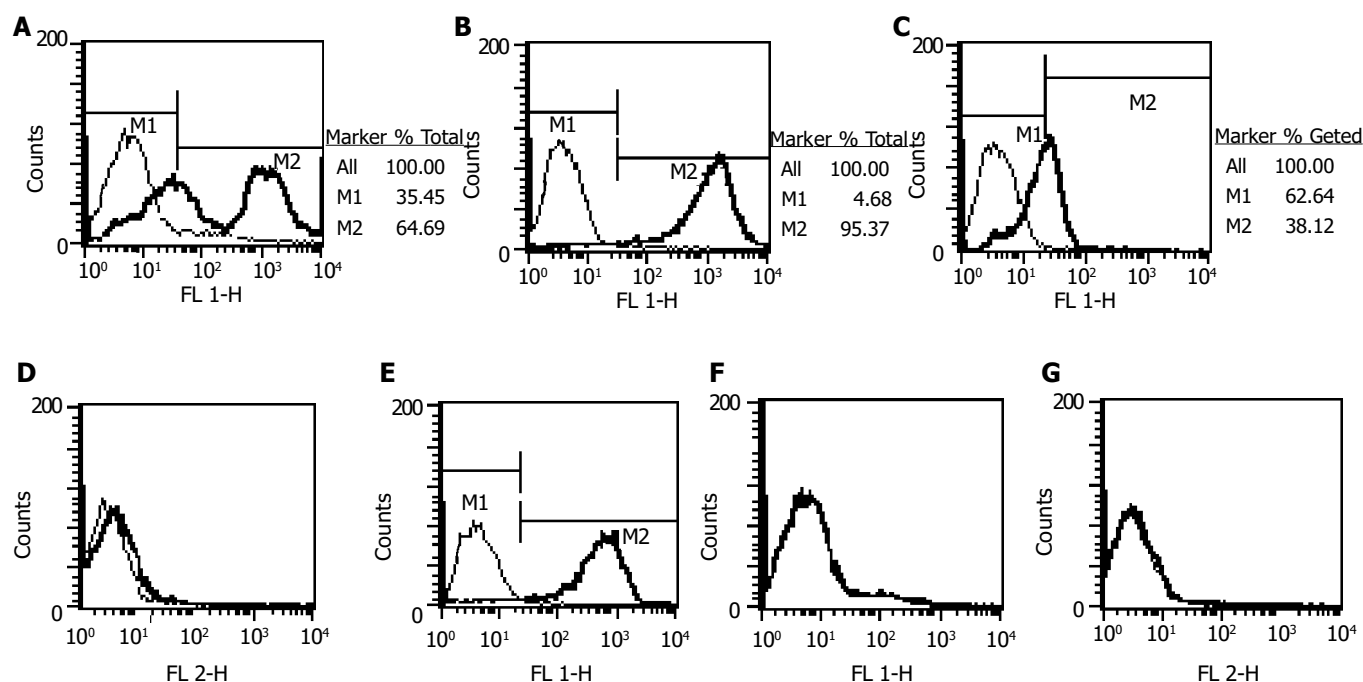

Figure 2 Phenotype analysis of MSCs and Thy-1.1⁺ cells. A: Thy-1.1 of mononuclear bone marrow cells before MACS; B, C, D: Thy-1.1, CD45, CD34 after MACS purification; E, F, G: Thy-1.1, CD45, CD34 of MSCs.

purification, the number of Thy1.1⁺ cells was about 2.36×10^7 . The recovery rate of Thy1.1⁺ cells from mononuclear bone marrow cells was 64.65%. Before differentiation, MSCs exhibited a fibroblastic morphology with spindle cell bodies (Figure 1A), while after differentiation, the cells contracted obviously and were inclined to be round in shape (Figure 1B). This change occurred early on d 4 after MSC differentiation protocol. Thy1.1⁺ cells were small and round in shape when freshly isolated (Figure 1C), and became typical polygonal, much bigger in size after cultured in differentiation media (Figure 1D).

Quantitative analysis of cell-surface antigen expression

The percentage of Thy-1.1⁺ of rat bone marrow mononuclear cells was 56.65%. After MACS, this percentage was 93.45% in positive subset (Figure 2A, B). Thy-1.1⁺ subset was CD34⁺, and partial CD45⁺ (Figure 2C, D). The percentage of CD45 positivity in Thy-1.1⁺ subset was 36.68%. As displayed in Figure 2E-2G, MSC was Thy-1.1⁺, CD45⁺, CD34⁺.

RT-PCR analysis of hepatic gene expression of CK18, albumin, and AFP

We analyzed hepatic gene expression of the cells before and after differentiation protocol. Adult rat liver or newborn rat liver tissue

Figure 3 RT-PCR analysis of hepatic gene expression before and after differentiation. A: Analysis of CK18 mRNA before differentiation, lane 1: Adult liver, lane 2: Mononuclear BM cells.

Figure 4 Immunocytofluorescence. A: MSCs-albumin, B: Thy1.1⁺ cells-CK18, C: Thy1.1⁺ cells-AFP.

was used as positive control. Before differentiation, Thy-1.1⁺ cells showed a CK18 signal, so did MSCs. However, Thy-1.1⁻ cells did not express CK18 (Figure 3A). After differentiation, Thy-1.1⁺ cells were AFP mRNA positive and had decreased signals of albumin, while MSCs expressed albumin only and the signals of albumin increased with the extension of differentiation time (Figure 3B, C). Both cells had a continuous CK18 expression during the process of induction (Figure 3D).

Immunocytochemical analysis

MSCs showed positive staining for albumin (Figure 4A), and Thy1.1⁺ cells showed CK18 and AFP positive staining (Figure 4B, C).

DISCUSSION

As stromal cells of bone marrow, MSCs could differentiate into cells of all mesodermal origin, including adipocytes, osteocytes, chondrocytes and myocytes^[16-19], *etc.* Besides these, MSCs are also capable of "transdifferentiation" into ectodermal cells, such as neural cells^[20,21]. So MSCs are multipotential adult stem cells. Regarding hepatic differentiation of MSCs, there has been no specific report yet. Schwartz *et al.*^[7] isolated a non-hematopoietic stem cell subset (CD45⁻GlyA⁺ in humans or CD45⁻Ter119⁻ in mice) from bone marrow, termed multipotent adult progenitor cells (MAPCs). MAPCs should be ascribed to MSCs, since they were copurified with MSCs at the same time^[22]. Under serial conditions, Schwartz *et al.*^[7] induced MAPCs into cells with morphological, phenotypic, and functional characteristics of hepatocytes *in vitro*. In our study, we tried to induce standard MSCs into hepatocytes, and found hepatic specific gene CK18 was already expressed by MSCs without differentiation protocol. After induction, MSCs also expressed albumin besides CK18. Albumin mRNA appeared early on d 4 after differentiation (data not shown), coinciding with the change of morphology. Albumin signals had a gradual increase with the extension of differentiation time. Immunocytochemical staining confirmed the results of the PCR analysis at protein-level. There were no early markers of hepatocytes before or during differentiation protocol. Morphologic change of MSCs was apparent. Cell shape changed from spindle and fibroblast-like to round and epithelia-like.

HSCs are another subset of stem cells from bone marrow. A large number of papers demonstrated that HSCs could differentiate into hepatocytes or hepatocyte-like cells. Among the papers, CD34, the most general marker of HSCs in humans and mice, was used. Theise *et al.*^[2] reported 200 CD34⁺ marrow cells produced the same degree of hepatic engraftment as 20 000 unfractionated bone marrow cells in gender mismatch bone marrow transplantation model of mice. Human investigations with G-CSF mobilized CD34⁺ stem cells have shown that these cells were also able to transdifferentiate into hepatocytes^[23]. Thy1.1 antigen has been a well-accepted marker of rat HSCs since 1978^[24]. Recently, Avital *et al.*^[25] identified a population of bone marrow-derived hepatocyte stem cells in rats, which were beta 2 microglobulin-negative and Thy-1-positive (β_2m^- /Thy-1⁺). Moreover, according to Petersen *et al.*^[26], Thy-1 is a new marker for identification of hepatic oval cells. Using Thy-1 would facilitate both *in vivo* and *in vitro* studies of hepatic oval cells. There was no colony-formation in Thy-1.1⁻ bone marrow cells in our studies (data not shown). Thy-1.1⁻ cells did not express CK18 mRNA when freshly isolated, while Thy-1.1⁺ cells had a strong CK18 expression. During hepatic differentiation, Thy-1.1⁺ cells expressed AFP mRNA and had a weak albumin signal. Expression of CK18 of Thy-1.1⁺ cells continued. The cells were polygonal in shape, exhibiting epithelial morphology.

HSCs and MSCs are two separate stem cell subsets of bone marrow. They have different functions in hematopoiesis. Previous studies have explored the ability of hepatic differentiation of different subsets from bone marrow. However, what

relationship they have or what similarity or difference exists among the two subsets is unknown. Our study combined two subsets for the first time, and investigated their different abilities of hepatic differentiation simultaneously. Our results indicated that both of them had hepatic differentiation ability, however, they were different. MSCs could differentiate into mature hepatocyte-like cells, not expressing early hepatic specific genes. Under a similar induction condition, Thy-1.1⁺ cells were inclined to become hepatic stem cell-like cells, with a continuous AFP expression and weak albumin signal. To our interest, CK18 mRNA was positive in Thy-1.1⁺ cells and MSCs, negative in Thy-1.1⁻ cells. It seemed that CK18 had some relationship with Thy-1.1 antigen, and it would be an indicative marker of hepatic differentiation ability.

Hepatic stem cells, especially bone marrow-derived hepatic stem cells may be therapeutically useful for treating a variety of diseases that affect the liver. This has been proved in some animal models^[3,27]. Compared with other liver-related stem cells, such as embryonic stem cells^[28], pancreatic stem cells^[29], and neural stem cells^[30], bone marrow-derived stem cells provide several advantages: (1) Bone marrow can be obtained from living donors or recipients themselves using a moderately invasive procedure. There is no problem of limited donors, which restrict liver transplantation and hepatocyte transplantation greatly. (2) Based on its ability of high self-renewal, the amplification of bone marrow stem cells could be obtained. (3) Utilizing patients' own bone marrow or repopulation of both bone marrow and hepatic system from the same donor could avoid or reduce immunological rejection, which usually affects recipients for a life-long time.

Abstract

AIM: To inquire into the effects and mechanism of Zuogui Wan (Pills for Kidney Yin) on neurocyte apoptosis in nuclei of arcuate hypothalamus (ARN) of monosodium glutamate (MSG)-liver regeneration rats, and the mechanism of liver regeneration by using optic microscope, electron microscope and *in situ* end labeling technology to adjust nerve-endocrine-immunity network.

METHODS: Neurocyte apoptosis in ARN of the experiment rats was observed by using optic microscope, electron microscope and *in situ* end labeling technology. Expression of TGF- β_1 in ARN was observed by using immunohistochemistry method.

RESULTS: The expression of TGF- β_1 in rats of model group was increased with the increase of ARN neurocyte apoptosis index (AI) ($t = 8.3097, 12.9884, P < 0.01$). As compared with the rats of model group, the expression of TGF- β_1 in rats of Zuogui Wan treatment group was decreased with the significant decrease of ARN neurocyte apoptosis ($t = 4.5624, 11.1420, P < 0.01$).

CONCLUSION: Brain neurocyte calcium ion overexertion and TGF- β_1 protein participate in the adjustment and control of ARN neurocyte apoptosis in MSG-liver regeneration-rats. Zuogui Wan can prevent ARN neurocyte apoptosis of MSG-liver regeneration in rats by down-regulating the expression of TGF- β_1 , and influence liver regeneration through adjusting nerve-endocrine-immune network.

INTRODUCTION

MSG-liver regeneration rat model is very useful in study about the correlative mechanism of liver regeneration with high-grade nerve center, hypothalami-hypophysis-liver axial and nerve-endocrine-immune network (NEIN). Experiment results showed that the process of liver regeneration in MSG-liver regeneration rats was disproportional, liver regeneration was faster in the initial stage (the postoperative 1st d), significantly restrained in the intermediate and advanced periods, finally the degree of liver regeneration, meiosis index of liver cells (MI) and the ratio of liver mass to body mass all could not recover the normal level^[1-2], but the above mentioned indexes could be significantly improved after MSG-liver regeneration rats were treated with Zuogui Wan^[2-5]. Functional disorder of NEIN is probably one of the important mechanisms of serious imbalance of liver regenerative process. In order to research the effects of Zuogui Wan on neurocyte apoptosis of MSG-liver regeneration in rat hypothalamus and the mechanism to interfere with liver regeneration by adjusting nerve-endocrine-immunity network, we studied the apoptosis of neurocytes on experimental rats' nuclei of arcuate hypothalami (ARN) and the expression of apoptosis related gene TGF- β_1 with *in situ* end-labeling technique (ISEL), optic microscope, electronic microscope and immunohistochemical method.

MATERIALS AND METHODS

Materials

Wistar rats were offered by the Animal Laboratory, Academy of Medical Sciences of Hubei Province, YDZ19-008. Monosodium glutamate (MSG) was provided by Sigma Co. ISEL apoptosis test kit was from Boehringer Mannheim Co. Strept avidin-biotin complex (SABC) was used to detect the expression of TGF- β_1 by immunohistochemical method (Wuhan Boshide Limited Company).

Establishment of MSG-liver regeneration-rat model

Wistar rats were divided into two groups: Treatment group which was given monosodium glutamate dissolved in saline solution, the other group which served as control was given the vehicle only. MSG 4 mg/g.b.mb was injected on d 2, 4, 6, 8, and 10 after birth. On the 28th d, pups were weaned and caged in 8 groups (4 groups were male rats, 4 groups were female rats). The rats were maintained in an air-conditioned (temperature 24 \pm 1 °C) animal room with controlled lighting (12 h light, 12 h dark). They were provided with commercial diet and water. From the 6th week to the experiment end, treatment group rats were treated by gastrogavage of Zuogui Wan (Radix Rehmanniae Praeparata, Rhizoma Dioscoreae, Fructus Lycii, Fructus Corni, Semen Cuscutae, Radix Cyathulae, Colla Cornus Cervi, and Colla Plastris Testudinis) 5 g/kg^[1]. In the 8 wk, partial hepatectomy was performed by excision of the median and left hepatic lobes (occupying about 68% of whole liver) according to the method of Higgins and Anderson under pentobarbital anesthesia^[1]. Shamly-operated rats (MSG-rats) were anesthetized, and their

livers were exposed but not removed. All operations above were clean operations. Rats were operated and killed between 8 and 12 h a.m. to avoid the effects of diurnal variation. Rats subjected to partial hepatectomy were killed on the 1st, 3rd, 5th, 11th d after operation, and 6 were taken randomly in each group per batch (3 males and 3 females).

Neurocyte apoptosis observation

Using *in situ* end labeling (ISEL) method, the nuclei of positively apoptotic neurocytes were stained into blue purple, the starches of cells were intact. Each slice was randomly taken under five fields of vision, the positively stained area was surveyed, and the positive cell number was calculated on the unit area. Then five fields of vision were averaged to calculate the proportion of positive cells in the slice. The percentage of positive cells (apoptosis index, AI) was used to show the apoptosis degree in the tissue.

Pathology-histology observation

Hypothalamus tissue specimens were fixed in 10% formalin, embedded in paraffin, cut into 4 μ m thick sections, dewaxed and evaporated with routine procedures, stained with HE, observed with optic microscope. Hypothalamus specimens were embedded and sliced for observation under electron microscope (using ultramicrotome of AO type) and transmission electron microscope (EM10C, Germany OPTON).

Immunohistochemistry

We used SABC method. The cerebral nerve cells showing brown, homogeneous or fine grains were positive. These fine grains distributed all over the cell membranes and cytoplasm,

mainly in cell membranes. Five visual fields were taken randomly in each microsection, then the number of stained areas was surveyed and the number of positive cells was calculated according to the total count of cells in unit area. Finally, the number of positive cells in five visual fields was averaged, and the proportion of positive cells in the microsection was obtained. The percentage of positive cells was used to show the content of fine grains in the tissue.

Statistical analysis

The experimental data were statistically analyzed with HPIAS-1000 high acuity colored pathology image measurement system and Microsoft's Excel.

RESULTS

Effect of Zuogui Wan on MSG-liver regeneration rat hypothalamus pathology-histology alteration

Under light microscope, the neurocytes in arcuatus hypothalami (ARN) of MSG-liver regeneration rats reduced significantly and astrocytes increased significantly. Under electron microscope, neurocyte nucleus chromatin collected at the edge was stained deeply, and nuclear membrane was not regular, cytoplasm was concentrated. Neurocyte nucleus shape factor (approach 1 was regular, and >1 was not regular), circularity (approach 1 was round, and <1 was not round) and heteromorphic index (approach 3 was low for the heterotype degree, >3 was high for the heterotype degree) had significant differences ($P<0.05$). Pathological changes in Zuogui Wan treatment group were distinguished (Table 1, Figure1).

Figure 1 Effect of Zuogui Wan on alteration, apoptosis and TGF- β_1 expression in ARN of MSG-liver regeneration rats. A, B: Effect of Zuogui Wan on alteration in ARN of MSG-liver regeneration rats. C, D: Effect of Zuogui Wan on apoptosis in ARN of MSG-liver regeneration rats. E, F: Effect of Zuogui Wan on TGF- β_1 expression in ARN of MSG-liver regeneration rats.

Table 1 Effect of Zuogui Wan on alterations of ARN nuclei in MSG-liver regeneration rat on the postoperative 11th d ($n = 10$, mean \pm SD)

Group	Shape factor	Circular degree	Heteromorphic index
Normal saline	1.14 \pm 0.45	0.88 \pm 0.16	3.80 \pm 0.8
Model	3.10 \pm 1.14 ^b	0.32 \pm 0.17 ^b	6.24 \pm 1.83 ^b
Zuogui Wan	1.68 \pm 0.33 ^d	0.60 \pm 0.32 ^a	4.60 \pm 0.74 ^a

¹ $t = 5.0572, 7.5856, 3.8633$, ^b $P < 0.01$ vs control (Normal saline); ² $t = 2.4436, 2.6273$, ^a $P < 0.05$, ³ $t = 3.7836$, ^d $P < 0.01$ vs model.

Effect of Zuogui Wan on apoptosis index of MSG-liver regeneration rats in ARN

Apoptosis index (AI) of MSG-liver regeneration rats in ARN was higher than that of saline treated and shamly-operated MSG-rats, and the difference was significant ($P < 0.01$ or $P < 0.05$). AI of Zuogui Wan treated group reduced significantly on the postoperative 5th and 11th days compared to model group ($P < 0.01$) (Table 2).

Table 2 Effect of Zuogui Wan on ARN neurocyte apoptosis in MSG-liver regeneration rats (positive cells %, $n = 6$, mean \pm SD)

Group	Postoperative 1 st d	Postoperative 5 th d	Postoperative 11 th d
Normal saline	0.07 \pm 0.08	0.08 \pm 0.04	0.09 \pm 0.03
MSG-rats	2.45 \pm 0.32 ^d	2.32 \pm 0.45 ^d	2.56 \pm 0.59 ^d
Model	2.62 \pm 0.72 ^d	3.32 \pm 0.81 ^{ad}	4.23 \pm 1.22 ^{ad}
Zuogui Wan	1.62 \pm 0.65	1.43 \pm 0.75 ^f	1.12 \pm 1.14 ^f

¹ $t = 2.6435, 3.0185$, ^a $P < 0.05$ vs MSG-rats; ² $t = 17.6741, 12.1451, 10.2414, 8.6222, 9.7860, 8.3097$, ^d $P < 0.01$ vs control (Normal saline); ³ $t = 4.1938, 4.5624$, ^f $P < 0.01$ vs Model.

Effect of Zuogui Wan on expression of TGF- β_1 in ARN of MSG-liver regeneration rats

Results indicated that, the expression of TGF- β_1 in ARN of MSG-liver regeneration rats was significantly higher than that in saline control group and shamly-operated group (MSG-rats) ($P < 0.01$). Along with increased apoptotic index (AI) in ARN neurocytes, the expression of TGF- β_1 improved correspondingly, namely, the more the TGF- β_1 expressed, the larger the AI was. Besides, along with the weakened expression of TGF- β_1 , AI of ARN in Zuogui Wan treatment group decreased significantly ($P < 0.01$, Table 3).

DISCUSSION

Some studies found that neonate rats who were given high dose MSG on the 2nd, 4th, 6th, 8th, 10th days could destroy nucleus arcuatus hypothalami (ARN) selectively, and swelling and necrosis in ARN neurocytes were the main pathological lesions, and its mechanism in nervous poison might be concerned with the overexertion of calcium ions in cerebral neurocytes^[6-11]. Our experiment results showed that MSG could induce neurocyte apoptosis in the intermediate and advanced stage

after rats were injected with MSG, leading to acute swelling and necrosis in ARN neurocytes. We also could find apoptosis in cerebral neurocytes under electron microscopy and the number of apoptotic cells in model group is larger than that in control group, 8-10 wk after hypodermic injection of MSG. Furthermore, the shape factor, circularity and heteromorphic index that reflected the changes of neurocyte nuclei in ARN were different compared with saline control group. Quantitating apoptotic neurocytes in cerebra by *in situ* end-labeling technique also showed that cerebral IA was larger than that of control group. In ordinary physiological state, most neurons can survive all the life and do not renew, therefore, apoptosis can seldom be found. As a common secondary messenger of apoptosis, MSG could lead to overexertion of calcium ions in neuron cytoplasm, which may be one of the mechanisms underlying apoptosis in MSG-rats' and MSG-liver regeneration-rats' cerebral neurocytes. But the phenomenon that cerebral neurocyte apoptosis of MSG-liver regeneration rats was more conspicuous than that of MSG-rat group can not be explained completely with the mechanism, i.e. MSG leading to overexertion of calcium ions in neuron cytoplasm could induce neurocyte apoptosis. These studies showed that it probably involved other factors leading to cerebral neurocyte apoptosis, besides overexertion of calcium ions in neuron cytoplasm induced by MSG^[4].

TGF- β_1 can enhance apoptosis, so the considerable expression of TGF- β_1 is an important signal that apoptosis takes place. TGF- β_1 expressed excessively in cerebral neurocytes of MSG-liver regeneration rats, and the quantity was larger than that in MSG-rat group and saline control group, and the differences were significant^[12-22]. That overexertion of calcium ions in cerebral neurocytes induced by MSG and the considerable expression of TGF- β_1 induced by partial hepatectomy in ARN of MSG-liver regeneration rats hint that both of them have synergistic effects on inducing MSG-liver regeneration-rat cerebral neurocyte apoptosis. AI of MSG-liver regeneration rat cerebular neurocytes is closely correlated with considerable expression of TGF- β_1 . Neurocyte apoptosis in ARN of MSG-liver regeneration rats is one of the important mechanisms of functional disorder in nerve-endocrine-immune network. TGF- β_1 protein could participate in the regulation of neurocyte apoptosis in ARN of MSG-liver regeneration rats^[2-5].

One of the major research achievements of the kidney's essence is deficiency of kidney-yang in hypothalamus, and deficiency of kidney-yang is closely correlated with functional disorder in nerve-endocrine-immune network^[23-30]. Our results showed that deficiency of kidney-yin was located in hypothalamus also^[2-5,27], and neurocyte apoptosis in ARN of MSG-liver regeneration rats significantly lessened and indexes such as shape factor, circularity, heteromorphism which reflect the changes of ARN neurocyte nuclei improved significantly by replenishing kidney-yin with Zuogui Wan. Meanwhile, its expression of TGF- β_1 was also less than that in model group.

In summary, Zuogui Wan could prevent cerebral neurocyte apoptosis MSG-liver regeneration rats and down-regulate the overexpression of TGF- β_1 and its acceptors. Thus Zuogui Wan

Abstract

AIM: To construct pEGFP-hepatocyte growth factor (HGF) expression vector, to detect its expression in transfected human hepatocytes, and to investigate the influence of autocrine HGF expression on the proliferative potential and cytoprotective effects in human hepatocytes.

METHODS: Human HGF cDNA was ligated to the pEGFP vector. Recombinant plasmid was transfected into human hepatocyte line QZG with liposome. Expression of HGF protein was observed by fluorescence microscopy and immunohistochemistry. Hepatic cells were collected 24, 48, and 72 h after transfection to detect the number of [³H]-TdR uptake in DNA. DNA synthesis was observed by using PCNA stain immunohistochemistry. Acute liver cell damage was induced by carbon tetrachloride. Cytoprotective effect was observed by examining the survival rate of hepatocytes and leakage of intracellular alanine transaminase (ALT) and potassium ions.

RESULTS: HGF identification of pEGFP-HGF by enzyme digestion showed that HGF fragment was cloned into *Bam*H I and *Sal*I sites of pEGFP-N3. Expression of GFP in transfected hepatocytes was observed with fluorescence microscopy. The [³H]-TdR uptake became 7 times as many as in the control group 96 h after transfection. After HGF transfection, the survival rate of hepatocytes poisoned by CCl₄ significantly increased (83% vs 61%, *P* < 0.05), and the leakage of intracellular alanine transaminase and potassium ions decreased (586 nkat/L vs 1089 nkat/L, *P* < 0.01; and 5.59 mmol/L vs 6.02 mmol/L, *P* < 0.01 respectively). Culture of transfected hepatic cells promoted the proliferation of other non-transfected cells.

CONCLUSION: Transfected HGF is expressed in hepatic cells and has the activity of promoting cell division and protecting hepatic cells against poisoning.

INTRODUCTION

Hepatocyte growth factor (HGF) was originally isolated as the most potent mitogen for primary hepatocytes. HGF has subsequently been revealed to be a multifunctional cytokine in a wide variety of epithelial cells, endothelial cells, and some mesenchymal cells during the past two decades^[1-7]. In addition to mitogenic activity, HGF has some unique morphogenic activities such as an induction of epithelial tubulogenesis including in cells derived from the kidney, liver and mammary gland^[8,9]. Characterization of scatter factor, which enhances epithelial cell motility, revealed that it had the same molecule as HGF. HGF is a heterodimeric glycoprotein composed of a 69 ku α -chain and a 34 ku β -chain, and has four homologous kringle domains in the α -chain^[10]. The receptor capable of signal transduction of HGF is a c-met protooncogene product of heterodimeric tyrosine kinase^[11,12]. Extensive studies on the physiological function of HGF have established that the growth factor functions as a potent hepatotrophic factor for liver injuries, but elevated plasma HGF levels have not been noted in patients with hepatic diseases^[13-19].

HGF and its receptor MET, ordinarily constitute a paracrine signaling system in which cells of mesenchymal origin produce the ligand (HGF) which binds to its receptor (MET) that is predominantly expressed in cells of epithelial origin^[10]. While the effects of exogenous HGF on promoting normal hepatocyte growth have been well characterized, there appears to have a controversy on effect of autocrine HGF on hepatocytes. In this study, the effects of forced autocrine expression of HGF in hepatocytes were examined. huHGF was expressed by transducing hepatocytes with a vector containing huHGF cDNA. It was demonstrated that the forced expression of HGF in hepatocytes led to an increase in the population of transduced hepatocytes compared to non-transduced hepatocytes in the same cultures. The results suggest that autocrine expression presents an advantage for the proliferation and survival of hepatocytes poisoning.

MATERIALS AND METHODS

Materials

PBS-7 vector containing human HGF cDNA was donated by Professor Toshikazu Nakamura (Division of Biochemistry, Osaka University Medical School, Japan). The transfer vector pEGFPN₃ containing a humanized green fluorescence protein (GFP) cDNA was purchased from Clontech Biology Company (USA).

Culture of hepatocytes

Human hepatocyte QZG (donated by the Department of Pathology, Fourth Military Medical University) was cultured in RPMI 1640 medium (Gibco) supplemented with 150 mL/L fetal bovine serum (100 kU/L penicillin, 100 kU/L streptomycin) and incubated at 37 °C in humidified atmosphere of 50 mL/L CO₂ incubator.

Construction of pEGFP-HGF vectors

Construction of pEGFP-HGF vector was previously described^[20]. The human HGF cDNA was isolated from pBluescript SK⁺ as a 2.3 kb *Bam*H I-*Sal*I fragment. The resulting cDNA fragment

was then inserted into the *Sal* I and *Bam*HI-sites of the pEGFP-N₃ vector.

Transduction of rat hepatocytes

Exponentially growing QZG cells were seeded into 35 mm tissue culture dishes and grown to 60-70% confluency in culture medium. Each culture dish was then transfected with 5 µg pEGFP-HGF constructs by using lipofectamine according to the instructions of the manufacturer (Gibco BRL, Eggenstein, Germany). Encapsulated pEGFP-HGF was incubated for 5 h on cells in serum free medium, then in medium containing 15 mL/L bovine serum. After a further incubation of the cells for 24 h, the culture medium was discarded and replaced by normal culture medium. Seventy-two hours after transfection, the QZG cells and their media were harvested for further analysis.

Analysis for HGF expression in hepatocyte

After transfected with pEGFP-HGF, the cells were examined for the presence of green fluorescence by using an inverted fluorescent light microscope. Immunocytochemical staining was performed by using HGF antibody on logarithmically growing cell lines. Firstly, the cells were plated onto coverslips, adhered overnight. Then, after rinsed three times with PBS, the cells were fixed in cold acetone for 8-10 min. Endogenous peroxidase was blocked with 10 mL/L hydrogen peroxide in absolute methanol for 30 min. The primary antibodies were applied for 2 h at 37 °C at 1:50 dilution in a humidified chamber. Then the typical SABC strategy followed.

Assay of DNA synthesis by ³H-TdR incorporation

The cells were cultured in an appropriate medium for 24 h prior to beginning the experiment, and incubated with [³H] thymidine (18.5 MBq/L, 37 kBq/well). After 6 h the cells were harvested with trypsin/EDTA, and collected from the acetic fiber filter with a cellular collector and washed three times with PBS. The filter was dried overnight at 37 °C, and transferred into a liquid scintillation counter (containing 10 g/L PO and 20 g/L POP in xylene) and cpm value was determined by the liquid scintillation counter (LS6500, Beckmen Co.)

Cell proliferation

The level of expression of proliferating cell nuclear antigen (PCNA) was used as a marker of cell proliferation. In the present study PCNA was measured by ABC immunohistochemical method.

Cytoprotective effects on CCl₄-intoxicated human hepatocytes

For assaying cytoprotective effect of autocrine HGF, hepatocyte QZG was poisoned by carbon tetrachloride (CCl₄). After treated with 15 mmol/L CCl₄ for 40 min, survival rate of cells was measured by trypan blue method. Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) in supernatant were measured by using a biochemical analyzer. Leakage of intracellular potassium ions was measured by using an ion analyzer.

In situ hybridisation

This was performed as previously described. Hepatocytes were transduced with pEGFP-HGF, trypsinized after 48 h and centrifuged onto slides (roughly 40 000 cells/cm²). These slides were used for *in situ* hybridization. Results were evaluated by counting at least 3 viewing fields per slide at a magnification ×200.

Statistical analysis

The results are expressed as mean±SE. Statistical analysis was performed by the Student's *t*-test. *P*<0.05 was considered statistically significant.

RESULTS

Identification of recombinant pEGFP-HGF expression vector

The recombinant pEGFP-HGF vector was digested by *Bam*HI and *Sal* I. pEGFP-HGF contained a 2300-bp and a 4700-kb gene fragments separated by electrophoresis in 12 g/L agarose gel (Figure 1). It proved that the HGF gene was correctly inserted in pEGFP-HGF.

Figure 1 Identification of recombinant plasmids digested with restriction enzymes *Bam*HI and *Sal* I. 1, 4, 5: pEGFP-HGF plasmid digested with *Bam*HI and *Sal* I; 2: pBS-7 plasmid digested with *Bam*HI+*Sal* I; 3: λDNA/*Hind*III marker.

Figure 2 Green fluorescence in QZG cells transfected with pEGFP-HGF fusion constructs, Inverted fluorescent light microscope ×200.

Figure 3 Expression of HGF protein in QZG cells transfected with pEGFP-HGF. SABC ×400.

Expression of pEGFP-HGF fusion proteins in QZG cell line

Green fluorescence was visible after transfection with pEGFP-HGF fusion constructs (Figure 2). The pEGFP-HGF fusion proteins were localized primarily in cytoplasm. The expression of HGF in the transfected QZG cells was also detected by immunohistochemical staining. A lot of brown granules were seen in HGF transfected QZG cell cytoplasm (Figure 3) proving that HGF gene could be expressed in QZG cells.

Effect on DNA synthesis

DNA synthesis as mirrored by [³H]thymidine uptake of QZG cells was determined after transfection with pEGFP-HGF. DNA synthesis in QZG cells transfected by pEGFP-HGF was accelerated

in a time-dependent fashion increased by 7-fold compared to control group after 96 h transfection with pEGFP-HGF (Figure 4).

Cell proliferation

As shown in Figure 5, the expression rate of PCNA on QZG cells increased after transfection with pEGFP-HGF.

Figure 4 Relative values of ³H-TdR incorporation in QZG cells transfected with pEGFP-HGF (relative to QZG cells transfected with pEGFP).

Figure 5 Expression of PCNA protein in QZG cells transfected with pEGFP-HGF (A) and transfected with pEGFP (B). $\times 200$.

Table 1 Survival rate of hepatocytes and leakage of intracellular ALT and K⁺

Group	Survival rate (%)	ALT (nkat/L)	K ⁺ (mmol/L)
QZG	96 \pm 2	403 \pm 70	5.21 \pm 0.04
pEGFP-HGF	98 \pm 1	429 \pm 80	5.18 \pm 0.02
QZG intoxicated by CCL ₄	61 \pm 7 ^a	1 089 \pm 223 ^b	6.02 \pm 0.17 ^b
pEGFP-HGF intoxicated by CCL ₄	83 \pm 6 ^c	586 \pm 124 ^d	5.59 \pm 0.07 ^d

^a $P < 0.05$, ^b $P < 0.01$, vs QZG group; ^c $P < 0.05$, ^d $P < 0.01$, vs QZG intoxicated by CCL₄ group.

Cytoprotective effect on hepatocytes injured by CCL₄

After pEGFP-HGF was transfected, the survival rate of QZG cells intoxicated by CCL₄ was significantly increased (83% vs 61%, $t = 3.89$, $P < 0.05$). The leakage of intracellular alanine transaminase (ALT) (586 nkat/L vs 1 089 nkat/L, $t = 13.07$, $P < 0.01$) and potassium ions (5.59 mmol/L vs 6.02 mmol/L, $t = 12.91$, $P < 0.01$) was decreased (Table 1).

DISCUSSION

Hepatocyte growth factor (HGF) is well known as a pleiotropic substance with mitogenic, motogenic, morphogenic, and tumor suppressor activities. HGF was found in the serum of partially hepatectomized rat and in rat platelets as the most potent stimulator of hepatocyte growth and DNA synthesis *in vitro*^[21]. The mitogenic function of HGF was confirmed *in vivo*. In normal rats as well as partially hepatectomized rats, infusion of HGF stimulated a 6-fold increase in the mitotic labeling index of hepatocytes. It also stimulated protein synthesis, seen as increased hepatic messenger RNA content and serum albumin levels. HGF has been intensively investigated in terms of its beneficial effects on hepatic injury^[22-24]. It has been documented that HGF reduced the hepatotoxicity of alpha-naphthylisothiocyanate, D-galactosamine, and carbon tetrachloride in rats^[25,26]. Moreover, HGF increased survival of cirrhotic rats subjected to a major hepatic resection and treatment with dimethylnitrosamine^[27-29]. These results suggest that HGF may play important roles in protection from and regeneration of hepatic injury and serve as a therapeutic agent.

HGF and its receptor MET, ordinarily constitute a paracrine signaling system in which cells of mesenchymal origin produce the ligand (HGF) which binds to its receptor (MET) that is predominantly expressed in cells of epithelial origin. In the present study, we demonstrated that HGF gene transfer into hepatocytes caused increased proliferation of hepatocytes by method of PCNA stain and increased DNA synthesis by method of [³H]thymidine uptake. Forced HGF expression by cultured human hepatocytes had a mitogenic effect. The detection of HGF protein assessed by immunocytochemical staining confirmed the successful transfection of HGF gene.

Accumulated evidence has revealed that HGF has a cytoprotective effect on various types of liver cells. In hepatocytes, HGF attenuated the liver injury induced by lipopolysaccharide and D-galactosamine^[30]. Moreover, HGF abrogated Fas-induced massive liver apoptosis and lethal hepatic failure by inducing Bcl-xL expression, with subsequent blockage of a Fas-mediated signaling pathway upstream of CPP32 in the liver, suggesting that HGF has an inhibitory effect on Fas-mediated apoptosis. HGF could also ameliorate hepatocellular dysfunction and posthepatectomy hyperbilirubinemia in an α -naphthylisothiocyanate-induced cholestasis model, in which the epithelia of bile ducts, as well as hepatocytes, became necrotic. This finding indicates that HGF could promote tissue repair of both epithelial cells and hepatocytes^[31,32]. In the present study we demonstrated the cytoprotective effect of HGF transgene on hepatocyte injury by CCL₄. HGF transgene markedly increased the survival rate of hepatocytes against CCL₄ injury, decreased the leakage of intracellular alanine transaminase and potassium ions.

Since its introduction into cell biological research, the green fluorescent protein (GFP) of jellyfish *Aequorea victoria* has become a versatile tool for the analysis of protein function and dynamics at the cellular level. GFP, consisting of 238 amino acids, has been used as a tag for localization of a broad range of proteins in a wide variety of eukaryotic cells. A mutant of GFP, S65T with an excitation peak of 489 nm and an emission peak of 511 nm, could emit 4 to 6 times more fluorescence energy compared with wild-type GFP. GFP may be fused generically to

a target protein, and the fluorophore of GFP forms spontaneously in the presence of oxygen, thus rendering it an ideal probe for *in vivo* applications. The *in vivo* expression of GFP could obviate the fixation and permeabilization of cells for immunofluorescence or the microinjection of labeled proteins. GFP fusion proteins constitute a major advance in the study of the dynamics of intracellular processes in living cells^[33-37]. A major concern in the application of GFP as a fluorescent tag relates to whether the distribution of GFP fluorescence is identical to that of the protein to which it is fused. We have constructed GFP-HGF fusion gene and transfected into hepatocytes. The results indicate that the fusion protein can still be expressed in the nuclei of hepatocytes. Because liver disease, especially viral liver diseases are common in China, our study is of much more significance.

Abstract

AIM: To investigate the effects of herbal compound 861 (Cpd 861) on cell proliferation in human hepatic stellate cells (LX-2) and human hepatocellular liver carcinoma cells (HepG2), and expression of α -smooth muscle actin (α -SMA) in LX-2 cells.

METHODS: LX-2 and HepG2 cells were incubated with various concentrations of Cpd 861 (0.1-0.003 mg/mL) for 1, 2, 3, 5 and 7 d. Cell proliferation was analyzed by 3-(4, 5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium (MTS) assay. Effects of Cpd861 on the expression of α -SMA mRNA in LX-2 cells were measured by real-time quantitative PCR method using SYBR Green I technology.

RESULTS: Cpd 861, at 0.1 mg/mL, significantly inhibited LX-2 cell proliferation (15% decrease relative to control, $P<0.05$) after 3 d of incubation. The inhibitory effects seemed to increase with the treatment time (25% decrease after 5 d of incubation and 35% decrease after 7 d of incubation, $P<0.01$). However, Cpd 861 did not affect HepG2 cell proliferation at the same concentration used for LX-2 cells. The expression levels of α -SMA mRNA decreased significantly when LX-2 cells were exposed to Cpd 861 for 48 h (59% decrease relative to control, $P<0.05$) or 72 h (60% decrease relative to control, $P<0.01$).

CONCLUSION: Cpd 861 can significantly inhibit LX-2 cell proliferation in a dose-dependant manner, and reduce the expression levels of α -SMA mRNA in LX-2 cells. Since hepatic cell proliferation and high level of α -SMA are associated with liver fibrosis, the results suggest that Cpd 861 may be useful in the treatment of this disease.

INTRODUCTION

Hepatic fibrosis is a reversible wound healing response to chronic liver injury due to a variety of insults, including viral hepatitis (especially hepatitis B and C), alcohol abuse, drugs, metabolic diseases, autoimmune attack of hepatocytes or congenital abnormalities^[1,2]. As shown in many recent studies, hepatic stellate cells (previously called Ito cells, lipocytes, perisinusoidal cells, or fat-storing cells) are primary cell types to mediate fibrogenesis^[1,2]. In normal liver, hepatic stellate cells (HSCs) are nonparenchymal quiescent cells with functions to store vitamin A. Following liver injury of any etiology, HSCs undergo a process of activation, transform from quiescent vitamin A-rich cells to proliferative, fibrogenic, contractile myofibroblasts. Activated HSCs lose lipid droplets, feature high level expression of α -smooth muscle actin (α -SMA), and also are responsible for the deposition of the majority of excess extracellular matrix (ECM, predominantly types I and III collagen), which leads to form action of scar tissue in the fibrotic liver^[1-4].

Herbal compound 861 (Cpd 861) is an extract of 10 herbs with *Salvia miltiorrhiza*, *Astragalus membranaceus* and *Spatholobus suberectus* as its chief components. The recipe of this mixed compound was based on the therapeutically indications of Chinese medicine. Clinical studies showed Cpd 861 could significantly improve clinical symptoms in hepatic fibrosis patients as well as the biochemical parameters associated with diseases in clinical tests for patients^[5,6]. Experimental researches also showed that Cpd 861 could inhibit cell proliferation, reduce the level of α -SMA and reverse the process of liver fibrosis on rat model^[5-7]. In this study, we aimed to investigate the effects of Cpd 861 on LX-2 and HepG2 cell proliferation and expression of α -SMA in LX-2 cells.

MATERIALS AND METHODS

Materials

Human activated hepatic stellate cell line LX-2 was a gift from Dr. Friedman of Mount Sinai School of Medicine. LX-2 cells were a low-passaged human cell line from normal human stellate cells that were spontaneously immortalized^[8,9]. The cells exhibited typical features of stellate cells and expressed α -SMA under all culture conditions and were regarded as at least partially activated even after immediate replating. LX-2 cells underwent further activation during growth and expansion on plastic surfaces^[8].

Human hepatocellular carcinoma cell line HepG2 was purchased from the Chinese Academy of Medical Sciences (Beijing, China). Dulbecco's modified Eagle's medium (DMEM), L-glutamine and streptomycin were purchased from Gibco, Invitrogen, Carlsbad, CA. Fetal bovine serum (FBS) was from Hyclone, USA. Penicillin and phenazine methosulfate (PMS) were from Sigma, USA. MTS and oligo (dT)₁₅ primers were acquired from Promega, USA. TRIzol reagent and Moloney murine leukemia virus reverse transcriptase (M-MLV RT) were the products of Invitrogen, CA. SYBR Green I was purchased from OPE Technology Development Company, Shanghai, China. Hotstar Taq DNA polymerase was purchased from TW-Biotech, China.

Cell culture and cell proliferation assay

LX-2 cells were cultured in DMEM supplemented with 50 mL/L heat-inactivated FBS, 200 mmol/L *L*-glutamine, 100 U/mL penicillin and 100 µg/mL streptomycin. HepG2 cells were cultured in DMEM containing 100 mL/L FBS, 200 mmol/L *L*-glutamine, 100 U/mL penicillin and 100 µg/mL streptomycin.

MTS assay was used to determine the effect of Cpd 861 on the proliferation of LX-2 and HepG2 cells. In metabolically active cells, MTS was reduced by dehydrogenase enzymes into an aqueous, soluble formazan product. The absorbance was measured directly at 490 nm from 96-well assay plates without additional processing. The quantity of formazan was considered to be directly proportional to the number of viable cells in the culture^[10,11].

LX-2 and HepG2 cells were seeded into 96-well tissue culture plates containing 100 µL DMEM containing 50 mL/L FBS (5000 LX-2 cells/well and 8000 HepG2 cells/well). After 24 h of incubation (37 °C, 50 mL/L CO₂), the medium was carefully removed and 100 µL fresh medium containing various concentrations of Cpd 861 was added into the wells. The cells were treated continuously with Cpd 861 for 1, 2, 3, 5 and 7 d and the medium containing Cpd 861 was changed every other day. At the end of experiments, 20 µL/well of combined MTS/PMS solution was added. After 3 h of incubation at 37 °C in a humidified incubator, the absorbance was analyzed on a VERSAmax microplate reader at 490 nm. Absorbance values were the mean±SE of 3 replicates for each treatment. The cells in only controls and compound controls were included.

RNA isolation and reverse transcription

LX-2 cells were seeded into 60 mm dishes in DMEM containing 50 mL/L FBS. After 3 d of seeding, the medium was carefully removed and fresh medium containing Cpd 861 (0.01 mg/mL) was added. After 24, 48 and 72 h of Cpd 861 treatment, total RNA was extracted from LX-2 cells using TRIzol reagent as the lysis buffer. Complementary DNA (cDNA) was synthesized using oligo (dT)₁₅ primers and M-MLV RT.

Real-time quantitative PCR using SYBR Green I

After the reverse-transcription reaction, cDNA templates were amplified by quantitative real-time PCR. The reaction was performed using the iCycler iQ real-time PCR detection system (Bio-Rad, USA) with SYBR Green I. Human α-SMA and G3PDH (glyceraldehyde-3-phosphate dehydrogenase) primers were designed using Primer 3 software (Table 1).

Each experiment was performed in 25 µL of reaction volume [1.25 µL of 20× SYBR Green, 1 µL of first strand cDNA (50 ng RNA), 2 µL of each 5 nmolar primer, 0.75 U Hotstar Taq DNA polymerase, 2.5 µL of 10× amplification buffer (Mg⁺⁺ free), 2.5 µL of 25 mmol/L MgCl₂, 0.5 µL of 10 mmol/L

solution of four dNTP and 15.1 µL of dH₂O]. In the last tube, 1 µL of ddH₂O was added as a non-template control. The conditions of amplification cycles were as follows: 40 cycles consisting of denaturation at 95 °C for 40 s, annealing at 59 °C (for α-SMA) or at 60 °C (for G3PDH) for 40 s, and extension at 72 °C for 30 s.

The iCycler apparatus was used to measure the fluorescence of each sample in every cycle at the end of the extension^[12]. A series of consecutive 10 fold dilution of α-SMA and G3PDH plasmid DNA ranging from 10⁹ copies/µL to 10³ copies/µL were used as the templates for the standard curves. The iCycler software was used to construct the calibration curve by plotting the Ct (threshold cycle) vs the logarithm of the number of copies for each calibrator. The number of copies in unknown samples was calculated by comparing their Ct's with the standard calibration curve. The quality and quantities of samples were normalized based on that of G3PDH.

After PCR, a melting curve was obtained by increasing the temperature from 55 °C to 95 °C with a temperature transition rate of 0.1 °C/s. The melting curves of all final PCR products were analyzed. The differences in melting temperature of PCR products allowed us to distinguish genuine products from nonspecific products, and primer dimers. To ensure that the correct product was amplified in the reaction, all samples were also separated on 20 g/L agarose gel electrophoresis. All PCR conditions and primers were optimized to produce a single product of the correct basepair size.

Table 1 Oligonucleotide PCR primers for human α-SMA and G3PDH

Oligonucleotide	Oligonucleotide primer sequence	Fragment size

Statistical analysis

Data were expressed as mean±SE. Statistical analysis was performed using GraphPad Prism (version 3.0) software. The *t* test was used for comparison between the groups. *P*<0.05 was considered statistically significant.

RESULTS

Cell proliferation assay

We examined the effects of Cpd 861 on the proliferation of LX-2 and HepG2 cells (Figures 1, 2). Cells were incubated

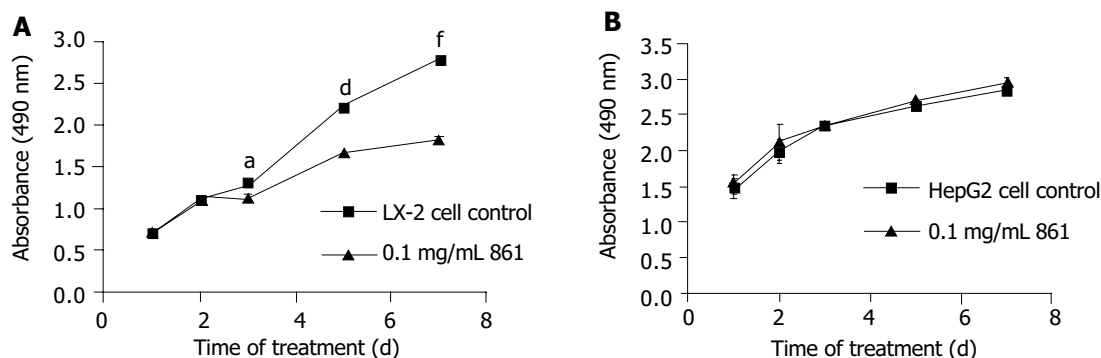

Figure 1 Regulation of proliferation in LX-2 and HepG2 cells by Cpd 861. A: Effect of 0.1 mg/mL Cpd 861 on LX-2 cell proliferation. B: Effect of 0.1 mg/mL Cpd 861 on HepG2 cell proliferation. Data are expressed as the mean±SE of 3 replicates. ^a*P*<0.05 vs LX-2 cell controls after 3 d of incubation. ^d*P*<0.01 vs LX-2 cell controls after 5 d of incubation. ^f*P*<0.01 vs LX-2 cell controls after 7 d of incubation.

with 0.1 mg/mL, 0.03 mg/mL, 0.01 mg/mL and 0.003 mg/mL of Cpd 861 for different days (Figure 1). Cell proliferation was performed by MTS assay. As shown in Figure 2, the effects of Cpd 861 on LX-2 cell proliferation seemed to be correlated with the dose. A significant proliferation inhibition was observed when Cpd 861 concentration was over 0.03 mg/mL (Figure 2). As shown in Figure 1A, 0.1 mg/mL Cpd 861 significantly inhibited LX-2 cell proliferation (15% decrease relative to control, $P < 0.05$) after 3 d of incubation. The inhibition effects seemed to increase with the treatment time (25% decrease after 5 d of incubation and 35% decrease after 7 d of incubation, $P < 0.01$). The inhibition of cell proliferation Cpd 861 at 0.03 mg/mL concentration was also observed on d 3 (15% decrease relative to control) and on d 5 (21% decrease relative to control) (data not shown), and still could be observed on d 7 (18% decrease relative to control) (Figure 2). However, Cpd 861, at 0.01 mg/mL and 0.003 mg/mL concentrations, did not inhibit LX-2 proliferation evidently. The effects of Cpd 861 on LX-2 cell proliferation seemed low at early time points (on day 1 and day 2). We also examined the effects of Cpd 861 on the proliferation of HepG2 cells. As shown in Figures 1B and 2, Cpd 861 did not affect HepG2 cell proliferation.

Figure 2 Dose dependent effects of Cpd 861 on cell proliferation in LX-2 and HepG2 7 d after incubation. Data are expressed as the mean \pm SE of 3 replicates. ^b $P < 0.01$ vs LX-2 cell controls.

Quantification of expression of α -SMA mRNA in Cpd 861-treated LX-2 cells

We examined the effect of Cpd 861 on the expression of α -SMA, a phenotypic marker of activated HSCs. The PCR amp/cycle graph and standard curve graph of α -SMA are shown in Figure 3. The standard curve showed a correlation coefficient

Figure 3 Fluorescence data (A) and standard curve (B) for α -SMA generated on iCycler iQ real-time PCR detection system. Plasmids containing the fragments for α -SMA were diluted from 10^9 to 10^3 copies.

Figure 4 Melting curve for all PCR products after amplification.

>0.99, indicating a precise log-linear relationship. As shown in melt curve graph (Figure 4), single and sharply defined melting curves with narrow peaks were obtained for PCR products of α -SMA gene. Bands visible after electrophoresis on 2% agarose gel and ethidium bromide staining correlated well with the quantitative PCR results. As shown in Figure 5, Cpd 861 could reduce the expression levels of α -SMA in LX-2 cells after treatment. When LX-2 cells were exposed to Cpd 861 for 48 or 72 h, the expression levels of α -SMA decreased significantly (59% decrease relative to control at 48 h, $P<0.05$, and 60% decrease relative to control at 72 h, $P<0.01$) (Figure 5).

Figure 5 Effects of Cpd 861 on expression of α -SMA mRNA in LX-2 cells. LX-2 cells were incubated with 0.01 mg/mL Cpd 861 for different time. The relative number of molecules of α -SMA mRNA after normalization to G3PDH was calculated. The data represent mean \pm SE of 4 replicates for each treatment. ^a $P<0.05$ vs LX-2 cell controls after 48 h of incubation. ^d $P<0.01$ vs LX-2 cell controls after 72 h of incubation.

DISCUSSION

In the liver, activated stellate cells are the key mediators of fibrosis^[4]. During hepatic fibrogenesis, HSCs undergo an activation process, becoming highly proliferative and α -SMA positive myofibroblast-like cells.

Cpd 861 is an effective herbal compound for treatment of patients with hepatic fibrosis^[5]. Its function to effectively reverse hepatic fibrosis has been confirmed by liver biopsies^[5-7]. In other studies, data showed that Cpd 861 also could suppress inflammation and fibrogenesis of the liver tissue^[7, 13, 14] and reduce expression of collagens and fibrosis related cytokines^[14-19]. It could also inhibit rat hepatic stellate cell proliferation in a dose-dependent manner and decrease activation of rat HSCs *in vivo* and *in vitro*^[20,21].

Our results suggested that Cpd 861 could significantly inhibit human hepatic stellate cell LX-2 proliferation in a dose-dependant manner when its concentration was over 0.03 mg/mL. The inhibition function increased obviously with the incubation time. However, the results showed that Cpd 861 did not inhibit HepG2 cell proliferation at the same concentration, indicating that Cpd 861 probably could specifically inhibit hepatic stellate cell proliferation, although further study is needed.

RT-PCR is a technique that has been widely used to quantify physiological changes in gene expression^[22]. However, there is lack of accurate quantification in most of the cases^[22,23]. Real-time PCR techniques developed during the last decade could offer much more accurate and precise quantitation of DNA and RNA^[23,24]. In our study a reliable and accurate real-time PCR method using SYBR Green I technology^[25,26] was taken to measure the effects of Cpd 861 on expression of α -SMA mRNA in LX-2 cells. To quantify the number of molecules of α -SMA mRNA, standard curves were constructed with plasmids containing the fragments for α -SMA and

G3PDH as the templates. A high linearity was observed over a dynamic range of at least 5 orders of magnitude (from 10^9 to 10^3 copies). All PCR conditions and primers were optimized to produce the target products of the correct basepair size just as shown in melt curves. Quantities of α -SMA were expressed as relative ratio to the copy number of G3PDH. The results indicated that the expression levels of α -SMA mRNA decreased significantly when LX-2 cells were exposed to Cpd 861 at 0.01 mg/mL concentration for 48 or 72 h. Although at the same concentration, Cpd 861 did not inhibit LX-2 cell proliferation.

In conclusion, Cpd 861 can significantly inhibit LX-2 proliferation in a dose-dependant manner when its concentration is over 0.03 mg/mL. Additionally, Cpd 861 can reduce the expression levels of α -SMA mRNA in LX-2 cells and this function seems independent of its effects on inhibition of cell proliferation.

ACKNOWLEDGEMENT

We thank Dr. Friedman and Mount Sinai, School of Medicine, for their help in providing the LX-2 cell line.

Abstract

AIM: To examine the effects of tegaserod, a serotonin (5-HT) 4 receptor partial agonist, on abdominal withdrawal reflex (AWR) to rectal distention (RD) and c-Fos expression in limbic system.

METHODS: Neonatal Sprague-Dawley rats randomly received colonic irritation by acetic acid from postnatal day 8 to d 21 as a visceral hypersensitive model (group H) or by intrarectal saline as a control group (group C). When they became adults, rectal distention (RD) was performed by a balloon (6F; Fogarty arterial embolectomy catheter; length, 20 mm; diameter, 2 mm) which was rapidly inflated with increasing volumes of saline (0.4, 0.8 and 1.2 mL) for 20 s at five-minute intervals. Five subgroups of group H (H-saline, H-vehicle, H-Teg0.1, H-Teg0.3 and H-Teg1.0) were injected randomly with saline, vehicle (1-methyl-2-thpyrrolidone) or tegaserod at doses of 0.1, 0.3 and 1.0 mg/kg ip, respectively. Two subgroups of group C (C-Saline and C-Teg1.0) were injected with saline or tegaserod (1.0 mg/kg) ip. RD was performed 10 min after injection, AWR was recorded and c-Fos expression in limbic system was analyzed quantitatively by immunohistochemistry.

RESULTS: Compared to saline, tegaserod significantly inhibited AWR in group H (0.4 mL: from 2.0 to 0.5; 0.8 mL: from 3.5 to 1.5; 1.2 mL: from 4.0 to 3.0, $P < 0.01$), but had no significant effect on group C. Tegaserod dose-dependently attenuated the number of c-Fos positive neurons in limbic structures, anterior cingulate cortex (ACC) showed the greatest attenuation. In group H, tegaserod (1.0 mg/kg) resulted in a significant overall decrease to 57% of H-saline (283 ± 41 vs 162 ± 16 , $P < 0.01$), in ACC to 42% of H-saline (72 ± 10 vs 31 ± 8 , $P < 0.01$). In group C, tegaserod (1.0 mg/kg) resulted in an overall decrease to 77% of C-saline (214 ± 13 vs 164 ± 22 , $P < 0.01$), in ACC to 65% of C-saline (48 ± 8 vs 31 ± 7 , $P < 0.01$).

CONCLUSION: Tegaserod inhibits the response to rectal distention in rats with visceral hypersensitivity and dose-dependently attenuates c-Fos expression in limbic system, especially in anterior cingulate cortex.

INTRODUCTION

Irritable bowel syndrome (IBS) is a common disorder characterized by abdominal pain and altered bowel habits, consisting of constipation, diarrhea, or both. Several pathophysiological mechanisms have been suggested to play a role in the genesis of symptoms in patients with IBS, among others visceral hypersensitivity, autonomic nervous system dysregulation^[1], alterations of gastrointestinal (GI) motility^[2], and abnormalities in neurotransmitter systems^[3]. It has been shown that at least a subgroup of IBS patients shows a hyperalgesic response to visceral stimuli, and discomfort in response to colorectal balloon distension under experimental conditions^[3,4]. Abnormalities which upregulate afferent (sensory) signal intensity anywhere in the "brain-gut axis" could induce visceral hypersensitivity^[5].

It has been shown in experimental rats that rectal distention is a non-invasive, reproducible visceral stimulus, which can induce a range of pseudoaffective responses, including vasomotor, visceromotor, and respiratory responses^[3]. Abdominal withdrawal reflex (AWR) is an involuntary motor reflex similar to the visceromotor reflex^[6]. Intestinal distention can be considered to as an appropriate stimulus for studies of visceral nociception^[7].

In previous studies, it has been shown that noxious distension of hollow viscera induces a specific pattern of c-Fos expression in rat limbic brain structures^[3,8], which involved in higher cognitive functions (*i.e.* emotion, memory, motivation) and led to the perception of visceral pain^[9]. Induction of c-Fos expression is a well established marker of neuronal activation, and immunohistological detection of c-Fos-like immunoreactivity allows a mapping of activated brain nuclei on a single cell level^[3].

Serotonin (5-HT) is thought to play a role in visceral nociceptive mechanisms. There is considerable evidence that serotonin is involved in the regulation of motility and sensation in the gut^[3]. In animal studies, tegaserod was reported to inhibit abdominal contraction response to noxious intestinal distention^[10]. Tegaserod, a 5-HT₄ receptor partial agonist, could relieve symptoms in irritable bowel syndrome patients with abdominal pain, bloating and constipation^[11]. However, little is known about the effect of tegaserod on neuronal activity in limbic structures at noxious rectal distention. Therefore, in the present study, we established a rat model to investigate the role of 5-HT₄ receptors in mediating activation of limbic structures at rectal distention, as assessed by c-Fos expression. We aimed to establish a mechanism of the action of 5-HT₄ receptors specific to visceral nociceptive neurotransmission.

MATERIALS AND METHODS

Animals

Experiments were performed using Sprague-Dawley rats obtained as preweanling neonates (younger than 8 d) from the Animal Center in the First Hospital of Peking University. Rats were housed in plastic cages containing corn chip bedding and maintained on a 12:12-h light-dark cycle (lights on at 7 AM) at 22 to 23 °C and in 60-65% humidity. The irritation procedure and the experimental testing were conducted during the light component of the cycle. The neonates were housed

12 in a cage with their mothers until they were 25 d old. Mothers had access to food and water *ad libitum*. After separation, the rats were housed 4 in a cage with access to food and water *ad libitum*. The animals were deprived of food but water 18 h before rectal distention (RD). Animal care and experimental procedures were followed institutional ethics guidelines and conformed to the requirements of the State Authority for Animal Research Conduct.

Weight

Each rat was weighed every 3 d from days 9 to 40.

Colon irritation

Neonatal Sprague-Dawley rats (8 d old) were divided into 2 groups (group C: control and group H: hypersensitivity) undergoing different treatments. Forty-eight rats in group H received intracolonic injections of 5 mL/L acetic acid (0.5 mL) daily between the ages of 8 and 21 d. Acetic acid was injected into the colon via the PE90 tube inserted to 2 cm from the anus. Twenty-four rats in group C received intracolonic injections of 9 g/L saline (0.5 mL) daily between the ages of 8 and 21 d^[12].

Drug administration protocol

Because tegaserod (HTF 919; Novartis Pharma AG, Basel, Switzerland) is poorly soluble in water, the fractions were made up using 0.1 mL of 1-methyl-2-pyrrolidinone (vehicle)^[10]. After dissolved in the vehicle, distilled water was added to make the solution up to 0.5 mL. According to the drugs injected intraperitoneally 10 min before RD, 48 rats in group H were divided into 6 subgroups (H0, H-saline, H-vehicle, H-Teg0.1, H-Teg0.3, and H-Teg1.0), and 24 rats in group C were divided into 3 subgroups (C0, C-saline, and C-Teg1.0), eight rats in each subgroup. Rats in group C-saline and H-saline were injected with saline (0.5 mL), in group C-Teg1.0 with tegaserod (1.0 mg/kg), in group H-vehicle with vehicle (0.1 mL and distilled water 0.4 mL) and in group H-Teg0.1, H-Teg0.3, and H-Teg1.0 with tegaserod at a dose of 0.1, 0.3 or 1.0 mg/kg, respectively. Groups H0 and C0 were not distended and only histological examination and myeloperoxidase (MPO) activity assay were done.

Histological examination and myeloperoxidase (MPO) activity assay

Three weeks after cessation of the irritation protocol, in groups H0 and C0, the distal 4–5 cm of the descending colon and rectum was removed and histological analysis and MPO activity assay were performed. MPO activity assay was performed as described previously^[13,14]. MPO activity was expressed as U/g protein.

Behavioral testing^[6,12]

Behavioral responses to RD were assessed in all groups 3 wk after cessation of the irritation protocol by measuring the abdominal withdrawal reflex (AWR) using a semiquantitative score. AWR is an involuntary motor reflex similar to the visceromotor reflex. However, the advantage of AWR over the visceromotor reflex is that the latter requires additional surgery to implant recording electrodes and wires in the abdominal muscles, which may cause additional sensitization in an already sensitized system. Distention balloons (described below) were placed in the rectum of lightly sedated adult rats (ether) and secured by taping the attached tube to the rat's tail. The rats were then housed in small Lucite cubicles (20 cm×8 cm×8 cm) on an elevated Plexiglas platform and allowed to wake up and adapt (20 min). Measurement of the AWR consisted of visual observation of animal response to graded RD (0.4, 0.8 and 1.2 mL) by blinded observers and assignment of AWR scores: 0, no behavioral response to RD; 1, brief head movement followed by immobility; 2, contraction of abdominal muscles; 3, lifting of

abdomen; 4, body arching and lifting of pelvic structures. The rats were given RD for 20 s every 5 min. To achieve an accurate measure, distensions were repeated 5 times for each volume. The data for each animal were averaged for analysis. The results obtained were compared among groups. A change in the magnitude of an evoked response indicated a change in visceral pain processing.

Colon stimuli^[12]

Colon stimulation consisted of graded RD produced by inflating a balloon inside the rectum. The balloon, 2 cm in length and 2 mm in diameter (6F, Fogarty arterial embolectomy catheter, Baxter, USA), was carefully inserted intrarectally and fixed at a distance of 1 cm with an adhesive tape at the tail of the rat. Distension was produced by rapidly inflating the balloon to the desired volumes with saline (0.4, 0.8 or 1.2 mL) for 20 s at 5-min intervals. Before they were used, the balloons were blown up and left overnight so the latex stretched and the balloons became compliant. Tegaserod (0.1, 0.3 or 1.0 mg/kg) or saline or vehicle was administered 10 min prior to RD. Only a single dose was tested in each animal.

c-Fos immunohistochemistry^[15]

Within 30 min following the end of the distention procedure, the animals were deeply anesthetized with an overdose of sodium pentobarbitone (60 mg/kg intraperitoneally) and then perfused through the ascending aorta with saline (9 g/L), followed by 500 mL of cold 0.1 mol/L phosphate buffer (PB, 4 °C) containing 40 g/L paraformaldehyde (pH 7.4). The brain was immediately removed and postfixed in the same fixative at 4 °C overnight, and then placed in 300 g/L sucrose with 0.1 mol/L PB for 72 h at 4 °C. Coronal sections (40 µm thick) were cut from frozen blocks at the levels of brain regions of interest (1.5 mm to 5 mm posterior to bregma, according to the atlas of Paxinos and Watson). Every fifth section was stained for c-Fos-like immunoreactivity (c-Fos-ir) using the method of free floating for immunohistochemistry. Briefly, sections were first washed 3 times in phosphate buffered saline plus 3 g/L Triton X-100 (PBS-T) (5 min each time) at room temperature, and incubated for 10 min with PBS-T containing 50 mL/L normal goat serum to block nonspecific binding sites and facilitate tissue penetration. Then sections were washed with PBS-T and incubated for 24 h at room temperature with PBS-T containing rabbit polyclonal anti-Fos protein antiserum (Zhongshan, China) (diluted 1:200). After washed with PBS-T, sections were incubated with biotinylated anti-rabbit IgG (1:300, Zhongshan, China) for 120 min. The sections were then incubated with strepta-vidin-peroxidase conjugate (1:300) for 120 min and subsequently visualized using diaminobenzidine (DAB) as chromogen. Sections were mounted on gelatin-coated glass slides, air dried, dehydrated in ethanol, and xylene, then coverslipped with DePeX. Brain sections were examined using bright-field microscopy. The same lot of antibody was used for each study outlined below. The primary c-Fos antibody was omitted in one well of each immunohistological reaction as a negative control. In each study, every staining process included free-floating sections of all groups using the same buffers and solutions.

Fos-like immunoreactive nuclei

The number of c-Fos-like immunoreactive (c-Fos-ir) nuclei was counted in 5 sections of each rat as identified by morphology using an image analysis package (Leica Q550CW running QWIN software; Leica UK Ltd, Milton Keynes, UK). In the anterior cingulate cortex (ACC), thalamus (TH), hippocampus (HP), hypothalamus (HypoTH) and amygdala (Amy), c-Fos-ir nuclei were counted individually and expressed as the number per 600×500 pixel. All brain regions were counted bilaterally in

each section. The total number of c-Fos-ir nuclei in five sections was used for subsequent data analysis. The counts comprising all those nuclear immunoreactive signals could be clearly distinguished from the background.

Data and statistical analysis

Statistical analysis was done using SPSS for windows 11.0. The results of weight, MPO activity and the number of c-Fos-ir were expressed as mean \pm SD, and statistical significances were determined using Student's paired *t* test or one way analysis of variance (ANOVA), followed by Dunnett's post hoc test. The median values of the AWR scores among all groups at each volume of RD were compared using the Mann-Whitney *U*-test. *P*<0.05 was considered statistically significant.

RESULTS

Comparison of body masses of rats in each group

Masses on d 9 and 40 were not statistically different between groups H and C (18.9 \pm 3.2 g vs 19.6 \pm 3.2 g, 154.4 \pm 12.7 g vs 149.3 \pm 16.5 g, respectively). The model did not alter the growth rate of the rats.

Histological analysis and MPO activity assay

The identifiable histopathology was absent in the adult colons. The tissues showed no significant structural damage or loss of crypts. Mucin depletion or increase in intraepithelial lymphocytes was not seen in any of the tissues examined. MPO activity was not statistically different between groups H and C (20.49 \pm 1.64 U/g protein and 17.49 \pm 6.35 U/g protein, respectively).

Table 1 AWR scores in group H (median, min-max) (*n* = 8)

	0.4 mL	0.8 mL	1.2 mL
H-saline	2.0 (1-3)	3.5 (3-4)	4.0 (4-4)
H-vehicle	2.0 (0-3)	3.0 (2-4)	4.0 (3-4)
H-Teg0.1	1.0 (0-2) ^b	2.0 (1-3) ^{a, b}	3.0 (3-4) ^{a, b}
H-Teg0.3	1.0 (0-1) ^b	1.5 (0-3) ^b	3.0 (3-4) ^{a, b}
H-Teg1.0	0.5 (0-1) ^b	1.5 (1-2) ^b	3.0 (1-3) ^b

^b*P*<0.01 vs H-saline; Difference between H-Teg0.1 and H-Teg0.3 was not significant at all volumes; ^a*P*<0.05 H-Teg0.1, H-Teg0.3 vs H-Teg1.0.

Table 2 AWR scores in group C (median, min-max, *n* = 8)

	0.4 mL	0.8 mL	1.2 mL
C-saline	1.0 (0-2)	2.5 (2-3)	3.0 (3-4)
C-Teg1.0	0.0 (0-2)	2.0 (2-2)	3.0 (3-4)
Z value	1.465	2.236	0
P value	0.195	0.105	1.000

The differences between C-saline and C-Teg1.0 were not significant at all volumes.

Comparison of tegaserod effects on AWR (Tables 1, 2)

H-saline vs C-saline Median AWR scores at volumes of 0.4, 0.8, and 1.2 mL were significantly higher in H-saline than in C-saline (2.0, 3.5, and 4.0, vs 1.0, 2.5, and 4.0, respectively) (*P*<0.05). These results suggested that the model of visceral hypersensitivity in this study was reliable (Figure 1A).

AWR in subgroups of group H Median AWR scores were similar in H-saline and in H-vehicle, so the effect of vehicle could be negligible. AWR scores were significantly higher in H-saline than in H-Teg0.1, H-Teg0.3, and H-Teg1.0. The 5-HT₄ receptor agonist tegaserod (0.1, 0.3, and 1.0 mg/kg) significantly inhibited

the response to rectal distention in rats with hypersensitivity (*P*<0.01). The difference between H-Teg0.1 and H-Teg0.3 was not significant at all volumes. The difference between H-Teg0.1 and H-Teg1.0 was significant at the volumes of 0.8 mL and 1.2 mL (*P*<0.05). The difference between H-Teg0.3 and H-Teg1.0 was significant only at 1.2 mL (*P*<0.05). At the volume of 0.4 mL, differences of AWR scores in H-Teg0.1, H-Teg0.3, and H-Teg1.0 were not significant (Figure 1B, Table 1).

C-saline vs C-Teg1.0 Median AWR scores were similar in C-saline and in C-Teg1.0 at all volumes. These results suggested that tegaserod (1.0 mg/kg) had little effect on the AWR response to RD in control rats (Figure 1C, Table 2).

C-Teg1.0 vs H-Teg1.0 At 1.2 mL, AWR scores were higher in C-Teg1.0 than in H-Teg1.0 (*P*<0.05). While at 0.4 mL and 0.8 mL, the differences between H-Teg1.0 and C-Teg1.0 were not significant. It seemed that the inhibitory effect on AWR at largest volume (1.2 mL) was stronger in hypersensitive condition than in normal condition (Figure 1D).

Table 3 Number of c-Fos positive neurons in limbic structures in group H (mean \pm SD, *n* = 8)

	ACC	Hippocampus	HypoTH	Amygdala	Thalamus	Overall
H-saline	72 \pm 10	54 \pm 13	51 \pm 17	44 \pm 16	62 \pm 19	283 \pm 41
H-vehicle	72 \pm 10	54 \pm 13	49 \pm 15	43 \pm 15	62 \pm 19	281 \pm 37
H-Teg0.1	53 \pm 14 ^b	48 \pm 10	47 \pm 13	42 \pm 11	50 \pm 13	239 \pm 31 ^a
H-Teg0.3	40 \pm 11 ^b	45 \pm 7	41 \pm 11 ^a	37 \pm 11	45 \pm 11 ^a	208 \pm 25 ^b
H-Teg1.0	31 \pm 8 ^b	36 \pm 9 ^b	31 \pm 10 ^b	30 \pm 8 ^b	34 \pm 10 ^b	162 \pm 16 ^b
F value	60.583	11.605	8.199	5.362	14.574	61.989
P value	0.000	0.000	0.000	0.000	0.000	0.000

^a*P*<0.05, ^b*P*<0.01 vs H-saline.

Table 4 Number of c-Fos positive neurons in limbic structures in group C (mean \pm SD, *n* = 8)

	ACC	Hippocampus	HypoTH	Amygdala	Thalamus	Overall
C-saline	48 \pm 8	46 \pm 7	36 \pm 8	39 \pm 7	45 \pm 11	214 \pm 13
C-Teg1.0	31 \pm 7 ^b	36 \pm 8 ^b	30 \pm 9	33 \pm 10	34 \pm 7 ^a	164 \pm 22 ^b

^a*P*<0.05, ^b*P*<0.01 vs C-saline.

Comparison of tegaserod effects on c-Fos expression in limbic structures (Tables 3, 4)

Repetitive RD significantly induced changes in neuronal activity in all animals, as determined by increased density of c-Fos-ir cells (Figure 2). c-Fos expression was located bilaterally in discrete areas of limbic structures. The overall number of c-Fos-ir cells in H-saline was significantly more than that in C-saline (283 \pm 41 vs 214 \pm 13, *P*<0.001), but the difference was not significant in hippocampus (54 \pm 13 vs 46 \pm 7, *P* = 0.374). Tegaserod given ip 10 min prior to RD produced a significant, dose-dependent attenuation in the total number of c-Fos-ir nuclei in limbic brain compared with saline. These effects were especially clear in anterior cingulate cortex (ACC). In the hippocampus and amygdala, the effect of tegaserod was significant only at the high-dose (1.0 mg/kg). Tegaserod (0.1 mg/kg) decreased the overall c-Fos-ir to 85% of saline (*P*<0.05). The greatest attenuation was in ACC (74% of H-saline), while amygdala was least affected (95% of H-saline). Tegaserod (0.3 mg/kg) significantly attenuated c-Fos expression in ACC, hypothalamus, and thalamus (to 56%, 80% and 73% of saline, respectively). A high dose of tegaserod (1.0 mg/kg) resulted in a significant (*P*<0.01) overall decrease of c-Fos in five areas, the overall number was decreased to 57% of saline. Similar to the low dose, ACC showed the greatest attenuation (42% of H-saline), while other regions were decreased to approximately 60% of H-saline (Figure 3A).

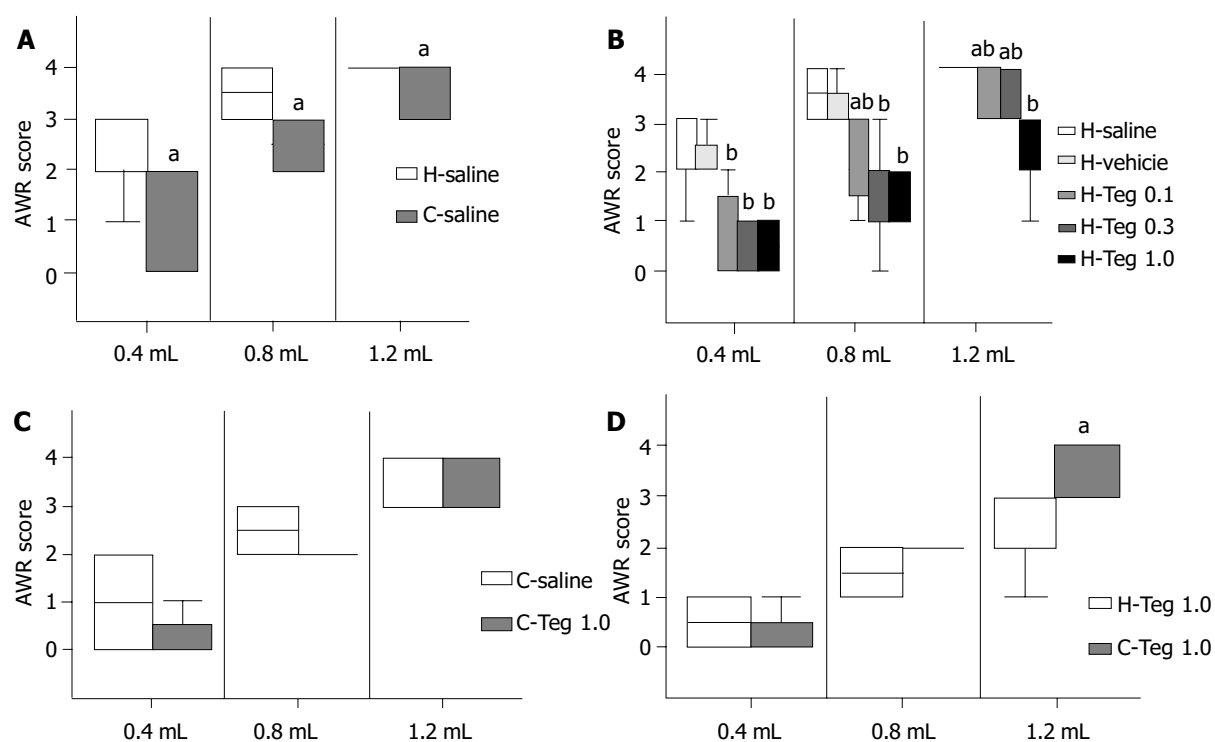

Figure 1 AWR scores of H-saline and C-saline, group H, group C, H-Teg1.0 and C-Teg1.0, ^a $P < 0.05$; ^b $P < 0.01$. A: AWR scores of H-saline and C-saline. B: AWR scores of group H. C: AWR scores of group C. D: AWR scores of H-Teg1.0 and C-Teg1.0.

Figure 2 c-Fos-ir nuclei in anterior cingulate cortex (ACC) (200×). A: H-saline; B: H-Teg0.1; C: H-Teg0.3; D: H-Teg1.0; E: C-saline; F: C-Teg1.0.

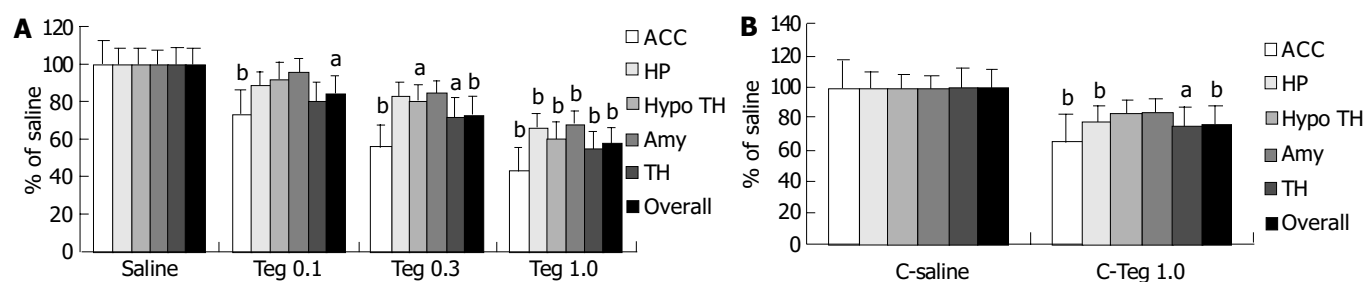

Figure 3 Number of overall c-Fos-ir nuclei and in each of the 5 areas as a percent of H-saline and C-saline. A: Number of overall c-Fos-ir nuclei and in each of the 5 areas as a percent of H-saline. B: Number of overall c-Fos-ir nuclei and in each of the 5 areas as a percent of C-saline.

In group C, although the inhibitory effect of tegaserod on AWR was not significant, the attenuation effect on c-Fos expression was also observed. Tegaserod (1.0 mg/kg) resulted in a significant overall decrease in c-Fos to 77% of C-saline. Similarly, ACC also was the greatest attenuation (65% of C-saline). In addition, tegaserod could decrease c-Fos in thalamus and hippocampus (76% and 78% of C-saline, respectively) (Figure 3B).

DISCUSSION

Experimental data suggested that patients with IBS had visceral sensory dysfunction so that physiological stimuli could induce their symptoms. Visceral afferent input is modulated by a variety of mechanisms operating between the gastrointestinal tract and the brain, and dysfunction of these regulatory mechanisms could distort gastrointestinal perception^[16]. Intestinal discomfort reaches awareness via neural connections termed the “brain-gut axis”. Abnormalities which upregulate afferent (sensory) signal intensity anywhere in this system could induce hypersensitivity, pain, and discomfort. Several features of IBS suggest involvement of the brain’s emotional limbic system, such as higher prevalence of anxiety and psychosocial stressors, augmented intestinal and stress responses and response to centrally acting medication. Recent brain imaging data suggested that pathways involved in visceral pain perception overlapped with limbic pathway^[17,18]. In the brain, increased thalamic activation has been seen in IBS, which could indicate increased afferent output from lower levels. Activation of the anterior cingulate cortex, the limbic center that encodes pain suffering, appeared to be enhanced in IBS, especially under the influence of anxiety^[5].

Colonic irritation with acetic acid in neonatal rats could lead to a state of chronic visceral hypersensitivity in adults^[19-21]. This model did not alter the growth rate of the rats. This hypersensitivity occurs in the absence of identifiable histopathology in the adult colon and does not change MPO activity of colonic tissue. Myeloperoxidase (MPO), a hydrogen peroxide (H₂O₂) oxidoreductase, is specifically found in mammalian granulocytic leukocytes, including polymorphonuclear leukocytes (PMNs), monocytes, basophils and eosinophils. MPO activity has been widely accepted as an enzyme marker to measure and quantitate the PMN content in a variety of tissues. It has been suggested that measurement of MPO provides a simple and specific method to quantitate PMN accumulation or infiltration in a variety of pathological processes accompanied with inflammation^[22].

5-HT₄ receptors have been found to be involved in regulating the sensitivity of rectal mechanoreceptive afferents^[23]. Tegaserod is a 5-HT₄ receptor partial agonist with a relatively long half-life (approximately 11 h in dogs and humans)^[24]. It could dose-dependently inhibit the abdominal contraction response to noxious intestinal distention not linked to alterations in compliance^[10]. In our study, in rats with hypersensitivity but

not in control rats, tegaserod potentially inhibited AWR at all volumes of distention. It seemed that the inhibitory effect on AWR at the highest volume (1.2 mL) was more powerful in hypersensitive condition than in normal condition. The results are inconsistent with the study of Coelho *et al.*^[10]. Two reasons may have been responsible for these phenomena. One reason might be that the patterns of intestinal distention were different. In the study of Coelho *et al.*, the balloon was an inflated 5 min step of 15 mmHg, from 0 to 60 mmHg. The other reason might be that 5-HT₄ receptors played a relatively modest role in modulating visceral sensation under basal physiological condition^[25]. Thus, we tentatively suggest that the number of 5-HT₄ receptors may be upregulated and/or the effect followed by the activity of 5-HT₄ receptor may be increased under hypersensitive status. The exact mechanisms of its action need to be further researched.

c-fos, an immediate-early gene, could be expressed within the neurons following voltage-gated calcium entry into the cells^[26]. *c-fos* was induced by noxious stimulus, generally as the result of an injury^[27]. *c-Fos* protein encoded by *c-fos*, has been regarded as a third messenger molecule which couples the short term extracellular signals with the long term alteration in cell function when neurons are excited^[28]. *c-Fos* could be interpreted as an increase in activity of those neurons expressing the protein^[27], so it is usually used as a marker to indicate the activation of neurons^[29]. Following injury there was a correlation between the expression of *c-Fos* and magnitude of hyperalgesia, and *c-Fos* expression following noxious intensities of intestinal distention could reflect the intensity of stimuli and the degree of discomfort^[27]. Previous study has demonstrated that *c-Fos* is expressed in limbic brain structures in response to noxious rectal distention^[9]. Limbic structures play an important role in visceral pain processing. The present report provided quantitative data on expression of *c-Fos* protein induced by rectal distention and the effect of tegaserod at different doses on *c-Fos* expression in brain nuclei, such as hypothalamus, thalamus, amygdala, hippocampus, and anterior cingulate cortex following noxious rectal distention. Functional brain imaging researches have demonstrated that colorectal distention could cause abnormal activation in ACC^[17] and thalamus in IBS patients compared with control^[17,18]. From our results, we conclude that tegaserod dose-dependently attenuates *c-Fos* expression in limbic structures. Especially in ACC and thalamus, the effect of tegaserod is more evident. This may do good for IBS patients.

5-HT₄ receptors are widely distributed in peripheral and central sites. In gut, 5-HT₄ receptors are located primarily on the enterochromaffin cells and less on smooth muscle cells, enterocytes, and neurons^[24]. 5-HT₄ receptors are highly expressed in several brain regions, such as limbic areas, periaqueductal grey matter and sensory terminals^[30] and in spinal cord and dorsal root ganglion neurons^[25]. The site of action of tegaserod was not established in the present study, but could be at the level of enteric or primary sensory neurons,

or via spinal or supraspinal neuronal circuits concerned with the modulation of nociceptive transmission. A study by Schikowski *et al.*^[23] demonstrated that tegaserod might have a direct effect on the mechanoreceptive afferents. We supposed that 5-HT₄ receptors might directly decrease the signals ascending to the central nervous system (CNS) or might decrease the activity of CNS (as demonstrated by c-Fos-ir nuclei), which would benefit for IBS patients. Little is known about the effect of tegaserod on response following intracerebroventricular injection. Further studies are needed to determine the central action of 5-HT₄ receptors.

In conclusion, tegaserod inhibits response to noxious distention, and the effect is more evident in hypersensitive condition than in control. Tegaserod dose-dependently attenuates c-Fos expression in limbic structures, especially in anterior cingulate cortex. Therefore, tegaserod decreases central sensitization. Tegaserod may be of potential use in the treatment of visceral pains.

Abstract

AIM: To examine the effects of berberine, an isoquinoline alkaloid with a long history used as a tonic remedy for liver and heart, on ion channels of isolated rat hepatocytes.

METHODS: Tight-seal whole-cell patch-clamp techniques were performed to investigate the effects of berberine on the delayed outward potassium currents (I_K), inward rectifier potassium currents (I_{K1}) and Ca^{2+} release-activated Ca^{2+} currents (I_{CRAC}) in enzymatically isolated rat hepatocytes.

RESULTS: Berberine 1-300 $\mu\text{mol/L}$ reduced I_K in a concentration-dependent manner with EC_{50} of $38.86 \pm 5.37 \mu\text{mol/L}$ and n_H of 0.82 ± 0.05 ($n = 8$). When the bath solution was changed to tetraethylammonium (TEA) 8 mmol/L, I_K was inhibited. Berberine 30 $\mu\text{mol/L}$ reduced I_K at all examined membrane potentials, especially at potentials positive to +60 mV ($n = 8$, $P < 0.05$ or $P < 0.01$ vs control). Berberine had mild inhibitory effects on I_{K1} in rat hepatocytes. Berberine 1-300 $\mu\text{mol/L}$ also inhibited I_{CRAC} in a concentration-dependent fashion. The fitting parameters were $\text{EC}_{50} = 47.20 \pm 10.86 \mu\text{mol/L}$, $n_H = 0.71 \pm 0.09$ ($n = 8$). The peak value of I_{CRAC} in the I-V relationship was decreased by berberine 30 $\mu\text{mol/L}$ at potential negative to -80 mV ($n = 8$, $P < 0.05$ vs control). But the reverse potential of I_{CRAC} occurred at voltage 0 mV in all cells.

CONCLUSION: Berberine has inhibitory effects on potassium and calcium currents in isolated rat hepatocytes, which may be involved in hepatoprotection.

INTRODUCTION

Many natural drugs for liver diseases are currently used in popular medicine. For example, quaternary protoberberine alkaloids from *Flissitigma* and *Goniothalamus* have been used in popular medicine for hepatomegaly and hepatosplenomegaly^[1,2]. The use of alkaloids from *Berberis aristata* for liver injury induced by chemical carcinogenesis and alkaloids from *Enantica* for disorders of bilirubin has also been reported^[3,4].

Berberine is an isoquinoline alkaloid with a long history in

both Ayurvedic and Chinese medicine. It exists in *Hydrastis canadensis* (golden seal), *Coptis chinensis* (Coptis or golden thread), *Berberis aquifolium* (Oregon grape), *Berberis vulgaris* (barberry), and *Berberis aristata* (tree turmeric). Berberine alkaloid can be found in roots, rhizomes, and stem bark of plants^[5]. Berberine has been extensively studied and is known to exhibit multiple pharmacological activities such as antiprotozoal, antihypertensive^[6], antibacterial^[7], anti-inflammatory, anticholinergic^[8] and antiarrhythmic activities^[9]. Hwang *et al.* reported that berberine inhibited hepatotoxicity induced by *tert*-butyl hydroperoxide (*t*-BHP) via its antioxidant potential and could function as a chemopreventive agent in living systems^[10]. Previous studies have shown that berberine could block delayed rectifier potassium currents, inward rectifier potassium currents (I_{K1}) and L-type calcium currents ($I_{\text{Ca,L}}$) in guinea pig ventricular myocytes^[11,12]. So far, however, its hepatoprotective mechanism still remains unknown. No data are available on the relationship between ion currents in hepatocytes and the hepatoprotective effect of berberine.

Therefore, this study used patch-clamp techniques to record the whole-cell currents in isolated rat hepatocytes in order to investigate the hepatoprotective mechanism of berberine.

MATERIALS AND METHODS

Cell preparation

Rat hepatocytes were enzymatically isolated from Sprague-Dawley (SD) rats of either sex (150-200 g) by using slightly modified procedures described previously^[13]. Briefly, adult animals were anesthetized with an intraperitoneal injection of pentobarbital sodium (30 mg/kg) in strict accordance to the guidelines established by the Institutional Animal Care and Use Committee, which follow all applicable state and federal laws. Portal vein and inferior vena cava were cannulated. The liver was initially perfused at a flow rate of 25 mL/min via a constant-flow system with modified oxygenated Ca^{2+} , Mg^{2+} -free Hanks' solution for several minutes, followed by perfusion with a Ca^{2+} , Mg^{2+} -free Hanks' solution containing collagenase (0.3 g/L, type I) for 10 min. The solutions were gassed with 950 mL/L O_2 +50 mL/L CO_2 and heated to 37 °C. After these perfusions, the liver was excised and then minced in Ca^{2+} , Mg^{2+} -free Hanks' solution at 0 °C. The cells were filtered through a 200 μm nylon mesh, and washed 3 times by centrifugation at 50 g for 2 min. The cell pellets were resuspended in KB medium that yielded approximately 85% to 95% viable hepatocytes. A small aliquot of the medium containing single cells was transferred into a 1-mL chamber mounted on the stage of an inverted microscope (IX-70, Olympus, Japan). Spherical and smooth cells were used for the whole-cell patch-clamp studies. All experiments were performed at room temperature (20 °C to 22 °C).

Voltage-clamp recording

A programmable vertical puller (pp-83, Narishige, Japan) was used to pull the electrodes. The resistance of capillary glass electrodes (GC150TF-10, Clark Electromedical Instruments, UK) used was 2 to 4 M Ω when filled with internal solution. A patch-clamp amplifier (EPC-9, Germany) was used to record the whole-cell currents with four-pole Bessel filter set at 1 kHz, digitized at 5 kHz. The protocols for voltage-clamp and data analysis were established with routines using pClamp 6.0 software (Axon Instrument, USA), and data

were stored in computer for subsequent analysis. Drug actions were measured only after steady-state conditions reached, which were judged by the amplitudes and time courses of currents remaining constant with further perfusion of drugs.

Drugs and solutions

Berberine hydrochloride was obtained from Yichang Pharmaceutical Company of China as base powders, dissolved in distilled water and made into a stock solution at 0.1 mol/L. Berberine was added to bath solutions for extracellular application. All drugs were purchased from Sigma (USA) unless otherwise indicated.

Ca²⁺, Mg²⁺-free Hanks' solution for cell-isolation (mmol/L) contained NaCl 137, KCl 5.4, NaH₂PO₄ 0.5, Na₂HPO₄ 0.58, NaHCO₃ 4.16 and glucose 5.5 (pH 7.3). Kraft-bruhe (KB) medium for cell-preservation (mmol/L) contained L-glutamic acid 70, KCl 130, taurine 15, KH₂PO₄ 10, MgCl₂ 0.5, glucose 11, N-(hydroxyethyl) piperazine-N'-2-ethanesulphonic acid (HEPES) 10 and ethylene glycol-O-O'-bis (2-aminoethyl) -N,N,N',N'-tetraacetic acid (EGTA) 0.5 (pH 7.4).

In studies of I_K , the bath solution was a modified Tyrode's solution (mmol/L) containing NaCl 144, KCl 4.0, CaCl₂ 1.8, MgCl₂ 0.53, Na₂HPO₄ 0.33, HEPES 5 and glucose 5.5 (pH 7.3). The patch pipette solution contained (mmol/L) KCl 130, K₂ATP 5.0, creatine phosphate 5.0 and HEPES 5.0 (pH 7.4).

For experiments on I_{K1} , both the bath solution and the pipette solution contained (mmol/L) KCl 7, MgCl₂ 2, EGTA 1, K-glutamate 130 and HEPES 10 (pH 7.4).

For I_{CRAC} recording, the bath solution (mmol/L) contained NaCl 140, KCl 2.8, CaCl₂ 10, MgCl₂ 0.5, glucose 11 and HEPES 10 (pH 7.4). The pipette solution used (mmol/L) contained K-glutamate 145, NaCl 8, MgCl₂ 1, MgATP 0.5, EGTA 10 and HEPES 10 (pH 7.2).

Data analysis

All the data were expressed as mean±SD and error bars were plotted as SD. Statistical significance was evaluated by a *t* test. Statistical differences were considered to be significant when *P* value was less than 0.05.

RESULTS

Effects of berberine on I_K

Under conventional whole-cell patch-clamp mode, the membrane potential was clamped at -50 mV, and I_K was elicited in isolated rat hepatocytes by depolarizing pulse to +140 mV for 900 ms. The current at the end point of the test pulse was measured as the amplitude of I_K .

The percentage block of I_K was defined as $(I_{\text{Control}} - I_{\text{berberine}}) / I_{\text{Control}}$ and plotted as a function of logarithm [berberine] in

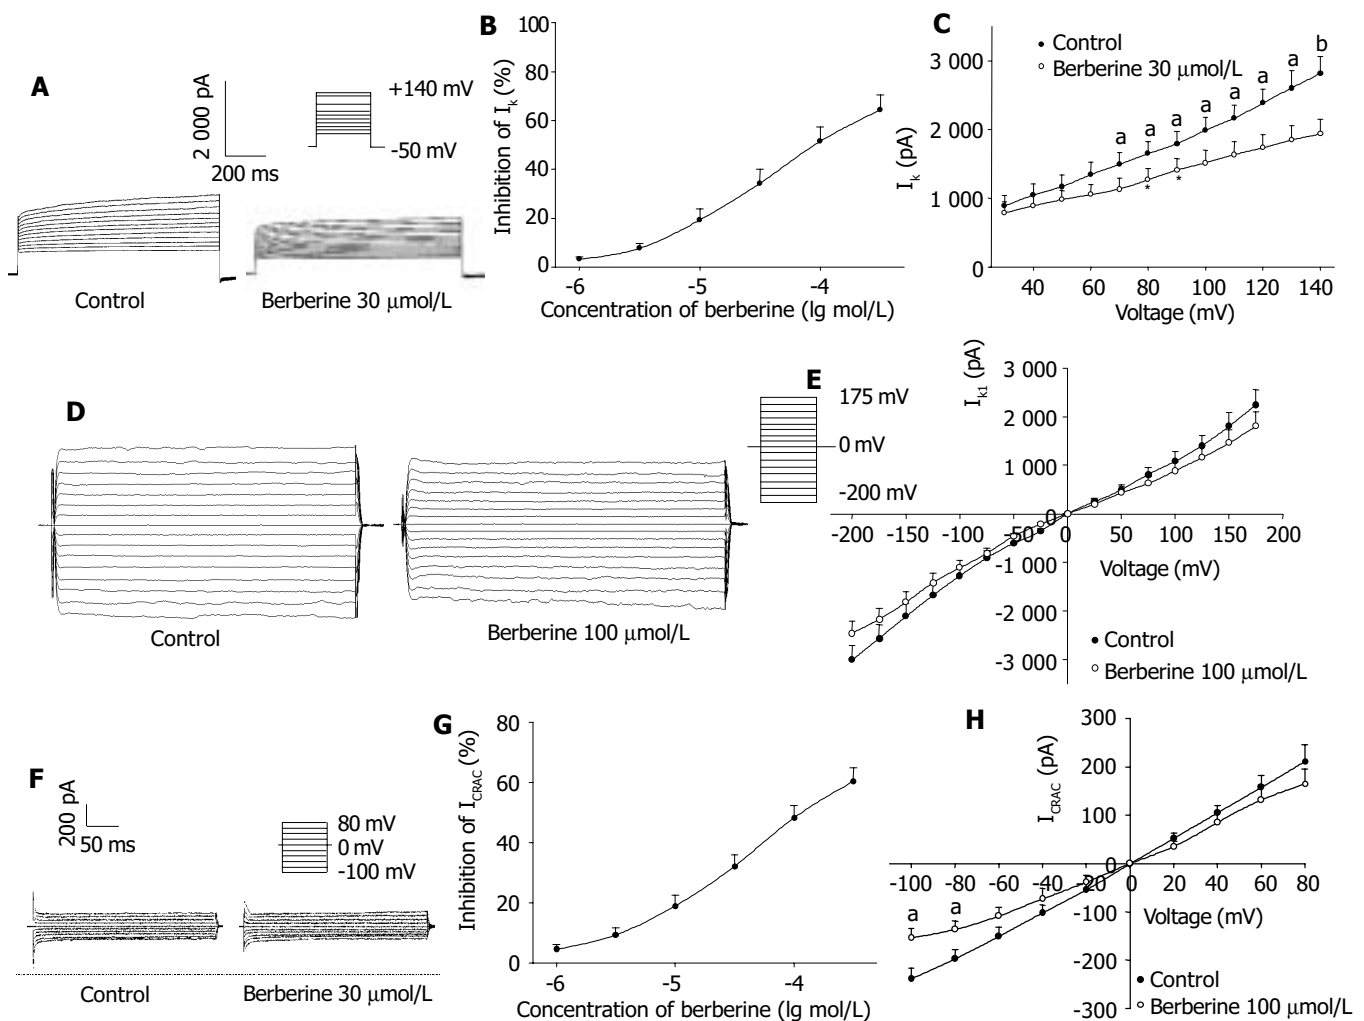

Figure 1 Effects of berberine on I_K . A: Families of I_K recorded with changes in the absence or presence of berberine 30 $\mu\text{mol/L}$ and 100 $\mu\text{mol/L}$. Dotted line indicates zero current level; B: Dose-response curve for effects of berberine on I_K ; C: I-V relationship of I_K under control (●) and berberine 30 $\mu\text{mol/L}$ (○). D: Families of I_{K1} recorded with changes in the absence or presence of berberine 100 $\mu\text{mol/L}$. Dotted line indicates zero current level; E: I-V relationship of I_{K1} under control (●) and berberine 100 $\mu\text{mol/L}$ (○). F: Families of I_{CRAC} recorded with changes in the absence or presence of berberine 30 $\mu\text{mol/L}$. Dotted line indicates zero current level; G: Dose-response curve for effects of berberine on I_{CRAC} ; H: I-V relationship of I_{CRAC} under control (●) and berberine 30 $\mu\text{mol/L}$ (○). The voltage steps used to elicit I_K are shown in the inset. *n* = 8, mean±SD, ^a*P*<0.05, ^b*P*<0.01 vs control.

Figure 1B. At +140 mV, berberine 1-300 $\mu\text{mol/L}$ decreased the I_K amplitude concentration-dependently in all cells tested, which was poorly reversible after washout. The data points were fitted according to the Hill equation: Inhibition of current (%) = $100/[1 + (\text{EC}_{50}/C)^{n_H}]$, and an EC_{50} value of $38.86 \pm 5.37 \mu\text{mol/L}$ and n_H of 0.82 ± 0.05 were obtained ($n = 8$). When the bath solution was changed to tetraethylammonium (TEA) 8 mmol/L, I_K was inhibited.

Figure 1A shows the effects of berberine 30 $\mu\text{mol/L}$ on the steady-state I-V relationship for I_K generated by applying 12 steps voltage command pulse from +30 mV to +140 mV for 900 ms with a 10 mV increment from a holding potential of -50 mV. By comparing these two I-V curves shown in Figure 1C, I_K was reduced by berberine 30 $\mu\text{mol/L}$ at all membrane potentials examined, especially at potentials positive to +60 mV ($n = 8$, $P < 0.05$ or $P < 0.01$ vs control). The results clearly indicated that berberine had a depressant action on I_K in rat hepatocytes.

Effects of berberine on I_{K1}

Hyperpolarizing and depolarizing potentials over a range from -200 mV to +175 mV with a 25 mV increment for 40 ms were applied from a holding level of 0 mV. The absolute value at the end of test pulse was measured as the amplitude of I_{K1} . After administration of berberine 100, 300 $\mu\text{mol/L}$, the I_{K1} amplitude at -200 mV was decreased from $-3044.75 \pm 262.06 \text{ pA}$ to $-2451.33 \pm 226.45 \text{ pA}$ and $-2310.66 \pm 182.65 \text{ pA}$, respectively. The inhibition rates were $17.49 \pm 2.51\%$ and $24.11 \pm 3.60\%$, respectively. Figures 1D and 1E shows the I-V relations of berberine 100 $\mu\text{mol/L}$ on I_{K1} . As shown in Figures 1D and 1E, berberine only had mild inhibitory effects on I_{K1} in isolated rat hepatocytes.

Effects of berberine on I_{CRAC}

When the holding potential was 0 mV, and the cells were depolarized to -100 mV for 200 ms at a frequency of 0.2 Hz, I_{CRAC} was evoked. As shown in Figure 1G, I_{CRAC} also was blocked by berberine in a concentration-dependent fashion, with an EC_{50} value of $47.20 \pm 10.86 \mu\text{mol/L}$ and n_H of 0.71 ± 0.09 ($n = 8$). Figure 1H shows the effect of berberine 30 $\mu\text{mol/L}$ on the steady-state I-V relationships generated by applying a series depolarizing pulses from a holding potential of 0 mV to different membrane potentials (-100 mV to +80 mV) with a 20 mV increment. The peak value of I_{CRAC} was reduced on either inward or outward components, especially from -100 mV through -80 mV ($n = 8$, $P < 0.05$ vs control). But the reverse potential of I_{CRAC} occurred at voltage 0 mV in all cells.

DISCUSSION

In this study, for the first time, we characterized the effects of berberine on I_K , I_{K1} and I_{CRAC} by patch-clamp techniques and demonstrated that berberine mainly inhibited I_K , I_{CRAC} and I_{K1} in isolated rat hepatocytes.

Potassium channels are ubiquitous in eukaryotic cells and could play roles in resting membrane potential, frequency of action potential, membrane potential repolarization rates and cell functions. It has been found that membrane potential is important in regulating metabolic processes in the liver, including gluconeogenesis, amino acid transport, and the rate of uptake of bile salts^[14,15]. Changes in K^+ permeability could affect the transmembrane potential. Bile formation was involved in anion accumulation within the apical lumen of hepatocytes. Potassium flux through hepatocellular basolateral membrane channels might provide the counterion for apical anion efflux^[16]. Transcellular bile acid transport could be integrated in the regulation of intracellular pH, K^+ homeostasis and membrane potential. Hepatocellular K^+ -depletion could result in the inhibition of bile acid secretion despite increasing the intracellular concentration^[17-19].

During ischemia and hypoxia, hepatocellular volume and K^+ conductance were increased and would lead to cell death^[20,21].

Nietsch *et al.* demonstrated TNF (25 ng/mL) elicited a 2- and 5-fold increase in K^+ current in hepatoma tissue culture cells. K^+ channel activation might participate in pathways that leading to TNF-mediated cell death, thus representing potential therapeutic targets to attenuate liver injury from TNF^[22]. The inhibition of K^+ channels could delay hepatocyte apoptosis and death. Churchill *et al.* reported that potassium channel antagonists had protective effects on rat liver via regulating the energy metabolism^[23].

Previous studies showed that berberine (0.5, 5 mg/kg, i.p.) protected rat liver from hepatotoxicity induced by *t*-BHP^[10]. As shown previously, *t*-BHP could shrink hepatocytes by release of cellular K^+ . Single-channel patch-clamp studies demonstrated *t*-BHP activated a 35-pS K^+ channel and contributed to the K^+ release of hepatocytes following exposure to *t*-BHP^[24]. In this study, we observed that the concentration of berberine on I_K was consistent with the dose reported by Hwang^[10]. The hepatoprotective effect of berberine on *t*-BHP may have some relations with the inhibitory effect on potassium channel.

However, as we reported previously, AP-Q had a protective effect on CCl_4 -induced liver injury, probably by selectively increasing I_K . In this experiment, we observed that berberine had a protective effect on *t*-BHP induced liver injury by decreasing I_K . The contradiction may be due to the different mechanism of CCl_4 -induced and *t*-BHP induced liver injury. CCl_4 -induced hepatocyte injury paralleled with membrane depolarization by blocking the potassium channel in damaged hepatocytes^[25-27]. However, *t*-BHP-induced liver injury is concerned with the release of cellular K^+ by activating potassium channel. A previous study showed that berberine had not any protective effects on CCl_4 -induced liver injury^[28].

Calcium has been demonstrated to play an important role in hepatocyte damage. An increase in calcium ion concentration in cytoplasm due to the influence of various toxic agents caused disturbances in the structure and function of hepatocytes, leading to their damage and even death^[29]. Previous studies showed that hepatocellular Ca^{2+} overload and impaired Ca^{2+} signaling were related to hemorrhage/resuscitation liver injury. Increased Ca^{2+} uptake could result from a receptor-gated Ca^{2+} influx and/or oxygen-free radical induced membrane Ca^{2+} leaks. A protective effect of calcium channel blockers on hepatotoxins has been reported^[30].

Calcium ions could enter the cells mostly through calcium channels. However, hepatocytes as the nonexcitable cells were short of the voltage-dependent Ca^{2+} channels but possessed plasma membrane Ca^{2+} channels that had a high selectivity for Ca^{2+} , and were activated by a decrease in the concentration of Ca^{2+} in intracellular stores, which was named I_{CRAC} ^[31,32]. Berberine inhibited I_{CRAC} with EC_{50} of 47.20 $\mu\text{mol/L}$, which was different from the EC_{50} of $I_{Ca,L}$ in cardiac myocytes^[33]. The differential drug sensitivity of the two currents also provided further support for the idea that I_{CRAC} is different from voltage-gated Ca^{2+} channel.

Berberine inhibited I_K , I_{K1} and I_{CRAC} concentration-dependently in isolated rat hepatocytes and the inhibitory extent was $I_K > I_{CRAC} > I_{K1}$. Therefore, berberine could block K^+ channel and decrease the extracellular K^+ to regulate the metabolic processes in the liver. Berberine could also inhibit I_{CRAC} effectively and protect hepatocytes from calcium overload via the inhibition of I_{CRAC} . The inhibitory effects on potassium and calcium current may partly contribute to the hepatoprotective action of berberine. As berberine has already been used for liver damage in human beings^[34], it may be a good candidate for further study and used in treatment of liver damage.

Abstract

AIM: To analyze a 30-year historical series of patients treated in our hospital, who ingested corrosive substances, and to assess the effectiveness of surgical therapy administered in patients with strictures after caustic injury in esophagus during this period.

METHODS: A total of 79 cases of caustic burns in esophagus were treated in Tangdu Hospital from 1971 to 2001. Their clinical and pathological data were reviewed, and collected from the medical records of patients and interviews with them.

RESULTS: More men ($n = 61$) than women ($n = 18$) ingested caustic substances with a sex ratio of 3.4:1 during the 30-year period. The caustic materials were liquid lye and acids (54 cases and 25 cases, respectively). Sixty-eight patients were given esophageal replacement in more than three months after caustic injury with no postoperative death, of which 17 cases developed postoperative complications making a complication rate of 25%. The most common one was cervical anastomotic leakage. All patients had improvement in swallowing afterwards.

CONCLUSION: The presence and severity of injuries are correlated with the amount of caustic substances ingested. Surgical treatment is a good option in patients with severe strictures, and colonic interposition might be the best surgical process. The most important factors to guarantee a successful outcome for surgery are good vascular supply and absence of tension in the anastomosis.

INTRODUCTION

Potentially catastrophic presentation and life long complications resulting from caustic ingestion make it one of the most challenging clinical situations in gastroenterology. Caustic material ingestion is most frequently encountered in children who accidentally swallowed caustic materials or in adults who ingested caustic materials for suicidal purposes^[1,2]. Alkaline caustics and acids are the commonest chemicals implicated in caustic burns. Burns from ingestion of such agents may include

the oral, pharynx, larynx, esophagus and stomach. Destruction of tissues or of these organs may lead to complications, of which respiratory compromise, esophageal and gastric perforation, septicemia, or even death might occur. Stricture formation with inability to swallow food after the injury is inevitable in some cases. Many different therapies have been recommended. The literature regarding the treatment of these patients is quite controversial and inconclusive. Repeated dilations to maintain an adequate lumen diameter were given in patients with chronic strictures. As for the complications and ineffectiveness of the dilation in more severe strictures, surgical replacement of esophagus may be required. The objective of this study was to analyze a 30-year historical series of patients treated in our hospital who ingested caustic substances, and to assess the effectiveness of surgical therapy administered in patients with strictures after caustic injury in esophagus as well as the best time for operation.

MATERIALS AND METHODS

Subjects

From 1971 to 2001, 79 cases of caustic burns in esophagus were treated in Tangdu Hospital. Their clinical and pathological data were reviewed, and collected from the medical records of patients and interviews with them. Sixty-one men and 18 women ingested caustic substances (sex ratio 3.4:1), respectively. Patients aged from 2 to 72 years (mean, 20.8 ± 2.5 years). The caustic materials for injuries were liquid lye and acids (54 cases and 25 cases, respectively). Ingestion was associated with suicidal intent in 70% of cases and accidental in 29% of cases. The amount of substances ingested ranged from 5-15 mL to as much as 40 mL, with the amount tending to be larger in the suicide attempts. To determine the amount of caustic substances ingested, patients or witnesses were asked to compare the amount ingested to the amount of water in a cup. The time intervals the patient came to our hospital after ingestion varied from several hours to several days. A total of 73 cases presented lesions of the esophagus. Two patients, who ingested a large amount of more than 60 mL caustic substances, died of stomach and esophageal perforation during the acute phase as a result of generalized infection and bleeding. Four patients, who ingested less than 15 mL, did not present severe complications. Esophageal strictures were found in 72 cases, the presence of stenosis was determined 2 wk after ingestion (chronic phase) by endoscopy and radiological signs.

Treatment

All the patients were given early emergency managements including early administration of an appropriate neutralizing agent such as ingesting water or milk after the ingestion, although it did not seem to prevent stenosis^[3], and antibiotics, as well as the correction of any apparent hydration deficiency or acid-base imbalance, and corticosteroid treatment to the patients with signs of esophagitis. Forty-eight patients of 77 cases underwent emergent endoscopy to assess the degree of damage after patients were stabilized, which was very important for the diagnosis and evaluation of the degree of injuries. Patients with ulceration, blisters, even areas of extensive

necrosis always tended to develop esophageal strictures^[4,5]. Among the 79 patients, 72 might undergo a long period of dysphagia, and gastrostomy or jejunostomy was performed for feed routinely soon after the injury except 4 patients who were lucky enough to escape severe injury and suffered from only oral burn, and 1 patient refused for further treatment because of economical reasons. No emergency thoracotomy was performed for the esophagectomy or gastrectomy in this group. Sixteen patients were performed repeated dilations 1-2 mo after ingestion (Table 1).

Table 1 Previous management before esophagus replacement (*n* = 79)

Procedures	<i>n</i>	%
Gastrostomy	25	31.6
Jejunostomy and pyloroplasty	12	15.2
Jejunostomy	19	24.1
Repeated dilation after gastrostomy or jejunostomy	15	19.0
Dilation and stent placement after gastrostomy or jejunostomy	1	1.2
No surgery	7	8.8

Esophageal replacement

Sixty-eight patients, among whom 12 had been given repeated dilation with failure therapy, were performed esophagus replacement for diffuse or multiple caustic esophageal strictures and 3 patients were cured after corticosteroid treatment and repeated dilations, 1 patient was performed stent placement. Among the 68 patients, 65 underwent the operation 6 mo and 3 three months after the injury. Stomach, jejunum and colon were used for esophageal replacement (Table 2). The colon (63/68) was commonly used as an esophageal substitute in reconstruction, and all went through the substernal route.

Table 2 Operation procedure of esophageal replacement (*n* = 68)

Procedure	<i>n</i>	%
Colonic interposition	63	92.6
Esophagogastrostomy	3	4.4
Jejunal interposition	2	3.0

Surgical procedure of colonic interposition

As colonic interposition was mostly used in our study, the surgical procedure was prescribed. The operation was carried out through an upper abdominal incision and a cervical oblique incision along the inner border of the sternocleidomastoid muscle in 62 patients and in 1 patient with a right thoracotomy respectively. The cervical esophagus was explored. It was transected in the level that esophagus was normal. In case the cervical esophagus was thickened and stiff in consistency, indicating that the organ was too extensively injured, a hypopharyngocolostomy had to be performed. This was occurred in 7 cases in this series.

A sufficient colon segment for graft was mobilized from colonic mesentery. The middle and left colonic arteries were identified and freed respectively. The root of the vessels elected was clamped with bulldog clamps for about 15 min. In the same time, the estimated ends of graft were clamped with intestinal clamps and watched. If the colon acted as replacement expressed normal in color, peristalsis and marginal arterioles would be pulsating (especially those in both ends of the segment), it would be transected. The colonic segment used in this group consisted of left colon in 30 cases, right colon and transverse colon in 33 cases. The peristaltic orientation of graft consisted

of isoperistalsis in 40 cases and antiperistalsis in 23 cases.

The substernal tunnel in 61 cases and the subcutaneous tunnel in 2 were prepared. The proximal end of graft was elevated gently from abdomen up to the neck through the tunnel. A proximal esophagocolic or hypopharyngocolic anastomosis was performed in an end-to-end or end-to-side fashion with hand-suturing single-layer technique in 56 and 7 cases, respectively.

Cologastric anastomosis was performed over the midportion of the anterior wall of the stomach without extensively injuring the stomach, and the anastomosis between the distal portion of graft and a Rouxeny loop of jejunum was performed.

Additional procedure included resection of upper portion of sternum in 5 patients in order to avoid or decrease compression on the proximal colonic graft at the level of the thoracic inlet.

RESULTS

After early emergency management in these patients, 2 patients who ingested more than 60 mL of caustic substances died of stomach and esophageal perforation during the acute phase as a result of generalized infection and bleeding. Four patients, who ingested less than 10 mL, did not present complications in the present study. On this basis, we believed that the presence and severity of injuries were correlated with the amount of caustic substances ingested, which was similar with the result of Chien *et al.*^[6]. Sixteen patients were performed repeated dilation 1-2 mo after ingestion in fear of perforation in earlier dilations and 12 patients needed further surgical treatment.

Sixty-eight cases were performed esophageal replacement because of the later stricture, which caused persistent dysphagia and weight loss in these patients. Results of operation were satisfactory with no postoperative death and improved swallowing ability, among which 17 cases developed postoperative complications making a complication rate of 25% (Table 3). The most common one was cervical anastomotic leakage, which occurred in 9 cases in this series. Postoperatively, swallow ability was considered good in 65 patients (95.7%) after an average of 22-mo follow-up (six months to eight years). The swallow ability was determined through the questionnaire about the sorts and amounts of food that could be swallowed compared with the condition before injury and operation in a general analysis.

Table 3 Postoperative complications (*n* = 17)

Complication	<i>n</i>	%
Cervical anastomotic leakage	9	52.9
Cervical wound infection	2	11.7
Anastomotic stenosis	3	17.6
Intestinal obstruction	1	5.8
Pneumothorax	1	5.8
Aspiration pneumonitis	1	5.8

DISCUSSION

A successful management of corrosive injury involves prompt recognition and early treatment. Unfortunately, it is sometimes not possible to maintain an esophageal lumen despite all the measures. Clinically apparent esophageal strictures occurred in 10-30% of patients with a caustic injury^[7], even higher in some other reports^[8,9]. In our study, 68 patients (85%) presented strictures that needed replacement, which might be due to the ingestion of relatively large amount of caustic substances for suicidal intent. Treatment of the strictures after esophageal injury was very difficult, and dilation has been used in many hospitals^[10]. Even after many times of dilation, strictures were

found in about 48% cases^[11], and although the danger of severe complications, such as perforation of the esophagus per procedure, was low (0.9-1.5%)^[12,13], a significant number of people, especially children were at risk with a relatively high mortality^[14,15]. Dilatation therapy, furthermore, required frequent admissions to hospital and multiple anesthetics with inherent risks. Surgical intervention, which is a good way to solve the problem of strictures, in the form of esophageal replacement, was carried out in more than half patients with established esophageal strictures^[16].

Most beneficial time for surgery

The time for operation of esophageal replacement after corrosive injury is still under controversy. Certainly, emergency surgical exploration is indicated if perforation or penetration is demonstrated.

Bassiouny *et al.*^[17] found in rats that collagen deposition peaked during the second week but continued for a long time after corrosive injury of esophagus. Scar retraction began as early as the end of the second week, and lasted for about six months. It took about 6-12 mo before full fibrosis stopped to develop after the injury^[18], which showed that the edge of the stricture in the esophagus might not be confirmed until then. A too earlier operation, when the scar has not completely formed, may promote the risk of anastomotic stenosis. So, it is believed that the chance of successful surgical management is greater if the operation is carried out at least six months after the injury. In our study, 3 patients with strictures in the lower segment of esophagus, who developed severe dysphagia and refused gastrostomy, were performed partial esophagectomy and esophagogastrostomy about 90 d after caustic injury. However, anastomotic stenosis occurred in 2 patients (67%) 2 mo after operation, a higher incidence of stenosis. The other 65 patients were performed operation 6 mo after injury with only one esophageal stenosis occurred.

Although it was reported that esophageal replacement could be performed even 2-3 mo after injury^[19], but many conditions must be met and the mucosa in the pharynx must be normal. So we think that the most beneficial time for surgery is no less than six months after the injury.

Choice of replacement organs

The organs used for esophageal replacement in patients after caustic injuries included stomach, jejunum and colon in previous studies^[20,21]. Stomach has the disadvantages of long-term gastroesophageal reflux, possible ulceration, anastomotic stenosis and progressive dysfunctional propulsion^[22]. The stomach is always not long enough to reestablish a continuity of esophagus when anastomosis had to be performed in the neck because the diffused injuries of esophagus, when patients had to be given partial gastrectomy after caustic injuries. In our study partial esophagectomy and esophagogastrostomy were performed only in 3 patients on the condition that strictures were located in the lower segment of esophagus. Jejunal interposition is seldom used because of the difficulty for operation since blood vessels of jejunum are too thin and easier to be affected after anastomosis. Furthermore, the jejunum is fragile to the erosion of acid in a long run, so the jejunum should not be the first choice. In our study, only 2 cases of jejunal interposition were performed, because the patients had undergone abdominal operation before and the stomach and colon were unable to be mobilized. With good blood supply and improved somatic growth, colon is long enough for esophageal replacement, and it causes fewer late complications of esophagitis and stricture because of the resistance to acid. So colon could offer potential advantages over other organs^[20,23], and is believed to be an ideal organ for the replacement. We used colon for replacement in 63 cases, and the result was

satisfactory. Our experiences support the idea that colon interposition is the best process for reconstruction of esophagus in caustic injury strictures.

Choice of colon segment as a graft is also a key point for reconstruction of esophagus. The left colon has been considered by many surgeons to be a preferable conduit for several reasons. But left colon interposition could always be used in an antiperistaltic fashion, which may cause inflammation of the anastomosis, and affect the healing process. In our study, leakage of cervical anastomosis appeared in 7 cases of the antiperistaltic anastomosis group, which was much higher than the isoperistaltic groups. So, it is suggested that the reversed peristalsis might cause more complications of anastomosis than isoperistalsis. The choice of a colon segment for substitution in our study was also affected by the supply of blood vessels during operation, and the color of intestine, and pulsation of marginal arteries after the supplying artery of colon was clamped. The mortality and morbidity in the literature after colonic interposition was very high^[24]. The most severe complication was complete necrosis of the transplanted colon. When it happened, a more complex reconstruction procedure should be considered. We had no experience in facing such a catastrophe. In 1 case, local necrosis in the proximal end of transplanted colon was observed when anastomotic leakage was diagnosed 3 d after the procedure. The anastomotic leakage was the most common complication in 9 of 63 cases, making an incidence as high as 13.3%. Considering the fact that most patients in whom esophageal disease was caused by caustic injury accompanied with bad nutritional status, this rate of postoperative complication after colon interposition is acceptable. Anastomotic leakage of the patients was managed by opening the cervical wound, and it seemed to have no effect on the late swallow ability of patients after anastomotic leakage compared with the patients without leakage in the follow up interviews. There was no death in the group. The outcome was favorable when compared with published literature^[24].

Residual esophagus

It is still a subject of a controversy whether the residual esophagus should be resected after colonic interposition. Many studies have focused on the relation between esophageal injury and carcinoma. Although the scarred and damaged esophagus might have an increased incidence of carcinoma^[25,26], there is no evidence that has been reported. In our study, esophagectomy was only performed in the esophagogastrostomy and jejunal interposition groups, and no residual esophagus was resected in the colonic interposition group. In our follow-up study, no carcinoma of residual esophagus occurred even 8 years after operation. In our experience, an additional thoracotomy or esophagectomy to resect the injured esophagus is a big burden for patients, when an abdominal incision is enough in colonic interposition procedure. Adhesion and inflammation of the residual esophagus after long time caustic injuries may be a great strike for patients to receive esophagectomy, with a higher risk of complications, even death than expected. It is therefore suggested that a long term follow-up and observation for the residual esophagus may be a preferable option for the treatment of caustic injuries of esophagus. Resection of the residual esophagus should be seriously considered anyhow.

Keys for success of surgical procedure

Certainly good nutrition and careful peri-operation treatment are important for the healing process of anastomosis. Gastrostomy or jejunostomy must be performed for the nutrition of patients. In addition to an effective nutritional support, the pivotal keys for a successful surgical procedure are the adequate and good vascular supply for the esophageal replacement, as well as the absence of tension at the anastomosis. Thus, an

enough length of substitutes must be prepared. Resection of parts of the sternum should be considered for colonic interposition to allow a spacious room for the graft colon, if the sternum exerts pressure upon the graft colon .

Abstract

AIM: Laparoscopic resection of tumors on the posterior wall of gastric fundus, especially when they are next to the esophagocardiac junction (ECJ), is both difficult and time-consuming. Furthermore, it can lead to inadvertent esophagus stenosis and injury to the spleen. In order to overcome these difficulties, laparoscopically extraluminal resection of gastric fundus was designed to manage submucosal tumors located on the posterior wall of gastric fundus and next to ECJ.

METHODS: From January 2001 to September 2003, laparoscopically extraluminal resection of gastric fundus was successfully carried out on 15 patients. There were 11 males and 4 females with an average age of 58 years (range, 38 to 78 years). The mean diameter of the tumors was 4.8 cm. The distance of the tumor border from ECJ was about 1.5-2.5 cm. The four-portal operation procedures were as follows: localization of the tumor, dissection of the omentum, mobilization of the gastric fundus and the upper polar of spleen, exposure of ECJ, and resection of the gastric fundus with Endo GIA.

RESULTS: The laparoscopic operation time averaged (66.2 ± 10.4) min, the average amount of bleeding was (89.4 ± 21.7) mL. The mean post-operative hospital stay was (5.3 ± 1.1) d. Within 36 h post-operation, 73.3% of all the patients recovered their gastrointestinal function and began to eat something and to walk. In all the operations, no apparent tumor focus was left and no complication or conversion to open surgery occurred.

CONCLUSION: Our newly designed procedure, laparoscopically extraluminal resection of the gastric fundus, can avoid contamination of the abdominal cavity, injury to the spleen and esophageal stenosis. The procedure seems to be both safe and effective.

INTRODUCTION

Malignant gastric tumors are still considered a contraindication for laparoscopic surgery by many surgeons. However, the

removal of benign tumors laparoscopically has been widely accepted as a feasible alternative to laparotomy^[1-6]. The most frequent benign gastric tumor is leiomyoma, and extensive resection is indicated because it is difficult to differentiate it from leiomyosarcoma only by biopsy. When a gastric submucosal tumor is laparoscopically removed, it is recommended to resect a sufficient margin of the surrounding normal tissues in the event that the tumor is malignant^[5,7-14].

Laparoscopic resection of a gastric fundus tumor on the anterior wall is relatively easy, in which a wedge of stomach can be resected under laparoscopic vision using an Endo GIA after the lesion is marked endoscopically. However, laparoscopic resection of tumors on the posterior wall of gastric fundus, especially when they are next to the esophagocardiac junction (ECJ), is both difficult and time-consuming. Furthermore, it can lead to inadvertent esophagus stenosis and injury to the spleen^[14-18]. In order to overcome these difficulties, we proposed a new technique for the management of submucosal tumors located on the posterior wall of gastric fundus and next to ECJ, which was *laparoscopically extraluminal resection of the gastric fundus*.

MATERIALS AND METHODS

Materials

From January 2001 to September 2003, 15 procedures of laparoscopically extraluminal resection of the gastric fundus were carried out for the submucosal tumors located on the posterior wall of gastric fundus and next to ECJ. There were 11 male and 4 female patients with an average age of 58 years (range, 38 to 78 years). The complaints at admission included upper gastrointestinal bleeding (10 cases, 66.7%) and abdominal pain (4 cases, 26.7%). The remaining one (6.7%) was diagnosed when having a physical checkup. Preoperative examinations included gastroscopy, ultrasonic gastroscopy, and barium swallow examination of the upper gastrointestinal tract, all of which revealed a submucosal lesion on the posterior wall of gastric fundus near the ECJ with a regular margin. Since these tumors could not be lifted by intrasubmucosal injection of normal saline, gastroscopic local tumor resections were not indicated. Besides, gastroscopy suggested the presence of ulcers at the center of tumor surfaces in 11 patients. The neoplasm diameter ranged 3.0-6.5 cm with a mean value of 4.8 cm. The distance of the neoplasm margin from ECJ was about 1.5-2.5 cm (Figure 1).

Surgical Methods

Anesthesia and position After general anesthesia under bronchial intubation, the patient was placed in a supine position with both legs abducted 30°. The surgeon stood between the patient's legs while the laparoscopic holder and the operative assistant on the right and left sides of the patient, respectively.

Portal positions Trocars with 5 mm or 10-12 mm in diameter were placed in the umbilicus, the left or right midclavicular line, and under the xiphoid (Figure 2).

Localization of tumors Under laparoscopy, three methods could be used for neoplasm localization: naked eye inspection, instrument exploration, and intra-operative gastroscopy^[19]. In

Figure 1 Submucosal tumors on gastric fundus diagnosed in preoperative examinations. A: A lesion near to ECJ with a clear-cut margin shown in barium swallow examination of upper gastrointestinal; B: A lesion with a clear-cut margin protruded into gastric lumen shown in ultrasonic gastroscopy; C: A hemisphere-like projection in the posterior wall of gastric fundus and an ulcer in its center shown in gastroscopy.

this series, the neoplasms had a relative large diameter. So the localization was realized via naked eye inspection and instrument exploration except in four cases under the help of gastroscopy. To perform this operation, it was also important to confirm the distances between tumors and ECJ after the tumors were localized.

Dividing omentum, entering omental bursa, and dividing splenogastric ligament Omentum dissection was begun from the middle-inferior pole of spleen and proceeded along outside of gastroepiploic vascular arch. After entering the omental bursa, the gastric posterior wall was turned to right by three-finger forceps. Next, the short gastric vessels were coagulated and cut with the ultrasonically activated scalpel to completely divide the gastric fundus from the superior pole of spleen.

Dissection of the left side of cardiac orifice to expose ECJ

Resection of gastric fundus using Endo GIA Figure 3A shows the cutting line of Endo GIA. The firing times of Endo GIA depended on the size of tumors. Complete resection of tumors with a sufficient margin usually required 2-3 sequential firings. When Endo GIA was placed near the left side of cardia, special care was taken to ensure that ECJ was not involved to avoid postoperative esophagus stenosis (Figure 3B).

Taking out of specimens Specimens were taken out through portal B after they were put in the specimen bag. Pathological examination was routinely carried out during the procedure.

The surgical field was irrigated and drainage tube was placed under the left diaphragm.

Figure 4 Resected specimens. Line a: the distance of the tumor to ECJ.

RESULTS

In this series, the mean operative time, blood loss, and postoperative hospital stay were 66.2 ± 10.4 min (range, 55 to 90 min), 89.4 ± 21.7 mL (range, 50-200 mL), and 5.3 ± 1.1 d (range, 4-7 d), respectively. On the first postoperative day, the abdominal drainage was 40-180 mL (average, 60.7 ± 14.3 mL). Of all the patients, 73.3% recovered their gastrointestinal function within 36 h after operation and began to eat and to walk. The slowest recovery of gastrointestinal function occurred 60 h post-operation.

Figure 4 shows the resected specimens. The distance of the tumor to the section edge was: (1) 1-1.5 cm to ECJ, with an average of 1.1 ± 0.3 cm; (2) 2.5-6 cm to the other three edges, with an average of 3.9 ± 1.2 cm. The intra-operative frozen sections suggested that all the tumors were benign. But the postoperative paraffin-embedded sections revealed two cases of mesenchymoma with a low malignancy. In these two cases, the distance of the tumor to ECJ was 1.3 cm and 1.5 cm respectively, and the distance to the other three edges was greater than 3 cm. The

extensive salvage operation was not carried out, and a follow-up period of 18 mo and 22 mo, respectively, did not find any recurrence and metastasis. In the other 13 cases, leiomyoma was diagnosed in 8 cases, mesenchymoma in 4 cases, and neurofibroma in 1 case.

All the 15 laparoscopic surgeries were carried out successfully with no apparent lesion left, and no complication and conversion to open surgery occurred. Follow-up was continued for 3.5-33 mo and revealed no abnormality.

DISCUSSION

Clinically, gastric benign tumors are difficult to differentiate into malignancy. Even in benign tumors, canceration and severe complications of obstruction and bleeding may take place latter. So, active measures should be taken to surgically resect the tumors. As to the resection depth, the tendency was to remove the total layer of gastric wall^[20-22]. Under gastroscopy, some gastric tumors could be excised via the intrasubmucosal injection of normal saline. However, this technique is applied mainly to the resection of mucosal tumors and not effective on submucosal neoplasms. Furthermore, the whole thickness of gastric wall could not be removed using this method. In the past, laparotomy was primarily performed to resect gastric submucosal tumors. With the advent of minimally invasive surgery, laparoscopic resection has become the first choice of many surgeons^[23-26].

Submucosal tumors in the fundus or cardia of stomachs can be managed via laparoscopic proximal gastrectomy. However, postoperative reflux esophagitis is common. For most benign gastric submucosal tumors, the range of excision is too large and the procedure is too invasive^[27-31]. Laparoscopic wedge resection of stomachs is the most commonly seen procedure for submucosal tumors of gastric fundus^[31-34]. The tumor on the anterior wall of fundus is easy to excise with Endo GIA^[20]. But for submucosal tumors on the posterior wall of gastric fundus, especially when next to ECJ, the wedge resection of stomachs is quite difficult, and caution should be taken to protect ECJ from postoperative esophageal stenosis and the spleen from injury, especially its superior polar.

In our early experience, we managed to resect submucosal tumors on the posterior wall of gastric fundus through the window of gastrotomy on the anterior gastric wall. The procedure was performed as follows: to cut open the anterior wall of the gastric body or fundus firstly (gastrotomy on the anterior gastric wall), to extract the posterior wall of gastric fundus through this cut, and to excise the tumor on the posterior gastric wall with Endo GIA or the method of stripping plus endoscopic suturing^[35]. This method, though relatively easy to carry out and with quite a good outcome, has the disadvantage of seriously intra-operative abdominal contamination of gastric juice. Furthermore, this method cannot achieve good exposure of ECJ and has not been used in the excision of tumors on the posterior wall near ECJ. Sekimoto *et al.*^[20] reported that intraluminal resection of the full thickness of posterior gastric wall lesion was performed to manage submucosal tumors on the posterior wall of gastric fundus near ECJ. In this study, balloon-tip trocars were inserted directly into the gastric lumen and gas was charged into the stomach through the trocars, then wedge resection of the posterior wall tumor was completed under direct vision with Endo GIA. The authors believe that the procedure has fewer traumas to patients and less opportunity of intraperitoneal contamination by gastric juice than gastrotomy on the anterior gastric wall. ECJ was always in the surgeon's sight, so the distance between the resection line and ECJ could be continuously monitored, which means less morbidity of postoperative esophageal stenosis. However, we think that the above two methods have the same disadvantage

of a limited range of resection and a higher incidence of spleen injury in that the short gastric vessels were not cut and especially that the superior pole of the spleen was not completely divided from gastric fundus. Moreover, care must be taken that the lateral tension to the gastric wall from gas inflation cannot be excessive, otherwise, injury of splenic capsule or gastric wall laceration might occur^[15-18,20].

In order to solve these problems, we proposed a new laparoscopic approach to surgical resection of submucosal tumors on the posterior wall of gastric fundus. In this technique, the omentum is dissected to get access to the omental bursa. So, the splenogastric ligament could be severed to completely dissect the gastric fundus away from the superior pole of spleen. Then the left side of cardiac orifice is dissected to expose ECJ, and the gastric fundus is resected with the Endo GIA. Through these measures, the newly designed approach, *laparoscopically extraluminal resection of gastric fundus*, could avoid intraperitoneal contamination, the spleen injury and the postoperative esophagus stenosis. Meanwhile, it could also provide a sufficient range of gastric resection. The main disadvantage is the increased steps required. However, with necessary training and skills in the laparoscopic surgery, the procedure can be accomplished not quite both difficult and time consuming. The average operation time in our series was only 66.2±10.4 min. The procedure, we think, is both safe and effective in that the ECJ and the superior pole of spleen are under the continuous supervision of the operator when resecting the gastric fundus, and that the procedure can provide a more sufficient range of resection.

When the laparoscopically extraluminal resection of gastric fundus is performed, two key points must be stressed. One is that the interspace between gastric fundus and superior pole of spleen must be adequately dissected. The other is that when Endo GIA is placed near the cardia, special care must be taken to ensure that ECJ is not involved. So long as the above key points are fulfilled, our method is safe, easy and beneficial to the laparoscopic resection of submucosal tumors on the posterior wall of gastric fundus.

Abstract

AIM: Living related liver transplantation (LRLT) has been developed in response to the paediatric organ donor shortage. Though it has been succeeded in many centers worldwide, the safety of the donor is still a major concern, especially in donors with anatomy variation. We succeeded in performing the first two cases of living related liver transplantation with complicated anatomy of blood vessels as a way to overcome cadaveric organ shortage in Beijing.

METHODS: Two patients, with congenital liver fibrosis and congenital biliary atresia were performed with living donor liver transplantation in our hospital and then followed up from November 12 to December 13, 2001. The two living donors, mother and father, were healthy aged 34 and 35 years. One right lobe (segment V, VI, VII, VIII) and one left lateral lobe (segment II and III) were used. The grafts weighed 394 g and 300 g. The ratio of graft weight to the standard liver volume (SLV) of donors was 68% and 27%. The graft weight to recipient body weight ratio was 3.2% and 4.4%. The graft weight to recipient estimated standard liver mass (ESLM) ratio was 63% and 85%. The two donors had complicated blood vessel variation.

RESULTS: Two patients undergone living donor liver transplantation had good results. Abnormal liver function with high bilirubin level appeared in a few days after operation, but liver function returned to normal one month after operation with bilirubin level almost decreased to near normal. No bleeding, thrombosis, infection and bile leakage occurred. One had an acute rejection and recovered. The two donors recovered in two weeks. One had slight fever because of a little collection in abdomen and recovered after paracentesis and drainage.

CONCLUSION: Living donor liver transplantation has been proved to be a good way that offers a unique opportunity of getting a timely liver graft as a response to shortage of pediatric donors, though it could be a technically difficult operation if there is anatomical variation.

INTRODUCTION

Orthotopic liver transplantation is an effective therapy for end-stage liver disease and has been proved to be a major advance in the treatment of children with liver disease. But the development of liver transplantation in infants and young children has been hampered by the shortage of donors, especially the scarcity of size-matched donors. Though reduced-size liver transplantation (RLT) was used in some centers, it does not expand the pool of potential donors and the mortality rate of recipients on the waiting list has remained high.

From November 12 to December 13 of 2001, the first two cases of living related liver transplantation in Beijing were successfully performed in our hospital. The donors were mother and father. The recipients were their 12-year-old and 31-month-old daughters. The donors and recipients all recovered about two months after operation. These two cases indicate the potential benefit of living related liver transplantation in Beijing.

MATERIALS AND METHODS

Patients

Between November 12 and December 13 of 2001, living related liver transplantation was successfully performed on two cases in the First Hospital, Peking University. They were two girls. Underlying diseases were congenital liver fibrosis and congenital biliary atresia.

Donor selection and evaluation

The living donors were mother and father with ABO identical blood group to the patients. There was no biochemical or serologic evidence of liver disease. Computerized tomography (CT) with volumetric measurement was performed to assess the volume of the right lobe and the left lateral lobe in order to determine the graft to be harvested. Angiographies to assess the vascular anatomy were performed in both donors. We found that both donors had blood vessel variations. In donor 1, the right hepatic artery (RHA) was from the superior mesenteric artery (SMA) (Figure 1A). The two branches of right portal veins (anterior and posterior right portal vein, ARPV and PRPV) of the mother were combined to the left portal veins (LPV) separately inside the liver parenchyma, no common trunk of right portal vein was found (Figure 1B). In donor 2, the left hepatic artery was derived from the right anterior hepatic artery, which was nearly inside the liver parenchyma (Figure 1C).

Donor operation

Laparotomy was performed via bilateral subcostal incision with an upward midline extension to the xiphoid process. Cholecystectomy was performed and the cystic duct was cannulated for cholangiography using undiluted radiographic contrast in order to delineate the ductal anatomy.

In donor 1, the cholangiography showed that it had the similar variation to the portal vein, the two branches of right bile ducts (anterior and posterior right bile ducts, ARBD and PRBD) of the mother were combined to the left bile duct separately which were inside the liver parenchyma (Figure 2).

Intraoperative ultrasonography was then performed to

Figure 1 Angiography of the donors. A: Right hepatic artery (RHA) from superior mesenteric artery (SMA). B: Two branches of right portal veins (anterior and posterior right portal veins, ARPV and PRPV) of the mother. C: Left hepatic artery (LHA) derived from right anterior hepatic artery (RAHA).

determine the configuration of the right hepatic vein, the junction of the middle hepatic vein with the left hepatic vein and to mark on the liver surface the position of the middle hepatic vein, which would be the liver transection plane. No right inferior hepatic veins were found in these two donors. The transection line was determined by the optimal graft volume and the anatomy of its drainage veins. The entire drainage area of the right and left hepatic veins were also identified by intraoperative ultrasonography. All of the right and left hepatic venous branches were traced to the periphery in the medial segment and marked with electrocautery on the liver surface. Hilar dissection was performed to free the right hepatic artery and portal vein. Branches of the right and left portal veins supplying the caudate process were divided and ligated.

In donor 1, dissection of the right portal veins (ARPV and PRPV) and the right hepatic ducts (ARBD and PRBD) was not made until the liver was transected, because they were inside the liver parenchyma due to anatomical variation. Parenchymal transection was performed by intraoperative ultrasonography with an ultrasonic dissector without vascular occlusion. The right hepatic ducts (the anterior and posterior ducts) were divided near the confluence of the bile ducts. The defect on the left hepatic duct was closed with 5-0 PDS monofilament absorbable sutures. After mobilization of the right liver, the right portal veins (the anterior and posterior veins), the right hepatic artery (from superior mesenteric artery) and vein were clamped at the junction with the main trunks and divided. At the back table, the graft was immersed in ice sludge and flushed with University of Wisconsin (UW) solution through the right portal venous cannula. The stumps of the right hepatic artery, the right hepatic vein and portal vein on the donor liver remnant were sutured.

In donor 2, The left hepatic artery, portal vein and hepatic vein were freed and hepatic parenchymal transection was accomplished using an ultrasonic dissector without vascular occlusion. Because the left hepatic artery was from the anterior right hepatic artery, the dissection of the left hepatic artery was partly inside the liver parenchyma when the liver transection was finished. The left duct was divided close to the cut surface of the liver, with an intact Glissonian sheath. The left hepatic duct was divided near the confluence of the bile ducts. The isolated graft was perfused in situ with the left portal vein clamped and cannulated by a catheter connected with cold lactated Ringer's solution followed by a cold UW solution, when the left hepatic vein was opened.

Recipient operation

The abdomen was entered through a bilateral subcostal incision with midline extension. Hilar dissection was performed to isolate and divide branches of the hepatic artery and portal vein. Then, total hepatectomy was performed with the inferior

vena cava preserved.

In recipient 1, the graft right hepatic vein (RHV-D) was anastomosed end-to-end to the recipient right hepatic vein (RHV-R). The graft anterior right portal vein (ARPV-D) was anastomosed end-to-end to the recipient left portal vein (LPV-R) and the graft posterior right portal vein (PRPV-D) was anastomosed end-to-end to the recipient right portal vein (RPV-R). The similar method was used to reconstruct the bile duct without stenting after the hepatic artery anastomosis (Figure 3).

Figure 2 Cholangiography of the donor 1 Two branches of right bile duct (anterior and posterior right bile ducts, ARBD and PRBD) of the mother.

Figure 3 End-to-end anastomosis of the graft right hepatic vein (RHV-D) to the recipient right hepatic vein (RHV-R).

In recipient 2, the graft left hepatic vein was anastomosed end-to-end to the confluence of the recipient left and middle hepatic veins. The graft left portal vein was anastomosed end-to-end to the truncated bifurcation of the recipient portal vein. The left hepatic duct was anastomosed to the Roux-en-Y limb of jejunum with an internal stent after the hepatic artery anastomosis.

The hepatic artery of the graft was anastomosed to the recipient hepatic artery using microvascular techniques.

Postoperative immunosuppression

Induction and maintenance immunosuppressive therapy consisted of a triple-drug regimen of steroid, cyclosporine A, and azathioprine. Acute rejection episode suspected on clinical and biochemical features and confirmed by percutaneous liver biopsy, was treated by intravenous bolus of methyl-predimetholone.

RESULTS

There was no operative mortality in the two living donors. One donor had postoperative complication of abdominal collection about two weeks after operation and recovered by percutaneous drainage about three weeks after operation. Blood losses during the donor operations were 150 mL and 70 mL respectively, and no blood transfusion was required in these two donor operations. Blood losses during the recipient operations were 50 mL and 100 mL respectively, and recipient 2 received 200 mL blood transfusion in the operation. The first warm ischaemia time of the grafts was 30 s and almost 0 s. The cold ischaemia time of the grafts was 120 min and 180 min. The second warm ischaemia time of the graft was 40 min and 50 min. The portal and arterial reperfusion interval time was 70 min and 90 min.

The weight of grafts was 394 g and 300 g, respectively. The ratio of graft weight to the standard liver volume (SLV) of donor

was 68% and 27%, respectively. The graft weight to recipient body weight ratio was 3.2% and 4.4% respectively, and the graft weight to recipient estimated standard liver mass (ESLM) was 63% and 85%.

The duration of postoperative hospital stay of the donors was 7 d and 21 d. Most laboratory profiles returned to normal about two weeks after operation. The two donors had normal liver function and were able to return to their preoperative activities 3 mo after the operation.

Both patient and graft survived well 3 mo after operation. No postoperative complication occurred in recipient 1. Recipient 2 had an attack of acute rejection one week after the operation, and recovered after bolus treatment of methylprednisolone (1 g methylprednisolone per day for three days, iv).

Data on the postoperative serum total bilirubin (TBIL), direct bilirubin (DBIL), alanine aminotransferase (ALT), aspartate aminotransferase (AST) and prothrombin activities (PTA) are shown in Tables 1-4.

DISCUSSION

The well-known inverse relationship between the availability of cadaveric pediatric organs and the epidemiology of pediatric liver disease has resulted in a substantial mortality rate among children on the waiting list^[1,2]. Although RLT could alleviate the shortage of small donor organs, it did not expand the pool of potential donors, but induced a shift of grafts from a limited pool of adult cadaveric donors to pediatric recipients^[3]. The use of liver donors has provided a means for increasing the overall supply of livers^[4,5].

Though liver consists of paired structures anatomically, safe separation of liver into its right and left halves requires considerable experience^[6,7]. Fan *et al.*^[14] identified the reasons for unsatisfactory outcomes such as the presence of necrotic tissue on the liver transection surface, inadequate hepatic venous drainage, missed right posterior hepatic duct, and more than one right hepatic duct orifice on the graft. All these made its reconstruction difficult^[8]. We followed the procedure "living donor liver transplantation using right lobe graft" by preferring the division of liver parenchyma along the Cantlie line^[9]. To define the Cantlie line, we used the middle hepatic vein as a reference by using the intraoperative ultrasonogram^[10,11]. To reduce the bleeding in the operation, we also decreased the central venous pressure to about 5 cm H₂O^[12].

The blood supply to the hepatic duct is dependent on a peribiliary plexus^[13]. In the harvesting of the right or the left

lobe graft, the blood supply is mainly from tiny arterial arcades from the right or the left portion of the caudate lobe^[13]. So, the liver tissue cranial to the hepatic duct was cleared by ultrasonic dissector down to the caudate process and care was taken to avoid thinning the wall of the hepatic duct with ultrasonic dissector. We also noticed to maintain the blood pressure stable in the operation because hypotensive episodes would render the hepatic duct stump vulnerable to ischemia and necrosis^[14].

In our group, the two donors had complicated anatomy variation. In donor 1, ARPV and PRPV were parallelly combined to the left portal vein, which were inside the liver parenchyma, no common trunk of right portal vein was found in extraparenchyma of the liver. The right hepatic duct had the similar anatomical variation with two parallel branches. This was rare in our past experiences and made the operation quite complicated. A series of 990-arteriportographic studies and 3 000-endoscopic retrograde cholangio-pancreatic-graphic studies of the liver showed that the incidence of this kind of portal vein variation and hepatic bile duct variation was 0.15% and 5.08%, respectively^[15-17]. When we tried to expose the ARPV and PRPV, we did not follow the main trunk of portal vein from the hilum, but dissected the hepatic parenchyma with intraoperative ultrasonography by an ultrasonic dissector without vascular occlusion in combination with hilar dissection to free the ARPV and PRPV^[11]. Dissection of right hepatic ducts was not carried out until the liver was transected. Chen *et al.*^[4] reported that 83.33% intrahepatic ducts had the similar anatomy variation as the portal veins^[18]. We paid more attention to intraoperative cholangiography and certified the similar anatomical variation in our group. We performed the same procedure to finish the dissection of anterior right hepatic duct and posterior right hepatic vein^[19,20].

In donor 2, angiographic study showed that the left hepatic artery was from the anterior right hepatic artery. To avoid ischemia due to excessive hepatic artery dissection, which might cause biliary stricture or leakage^[21], we dissected the left hepatic artery just on the left side of the common hepatic duct and carefully preserved the posterior right hepatic artery from the left side of the left hepatic artery. We also performed a little dissection in liver parenchyma with an ultrasonic dissector to get enough length of left hepatic artery for anastomosis^[4]. It is important not to isolate the left hepatic artery too far into the left side of the liver parenchyma to avoid devascularization of the left hepatic duct^[22].

Since these are the first two cases of living related liver transplantation in Beijing, ethical issues need to be considered when one contemplates liver transplantation from parent to child. These issues are similar to those associated with the transplantation of renal grafts from living related donors^[23]. With the experience in liver resection, we conclude that the surgical risk is low enough to be acceptable for a parent or other close relatives if they volunteer to be an organ donor. Sure, it is an ethical dilemma of subjecting a healthy person to major hepatic resection to obtain a graft for a patient with end-stage liver disease^[24-26]. We all agree with the consensus that living-donor liver transplantation is not justified when there are sufficient cadaveric donors. However, the procedure could be justified for a patient with fulminant hepatic failure when no cadaver donor was available and when the recipient had a reasonable chance of a successful outcome^[27].

The success of these first two cases has led to the acceptance of living related liver transplantation (LRLT) for clinical application in our center. With the excellent results in many centers and our present study^[28,29], we consider that LRLT should be a good way for the care of patients with end-stage liver diseases or fulminant liver failure, particular in countries where cadaveric organ donation is limited or not available^[30,31]. Though it might be very difficult technically, we should not give it up when we consider safety of the donor as our absolute

priority first.

Abstract

AIM: Pelvic magnetic resonance imaging (MRI) and endoanal ultrasound which are established imaging methods for perianal inflammatory lesions in patients with Crohn's disease require expensive specialized equipments and expertise. We investigated the feasibility and sensitivity of transcutaneous perianal ultrasound (PAUS) using regular ultrasound probes in the imaging of perianal inflammatory lesions. The sonographic findings were correlated to pelvic MRI-scans.

METHODS: We performed PAUS in 25 patients with Crohn's disease and clinical signs of perianal inflammatory disease. Within a median of 10 d (range 0-75) these patients underwent MRI of the pelvis. Regular convex and linear high resolution probes were used for PAUS. The sonographic findings were correlated to the MRI findings by blinded investigators.

RESULTS: The sonographic investigations were well tolerated by all patients. Fistulae typically presented as hypoechoic tracks. Twenty-nine fistulae were detected in 22 patients. Abscesses were detected in 7 patients and presented as hypo- or anechoic formations. Twenty-six of 29 fistulae and 6 of 7 abscesses could be confirmed by MRI. Kappa statistics showed an excellent agreement ($\kappa > 0.83$) between the two imaging methods.

CONCLUSION: PAUS is a simple, painless, feasible, real-time method that can be performed without specific patient preparation which is comparable in its sensitivity to pelvic MRI in the detection of perianal fistulae and/or abscesses. PAUS can especially be recommended as a screening tool in acute perianal disorders such as perianal abscess and for follow-up studies of perianal inflammatory disease.

INTRODUCTION

Perianal disease is a common complication in Crohn's disease. Approximately 20% of patients with Crohn's disease would suffer from perianal fistulae and/or sinus tracks^[1,2]. The diagnosis and treatment of perianal fistulae can be difficult and represent a challenge for physicians. Treatment modalities include conservative as well as surgical approaches. Therefore comprehensive imaging is necessary in order to develop adequate treatment strategies and to evaluate treatment outcomes^[3]. Endoanal ultrasound (EAUS) as well as MRI of the pelvis are frequently used for imaging of perianal fistulae, sinus tracks or abscesses. The combination of MRI and EAUS is capable of detecting perianal fistulae with a sensitivity of 100%^[4,5]. Recent studies for the medical treatment of perianal disease used either MRI of the pelvis or transanal ultrasound as a follow-up tool to evaluate the therapy outcomes after infliximab treatment^[6-8].

However, both imaging methods require specialized and fairly expensive equipments as well as an experienced investigator. The use of a rigid EAUS probe can be painful or even impossible in patients with inflammatory perianal disease due to anal stenosis. Furthermore, EAUS does not allow the assessment of pathological changes extending to the gluteal region. MRI allows the evaluation of the whole pelvic region, however, it lacks the real time capacity of ultrasound and the high resolution of high frequency linear ultrasound probes.

Transcutaneous perineal/perianal ultrasound (PAUS) represents another method to detect perianal inflammatory disease which can be performed using regular ultrasound probes without special patient preparation. Furthermore, it can be used in patients with anal stenosis. However, despite its methodical simplicity, PAUS is not yet widely used in the detection of perianal fistulae and/or abscesses. Several investigators have applied perineal ultrasound in female patients for diagnosis of incontinence including postpartum anal sphincter tears^[9-15]. These investigations were regularly performed in the lithotomy position and supplemented or compared with transvaginal or transrectal ultrasound. Rubens *et al.*^[16] described PAUS as a valuable tool to image perianal inflammatory disease in their pictorial essay, while Stewart *et al.*^[17] recently described PAUS using a combination of transvaginal and transperineal ultrasound in female and transperineal ultrasound in male patients to detect perianal fistulas and abscesses. Beside a linear probe, Parks *et al.*^[18] used a transvaginal probe for the PAUS to take advantage of its small footprints and they were able to classify fistulae according to the Parks classification. In their recent published study Mallouhi *et al.*^[19] showed a high correlation of perineal ultrasound findings and surgical examination. However, as Mallouhi *et al.*^[19] pointed out correctly surgical exploration in some cases, might not allow the detection of every perianal fistula. Despite the obvious advantages of perianal/perineal ultrasound no studies exist so far that compared the effectiveness of PAUS with the established imaging methods such as MRI and/or EAUS. Therefore, we investigated patients with clinical signs of perianal fistulae or abscesses using PAUS and compared the detected pathology with results of MRI scans of the pelvis as the gold standard. Also, we performed follow-up

studies in certain patients to monitor the treatment effectiveness.

MATERIALS AND METHODS

Patients were recruited either from the inflammatory bowel disease outpatient clinic or from the gastroenterology wards of our institution. Ultrasound examinations were performed in 25 patients (17 females, 8 males) with a mean age of 36.2 ± 2.5 years. All patients had prediagnosed Crohn's disease confirmed by biopsy and presented with complaints suspicious of perianal disease. No specific preparations of the patients such as enemas were performed. Either a Toshiba Aplio (3.3 Mhz [Tissue Harmonic Imaging, THI] and 12 Mhz transducer), a Toshiba Powervision (6 Mhz and 12 Mhz transducer, Toshiba, Neuss, Germany) or a Siemens Elegra (3.75 [THI] and 9 Mhz transducer, Siemens, Erlangen, Germany) was used depending on availability for the ultrasound examination. Colour Doppler ultrasound was applicable with all probes. The ultrasound probe was covered with contact gel, and introduced into a regular latex examination glove with the fingers of the glove tied up in knots for hygienic reasons (Figure 1A). For sufficient contact, contact gel was spread on the outside of the glove before the examination was performed. PAUS was performed with the patient in the left lateral position by placing the probe directly above the anus in the sagittal plane (Figure 1B). For better orientation, the examination was started with a convex transducer identifying bladder, rectum and prostate/vagina (Figure 2). Details and pathological findings were imaged and further investigated using the linear high resolution probes. The maximal penetration for good visualisation using linear transducers was 6 cm. Depending on the specific findings the probe was turned or shifted in the perianal area. The probe was placed above any pathological opening. Colour Doppler was used to distinguish blood vessels from other anechoic/hypoechoic lesions such as fistulae. All ultrasound examinations were checked by either J.S.B. or M.J.G. who both held the highest DEGUM (German society for ultrasound in medicine) ultrasound certificates (DEGUM III, Seminarleiter). Colour Doppler ultrasound was applicable with all probes. Fistulae were categorized as superficial, intersphincteric, transsphincteric, suprasphincteric, extrasphincteric, recto-vaginal fistulae and/or abscesses.

Within a median of 10 d (range 0-75) the patients were also examined by pelvic MRI. MRI was performed to identify inflammatory changes, abscess formations and fistulae. A 1.5 Tesla MR scanner (GE Signa Horizon Echospeed, Milwaukee, Wisconsin) was used. A phased array surface coil was placed on the pelvis. Transverse and sagittal T1-spin echo (T1SE), fat-saturated T2-fast spin echo (fsT2FSE) sequences were applied. Also, transverse and oblique coronal (angulated adjacent to the anal canal) T2FSE sequences without fat saturation were applied in order to detect fistulous tracks. Either respiratory compensation or respiratory trigger was used to avoid artefacts from respiratory motion. After intravenous gadolinium administration (0.1 mmol/kg Gd-DTPA, Magnevist, Schering, Berlin, Germany) transverse and oblique coronal fat-saturated T1-spin echo (fsT1SEpostGd) sequences were performed. Raised signal intensity in the T2-weighted images and an increased uptake of Gd-DTPA served as markers for active inflammatory changes, whereas low signal intensity bands distorting normal fibrofatty tissue in both T1 and T2 weighted images were considered to be fibrous scarring. The results were reviewed by two radiologists in consensus reading. The investigators of either method were not aware of the results generated by the other.

Results were compared by calculating the kappa coefficient according to Cohen.

RESULTS

General Images

PAUS was well tolerated in all patients. In cases of subcutaneous perianal abscesses or significant inflammatory changes, slight local pain was reported during the examination when pressure was applied with the ultrasound probe. Two patients who had a history of significant anal stenosis and repeated surgical anal dilations were included in the study and evaluated with PAUS, because endoanal ultrasound could not be performed in these cases.

A general view was achieved using a regular convex probe (as listed in the Materials and Methods section) that showed rectum, bladder, prostate gland and urethra or vagina and uterus (Figure 2). Small intestinal bowel loops could be shown as well as pathological pelvic intraabdominal fluid collections. However, for comprehensive imaging of perianal inflammatory disease, a high frequency linear probe provided a much more detailed imaging. The penetration that could be achieved using a linear transducer (as listed in Materials and Methods) was sufficient to detect most of the perianal inflammatory changes. The anal canal presented as an anechoic area (Figure 3A,B). The external anal sphincter presented with hyperechoic striped bands while the internal sphincter had a homogenic hypoechoic texture (Figure 3B).

Pathological findings were detected in 96% (24/25) of the patients examined with PAUS. Pathological findings included entero-cutaneous perianal fistulae, sinus tracts without cutaneous openings, bifurcated complex perianal fistulae, perianal or subcutaneous abscesses, rectovaginal fistulae and inflammatory remnants post perianal abscess.

Fistulas

In 88% (22/25) of patients investigated, fistulae and/or sinus tracts could be visualized by PAUS. A total of 29 fistulae were detected. Fistulae and sinus tracks presented as hypo/anechoic tracks. Figure 3 shows typical PAUS images of entero-cutaneous perianal fistulae. Regularly small hyperechoic dots could be detected representing air bubbles within the fistulous tracks. In 45% (10/22) of the fistulae, it was possible to trace small hyperechoic dots which would move within the fistulae and therefore enabling the investigator to detect even minor fistulous tracks indicating active fistulae.

MRI confirmed 90% (26/29) fistulae in 91% (20/22) of these patients. All fistulae detected by MRI were also detected by PAUS. The kappa coefficient for fistulae was calculated as 0.83 resembling an excellent agreement. In two patients both methods described incomplete fistulae (sinus tracks with no visible cutaneous opening). Figure 4 shows a perianal enterocutaneous fistula imaged by PAUS and MRI.

As PAUS included inspection of the anoderm, cutaneous openings of fistulae could easily be detected. In two cases MRI was not able to confirm perianal fistulae that were detected by PAUS. However, discharge from a cutaneous opening proved the presence of a perianal fistula in both of these cases, which could be visualized with PAUS. Both of these fistulae were short intersphincteric fistulae of type 1 according to the Parks classification^[18]. In one of these cases the fistula described in PAUS could be detected in a repeat MRI performed using a vaginal tampon for better anatomical differentiation. However, the investigators were aware of the findings made in the PAUS in this second examination.

Follow-up PAUS investigations were performed in 8 of the 25 patients. Improvement under therapy was noted in 4 cases, no change in 2 cases and progressive disease in 2 patients. The sonographical improvement was consistent with clinical findings. In one case follow-up MRI was performed confirming the PAUS findings as both imaging methods described an abscess within the fistulous track.

Figure 1 A regular latex examination glove filled with ultrasound contact gel was used to cover the probes for hygienic reasons (A). The examinations were performed in the left lateral position with the probe placed above the anus (B).

Figure 2 A general overview over perianal anatomy and pathology can be obtained using a regular convex 3.5 Mhz probe.

Figure 3 Perianal imaging of entero-cutaneous fistulae using a 10 MHz ultrasound probe. Hyperechoic dots resemble air bubbles within the fistulous track. The rectum represents as hypo- anechoic structure. External and internal anal sphincter can be distinguished.

Recto-vaginal fistulae

PAUS was able to visualize rectovaginal fistulae in 3 cases.

MRI confirmed recto-vaginal fistulae in two of the three cases. In the remaining case MRI showed a fistula from the sigmoid colon to the vagina, in contrast, PAUS described a recto-vaginal fistula. While gynaecological examination did not confirm the presence of any fistula, drainage of blue stain into the vagina after the introduction of a methylene blue soaked swab into the rectum finally proved the presence of a recto-vaginal fistula as was described by PAUS. The sigmoid-vaginal fistula was not detected in the PAUS examination.

Figure 4 Enterocutaneous fistula detected with PAUS (A) was confirmed using MRI (oblique coronary T2-FSE sequence without fat saturation) (B).

Figure 5 Typical appearance of a pararectal abscess, dorsal of the rectum. Furthermore a sinus track could be detected that perforated the external sphincter and ceased in multiple small sinus tracks that did not have a cutaneous opening.

Abscesses

Perianal fluid collections/abscesses were detected by PAUS in 28% (7/25) of the patients. Abscesses presented as oval shaped hypo- to anechoic masses which were demarcated off the regular tissue by a hypoechoic seam (Figure 5). In 5 cases a direct association of a fistulous and/or sinus track to the abscess formation could be demonstrated. Figure 5 shows a perianal sonographic scan of a male patient that presented to our outpatient clinic with severe perianal discomfort. While inspection and digital examination of the anus were inconspicuous, the transcutaneous perianal ultrasound examination revealed hypoechoic fluid collections dorsal of the rectum in this patient. The abscess shown in Figure 5 had a fistulous track connecting the rectum and a complex intrasphincteric fistulous system. In 6 cases fluid collections could be confirmed using MRI, and no fluid collection detected in MRI was missed by PAUS. In one case MRI could not confirm a fluid collection. However the two examinations were performed at an interval of 23 d. The smallest abscess detected in PAUS measured 14 mm×12 mm× 8 mm. In three of the cases with significant, drainable abscesses examination under anaesthesia (EUA) could confirm PAUS/MRI findings.

Figure 6 shows an example of a perianal abscess as imaged by PAUS and MRI. Clinical inspection of the anal region did not show any abnormalities in this patient. However anal

discharge upon digital examination was observed and further imaging was initiated. Both PAUS and MRI showed a significant fluid collection with a diameter of approximately 4.5 cm. In contrast to MRI, PAUS detected a fistulous connection to the rectum. In addition to the abscess, a sinus track was detected that emanated from the abscess, and ended within the gluteal fat. The sinus tract could clearly be visualized by both methods (Figure 6). Interestingly, EUA failed to reproduce the pathological findings in the first place and had to be repeated to confirm the PAUS/MRI findings and to achieve appropriate drainage of the abscess. In Figure 7 a small subcutaneous abscess was imaged by PAUS and MRI. Both methods were able to show an active fistulous track reaching from the rectum to the subcutaneous fluid collection.

Figure 6 PAUS (A+B) and MRI (C+D) imaging (coronary fat-saturated T1-SE sequence after gadolinium administration) of a perianal abscess. In contrast to MRI, PAUS was able to clearly identify a connection between the rectum and the abscess (A+C). Both methods could identify a sinus track that began within the abscess and ended in the gluteal fat (B+D). A scale (cm) is shown on the left side of the PAUS images for orientation.

Figure 7 Comparison of PAUS (A) and MRI (B) imaging (transverse T1-SE sequence) of a subcutaneous abscess. A small fistula from the rectum to the abscess could be detected with PAUS and MRI.

DISCUSSION

In this study we investigated the feasibility of transcutaneous PAUS for the evaluation of perianal inflammatory disorders in patients with Crohn's disease.

We showed that perianal fistulae, complex fistulous systems as well as perianal abscesses could be detected with high sensitivity using PAUS. The results were comparable to pelvic MRI that

currently represents in combination with EAUS, the gold standard for the imaging of perianal inflammatory disease. However, PAUS still has certain limitations when performed in the left lateral position compared to EAUS and MRI. The localization of fistulae within the sphincter apparatus is important when surgical interventions are indicated. While imaging of the internal anal sphincter is difficult using PAUS, the external sphincter can be clearly distinguished due to its hyperechoic striped appearance. In terms of impact on treatment, the definite description of the anatomical relationship of pathological changes to the external anal sphincter according to the Parks classification is most important^[18]. Still, accurate localization of pathological changes to the internal/external sphincter requires an experienced investigator.

Despite the limitations stated above, we believe that PAUS has several advantages compared to EAUS and MRI. PAUS is as effective as MRI in the detection of perianal fistulae, but the detection of air bubbles within a fistulous track can clearly indicate active fistulae. Real time imaging in sonography is an advantage that can be helpful in detecting possible connection to the rectal lumen. In two cases investigated by MRI and PAUS, MRI was not able to detect a short perianal fistulae, while the cutaneous openings of the fistulae were obvious on clinical inspection. While EAUS is limited to pathological changes associated to the rectal lumen, perianal ultrasound can be used to identify fistulous tracks in the gluteal region. PAUS therefore combines the high resolution and real time capabilities of EAUS and the panoramic view generated by MRI.

The presence of perianal abscesses is an important condition for surgical interventions in patients with perianal Crohn's disease. Abscesses were detected by PAUS with the same sensitivity as by MRI. PAUS therefore is a valuable tool in the screening for perianal disease. Especially when immediate action is necessary and sophisticated diagnostic imaging could delay diagnosis due to limited availability, PAUS might be a feasible alternative to EAUS and MRI. For example, we were able to detect perianal abscesses in two patients that presented with severe perianal discomfort using PAUS. These patients did not have a history of perianal inflammatory disease and neither inspection of the anus nor digital rectal examination revealed pathological findings. These two patients underwent immediate surgical drainage of their abscesses without further imaging and therefore had to be excluded from this study. Vice versa a perianal abscess was suspected in a patient that presented with a painful perianal swelling with typical redness and induration. An abscess was ruled out using PAUS and the patient was spared a surgical intervention and had complete remission of symptoms. Again no further imaging was performed in this patient. In the future, a mobile application of PAUS in the operating room to guide drainage operations is conceivable. This, however, has not been tested in this study yet.

With more advanced imaging techniques in medicine, the costs of diagnosis and treatment have become a serious and important issue. Especially in chronic diseases, such as Crohn's disease which require regular examination for follow-up and treatment-evaluation alternative, easily available methods to EAUS and MRI as rather expensive diagnostic tools are more than welcome. We believe that PAUS represents such an alternative for it can be performed with regular ultrasound probes and is therefore widely available. It is fast and does not require special patient preparations such as enemas or injection of contrast agents. Basically it can be performed in any outpatient radiology or internal medicine practice. Depending on on-site experience additional imaging of perianal disease with EAUS or MRI might be necessary. However, after initial comparison with the established methods, follow-up can easily be performed with PAUS alone. In follow-up studies the application of more sophisticated imaging methods such as

EAUS or MRI would then be limited to investigate significant clinical changes not detectable by the transcutaneous approach.

In general PAUS was well tolerated by our patients. As a matter of fact one of the reasons to perform this study was that several patients refused diagnosis with EAUS. As perianal inflammatory disease can result in fibrosis and consecutive anal stenosis, EAUS might not be applicable at all in some patients.

The use of contrast agents such as hydrogen peroxide or Levovist might improve the imaging quality of perianal ultrasound^[20-23]. However, the main goal of this study was to determine whether a simple alternative approach was helpful in the imaging of perianal disorders.

We would like to encourage the readers of this article who perform EAUS to employ PAUS using regular ultrasound probes. Since PAUS has been established in our department, the use of EAUS for inflammatory disease has been drastically reduced and is now limited to very few cases that can not be clarified with PAUS and/or MRI.

In conclusion, PAUS represents a sensitive, non-invasive tool that can be used for initial screening and follow-up in the detection of perianal inflammatory disease.

Abstract

AIM: To evaluate the clinical value of plasma apolipoprotein A-I (Apo A-I) as a marker of fibrosis in children with chronic hepatitis B (CHB).

METHODS: Liver biopsy specimens from 49 children with CHB were evaluated by using Knodell index. Plasma Apo A-I level was measured after 12-h fasting. Student's *t* test, Spearman's correlation test and receptor-operating characteristic (ROC) curve were used for statistical evaluation.

RESULTS: Mean Apo A-I level of the patients was not different from that of controls ($P>0.05$). Six (8.7%) children had fibrosis score of more than 2 (severe fibrosis). No difference in the level of mean plasma Apo A-I was found among children with and without severe fibrosis ($P>0.05$). No correlation between Apo A-I level and fibrosis scores was found ($P>0.05$). The area under the ROC curve was 0.407 ± 0.146 ($P>0.05$).

CONCLUSION: Severe fibrosis is not common in children with CHB and plasma Apo A-I level is not a reliable indicator of fibrosis.

Selimoglu MA, Yagci RV, Yüce G. Low plasma apolipoprotein A-I level is not a reliable marker of fibrosis in children with chronic hepatitis B. *World J Gastroenterol* 2004; 10(19): 2864-2866 <http://www.wjgnet.com/1007-9327/10/2864.asp>

INTRODUCTION

Apolipoprotein A-I (Apo A-I) is produced mainly by hepatocytes and its level varies according to the degree of liver fibrosis^[1-4]. In our previous study, we demonstrated the inverse correlation of Apo A-I with the Child-Pugh score^[3] in children with cirrhosis. Data of Apo A-I levels in chronic hepatitis were mainly from studies performed in adults with hepatitis C^[5,6]. A recent study showed that serum Apo A-I level was inversely correlated with liver fibrosis in adult patients with chronic hepatitis B (CHB)^[7].

Liver biopsy is an invasive procedure especially for children. It is well known that serum alanine transaminase (ALT) is a good indicator of portal inflammation in chronic hepatitis^[8],

but a reliable biochemical fibrosis index is not available for children. The aim of this study was to determine if low plasma Apo A-I level was a reliable indicator of fibrosis in childhood CHB.

MATERIALS AND METHODS

Forty-nine hepatitis Be antigen (HBeAg) positive children (13 females and 36 males) with pathology verified chronic HBV infection were included in this study. Their mean age was 9.1 ± 4.1 years (3 to 18 years). Patients were excluded if they had hepatitis D or C or HIV infection. No patient had evidence of decompensated liver diseases or autoimmune hepatitis. Parents of the patients were required to give written informed consent before entering the study.

Pretreatment liver biopsy specimens were obtained from all patients and scored with the use of the Knodell index^[9], which grades the histological activity of hepatitis on a scale from 0 to 22, with higher scores indicating more severe abnormalities. The overall Knodell score is the sum of the scores for periportal/bridging necrosis (0 to 10), intralobular degeneration and focal necrosis (0 to 4), portal inflammation (0 to 4), and fibrosis (0 to 4). Before the patients entered the study, blood samples were taken for the test of blood cell counts, serum alanine aminotransferase (ALT), Apo A-I, hepatitis B surface antigen (HBsAg), HBeAg, antibody to HBeAg, antibody to HBsAg and HBV DNA.

Plasma Apo A-I levels of 20 gender- and age-matched healthy children were used as controls. Student's *t* test, Spearman's correlation test and ROC curve were used for statistical analysis.

RESULTS

Pre treatment ALT, Apo A-I, hepatic activity index (HAI), portal fibrosis, inflammation and necrosis scores, and HBV DNA levels of the children are shown in Table 1. Mean plasma Apo A-I level of 49 children with CHB was not different from that of controls (39.3 ± 5.8 $\mu\text{mol/L}$ vs 40.71 ± 4.8 $\mu\text{mol/L}$, $P>0.05$).

Table 1 Some pretreatment biochemical, pathological and serological findings in children with chronic hepatitis B

Parameter	mean \pm SD	Range
ALT (IU/L)	80 \pm 80	21-396
Apo A-I ($\mu\text{mol/L}$)	39.3 \pm 5.8	29.2-57.5
Hepatic activity index	7.0 \pm 3.0	3-17
Portal fibrosis	1.4 \pm 0.9	0-4
Portal inflammation	2.0 \pm 1.2	0-4
Focal necrosis	1.6 \pm 0.9	0-4
Bridging necrosis	2.0 \pm 1.6	0-6
HBV DNA (ng/L)	1 537 \pm 712	118-3 111

Children with CHB were divided into 2 groups according to their fibrosis stage: group 1, whose portal fibrosis scores were 0, 1 or 2; group 2, whose portal fibrosis scores were 3 or 4. In groups 1 and 2, the mean Apo A-I levels were 39.6 ± 5.6 $\mu\text{mol/L}$

and $36.9 \pm 6.8 \mu\text{mol/L}$, respectively ($P > 0.05$). Only 6 (8.7%) children had a fibrosis score of more than 2.

No correlation among Apo A-I and HAI, portal inflammation, portal fibrosis, focal necrosis, bridging necrosis scores was found ($P > 0.05$). A positive correlation between ALT and portal inflammation scores and between ALT and HAI was found ($P < 0.05$ and $P < 0.01$, respectively).

The area under the ROC curve of Apo A-I was 0.407 ± 0.146 ($P > 0.05$, Figure 1).

Figure 1 ROC curve of Apo A-I.

DISCUSSION

Fibronectin, a major liver extracellular matrix component, can interact with Apo A-I both by downregulating its mRNA level in liver cells and by binding to this molecule after its secretion in the extracellular space^[1,2]. Since fibronectin is the first matrix component to be produced in excess and deposited in liver fibrosis, it has been thought to be involved in the decrease in Apo A-I in alcoholic patients with liver fibrosis and cirrhosis^[1,2].

Because liver biopsy is an invasive method with a 1/10 000 mortality rate, noninvasive serum markers of liver fibrosis are under investigation^[10]. Furthermore, although histological analysis is considered to be the gold standard for the diagnosis of extensive fibrosis and cirrhosis, the rate of false-negative results was approximately 15-20%^[10]. Clinical investigations on fibrosis markers were generally focused on hepatitis C rather than hepatitis B^[5,6]. One of the few studies performed of patients with CHB was the study Huang *et al.*^[7]. They investigated the value of serum biochemical markers in the diagnosis of liver fibrosis of patients with hepatitis B and observed that levels of ALT, total bilirubin, alpha 2-macroglobulin, GGT and Apo A-I were significantly correlated with the clinical staging of liver fibrosis, and concluded that a combined assessment of these indices might help obtain an accurate diagnosis of liver cirrhosis with less need of pathological biopsy in this population^[7].

Besides noninvasive biochemical markers, some studies strongly recommended using some historical features such as sex, age at biopsy and alcohol consumption as independent predictors of fibrosis in chronic hepatitis C adults^[5]. They demonstrated that a simple index including age, sex, and five biochemical markers could accurately predict significant hepatitis C-related fibrosis^[5].

Teare *et al.*^[11] compared aminoterminal type III procollagen propeptide (PIIP) with the PGA index, which combines the prothrombin time, gamma-glutamyl transpeptidase activity, and serum Apo A-I concentration, in predicting liver fibrosis in patients with alcoholic liver disease, primary biliary cirrhosis, and CHB. They stated that PGA and PIIP values were increased in all patients with CHB in comparison with controls. For the detection of cirrhosis they found that PGA was 91% sensitive and 81% specific^[11]. Similarly Ding *et al.*^[12] evaluated the diagnostic value of serum liver fibrosis markers by analyzing the correlation between liver fibrosis stage in patients with

CHB and serum liver fibrosis markers, such as hyaluronate, type III procollagen, laminin, and type IV collagen in 278 patients. They found that liver fibrosis stage was correlated to inflammation degree and that serum hyaluronate, type III procollagen, laminin, and type IV collagen could reflect the state of liver fibrosis^[12].

The difference between mean Apo A-I level of children with CHB and controls was not significant ($39.3 \pm 5.8 \mu\text{mol/L}$ vs $40.71 \pm 4.8 \mu\text{mol/L}$). In 2002, we reported similar figures for children with chronic hepatitis, most of them had CHB^[4]. However, Norton *et al.*^[13] reported that Apo A-I and apo C-III steady-state mRNA levels were suppressed by HBV replication and/or gene expression. Other studies revealed that the levels of Apo A-I and Apo A-II were reduced during acute hepatitis, when virus levels were high, and normalized after viral clearance^[14,15]. Similar results were reported for chronic HBV infection. Reduced levels of circulating lipoproteins and apolipoproteins have been correlated with increased viral replication^[16-18]. In our study no correlation between HBV DNA and Apo A-I levels was detected.

Of the 49 children, only 8.7% had significant fibrosis according to Knodell index (>2), suggesting that fibrosis is not prevalent in this age group. Although the mean plasma Apo A-I level was lower in this small population compared to children with mild/no fibrosis ($36.9 \pm 6.8 \mu\text{mol/L}$ vs $39.6 \pm 5.6 \mu\text{mol/L}$), statistical significance was not detected.

Recently it has been recommended to use ROC curves in determination of the indices of hepatic fibrosis in clinical practice^[19,20]. In this study, plasma Apo A-I level as a fibrosis marker was measured in children with CHB and compared with Knodell scores to determine if it had any clinical value as a marker of fibrosis. In conclusion, severe fibrosis and Knodell score higher than 2, are not common in CHB children and plasma Apo A-I level is not a reliable indicator of fibrosis.

Abstract

AIM: There is limited information on the natural history of HCV infection in China. We investigated the outcome of HCV infection after nine-year follow-up and the risk factors in blood donors in China in order to provide the foundation for prevention and therapy.

METHODS: A total of 172 cases of HCV infection with anti-HCV positive and ALT abnormality were enrolled in the archives when was screened blood in Hebei Province in 1993. In them 142 blood donors were followed up till July 2002. No antiviral treatment was applied to them during the period of infection. In the present study, anti-HCV, HCV-RNA and aminotransferase were detected and genotyping was conducted by the method of restriction fragment length polymorphism(RFLP). B-type ultrasound detection was performed in all the patients. Age, sex, alcohol consumption and clinical symptoms were questioned.

RESULTS: After nine years' follow-up, 10.56% (15/142) of the cases were negative for anti-HCV and 16.42% (12/134) of them were negative for HCV-RNA. The genotypes 1b, 2a and 1b/2a were 91.07%, 6.25% and 2.68% respectively. Twelve cases (8.45%) were negative for both HCV RNA and anti-HCV. The rate of chronicity in this group was 83.58% (112/134), and the rate of viral spontaneous resolution was 16.42% (22/134). The mean level of ALT, AST, γ -GT in HCV RNA positive cases was significantly higher than that in HCV RNA negative cases ($P < 0.001$). The abnormal rate of ALT and/or AST in male donors was significantly higher than that in female donors ($P = 0.005$). The rate of progression to liver cirrhosis from chronic hepatitis C was significantly higher in the cases of super-infection with HBV than that in the cases of single HCV infection. Overdose alcohol consumption promoted the progression to chronicity.

CONCLUSION: This area (Hebei Province) has a higher rate of chronicity in HCV infection, and measures should be taken to prevent its progression to serious liver diseases, especially for patients super-infected with HCV and HBV.

study in 142 cases of hepatitis C virus infection. *World J Gastroenterol* 2004; 10(19): 2867-2869

<http://www.wjgnet.com/1007-9327/10/2867.asp>

INTRODUCTION

Hepatitis C virus is the major cause of post-transfusion hepatitis. It has been estimated that nearly 170 million people are infected with HCV in the world. High chronicity is an obvious characteristic of HCV infection. Eighty-five percent of infected patients developed chronic infection and 8-45% of them could resolve. Liver cirrhosis developed in 10-50%, hepatocellular carcinoma in 1-23%, liver disease related mortality in 4-15%^[1-3] in twenty years of natural infection. There is limited information about the long-term follow-up study in China. Many donors were infected with HCV by means of plasmapheresis in the 1990 s^[4]. In the present study, 172 cases of blood donors infected with HCV were diagnosed in August of 1993, and 142 of them were followed up till July 2002. The outcome in natural history of HCV infection and related factors affecting the outcome were investigated.

MATERIALS AND METHODS

Patients

A total of 172 cases of blood donors from a rural area of Zhao County in Hebei Province were diagnosed as HCV infection by etiology and biochemistry detection (including anti-HCV and hepatitis B surface antigen) in August of 1993. Thirteen cases of them were co-infected with hepatitis C virus and hepatitis B virus. Nine years later, only 142 persons (66 men and 76 women with a mean age of 36.67 ± 9.10 years at time of infection and 45.70 ± 9.11 years at time of investigation) were followed up. Additionally, three children with aged of 2 to 8 years at the time of infection were checked-up in our series. It was noted that all of the donors received no antiviral treatment during the nine years of infection.

Methods

Anti-HCV antibodies Five-milliliter peripheral vein blood was collected for biochemical and etiology detection. All patients were tested for the presence of anti-HCV antibodies with Abbott diagnostic test kit (Abbott, USA) according to the manufacturer's instructions in 1993 and 2002. The rest of the blood samples were stored at -80°C .

HCV RNA detection and genotyping Primers were designed from the conserved 5'-noncoding (5'-NC) region of the HCV genome. P1: 5'-GTGTGAGGAAGTACTGTGTT-3', P1': 5'-AACACTACTCGGCTAGCAGT-3', and P2: 5'-TTCACGCAGAAAGCGTCTAG-3', P2': 5'-GTTTATCAAGAAAGGACCCG-3'. RT-PCR procedure was performed as previously described^[5]. PCR products positive for HCV RNA were genotyped with restriction fragment length polymorphism (RFLP) method^[5].

Risk factors for HCV chronicity All data of risk factors for HCV chronicity were collected by using special questionnaires, including sex, age, symptoms, alcohol consumption, alanine aminotransferase (ALT), aspartate aminotransferase (AST), γ -glutamyltransferase (γ -GT), alkaline phosphatase (ALP), total bilirubin (Tbil), direct bilirubin (Dbil), total protein (TP) and

albumin (ALB) in 12 by using fully automatic biochemical analysis compliance 7071A (Hitachi, Japan). HBV markers were also detected by Abbott diagnostic kit.

Diagnostic criterion Chronic hepatitis C and liver cirrhosis were diagnosed based on the criteria modified at the Sixth (Xi' an) National Convention of Infectious, Parasitic and Liver Diseases^[6].

Statistical analysis

Quantitative values were expressed as mean±SE. Unpaired Student's *t* test, χ^2 and Fisher's exact test were used for statistical comparison of the data. *P*<0.05 was considered statistically significant.

RESULTS

Outcome of HCV infection

In the 172 cases enrolled in this study in 1993, seven cases were already died at the time of investigation. Two (1.16%) out of seven cases died of suspected hepatocellular carcinoma. Twenty-three cases were out of follow-up. In the present study, only 142 cases were followed-up under the investigation. Out of the 142 cases, HCV RNA was detected in 134 cases. The result showed that 112 cases (83.58%) of the donors were positive for HCV RNA and 16.42% were negative for HCV RNA; 89.44% were positive for anti-HCV and 10.56% were negative for anti-HCV; 8.45% of them were negative for both anti-HCV and HCV RNA. Out of the 142 infected persons, most but one (who was with chronic moderate hepatitis C) with mild chronic hepatitis C had no obvious clinical symptoms according to the viral hepatitis prevention project. In the cases with persistent infection, B-type ultrasound detection showed 2.68% with liver cirrhosis, 86.61% with chronic hepatitis and 10.71% with fatty liver.

Anti-HCV, HCV RNA and abnormality of liver function

Ninety-one point sixty percent of the cases were positive for HCV RNA in the positive group of anti-HCV. Eight cases of severe hepatitis and three cases of liver cirrhosis were positive for both anti-HCV and HCV RNA. Another two patients with liver cirrhosis and severe hepatitis were co-infected with both HCV and HBV in 1993 and turned positive for anti-HCV, negative for HCV RNA and positive for hepatitis B surface antigen in the present study. The rate of ALT and/or AST abnormalities in the positive group of anti-HCV was 28.57% (34/119), while that in the negative group of anti-HCV was zero (Table 1). The average level of ALT, AST and γ -GT in the positive group of HCV RNA was significantly higher than that in the negative group (*P*<0.001) (Table 2). On the other hand, the abnormal rate of ALT and / or AST in the positive group was also significantly higher than that in negative group (29.46% vs 4.55%, *P*=0.014).

Clinical symptoms

Fifty out of 112 cases (44.64%) of chronic HCV infection had mild symptoms, including abdominal pain (18.75%), fatigue (17.86%), and arthralgia (16.96%). The rates of cases with symptoms in the group of liver cirrhosis was 50.0%. Surprisingly, six cases with negative viral markers had fatigue.

Table 1 Abnormal of serum alanine aminotransferase in patients infected with HCV after 9 years' follow-up in different groups

Group	Liver function	
	Normal cases (%)	Abnormal cases (%)
Anti-HCV(+)HCV RNA(+)	76 (69.72)	33 (30.28)
Anti-HCV(+)HCV RNA(-)	9 (90.00)	1 (10.00)
Anti-HCV(-)HCV RNA(+)	3 (100.0)	0
Anti-HCV(-)HCV RNA(-)	12 (100.0)	0
Anti-HCV(+)HCV RNA(undetected)	4 (50.00)	4 (50.00)
Total	104 (73.24)	38 (26.76)

Note: The number in the bracket is the percentage of normal and abnormal cases in each group.

Co-infection with HBV and alcohol consumption

Thirteen of 142 cases had co-infection with HBV in 1993. Twelve cases of them were positive for hepatitis B surface antigen (HBsAg) and the rest were negative for HBsAg and positive for anti-hepatitis B core (anti-HBc). Nine years later, three of them turned negative for HbsAg, suggesting that spontaneous resolution of HBsAg per year was 2.77% similar to the of standard rate of resolution (2.01%) in our country^[7]. The rate of spontaneous resolution of anti-HCV was 7.69% in the group of co-infection with HBV while 8.53% in the group of single HCV infection. There was no significant difference between the two groups. Thirty point seventy-seven percent lost their HCV RNA in the group super-infected with HCV and HBV and 14.88% lost their HCV RNA in the group with single HCV infection. However, there was no significant difference between them. Two (15.38%) out of thirteen cases with co-infection developed liver cirrhosis while two (1.55%) out of 129 cases with single HCV infection also developed liver cirrhosis. The progression to liver cirrhosis due to co-infection was significant faster than that due to single infection (*P*<0.05). Thirteen of 142 cases had alcohol consumption of more than 100 g every day and all developed persistent infection. We also found that all cases with viral resolution had no history of excessive alcohol consumption, suggesting that alcohol consumption might promote the progression of HCV infection to chronicity.

Age at the time of primary infection

We divided the donors into three groups according to the age of infection: 18-30 years, 31-40 years and ≥ 41 years. The rate of spontaneous viral resolution in the three groups was 17.95%, 15.09% and 16.67% respectively. There was no significant difference. There was no linear correlation between the age of infection and the viral load (*r* = -0.144). Liver function was normal in the three investigated children. One of them was negative for viral markers and the other two developed persistent infection.

Influence of sex on the viral resolution

Sixty-two male cases and seventy-two female cases were detected for HCV RNA. The rate of viral resolution was 12.90% in the male group and 19.44% in the female group. No significant

Table 2 Comparison of ALT, AST, ALP, γ -GT, TBIL and DBIL between positive (+) and negative (-) HCV RNA patients (mean±SE)

HCV RNA	Case	ALT (IU/L)	AST (IU/L)	ALP (IU/L)	γ -GT (IU/L)	Tbil (μ mol/L)	DBIL (μ mol/L)
+	112	31.2±32.6 ^b	34.8±27.0 ^b	82.0±36.6	20.0±17.6 ^b	13.2±5.6	6.0±2.3
-	22	16.1±8.6	22.9±6.5	78.9±40.1	12.4±5.8	12.1±7.4	5.4±2.2

^b*P*<0.001 vs the negative group of HCV RNA.

difference was found between them. Four cases of liver cirrhosis were all male cases. The rate of ALT and/or AST abnormalities was significantly higher in male donors than in female donors ($P=0.005$).

Related factors affecting the outcome of HCV might include co-infection with HBV and long-term excessive alcohol consumption, which could promote the progression of HCV infection to chronicity and liver cirrhosis. In the present study, we could not find the significant correlation between the outcome of HCV and age of infection and sex.

DISCUSSION

The harm of hepatitis C is only next to hepatitis B in our country. The epidemic rate is 3.2% in Chinese population and it is estimated that 41 million people were infected^[8]. Economic burden for HCV is 11.7-21.6 billion RMB per year in China. New cases have been decreased through the detection of blood donors since 1990 s, but part of patients would progress to chronic hepatitis, liver cirrhosis and hepatocellular carcinoma. Although there are many reports on this aspect in Western countries^[9-13], few similar researches have been carried out in China. So it is very necessary to summarize the natural outcome of HCV in China.

Chronicity rate

The rate of spontaneous resolution in the present study was 16.42%, lower than 29.01%^[14] reported before in China after 12-25 years of infection. It may be because the qualitative method used in the study was more sensitive than quantitative method used in another area. Additionally, during our investigation, the infection was spontaneously resolved in some cases, which might be one of the causes of high chronicity in HCV infection in this study. Two patients died of suspected liver disease, and the case fatality rate was 1.16% in the group studied, which was lower than the previously reported^[10]. B-type ultrasound detection reflected liver inflammation in some degree under the condition that liver biopsy was not taken. After nine years of infection, 2.68% of the patients developed liver cirrhosis, which was lower than 7-16% after 8-16 years of infection^[1]. Our results showed that the clinical symptoms were latent in the donors studied. Compared with the patients with HBV infection, higher chronicity and faster progression to liver cirrhosis were observed in the patients with HCV infection.

Factors affecting the outcome

Age As described previously^[15-17], age appear to be an important determinant of progression. The data suggest that the younger the age at infection, the lower the rate of progression. In the present study, no difference was found in the rate of viral resolution in the different age groups, which is consistent with a previous report^[14]. The rate of chronicity was higher in the group than in children and young women of other countries.

Sex Regarding sex, there is evidence that the rate of progression of liver disease was lower in women than in men. The cases who progressed to liver cirrhosis in our study were all males. The rate of ALT and/or AST abnormalities in males was significantly higher than that in females, indicating that males might relate with the more serious liver disease.

Super-infection with HBV The rate of viral resolution in the donors super-infected with HBV was a little higher than in the donors without HBV infection, but there was no significant difference. The rate of progression to liver cirrhosis in the cases super-infected with HCV and HBV was significantly higher than that in the cases only infected with HCV, which is consistent with previous reports.

Alcohol consumption Several reports showed that overdose alcohol consumption might contribute to the progression to liver cirrhosis and hepatocellular carcinoma. In the present study, alcohol consumption was shown the progression to chronicity. Whether alcohol consumption affects the progression of liver diseases, needs to be further studied.

In summary, this area (Hebei province) has a higher rate of chronicity in HCV infection, and measures should be taken to prevent the progression to serious liver diseases, especially for the patients super-infected by HCV and HBV.

Abstract

AIM: To explore the ability of recombinant toxin luteinizing hormone releasing hormone-*Pseudomonas aeruginosa* exotoxin 40 (LHRH-PE40) and LHRH binding to LHRH receptor (LHRHR) on the membrane surface of human liver cancer HEPG cells.

METHODS: LHRH was labeled by using ^{125}I with enzymatic reaction. The affinity and receptor volume of LHRH-PE40 and LHRH binding to LHRHR on the membrane surface of human liver cancer cells were measured with radioligand receptor assay.

RESULTS: The specific activity of LHRH labeled with ^{125}I was 2.7×10^4 kBq/ μL , and its radiochemical purity reached to 99.2-99.7%. The binding of ^{125}I to LHRH was maximal for 240 min in the warm cultivation, and this binding was stabilized. The inhibiting rates of ^{125}I -LHRH and LHRH on the proliferation of human liver cancer HEPG cells were not significantly different. On the basis of the saturation curve of ^{125}I -LHRH binding to the membrane LHRHR of HEPG cells, ^{125}I -LHRH of 1×10^5 cpm was selected for radioligand receptor assay. The affinity constants (Kd) of LHRH-PE40 and LHRH binding to the membrane LHRHR of HEPG cells were 0.43 ± 0.12 nmol/L and 4.86 ± 1.47 nmol/L, respectively, and their receptor volumes were 0.37 ± 0.15 $\mu\text{mol/g}$ and 0.42 ± 0.13 $\mu\text{mol/g}$, respectively. The binding of LHRH-PE40 to the membrane protein of normal liver cells was not observed.

CONCLUSION: The recombinant toxin LHRH-PE40 binding to the membrane surface of LHRHR of human liver cancer HEPG cells was very strong, while the specific binding of it to normal liver cells was not observed. The results provide an important experimental basis for the clinical application of LHRH-PE.

INTRODUCTION

Guide medicine is currently one of the focuses in the field of medicine and biology. We can couple some tumor specific antibodies, cytokines or hormones, etc. with toxins (such as animal and plant toxin, radiotherapy and chemotherapy medicines or bacterial toxins, etc.) through chemical method or connection by gene fusing technology, and then express fusing protein to make a guide medicine with specific target characteristics and killing cell toxicity, that is biological missile, which can selectively kill homologous antigen-associated cells or antibody-associated cells, while exerts little effect on irrelative cells^[1]. So far, a series of recombinant immune toxins have shown perfect effects through *in vitro* and animal experiment^[2-4], moreover the results in some clinic investigations are also satisfactory^[5,6]. DAB389IL-2 which IL-2 receptor used as a guide medicine of target has passed FAD's warrant and come into use^[7].

Luteinizing hormone-releasing hormone (LHRH) is also termed gonadotropin-releasing hormone (GnRH). It is a peptide hormone synthesized and secreted mostly from hypothalamus. *Pseudomonas aeruginosa* exotoxin 40 (PE40) was obtained by removing I a region of PE. A fusing protein LHRH-PE40 was recombined by the fusion of both LHRH gene and PE40 gene with genetic engineering *in vitro*. LHRH-PE40 is a guide medicine to treat cancer. PE40 has effect on antitumor and immune regulation. The key of LHRH-PE40 biological effect is selectively to kill carcinoma cells. This effect is gained by the distributing difference of membrane surface LHRH receptor (LHRHR) in live cancer cells and normal liver cells. Many experimental results showed that LHRHR expressed greatly in the membrane surface of some carcinoma cells, but not in that of normal liver cells^[8-13]. The results provide an important basis for studying and preparing guide medicine to treat cancer^[14]. Therefore, LHRHR is acted as a sign to distinguish carcinoma cells from normal cells. The abilities of LHRH-PE40 binding to the membrane surface LHRHR of liver cancer cells and normal liver cells were observed with radioligand receptor assay for providing an important experimental basis for LHRH-PE40 clinical application.

MATERIALS AND METHODS

Liver cancer cell line and normal liver tissues

Human liver cancer HEPG cell line was bought from the Cell Center, Institute of Cell Biology, Chinese Academy of Medical Sciences (Beijing, China). Human liver tissues (3 cases) were provided by the Center of Medicolegal Examination, Criminal and Police Team, Liaoyuan City, Jilin, China.

Human liver cancer HEPG cell line was maintained in 75 cm² culture flasks at 37 °C in a humidified 50 mL/L CO₂-in-air mixture. The cells were passed weekly. After cells were harvested in exponential growth phase, they were dissociated with a non-enzymatic cell dissociation solution (Sigma, USA), and then counted by a hemacytometer. The cells were washed twice with phosphate-buffered saline (PBS) before cell membrane protein was prepared.

Reagents and hormones

^{125}I was from Amersham, UK. LHRH and thyrotropin releasing hormone (TRH) were bought from Institute of Biochemistry, Shanghai. LHRH-PE40 was synthesized by the Institute of Military Veterinary Medicine, Quartermaster University of PLA. Lactoperoxidase, glucoseoxidase and Sephadex G-25 gel were made in Sigma, USA.

LHRH labeled with ^{125}I of enzymatic reaction

The lactoperoxidase-glucoseoxidase method by Piyachaturawata *et al.*^[15] was slightly modified to label LHRH using ^{125}I with enzymatic reaction. Half mol/L PBS of 20 μL (pH 7.6), LHRH of 5 μg (dissolved in 0.1 mol/L NaAc of 5 μL), 2.3 mU lactoperoxidase (dissolved in 0.1 mol/L NaAc of 10 μL , pH 5.6), 2.8 mU glucoseoxidase (dissolved in 0.1 mol/L NaAc of 10 μL , pH 5.6) and 5 g/L $\beta\text{-D}$ (+) glucose of 5 μL in proper order were added into the test tube with 3.7×10^4 kBq fresh ^{125}I of non-reducer, oscillated and mixed, to make ^{125}I quickly labeling to LHRH. After the reaction for 5 min at 22–25 $^{\circ}\text{C}$, 0.1 mol/L boric acid buffer of 50 μL was added into the test tube to stop the reaction. The reactant of LHRH labeled with ^{125}I in test tube was separated and purified by column chromatography (the column of 1 cm \times 25 cm) with Sephadex G-25 gel to removing free ^{125}I , eluted with 0.1 mol/L boric acid buffer (containing 1 g/L gelatin and 0.2 g/L sodium azide, pH 9.2, flow rate: 3 mL/3 min, 3 mL/tube). Thirty-six tubes were collected. The radioactivity (counts per minute, cpm) of ^{125}I -LHRH of 10 μL in each tube was determined. The specific activity of ^{125}I -LHRH determined with self-displacement curve was $2.69\text{--}3.7 \times 10^4$ GBq/g LHRH.

Inhibiting rate of liver cancer cell proliferation measured with MTT

Inhibiting rates of both ^{125}I -LHRH and LHRH on the proliferation of human liver cancer HEPG cells were measured using enzyme-linked immunosorbent assay meter (Bio-Rad, USA) with MTT (thiazolyl blue) method^[16].

Preparation of cell membrane protein

The preparation of the membrane protein in human liver cancer HEPG cells: The cells were centrifuged in culture fluid, counted, washed once with PBS and centrifuged (500 r/min, 4 $^{\circ}\text{C}$, 5 min). The centrifuged sediment was suspended in ice-cold sucrose buffer for 20 min. The suspension was again centrifuged (300 r/min, 4 $^{\circ}\text{C}$, 5 min) after the cells in the suspension were ground with ultrasonic meter at ice bath. The centrifuged supernatant was further centrifuged (18 000 g, 4 $^{\circ}\text{C}$, 30 min). The centrifuged sediment was a membrane protein. Then the purer membrane protein of liver cancer cells was gained after the membrane protein was washed once with PBS.

Preparation of membrane protein in normal human liver cells: The liver tissue was sheared into fragments with ophthalmic scissors after the frozen tissue was thawed in sucrose buffer. The fragments were homogenized at ice bath for 1 min and centrifuged (1 500 r/min, 4 $^{\circ}\text{C}$, 10 min). The centrifuged supernatant was again centrifuged (31 000 g, 4 $^{\circ}\text{C}$, 15 min). Then the purer membrane protein of normal liver cells was gained after the membrane protein was washed once with PBS.

Competitive binding of LHRH-PE40 and LHRH to LHRHR of HEPG cell membrane

Polypropylene test tubes dried after soak with 10 g/L bovine serum albumin (BSA) were used as the reactive tubes. The tri-tube was used as a determined value. LHRH-PE40 or LHRH of different concentrations and ^{125}I -LHRH (1×10^5 cpm) of 100 μL in proper order were added into the reactive tube in ice bath, respectively, and mixed. Then, 100 μL suspension of the cell membrane (containing 180–220 μg protein) was added into the reactive tube. The reactive tubes were cultivated at 4 $^{\circ}\text{C}$ for 4 h

after oscillation. Excessive LHRH-PE40 or LHRH (200 μg) was added into the non-specific binding tube. The total volume in the reactive tube was 0.3 mL. The reactant was filtrated by using a microfilter with 32# glass fiber filter paper at 93.3 kPa negative pressure vacuum. The reactive tube and filter pore were washed 3 times with 0.5 mL of precolded 0.5 mol/L PBS (pH 7.4): physiological saline at 1:50. The radioactivity of the sediment on the filter paper filtered at vacuum and dried for 5 min was measured with ^{125}I automatic radio-immunity analyzer. The protein was measured with Lowry modification, and its standard curve was done with human serum albumin.

RESULTS

Characteristics of LHRH labeled with ^{125}I

The specific activity of LHRH labeled with ^{125}I of enzymatic reaction was 2.7×10^4 kBq/ μg . Its radiochemical purity measured using paper chromatography with the developer of 5% KI and 1 mol/L HCl (1:1) reached 99.2–99.7%. ^{125}I -LHRH did not produce free ^{125}I 3 and 7 d after preservation at -80 $^{\circ}\text{C}$, and produced 5% free ^{125}I after 10 d. The inhibiting rate of ^{125}I -LHRH on the proliferation of cancer cells was not significantly different as compared with that of LHRH (Figure 1).

Figure 1 Inhibitory rates of unlabeled LHRH and ^{125}I -LHRH on human liver cancer HEPG cell proliferation.

Warm cultivation time of ^{125}I -LHRH binding to HEPG cell membrane protein

The ^{125}I -LHRH binding to HEPG cell membrane protein was observed for 60, 90, 120, 150, 180, 240 and 300 min in warm cultivation. The binding increased with the prolongation of warm cultivation time, and reached the peak value at 240 min. If the time in the warm cultivation was prolonged further, the binding decreased.

Radioligand receptor assay of competitive binding of LHRH-PE40 and LHRH to HEPG cell membrane protein with ^{125}I -LHRH

The specific binding of HEPG cell membrane protein to ^{125}I -LHRH increased with the protein concentration. The increase of the binding was not obvious as protein concentration exceeded 250 μg per 0.3 mL, while the non-specific binding increased obviously. According to the experimental results, the protein concentration of 180–220 μg per 0.3 mL was used as radioligand receptor assay.

The saturation curve of ^{125}I -LHRH binding to LHRHR of HEPG cells was firstly done. ^{125}I -LHRH of 1×10^5 cpm in 50% linear range of the saturation curve was selected as radioligand receptor assay (Figure 2). Figure 3 shows the inhibiting curve of competitive binding of non-labeled LHRH-PE40 and LHRH to HEPG cell membrane protein LHRHR with ^{125}I -LHRH. ^{125}I -LHRH binding to LHRHR reduced with increase of the non-labeled ligands to demonstrate a specific inhibiting curve of competitive binding. LHRH-PE40 could bind to HEPG cell surface LHRHR, while TRH could not. Figure 4 was drawn with Scatchard method

to gain two straight lines. The affinity constants (K_d) of binding of LHRH-PE40 and LHRH to LHRHR of HEPG cells were $0.43 \pm 0.12 \mu\text{mol/g}$ and $4.86 \pm 1.47 \mu\text{mol/g}$, respectively, and their receptor volumes were $0.37 \pm 0.15 \mu\text{mol/g}$ and $0.42 \pm 0.13 \mu\text{mol/g}$, respectively.

Figure 2 Saturation curve of ^{125}I -LHRH binding to LHRHR of human liver cancer HEPG cells. TB: total binding, NB: non-specific binding, SB: specific binding.

Figure 3 Inhibiting curve of competitive binding of non-labeled LHRH-PE40, LHRH and TRH to human liver cancer HEPG cell LHRHR with ^{125}I -LHRH.

Figure 4 Scatchard analysis of LHRH-PE40 and LHRH binding to LHRHR of human liver cancer HEPG cells.

Figure 5 Inhibiting curve of competitive binding of non-labeled LHRH-PE40 and TRH to normal human liver cell LHRHR with ^{125}I -LHRH.

The binding curve of LHRH-PE40 to the membrane protein of normal liver cells was not significantly different from that of negative control TRH (Figure 5). The labeled ligand ^{125}I -LHRH binding to the membrane protein of normal liver cells did not change with increase of the non-labeled ligand LHRH-PE40. The result suggested that LHRH-PE40 binding to trace LHRHR in the membrane of normal human liver cells could not be examined.

DISCUSSION

The specific activity of LHRH labeled with ^{125}I of enzymatic reaction was $2.7 \times 10^4 \text{ kBq}/\mu\text{L}$, and its radiochemical purity reached 99.2-99.7%. The ^{125}I binding to LHRH was maximal at 240 min in the warm cultivation. This binding was stabilized, i.e. ^{125}I -LHRH did not produce free ^{125}I 3 and 7 d after preservation at -80°C , and produced 5% free ^{125}I after 10 d. The inhibiting rates of ^{125}I -LHRH and LHRH on the proliferation of human liver cancer HEPG cells measured with MTT (thiazolyl blue) method were not significantly different. The results suggest that LHRH satisfactorily labeled with ^{125}I of enzymatic reaction may be used as radioligand receptor assay.

LHRH-PE40 is a guide medicine to treat cancer. It is composed of the guide fraction of LHRH peptides and the toxicity fraction of PE40 protein. The active principle of LHRH-PE40 is that its toxicity fraction PE40 enters in cells through transmembrane transport to kill cancer cells after its guide fraction LHRH binds to LHRHR of cancer cell membrane surface. The expression of LHRH and its receptor as a part of a negative autocrine regulatory system of cell proliferation has been demonstrated in a number of human malignant tumors. Moreover, the dose-dependent antiproliferative effects of LHRH agonists on cell lines derived from these cancers have been observed by various investigators^[17-19]. The effect exerts through the signal transduction in cancer cells^[20, 21]. So, the specific binding of guide fraction LHRH to LHRHR of cancer cell membrane surface becomes the key in the treatment of carcinoma. It has been currently demonstrated that there also are LHRH and its receptor LHRHR in some tissues besides hypothalamus and pituitary. Some literatures indicated that there was LHRHR in the membrane surface of normal liver cells, but its content was very low^[8, 9]. The fact brings forward a challenge against the LHRHR specificity of killing cancer cells. However, our experimental results showed that specific binding of LHRH-PE40 to the membrane surface LHRHR of human liver cancer HEPG cells occurred, while did not to normal human liver cell membrane surface where there may be trace LHRHR. Of course, the negative result of this non-specific binding may be affected by the precision limitation in the experimental method itself. For example, some methods could be used only when the K_d of sample was less than 10^{-8} nmol/L ^[22]. Both epidermal growth factor (EGF) and interleukin-2 (IL-2) used as the guide medicines are also faced with the same problem that their trace receptors exist on the surface of normal liver and kidney cells, but they have been used in clinic. Although this kind of medicines may also have a weak liver toxicity, their side effects are less as compared with chemotherapy. So, LHRH-PE40 has some value in curing liver cancer with numeric proliferation of LHRHR.

The binding of hormone to its receptor was limited by many factors^[23]. Among these factors the space of hormone protein can directly affect the binding to its receptor. LHRH is a decapeptide without free amino and carboxyl. The amino acids at its 4-6 sites can form β -sheet like a barrette, which makes it binding to receptor. Furthermore, the amino acids at this hormone's first and 4-10 sites can bind to its receptor too. LHRH of LHRH-PE40 replaces I a section of PE. A linking bridge of both His and Met amino acids added between two molecules maintains the primary structure of LHRH. But whether LHRH's space configuration of this fusing protein changes should be

further explored. The results from this experiment were that the affinity constants (Kd) of LHRH-PE40 and LHRH binding to LHRHR of HEPG cells were 0.43 ± 0.12 nmol/g and 4.86 ± 1.47 nmol/L, respectively, and their receptor volumes were 0.37 ± 0.15 μ mol/g and 0.42 ± 0.13 μ mol/g, respectively. The affinity constant of LHRH-PE40 is nearly one-tenth of LHRH. Therefore, we can infer that LHRH-PE40 maintains the characteristics of LHRH binding to its receptor, and its binding capacity is stronger than LHRH itself. The result is identical with the report published elsewhere^[6]. This enhancing binding capacity may be caused by its molecular mass being larger than LHRH, which makes itself more stable and decomposed difficultly *in vitro*. These results proved that LHRH-PE40 can bind to LHRHR on the surface of liver cancer cells, and then exerts its guide action.

Up till now, some problems still need to be resolved on the guide medicine for the treatment of cancer. Somebody testified that positive rate of LHRHR in adjacent tissues of cancers was even higher than that in cancer tissues^[24], which should be attached importance. The articles demonstrated that the signal transduction pathways mediated by LHRHR were different^[25], LHRHR of cancer cell surface could mediate cell apoptosis^[26,27].

ACKNOWLEDGEMENTS

Abstract

AIM: To explore a safe and efficient strategy of tumor therapy using anti-angiogenetic agents.

METHODS: Endostatin gene with a signal sequence of human IgG γ chain was amplified by PCR and cloned into pVAX1 plasmid which was the only vector authorized by FDA in clinical trial to construct a recombinant plasmid named as pVAX-sEN. The recombinant plasmid was detected with *EcoRI/KpnI* and DNA sequencing. BALB/c mice bearing hepatocarcinoma cell line H22 were treated with naked pVAX-sEN or liposome-DNA complex in which the dose of DNA and the ratio of DNA and liposome were different from each other. To compare the efficiency of gene transfection, expression of endostatin at the treated tumor site was assayed with ELISA. To investigate the effect of pVAX1-sEN on hepatocellular carcinoma, pVAX-sEN either naked or in liposome-DNA complex was injected into BALB/c mice bearing H22, then the diameter of tumors was measured, microvessel density was detected by immunohistochemistry, endostatin expression *in vivo* was assayed at different time points.

RESULTS: DNA sequencing showed the endostatin gene with the signal peptide was correctly cloned. *In situ* gene expression assay indicated that both the ratio of DNA and liposome and the dose of DNA could affect the gene transfection efficiency. Interestingly, naked pVAX-sEN had a similar *in situ* endostatin expression to pVAX-sEN with liposome. Animal experiments showed that pVAX-sEN together with pVAX-sEN-liposome complex could efficiently suppress the growth of mouse hepatoma cells.

CONCLUSION: Naked endostatin plasmid intratumoral injection can get a similar gene transfection efficiency to liposome-DNA complex when used *in situ*.

INTRODUCTION

Tumor neovascularization is necessary to the growth and metastasis of tumors^[1]. Anti-angiogenesis is an effective method to treat cancer^[2,3]. Endostatin, an endogenous angiogenesis inhibitor, was found in 1997^[4]. It can specifically suppress endothelial cell proliferation. Animal experiments have demonstrated that endostatin can strikingly inhibit the growth of many kinds of tumor cells without drug resistance and toxicity. Endostatin is a promising agent to treat cancer^[5,6]. However, to produce a large quantity of biologically active proteins has been proven difficult, the treatment requires repeated administration and high doses of recombinant protein, which limits endostatin's clinical application. Gene therapy can overcome the above disadvantages and become a potential method for cancer therapy. In this article, we constructed the recombinant eukaryotic plasmid using pVAX1 which is the only vector authorized by FDA in clinical trial. It can express secretive endostatin *in vivo*. Efficient gene transfer and expression are the key to gene therapy. In order to explore an efficient and easy gene transfer method, we also compared the inhibitory effect of liposome and naked DNA transfection on mouse hepatoma cells *in vivo*.

MATERIALS AND METHODS

Plasmids

Eukaryotic expression vector pVAX1 authorized by FDA in clinical trial was purchased from Invitrogen(USA). Cloning vector pGEM-T-EN containing human endostatin genes was constructed and preserved in our laboratory^[7].

Cells and cultures

Mouse hepatoma cell line H22 was purchased from Shandong Medical Science Institute and grown in BALB/c abdominal cavity.

Animals

BALB/c female mice, 5-6 wk of age, were provided by Experimental Animal Center of Shandong University. A total of 1×10^6 H22 cells were transplanted subcutaneously into mice. Treatment began 1 wk later, when tumor volume ranged between 0.4 to 0.5 cm³.

Primer design

According to the sequences in GeneBank, primers were designed to amplify endostatin genes. In order to get a secretory protein, signal sequence of human IgG γ chain was added to the 5' end of forward primer, and sequences recognized by *KpnI* and *EcoRI* were respectively added to the forward primer and reverse primer: forward(P1): 5' TTAGGTACCATGGAAGCCCCAGCTCAGCTTCTCTTCTCTCTGCTACTCTGGCTCCCAGATACACC GGACACAGCCACCGC 3'; reverse(P2): 5' CGGCGAATTCC TTGGAGG CAGTC 3'. All of these oligonucleotide primers were synthesized by Shanghai BioAsia Bio-technology Co.Ltd.

PCR

The endostatin gene containing signal sequence of human

IgG γ chain was amplified by PCR taking pGEM-T-EN as template and P1 and P2 as primers. PCR reaction was performed in 25 μ L volume containing: 1 μ L of plasmid DNA, 2.5 μ L of 10 \times buffer, 0.5 mmol/L Mg^{++} , 5 nmol/L dNTP, 3 units of Taq polymerase, 10 nmol/L primers (forward and reverse). Reaction conditions were at 95 $^{\circ}$ C for 5 min, then 30 cycles each at 95 $^{\circ}$ C for 1 min, at 62 $^{\circ}$ C for 1 min, at 72 $^{\circ}$ C for 3 min, followed by a final extension at 72 $^{\circ}$ C for 5 min. PCR products were purified by UNIQUE-10 Kit (Shanghai Shenggong Biological Co.Ltd) after 20 g/L agarose gel electrophoresis.

Construction of recombinant eukaryotic plasmid expressing secretive endostatin

PCR products and pVAX1 were digested by *Eco*RI and *Kpn*I (TaKaRa Biotechnology, Dalian) respectively, then purified and ligated with T4DNA ligase (TaKaRa Biotechnology, Dalian) at room temperature overnight. *E.coli*, DH5 α , competent cells were transfected using $CaCl_2$. Recombinant clones were detected by *Eco*RI and *Kpn*I and then sequenced by Shanghai BioAsia Biotechnology Co.Ltd.

In situ expression of secretary endostatin

Five-to-six week old female BALB/c mice were injected subcutaneously with 1×10^6 logarithmically growing H22 cells to axillary. One week later, when tumor volume was about 0.4 to 0.5 cm^3 , naked plasmid or liposome-DNA complex (LipofectamineTM2000 from Invitrogen) was administered intratumorally. The ratio of liposome and recombinant plasmid in liposome-DNA complex was 1:1, 1:3, 1:8 respectively. Animals were sacrificed 3 d after injection and about 0.5 cm^3 of tumor was separated and cut into pieces, then cultured in 0.5 mL MEM medium with 100 mL/L of FCS at 37 $^{\circ}$ C, 50 mL/L CO_2 atmosphere for 24 h. Supernatants were collected and centrifuged at 1 000 r/min for 5 min, then stored at -20 $^{\circ}$ C for gene expression assay.

In vivo inhibition assay

One week after BALB/c mice were injected subcutaneously with 1×10^6 logarithmically growing H22 cells to axillary, naked recombinant plasmid (20 μ g) or the liposome-DNA complex containing 20 μ g recombinant plasmid was administered intratumorally once a week for two weeks. The ratio of liposome and recombinant plasmid in liposome-DNA complex was 1:1. pVAX1 and NS were respectively injected into animals as control. The length (a) and width (b) of tumor were measured twice a week. The tumor volumes were then calculated using the formula: $Volume = a \times b^2 \times 0.52$.

The experiment was done in triplicate with 5 animals in each group.

In vivo expression assay of endostatin

In order to determine the association of anti-tumor effects and the expression level of endostatin, peripheral blood was prepared from tail at different time point and serum was used to detect the expression of endostatin with ELISA.

ELISA

Expression of endostatin was detected with human endostatinTM protein accucyte^REIA kit (Oncogene) following the manufacturer's instructions.

Immunohistochemistry

Mice were killed 3 d after the fourth administration. Tumors were excised, fixed in formalin and prepared for paraffin-embedded sections. Factor VIII-related antigen was detected with S-P immunohistochemistry kit (Beijing Zhongshan Biocompany) according to the manufacturer's instructions.

Tumor microvessel density (MVD) was evaluated as described by Weidner^[8].

Statistical analysis

All data were expressed as mean \pm SD. Student's *t*-test was used for statistical analysis. A *P* value <0.05 was considered statistically significant.

RESULTS

Plasmid construction

Endostatin gene with signal sequence of human IgG γ chain was amplified by PCR and cloned into eukaryotic vector pVAX1 named as pVAX-sEN. Two percent agarose gel electrophoresis demonstrated two bands about 3 kb and 610 bp in size as expected after the recombinant plasmid was digested by *Kpn*I and *Eco*RI (Figure 1). DNA sequencing analysis indicated both the sequence of endostatin and signal peptide were in accordance with those in the GenBank.

Figure 1 Detection of the recombinant plasmid pVAX-sEN using *Eco*RI and *Kpn*I digestion. A: Marker 15 000; B: pVAX1 digested by *Eco*RI; C: Recombinant plasmid pVAX-sEN digested by *Eco*RI; D: Recombinant plasmid pVAX-sEN digested by *Eco*RI and *Kpn*I.

In situ gene expression assay of naked DNA and liposome-DNA complex

To compare the efficiency of gene transfection, expression of endostatin transgenic protein at the tumor site of the treated group was assayed with ELISA. Endostatins were detected in all samples treated with naked or liposome-DNA complex but not in the control groups (Figure 2). Endostatin expression was about 30 ng/mL when the ratio of liposome and DNA was 1:1. With the addition of the liposome into complex the expression of endostatin was increased gradually. When the ratio reached 1:8, the endostatin was 92 ng/mL. Interestingly, naked DNA administration could get a pretty high gene expression which was about 86 ng/mL.

Figure 2 Comparison of *in vivo* transfection using different ratios of liposome and DNA in liposome-DNA complex and naked DNA.

To compare gene transfection using liposome-DNA complex containing different doses of DNA *in vivo*, liposome-DNA

complex was prepared with the ratio of liposome and DNA 1:1 which contained different doses of DNA. Twenty-four hours after transfection endostatins were detected by ELISA (Figure 3). The result indicated that when DNA was less than 20 μg , with the elevation of DNA doses, the expression of endostatin increased. When the DNA dose reached 20 μg , endostatin reached 152 ng/mL, the peak expression. On the contrary, when the DNA reached 50 μg , the expression of endostatin dropped to 80 ng/mL.

Figure 3 Comparison of *in vivo* transfection using liposome complex (the ratio of liposome and DNA is 1:1) containing different doses of DNA.

In vivo inhibitory effect of pVAX-sEN on mouse hepatoma cells

Changes of tumor volumes indicated pVAX-sEN-liposome complex could obviously inhibit the growth of mouse hepatoma cells when administered intratumorally (Figure 4). The tumor volume was only $0.451 \pm 0.26 \text{ cm}^3$, obviously less than that in NS treated group ($1.86 \pm 0.62 \text{ cm}^3$) and pVAX1 treated group ($1.56 \pm 0.37 \text{ cm}^3$) ($P < 0.05$). The inhibition rate was about 73%. Interestingly, pVAX-sEN alone could produce an inhibitory effect. The tumor size in pVAX-sEN treated group was $0.4 \pm 0.25 \text{ cm}^3$, and the inhibitory rate was about 80%, which was not significant from pVAX-sEN-liposome complex treated group ($P > 0.05$).

Figure 4 Inhibitory effect of recombinant secretive endostatin on mouse hepatoma cells.

Figure 5 *In vivo* endostatin expression in peripheral blood of treated mice.

In vivo expression of endostatin

ELISA showed that the expression of endostatin in peripheral blood varied with the administration of recombinant plasmid. Three days after the first treatment of recombinant plasmid, both naked and in combination with liposome, the expression of endostatin could be detected ($56.8 \pm 3.8 \text{ ng/mL}$ and $54 \pm 5.8 \text{ ng/mL}$, respectively. $P > 0.05$) and then the expression decreased 2 d later. After the second administration the expression raised to $79.8 \pm 6.1 \text{ ng/mL}$ and $60.43 \pm 8.3 \text{ ng/mL}$ and it could be lasted for another 3 d. The expression level in naked plasmid treated mice was lower than that in DNA-liposome complex treated mice ($50.1 \pm 6.3 \text{ ng/mL}$ vs $70.4 \pm 6.4 \text{ ng/mL}$, $P < 0.05$) (Figure 5).

Inhibition of tumor angiogenesis by pVAX-sEN

Immunohistochemical analysis showed a potent inhibition of angiogenesis in tumors treated by pVAX-sEN. The MVD was counted and results are shown in Figure 6. Expression of endostatin mediated by naked pVAX-sEN or liposome-DNA complex injection caused a significant reduction in MVD compared with the NS control group or the pVAX1 treated group ($P < 0.05$). However, the difference in MVD between naked DNA and liposome-DNA complex injection groups was not statistically significant.

Figure 6 Inhibition of tumor neovascularization by injecting recombinant plasmid.

DISCUSSION

Growth and metastasis of tumor depend on the neovascularization. Anti-angiogenesis can effectively suppress tumor growth. Endostatin was found to specifically inhibit endothelial cell proliferation but not actively proliferating cells such as carcinoma cells, intestinal cells, epithelial cells, bone marrow cells^[4]. So the application of endostatin did not cause bone marrow ablation, stomach and intestinal reaction, and other side effects^[5]. Moreover, endostatin could be used for a long time without drug resistance since its target cells, endothelial cells have a relatively stable gene structure and low mutation rate^[5,6]. Consequently endostatin is an attractive new strategy in cancer therapy.

Recombinant endostatin protein has been used in clinical trials at present^[9]. However poor solubility of recombinant endostatin protein and its high effective dose have limited its wide spread application^[4]. Gene therapy by which endostatin can express *in vivo* is an efficient method for anti-angiogenesis cancer therapy^[10-12].

The key point of gene therapy is to establish an effective gene delivering system. Vectors used to deliver genes nowadays mainly include viral and non-viral vectors. Because of limitations of viral vectors such as potent danger, immune response and limitations of the gene length^[13-15], more and more researchers have paid their attention to non-viral vectors. In this paper, a highly safe vector pVAX1 authorized by FDA in clinical trial was selected to construct a recombinant vector expressing

secretive endostatin which was named as pVAX-sEN. DNA sequencing indicated endostatin gene together with a signal peptide was correctly cloned. Animal experiments showed pVAX-sEN could efficiently suppress the growth of mouse hepatoma cells. This study provides an experimental basis for further study on safe and efficient gene therapy with endostatin.

Non-viral gene can be transferred by physical and chemical methods. The cationic liposome-mediated gene transfer system is popular because of its low immunity, high safety, easy preparation, no limitation to gene sequence and potential to be used repeatedly^[16,17]. Gene transfer efficiency of liposome can be affected by many factors. Studies indicated that a suitable quantity ratio of DNA and liposome was one of the essential factors^[18]. Naked DNA injection is another simple safe gene transfer method. Many researchers have verified that naked DNA administration could induce a high gene expression level^[19,20]. In 2003 VEGF administered into cardiac muscle using naked DNA was applied to clinical trial^[21]. In our study, cationic liposome was used to transfer endostatin DNA into mouse hepatoma cells *in vivo*. It showed that when the quantity ratio of liposome and DNA was 1:1, the expression of endostatin was pretty high. When the quantity ratio was 1:8, endostatin reached the highest expression (92 ng/mL). With the elevation of DNA dose, the expression of endostatin increased. When the DNA dose reached 20 µg, the expression of endostatin amounted to 152 ng/mL. However, if DNA dose reached 50 µg, the expression of endostatin dropped to 80 ng/mL. The possible reason was that the high dose of liposome in the complex might be deposited^[18]. So the transfection efficiency was lower. Results also indicated that naked DNA could also get a pretty high gene expression (86 ng/mL). Our *in vivo* inhibition assay even showed that naked DNA could get an inhibition as efficient as DNA-liposome complex. In 2002, Shi *et al.*^[22] compared the transfection rate of naked DNA with liposome-DNA complex and found the expression of IL-12 was equal. Their result is in accordance with ours. However, *in vivo* gene expression assay indicated that the peripheral expression of endostatin in naked DNA treated mice decreased more quickly than that in DNA-liposome complex treated mice.

In conclusion, we successfully constructed the recombinant vector secretively expressing endostatin using highly safe vector pVAX1 named pVAX-sEN. Animal experiments showed it could efficiently suppress the growth of hepatoma cells. It is a promising method in cancer therapy. At the same time we compared the transfection efficiency of naked pVAX-sEN DNA with liposome-DNA complex. Results indicated naked DNA could produce both a high endostatin gene expression and a good tumor inhibition effect when used *in situ*, strongly suggesting that naked DNA administration is a simple, safe and efficient gene transfer method.

Abstract

AIM: To investigate the expression level of plasma vascular endothelial growth factor (P-VEGF) in patients with hepatocellular carcinoma (HCC) and its relationship with the clinicopathologic characteristics, and to examine the changes of P-VEGF in the course of transcatheter arterial chemoembolization (TACE).

METHODS: Peripheral blood samples were taken from 45 HCC patients before and 1, 3, 7 d, and 1 mo after TACE. Plasma VEGF level was measured with the quantitative sandwich enzyme-linked immunosorbent assay (ELISA). Twenty patients with benign liver lesions and 17 healthy control subjects were also included in this study.

RESULTS: Plasma VEGF levels in HCC patients were significantly elevated as compared to those in patients with benign liver lesions ($P = 0.006$) and in the normal controls ($P = 0.003$). Significant differences were observed when P-VEGF was categorized by tumor size ($P = 0.006$), portal vein thrombosis ($P = 0.011$), distant metastasis ($P = 0.017$), arterial-portal vein shunting ($P = 0.026$), and International Union Against Cancer (UICC) TNM stage ($P = 0.044$). There was no correlation between plasma level of VEGF and the level of alpha fetoprotein (α -FP) ($r = 0.068$, $P = 0.658$) and weakly correlated with the number of platelets ($r = 0.312$, $P = 0.038$). P-VEGF levels increased significantly and reached the peak value on the first day after TACE, and then decreased gradually. The change rate of P-VEGF concentration (one month post-TACE/pre-TACE $\times 100\%$) was correlated with the retention rate of lipiodol oil ($r_s = 0.494$, $P = 0.001$) and the tumor volume change ($r_s = 0.340$, $P = 0.034$). The patients who achieved a partial or complete response to TACE therapy showed significantly less pre-treatment P-VEGF than those nonresponders ($P = 0.025$). A high pre-therapeutic P-VEGF level was associated with poor response to treatment ($P = 0.018$).

CONCLUSION: A high pre-treatment P-VEGF level is a useful marker for tumor progression, especially for vascular

invasion. TACE increases the level of P-VEGF only temporarily which may be associated with tumor ischemia. P-VEGF may be useful in predicting treatment response, monitoring disease course after TACE and judging the effect of different TACE regimens.

INTRODUCTION

Transcatheter arterial chemoembolization (TACE) is the most frequently applied palliative treatment in HCC patients who are considered to be unsuitable candidates for surgery. But the indications and outcome of TACE are not clearly defined in the literature^[1,2]. TACE therapy is invasive and associated with high financial costs^[3]. To predict which patients are likely to benefit from TACE would be useful to both oncologists and patients.

Tumor angiogenesis is essential for solid tumorigenesis, growth, invasion and metastasis^[4-6]. Tumor angiogenesis is mediated by angiogenic factors and vascular endothelial growth factor (VEGF) is one of the most potent factors. Strong VEGF expression has been demonstrated in various solid tumor types. In HCC, VEGF expression in tumor tissue has been reported to be correlated with aggressive behavior, early metastasis spread, and poor prognosis^[7,8]. Recently, the expression of VEGF in patients with various malignancies has been made possible by measuring circulating VEGF concentrations with the enzyme-linked immunosorbent assay (ELISA)^[9]. The elevation of VEGF in blood implies a promotion of tumor angiogenesis, and several studies have revealed the predictive value of circulating VEGF level in disease progression and prognosis in various types of cancer^[10,11]. Raised pre-treatment circulation VEGF levels in small-cell lung carcinoma, esophageal carcinoma, gastrointestinal cancer and non-Hodgkin's lymphoma have been associated with a poor outcome^[12-15].

Although elevated circulation VEGF levels have been measured in patients with various tumors. To our knowledge few data are available with regard to plasma VEGF (P-VEGF) levels in patients with HCC^[16]. Data concerning the change of P-VEGF in the course of TACE therapy and its significance in prediction of patient's response to chemoembolization have not been reported to date.

Therefore, in this prospective study, we analyzed the P-VEGF level in patients with HCC prior to treatment to determine the clinicopathologic significance of P-VEGF, and to assess the clinical usefulness of pre-treatment P-VEGF as a predictor of outcome in patients undergoing TACE therapy for HCC.

MATERIALS AND METHODS

Patients and treatment design

The study consisted of 45 patients (37 males, 8 females, mean age 50 years, range 29-77 years) with unresectable HCC who underwent TACE at the Department of Interventional Radiology, Wuhan Union Hospital between October 2000 and February 2002. HCC was diagnosed by distinctive radiographic findings, serum alpha fetoprotein, and with ($n = 8$) or without histological proof. All patients were treated with TACE therapy alone without any other therapies such as surgery, percutaneous ethanol injection, or systemic chemotherapy. The chemoembolization agents consisted of 100 mg/m² of carboplatin, 50 mg/m² of doxorubicin hydrochloride, 1 g of 5-fluorouracil and 5-25 mL of iodized oil (Lipiodol; Guerbet, Aulnay-sous-Bois, France). For those with hepatic arterial-portal vein fistula, gelfoam piece was used to block the fistula before iodized oil was used.

Twenty patients underwent TACE therapy for benign diseases (ten patients underwent partial hepatic artery embolization for hepatic cavernous angioma, ten patients underwent partial spleen artery embolization for hypersplenism) and seventeen healthy volunteers were also involved in this study, served as control to evaluate the P-VEGF cut-off level.

Clinicopathologic data

Physical examination, chest X-ray, routine liver function test were performed. Complete blood count, hepatitis B surface antigen status and serum alpha fetoprotein (α -FP) were prospectively collected from each patient. Tumor characteristics such as size, location, capsular, portal vein involvement, lymph node or extrahepatic metastasis, were assessed on the basis of radiographic findings. Tumor vascularity and arteio-portal vein shunting (A-V shunting) were studied by superselective digital subtraction angiography (DSA). Tumor staging was performed using the International Union Against Cancer (UICC) TNM classification^[17].

Blood sampling and enzyme immunoassay of P-VEGF concentration

Peripheral venous blood was taken before ($n = 45$) and 1 ($n = 30$), 3 ($n = 44$), 7 ($n = 18$) and 1 mo ($n = 45$) after TACE therapy. Blood samples were collected in sterile glass tubes containing 0.057 mL of 15% EDTA. Plasma was separated by centrifugation at 2000 r/min for 15 min to eliminate platelets and stored at -70 °C till use.

Plasma VEGF was measured in duplicate by commercially available ELISA kits (Quantikine human VEGF, R&D System, Minneapolis, MN, USA). According to the manufacturer the minimal detectable dose of VEGF was <5.0 ng/L, the intra-assay and the inter-assay variabilities were 6.7-5.1% and 8.8-6.2%, respectively. Absorbance was determined using a biokinetics reader EL312e (Bio-Tek Instruments, Winooski, VT, USA) at 450nm.

Definition of response to TACE treatment

Response to treatment was assessed by image examinations one month after TACE Therapy. Treatment was evaluated according to the tumor volume change and retention rate of the iodized oil. The tumor volume was calculated using the summed products of the longest dimensions of the lesion, and patients were categorized as responding group (tumor size decrease or stable, no new-born nest) and non-responding group (enlargement of the tumor or the presents of new-born nest). According to the retention rate of the oil, patients were categorized as groups >75%, 50-75%, 25-50% and <25%.

Statistical analysis

Statistical analysis was carried out by the SPSS 10.0 packed program. To investigate the relationships between P-VEGF

levels and other variables, *t* test, ANOVA test, Chi-square test, Fisher exact probability test, correlation coefficient (*r*) and spearman's rank correlation (*rs*) were used when appropriate. $P < 0.05$ based on a two-tailed test was considered statistically significant.

RESULTS

Pre-TACE P-VEGF in patients with HCC

The pre-operative P-VEGF levels were significantly higher in HCC patients (63.83 ± 51.09 ng/L) than those in benign liver diseases (28.99 ± 6.67 ng/L) ($P = 0.006$) and in healthy controls (25.60 ± 5.47 ng/L) ($P = 0.003$). There was no significant difference in P-VEGF levels between the patients with benign liver diseases and healthy control. The sensitivity of P-VEGF in detecting HCC, using the mean P-VEGF of the patients with benign liver diseases (28.99 ng/L) as cut-off level, was found to be 73.3% with 62.2% specificity.

Correlation between pre-TACE P-VEGF and clinicopathologic features

There was no significant association between pre-TACE P-VEGF levels and various clinical and laboratory variables, except the gender ($t = 4.111$, $P = 0.003$). There was a weak correlation between P-VEGF levels and the platelet number (PLT) ($r = 0.312$, $P = 0.038$) and no correlation with the levels of α -FP ($r = 0.068$).

There was no significant association between the P-VEGF level and the presence of cirrhosis, tumor location, tumor capsule, ascites, lymph node metastasis, or the tumor vascularity. Significant differences were observed when P-VEGF was categorized by tumor size ($P = 0.006$), distant metastasis ($P = 0.017$), portal vein thrombosis ($P = 0.011$), arterio-portal vein shunting ($P = 0.026$), and advanced TNM stage ($P = 0.044$) (Table 1, Figure 1).

Figure 1 Mean plasma vascular endothelial growth factor levels at each disease stage in patients with hepatocellular carcinoma.

Using mean concentration of TII tumors as cut-off level, P-VEGF was able to predict TIII/TIV tumors with 75.9% sensitivity and 62.5% specificity. Using mean concentration of portal vein thrombosis of negative tumors as cut-off level, P-VEGF was found to have a sensitivity of 62.5% and a specificity of 64.9% in detecting portal vein thrombosis of positive tumors. Using mean concentration of the distant metastasis-free group as cut-off level, P-VEGF was able to exclude distant metastasis with a negative predictive value of 89.3%, a sensitivity of 50% and a specificity of 64.1%. P-VEGF could predict the presence of A-V shunting with 75% sensitivity and 67.6% specificity by using mean concentration of the non-A-V shunting patients as cut-off level (Table 2).

Change of P-VEGF levels during TACE course

P-VEGF levels were significantly elevated in patients with HCC

Table 1 Pre-TACE plasma VEGF levels in patients categorized by radiological parameters

	Group	No. of patients	Median plasma VEGF (ng/L)	Statistic value	P value
Cirrhotic liver	No	13	80.15	$t = 1.380$	0.175
	Yes	32	57.19		
Tumor location	Left lobe	4	77.82	$F = 0.275$	0.843
	Right lobe	26	66.62		
	Spiegel's lobe	5	50.38		
	Multiple lobe	10	57.68		
Tumor capsule	No	32	68.15	$t = 0.888$	0.379
	Yes	13	53.18		
Ascites	No	37	62.81	$t = 1.151$	0.280
	Yes	8	82.60		
Lymph node involvement	No	39	61.68	$t = 1.677$	0.101
	Yes	6	101.31		
Tumor vascularity	Hypervascularity	31	75.59	$F = 0.922$	0.406
	Median	9	55.31		
	Hypovascularity	3	39.1		
Tumor size	<5 cm	7	27.57	$F = 5.804$	0.006
	5-10 cm	22	55.59		
	>10 cm	11	101.54

	Yes	8	99.9		

TNM: tumor-node-metastasis. Tumor vascularity and arterial-portal vein shunting were studied by superselective digital subtraction angiographic (DSA).

Table 2 Effect of different VEGF levels on specificity and sensitivity in predicting tumor load in patients with HCC

	Cut-off VEGF value (ng/L)	Sensitivity (%)	Specificity (%)	Positive predictive value (%)	Negative predictive value (%)
TII and TIII/IV	36.55	75.9	62.5	78.6	58.8
Portal vein thrombosis	57.97	62.5	64.9	27.8	88.8
Extra hepatic metastasis	59.39	50	64.1	17.6	89.3
Arterio-portal vein shunting	56.03	75	67.6	33.3	92.6

**Figure 2** Effect of TACE on mean plasma vascular endothelial growth factor levels.

on the first post-TACE day (102.97 ± 89.26 ng/L) compared to pre-TACE (63.83 ± 51.09) ($P = 0.018$). Then VEGF level decreased gradually to 84.04 ± 79.16 ng/L on the third day and 76.08 ± 45.38 ng/L on the seventh day post-TACE, showing no statistical difference with pre-TACE P-VEGF levels (Figure 2).

A similar change of P-VEGF was found in patients who underwent TACE for treatment of benign liver diseases (data not shown).

One month after TACE, the P-VEGF level was 71.47 ± 50.87 ng/L, no statistical difference was found between them and pre-TACE P-VEGF levels.

Correlation between P-VEGF and response to TACE therapy

Treatment response was evaluated according to the change in tumor volume and retention of the oil. Forty five patients were categorized as responding group (18 cases) and non-responding group (27 cases). The change rate of P-VEGF levels was associated with the change in tumor volume ($r_s = 0.340$, $P = 0.034$). No statistic difference was found between changes in α -FP levels and tumor volume ($r_s = 0.230$, $P = 0.138$).

The pre-TACE P-VEGF level in non-responding group (73.33 ± 70.32 ng/L) was significantly higher than that in the responding group (49.52 ± 25.33 ng/L, $P = 0.025$). The response rate of the low VEGF group (P-VEGF < 49.5 ng/L) was significantly higher than that of the high VEGF group (P-VEGF > 49.5 ng/L) (51.6% vs 14.29%; $P = 0.018$, Fisher exact probability test) (Table 3).

Table 3 Correlation between plasma VEGF concentration and response to treatment

Clinical response	Plasma VEGF (ng/L)		No. of patients		
			Low VEGF	High VEGF	
Responder	49.52±25.33	$t = 2.285$	16	2	$\chi^2 = 5.599$
Non-responder	73.33±70.32	$P = 0.025$	15	12	$P = 0.018$

According to the retention rate of the iodized oil, 45 patients were classified as follows: 11 cases >75%, 16 cases 50 - 75%, 9 cases 25 - 50% and 9 cases <25%. The change rate of P-VEGF levels was strongly associated with oil retention ($r_s = 0.494$, $P = 0.001$). No statistical difference was found between the change rate of α -FP and oil retention ($r_s = 0.209$, $P = 0.179$).

DISCUSSION

By alternate splicing of the VEGF gene, VEGF could exist at least in one of the four forms, namely, VEGF206 (tissue bound), VEGF189 (tissue bound), VEGF165 (the most abundant form, soluble, and partly tissue bound) and VEGF121 (soluble)^[18]. Compared with bioassays, detection of soluble VEGF isoforms with immunoassay was characterized by low detection limits and greater specificity, reproducibility, and practicability^[19,20].

Recently, serum VEGF was measured by an enzyme-linked immunosorbent assay (ELISA) in patients with various types of cancer^[20]. Increased levels of VEGF were demonstrated in most patients with cancer and closely related to tumor progression and metastasis^[21,22]. However, some studies have shown that VEGF is not only secreted from tumor cells but also from a variety of CD34⁺ hematological cells (including platelets, megakaryocytes, monocytes, T-lymphocytes and leukocytes) during clotting^[23]. Serum VEGF concentrations could reflect blood platelet counts rather than VEGF synthesis by tumor tissues, and plasma rather than serum should be considered suitable for the measurement of circulating VEGF^[24]. So in our study, plasma VEGF concentrations were analyzed and ethylenediamine tetraacetic acid (EDTA) was used as anticoagulant.

Hepatocellular carcinoma (HCC) is a highly vascular tumor characterized by neovascularization and a high propensity for venous invasion. A strong VEGF expression was observed in the tissue of HCC and closely associated with tumor progression and metastasis^[6]. Recently, Poon *et al.*^[25] reported that serum VEGF level was significantly elevated in patients with HCC, and significantly high serum VEGF levels were associated with the absence of tumor capsule, the presence of venous invasion and microsatellite modules, and advanced TNM stage. Li *et al.*^[26] also considered that serum VEGF was a predictor of invasion and metastasis of HCC. To our knowledge, only one previous study measured P-VEGF changes in HCC patients. Jinno *et al.*^[16] reported that P-VEGF was a promising tumor marker for remote metastasis of HCC and its specificity, sensitivity and overall accuracy were high enough to be clinically useful.

In the current study, pre-TACE P-VEGF was found to be markedly elevated in the majority of patients with HCC and the increase was closely related to a more advanced stage of diseases. This finding suggested that HCC cells were an important source of P-VEGF. But the lower P-VEGF levels in HCC patients overlapped considerably with those in normal controls, thus limiting the application of VEGF as a tumor marker in early detection of HCC.

We found that high P-VEGF levels were associated with the presence of extrahepatic metastasis and portal vein involvement. Because vascular invasion by tumor cells is indispensable for remote metastasis, metastasis, portal vein involvement and A-V shunting can reflect the ability of tumor cells to invade blood vessels. These results indicated that P-VEGF could be used as a tumor marker in detecting vascular invasive phenotypes of

HCC. It is clinically important to search for the metastasis radiologically in patients with high P-VEGF levels.

In the present study, there was a weak correlation of PLT number with P-VEGF level. It has been suggested that platelets aggregate at metastatic sites, due to factors released from metastatic cells and vascular invasion, resulting in microthrombosis, tumor adhesion, and may release VEGF to the circulation^[27,28]. Therefore, we considered that in metastatic HCC patient platelet activation was a part of the sources of plasma VEGF.

The finding that there was no significant association between the P-VEGF level and tumor vascularity shown by DSA is of great interest. This might suggest that circulation VEGF levels could reflect the formation of new vessels rather than the degree of existing tumor vascularity.

No correlation was found between P-VEGF and serum α -FP, suggesting that they had different mechanisms of production, and P-VEGF might be an independent predictive factor.

Suzuki *et al.*^[29] found serum VEGF increased significantly and reached the peak value 7 d after TACE, suggesting that VEGF might play a role as a sensitive marker for tumor ischemia. We observed that P-VEGF increased and reached the peak value on the first day after TACE and then decreased gradually. We thought that the changes of serum VEGF during TACE might be associated with chemotherapy-induced thrombocytopenia and a subsequent rebound increase in platelet number^[30]. Although the exact mechanism is currently unknown, hypoxia caused by TACE, clotting and platelets aggregation after TACE, tumor cell lysis (and release of VEGF)^[31], elevation of VEGF in acute hepatitis^[32], and tissue trauma^[33] might contribute to the increase of P-VEGF in the early post-TACE period.

It has been reported that high pre-treatment levels of circulating VEGF are correlated with a poor response to the conventional chemotherapy^[12-15]. Similar results were found that the mean P-VEGF of the responding group was significantly higher than that of the non-responding group. Two treatment response indicators (tumor volume change and retention of the iodized oil) were associated with the change rate of P-VEGF levels rather than the change rate of α -FP. These results indicated that P-VEGF might act as a follow-up marker for post-TACE monitoring of the disease course and evaluation of curative effect, especially in α -FP negative patients. It may be useful in predicting treatment response and judging the effect of different TACE regimens.

In summary, P-VEGF level is an independent predictive factor of tumor progression, especially vascular invasion. TACE increases the level of P-VEGF only temporarily which may be associated with tumor ischemia. P-VEGF may be useful in predicting treatment response, monitoring disease course after TACE and judging the effect of different TACE regimens.

Abstract

AIM: To quantify the inhibition of HBV replication by targeted ribonuclease by using real-time fluorescent PCR.

METHODS: Targeted ribonuclease was introduced into 2.2.15 cells by liposome-mediated transfection or HIV-TAT mediated protein transduction. Forty-eight hours after the transfection and 24 h after the transduction, supernatants of 2.2.15 cells were collected and HBV DNA in the supernatants was quantified by real-time fluorescent PCR with a commercial kit.

RESULTS: HBV DNA concentrations in the supernatants of 2.2.15 cells transfected or transduced with targeted ribonuclease were $4.9 \pm 2.4 \times 10^8$ copies/L and $8.3 \pm 4.0 \times 10^8$ copies/L, respectively. Compared with controls, transfection or transduction of targeted ribonuclease reduced HBV DNA concentration in the supernatants of 2.2.15 cells by 90.4% and 90.1%, respectively ($P < 0.05$).

CONCLUSION: Targeted ribonuclease can inhibit HBV replication in 2.2.15 cells.

INTRODUCTION

Chronic hepatitis B virus (HBV) infection is a major health problem worldwide. Globally, more than 350 million people are infected with HBV, and some of them will evolve into liver cirrhosis and hepatocellular carcinoma (HCC). Current treatment regimens for chronic HBV infection, including interferon- γ , lamivudine, adefovir, or different combinations of these drugs, have only a limited long-term efficacy, but many adverse effects and drug resistance^[1,2]. Therefore, the exploration of novel treatment strategies for HBV infection is both necessary and urgent. In fact, many ingenious treatment strategies have been tested for inhibition of HBV replication, such as antisense nucleotides, ribozymes, intracellular antibodies, targeted nucleases, RNA interference^[3-13]. All of them can inhibit HBV replication to various degrees.

To explore alternative treatment methods against HBV

infection, targeted ribonuclease (TN), a fusion protein of HBVc and human eosinophil-derived neurotoxin (hEDN), was constructed and its effect on HBV replication was tested. After the targeted ribonuclease was introduced by transfection or transduction into 2.2.15 cells, a cell model of HBV infection, we found that it significantly reduced the serological markers of HBV replication, namely HBsAg and HBeAg, in the supernatants of 2.2.15 cells, suggesting that the targeted ribonuclease could inhibit HBV replication.

To further characterize the anti-HBV effect of the targeted ribonuclease, the HBV DNA was quantified in the supernatants of 2.2.15 cells treated by the targeted ribonuclease. Our results showed that the targeted ribonuclease markedly reduced HBV DNA concentration in the supernatants, which together with our previous findings, demonstrate that HBV replication can be inhibited by targeted ribonuclease.

MATERIALS AND METHODS

Cell culture

2.2.15 cells, a human hepatoblastoma Hep G2 cell line stably transfected by HBV genome, were cultured in Dulbecco's modified Eagle's medium (DMEM, purchased from Gibco Life Technologies, Grand Island, NY) supplemented with 100 mL/L fetal calf serum (Sijiqing Biotech Company, Hangzhou, China).

Transfection

The transfection methods were previously described^[14]. Briefly, twenty-four hours before transfection, 2.2.15 cells were seeded into a culture plate at the density of 2×10^8 /L. LipofectamineTM 2000 reagent (Gibco Life Technologies) was used for the transfection of 2.2.15 cells by p/TN, p/TNm, p/hEDN, p/HBVc, pcDNA3.1 (-), or mock solution (DMEM plus LipofectamineTM 2000 reagent containing no plasmid) according to the manufacturer's protocol. p/TN, p/TNm, p/hEDN and p/HBVc are the eukaryotic expression plasmids for targeted ribonuclease, point-mutated targeted ribonuclease without ribonuclease activity, human eosinophil-derived neurotoxin, and HBV core protein, respectively.

Transduction

2.2.15 cells were seeded into a culture plate at the density of 2×10^8 /L. Twenty-four hours later, purified recombinant proteins with protein transduction domain, TAT-TN, TAT-TNm, TAT-hEDN, and TAT-HBVc were added into the culture medium. For mock transduction, an equal volume of DMEM instead of protein was added into the culture medium.

Real-time fluorescent PCR

Forty-eight hours after transfection and 24 h after transduction, the supernatants of 2.2.15 cells were collected and HBV DNA in the supernatants was quantified by using fluorescent PCR kit for quantification of HBV DNA (Daan Gene Company, Guangzhou, China) according to the manufacturer's protocol. PCR primers were: P1: 5' ATCCTGCTGCTATGCCTCATCTT3', P2: 5' ACAGTGGGGAAAGCCCTACGAA3'. The probe was 5'TGGCTAGTTTACTAGTGCCATTTTG3'. PCR reaction was analyzed by PE 5700 (Perkin Elmer, USA).

Statistical analysis

All data were analyzed by SPSS 10.0 software. Differences were considered statistically significant when $P < 0.05$.

RESULTS

HBV DNA in the supernatants of 2.2.15 cells transfected or transduced with the targeted ribonuclease and controls was quantified by real-time fluorescent PCR. The results are shown in Figure 1. Compared with the controls, HBV DNA concentration in the supernatant of 2.2.15 cells was markedly reduced by the targeted ribonuclease, which was introduced into the cells by both pathways, *i.e.* transfection and transduction. The transfected targeted ribonuclease reduced HBV DNA concentration by 90.4% and the transduced targeted ribonuclease by 90.1% ($P < 0.05$). Either hEDN or HBVc alone had no such an effect, indicating that it was the fusion protein itself, *i.e.* the targeted ribonuclease, but not its constituent molecules that exerted the anti-HBV effect. Interestingly, TNm which was mutated at just one amino acid residue (Lys113→Arg) but had no ribonuclease activity as compared with TN, did not decrease HBV DNA concentration either, suggesting that the ribonuclease activity was needed in the anti-HBV effect of the targeted ribonuclease. To exclude the possibility that the anti-HBV effect of the targeted ribonuclease was due to nonspecific killing of 2.2.15 cells, we also detected cell viability of the transfected and transduced cells by MTT assay. The results showed that the targeted ribonuclease had no adverse effects on cell viability and proliferation as compared with controls ($P > 0.05$, data not shown).

Figure 1 HBV DNA concentration in the supernatants of transfected and transduced 2.2.15 cells. A: HBV DNA concentration in the supernatants of transfected 2.2.15 cells. TN, TNm, hEDN, HBVc, pcDNA3.1 (-), and MOCK represent the supernatants collected from 2.2.15 cells transfected by p/TN, p/TNm, p/hEDN, p/HBVc, pcDNA3.1 (-), or mock solution (DMEM plus Lipofectamine™ 2000 reagent containing no plasmid), respectively. B: HBV DNA concentrations in the supernatants of transduced 2.2.15 cells. TAT-TN, TAT-TNm, TAT-hEDN, TAT-HBVc, and MOCK represent the supernatants collected from 2.2.15 cells transduced by purified proteins of TAT-TN, TAT-TNm, TAT-hEDN, TAT-HBVc, or mock solution (DMEM), respectively.

DISCUSSION

Real-time fluorescent PCR is a simple, sensitive, specific and precise method to quantitate nucleic acids over a vast dynamic range^[15]. Due to these advantages, real-time fluorescent PCR has been widely used in both basic research and clinical diagnosis to measure the quantity of nucleic acids. As for HBV, real-time fluorescent PCR has been used in monitoring viral load during the course of antiviral treatment to evaluate the efficacy of the treatment and predict the possibility of emergence of drug-resistant variants, in the analysis of anti-HBV effect of small interfering RNA transfected into HBV-producing cell lines, and in the study of HBV pathogenesis^[10,16-19]. In the current research, we also used real-time fluorescent PCR to precisely quantify HBV DNA in the supernatants of 2.2.15 cells to detect the effect of the targeted ribonuclease on HBV replication. The targeted ribonuclease reported here is a fusion protein against HBV infection constructed by us, based on the principle of capsid-targeted viral inactivation (CTVI)^[5,20]. Our previous studies showed that it significantly reduced HBsAg and HBeAg in the supernatants of 2.2.15 cells, suggesting that the targeted ribonuclease could inhibit HBV replication. In consistent with our previous findings, in this study we observed the targeted ribonuclease notably reduced HBV DNA in the supernatants of 2.2.15 cells. Taken together, these results demonstrate that the targeted ribonuclease strongly inhibits HBV replication. The targeted ribonuclease may therefore be one of the promising alternative anti-HBV agents which are being studied in the pursuing of a satisfactory treatment for chronic HBV infection.

Although the precise mechanism of anti-HBV effect of targeted ribonuclease still remains unknown and awaits further study, the principle of capsid-targeted viral inactivation (CTVI) implies that it may specifically recognize pregenomic RNA (pgRNA) of HBV, the template for HBV replication, intracellularly by the HBVc domain of fusion protein, and then degrades pgRNA by the hEDN domain. This will in turn lead to a decrease in the replication of HBV DNA and synthesis of viral proteins, which finally results in a reduction of extracellular HBV DNA and viral proteins (HBsAg and HBeAg). In fact, we have found that purified targeted ribonuclease can degrade RNA *in vitro* (unpublished data) which supports this mechanism. Experiments are ongoing in this laboratory to clarify the mechanism and to apply the targeted ribonuclease to small animal models.

Abstract

AIM: To study the expression of survivin, a novel member of inhibitors of apoptosis protein (IAP) and its significance in colorectal carcinoma.

METHODS: Survivin mRNA expression was evaluated by semi-quantitative reverse transcriptase polymerase chain reaction (RT-PCR) in 52 colorectal carcinoma samples and 48 adjacent normal colorectal tissue samples. PCR product was sequenced to verify the desired result. Expressions of survivin protein, proliferating cell nuclear antigen labelling index (PI) and apoptotic index (AI) were detected immunohistochemically in 52 human colorectal carcinomas.

RESULTS: The expression of survivin mRNA was detected in a significantly greater proportion of colorectal carcinoma samples than in adjacent normal colorectal tissues (67.3% vs 25%; $P < 0.01$). There was no relationship between survivin mRNA expression in colorectal carcinomas and sex, tumor size, histological types, lymphnode metastasis, distant metastasis and Dukes' stage. The PCR product shared 99% of homology with human counterparts. Survivin expression was observed immunohistochemically in 27 of 52 cases of colorectal carcinoma (51.9%). The AI was significantly lower in survivin positive group than in survivin negative group ($0.67 \pm 0.18\%$ vs $1.14 \pm 0.42\%$; $P < 0.001$), while the PI was greater in survivin positive group than in survivin negative group ($51 \pm 22\%$ vs $27 \pm 18\%$, $P < 0.001$).

CONCLUSION: Survivin is a special tumor marker independent of histopathological characteristics. It may play an important role during human colorectal tumorigenesis by inhibiting apoptosis and accelerating proliferative activity of colorectal tumor cells.

INTRODUCTION

Apoptosis is an evolutionally conserved genetic program of

cellular suicide and also central to the homeostasis of adult tissues by maintaining the balance between cell production and cell elimination. There is compelling evidence that defects in apoptosis contribute to human diseases such as malignancies. In the evolution of colorectal cancer (CRC) the imbalance between cell proliferation and cell apoptosis may be an important potential factor. A large number of evidences show that many molecules such as p53 and bcl-2 are involved in the regulation of apoptosis during colorectal tumorigenesis. The inhibitor of apoptosis proteins (IAPs), which are widely expressed in all kinds of malignancies, is encoded by the highly-conservative anti-apoptosis gene family and plays an important role in the regulation of apoptosis. IAP molecules contain 1-3 copies of a -70 amino acid zinc-finger fold, and designate the baculovirus IAP repeat (BIR) and their mechanism of action has been directly attributed to the binding of Caspases, thus preventing enzyme activity of the Caspases^[1,2]. Among molecules of the IAP family, survivin, a novel anti-apoptosis gene is prominently expressed in CRC and several other malignancies^[3,13-18]. The role of survivin in blocking apoptosis is unclear and its ability to inhibit Caspase-3 activity has been widely debated^[3-5]. Survivin may play an important role in the development of CRC. The present study was to examine the expression of survivin in CRC and to evaluate the association between expression of survivin and clinicopathological characteristics of patients with CRC. We also investigated the significance of survivin expression in CRC.

MATERIALS AND METHODS

Patients

Specimens used for this study were obtained from 52 carcinomas and 48 adjacent normal tissues from the resection margins at the First Affiliated Hospital of Suzhou University. The suspected de novo cancers and patients with a known familial colon cancer syndrome history were excluded. All patients had received neither chemotherapy nor radiation therapy before tumor resection. The diagnosis and histopathologic classification were determined according to the General Rules for Pathologic Studies of National CRC Cooperation Group. In CRC patients, there were 31 males and 21 females, and the mean age of the patients was 61.1 years. According to histological differentiation grade, 52 cases of CRC were classified as well, moderately and poorly differentiated subgroups which included 6, 39 and 7 cases respectively. Seven, 19, 17 and 9 cases were staged as Dukes' A, B, C and D respectively. After washed with physiological saline, all cancer tissue samples were cut into two pieces by sterile blade. One piece was fixed with formalin for H&E, the other was frozen in liquid nitrogen immediately after the lesion was resected and stored at -80 °C for subsequent assay.

Semi-quantitative RT-PCR

Briefly, total RNAs were extracted from colorectal cancer and normal mucosae, using TRIzol reagent (Life Technologies, Rockville, MD). Prepared RNA (2 µg) was mixed with the random hexamer (100 ng), incubated for 5 min at 70 °C, and then quickly chilled at 4 °C for 5 min. RNA samples were reverse-transcribed at 37 °C for 60 min into first-strand cDNA in reverse transcription solution [50 mmol/L Tris-HCl (pH8.3), 40 mmol/L KCl, 8 mmol/L

MgCl₂, 0.5 mmol/L each dNTP, 225 mg/mL BSA, 5 mmol/L DTT, 25 units of RNasin (Promega, Madison, WI), and 200 units of Mo-MLV reverse transcriptase (Life Sciences, Rockville, MD)] with a total volume of 40 µL. The cDNA samples were incubated at 95 °C for 5 min to inactivate the reverse transcriptase and then chilled. The samples were amplified by adding of 50 µL of PCR mixture [50 mmol/L Tris-HCl (pH 8.3), 40 mmol/L KCl, 2 mmol/L MgCl₂, 0.2 mmol/L each dNTP, 10 pmol of each sense and antisense primer, and 1.5 units of Taq polymerase (MBI)]. Amplification of β_2 -microglobulin (β_2 -MG) gene was performed 28 cycles, each for 30 s at 94 °C, for 30 s at 58 °C, and 60 s at 72 °C, followed by an extension at 72 °C for 7 min. Amplification of survivin gene was performed 32 cycles, each for 45 s at 94 °C, 45 s at 61 °C, and for 60 s at 72 °C, followed by an extension at 72 °C for 7 min. The products were electrophoresed on 15 g/L agarose gels and then scanned. Specific primers for survivin gene, targeting a 528-bp fragment, were: 5'-TTGAA TCGCG GGACC CGTTG G-3' (sense) and 5'-CAGAG GCCTC AATCC ATGGC A-3' (antisense). As internal standards, β_2 -microglobulin (β_2 -MG) gene was used. Primer pairs specific to β_2 -MG gene, targeting a 330-bp fragment, were used sense: 5'-CTCGC GCTAC TCTCT CTTTC-3' and antisense: 5'-CATGT CTCGA TCCCACTTAA-3'.

Sequencing of survivin

The PCR products of survivin were isolated and purified using UNIQ-10 purification kit (MBI) and then ligated with pGEM easy T vector by T4 DNA ligase and transformed *E. coli* JM109. Recombinant vectors were identified through *Eco*RI digestion and agarose gel electrophoresis. Positive plasmids were sequenced by an ABI PRISM 377 DNA sequencer (Perkin-Elmer Company).

Immunohistochemistry

Immunohistochemical staining of survivin was performed by SP method. For PCNA, SABC method was performed. TUNEL assay was used to detect apoptosis. In brief, paraffin sections (4 µm thick) were dewaxed, dehydrated, and then immersed in a 10⁻³ mol/L sodium citrate buffer (pH 6.0). For detection of survivin, antigen retrieval was performed by boiling the sections for 20 min in a pressure cooker. For detection of PCNA, the sections were heated in a microwave oven for 10 min to retrieve the antigens. Endogenous peroxidase was inactivated by incubating the sections with 30 mL/L hydrogen peroxide. Nonspecific reactions were blocked by bovine serum. The sections were incubated with a primary antibody overnight at 4 °C. The antibody used was an 8E2 monoclonal antibody (Chemcon, USA) at 1:5 dilution. Rinsed with PBS, the sections were incubated for 30 min at 37 °C with biotinylated secondary antibody and streptavidin conjugated to horseradish peroxidase, respectively. After three rinse with PBS, the sections were incubated with diaminobenzidine substrate, then rinsed with distilled water and counterstained with hematoxylin. As a negative control, PBS was used instead of the primary antibody. PCNA (Maxim, USA) and TUNEL (Roche, USA) assay were performed according to the manufacturer's instructions.

Scoring criteria

The mean percentage of positive tumor cells for the expression of survivin was determined in at least five areas at 400-fold magnification, and cases with less than 10% positively stained cells were defined as negative. Cases with 10-29% positively stained cells were defined as "+", 30-59% as "++", and 60% or more as "+++". These scorings were performed in a blind fashion.

PI and AI were expressed as the ratio of positively stained tumor cells to all tumor cells. If possible, five areas were randomly selected for counting under 400-fold magnification. Otherwise, the whole section underwent assessment.

Statistical analysis

All results were analyzed by software of SPSS 10.00. $P < 0.05$ was considered statistically significant.

RESULTS

Expressions of survivin mRNA in colorectal carcinoma samples and adjacent normal mucosa samples

Fifty two CRC samples and forty eight normal mucosa samples were available for analyses. The expressions of survivin mRNA were detected in a significantly greater proportion of CRC than in normal mucosa samples (67.3% vs 25% $P < 0.01$). Survivin mRNA was not detected in normal tissue when the associated cancer was survivin negative (Figure 1).

Figure 1 RT-PCR products of paired samples from normal colonic mucosae (lanes 4, 6, 8) and CRC (lanes 3, 5, 7) from three different resection specimens. Lane 1: positive control (U937 cell line), lane 2: negative control, lane M: DNA mark. Expression of β_2 MG confirmed the fidelity of reverse transcription.

Relationship between expressions of survivin mRNA and clinicopathological characteristics of patients with CRC

No relationship was found between survivin mRNA expression in CRC and sex, tumor size, histological types, lymphnode metastasis, distant metastasis and Dukes' stage (Table 1).

Table 1 Correlation between expression of survivin mRNA and clinicopathological characteristics of patients with CRC

Variable	Total No β_2 MG	Survivin	P Value
Sex			
Male	31	0.74±0.63	>0.05
Female	21	0.77±0.56	
Tumor size			
≥5 cm	20	0.71±0.59	>0.05
<5 cm	32	0.78±0.61	
Histological type			
High	7	0.62±0.51	>0.05
Middle	39	0.75±0.59	
Low	6	0.92±0.74	
Lymphnode metastasis			
Positive	22	0.80±0.65	>0.05
Negative	30	0.72±0.57	
Distant metastasis			
Positive	9	0.93±0.18	>0.05
Negative	43	0.72±0.65	
Duke stage			
A	7	0.55±0.57	>0.05
B	19	0.73±0.62	
C	17	0.77±0.73	
D	9	0.93±0.18	

Correlations between expression of survivin, AI and PI

The expression of survivin protein was observed in cytoplasm of malignant tumor cells. Survivin expression was observed immunohistochemically in 27 of 52 cases of colorectal carcinoma (51.9%). To examine whether the expression of survivin correlated with AI and PI, tissue samples obtained from

Figure 3 Immunohistochemical analysis of apoptosis, proliferation, and survivin in CRC. Survivin expression was restricted to the cytoplasm of cancer cells (brown staining, $\times 400$ fold). Apoptotic cells and proliferative cells were detected in the nuclei of cancer cells (brown staining, $\times 400$ fold).

carcinoma were divided into two groups according to the expression of survivin and compared to AI and PI (Figure 2). Survivin positive tumors had significantly lower values for AI than survivin negative tumors ($P < 0.001$), and PI in survivin positive tumors was higher than in survivin negative tumors ($P \leq 0.001$, Figure 3).

Figure 2 Correlations between survivin expression and AI and PI. $P < 0.001$ as PI in survivin positive tumors ($51 \pm 22\%$) compared with survivin negative tumors ($27 \pm 18\%$), $P < 0.001$ as AI in survivin positive tumors ($0.67 \pm 0.18\%$) compared with survivin negative tumors ($1.14 \pm 0.42\%$).

DISCUSSION

Hybridization screening of a human PI genomic library with the cDNA of effector cell protease receptor-1 (EPR-1) yielded a new gene spanning -15 kb containing four exons and three introns, and located to band 17q25 by Ambrosini *et al.* in 1997^[6]. Survivin is the smallest member of the IAP gene family, structurally characterized by a single BIR module and a -COOH-terminus α -helix coiled domain, substituting a canonical ring finger^[6]. Prominently expressed in a variety of apoptosis-regulated organs during embryonic and fetal development^[7], survivin is undetectable in most normal adult tissues, and becomes abundantly reexpressed in a variety of human cancers. The PCR based approach used in our study is exquisitely sensitive and may detect gene transcripts even in a single cell or cell cluster with a comparable specificity. The present study showed that expression of survivin mRNA was detected in a significantly greater proportion of CRC samples than in adjacent normal colorectal tissues (67.3% vs 25%, $P < 0.01$). The data were consistent with a study by Adida *et al.*^[8]. Furthermore, the prevalence of survivin mRNA expression in the present study correlated well with the expression of survivin protein (unpublished data). Recent studies demonstrated that the novel splice variants survivin- Δ Ex3 and survivin-2B were expressed in malignancies^[9,10]. Survivin- Δ Ex3, which lacks exon 3, exhibited a pronounced anti-apoptotic activity, whereas survivin-2B containing a part of intron 2 as an additional cryptic

exon, largely lost its anti-apoptotic activity. These alternative splice variants have not been explored so far. In gastric carcinomas, Mahotka *et al.*^[10] showed that survivin-2B might act as a naturally occurring antagonist of survivin and might play a role in tumor progression. We found that CRC also expressed survivin- Δ Ex3, survivin-2B and survivin. The latter was a dominant transcript (Figure 1), and shared 99% of homology with human counterparts by sequencing.

The expression of survivin mRNA was independent of clinical pathological characteristics. The result was consistent with previous studies^[8,11]. However, in endometrial carcinoma, survivin expression correlated with clinical stage, histological grade, invasive behavior and survival rate^[12]. The expression of survivin has been proved as a prognostic mark in non-small cell lung cancer^[13], breast carcinoma^[14], oesophageal carcinoma^[15] and hepatocellular carcinoma^[16]. In CRC, Adida *et al.*^[8] reported that the predictive value of survivin expression was limited to patients with stage II CRC, those with survivin negative tumors had a five year survival rate of 94.4% compared with 44.8% for patients with survivin positive tumors. Recent studies showed the phenomena of chemo-radioresistance were prevalent in survivin positive tumors and molecular manipulation of survivin expression might enhance chemotherapy and radiation therapy^[17-22]. These findings indicate that survivin may play an important role in chemoresistance of cancer cells. However, the clinical importance of survivin expression remains unclear in patients with cancer.

We found that survivin positive tumors had significantly lower values for AI than survivin negative tumors, and PI was higher in survivin positive tumors than in survivin negative tumors ($P < 0.001$ for both). These findings indicate that the overexpression of survivin not only inhibits cell death but also reflects the presence of a greater number of proliferating cells. By inhibiting apoptosis and promoting proliferation, survivin plays an important role in colorectal tumorigenesis.

There has been a considerable interest in survivin biomedical researches. The exploitation of survivin might provide important predictive and prognostic clues in diagnosis, and offer new therapeutic alternatives for cancer. Further studies are required to identify the potential role and mechanism of survivin in the development of CRC.

Abstract

AIM: To investigate the expression of toll-like receptor 4 (TLR4) and MD-2 gene and protein in Kupffer cells (KCs) and their role in ischemia-reperfusion (IR) injury of rat liver graft.

METHODS: KCs were isolated at 0 (control group), 2, 12, 24 h (IR group) following IR in rat liver graft. mRNA expression of TLR4 and MD-2 was detected by RT-PCR analysis, protein expression of TLR4/MD-2 was detected by flow cytometric (FCM) analysis, and tumor necrosis factor- α (TNF- α) level in supernatant was measured by ELISA. Then isolated KCs were incubated with anti-TLR4 polyclonal antibody (anti-TLR4 group), and TNF- α level was measured again.

RESULTS: The mRNA and protein expression of TLR4/MD-2 and the level of TNF- α in IR group increased significantly at 2 h following IR, and reached the maximum at 12 h, and slightly decreased at 24 h, but were still significantly higher than those in the control group ($P < 0.01$). The expression of these factors was markedly decreased after anti-TLR4 antibody treatment as compared with the IR group ($P < 0.01$).

CONCLUSION: Lipopolysaccharide (LPS) following IR can up-regulate TLR4/MD-2 gene and protein expression in KCs, and synthesize cytokine TNF- α . Anti TLR4 antibody can inhibit the production of TNF- α induced by LPS. TLR4 and its partner molecule MD-2 may play an important role in Kupffer cell activation and IR injury.

INTRODUCTION

Toll-like receptor 4 (TLR4) is a transmembrane protein, mainly existed in monocytes/macrophages^[1-3]. It plays an important role in recognizing endotoxin (lipopolysaccharide, LPS) or LPS-CD14 complex, and mediating monocyte/macrophage activation and pro-inflammatory cytokine release^[2,4,5]. MD-2 molecule is

a secreting protein, linking with the exocytic area of TLR4, and facilitating the binding of TLR4 and LPS to enhance cell activation induced by LPS^[6-10]. Kupffer cells (KCs) are not only the biggest residing macrophages in the body, but also are the main participant of ischemia-reperfusion injury (IRI) in liver transplantation^[11-14]. Therefore, studying the expression of TLR4 and MD-2 gene and protein in KCs following IR is very important to clarify the source of cytokines involved in IRI. The aim of the current study was to investigate the expression of TLR4 and MD-2 gene and protein, and the production of cytokines in liver graft by isolating and culturing KCs following IRI, and to probe the role of TLR4 and MD-2 in IRI injury.

MATERIALS AND METHODS

Establishment of animal model of IRI following liver transplant in rat

Male Wistar rats weighing 210-250 g, supplied by Chongqing Medical University, were used as donors and recipients. Orthotopic liver transplantation was performed with improved two-cuff technique introduced by Peng *et al.*^[15] as following: (1) Graft procurement: portal vein (PV), hepatic artery (HA), infrahepatic vena cava (IHVC), and bile duct were divided. Then the graft was infused and harvested for preparation. PV and IHVC were prepared by cuff technique, and a drainage Teflon catheter was inserted into the bile duct. (2) Implantation of graft: the graft was placed orthotopically in the recipient's abdominal cavity after the original liver was removed. The suprahepatic vena cava was sutured end to end, and the portal vein was anastomosed by cuff method, then the liver was perfused. After the anastomosis of IHVA and HA was completed, the bile duct was reestablished end to end by Teflon catheter.

KC isolation and culture

KCs were isolated at 0, 2, 12, 24 h following IR with *in situ* collagenase perfusion technique described by Gong *et al.*^[16]. In brief, the liver was removed with portal vein perfusion with Hank's balance salt solution (HBSS) and digested in a solution of 0.5 g/L collagenase (type IV, Sigma, USA). The digest was washed thoroughly and plated on plastic dishes in RPMI medium containing 100 mL/L fetal calf serum (FCS). After 6 h incubation at 37 °C in humidified atmosphere containing 50 mL/L CO₂ in air, the nonadherent cells were removed by pipet. The adherent cells were collected with a rubber policeman. KC purity exceeded 90% as assessed by light microscopy, and viability was greater than 95% as determined by trypan blue exclusion assay. The KCs at 0 h were regarded as control group, and those at 2, 12 and 24 h were as IR group.

RNA isolation and complementary DNA synthesis

Total RNA was isolated from rat KCs using the TRIZOL reagent (Life Technologies, USA). The quality of RNA was controlled by the intactness of ribosomal RNA bands. A total of 5 μ g of each intact total RNA sample was reverse-transcribed to complementary DNA (cDNA) using AMV reverse transcriptase (Roche, USA).

Determination of TLR4 and MD-2 mRNA by RT-PCR

The PCR primers used are shown in Table 1. The conditions for

amplification were as follows: denaturation at 94 °C for 1 min, annealing at 58 °C for 1 min, and extension at 72 °C for 1 min for 30 cycles, and extension at 72 °C for 7 min again. The PCR products were electrophoresed on 20 g/L agarose gels containing ethidium bromide, and video photographed on an ultraviolet transilluminator, and the results were shown as the ratio of relative absorbance of TLR4 or MD-2/ β -actin analyzed with Quantity one 4.1.0 software.

Table 1 Primer used for PCR amplification of TLR4 and MD-2 gene

	Primer sequence	Size (bp)
TLR4	5' TGGATACGTTTCCTTATAAG 3'	311
	5' GAAATGGAGGCACCCCTTC3'	
MD-2	5'ATGGTCTTCCTGGCGAGTTT3'	332
	5'CCATGGCACAGAACTTCCTT3'	
β -actin	5'ATCATGTTTGAGACCTTCAACA 3'	300
	5'CATCTCTTGCTCGAAGTCCA 3'	

Flow cytometric analysis

Expression of TLR4 and MD-2 membrane protein in KCs was determined by flow cytometric analysis. In brief, KCs were incubated with rabbit anti-rat TLR4 polyclonal antibody (1 μ g/mL) labeled with FITC and goat anti-rat MD-2 polyclonal antibody (1 μ g/mL) labeled with PE (Sigma, USA). After washed three times, 10 000 cells were analyzed by flow cytometry (Coulter, USA), and the percentage and mean fluorescence intensity (MFI) of TLR4 and MD-2-positive cells were taken as the indexes.

TNF- α level in supernatant

Supernatants were collected to measure the levels of TNF- α with ELISA kit (Jingmei Biotechnology Company, China) following the manufacturer's instructions.

Blocking test of anti-TLR4 antibody

To determinate the role of TLR4 and MD-2 in LPS-induced KC activation, KCs were harvested and adjusted to the concentration of 1×10^6 (mL/well). Then, 0.2 mL of anti-TLR4 antibody (1: 100) was added to the medium, and incubated for 30 min at 37 °C. The supernatants were collected again for measuring the levels of TNF- α by ELISA analysis following the manufacturer's instructions.

Statistical analysis

All results were expressed as mean \pm SD. Statistical difference between means was determined by Student's *t* test using SigmaPlot 2000 software (SPSS Inc., USA). A *P* value < 0.01 was considered statistically significant.

RESULTS

Expression of TLR4 and MD-2 mRNA in KCs

RT-PCR analysis showed that KCs from control group had low but detectable levels of TLR4 and MD-2 mRNA. The mRNA level was significantly increased with time, reaching its maximum of nine-fold at 12 h following IR, and slightly declined 24 h after IR, but was still significantly higher than that in the control group (*P* < 0.01) (Figure 1).

Binding of FITC, PE to KCs

To confirm the expression of TLR4 and MD-2 membrane protein on KCs, we examined the binding of FITC/PE to the cells. TLR4 and MD-2 positive cells were 7.94% and 6.51% in control group. But in the rats with IR, the mean fluorescence intensity (MFI) was significantly increased, and TLR4 positive cells were 45.71%,

78.46%, and 61.72% and PE positive cells were 38.64%, 74.15%, and 58.47%, respectively, at 2 h, 12 h and 24 h following IR, which were significantly higher compared with the control group (*P* < 0.01) (Figure 2).

Figure 1 Expression of TLR4 and MD-2 mRNA by RT-PCR analysis. A: PCR products were electrophoresed on agarose gels and photographed. B: Quantitative data of mRNA levels were shown as the ratio of relative absorbance and expressed as mean \pm SD. Expression of TLR4 and MD-2 mRNA were significantly increased in the IR group compared with the control group (*P* < 0.01).

Figure 2 Percentage of TLR4 and MD-2 positive cells. The percentage of TLR4 and MD-2 positive cells was significantly increased after IR compared with the control group.

Figure 3 Comparison of TNF- α production in supernatant of KCs. In IR group, the TNF- α level in supernatant was increased with time, and reached the maximum (529.1 ± 30.9 ng/mL) at 12 h. But in anti-TLR4 group, the production of TNF- α was obviously inhibited by Ab against TLR4 compared with the IR group (*P* < 0.01).

Decrease of TNF- α levels after anti-TLR4 treatment

In IR group, the level of TNF- α in supernatant of KCs was 267.4 ± 24.1 , 529.1 ± 30.9 , and 329.7 ± 24.6 ng/mL at 2, 12 and 24 h after IR, respectively. In group of anti-TLR4 antibody blockade, the production of TNF- α in supernatant was obviously inhibited by Ab against TLR4 when compared with that in IR group ($P < 0.01$), and it was 102.5 ± 10.4 , 207.6 ± 18.4 , and 185.3 ± 12.7 ng/mL at 2, 12 and 24 h after IR, respectively (Figure 3).

DISCUSSION

Toll protein is a transmembrane protein which mainly acts as a necessary tool for immune defence to microorganism^[6,17-20]. The first toll-like protein in human cells was reported by Janeway, and named toll-like receptor (TLR)^[3,21]. About ten members of TLR superfamily in mammals have been reported in recent years. Among them, TLR4 plays a key role in LPS signal transduction^[4,22,23].

When LPS enters blood, it first binds to LBP (LPS binding protein), forming a LPS-LBP compound, and then binds to TLR4 on cell membranes leading to activation of cells^[18,24,25]. Recent studies have confirmed that the activation of cells induced by LPS needs another important molecule, namely MD-2. MD-2 is a key regulator protein, which could promote LPS signal transduction through connecting with TLR4 on cell membranes and forming the TLR4/MD-2 compound^[26-28].

Kupffer cells are special macrophages residing in hepatic sinusoids, which constitute 80% to 90% of total fixed macrophages in the body^[13,29]. Because of their special location, KCs act as an important defensive barrier for gut-derived endotoxemia. A large amount of endotoxins contact with KCs through portal circulation following ischemia-reperfusion after liver transplantation, and activate the KCs^[30,31]. Thus, it is very important to study the expression of TLR4 and MD-2 in KCs to clarify the origin of cytokines and the mechanism of IRI.

In our study, we found there were weak expressions of TLR4 and MD-2 gene and protein in resting KCs, which might play a critical role in maintaining the normal function of KCs, and might be essential for keeping KCs to be ready for activation after stress. But after IR, a large amount of LPS entered liver sinusoids, activated KCs, resulting in increased release of harmful cytokines such as TNF- α , which reached the maximum at 12 h after IR. To correctly illuminate the relation between TLR4 and MD-2 and downstream cytokines, we used anti-TLR4 antibody to inhibit the binding function of TLR4, and found that the production of TNF- α was greatly decreased, suggesting that the expression of TLR4 and MD-2 protein is indispensable to the secretion of downstream cytokines.

In summary, the present data suggest that there are weak expressions of TLR4 and MD-2 mRNA and protein in Kupffer cells. Expressions of TLR4 and MD-2 can significantly increase following ischemia-reperfusion in rat liver transplantation. LPS can induce activation of KCs by combining with TLR4 and MD-2, and subsequently release harmful cytokines, which ultimately attack the graft. Further studies are needed for elucidating TLR4/MD-2-mediated signal transduction pathways which lead to the secretion of cytokines during IRI on liver graft.

Abstract

AIM: To investigate the effects and molecular mechanisms of recombinant human growth hormone (rhGH) on protecting liver function and alleviating portal hypertension of liver cirrhotic rats.

METHODS: Liver cirrhosis of male Sprague-Dawley rats was induced by administration of thioacetamide. The rats with or without liver cirrhosis were randomly divided into four groups. Group A consisted of the normal rats was treated with normal saline (NS), group B consisted of the normal rats was treated with rhGH, group C consisted of cirrhotic rats was treated with NS, and group D consisted of cirrhotic rats was treated with rhGH. The rats of different groups were subcutaneously injected with 0.5 mL of NS or 333 ng/kg of rhGH daily for 7 d. After treatments, the following parameters were examined, including GH-binding capacity (R_T) by ^{125}I -hGH binding, growth hormone receptor mRNA (GHR mRNA) expression by RT-PCR, relative content of collagen (RCC) by histomorphometry, and level of malon-dialdehyde (MDA) and superoxide dismutase (SOD) in liver tissue by thiobarbituric acid reaction and pyrogallol acid self-oxidation, respectively. Serum albumin (ALB), alanine transaminase (ALT) and portal vein pressure (PVP) were also examined.

RESULTS: rhGH up-regulated both the GH-binding capacity (R_T) and the expression of GHR mRNA *in vivo*. R_T in group A (72 ± 12 fmol/mg protein) was significantly higher than that in group C (31 ± 4 fmol/mg protein) ($P < 0.05$). R_T in group B (80 ± 9 fmol/mg protein) increased markedly compared to group A ($P < 0.05$). R_T in group D (40 ± 7 fmol/mg protein) raised remarkably compared with group C ($P < 0.05$), but less than that in group A, and there was no significant GH binding affinity contrast (Kd) change. The GHR mRNA level (IOD, pixel) in group A (29 ± 3) was significantly higher than that in group C (23 ± 3) ($P < 0.05$). GHR mRNA levels were significantly raised in group B (56 ± 4) and group D (42 ± 8) compared with groups A and C (29 ± 3 and 23 ± 3 , respectively) ($P < 0.05$). Compared with the normal liver,

MDA level was higher and SOD level was lower in cirrhotic livers. After rhGH treatment, MDA level was significantly declined to 12.0 ± 2.2 nmol/mg protein and SOD was raised to 1029 ± 76 U/mg protein in group D ($P < 0.05$). ALB levels in groups B and D (42 ± 7 g/L and 37 ± 7 g/L, respectively) were significantly raised compared with those in groups A and C (35 ± 5 g/L and 29 ± 4 g/L, respectively) ($P < 0.05$). ALT level was markedly lower in group D (69 ± 7 U/L) compared to group C (89 ± 15 U/L) ($P < 0.05$), and close to group A (61 ± 10 U/L). RCC in group C ($22.30 \pm 3.86\%$) was significantly higher than that in group A ($1.14 \pm 0.21\%$) and group D ($14.70 \pm 2.07\%$) ($P < 0.05$). In addition, rhGH markedly alleviated portal hypertension in liver cirrhotic rats (group D *vs* C, 9.3 ± 1.5 cmH₂O *vs* 14.4 ± 2.0 cmH₂O) ($P < 0.05$).

CONCLUSION: Pharmacological doses of rhGH can increase R_T and GHR mRNA expression, ameliorate liver functions, repress fibrosis and decline portal hypertension, suggesting it has potentially clinical usage as a hepatotropic factor.

INTRODUCTION

Liver cirrhosis is a common pathway of a variety of chronic liver diseases^[1], and is associated with high protein catabolism, low anabolism and negative nitrogen balance^[2], resulting in hypoproteinemia which contributes to ascites, dysfunction of coagulation and suppression of immune response^[3]. Early reports showed that cirrhotic patients undergone emergency abdominal surgery exhibited a higher mortality^[4]. In retrospective studies of liver transplant recipients, protein-calorie malnutrition has been associated with adverse outcomes in patients with end-stage liver diseases^[5,6]. A prospective study showed that cirrhotic patients with hypermetabolism and emaciation had a much higher mortality rate after liver transplantation than those with normal metabolism^[7]. It is critical for patients with hepatic cirrhosis to correct malnutrition. To date, studies have shown that nutritional support is always not effective enough to prevent protein loss and optimize the care of these patients in severe catabolic illnesses, including cirrhosis^[8,9].

Growth hormone (GH) is essential for body growth in children. In adults, GH continues to stimulate many anabolic processes. GH secreted by the pituitary gland is pulsatile, and its action depends on its binding to growth hormone receptor on cell membrane^[10-13]. New insights have initiated new applications and a growing potential for GH replacement therapy in adults. Recombinant human growth hormone (rhGH) has been clinically used in many states, such as after abdominal operation^[14], organ transplantation^[15], major trauma^[16] and severe burns^[17], to enable the patients to survive an aggressive surgery^[18]. After treatment with rhGH, donor site healing rate

in children with severe burns was enhanced and hospitalization time was decreased^[19-21]. It significantly enhanced cell-mediated immunity and decreased wound infection rates and length of hospitalization in a large group of postoperative patients^[22]. Some clinical trials reported that growth hormone enhanced nitrogen retention of patients with chronic obstructive lung diseases^[23], severe sepsis^[24,25] and emaciated AIDS^[26,27], in addition to fasted adult volunteers. Although there are many controversies^[28-32], it has been confirmed that rhGH is an effective drug to accelerate protein anabolism^[33] and plays a central role in metabolic intervention with a significant cost-effect benefit^[34].

In this study, we investigated the effects and molecular mechanism of pharmacological doses of recombinant human growth hormone (rhGH) on expression of growth hormone receptor (GHR) in liver tissue, liver function and portal vein pressure in a rat cirrhotic model with portal hypertension.

MATERIALS AND METHODS

Induction of liver cirrhosis

Male SD rats were purchased from Medical Animal Center of Sun Yat-Sen University. Rat liver cirrhosis was induced by daily intraperitoneal injection of 30 g/L thioacetamide (TAA, 50 mg/kg for 9 to 12 wk). Twenty normal rats (body mass 200-300 g) were randomly divided into two groups: group A ($n = 10$) was treated with normal saline (NS), and group B ($n = 10$) was treated with rhGH. Twenty cirrhotic rats (body mass, 200-300 g) were randomly divided into two groups: group C ($n = 10$) was treated with NS and group D ($n = 10$) was treated with rhGH. The rats were injected subcutaneously with 0.5 mL of NS or 333 ng/kg of rhGH daily for 7 d.

Experimental methods and observation indexes

Rats were anesthetized with pentobarbital (30 mg/kg, subcutaneous injection), weighed, antiseptised. Then peritoneum was incised to explore the liver.

Measurement of portal vein pressure (PVP) After the portal vein was punctured, PVP was measured directly.

Estimation of liver function Blood samples from inferior vena cava were collected to measure serum albumin (ALB) and alanine transaminase (ALT) levels by biochemical autoanalyzers.

Tissue sampling Partial liver tissue samples were frozen in liquid nitrogen immediately, then stored at -80°C for use. The rest part was fixed in 100 g/L formaldehyde solution and stained with Masson trichrome stain for regular pathological examination.

GH binding capacity (R_T) analysis One hundred μL (approximately 20 000 cpm) of ^{125}I -hGH (NEN inc, USA) with a specific activity of about 108 $\mu\text{Ci}/\mu\text{g}$, 100 μL of unlabelled hGH with various concentrations (0-3 nmol/L was divided into 7-9 concentration gradients, standard samples were bought from Northern Biological Technical Company), and 100 μL of liver membrane microsomes (preparation with gradient centrifugation technique) were mixed and incubated at 4°C overnight. Dissociated ligands were eliminated by filtration.

The precipitates were subjected to a radioactive counter, and then ^{125}I -GH binding capacity (R_T , fmol/mg protein) and binding affinity contrast (kd, nmol/L) were calculated by Scatchard analysis.

Expression of GHR mRNA in liver tissue Self-designed primers were as follows: forward, 5'-ATGTGAGATCCAGACAACG-3', and reverse, 5'-ATGTCAGGGTCATAACAGC-3'. The amplification segment containing introns was supposed to be 499 bp in length. Total RNA of the rats' liver tissues was extracted with Trizol following the manufacturer's instructions. RT-PCR was performed with RT-PCR kits (Epicedure inc. USA) as previously described^[35]. After thirty amplification cycles were performed, the PCR products were detected by gel electrophoresis. The level of GHR mRNA was expressed as iOD (pixel, the integral optical density of amplification segment).

Level of malon-dialdehyde (MDA) and superoxide dismutase (SOD) Thiobarbituric acid reaction and pyrogalllic acid self oxidation method were adopted to measure the amount of MDA (the degradation products of peroxide lipid in liver) and the activity of SOD, respectively.

Measurement of relative content of collagen (RCC) in liver Liver fibrosis levels was expressed as RCC. After stained with Masson's trichrome stain, liver collagen content was calculated by histomorphometric measurement. Three random areas were chosen and analyzed by computers with Kontron IBAS2.5 system (Germany) for digital image analysis. The total area and the fibrotic area with positive staining were automatically selected, outlined and evaluated by planimetry. RCC was calculated as a percentage of positive staining area in the total area.

Statistical analysis

The data were processed with duplex factor χ^2 analysis by software statistica 5.0. Least significant difference (LSD) was adopted to compare the inter-group variance. Values were expressed as mean \pm SD. $P < 0.05$ was considered statistically significant.

RESULTS

GH-binding capacity (R_T) analysis

As shown in Table 1, R_T in group A was significantly higher than that in group C ($P < 0.05$). R_T in group B increased markedly compared with group A ($P < 0.05$). It significantly increased in group D compared with group C ($P < 0.05$), but was lower than that in group A. There was no significant difference in Kd.

GHR mRNA expression in liver tissue

As shown in Table 1 and Figure 1, the expression of GHR mRNA (iOD, pixel) in group A was significantly higher than that in group C ($P < 0.05$). It was significantly raised in groups B and D after rhGH treatment, which was 1.9 and 1.8 times higher than that in groups A and C, respectively ($P < 0.05$). It was higher in group D than in group A.

Serum ALB and ALT level

Without rhGH treatment, ALB level in cirrhotic rats (group C)

Table 1 Effects of rhGH treatment on various parameters (mean \pm SD)

Group	R_T (fmol/mg protein)	GHR mRNA (iOD)	ALB (g/L)	ALT (U/L)	MDA (nmol/mg protein)	SOD (U/mg)	RCC (%)	PVP (cmH ₂ O)
A	72 \pm 12	29 \pm 3	35 \pm 5	61 \pm 10	10.2 \pm 1.4	1078 \pm 185	1.14 \pm 0.21	5.6 \pm 0.7

D	40 \pm 7 ^{ac}	42 \pm 8 ^{ac}	37 \pm 7 ^c	69 \pm 7 ^{ac}	12.0 \pm 2.2 ^{ac}	1029 \pm 76 ^c	14.70 \pm 2.07 ^{ac}	9.3 \pm 1.5 ^{ac}

^a $P < 0.05$ vs control groups A and B, ^c $P < 0.05$ vs before rhGH treatment (group A or C).

was significantly lower than that in normal rats (group A), and ALT in cirrhotic rats was markedly higher than that in normal rats ($P < 0.05$) (Table 1). After rhGH administration, ALB in groups B and D increased significantly ($P < 0.05$), ALT in group D decreased remarkably ($P < 0.05$), which was close to normal rats (Table 1).

Figure 1 Expression of GHR mRNA in normal and cirrhotic liver tissues after NS or rhGH administration. Lane 1: control group +NS (group A); Lane 2: control group +rhGH (group B); Lane 3: cirrhotic group +NS (group C); Lane 4: cirrhotic group +rhGH (group D); and Lane M: DNA standard marker of 100, 200, 300, 400, 500, 600, 700, 800, 900, 1 000, 1 100 and 1 200 bp, respectively.

Changes of MDA and SOD in liver tissue

Before the treatment with rhGH, the amount of MDA in cirrhotic rats (group C) was significantly higher than that in normal rats (group A) ($P < 0.05$), and SOD in cirrhotic rats was significantly lower than that in normal rats ($P < 0.05$). After rhGH administration, MDA and SOD in group B were not obviously changed, but in group D, MDA was significantly lower than that in group C ($P < 0.05$), while SOD was significantly higher than that in group C ($P < 0.05$). The curve correlation analysis manifested a significant correlation between SOD and MDA ($P < 0.01$). (Table 1, Figure 2).

Figure 2 Correlation analysis of SOD and MDA.

RCC in liver tissue

As shown in Table 1, RCC in group C was significantly higher than that in group A ($P < 0.05$). Compared with group C, it was significantly lower in group D ($P < 0.05$).

Changes of PVP

As shown in Table 1, PVP in cirrhotic rats (group C) was significantly higher than that in normal rats (group A) ($P < 0.05$). After rhGH administration, no significant change was found in normal rats, however PVP in cirrhotic rats (group D) was significantly lower than that in group C ($P < 0.05$).

DISCUSSION

In cirrhotic patients, nutritional status was an important predictor

of morbidity, mortality, and survival after transplantation^[36]. The poor status of these patients was associated with the state of acquired GH resistance^[37,38], which is common in conditions associated with malnutrition and protein catabolism, trauma or surgery, organ failure and critical illness. Much has been done regarding the expression of GHR and signal transduction^[10-13], but the expression of GHR and GHR mRNA in some pathological states such as cirrhotic hepatocytes, malignant cells, remains to be established. Chang *et al.*^[39] reported that ¹²⁵I-rhGH binding activity in 6 cases of hepatocellular carcinoma and adjacent cirrhotic liver tissues could not be detected and they believed that GHR in cirrhotic hepatic tissues disappeared although the study only examined one aspect of the GHR and GH binding. Another study^[40] showed that specific binding of ¹²⁵I-hGH in liver tissues from liver transplant of 17 patients with end-stage liver diseases was lower than that in normal controls, but only in 3 cirrhotic livers Scatchard analysis was performed for calculation of GH binding capacity and affinity. In this setting of tissue-based GH binding assay, there was still a controversy about the expression of GHR on cirrhotic liver cells.

Our study showed that rhGH could significantly increase serum ALB and SOD levels, decrease ALT and MAD to nearly the normal level in liver cirrhotic rats. In addition, after rhGH treatment, both the liver fibrosis level and PVP were remarkably decreased.

In our study, the expression of GHR mRNA in cirrhotic liver tissue was lower than that in normal liver tissue, suggesting that liver cirrhosis could down-regulate GHR gene transcription and result in decrease of GHR, which might be an important reason of malnutrition in liver cirrhosis.

Simultaneously, we found that rhGH up-regulated GHR and its mRNA in both cirrhotic and normal liver tissues. In normal liver, the changes before and after rhGH treatment were not obvious. We hypothesized that the up-regulation of GHR and its mRNA in cirrhotic rats could improve liver function, and decrease liver fibrosis levels and PVP. This implied that the effects of rhGH on the expression of GHR and GHR mRNA in cirrhotic liver tissues might play an important role in ameliorating the sensibility of cirrhotic liver tissues to rhGH, thereby exerting a therapeutic effect on liver cirrhosis.

In conclusion, rhGH can up-regulate the expression of GHR and its mRNA in livers, particularly in cirrhotic livers, which can increase the sensibility of cirrhotic liver tissue to growth hormones. Thus, rhGH can protect liver function, repress fibrosis, alleviate portal hypertension of cirrhotic livers.

Abstract

AIM: To study the protective effects of tumor necrosis factor α (TNF α) antibody on pancreatic encephalopathy in rats.

METHODS: One hundred and twenty SD rats were randomly divided into normal control group, acute necrotizing pancreatitis group and TNF α antibody treated group. Acute hemorrhage necrotizing pancreatitis model in rats was induced by retrograde injection of 50 g/L sodium taurocholate into the pancreatobiliary duct. Serum TNF α was detected and animals were killed 12 h after drug administration. Changes in content of brain water, MDA and SOD as well as leucocyte adhesion of brain microvessels were measured.

RESULTS: In TNF α antibody treated group, serum TNF α level was decreased. Content of brain water, MDA and SOD as well as leucocyte adhesion were decreased significantly in comparison with those of acute necrotizing pancreatitis group ($P < 0.05$).

CONCLUSION: TNF α antibody can alleviate the brain damage of rats with acute hemorrhage necrotizing pancreatitis.

INTRODUCTION

Pancreatic encephalopathy, a syndrome of mental retardation induced by severe acute pancreatitis, has been greatly concerned by clinicians. Unfortunately, the pathogenesis and mechanism of pancreatic encephalopathy are still unclear although many factors are thought to be related to it, such as pancreatin, epiphyte infection, electrolyte disturbance, lack of vitamin, alcoholism, hypoxemia^[1-3]. Recent reports have shown that overactivation of leucocytes and overexpression of cytokines play important roles in the pathogenesis of pancreatic encephalopathy. Moreover, the high level of TNF α in patients has a remarkable correlation with pancreatic encephalopathy^[4-9]. In the present study, we attempted to block or relieve pancreatic encephalopathy by using TNF α antibody.

MATERIALS AND METHODS

Animals

One hundred and twenty male Spargue-Dawley (SD) rats

weighing 230 ± 20 g, were obtained from Animal Research Center of Shaanxi Academy of Traditional Medicine, and fed with standard rat chow.

Drugs

Sodium taurocholate (Sigma) was diluted to 50 g/L with saline prior to use. TNF α monoclonal antibody (Jingmei Co.Ltd., Guangdong, China) was diluted at 1:100 with saline prior to use.

Experimental grouping

One hundred and twenty SD rats were randomly divided into three groups: Group I: normal control group ($n = 40$), sham operation was performed and saline was retrograde injected into the pancreatobiliary duct of the rats; Group II: acute necrotizing pancreatitis group ($n = 40$), in which an acute hemorrhage necrotizing pancreatitis model was induced by retrograde injection of 50 g/L sodium taurocholate into the pancreatobiliary duct; Group III: TNF α antibody treated group ($n = 40$), in which 1 mL TNF α antibody (2.0 mg/kg) was injected into the rats through dorsum veins of penis 5 min prior to operation. Blood samples (2 mL) were taken from inferior vena cava of all animals in each group 12 h after operation. Then the rats were killed and samples were obtained for analysis.

Operation

The animals were fasted but free to drink water 12 h before operation. Then the rats were intraabdominally anesthetized by 100 g/L pentobarbital sodium (30 mg/kg), and incised through median incision of the abdomen. After the common bile duct was clamped in hepatoduodenal ligament by small artery clamps, a cannula was inserted into pancreatobiliary duct through mammary papilla from anterior wall of duodenum. Then sodium taurocholate (50 g/L) was injected by the cannula with even speed of 0.1 mL/min, the scatheless vascular clamp was removed 10 min later. Finally, the abdomen incisions were closed and the animals were given gentamicin to prevent infection^[10,11].

Evaluation of TNF α in serum

Evaluation of serum TNF α was performed by sandwich ELISA method with double antibodies. The kit was purchased from Endogen Company (USA) and the procedures were made according to the manufacturer's instructions.

Evaluation of water content in brain

Evaluations of water content in brain of 20 rats in each group were completed by the methods of dry and wet weight estimation. Water content in brain = (wet weight - dry weight) \div wet weight $\times 100\%$.

Evaluation of brain MDA and SOD content

Skulls of 20 rats in each group were opened to get frontal lobe of the brain. Then brain tissues were homogenized and centrifuged. MDA and SOD contents were gained by chemical colorimetry (kit purchased from Bioengineer Institute of Nanjing Jiancheng, China).

Congregation of leucocytes and mural counting in blood capillary

After stained by HE, the whole number of leucocytes in 20 sections

Table 1 Serum TNF α level, content of brain water, MDA and SOD as well as leucocyte mural counting in brain blood capillary in three groups

Group	Serum TNF α level (pg/mL)	Brain water content (%)	Brain MDA content (nmol/mL)	Brain SOD content (nmol/mL)	Mural leucocytes (per 20 capillary)
I ^a	25.17 \pm 2.26	77.09 \pm 0.51	5.32 \pm 1.40	13.40 \pm 2.77	6.12 \pm 1.60
II	264.58 \pm 4.39	83.17 \pm 1.42	17.26 \pm 3.18	35.52 \pm 3.10	62.15 \pm 5.18
III ^c	74.33 \pm 1.78	81.41 \pm 1.52	11.71 \pm 3.26	23.65 \pm 1.93	38.37 \pm 3.43

^a $P < 0.05$ vs II, ^c $P < 0.05$ vs II.

of brain tissues was counted under light microscope to obtain the mean number.

Statistical analysis

The data were expressed as mean \pm SD and analyzed by software of SPSS10.0. $P < 0.05$ was considered statistically significant.

RESULTS

Serum TNF α level

The level of TNF α in blood serum in acute necrotizing pancreatitis group (264.58 \pm 4.39 pg/mL) was increased markedly ($P < 0.05$) compared with that in the normal control group (25.17 \pm 2.26 pg/mL). But the level of TNF α in blood serum in the TNF α antibody treated group (74.33 \pm 1.78 pg/mL) was decreased markedly ($P < 0.05$) compared with that in acute necrotizing pancreatitis group.

Brain water content

Brain water content in the acute necrotizing pancreatitis group (83.17 \pm 1.42%) was significantly higher than that in the normal control group (77.09 \pm 0.51%). But it was significantly lower in the TNF α antibody treated group (81.41 \pm 1.52%) than in the acute necrotizing pancreatitis group ($P < 0.05$).

Brain MDA content

Brain MDA content of in the acute necrotizing pancreatitis group (17.26 \pm 3.18 nmol/mL) was increased remarkably ($P < 0.05$) compared with that in the normal control group (5.32 \pm 1.40 nmol/mL). It was decreased remarkably in the TNF α antibody treated group (11.71 \pm 3.26 nmol/mL) in comparison with acute necrotizing pancreatitis group ($P < 0.05$).

Brain SOD content

Brain SOD content in the acute necrotizing pancreatitis group (35.52 \pm 3.10 nmol/mL) was increased remarkably compared with that in the normal control group (13.40 \pm 2.77 nmol/mL). It was decreased remarkably in the TNF α antibody treated group (23.65 \pm 1.93 nmol/mL) in comparison with acute necrotizing pancreatitis group ($P < 0.05$).

Leucocyte mural counting of brain blood capillary

The number of leucocyte mural counts in blood capillary in every 20 blood capillaries in the TNF α antibody treated group (38.37 \pm 3.43) was significantly lower ($P < 0.05$) than that in the acute necrotizing pancreatitis group (62.15 \pm 5.18).

DISCUSSION

Cytokines, mainly excreted by immunocytes in human body, are soluble peptides, which play important roles in immune activation and inflammatory reactions. In normal conditions, the content of cytokines is very low. However, the expression of cytokines is increased remarkably following multiple stimulations, such as infection and trauma. It is well known that the overactivation of cytokines could induce or even aggravate

tissue damage^[12-16]. Acute severe pancreatitis could always lead to systemic inflammatory response syndrome (SIRS) and multiple organ dysfunction syndrome (MODS)^[17-24]. The present studies have focused on the pathogenesis and therapy of respiratory failure, kidney failure, hepatic failure and cardiovascular function failure complicated by acute severe pancreatitis. However, investigations on mechanism of brain damage and related preventive measures after acute severe pancreatitis remain ineffective.

TNF α is excreted by activated macrophages, endothelial cells and B lymphocytes with multiple functions. It can play important roles in inflammatory reactions. Animal experiments suggested that serum TNF α in patients with acute severe pancreatitis could induce pancreatic and other organs' damages. In the early period of acute severe pancreatitis, TNF α was involved in occurrence and progress of acute severe pancreatitis. On the other hand, TNF α was closely related with the severity and mortality of this disease^[25-31].

In acute severe pancreatitis, the mechanisms of TNF α - induced brain damage included^[32-40]: (1) TNF α could stimulate differentiation of phospholipase A2 or directly activate phospholipase, aggregate and activate leucocytes to release cellular media, thus reinforcing permeability of blood capillary including platelet active factor (PAF), leukotriene B4 (LTB4), nitrogen monoxide (NO), thromboxane A2 (TXA2), prostaglandin (PG) and oxygen-derived free radicals. The media in positive feedback could accelerate the yield of TNF α , and thereby form "waterfall" cascade reaction. (2) TNF α could directly increase the permeability of blood endothelial cells, and also act through leucocytes, up-regulate adhesive factors of endothelial cells, such as ELAM-1 and ICAM-1, thus facilitating adhesiveness and contraction of leucocytes to cause leakage of blood capillary and tissue damage. (3) TNF α could induce inflammatory injuries of myelin sheath by direct toxicity or activating immune cells.

In the present study, we attempted to relieve pancreatic encephalopathy by using TNF α antibody. The results showed that the level of serum TNF α , content of brain water, MDA and SOD as well as mural leucocyte count of the rats in TNF α antibody treated group, reduced significantly compared with those in acute necrotizing pancreatitis group. The present data suggest that TNF α antibody plays an important protective role in pancreatic encephalopathy in rats. But the optimal concentration of TNF α antibody and its influence on body immune system still need further investigation.

Abstract

AIM: To assess the effects of intramuscular analgesics (morphine, Ap-237, pethidine and tramadol) on human Oddi's sphincter motility with choledochoscope manometry.

METHODS: A total of 70 patients having T tubes after cholecystectomy and choledochotomy were assessed by choledochoscope manometry. They were randomly divided into morphine group, Ap-237 group, pethidine group and tramadol group. Basal pressure of Oddi's sphincter (BPOS), amplitude of phasic contractions (SOCA), frequency of phasic contractions (SOF), duration of phasic contractions (SOD), duodenal pressure (DP) and common bile duct pressure (CBDP) were scored and analyzed. All narcotic analgesic drugs were administered intramuscularly.

RESULTS: Levels of BPOS, SOCA and SOF were increased after injection of morphine and Ap-237 ($P < 0.05$), level of CBDP was increased from 4.97 ± 3.87 mmHg to 8.62 ± 7.43 mmHg (10 min later) and 7.32 ± 5.95 mmHg (20 min later) after injection of morphine ($P < 0.01$). No apparent change occurred after intramuscular injection of pethidine. Level of BPOS was increased from 7.01 ± 5.50 mmHg to 2.87 ± 2.78 mmHg 10 min after injection of tramadol and SOCA was decreased from 63.34 ± 35.29 mmHg to 45.90 ± 27.86 mmHg (10 min later, $P < 0.05$) and 35.97 ± 24.30 (20 min later, $P < 0.01$) after administration of tramadol.

CONCLUSION: All these findings indicate that Oddi's sphincter manometry via choledochoscope is a practical and new way to study the dynamics of Oddi's sphincter. The regular dose of morphine and Ap-237 could increase BPOS, SOF and SOCA. Morphine could increase the level of CBDP, demonstrating an excitatory effect on the sphincter of Oddi. Pethidine had no effect on Oddi's sphincter motility. Tramadol shows an inhibitory effect on the motility of the sphincter of Oddi and decreases levels of BPOS and SOCA.

INTRODUCTION

Morphine can cause excitatory effect on Oddi's sphincter motility and therefore induces upper abdominal pain with

characteristics of biliary colic in some patients. Morphine could increase intrabiliary duct pressure^[1-3], and delay bile flow to the duodenum^[4], for this reason, other opioid analgesics rather than morphine are recommended clinically to relieve the pain, especially biliary pain. It is believed that pethidine has less effect on the sphincter than morphine and therefore is usually the drug of choice for pain relief in acute pancreatitis. Pethidine is also commonly used during endoscopic retrograde cholangiopancreatography (ERCP). Because of potential interference, all narcotic analgesic drugs, including pethidine, are proscribed during Oddi's sphincter manometry (OSM). However, the performance of OSM with only diazepam sedation was difficult as pethidine markedly improves ERCP tolerance.

The aim of this study was to evaluate the effects of four analgesic drugs on human Oddi's sphincter motility by choledochoscope manometry, and to understand the different clinical responses to analgesics.

MATERIALS AND METHODS

Patients

OSM was performed for 70 patients (25 men, 45 women, and mean age 55.5 years, range 35-77 years) with PENTAX choledochoscope at the Second Affiliated Hospital of China Medical University between November 2001 and December 2003. All patients underwent cholecystectomy and choledochotomy, at least 1.5 mo (mean 2.5 mo) after T tube drainage. The patients were fasted overnight before manometry.

Methods

A triple lumen polyethylene manometry catheter 200 cm in length with an outer diameter of 1.7 mm was used for manometry. The three side holes in the distal end were located 2 mm apart. Sterile water was infused through the catheter at a flow rate of 0.5 mL/min by a hydraulic capillary infusion system. PC polygraph HR (Swedish CTD-Synetics medical company) and relevant program were used to record and analyze the tracings. Manometry was performed after all the stones were removed from the common bile duct. The catheter was introduced via the side-pore of choledochoscope into duodenum directly, when the pressure was stable, duodenal pressure-curve was recorded. It was then withdrawn in a stepwise fashion, the position of catheter in the sphincter could be confirmed by direct observation through choledochoscope or by the characteristic pressure changes on the screen. The Oddi's sphincter and common bile duct motility tracings were recorded respectively. Drugs were administered intramuscularly at 10 min intervals.

Patients were randomly administered one of the four different drugs. Morphine was administered in a dose of 0.1 mg/kg after the first measurement, the second and third manometries were performed respectively 10 min and 20 min later. Each of the other three analgesics was administered in a dose of 1 mg/kg. The procedures were same as in morphine group.

Basal pressure of Oddi's sphincter (BPOS), amplitude of phasic contractions (SOCA), frequency of phasic contractions (SOF), duration of phasic contractions (SOD), duodenal pressure (DP) and common bile duct pressure (CBDP) were recorded and analyzed with a special computer program. Statistical analysis was carried out using the Student's *t*-test.

Data were expressed as mean±SD. A single-tailed *P* value <0.05 was considered statistically significant.

RESULTS

Seventy patients with T-tubes had no evidence of ampullary abnormality underwent OSM. Clear tracings of pressure and phasic contractions were acquired. Data were compared.

Effect of morphine on Oddi's sphincter motility

Morphine at the dose of 0.1 mg/kg produced an immediate and marked stimulatory effect on the sphincter of Oddi and bile duct, which was obvious 10 min after injection. Levels of BPOS, SOCA, SOF and CBDP were all significantly increased (*P*<0.01) and the effect persisted for 20 min (Table 1). Ten patients (25%) had an increased BPOS between 30-40 mmHg, four patients had an increased BPOS over 40 mmHg after drug administration.

Effect of pethidine on Oddi's sphincter motility

No statistical difference before and after administration of pethidine (1 mg/kg). Pethidine showed no apparent effect on

Oddi's sphincter motility (Table 2).

Effect of Ap-237 on Oddi's sphincter motility

Marked increased levels of BPOS, SOCA and SOF were observed 10 min after injection of Ap-237, and high levels of BPOS and SOF persisted for 20 min, which showed an excitatory effect on Oddi's sphincter motility (Table 3).

Effect of tramadol on Oddi's sphincter motility

Levels of BPOS and SOCA were obviously reduced 10 min after administration of tramadol, which maintained at low levels for 20 min and showed an inhibitory effect of tramadol on Oddi's sphincter motility. (Table 4)

DISCUSSION

The most important development in our understanding of Oddi's sphincter motility came with the advent of Oddi's sphincter manometry (OSM) in the mid-1970s. Then, it was considered as the gold standard method for evaluating the function of Oddi's sphincter. OSM could be directly performed during surgery, or

indirectly during ERCP, via a T-tube or percutaneously. A basal pressure and phasic contractions of Oddi's sphincter could be obtained with OSM.

OSM during ERCP is a useful tool in the evaluation of patients with unexplained pancreaticobiliary pain or recurrent idiopathic pancreatitis^[5-7]. However, it might provoke serious pancreatitis^[8,9]. It is a technical procedure, because it requires selective deep bile duct and/or pancreatic duct cannulation during active duodenal peristalsis and in suboptimally anesthetized patients. These features account for the relatively high failure rate (up to 20%) even in expert hands^[10].

OSM via choledochoscopic approach allows easy and accurate recording of Oddi's sphincter pressure and makes a long time maneuver of manometry possible. The position of manometric catheter in the sphincter can be monitored on the screen with the characteristic phasic contractions. It also could be confirmed by direct observation through choledochofiberoscopy. And it is easy to get enough patients for manometry. However, it is difficult to get a relative normal value of the sphincter of Oddi via choledochoscope manometry, for patients with a T-tube tract often suffer from hepatobiliary or pancreatic diseases. Furthermore, whether irrigation of natural cold saline and the semi-closed state of bile duct during choledochoscopic procedure affect the motility of the sphincter of Oddi is unknown.

Morphine and pethidine are the two most commonly used analgesic drugs. Their effects on the sphincter of Oddi have well been researched. Helm *et al.*^[11] studied the effect of morphine on SO using OSM during ERCP. In a small cumulative dose of 2.5-5 µg/kg, morphine increased the frequency of phasic contractions to a maximum of 10-12/min, but it did not affect the mean amplitude of phasic contractions and the mean SO basal pressure. As the cumulative dose was increased from 10 to 20 µg/kg, no further increase in the frequency of phasic pressure waves was seen. Instead, the phasic wave amplitude and the mean SO basal pressure increased. Blaut *et al.*^[12] found that morphine increased the intraductal biliary pressure (IDP) with OSM via a T-tube, but the high intraductal biliary pressure caused by morphine could be counteracted by transcutaneous electrical nerve stimulation (TENS). Elta *et al.*^[13] performed ERCP manometry to evaluate the effect of pethidine at therapeutic doses on SO manometry, and found that after administration of pethidine the frequency of phasic contractions increased, but the mean SO basal pressure did not change. Using the same method, Sherman *et al.*^[14] found that biliary sphincter basal pressure and phasic wave amplitude were not significantly altered by pethidine, but phasic frequency increased and phasic duration decreased slightly after administration of pethidine, sphincter basal pressure of the pancreatic and the common channel's sphincters was not significantly altered, but their phasic wave amplitude decreased, phasic frequency increased, and phasic duration decreased.

The only study directly comparing morphine to pethidine with OSM was done in 1990 by Thune *et al.*^[15] They compared the effect of morphine and pethidine on patients intraoperatively after surgical placement of a catheter across the SO. Morphine was associated with an increase in phasic wave frequency, but no change was found in basal sphincter pressure, amplitude, or wave propagation direction. Pethidine showed a dose-dependent decrease in phasic wave frequency but without significant changes in the basal sphincter pressure, contraction amplitude or wave propagation direction.

We found that morphine could increase the basal pressure of Oddi's sphincter, common bile duct pressure, frequency and amplitude of phasic contractions. Morphine showed an excitatory effect on the sphincter of Oddi, and might be a cause of Oddi's sphincter dysfunction(SOD). SO may function as a peristaltic pump to actively expel fluid from the sphincter segment into the duodenum. The SO segment fills with fluid from the

common bile duct (CBD) only during the diastolic interval between phasic contractions. Outflow of fluid from the CBD is reduced or arrested when (1) the frequency of phasic contractions increases sufficiently to compromise diastolic filling of the sphincter segment, (2) phasic contractions propagate retrograde or occur simultaneously along the sphincter segment, or (3) passive filling of the sphincter segment is prevented by a BPOS that exceeds the CBDP. Morphine could cause functional obstruction of the SO by all three of these mechanisms^[11]. OSM shows a diagnostic value for Oddi's sphincter dysfunction. Elevated basal pressure (>40 mmHg) was the most important manometric finding in Oddi's sphincter dysfunction and its borderline was about 30-40 mmHg. Our study found that 10 patients (25%) had an increased BPOS between 30-40 mmHg, four patients had an increased BPOS over 40 mmHg. So morphine can cause spasm of SO and should not be used during ERCP manometry or choledochoscope examination. After administration of pethidine, no patients had an elevated BPOS up to 30 mmHg. Pethidine could be used for an additional analgesia during OSM. This may improve both patient's tolerance and the success rate of the procedure. But we should be cautious in patients with renal failure, hepatic failure or central nervous system diseases. For the pethidine metabolite, normeperidine, might invoke seizures at high doses or in patients with renal failure. Hubbard^[16] reports that pethidine invoked seizures in a patient with Oddi's sphincter dysfunction.

Tramadol has the same analgesic effect as morphine. But it has little effect on the respiratory system and circulation system, and can be used in old patients with respiratory system diseases. There were only a few researches about its effect on the sphincter of Oddi. Staritz *et al.*^[17] and Brandstatter *et al.*^[18] performed ERCP manometry to evaluate the effect of tramadol on SO manometry, and found that it had no apparent effect on Oddi's sphincter motility. Our study indicated that tramadol could decrease BPOS and the amplitude of phasic contractions, showing an inhibitory effect on the sphincter of Oddi, and tramadol could be used during ERCP manometry and choledochoscope examination.

As a fast acting analgesic, Ap-237 has little effect on visceral pain. A MEDLINE search found no report about its effect on the sphincter of Oddi. We found that Ap-237 could increase BPOS, amplitude and frequency of phasic contractions, showing an excitatory effect on the sphincter of Oddi, and Ap-237 should not be used in patients with hepatobiliary and pancreatic diseases.

Abstract

AIM: To discuss the angiographic features of gastrointestinal stromal tumor (GIST) and to evaluate their diagnostic role.

METHODS: Twelve patients with pathologically proved GIST underwent angiography (DSA) 1 wk before operation, using Puck and digital subtraction DSA. The origin, size, morphology and angiographic appearance of the lesions were reviewed.

RESULTS: Two tumors arose from stomach, 8 from jejunum, and 2 from ileum. Seven cases were benign and 5 were malignant. Obviously thickened supplying arteries were detected in 8 tumors, and early-developed veins were found in 3. Two types of angiographic changes of GIST were observed. Four cases had twisted irregular neoplastic vessels with partially coarse and indistinct margins, which were all malignant. Eight cases had ball-like neoplastic vessels with uniform tumor staining, of which 7 were benign and 1 was malignant.

CONCLUSION: Angiography facilitates localization and diagnosis of GIST, helps define their size, range and location, and is especially valuable to patients suffering from melena with unknown reasons.

INTRODUCTION

Gastrointestinal stromal tumor and its imaging features have been reported^[1-3]. However, to our knowledge, the appearance of GIST at angiography has been seldom discussed. We analyzed retrospectively the angiographic appearance of 12 cases of GIST, which was proved by surgical pathology (immunohistochemistry), and the diagnostic value of angiography was discussed.

MATERIALS AND METHODS

Subjects

Twelve patients (4 women and 8 men, aged 40-70 years with a mean age of 53.3 years) with pathologically proved GIST (immunohistochemistry) who underwent angiography 1 wk before surgery were included. All the patients suffered from

recurrent melena for 3 mo to 3 years, with syncope in 2 cases, a palpable abdominal mass in 1 case, and concomitant abdominal pain in another case.

After routine preparations, Seldinger's puncture of femoral artery and super selective catheterization, angiographies of superior mesenteric artery, inferior mesenteric artery and coeliac trunk were performed sequentially using 6-7 F catheters. Omnipaque (iodine content: 350 mg/mL) as contrast medium was administered with a dose of 30 mL and at a rate of 8 mL/s for superior mesenteric artery, 20 mL/s and 6 mL/s for inferior mesenteric artery, and 40 mL/s and 8 mL/s for coeliac trunk. Puck changer was used in all angiographies (with the sequence 2 films/s×3 s, 1 film/s×4 s, 1 film/2 s×4 s), and DSA was selected necessarily (with acquisition sequence 3.1 films/s×5 s, 1.6 films/s×5 s, 1 film/s×2 s). The dose and rate of contrast medium were same in two methods. The apparatus was GE medical systems, Hiline.

RESULTS

Size origin and morphology of the tumors

Two tumors arose from stomach, 8 from jejunum (Figures 1,2), and 2 from ileum. Most of them were originated from the jejunum with a percentage of 66.7% (8/12). The lesions had different sizes, ranged from 3 cm×3 cm×2 cm to 5 cm×6 cm×4 cm (mean 4 cm×4.5 cm×3 cm) in 7 benign lesions, of which 5 lesions were malignant (Figure 3). The smallest was 5.5 cm×4.5 cm×3 cm and the largest was 6.5 cm×10 cm×7 cm. All tumors were round or oval in shape, except an irregular malignant tumor and another dumbbell-shaped benign tumor growing endophytically and exophytically from the intestinal lumen at the same time.

Angiographic appearance

Thickened supplying arteries were observed in 8 tumors (Figure 1), of which 6 were benign and 2 were malignant. Early-developed veins were found in 3 cases (Figure 1), all of which were benign. Four cases having irregular twisted neoplastic vessels with different vessel size and partially coarse and obscure vessel margin were all malignant (Figure 3). Eight cases have ball-like neoplastic vessels with clear margins, included 7 benign and 1 malignant cases. However, the 7 benign cases all had predominantly homogeneous tumor staining with distinct margins (Figures 1, 2).

Boundary of tumors and relationship to surrounding structures

Four malignant tumors had an indistinct border, and the others had a clear margin. The surrounding organs were pushed by the tumors. Intestinal intussusception was found in 1 patient with recurrent abdominal pain.

Pathology

The neoplastic cells were fusiform or polygon in shape, and arranged in interlacing or swirl or fence-like. LSAB label was used in immunohistochemistry. Leiomyomas or leiomyosarcomas of other organs (uterus and soft tissue) and schwannomas of soft tissue were chosen for comparisons. High positive presentation of Vim, CD₁₁₇ and CD₃₄ was found in 12 cases of GIST. Negative presentation of CD₃₄ was found in leiomyomas or leiomyosarcomas, and positive S-100 and negative CD₃₄ were found in schwannomas.

Figure 1 Benign stromal tumor in a 54-year-old male.

Figure 2 Benign stromal tumor and marked homogeneous tumor-staining in a 41-year-old male. A: Benign stromal tumor; B: Marked homogeneous tumor staining.

Figure 3 Malignant stromal tumor and heterogeneous tumor staining in a 35-year-old female. A: Malignant stromal tumor; B: Heterogeneous tumor staining with irregular morphology.

Others

Five malignant tumors contained necrotic or cystic changes with different degrees and two possessed central hemorrhage. Six patients in this study underwent CT at the same time. Masses were revealed by CT in 4 cases, only intestinal intussusception was seen in 1 patient, and diagnosis could not be established with confidence in the other case because of the relatively small size. Of the 3 patients who underwent barium examinations, one was normal, one had an intestinal filling defect and another had his intestines pushed away. No metastasis was found before surgery and no lymphadenopathy was demonstrated during operation.

DISCUSSION

GIST included the majority of primary non-epithelial tumors of gastrointestinal (GI) tract. These tumors were originated from

cells located in the wall of the organ and showed a remarkable variability in their differentiation pathways. They can be divided into 4 major categories on the basis of their phenotypical features: tumors showing differentiation toward smooth muscle, tumors showing apparent differentiation toward neural elements, tumors showing dual differentiation toward smooth muscle and neural elements, tumors lacking differentiation toward either cell type even after exhaustive immunohistochemical and ultrastructural probing^[4,5]. However, with the development in immunohistochemistry and ultrastructural probing, it has been agreed generally that GIST is an independent kind of tumors originated from primitive mesenchymal cells of GI tract with non-directive differentiation, some of which have incomplete differentiation parts of smooth muscles and/or nerve sheath cells^[1,6-8]. Micro superstructures of these tumors are similar to those of primitive mesenchymal cells without any characteristics of differentiated cellularity. Vim, CD₁₁₇ and CD₃₄ are highly presented in immunohistochemistry. The standards were all compliant in this study.

GIST could be localized in any portion of the GI tract, but was most often found in the gastric part^[9,10]. The jejunum as the most frequent place (66.7%) in this group did not reflect the fact, because it is not necessary for gastric lesion to do angiography when endoscopy, endoluminal ultrasonography or barium study was available and effective.

CT and MR imaging features have been reported previously^[11-13,10]. To our knowledge, however, few articles included a description of the appearance of GIST on angiography. According to our study, two types of angiographic changes could be concluded. First, abnormally distributed twisted neoplastic vessels with different thickness and obscure margin were one of the malignant features, and heterogeneous tumor blush with ill-defined border in capillary phase was another. Second ball like vessels with a clear margin, well defined homogeneous tumor staining in round or oval shape, and early-developed veins, suggested a benign GIST. The differentiation points have been described in many previous documents already, including that the malignant tumor was characterized by a larger size more than 5 cm, necrosis, hemorrhage, an indistinct border, and adherence to or direct invasion of the structures nearby^[5,11]. The tumors in our group with first type of manifestations were all malignant, but they were found in a relatively small number of patients.

There are many diagnostic approaches for GIST, including barium meal, double-contrast barium study, ultrasonography, fibro-endoscopy, endoluminal ultrasonography, CT, MR imaging and angiography. The sensitivity of these procedures varied according to the different sites of lesions. CT has been considered as the most effective method^[1,9]. Therefore, angiography is used less and less in diagnosing tumors of GI, as a result, angiography is only recommended for patients with melena when no abdominal mass is palpable and the examination of upper GI is negative. It helps indicate the supplying arteries, differentiate benign from malignant tumors, and define their size, range and origin, despite the tumors grow exophytically or endophytically. On the other hand, we do not suggest routine use of this procedure because of its traumatic property, high risk and relative complicated technique.

Abstract

AIM: To investigate the growth hormone (GH) and growth hormone receptor (GHR) expression of and its clinical significance in patients with chronic atrophic gastritis (CAG).

METHODS: A total of 90 cases were enrolled in the study. Thirty were healthy controls, the other 60 patients were divided into two groups according to the endoscopic and histological diagnosis. Blood samples were drawn in the morning (menarche did not occur during the blood extraction in female patients), gastric mucosa was obtained by endoscopy. Serum GH and gastric mucosal GHR levels were measured using radioimmunoassay (RIA) and En Vision technique.

RESULTS: The average GH level was $1.021 \pm 0.132 \mu\text{g/L}$ in CAG patients, in controls it was $2.869 \pm 0.512 \mu\text{g/L}$. There was a significant difference between these two groups ($P < 0.01$). The positive rate of GHR in CAG patients was 10%, in controls the rate was 100%. There was a significant difference ($P < 0.01$). There was no significant change of GH level ($3.176 \pm 0.421 \mu\text{g/L}$) in patients with gastric carcinoma compared with controls ($P > 0.05$).

CONCLUSION: The study shows that levels of GH and GHR expression are low in CAG patients. CAG pathogenesis has a correlation with mucosal nutrient deficiency, decreased levels of GH and GHR have an adverse effect on the repair and regeneration of CAG. There is no significant change of GH in gastric carcinoma patients, GH does not play a role in the pathogenesis of gastric cancer.

INTRODUCTION

Growth factor family is a group of protein hormones discovered during the 20th century. This family includes growth hormone (GH), insulin-like growth factor (IGF), epidermal growth factor (EGF), transfer growth factor (TGF), and vascular endothelial growth factor (VEGF), etc. These factors can stimulate cell DNA, RNA and protein synthesis, control cell growth and differentiation,

and promote regeneration of injured epithelia^[1-7]. Studies in recent years have shown that there is an intimate relationship between growth factor and gastric mucosal disease^[6]. Growth hormone (GH) is a type of mono-peptide strain hormone released from anterior pituitary eosinophilic cells. In the gastrointestinal (GI) tract, GH is known to promote water and electrolyte transport and calcium absorption. The proliferative functions of GH have been reported as well. Administration of GH restores the intestinal and gastric mucosal weight after hypophysectomy in rats, it is regarded as an important nutrient factor^[8].

Chronic atrophic gastritis (CAG) is a gastric precancerous lesion and has a high morbidity in China^[9]. Gastric mucosal malnutrition is considered as an important factor in the pathogenesis of CAG^[10-13].

Since CAG was recognized as a precancerous condition of the stomach by the World Health Organization in the early 1980 s, a number of methods have been tested for their ability to reverse and prevent the development of cancer. Most gastric mucosa protectors promote the growth and repair of gastric mucosa by promoting the aggregation and secretion of growth factors such as EGF, TGF. In a previous animal study, GH/GHR expression was measured on atrophic gastritis rats. The levels of GH and GHR expression in rats with CAG were low^[14]. However, the effect and safety of GH in clinical use are uncertain in CAG. The purpose of the present study was to investigate the expression of GH/GHR in patients with CAG and gastric cancers.

MATERIALS AND METHODS

Research subjects

Ethical approval for this study was given by the Sir Run Run Shaw Hospital in May 1999. Clinical data were obtained by review of case records for all patients. Patients were selected at random from adult out-patients attending the gastroenterology clinics. Diagnosis was made on the basis of clinical, endoscopic and histological data according to standard criteria. We excluded the patients who had abnormal findings in other vital organs (such as the heart, liver, lung, pancreas and pituitary). Patients were divided in two groups. Thirty patients in group B were diagnosed as moderate-severe gastritis and 30 patients in group C were diagnosed as gastric cancer, 30 unrelated individuals served as controls. Characteristics of the research subjects are shown in Table 1.

Sample collection and processing

After an overnight fast, 3 mL of blood was taken from cubital vein. Blood samples were set for two hours, then centrifuged at 3 500 rpm for 15 min. Supernatant was saved and stored at -20 °C. Two samples were taken from gastric antrum tissue and two from gastric body tissue, or four from the primary focus, and immediately immersed in 10% buffered formalin and embedded in paraffin wax using standard techniques. Five μm thick sections were cut and stained with hematoxylin and eosin for histopathological analysis. Each slide was assessed.

Analytical methods

The level of serum GH was measured by radioimmunoassay

(RIA) (Reagents were from DPC Company in Tianjing). The detection of gastric mucosal GHR expression was carried out by immunohistochemistry and En Vision assay (reagents from Biogenesis Company).

Table 1 Base-line characteristics of the patients

Characteristic	Group A (n = 30)	Group B (n = 30)	Group C (n = 30)
Age (yr)	48±7	50±6	52±9
Male	19	17	20
Female	11	13	10
Endoscopical finding	normal gastric mucosa	chronic atrophic gastritis(CAG)	gastric cancer
Pathologic finding	mild superficial gastritis(non-active)	moderate-severe CAG with or without intestinal malplasia	gastric cancer

Statistical analysis

Concentrations of serum GH were expressed as mean±SD. Differences between the two groups were evaluated by *t*-test. Significance was shown as $P<0.05$. The expression of GHR was expressed as positive rate. Differences between groups were evaluated by χ^2 test. Significance was shown as $P<0.05$. All experimental data were analyzed with Spss-pc+ software.

RESULTS

The average level of serum GH was lower in group B than in groups A and C. There were significant differences between them, but there was no significant difference between groups A and C.

Table 2 Serum GH Level (ng/mL) in the studied groups (mean±SD)

Group	A group (n = 30)	B group (n = 30)	C group (n = 30)
GH level	2.869±0.512 ^{1,2}	1.021±0.132 ¹	3.176±0.421 ²

¹t_{AB} = 3.135 $P<0.01$ ¹t_{BC} = 3.537 $P<0.01$ ²t_{AC} = 1.893 $P>0.05$.

Table 3 Positive rate of gastric mucosal GHR expression in the studied groups (%)

Group	A group (n = 30)	B group (n = 30)	C group (n = 30)
GHR expression	100 (30/30) ¹	10 (3/30) ²	13 (4/30) ^{1,2}

¹ $\chi^2_{AB}=49$ $P<0.01$ ¹ $\chi^2_{AC}=45$ $P<0.01$ ² $\chi^2_{BC}=0.16$ $P>0.05$.

The positive rate of gastric mucosal GHR expression in groups B and C was lower than that in group A. There were significant differences between them, but there was no difference between groups B and C.

DISCUSSION

Growth hormone (GH) is a type of monoamine strain hormones released from anterior pituitary eosinophilic cells. Growth hormone receptor (GHR) is widely distributed in the gastrointestinal tracts. GH takes its effect on target tissues by combining with GHR. In the stomach, GHR is mainly distributed among parietal and chief cells. In 1995, Nagano *et al.* by using reverse transcription PCR technology and Southern blot analysis, found the wide distribution of GHR in the gastrointestinal tract especially in epidermal cells, suggesting that GH and GHR could play an

important role in the regulation of metabolism, growth, and differentiation of gastric mucosal cells. GH and GHR could improve protein synthesis, promote wound healing, stimulate gastrointestinal tract proliferation and repair, regulate immunological responses, and improve absorption of nutrients^[8]. Presently, clinical applications of recombinant human growth hormone (rhGH) in various gastrointestinal ailments such as malabsorption and short bowel syndrome were reported^[15-19].

Chronic atrophic gastritis (CAG) is a gastric precancerous lesion and listed as the first of cancer prevention by WHO. CAG pathogenesis has a correlation with mucosal nutrient deficiency. CAG patients had a decreased serum level of trace elements and beta-carotene with malnutrition^[20-21].

During the last several years, we have focused on exploring the correlation between CAG and GH. In a previous animal study, we measured the GH/GHR expression in atrophic gastritis rats, and found the levels of GH and GHR expression in rats with CAG were rather low. After removing the pituitary glands from rats, Crean GP discovered that there were gastric mucosal atrophy, shrinkage and decreased expression of parietal and chief cells. Increased secretion of gastric acid and pepsin, and exogenous GH have been shown to promote protein synthesis and increase gastrointestinal absorption of nutrients. We have considered using GH to treat CAG^[14].

Our present study showed the same results as before^[14]. The levels of GH/GHR expression in patients with CAG were significantly lower than normal. GH and GHR could regulate the metabolism, growth and differentiation of gastrointestinal epidermal cells, therefore, a decreased GH/GHR level would hinder the repair and recovery of CAG. Decreased levels of GH and GHR had an adverse effect on the progression of CAG. This study suggests that when CAG is treated, GH or GH-like drugs may be considered in the treatment regimen to promote mucosal repair and stop the progression of CAG.

Exogenous GH has been shown to significantly increase the expression of c-myc oncogene^[22]. Watanabe *et al.*^[23] showed that by using N-methyl-N-nitrosourea solution to induce gastric cancer in F344 rats, GH levels were elevated, suggesting that high concentrations of GH play a role in the pathogenesis of gastric cancer. Studies have shown that acromegalic patients, had an increased risk of developing gastrointestinal tumor and carcinoma^[24-28]. Therefore, cautions should be taken to monitor the possibilities of gastrointestinal cancers. Whether clinical usage of growth hormone and medicine which stimulates the release of growth hormone causes the carcinogenesis of atrophic gastritis is concerned. Our study showed that the serum GH level in gastric cancer patients and normal individuals was similar, the positivity rate of GHR expression was not high, suggesting that GH dose not play a role in the development of gastric cancer. Lobie *et al.*^[29] investigated the effect of GH on gastric structure and function in GH-deficient Lewis (dwarf) rats, Bovine GH (65 micrograms/100 g body wt), was administered twice daily to adult male dwarf rats for 6 d (DW+) while control animals received vehicle only (DW-). Administration of GH produced a significant increase in body ,stomach wt and stomach to body wt ratio. GH administration also resulted in an increase of total gastric DNA, RNA, and protein. The density of differentiated (parietal and chief) cell types was not significantly different in DW- and DW+ animals. They demonstrated that GH could stimulate proliferation and enlargement of the gastric mucosae without significant alterations in cellular composition. So we recommend using GH as a treatment agent for CAG, but a definite conclusion needs further clinical observations.

Received: 2003-09-18 **Accepted:** 2003-10-27

Abstract

AIM: To evaluate the therapeutic effectiveness of oxaliplatin on human gastric carcinoma and to explore its mechanisms.

METHODS: Twenty-two cases of stage IV gastric carcinoma received 4-6 (mean 4.6) cycles of first line combined chemotherapy with oxaliplatin (oxaliplatin 85 mg/m², iv, gtt, 1 h, d 1; leukovorin 200 mg/m², iv, gtt, 1 h, d 1 and d 2; 5-FU 300 mg/m², iv, d 1 and d 2, 5-FU, continuous iv, gtt, 48 h; 1 cycle/2 wk). Response rate, progression-free survival (PFS), total survival time, toxic side effects were evaluated. The inhibitory effect of oxaliplatin on human gastric cell line SGC-7901 was detected and IC₅₀ was calculated by MTT. Transmission electron microscopy, flow cytometry and TUNEL were performed to evaluate the apoptosis of cell line induced by the drug. The expression of Caspase-3 m-RNA was detected by RT-PCR. AC-DEVD-CHO, a Caspase-3 specific inhibitor, was used to elucidate the role of activated Caspase-3 in the process of apoptosis induced by oxaliplatin.

RESULTS: Total response (complete and partial) occurred in 9 (40.9%) patients. Mean PFS was 4.2 mo and mean total survival time was 7.2 mo. Cumulative neurotoxicity (all grade I-II), vomiting and diarrhea, myelosuppression appeared in 93.5%, 20%, 32.9% patients, respectively. IC₅₀ was calculated to be 0.71 mg/L by MTT assay. A maximal inhibitory rate reached 85.3%. Apoptosis index was elevated after incubated with 1 mmol/L oxaliplatin for 30 min, but without statistic significance ($P>0.05$). However it could be detected at a much higher degree both by flowcytometry and by TUNEL with a statistical significance ($68.47\pm7.92\%$ and $8.23\pm2.67\%$, respectively, $P<0.05$) after incubated with 1 mmol/L oxaliplatin for 2 d. By means of RT-PCR, we detected an enhancement of Caspase-3 m-RNA expression induced by oxaliplatin which was also in positive correlation with the apoptotic level. AC-DEVD-CHO, a Caspase-3 specific inhibitor, could significantly inhibit and delay apoptosis induced by oxaliplatin.

CONCLUSION: Oxaliplatin is effective and well-tolerated in patients with advanced gastric carcinoma. Oxaliplatin could significantly inhibit the growth of human gastric cell line SGC-7901. The induction of Caspase-3 m-RNA expression, activation of Caspase-3 and promotion of apoptosis may be some of the therapeutic mechanisms of oxaliplatin on gastric carcinoma. Annexin-V-fluorescein labeling flow cytometry is much more sensitive than TUNEL in detecting

early stage apoptosis.

INTRODUCTION

Gastric cancer is one of the common carcinomas in human being. Drug treatment draws more and more attention as an essential part of comprehensive treatment of gastric malignancy. Gastric carcinoma is relatively sensitive to chemotherapy. It is generally considered that chemotherapy may prolong patient's life and decrease relapse. Oxaliplatin (L-OHP) is an innovative third generation platinum compound with powerful anti-neoplasm competence, lack of cross drug resistance with CDDP, with a synergistic effect with 5-FU and satisfactory safety profile. This new anticancer drug provides us more choices in fighting against malignancy, especially colon cancer. At present, treating gastric cancer with oxaliplatin and the relationship between chemotherapy and cancer cell apoptosis draw more and more attention. The discovery of Caspase family (cysteine proteases) that is implicated in the execution of programmed cell death in organisms ranging from nematodes to humans, brings the fresh air to the research of malignant cell apoptosis. The Caspase family is big and family members interact with each other to promote or inhibit the process of apoptosis. Caspase-3 locates in the downstream of the Caspase cascade. The proteolytic activation of Caspase-3 plays a key role in apoptotic process. This article summarizes the effect and side effects of chemotherapy with oxaliplatin on 22 cases of stage IV human gastric cancer, and tries to elucidate the mechanisms of chemotherapy by detecting apoptosis of cancer cells and evaluating the role Caspase-3 plays in apoptotic process.

MATERIALS AND METHODS

Patients

A total of 22 cases of stage IV human gastric cancer patients who underwent chemotherapy in the Affiliated Xinhua Hospital of Shanghai Second Medical University from January 1999 to September 2002 were enrolled in this study. There were 17 men and 5 women, and their age ranged from 25 to 70 years (mean, 60 ± 10 years). Among the 22 patients, 16 had poorly differentiated adenocarcinoma and 6 had signet ring cell carcinoma.

Methods

Each case received a combination chemotherapy containing L-OHP (L-OHP 85 mg/m² by continuous intravenous infusion for 2 h on d 1, leukovorin 200 mg/m² by continuous intravenous infusion for 1 h on d 1 and d 2, 5-FU 300 mg/m² by bolus intravenous injection on d 1 and d 2, 5-FU 1200 mg/m² by continuous intravenous infusion for 48 h, one course lasting 2 wk for 4-6 courses).

Cell culture

Human gastric adenocarcinoma cell line SGC-7901, purchased

from the Shanghai Institute of Cell Biology, Chinese Academy of Sciences, was routinely maintained in RPMI 1640 containing 100 mL/L fetal bovine serum (FBS), 100 U/mL penicillin, 100 U/mL streptomycin at 37 °C in a humidified atmosphere containing 50 mL/L CO₂.

MTT assay

Cells were seeded at the density of 5×10^3 per well in 96-well plates in RPMI-1640 containing 100 mL/L FBS. After 24 h, fresh medium was added, containing oxaliplatin at concentrations of 0 to 10 mg/L. After 48 h incubation, MTT assay was performed, 150 μ L of stock MTT (0.5 mg/mL) was added to each well, and the cells were further incubated at 37 °C for 4 h. The supernatant was removed and 150 μ L DMSO was added to each well. An ELISA reader was used to measure the absorbance at a wavelength of 525 nm.

Transmission electron microscopy

The cells treated with 0.1 mg/L oxaliplatin were trypsinized and harvested after 24 h. Subsequently the cells were fixed in 40 g/L glutaral and immersed with Epon 821, embedded in capsules and converged for 72 h at 60 °C, then prepared into ultrathin sections (60 nm) and stained with uranyl acetate and lead citrate. Cell morphology was examined by transmission electron microscopy.

Flow cytometry

SGC-7901 cells were treated with oxaliplatin or oxaliplatin plus AC-DEVD-CHO at oxaliplatin concentrations of 0 to 10 mg/L for 30 min. Cells were digested by 2.5 g/L trypsin, washed in 0.01 mol/L PBS, fixed by cold alcohol at 4 °C and dyed with annexin-V (according to the description of annexin-V kit), and then analyzed by flow cytometry.

TUNEL

SGC-7901 cells were added to 6-well plates with cover glass-slides at 6×10^4 cells/well, after incubated with oxaliplatin or oxaliplatin plus AC-DEVD-CHO at different oxaliplatin concentrations of 0 to 10 mg/L and fixed in 40 g/L formaldehydum polymerisatum for 1 h. After washed in 0.01 mol/L PBS twice, the cells were treated with reaction buffer, labeled with fluorescein dUTP in a humid box for 1 hour at 37 °C, then combined with anti-fluorescein antibody, colorized with NBT/BCIP. Cells were visualized with light microscopy. The apoptotic index (AI) was calculated as follows: AI = (number of apoptotic cells/total number) \times 100%.

RT-PCR

Total RNA was extracted from cells using an RNA extraction reagent, TRIZOL (Life Technologies, USA), according to standard acid-guanidium-phenol-chloroform method^[17]. About 4 μ g of total RNA as reversely transcribed at 42 °C for 60 min in a total of 30 μ L reaction volume using a first-strand cDNA synthesis kit (Boehringer Mannheim, Germany). cDNA was incubated at 95 °C for 5 min to inactivate the reverse transcriptase, and served as template DNA for 28 rounds of amplification using the GeneAmp PCR system 2400 (Perkin-Elmer Applied

Biosystems, CA, USA). PCR was performed in a standard 25 μ L reaction mixture consisting of 1.5 mmol/L magnesium chloride (pH 8.3), 2.5 mmol/L dNTPs, 12.5 pmol each of sense and antisense primers and 2.5 U of Taq DNA polymerase (M BI, Canada). Amplification was performed for 1 min at 94 °C, for 1 min at 62 °C and for 1 min at 72 °C after heat-start for 5 min. Finally, an additional extension step was carried out for 10 min at 72 °C. As control, the DNA template of Caspase-3 was replaced by that of β -actin in the reaction. The amplification products were separated on 12 g/L agarose gels and visualized by ethidium bromide staining. PCR primers for Caspase-3 were as follows: forward primer, 5'- ATG GAG AAC ACT GAA AAC TCA -3'; reverse primer, 5'- TTA GTG ATA AAA ATA GAG TTC -3'; according to the Caspase-3 gene structure in GeneBank. An 834 bp PCR product of Caspase-3 and a 315 bp product of β -actin were obtained.

Statistical analysis

The difference between each two groups was analyzed by ANOVA. $P < 0.05$ was considered statistically significant.

RESULTS

Clinical results

Nine cases achieved objective responses (including 1 complete response and 8 partial responses), the response rate was 40.9% progression-free survival (PFS) 4.2 mo, and total survival time 7.2 mo. The rate of accumulative neurotoxicity, vomiting and diarrhea, bone marrow depression was 93.5%, 20% and 32.9%, respectively (Table 1).

Inhibitory effect of oxaliplatin on SGC-7901

Taking the means of data from MTT assay, we got a smooth inhibition curve, which was a typical inverse 'S', and the IC₅₀ was calculated to be 0.71 mg/L by GraphPad Prism software (Figure 1). The inhibition of L-OHP on SGC-7901 cell line was typically dose dependent. A maximal inhibitory rate reached 85.3%.

Figure 1 Relationship between SGC-7901 cell survival rate and L-OHP concentration.

Apoptosis induced by L-OHP

We used transmission electron microscopy, TUNEL and

Table 1 Side effects of combined chemotherapy with oxaliplatin in treating stage IV gastric carcinoma (cycles, $n = 102$)

Side effects	Anemia	Neutropenia	Thrombo-cytopenia	Nausea& vomiting	Diarrhea	Mucositis	Dysaesthesia
I	27	17	7	14	16	9	89
II	7	6	3	6	3	1	6
III	0	0	0	0	1	0	0
IV	0	0	0	0	0	0	-
Incidence (%)	32.9	22.9	10	20	20	10	93.5

Annexin-V labeling flowcytometry to quest for the mechanism of its anti-neoplastic effect. After treatment of SGC-7901 cells with oxaliplatin (0.1 mg/L) for 24 h, some cells showed apoptotic characteristics including chromatin condensation, chromatin crescent formation, nucleus fragmentation and apoptotic body formation by transmission electron microscopy (Figure 2). Apoptotic index was 0.38% in the control group. In the experimental group, the apoptotic index determined by the TUNEL method was 7.35% while receiving L-OHP 1mg/L (slightly higher than IC_{50}) for 4 h and 14.35% while increasing the L-OHP concentration to 5 mg/L. As time went on, the apoptotic index remained stable in the control group, and was significantly increased in two experimental groups (0.5 mg/L and 1 mg/L) which reached a peak of 7.93% and 10.15%, respectively on the 4th d and decreased slightly on the 7th d. The two experimental groups had a similar trend. We could conclude that the increase in apoptotic index correlated with the L-OHP concentration and time. The apoptotic level was positively correlated with L-OHP at a concentration within 0-2.0 mg/L, as detected by Annexin-V labeling flowcytometry. The apoptotic index reached a peak of 76.47% when the concentration of L-OHP was 2 mg/L. On the contrary, the apoptotic index dropped when the concentration reached 5 mg/L.

Figure 2 Oxaliplatin-induced apoptosis in SGC-7901 cells with transmission electron microscopy. It shows apoptotic cells with chromatin condensation, chromatin crescent formation, nucleus fragmentation ($\times 4000$).

Figure 3 Inhibitory effect of AC-DEVD-CHO on apoptosis detected by TUNEL.

Figure 4 Effect of AC-DEVD-CHO on apoptosis at different times detected by TUNEL.

Expression of Caspase-3 m-RNA

By means of RT-PCR, we detected an enhancement of Caspase-3

m-RNA expression (0.48 ± 0.47 vs 0.18 ± 0.20 , $P < 0.05$) induced by L-OHP which was also in positive correlation with the apoptotic level.

Role of activated Caspase-3 in apoptotic process induced by oxaliplatin

AC-DEVD-CHO, a Caspase-3 specific inhibitor, could significantly inhibit and delay apoptosis induced by L-OHP (Figures 3, 4).

DISCUSSION

Gastric carcinoma is one of the major causes of cancer morbidity and mortality in China. The natural history shows a high metastatic potential since many patients with gastric carcinoma at advanced stage will relapse or initially present with metastasis. One of the first issues solved by clinical research over the last decade is the value of chemotherapy in the metastatic setting. Indeed, chemotherapy has been shown to have a favorable impact on survival and quality of life compared with supportive care alone. However, in this disease some traditional chemotherapy regimens were considered as poorly tolerated or less effective^[1-4]. Oxaliplatin is an innovative platinum compound indicated as a first-line therapy in combination with 5-FU and folinic acid for metastatic colorectal cancer^[5-8]. Oxaliplatin has a powerful anti-neoplasm competence, little cross drug resistance with CDDP, a synergistic effect with 5-FU and a satisfactory safety profile^[9-11]. We replaced CDDP with oxaliplatin in a traditional FLP protocol, trying to explore its anti-neoplasm activity and side effects in treating advanced gastric carcinoma. In 22 patients, 9 cases achieved objective responses (including 1 complete response and 8 partial responses), the overall response rate reached 40.9%, PFS 4.2 mo, and overall survival time 7.2 mo. The toxicity was tolerable, the rate of vomiting and diarrhea (1 case with grade III diarrhea), bone marrow depression was 20% and 32.9%, respectively. No alopecia and skin toxicity were encountered. Although the incidence of accumulative neurotoxicity was as high as 93.5%, all of them were grade I-II. Acute symptoms manifesting as transient dysaesthesia and/or paraesthesia of the extremities were commonly observed, their occurrence was triggered or enhanced by exposure to cold. No patient experienced pharyngolaryngeal dysaesthesia characterized by a transient sensation of difficulty in breathing or swallowing without any objective evidence of respiratory distress, which was encountered during the multi-center research in treating colorectal cancer after 9 cycles^[12-14]. In all the cases in this study, symptoms improved after treatment discontinuation. It is suggested that oxaliplatin is effective and well-tolerated in patients with stage IV gastric carcinoma.

We chose human gastric cancer cell line SGC-7901 for experimental study. First, we used MTT to prove if L-OHP could inhibit SGC-7901 growth. using the means of our data from the experiments, we obtained a smooth inhibition curve, which was a typical inverted 'S'. IC_{50} was 0.71 mg/L and the maximal inhibitory rate reached 85.3%. The inhibition of L-OHP on SGC-7901 cell line was typically dose dependent.

Naturally occurring or programmed cell death can regulate cell number, facilitate morphogenesis, remove harmful or otherwise abnormal cells, and eliminate cells that have already performed their functions during the life development as well as in tissue homeostasis and aging. The role of apoptosis in the process of carcinogenesis, development of cancer and malignancy treatment has drawn more and more attention in recent years^[15-17]. In this study, we tried to evaluate the level of apoptosis induced by oxaliplatin. Transmission electron microscopy could reveal the changes of cell ultrastructure during the apoptotic process. TUNEL assay is a traditional method for detecting apoptosis, but its selectivity is poor. It could hardly differentiate the apoptotic cells from the necrotic ones.

Phosphatidylserine (PS) only exists in the cytoplasm side of cell plasma membrane, and externalization of PS occurs in the early stage of apoptosis. Annexin-V could specifically conjugate to the PS to detect the apoptotic cells^[18]. So we combined traditional transmission electron microscopy and TUNEL assay with relatively highly selective annexin-V labeling flowcytometry to detect SGC-7901 cell line apoptosis induced by oxaliplatin. After treatment of SGC-7901 cells with oxaliplatin, some cells showed typical morphologic changes of apoptosis including chromatin condensation, chromatin crescent formation, nucleus fragmentation and apoptotic body formation under transmission electron microscope. TUNEL assay showed the AI positively correlated with drug concentration and treatment time. Annexin-V-fluorescein labeling flowcytometry was much more sensitive than TUNEL in detecting the early stage apoptosis. The apoptotic level positively correlated with L-OHP at a concentration within 0-2.0 mg/L, as detected by annexin-V labeling flowcytometry. The apoptotic index reached a peak, when the concentration of L-OHP was 2 mg/L. On the contrary, the apoptotic index dropped while the concentration reached 5 mg/L. To put these results together, we believed that the induction of apoptosis played a key role in inhibiting malignant cells at a low drug concentration of L-OHP, and that cytotoxicity and apoptosis coexisted while the drug concentration was high. This discovery may provide a theoretical basis for this type of treatment.

The discovery of cytosolic aspartate-specific proteases, called Caspases, which are responsible for the deliberate disassembly of a cell into apoptotic bodies, brings the fresh air to the research of malignant cell apoptosis. The Caspase family is big and dozens of family members interact with each other to promote or inhibit the process of apoptosis. Caspases are present as inactive pro-enzymes, most of which are activated by proteolytic cleavage. There are two pathways of Caspase activation, namely the cell surface death receptor pathway and the mitochondria-initiated pathway. In the cell surface death receptor pathway, activation of Caspase-8 following its recruitment to the death-inducing signaling complex (DISC) is the critical event that transmits the death signal. This event is regulated at several different levels by various viral and mammalian proteins. Activated Caspase-8 can activate downstream Caspases, such as Caspase-3 by direct cleavage or by indirectly cleaving bid and inducing cytochrome C release from the mitochondria. In the mitochondrial-initiated pathway, Caspase activation is triggered by the formation of an Apaf-1/cytochrome C complex that is fully functional in recruiting and activating proCaspase-9. Activated Caspase-9 will then cleave and activate downstream Caspases such as Caspase-3, -6, and -7^[19-23]. So we can find out that Caspase-3 locates in the downstream of the Caspase cascade. The proteolytic activation of Caspase-3 has been found to play a key role in apoptotic process^[24-26]. Caspase-3 may then cleave vital cellular proteins or activate additional Caspases by proteolytic cleavage. In this study, we detected an enhancement of Caspase-3 m-RNA expression induced by oxaliplatin by means of RT-PCR. Caspase-3 m-RNA expression was also positively correlated with the apoptotic level. AC-DEVD-CHO, a Caspase-3 specific inhibitor, could significantly inhibit and delay apoptosis induced by oxaliplatin. Taken together, we believe that Caspase-3 synthesis and activation play a key role in the apoptotic process of SGC-7901 cell line induced by oxaliplatin.

Our research demonstrates that oxaliplatin is effective and well tolerable in treating gastric cancer. Inducing cancer cell apoptosis may be one of the anti-neoplasm mechanisms. This apoptosis may be mediated by up-regulation of Caspase-3 synthesis and activation. The efficacy and safety profile of oxaliplatin as a chemotherapeutic drug in combined anti-gastric carcinoma chemotherapy regimen should be further confirmed by double blind multi-center clinical studies.

Abstract

AIM: Of all the complications of laparoscopic cholecystectomy, bile duct injury (BDI) is the most serious complication. The prevention of injury to the common bile duct (CBD) remains a significant concern in laparoscopic cholecystectomy (LC). Different kinds of methods have been advanced to avoid this injury but no single method has gained wide acceptance. Because of various limitations of current methodologies we began a study using cold light illumination of the extrahepatic biliary system (light cholangiography LCP) to better visualize this area and thereby reduce the risk of bile duct injury.

METHODS: Thirty-six patients with cholelithiasis were divided into two groups. Group I (16 cases) received LCP and group II (20 cases) received methelenum coeruleum cholangiography (MCCP). In group I cold light was used to illuminate the common bile duct by leading an optical fiber into the common duct with a duodenoscope at the time of LC. The light coming from the fiber in the CBD could clearly illuminate the location of CBD and hepatic duct establishing its location relative to the cystic duct. This method was compared with the dye injection technique using methelenum coeruleum.

RESULTS: In group I thirteen cases were successfully illuminated and three failed. The cause of three failed cases was due to the difficulty in inserting the fiber into the ampulla of Vater. No complications occurred in the thirteen successful cases. In each of these successful cases the location of the common and hepatic ducts was clearly seen differentiating the ductal system from surrounding anatomy. In ten cases both the left and right hepatic ducts could be seen and in three only the right hepatic ducts were seen. In four of the thirteen cases, cystic ducts were also seen. In group II, eighteen of the twenty cases were successful. The location of extrahepatic ducts became blue differentiating the ductal system from surrounding anatomy. Two cases failed due to a stone obstructing the cystic duct, and extravasation of the dye turned the entire area blue. LCP showed the common and hepatic ducts more clearly than MCCP.

CONCLUSION: LCP is the only technique that can clearly and directly show the location of the extrahepatic biliary system and may be useful in selecting cases of uncertain anatomy in the prevention of bile duct injury.

injury in laparoscopic cholecystectomy. *World J Gastroenterol* 2004; 10(19): 2916-2918

<http://www.wjgnet.com/1007-9327/10/2916.asp>

INTRODUCTION

Bile duct injury continues to be one of the most serious complications of LC. The principal cause is the difficulty in recognition of the junction of the cystic duct to the hepatic duct. A number of methods have been advanced to avoid this error but no single method has gained wide acceptance. From March 2001 to October 2003 we used LCP for illumination of the biliary system in 36 cases and believe it is quite useful.

MATERIALS AND METHODS

Patients

Thirty-six patients with cholelithiasis, including 16 males and 20 females aged 41 to 66 years (mean age: 56 years) were selected for the procedure and divided into two groups. Group I (16 cases) received LCP and group II (20 cases) received MCCP.

Materials

Laparoscopic equipments were produced by Stryker and duodenoscopes with a channel diameter of 3.5 cm and 4.2 cm respectively were from Olympus. Optical fibers were specially produced according to our own design.

Methods

All patients drank 500 mL 100 g/L mannitol 15 h before operation and were fasted during this period. All cases received general anesthesia. In group I, Calot's triangle was dissected carefully and the relationship of the cystic duct to the hepatic and common bile ducts was noted. Duodenoscope was then introduced and the optic fiber was advanced into the common duct. When the light was turned on, the extra hepatic ducts were clearly seen. In group II, instead of placing the duodenoscope, a needle guided with the laparoscope was percutaneously punctured into the gall bladder. Five mL of bile was aspirated from the gall bladder. After that 5 mL of MCCP dye was injected. The bile ducts became blue.

RESULTS

In group I, thirteen cases were successfully illuminated and three failed. The cause of three failed cases was due to the difficulty in inserting the fiber into the ampulla of Vater. The time required for this examination ranged from 15 to 100 min with a median time of 35 min. No complications occurred in the thirteen successful cases. In each of these cases, the location of the common and hepatic ducts was seen clearly differentiating the ductal system from surrounding anatomy. In ten cases both the left and right hepatic ducts could be seen and in three only the right hepatic ducts were seen. In four of the thirteen cases, the cystic ducts were also seen. In two cases the ducts were clearly seen in spite of considerable fat over Calot's triangle.

In group II, eighteen of the twenty cases were successful.

The extrahepatic duct became blue differentiating the ductal system from surrounding anatomy. Two cases failed due to a stone obstructing the cystic duct, and extravasation of the dye turned the entire area blue.

DISCUSSION

Prevention of injury to the ductal system continues to be a matter of considerable concern of surgeons performing laparoscopic cholecystectomy. The accurate incidence of bile duct injury (BDI) during laparoscopic cholecystectomy (LC) is not known^[1]. The principal causes of CBD in LC are the uncertain anatomy and the laparoscopic view that is quite different from open cholecystectomy. A few methods have been practiced, *e.g.* using 30° laparoscope, applying three dimensional laparoscope and inserting laparoscope through the right side of umbilicus were used. Greater efforts have been concentrated on dealing with the uncertain anatomy. The key point continues to be how to best identify the anatomy and thereby avoid injury. Currently the primary means of preventing injury resulted from uncertain anatomy include careful dissection, the judgment of an experienced surgeon, conversion to open cholecystectomy and intraoperative cholangiography (IOC).

The major causes of uncertain anatomy are anatomic variation and unclear anatomy. Kurumi *et al.*^[2] classified confluent forms of the cystic duct and the bile duct into five different types, including four abnormal types. Sixteen instances (3.13%) of anatomic variation of the biliary tract were found among 511 patients, and four cases (4.35%) were found in 92 cadavers. Anatomic variation of the biliary tract is both common and complicated and can create a pitfall during laparoscopic cholecystectomy. Unclear anatomy resulted from inflammation and adhesion at Calot's triangle is an important factor associated with injury^[3-5]. The judgment of an experienced surgeon^[1,4,6] and conversion from laparoscopic to open cholecystectomy^[5,7] are now considered the primary means of preventing bile duct injury resulted from uncertain anatomy. Unfortunately these means do not always work effectively. Injuries are likely to occur despite better procedures and increased experience^[4]. Calvete *et al.* believed that no relation could be found between the experience of surgeons and the number of BDI over different periods of time^[8]. Therefore, BDI during LC can not be attributed solely to the learning curve. One approach is to convert to open cholecystectomy when the anatomy is uncertain. But even open cholecystectomy can not avoid CBD injury due to the uncertain anatomy. Yang *et al.*^[9] reported iatrogenic extrahepatic bile duct injury in 182 patients. Bile duct injury occurred in 152 patients during open cholecystectomy and in 30 patients during laparoscopic cholecystectomy. The incidence of BDI after LC was similar to that in the open procedure^[1].

Cautious dissection is necessary and essential to prevent BDI in LC^[4,6,10-12]. Illegible anatomy often poses dissection difficultly to operators and renders them quite helpless. Surgeons are seeking assisting measures to help them identify the anatomy during LC. Some surgeons recommended that IOC be attempted on all patients undergoing LC. They deemed that the routine use of IOC during laparoscopic cholecystectomy could not prevent bile duct injuries, but minimized the extent of the injuries so that they could be repaired easily, thus decreasing the rate of BDI^[13-16]. But its routine use during LC remains controversial. Routine IOC yields very little useful clinical information compared to selective policies. A large number of unnecessary IOC were performed under routine IOC policy, and therefore a selective policy has been advocated^[17]. IOC depends on the radiopaque dye introduced into the ductal system via the cystic duct and displayed by either a static film or fluoroscopy which does not always identify the relationship of the ductal system to adjacent anatomy. The primary purpose

of IOC is to identify anatomy and any aberration as well as to identify stones. The image of IOC obtained from static film or fluoroscopy is completely different from that obtained from the monitor and can not really tell where the cystic duct or common bile duct is. The information afforded by IOC can only help operators realize if there are continuity, stones, tumor and injury of the ducts but can not help them dissect easily and safely. Thus it is of limited value during dissection of the area. Nevertheless it has become the most common method of visualizing the area.

The use of MCCP has been advocated by Xu *et al.*^[18]. This technique does give a direct image but it is blurry. A mixture is got by injecting methylenum coeruleum into gall bladder. The color of the mixture is close to that of the tissue surrounding the extrahepatic duct, so that the bile ducts can not be identified clearly. The image is even more indistinct when there is much fatty tissue over the ducts. If there is extravasation, the entire area turns blue making dissection more difficult since the dye is not easily washed away. CBD does not keep the dye long enough. The dye diluted by the bile flows into duodenum soon, so that the operator can not observe Calot's triangle repeatedly. Finally, the procedure can not be used if the duct is blocked by a stone.

Because of these limitations of current methodologies, we advocated the new method of direct illumination of the extrahepatic ductal system (LCP). By adjusting the optic fiber, it can go into right or left hepatic duct and cystic duct. The movement of the fiber must be slow and soft. It is not very easy sometimes to insert the fiber into cystic duct for the duct may pass behind the common hepatic duct to enter on its posterior wall or on its left lateral aspect. If the inserting was difficult, we gave the attempt up in case that the duct wall was injured by the fiber. We do not think the illumination of cystic duct is absolutely necessary. The important thing is to know the locations of CBD and common hepatic duct, though the illumination of cystic duct may make the image of Calot's triangle appear completely.

Table 1 Comparison between group I and group II

	Group I (n=16)	Group II (n=20)
Examine method	LCP	MCCP
Examine time (min)		
Range	15-100	5-10
Median	35	7
Examination cost	\$ 200	\$ 5
Image	direct	direct
Legibility	clear	blurry
Observed time	unlimited	limited

Additional observations we made during this study revealed the importance of releasing any adhesions in the area of the ductal system to straighten the ductal system out facilitating the introduction of the optical fiber. The initial dissection of the ductal system along with our observations as to the probable location of the various elements was also helpful. In our opinion it is best to keep the optical fiber in the right hepatic duct until the dissection of the gall bladder and cystic duct is completed. This is particularly true in the occasional case when the cystic duct comes off the right hepatic duct. We do not feel routine LCP examination of the ductal system is indicated but in selected cases. The examination with LCP is extremely rewarding and not terrifically difficult in any hospital where the intraoperative endoscopic retrograde cholangiopancreatography (ERCP) is practiced. As far as the cost is concerned, the increase is quite acceptable (Table 1). Of course, if there is any reason

for intraoperative ERCP to be done, it can be easily accomplished during LCP, though it needs not to be done as a routine. LCP can not help operators realize if there are continuity, stones, tumor and injury of the ducts. When the forgoing conditions are suspected, cholangiography should be done with intraoperative ERCP.

LCP is currently the most effective way to directly observe the extrahepatic ductal system during laparoscopic cholecystectomy and may play a useful role in clarifying uncertain anatomy in selected cases. As a useful assisting measure, it plays an important role in preventing extrahepatic duct injury in LC.

Abstract

To present a patient diagnosed with pancreatic carcinoid that was extremely rare and produced an atypical carcinoid syndrome. We reported a 58-year old male patient who presented with long standing, prominent cervical lymphadenopathy and occasional watery diarrhea. Pathohistological and immunohistochemical examination of lymph node biopsy showed a metastatic neuroendocrine tumor, which was histological type A of carcinoid (EMA+, cytokeratin+, CEA-, NSE+, chromogranin A+, synaptophysin+, insulin-). Bone marrow biopsy showed identical findings. Primary site of the tumor was pancreas and diagnosis was made according to cytological and immunocytochemical analysis of the tumor cells obtained with aspiration biopsy of pancreatic mass (12 mm in diameter) under endoscopic ultrasound guidance. However, serotonin levels in blood and urine samples were normal. It is difficult to establish the precise diagnosis of a “functionally inactive” pancreatic carcinoid and aspiration biopsy of pancreatic tumor under endoscopic ultrasound guidance can be used as a new potent diagnostic tool.

INTRODUCTION

In 1907, Obendorfer applied the term “karzinoide” to describe a set of ileal tumors that behaved in a more benign manner than carcinomas. Since then, carcinoid tumors have been found to be relatively uncommon neuroendocrine tumors arising from neural crest cells known as “amine precursor uptake and decarboxylation cells” (APUD), which are derived from gut endoderm. Recent consensus meetings suggested that a more appropriate term “neuroendocrine tumor” should be used for all endocrine tumors of the digestive system, because these tumors derive from the diffuse neuroendocrine system^[1]. Pancreas, mucosa of the gastrointestinal tract^[2] and endocrine cells scattered in other endodermal sites (such as thyroid, lung, biliary tree and the urogenital tract) belong to APUD system. Neuroendocrine tumors can be subclassified into those with or without clinical syndromes and are termed “functionally active” and “functionally inactive” pancreatic carcinoid, respectively^[3].

Carcinoid of the pancreas is extremely rare and the diagnosis may puzzle physicians and pathologists^[4]. Pancreatic carcinoids produce an atypical carcinoid syndrome, skin flushing was reported in only 34%, the main symptom is pain, followed by diarrhea and weight loss.

We hereby described a patient with disseminated “functionally inactive” neuroendocrine tumor who presented with lymph node metastases, but without characteristic symptoms of carcinoid syndrome. The primary site of the tumor was pancreas.

CASE REPORT

A 58-years old male was admitted to Hematology Department in June 2001 with complaint of a left anterior neck mass and occasional massive, watery diarrhea. The patient noticed slow enlargement of neck mass for two years prior to admission, and also stated that in the last 12 mo he had episodes of diarrhea 1-2 times/wk. Diarrhea was massive and watery (up to 1 L/d) without visible blood or mucous and usually self-limited. Diarrhea was not associated with abdominal pain, tenesmus or with food intake. He lost 5 kg in 3-4 mo, inspite of good appetite. His previous medical history was unremarkable. Physical examination showed a left anterior neck mass (7 cm×6 cm in diameter), painless and movable in all directions. Chest X-ray showed paratracheal infiltrate. On bronchoscopy, external compression on posterior and lateral tracheal walls was seen. CT of chest showed enlarged mediastinal lymph nodes (up to 40 mm). CT of abdomen showed an enlarged pancreatic head (46 mm) with a mild hypodense area (12 mm in diameter). Pathohistological findings of tissue samples from the neck tumor (cuneiform biopsy) and bone marrow (trephine biopsy) were identical, namely a metastatic neuroendocrine tumor, which was histological type A of carcinoid. Immunophenotyping of cells from the neck tissue sample showed well-differentiated neuroendocrine tumor (APUDOMA) that was immunostained as follows: EMA+, cytokeratin 8+, CEA-, NSE+, chromogranin A+, synaptophysin+, insulin-. In an effort to find the primary site of APUDOMA, esophagogastroduodenoscopy, endoscopic enteroscopy, colonoscopy, small bowel barium enema, radial endoscopic ultrasound (radial EUS - Olympus device) were done (Figure 1). Ultrasound (linear EUS) guided aspiration biopsy of the pancreatic mass was performed (Figure 2). Cytological examination showed solid nodular nests of small uniform, epitheloid cells of dense heterochromatin. Immunocytochemical analysis revealed groups of epithelial cells with positive cytoplasmatic staining on NSE and chromogranin A that implied on tumor with neuroendocrine differentiation (Figure 3). Pathohistological examination of aspiration liver biopsy was normal, excluding possible liver micro-metastasis. To exclude MEN syndrome, X-ray and MRI of sellar region as well as thyroid US were done and all tests were normal. On 2D ultrasound the right heart was anatomically and functionally within normal limits. Blood count and biochemistry were normal except for occasional hypokalemia and mild hypoproteinaemia (with proportional decrease in all electrophoresis fractions). CEA was significantly increased (535.5 ng/mL), but pancreatic tumor marker (CA 19-9) and alpha-feto protein were within normal

limits. Serotonin level in blood and urine was normal (0.25 mmol/L and 359 mmol/24 h, respectively). 5-HIAA in the urine sample was increased (84 μ mol/L, reference range: 10.4-41.6 μ mol/L). Periodical diarrhea was controlled with loperamid and oral potassium supplementation. During hospitalization, patient developed urinary retention. Rectal examination and US revealed a prostatic adenoma (size 44 mm \times 54 mm \times 54 mm, 60 g weight) with normal values of prostate serum antigen. Transvesical adenectomy was performed, and pathohystologic findings confirmed it to be an adenoma. Postoperative period was complicated with prolonged wound healing and vesicodermal fistula. The patient also had changes of mental status, but CT of the head did not show any abnormalities. The patient was regularly followed up. In December 2001 he was doing well, still complaining of frequent diarrhea and minimal enlargement of the neck mass. Blood tests continued to show hypoproteinemia and hypokalemia, easily controlled with potassium supplementation. However, the patient died in January 2002 at home. His family recorded no particular circumstances related to his death.

DISCUSSION

Functionally active neuroendocrine tumors are presented with clinical symptoms because of excessive hormone release from the tumor cells as in insulinoma, gastrinoma, VIPoma, glucagonoma and carcinoid syndrome^[5]. Carcinoid tumors, except those originating from rectum, produced a variety of endocrine substances, the most frequent one was serotonin and kallikrein^[6-8]. Carcinoid syndrome that includes diarrhea, flushing, wheezing, and right-sided heart disease^[9] is caused by systemic serotonin release. Less than 10% of carcinoids had some of these symptoms^[10]. Explanation is efficient hepatic metabolism of vasoactive amines, and that is also the reason why carcinoid syndrome rarely occurred in the absence of liver metastasis. Exceptions are circumstances in which venous blood from a large tumor was drained directly into systemic circulation^[11].

Functionally inactive neuroendocrine tumors can be diagnosed in several ways: a) accidentally during routine ultrasonography performed for unexplained abdominal complaints, b) when a large tumor of the pancreatic head is causing obstruction and consequently extrahepatic jaundice, c) when a patient presents with abdominal pain secondary to bowel pseudo-obstruction, and d) as complications of the tumor such as bleeding. Our patient had occasional diarrhea that was not significant (less than 1L per day). Besides he had no other symptoms, and his blood tests failed to show any endocrine abnormalities. Histopathological and immunohistochemical analyses of the tissue sample from the neck mass showed a well-differentiated neuroendocrine tumor, which was histological type A of carcinoid (APUDOMA). At the time of diagnosis, metastatic disease of cervical and mediastinal lymph nodes, and bone marrow already existed which was confirmed by histopathological finding. Aspiration liver biopsy was done to exclude micro-metastases, that otherwise could not be visualized by imaging methods, and the result was negative. Primary site of the tumor was unknown. Because the most frequent localization of carcinoid was in the gastrointestinal tract, it was explored in whole, but primary tumor was not found. Aspiration biopsy of the pancreatic mass under endoscopic ultrasound guidance was done for the first time in Yugoslavia. Immunocytochemical report confirmed that the pancreatic mass was the primary site that only occurred in 2-3% of all cases^[4,12,13]. Also, carcinoid tumors up to 1 cm rarely metastasize, but that was not the case with our patient.

The slow growth rate and late invasion of adjacent organs rendered local resection of pancreatic carcinoid tumor possible, but the high incidence of distant metastases (69%) prevented long-term survival in the majority of patients^[4]. Diarrhea with hypokalemia and hypoproteinemia, as a manifestation of carcinoid syndrome in this case could be explained by increased release of vasoactive substances most probably from the

extensive metastasis in the bone marrow, and lymph nodes. However, these metabolic abnormalities were well controlled and could not be the main cause of his death.

In summary, atypical presentation in this and other reported cases of pancreatic carcinoids suggests that metastatic potential of functionally inactive neuroendocrine cells is originated from the pancreas.

Tacke F, Luedde T, Manns MP, Trautwein C. Regulation of plasma erythropoietin in chronic liver disease. *World J Gastroenterol* 2004; 10(19): 2922

<http://www.wjgnet.com/1007-9327/10/2922.asp>

To the Editor:

In a May-issue of the *World Journal of Gastroenterology*, there is a very interesting study by Bruno *et al.* on erythropoietin (EPO) levels in patients with chronic liver disease^[1]. We have very recently reported a similar, but much larger study by Tacke *et al.*^[2] on the role of EPO in chronic liver disease. By comparing Bruno's results with our patient cohort and applying their criteria in a re-evaluation of our study population, we uncovered interesting differences between the two studies and could answer some of the key questions in the article raised by Bruno *et al.*, e.g. on the correlation of EPO with liver dysfunction and potential regulating factors in the clinical setting of liver cirrhosis.

Therefore, we would like to briefly present our data and compare the results with Bruno's recent study. We think the role of EPO is important in the pathophysiology of chronic liver disease, and the recent studies provided new insights into its regulation in liver cirrhosis.

Chronic anemia is a common clinical complication in patients with liver cirrhosis and is regarded as an important prognostic factor^[3]. The great progress in the understanding of cytokine alterations in chronic liver diseases as well as the discovery and clinical application of different hematopoietic growth factors have raised attention to the potential pathophysiological role of erythropoietin (EPO) in liver diseases^[4,5]. In a recent issue of the *World Journal of Gastroenterology*, Bruno *et al.* reported that increased EPO plasma levels were only detected in cirrhotic patients with hemoglobin concentrations below 12 g/dL and that this EPO response was inadequate compared to patients with iron-deficiency anemia^[1]. Furthermore, the authors did not observe an association between EPO levels and the stage of liver cirrhosis or liver synthesis function. The regulating factors in the pathophysiological setting of advanced liver diseases as well as possible clinical consequences remained an open question.

We analyzed 111 patients with chronic liver diseases who were evaluated for potential liver transplantation and 220 healthy (non-anemic) controls with the same EPO ELISA (R&D Systems, Wiesbaden, Germany) kit. In contrast to Bruno *et al.* who studied mainly patients with viral hepatitis and advanced stages of cirrhosis, our much larger cohort comprised all Child's stages of cirrhosis in a fairly equal number of patients as well as different etiology subgroups. As we reported recently, EPO plasma levels

clearly increased with Child's stage of liver cirrhosis, independent of the disease etiology (Figure 1)^[2]. EPO also correlated directly with the markers of liver synthesis function, e.g. cholinesterase activity ($r = -0.448$, $P < 0.001$), albumin concentration ($r = -0.358$, $P < 0.001$), or prothrombin time ($r = 0.300$, $P = 0.001$). Interestingly, the absolute values of measured EPO levels in Bruno *et al.* and our studies were relatively similar (e.g. mean EPO 11.6 U/L for chronic hepatitis by Bruno *et al.*, median EPO 11.3 U/L for our "non cirrhosis" group), thereby raising the question whether the clear association between EPO and stage of liver cirrhosis could have been observed if the number of patients included in Bruno *et al.* study was high enough. Furthermore, it is hard to believe that EPO was normally distributed in anemic or non-anemic cirrhotic patients as the mean \pm SD values suggested by Bruno *et al.*, thus a different statistical analysis using median and U-test could possibly uncover these important correlations.

Figure 1 Erythropoietin plasma levels and stage of cirrhosis. EPO was significantly higher in patients with liver cirrhosis than in healthy controls and increased with Child's stages of cirrhosis.

We also found a significant inverse correlation between EPO levels and hemoglobin in patients with chronic liver diseases ($r = -0.498$, $P < 0.001$, Spearman rank correlation analysis). As this was described by Bruno *et al.* only for patients with iron-deficiency anemia, this correlation could not be observed when we divided our liver disease patient group by the criteria of Bruno *et al.* into so-called anemic or non-anemic patients ($hb \leq 12$, $n = 48$, vs $hb > 120$ g/L, $n = 63$). However, in accordance with Bruno *et al.*, we also found significantly elevated EPO levels in anemic vs non-anemic liver disease patients (median EPO 29.3 vs 11.4 U/L, $P < 0.001$, U-test). In contrast, the non-anemic liver disease patients also had elevated EPO levels as compared with controls ($P < 0.05$), which could be possibly explained by the much larger control group in our study.

In further investigating the potential regulating factors, one should consider the complex clinical picture of advanced liver cirrhosis. As we could show, the degrees of anemia and liver dysfunction not only were independent parameters associated with elevated EPO in chronic liver disease, but also impaired pulmonary function^[2]. Changes in pulmonary function test and blood gas analysis were commonly found in our study population, and EPO was inversely correlated with carbon dioxide tension (pCO_2) and elevated in patients with reduced (carbon monoxide) diffusion capacity. In addition, we noticed a positive correlation between interleukin-6 and EPO, thereby possibly linking the EPO response to a common protective cytokine response usually seen in liver cirrhosis^[6].

In conclusion, the recent studies by Bruno *et al.* and our group provide some new important insights in the regulation of plasma EPO in chronic liver diseases. EPO plasma levels are apparently upregulated in patients with liver cirrhosis, and one might speculate whether this increase is sufficient in the setting of chronic anemia when compared with other forms of anemia,

e.g. iron-deficiency. However, the regulation of plasma EPO is complex and multifactorial, and the degrees of anemia, liver dysfunction, impaired pulmonary function and cytokine alterations are the major factors in regulating plasma erythropoietin in patients with chronic liver diseases.

<http://www.wjgnet.com/1007-9327/10/2923.asp>

To the Editor:

I recently read the paper by Chen *et al.*^[1] published in your Journal. The paper shows that there have been a few cases where medications have caused eosinophilia. Clozapine is an antipsychotic medication that can cause eosinophilia. It is pointed out in your paper "The diagnostic criteria included . . . 5), exclusion of intestinal lymphoma, Crohn's disease or other tumors." Table 2 shows symptoms associated with eosinophilic gastroenteritis, which are very like those in Crohn's disease.

Miss Z, a 29 years old female received a diagnosis of Crohn's disease five years ago. It seemed to be the more aggressive fistulizing form of Crohn's disease. The inflammation seemed

to be located in her colon. She had several perianal abscesses. Miss Z took the antipsychotic, clozapine. Clozapine can cause constipation, diarrhea^[2-7], nausea^[6,8], vomiting^[3,6,8], allergic reactions, *etc.* Clozapine has also been linked with colitis^[5,14], gastrointestinal symptoms^[7], hepatotoxicity^[12], eosinophilia^[5,7,9], neutropenia^[9], colon perforation^[13], necrotizing colitis^[13], perianal abscesses^[9], and increased levels of TNF-alpha^[10], *etc.*

When Miss Z was growing up, she had no prodromal symptoms that, even with the benefit of hindsight one might be able to say, this was the beginning of Crohn's disease. The sickness and diarrhea started 32 d after the clozapine was titrated to its full dose of 300 mg/d in November 1998.

Tumor necrosis factor α (TNF α) is a proinflammatory cytokine that has an important role in the pathogenesis of Crohn's disease. Infliximab-a chimeric anti-TNF α monoclonal antibody binds to TNF α with high affinity, thereby neutralising its biological activity. Pollmacher *et al.*^[10], found that clozapine significantly increased the plasma levels of TNF-alpha.

Miss Z responded very well to infliximab. Steroids (prednisolone) had little effect on the symptoms. Stopping clozapine was not an option unless we were to be reasonably sure that it was responsible for causing or exacerbating the inflammation in Miss Z's colon.

I am particularly interested in the effect of clozapine. If it were to cause eosinophilia it might have effects on the colon. I wondered if the symptoms of nausea, vomiting, *etc.*, might persist all the time when clozapine was taken.

To the Editor:

I recently read the paper by Chen *et al.*^[1] published in your Journal. The paper shows that there have been a few cases where medications have caused eosinophilia. Clozapine is an antipsychotic medication that can cause eosinophilia. It is pointed out in your paper "The diagnostic criteria included . . . 5), exclusion of intestinal lymphoma, Crohn's disease or other tumors." Table 2 shows symptoms associated with eosinophilic gastroenteritis, which are very like those in Crohn's disease.

Miss Z, a 29 years old female received a diagnosis of Crohn's disease five years ago. It seemed to be the more aggressive fistulizing form of Crohn's disease. The inflammation seemed

to be located in her colon. She had several perianal abscesses. Miss Z took the antipsychotic, clozapine. Clozapine can cause constipation, diarrhea^[2-7], nausea^[6,8], vomiting^[3,6,8], allergic reactions, *etc.* Clozapine has also been linked with colitis^[5,14], gastrointestinal symptoms^[7], hepatotoxicity^[12], eosinophilia^[5,7,9], neutropenia^[5,6], colon perforation^[13], necrotizing colitis^[13], perianal abscesses^[9], and increased levels of TNF-alpha^[10], *etc.*

When Miss Z was growing up, she had no prodromal symptoms that, even with the benefit of hindsight one might be able to say, this was the beginning of Crohn's disease. The sickness and diarrhea started 32 d after the clozapine was titrated to its full dose of 300 mg/d in November 1998.

Tumor necrosis factor α (TNF α) is a proinflammatory cytokine that has an important role in the pathogenesis of Crohn's disease. Infliximab-a chimeric anti-TNF α monoclonal antibody binds to TNF α with high affinity, thereby neutralising its biological activity. Pollmacher *et al.*^[10], found that clozapine significantly increased the plasma levels of TNF-alpha.

Miss Z responded very well to infliximab. Steroids (prednisolone) had little effect on the symptoms. Stopping clozapine was not an option unless we were to be reasonably sure that it was responsible for causing or exacerbating the inflammation in Miss Z's colon.

I am particularly interested in the effect of clozapine. If it were to cause eosinophilia it might have effects on the colon. I wondered if the symptoms of nausea, vomiting, *etc.*, might persist all the time when clozapine was taken.

Adrian TE. Plagiarized and inaccurate papers in the *World Journal of Gastroenterology*. *World J Gastroenterol* 2004; **10**(19): 2925

<http://www.wjgnet.com/1007-9327/10/2925.asp>

To the Editor:

I was astonished to find this paper [Dong ML, Ding XZ, Collin P, Adrian TE. Red oil A5 inhibits proliferation and induces apoptosis in pancreatic cancer cells. *World J Gastroenterol* 2004; **10**(1): 105-111] published in your journal. This has been done without my knowledge or the other coauthor, Dr. Ding. There are numerous errors. These include (1) the exclusion of an important collaborating contributor; (2) the appearance that the work was carried out in China, when it was actually carried out at Northwestern University in Chicago; (3) an incorrect name for the compound being used; (4) an incorrect company name where the compound originated from. The following are the correct information. The authors list should be: Dong ML^[1], Ding XZ^[1], Collin P^[2], Adrian TE^[1]. The title should have been: CR-A5 inhibits proliferation and induces apoptosis in pancreatic cancer cells (the term oil A5 is meaningless; the product is called CR-A5). The address where the work was carried out was: ¹"Department of Surgery and Robert H. Lurie Comprehensive Cancer Center, Northwestern Feinberg School of Medicine, Chicago, IL" and ²"Coastside Research, Stonington, Maine". The funding sources that should have been acknowledged were: The American Institute of Cancer Research, the RAPID Program of the RAPID Program of the Chemoprevention Branch of the National Cancer Institute, the Michael Rolfe Foundation and the Maine Technology Institute. Dr. Dong did carry out this work in my laboratory with the help of others, however, we never discussed where the work would be published and I certainly did not sanction its publication in your journal. I consider what Dr. Dong has done to be dishonest. Most journals require the signature of all authors before a paper can be

accepted for publication, this would be a good policy for the World Journal of Gastroenterology to adopt. More seriously, regarding Dr. Dong, I have now found another paper that he has published in your journal [Dong ML, Zhu YC, Hopkins JV. Oil A induces apoptosis of pancreatic cancer cells via caspase activation, redistribution of cell cycle and GADD expression. *World J Gastroenterol* 2003; **(9)**: 2745-2750]. Again this paper was published without my knowledge. The other authors are unknown to me and the name John V. Hopkins appears to have been fabricated. The contents of this paper have been almost entirely plagiarized from a previous publication from a Medical Oncologist, Dr. Xin-Quan Li who worked in my laboratory and Xian-Zhong Ding in the laboratory (Li X, Ding XZ, Adrian TE. Arsenic trioxide induces apoptosis in pancreatic cancer cells via changes in cell cycle, caspase activation, and GADD expression. *Pancreas* 27: 174-179, 2003). More disturbingly, at least some of the data have clearly been fabricated. The data in Figure 5 of the *World Journal of Gastroenterology* paper have been entirely lifted from the arsenic trioxide data in Figures 6 and 7 in the *Pancreas* paper. Please find the enclosed MS Powerpoint file where I have indicated the stolen data in red. Furthermore, careful perusal of the data in Figures 3 and 7 has been assembled in the computer by cutting and pasting sections from different gels. Since some of the data have clearly been fabricated this sheds doubt on all of the other findings in the manuscript. I never saw the raw data for most of these experiments and doubt that they were ever performed. I request that this paper is immediately retracted from the journal with an explanation published. I am sure you will want to do this for the integrity of the journal. An internal committee will be set up at Northwestern University to investigate this matter. I will attempt to contact the Dean of Wenzhou Medical College to inform him of this situation with one of his faculty. Since my NIH grant number was also copied onto the WJG paper, I am informing the NIH of this matter. Please let me know if I should inform your editorial board of what has happened. Finally, as you have requested, I state that the contents of this letter represent my viewpoints rather than those of the journal.

Apology to Dr. Thomas E. Adrian

After we received the letter of Dr Thomas E. Adrian, Dr Mi-Lian Dong wrote a letter for Dr Thomas E. Adrian and the following is the statement from Dr Mi-Lian Dong (the letter was provided by Dr. Thomas E. Adrian). Statement from Dr Mi-Lian Dong for Dr Thomas E. Adrian. From: Mi-Lian Dong (mdong2@hotmail.com). Sent: Monday, June 28, 2004 8:54 AM. To: tadrian@northwestern.edu. Subject: Dear Dr. Thomas Adrian, I don't know how to start this letter, but I have to face it. I can imagine your anger and your disappointment for my unacceptable behavior. I feel very sorry and apologize for what stupid things I did. When I was in Chicago, my former supervisor-Dr. White from Lutheran General Hospital, a very nice gentleman, took care of me and introduced me to your lab. In your Lab, you and Dr. Ding trained me and I learned a lots new stuff, some I never heard before as a clinician in China. I believe I worked very hard and did my best in your lab to repay your generous help. I never forget those wonderful days. But now, I destroyed all those wonderful memories. Dr. Thomas Adrian, I already sent a letter to the journal to ask them to remove that article. Such stupid things never happened in my 40 years life. I cannot sleep well and cannot focus my daily work as a busy doctor. I took a few days off. I believe I got punishment from this, but I accept it. It is unforgettable lesson for my future life. But now, besides sorry and regret, I really don't know what else I can do. Again, I apologize for what I did. Sincerely, Mi-Lian Dong.

Abstract

AIM: Recombined plasmid pETNF-P16 was constructed to investigate its expression properties in esophageal squamous carcinoma cell line EC9706 induced by X-ray irradiation and the feasibility of gene-radiotherapy for esophageal carcinoma.

METHODS: Recombined plasmid pETNF-P16 was constructed and transfected into EC9706 cells with lipofectamine. ELISA, Western blot, and immunocytochemistry were performed to determine the expression properties of pETNF-P16 in EC9706 after transfection induced by X-ray irradiation.

RESULTS: Eukaryotic expression vector pETNF-P16 was successfully constructed and transfected into EC9706 cells. TNF α expressions were significantly increased in the transfected cells after different doses of X-ray irradiation than in those after 0Gy irradiation (1 192.330-2 026.518 pg/mL, $P<0.05-0.01$), and the TNF α expressions and P16 were significantly higher 6-48 h after 2 Gy X-ray irradiation (358.963-585.571 pg/mL, $P<0.05-0.001$). No P16 expression was detected in normal EC9706 cells. However, there was strong expression in the transfected and irradiation groups.

CONCLUSION: X-ray irradiation induction could significantly enhance TNF α and P16 expression in EC9706 cells transfected with pETNF-P16 plasmid. These results may provide important experimental data and therapeutic potential for gene-radiotherapy of esophageal carcinoma.

Wu CM, Huang TH, Xie QD, Wu DS, Xu XH. Construction of pETNF-P16 plasmid and its expression properties in EC9706 cell line induced by X-ray irradiation. *World J Gastroenterol* 2004; 10(20): 2927-2930
<http://www.wjgnet.com/1007-9327/10/2927.asp>

INTRODUCTION

Esophageal carcinoma is one of the most frequent malignant tumors. Its treatment choices include surgical resection,

radiation, chemotherapy and biological therapy. However, their limitations and adverse effects influence the therapeutic results. In 1992, Wechselbaum proposed the theory of gene-radiation combination treatment, that is, to ligate the promoter with irradiation-induced function and treatment gene so as to take advantages of the combined therapeutic functions of both modalities^[1].

In this study, pETNF-P16 plasmid was constructed and transfected into human esophageal cancer cell line EC9706. The expressions of TNF α and P16 in the transfected cells exposed to different doses of X-ray irradiation and the time course of the expressions after 2Gy X-ray irradiation were detected to explore the feasibility of gene-radiotherapy for esophageal carcinoma.

MATERIALS AND METHODS

Cell line and vectors

The EC9706 was maintained in Dulbecco's modified Eagle's medium (DMEM), high glucose media (Life Technologies) and generously supplemented with 100 mL/L fetal bovine serum (Hyclone Laboratories), penicillin, streptomycin and nonessential amino acids (Life Technologies). PIRES1 vector was bought from Promega-Biotec (Shanghai, Promega Corporation).

Construction of pETNF-P16 plasmid

The expression vector for TNF α and P16 was constructed as Figure 1.

Transfection

Transfection of EC9706 cells was carried out in a 6-well plate. The transfection procedure began when the cells reached 70% confluence on the surface of plate wells. Solution A was prepared by separate addition of 10 μ g of pETNF-P16 or PIRES1 to 100 μ L serum-free medium (SFM), and solution B by addition of 10 μ L liposome to 100 μ L SFM. Solutions A and B were combined at room temperature for 30 min then 0.8 mL SFM was added to the tube containing the above solutions, and then the mixture was added to rinsed cells. The medium was replaced with a fresh and complete medium after 6 h in transfection. The cells were exposed to irradiation after 36 h in transfection.

Protein determination

TNF α protein was detected using ELISA kit (Genzyme). P16 protein was studied using Western blot analysis and immunocytochemistry (P16 antibody, Boster).

Ionizing irradiation

X-rays of 180 kV and 12 mA with 0.25 mmCu and 1.08 mm Al as filter were given at a dose-rate of 0.8639 Gy/min for doses of 2-20Gy.

Statistical analysis

Student's *t* test was used to determine the difference between groups. *P* values of less than 0.05 were considered statistically significant.

Figure 1 Construction of plasmid pETNF-P16.

RESULTS

TNFα expressions in EC9706 cells transfected with pETNF-P16 after different doses of X-irradiation

EC9706 cells transfected with pETNF-P16 received different doses of X-ray irradiation. The cells of control group were transfected with PIREs1. Eight hours after irradiation, the protein was extracted and TNFα expression was detected by ELISA.

The results showed that TNFα expression in the 2, 4, 10 Gy groups was significantly higher than that in 0 Gy group ($P < 0.05-0.01$) (Figure 2).

Figure 2 TNFα expression in EC9706 cells after irradiation with different doses of X-ray (mean±SD, $n = 3$). ^a $P < 0.05$, ^b $P < 0.01$ vs 0 Gy group.

Figure 3 Expression time course of TNFα in EC9706 cells after 2 Gy of X-ray irradiation (mean±SD, $n = 3$). ^a $P < 0.05$, ^b $P < 0.01$, ^d $P < 0.001$ vs control group.

TNFα and P16 expressions in EC9706 cells transfected with pETNF-P16 at different time points after 2 Gy irradiation

EC9706 cells transfected with pETNF-P16 received 2 Gy of

X-ray irradiation while the control group did not receive. Proteins of TNFα and P16 were isolated at different time points after irradiation and detected by ELISA and Western blot.

ELISA results showed that TNFα expression increased from 2 to 24 h, and reached the peak level at the 24th h, about 7.5 times of control group ($P < 0.01$). TNFα expression in 48 h group was significantly higher than that in control group ($P < 0.001$), but lower than that in 24 h group ($P > 0.05$) (Figure 3).

The results of Western blot analysis showed no P16 expression in cells transfected with PIREs1 plasmid. After 2 Gy X-ray irradiation, P16 expression in the cells transfected with pETNF-P16 plasmid increased between 2 h and 48 h. The expression in the control group was lower than that in 4 h to 48 h groups (Figure 4).

Figure 4 Expression time course of P16 in EC9706 cells after 2 Gy x-ray irradiation Lane 1: transfected with PIREs1 plasmid Lane 2: control group Lane 3: 2 h after irradiation Lane 4: 4 h after irradiation Lane 5: 6 h after irradiation Lane 6: 12 h after irradiation Lane 7: 24 h after irradiation Lane 8: 48 h after irradiation.

Immunocytochemistry

Thirty-six hours after transfected with pETNF-P16 plasmids, EC9706 cells received 2 Gy X-ray irradiation while the control group did not receive. After 24 h, anti-P16 IgG and Biotin-labeled secondary antibody were used to detect the P16 expression in treated cells. P16 protein was positive in the nucleus, cytoplasm and cellular membrane as judged by the brown color.

Immunocytochemical analysis demonstrated that all the normal EC9706 cells had no P16 expression. After transfected with pETNF-P16 plasmid, positive P16 expression in EC9706 cells was detected. Then, the transfected cells received 2 Gy X-ray irradiation and P16 expression remained positive, but morphological changes of EC9706 cells occurred.

DISCUSSION

It was reported that Egr-1 was transcriptionally induced

Figure 5 P16 expression in EC9706 cells transfected with pETNF-P16 plasmid after 2Gy X-ray irradiation. A: Negative control group; B: Untransfected group; C: Transfected group; D: Transfected and irradiated group.

following exposure to irradiation^[2]. Sequences responsive to ionizing radiation-induced signals were determined by deletion analysis of the Egr-1 promoter. The results demonstrated that induction of Egr-1 by X-rays was conferred by serum response or CC (A/T) rGG elements. Further analysis confirmed that the region encompassing the three distal or upstream CC(A/T)rGG elements was functional in X-ray response^[3-5].

Weichselbaum *et al.*^[6] were forerunners in tumor gene-radiotherapy. In 1992 they put forward that ionizing radiation could be used to activate the transcription of exogenous genes encoding cytotoxic proteins, and established the techniques that might be used to target gene therapy during the treatment of human neoplasms.

Combination of gene therapy with radiation therapy could overcome some problems and side effects of either radiation or gene therapy alone, including radioresistance of some tumors and toxicities to normal tissues. Weichselbaum *et al.*^[7] linked DNA sequences from the promoter region of Egr-1 to a cDNA sequence that encoded human tumor necrosis factor (TNF) alpha. Egr-TNF construction was transfected into a human cell line of hematopoietic origin, HL525 (clone 2). The latter was injected into human xenografts of the radioresistant human squamous cell carcinoma cell line SQ-20B. Animals treated with radiation and clone 2 demonstrated an improvement compared with those treated with radiation or injections of clone 2 alone. Thereafter, a variety of downstream genes were introduced to Egr-1 promoter to treat different tumors and similar results were obtained^[8-10].

TNF has complex *in-vivo* anti-tumor actions and involves a series of biochemical reactions, and varies according to host metabolism. It could not only kill tumor cells directly, but also act indirectly by occluding the feeding vessels of tumors, promoting inflammation reaction of the host, stimulating cytotoxic activities of megakaryocytes and producing tumor-specific cytotoxic antibody. Up to now, TNF has been found to have the strongest direct tumor-killing action. However, severe side effects made the effects of systemic treatment unsatisfactory. By contrast, regional administration into the tumor had better therapeutic effects. It has been widely reported that intra-tumor TNF injection had no severe side effects on patients with malignant tumors^[11-12]. We constructed pEgr-TNF α plasmid

and injected it into mouse melanoma locally to induce its expression by X-ray irradiation. The results showed that pEgr-TNF α gene in combination with radiotherapy could significantly inhibit tumor and had no side effects^[13].

P16 is a tumor suppressor gene product. Serrano *et al.*^[14] demonstrated that P16 bound to CDK4 and inhibited the catalytic activity of CDK4/cyclin D enzymes. P16 seemed to act in a regulatory feedback circuit with CDK4, D-type cyclins and retinoblastoma protein. Overexpression of P16 gene could block cell cycle progression through the G₁-to-S phase boundary in a pRB-dependent manner^[15,16]. Many P16 mutants identified from human tumors have been shown to have defects in this activity^[17-19]. These suggested that the CDK4-inhibitory activity of p16 was involved in regulating cell cycle progression through the G₁/S boundary.

On the basis of anti-tumor function of TNF α and P16, we constructed pETNF-P16 plasmid and transfected EC9706 cells to investigate the expression properties of plasmid induced by X-ray irradiation. The results showed that TNF α expression in pETNF-P16-transfected cells induced by irradiation was higher than that in control group ($P < 0.05-0.01$). Time-course studies between 6 h and 48 h after 2Gy irradiation revealed that TNF α expression in X-ray induced groups was higher than that in the control group ($P < 0.05-0.001$). It gradually increased and peaked at the 24th h with the expression level of 7.5 times of control group ($P < 0.01$). Immunocytochemistry showed no P16 expression in the control group, but strong expressions in the transfected and irradiated group. However, the cellular morphology was altered in the latter group and the mechanism is to be clarified.

Esophageal carcinoma still has high morbidity and mortality in China^[20-22], and its treatment is still difficult^[23-30]. Our work might have laid some theoretical basis for further study on esophageal cancer gene-radiotherapy, which should have promising therapeutic potential.

ACKNOWLEDGEMENTS

We are very grateful to Professor Ming-Rong Wang, Institute of Cancer, Chinese Academy of Medical Sciences for his kindness in providing us with the EC9706 cell line.

Abstract

AIM: To characterize the histological types of esophageal and cardiac mucosa by endoscopic survey of a population in a high-risk area of esophageal cancer of China.

METHODS: A selected cohort of residents in Cixian County during December 2001 and May 2002 was surveyed by using Lugol's staining, followed by computer-based statistical analysis of the data with SPSS 10.0 software.

RESULTS: Histologically, the detection rates of squamous epithelial acanthosis, squamous epithelial atrophy, and basal cell hyperplasia in the esophagus were 1.9% (38/2 013), 0.1% (3/2 013) and 0.9% (18/2 013) respectively, and those of mild, moderate, and severe esophagitis were 34.9% (703/2 013), 1.6% (33/2 013) and 0.2% (2/2 013) respectively. Mild, moderate, and severe esophageal dysplasia were detected in 8.6% (172/2 013), 7.8% (157/2 013) and 2.6% (53/2 013) respectively in the selected population, whereas *in situ* carcinoma, intramucosal carcinoma, invasive squamous carcinoma of the esophagus in 2.5% (50/2 013), 0.2% (4/2 013) and 0.7% (14/2 013) respectively. The detection rates of non-atrophic gastritis and atrophic gastritis of the cardia were 36.3% (730/2 013) and 11.5% (232/2 013) respectively, with mild and severe dysplasia of the cardia detected in 2.5% (51/2 013) and 0.8% (17/2 013), respectively, in this population; the rates of intramucosal adenocarcinoma and invasive adenocarcinoma of the cardia were 0.1% (3/2 013) and 0.8% (17/2 013) respectively. The detection rate of esophageal cancer at early stage was 79.4% (54/68). The survey rate (ratio of examined population to expected population) was 73.8% (2 013/2 725).

CONCLUSION: Histologic types of the esophageal and cardiac mucosa were characterized by endoscopic survey in a high-risk population of esophageal cancer, which may help the early detection and treatment of esophageal and cardiac cancers and dysplasia, and reduce the mortality of such malignancies.

INTRODUCTION

Esophageal cancer (EC) is one of the most common malignant tumors with a high incidence in such regions as China, Iran, South Africa, Uruguay, France and Italy^[1], of which China has almost half of the total cases with also the highest mortality rate, the fourth leading cause of cancer-related deaths in China. According to the data derived from 1/10 sample death investigation in the whole population of China in 1990-1992, the mortality rate of esophageal cancer was 27.73/100 000 for men and 13.63/100 000 for women, which were 3.1 and 3.6 times, that reported by the World Health Organization (WHO) in 1998 respectively^[2]. Some southern regions of the Taihang Mountains on the borders of Henan, Shanxi and Hebei provinces have significantly higher mortality rates of esophageal cancer. Cixian County in Hebei Province is also one of the areas with the highest mortality rate in China, where an endoscopic survey was conducted by Hebei Cancer Institute during the period between December 2001 and May 2002, and in this paper the results are reported.

MATERIALS AND METHODS

Cixian County is located at 36.30° northern latitude, 114.40° eastern longitude, on the east side of the Taihang Mountains along the Zhanghe River. It occupies an area about 1 014 square kilometers with a population of 634 470. This region contains greatly diverse geographic conditions, ranging from mountainous, hilly regions to long-stretched plains, each constituting about one-third of its total area. The climate is mainly under the influence of the warm seasonal wind from the mainland, with an annual average temperature of 18-25 °C and a rainfall between 600-700 mm. The dominant brown and light-colored soil yields mainly such farm products as wheat, corn, millet, rice, sweet potato and beans. Iron and coal are the main mineral resources, and the residents use coal mainly for daily cooking and heating^[3].

As a key science research project sponsored by the National Tenth Five-Year Plan of China, the survey was conducted among the residents of 9 villages aged between 40 and 69 years in the hilly region of Cixian County, which is known for a higher incidence of esophageal cancer than the plain regions. The total population of the 9 villages was 12 048, and the annual incidence and mortality rate of esophageal cancer in this region during 1996-2000 were 176.0/100 000 and 126.2/100 000 respectively.

Before the survey, a county-wide conference was convened by the local government participated by the local county, countryside and village leaders and cancer prevention professionals. At the conference, special committees were set up at each of the 3 administrative levels to be responsible for the execution of the survey in the areas where they perform daily duties. After the conference, the residents in the target areas were acknowledged of the benefits of such a massive survey through a propaganda campaign. On the basis of the government record of the residents, 2 000 potential target subjects from the 9 villages were selected by the cancer prevention professionals, and two days prior to the survey, personal contacts with the subjects were made by local physicians to arrange for the details of the survey. At the

beginning of the survey, the subjects were asked to fill an epidemiological questionnaire, followed by physical examination performed by the physicians to exclude persons with serious contraindications to endoscopy. Endoscopic examinations were then performed by specialists following the procedures described by Wang *et al.*^[4]. The detailed results were recorded and the biopsy specimens obtained were fixed in 80% alcohol and stained by hematoxylin-eosin (HE) for subsequent pathological diagnosis by pathologists.

Finally, the data were input into a computer to set up a survey information database and statistical analysis was performed using SPSS 10.0 software with chi-square test.

RESULTS

Survey rate

Of the totally 12 048 residents of the 9 villages, 2 992 were within the age range between 40 and 69 years, and after exclusion of 267 residents with contraindications (including 32 patients with cancer, 22 with heart diseases, 29 with cerebrovascular diseases, 55 with hypertension, 56 with other diseases, 59 already died, and 14 emigrants), the total number of subjects enrolled in this survey was 2 013 (including 973 male and 1 040 female subjects, with the male to female ratio of 0.94:1), and the survey rate was therefore 73.8% (Table 1).

Endoscopic findings of the esophagus

As shown in Table 2, the histologic detection rates of *in situ* carcinoma, intramucosal carcinoma, and invasive squamous carcinoma were 2.5% (50/2013), 0.2% (4/2013), and 0.7% (14/2013), respectively; early cancerous changes were detected in 2.7% (54/2013) of the subjects, which occupied 79.4% (54/68) of total esophageal cancer cases. Male subjects had comparable incidence of esophagitis [35.9% (349/973)] with that in female subjects [37.6% (391/1 040), $\chi^2 = 0.645$, $P = 0.422$], but had significantly higher incidence of dysplasia [23.1% (225/973) vs 15.1% (157/1 040) in female, $\chi^2 = 21.072$, $P = 0.000$]. The incidence of esophageal cancer did not vary significantly between the male and female subjects [3.3% (32/973) vs 3.5% (36/1 040), $\chi^2 = 0.001$, $P = 0.98$].

Table 3 shows that with a 5-year increase in age, the histologic incidence of esophageal cancer and dysplasia all tended to be increased from the relatively low level in the 40-year-old group to the highest in the 65-year-old group (trend $\chi^2 = 135.943$, $^aP = 0.000$; trend $\chi^2 = 182.782$, $^bP = 0.000$). The rates of esophagitis in different age groups varied significantly ($\chi^2 = 12.475$, $P = 0.029$), as well as the rates of dysplasia ($\chi^2 = 141.184$, $P = 0.000$), and esophageal cancer ($\chi^2 = 74.855$, $P = 0.000$).

Table 2 Detection rates of the histologic changes in the esophagus (%)

Type	Male (%)	Female (%)	Total (%)
Normal squamous epithelium	308 (31.7)	392 (37.7)	700 (34.8)
Squamous epithelial acanthosis	19 (2.0)	19 (1.8)	38 (1.9)
Squamous epithelial atrophy	1 (0.1)	2 (0.2)	3 (0.1)
Esophagitis			
Mild	337 (34.6)	366 (35.2)	703 (34.9)
Moderate	11 (1.1)	22 (2.1)	33 (1.6)
Severe	1 (0.1)	3 (0.3)	4 (0.2)
Dysplasia			
Mild	114 (11.7)	58 (5.6)	172 (8.6)
Moderate	82 (8.4)	75 (7.2)	157 (7.8)
Severe	29 (3.0)	24 (2.3)	53 (2.6)
<i>In situ</i> carcinoma	25 (2.6)	25 (2.4)	50 (2.5)
Intramucosal carcinoma	2 (0.2)	2 (0.2)	4 (0.2)
Invasive carcinoma	5 (0.5)	9 (0.9)	14 (0.7)
Others	31 (3.2)	33 (3.2)	64 (3.2)
Total	973 (100.0)	1040 (100.0)	2013 (100.0)

Endoscopic findings of the gastric cardia

The incidence of cardiac cancer was much lower than that of esophageal cancer ($\chi^2 = 26.767$, $P = 0.000$), and early cardiac cancer only occupied 15% (3/20) of cardiac cancer cases. The rates of gastritis involving the cardia were 44.5% (433/973) in male and 50.8% (529/1 040) in female subjects, showing significant difference between them ($\chi^2 = 8.159$, $P = 0.004$). The rates of dysplasia also varied significantly between them [4.9% (48/973) in male vs 1.9% (20/1 040) in female, $\chi^2 = 13.955$, $P = 0.000$], but not that of cardiac cancer, [1.3% (13/973) in male vs 0.7% (7/1 040) in female, $\chi^2 = 2.246$, $P = 0.134$], as shown in Table 4.

At a 5-year interval, the incidence of cardiac cancer and dysplasia both increased from the level in the 40-year-old group to the highest in the 65-year-old group (trend $\chi^2 = 84.875$, $^aP = 0.000$; trend $\chi^2 = 36.209$, $^bP = 0.000$, Table 5). The rates of gastritis involving the cardia and dysplasia of the cardia also varied significantly ($\chi^2 = 11.223$, $P = 0.047$; $\chi^2 = 18.901$, $P = 0.002$), as well as that of cardiac cancer ($\chi^2 = 43.351$, $P = 0.000$).

Table 1 Statistics of the residents of the 9 target villages enrolled in this survey

Village	Total population	Aged between 40-69 (yr %)	Contraindication	Expected population	Examined population	Survey rate (%)
Hebei Village	1 184	304 (25.7)	29	275	220	80.0
Taichen Village	1 648	412 (25.0)	39	373	287	76.9
Xichengji Village	1 682	381 (22.7)	53	328	283	86.3
Zhonghao Village	699	183 (26.2)	23	160	130	81.3
Donghao Village	1 860	494 (26.6)	26	468	208	44.4
Chejiao Village	1 618	383 (23.7)	38	345	276	80.0
Bai Village	1 679	415 (24.7)	27	388	284	73.2
Donghelan Village	1 076	271 (25.2)	17	254	208	81.9
Xihelan Village	602	149 (24.8)	15	134	117	87.3
Total	12 048	2 992 (24.8)	305	2 725	2 013	73.8

The percentages in bracket indicate the rates of the population aged 40-69 years.

Total	973 (100.0)	1 040 (100.0)	2 013 (100.0)

DISCUSSION

The prognosis of esophageal and cardiac cancer is the poorest among the patients with digestive carcinomas as more than 90% of them are not clinically identified until at an advanced stage, when surgery is defied due to either local tumor invading the surrounding tissues or distant metastasis, and therefore the 5-year survival rate of esophageal cancer is below 10%^[5-7]. Early-stage asymptomatic esophageal cancer is basically curable with, for instance, conventional surgery and endoscopic resection, resulting in a 5-year survival rate of the patients reaching 90% or above^[8-10].

For esophageal cancer prevention and treatment, a series of systematic researches including clinical, laboratory and field investigation were carried out in high-risk areas such as Linxian and Cixian counties since 1959^[11-16], but at present the etiological factors have not yet been identified, and the incidence and mortality rates of esophageal cancer still remain high in those areas. A variety of detecting methods have been attempted by Chinese scientists to identify early esophageal cancer and precancerous lesions, such as exfoliative balloon cytology (EBC), occult blood bead (OBB), conventional endoscopy with

Others	75 (9.5)	71 (15.5)	73 (22.6)	56 (24.9)	43 (28.9)	15 (22.4)
Total	792 (100.0)	458 (100.0)	322 (100.0)	225 (100.0)	149 (100.0)	67 (100.0)

smear or biopsy, sparse hydrochloric acid preliminary screening, serum total salic acid detection (TSA), otolaryngologic examination and so forth, but all these methods are marred by certain disadvantages besides their respective advantages in the early detection of esophageal cancer and precancerous lesions^[17-19].

A massive screening in the population of 126 187 in Cixian was carried out by Hebei Cancer Institute and 16 748 high risk participants aged 40 years and older were screened with exfoliative balloon cytology, the survey rate was 71.4%, resulting in the identification of 179 cases of esophageal cancer, 172 esophageal precancerous lesions, 866 stage II severe esophageal epithelial dysplasia (SEED II), 3 179 stage I severe esophageal epithelial dysplasia (SEED I) and 5 346 mild esophageal epithelium dysplasia (MEED), with the detection rates of MEED, SEED I, SEED II, esophageal precancerous lesions and esophageal cancer being 31.92%, 18.98%, 5.17%, 1.03% and 1.07%, respectively^[20]. Most of the researches indicate that exfoliative balloon cytology is an effective, economic and practicable method, having higher detection rate for esophageal cancer than conventional endoscopy, but only cytological diagnosis is obtained and a further endoscopic biopsy and histopathologic confirmation are necessary. This method is now insufficient for esophageal cancer screening because of the severe discomfort and low acceptance by the target subjects.

Esophageal chromoendoscopy with multi-point biopsy and histopathologic examination has developed rapidly since 1974, which greatly increased the detection rate of esophageal cancer and precancerous lesions, and at the same time it is capable of characterizing and defining the scope of the lesions to provide guidance for treatment and follow-up, also suitable for the secondary prevention of esophageal cancer^[4,21-33]. Currently the secondary prevention with early detection, early diagnosis and early treatment through chromoendoscopy survey has become the major research concern in the prevention and control of esophageal cancer.

The occurrence and development of esophageal cancer is a slow process involving multiple factors and genes and undergoing multiple stages. Prior to cancerization of the squamous esophageal epithelium, the basal cell hyperplasia or simple hyperplasia takes place and evolves into mild, moderate, severe dysplasia cells that develop, in sequence, into *in situ* carcinoma, early invasive cancer and advanced cancer^[34-36]. As a part of the entire research project, a massive esophageal chromoendoscopic survey was initially conducted in the high-risk area without preliminary screening, and the high survey rate reaching 73.8% indicates that the population's compliance to the survey was high after adequate health education. The distribution of histologic types of the esophageal and cardiac mucosa in high-risk area can be accurately obtained by esophageal chromoendoscopic survey, which possesses the advantage of accurate pathologic diagnosis and differentiation of the histologic types, well defined scope of the lesions and their invasive depth.

This study will, after defining the incidences of the pathological changes of the esophageal and cardiac mucosa in the population, contribute to the early treatment of esophageal and cardiac cancer and dysplasia, increase their cure rates, and reduce the mortality of such malignancies.

Abstract

AIM: To detect the genetic alteration and abnormal expression of cyclin D1 in gastric carcinoma and investigate its clinicopathologic significance in advanced gastric carcinoma.

METHODS: Proteins of cyclin D1 were detected by immunohistochemistry in 42 cases of advanced gastric carcinoma with their follow-up data available, 27 cases of early stage carcinoma, 21 cases of gastric adenoma, 22 cases of hyperplastic polyp and 20 cases of normal mucosa adjacent to adenocarcinomas. Genetic alteration of cyclin D1 was detected by Southern blot and expression of cyclin D1 mRNA was detected by PT-PCR in 42 cases of advanced gastric carcinoma.

RESULTS: Cyclin D1 protein was not expressed in normal mucosa, hyperplastic polyp and gastric adenoma, while it was only positively expressed in gastric carcinoma. The expression rate of cyclin D1 protein in early stage gastric carcinoma, advanced gastric carcinoma and lymph node metastasis was 48.1%, 47.4% and 50.0%, respectively. The amplification of cyclin D1 gene was detected in 16.6% of advanced gastric carcinomas. The overexpression of cyclin D1 mRNA was detected in 40.5% of the samples. There was no significant correlation between cyclin D1 protein expression and age, lymph-node metastasis and histological grading in patients with advanced gastric carcinoma ($\chi^2 = 0.038, 0.059, 0.241, P > 0.05$). Significant correlation was observed between the expression of cyclin D1 protein and the 5-year survival rate ($\chi^2 = 3.92, P < 0.05$).

CONCLUSION: Detection of cyclin D1 protein by immunohistochemistry may be useful in the diagnosis of early gastric carcinomas. Patients with positive expression of cyclin D1 protein tend to have a worse prognosis.

INTRODUCTION

Hyperplasia is an essential characteristic of malignant tumors.

Close attention has been paid to the role of cell-cycle regulators associated with cell proliferation in oncogenesis. Under the stimulation of proliferation signals, cells could produce early stage transcription factors such as *c-fos*, *c-jun*. These factors could bind to DNA specifically in nuclei and initiate cell cycles^[1]. During the cell cycle, the progression from G1 phase to S phase (DNA synthesis phase) is essential for initiation of the cell cycle^[2]. Cyclin D1, a protooncogene identified in recent years, plays a positive-regulation role in the progression^[3]. The expression of cyclin D1 is an early event that is stimulated by growth factors or other mitogens. The major targets of cyclin D1-Cdk complexes are the retinoblastoma family of protein Rb^[4]. Phosphorylation of Rb in mid-G₁ leads to the release of active forms of the E2F family of transcription factors. Free E2F mediates transcription of E2f-dependent genes, including DNA polymerase, thymidine kinase^[5]. The role of cyclin D1 in the oncogenesis of gastric carcinoma is worth investigating^[6]. So far, there are few reports about the alteration of cyclin D1 in gastric carcinoma in China. In order to understand the alteration of cyclin D1 in gastric carcinoma, the protein expression of cyclin D1 in normal mucosa, hyperplastic polyp, adenoma, early stage carcinoma and advanced carcinoma of stomach was detected by immunohistochemistry. Genetic amplification and mRNA expression of cyclin D1 in advanced gastric carcinoma were detected by Southern blot and PT-PCR. The expression of cyclin D1 was also investigated in combination with other prognostic markers in advanced gastric cancer, such as patient's age, LN metastasis, histological grade and 5-year survival rate.

MATERIALS AND METHODS

Tissue specimens

Tissues from 132 cases were collected in Qilu Hospital of Shandong University. They included 42 cases of advanced gastric carcinoma with their follow-up data available (among them 16 cases had lymph node metastasis), 27 cases of early stage carcinoma (among them 7 cases had carcinomas *in situ*, the other 20 cases had early infiltrating carcinomas), 21 cases of gastric adenoma, 22 cases of hyperplastic polyp, 20 cases of normal mucosa adjacent to adenocarcinomas. All samples were fixed in 40 g/L formaldehyde and embedded in paraffin for histological diagnosis and immunohistochemistry study. Fresh tissues from advanced gastric carcinoma were obtained and stored in liquid nitrogen for DNA and RNA analyses.

Immunohistochemical staining

Immunohistochemistry was performed by the labeled streptavidin biotin (LSAB) method by using vectastain Elite kit (vector, Burlingame, CA). Monoclonal antibody to cyclin D1 was used at 1:100 dilution. The technique was performed as described^[6] except for an antigen retrieval step. Sections were placed in plastic coplin jars containing 10 mmol/L citrate buffer and heated in microwave oven for 10 min at 675 W for antigen retrieval. A positive section produced in preparative experiments was used as positive control.

Detection of cyclin D1 mRNA by reverse transcription polymerase chain reaction (RT-PCR)

Total RNA from cells was extracted by using acid guanidinium-phenol-chloroform as described^[7] and converted to single-strand cDNA by using random 9 mers. PCR was performed by using a thermal cycler as described^[8]. The sequence of primer for cyclinD1 was: 5'-CTGGAGCCCCGTGAAAAAGAGC-3', 5'-CTGGAGAGGAAGCGTGTGAGG-3'. A 10 µL of each mixture was analysed by electrophoresis on 20 g/L agarose gel. Each band was quantitated by gel figure analysis system (Alpha, No.IS-1220). β-actin was used as control. The sequence of primer for β-actin was: 5'-CTACAATGAGCTGCGTGTGGC-3', 5'-CAGGTCCAGACGCAGGATGGC-3'. CyclinD1 index = cyclin D1 data /β-actin data.

Detection of genetic alteration of cyclin D1 by Southern blot

Nucleic acids were prepared by the guanidinium thiocyanate method as described^[9]. Sample DNA (5 µg) was digested with restriction endonuclease *EcoR* I and fractionated by electrophoresis on 20 g/L agarose gel. The gel was denatured and DNA was transferred to nitrocellulose filters. The probe used for detection of cyclin D1 was 18-mer of oligodeoxynucleotide complementary to the initial stretch of bases in cyclin D1 mRNA from -1 to +17. The probe was labeled by 32p-dCTP. The filters were prehybridized and hybridized in conditions as described^[10], dried and exposed at -70 °C with intensifying screen for various periods of time to XAR5 Kodak films. β-actin was used as control for DNA loading amount, and normal tissue near carcinoma was used as normal control.

Statistical analysis

χ² test was used to evaluate the differences between two groups.

RESULTS

Expression of cyclin D1 protein in gastric carcinomas and its correlation with other prognostic factors

The cyclin D1 immunohistochemical signal was located exclusively in nuclei (Figure 1A) and variable in terms of staining intensity and the proportion of positive nuclei among the cells of an individual case. One thousand tumor cells in 10 visual fields chosen randomly were counted for each case. The case was defined as positive if the proportion of stained cells was more than 10% of the tumor cells. In 20 cases of normal mucosa, 22 cases of hyperplastic polyp and 21 cases of gastric adenoma (Figure 1A), only weak to undetectable staining was seen and no one was defined as positive. On the other hand, 13/27 (48.1%) cases of early stage gastric carcinoma (Figure 1B), 20/42 (47.6%) cases of advanced gastric carcinoma (Figure 1C), 8/16 (50.0%) cases of lymph node metastasis were defined as positive. There was no significant difference among the positive rates of them (Table 1, $P>0.05$). In the 20 cases of carcinoma with early stage infiltration, there was a good consistency of cyclin D1 expression between the *in situ* components and infiltration components. Seventeen cases showed the same immunostaining pattern in two components (85.0%). In the 16 cases of carcinoma with lymph node metastasis, 12 cases showed the same cyclin D1 immunostaining pattern in metastasis as in its primary lesion (75.0%).

Positive expression of cyclin D1 was observed in 9/24 (37.5%) patients who survived 5 years after operation. While in patients who died within 5 years, 11/18 (61.5%) cases had positive expression. There was a significant difference between the two groups (Table 1, $\chi^2 = 3.92$, $P<0.05$). No significant correlation was observed between cyclin D1 protein expression and age, lymph-node metastasis, histological grading in patients with advanced gastric carcinoma (Table 2, $\chi^2 = 0.038$, 0.059,

0.241, $P>0.05$).

Table 1 Cyclin D1 expression in early stage gastric carcinoma (EC), advanced gastric carcinoma (AC) and lymph node metastasis (LNM) and five-year survival

Cyclin D1	EC	AC	LNM	5-year survival rate	
				Alive	Dead
Positive	13	20	8	9	11
Negative	14	22	8	15	7
Total	27	42	16	24	18

Table 2 Relationship between cyclin D1 expression with age, lymph node metastasis (LDM) and histological grades (HG) in patients with advanced gastric carcinoma

Cyclin D1	Age (yr)		LDM		HD		
	>60	<60	Positive	Negative	I	II	III
Positive	14	6	8	12	5	11	5
Negative	16	6	8	14	4	12	4

Abnormal expression of cyclin D1 mRNA and genetic alteration of cyclin D1 gene in advanced gastric carcinoma

The amplification products of cyclin D1 and β-actin by RT-PCR were 434 bp and 206 bp respectively. Overexpression of cyclin

D1 mRNA (Figure 2) was observed in 17/42 cases (40.5%) and all these cases showed positive expression of cyclin D1 protein.

Figure 2 Overexpression of cyclin D1 mRNA detected by RT-PCR. M: marker; 1: Normal control; 3, 6, 7: Overexpression of cyclin D1 mRNA.

The level of amplification was estimated by densitometric tracing of the 4.0 kb cyclin D1 fragments of carcinomas and normal tissue. In this study, 7/42 (16.6%) cases had cyclin D1 gene amplification (2 to 4 fold), which also showed positive expression of cyclin D1 protein and overexpression of cyclin D1 mRNA. No gene rearrangement of cyclin D1 was observed in our study (Figure 3).

Figure 3 Genetic alteration of cyclin D1 in advanced gastric carcinoma detected by Southern blot. M: DNA marker; 1: Normal control; 6: Cyclin D1 gene amplification.

DISCUSSION

Cyclin D1 gene is located in the 11q13 region. Cyclin D1 protein consists of 295 amino acids, its function in normal cells is to regulate the progression through G1 phase of the cell cycle in combination with CDKs by phosphorylation of pRb. In normal human tissues, the expression of cyclin D1 protein was rather low and negative by immunohistochemistry^[11]. In our study, no one was positive in normal mucosa adjacent to adenocarcinomas. Negative staining was also observed in hyperplastic polyp and gastric adenoma. However, in 33/69 (47.8%) cases of gastric carcinoma, including 42 cases of advanced gastric carcinoma and 27 cases of early stage carcinoma, the expression of cyclin D1 was positive. The detection of cyclin D1 protein by immunohistochemistry is helpful in the diagnosis of early stage gastric carcinoma and could distinguish these cases from hyperplastic polyp. The expression of cell cycle regulators could be used as prognostic markers in some malignant tumors. Some studies showed that the positive expression of cyclin D1 was statistically associated with well-differentiated tumors^[12]. In our study, the expression of cyclin D1 protein had no correlation with age, lymph node metastasis and histological grading of the patients. But a significant correlation was observed between cyclin D1 expression and 5-year survival rate. The patients

with positive expression of cyclin D1 tended to have a worse prognosis.

Bartkora revealed a very good correlation in the expression of cyclin D1 between the *in situ* components and the invasive components of carcinoma^[13]. Our results were in accordance with it. In our study, the positive rates of cyclin D1 protein in early stage carcinoma, advanced gastric carcinoma and lymph node metastases were similar, with no significant difference among them. A very high degree of consistence was found in the same section of early stage carcinoma between carcinoma *in situ* and its infiltration component (89.5%). The consistence between primary tumors and lymph node metastases in the same patient with advanced gastric carcinoma was also high (75.0%). These results suggested that positive expression of cyclin D1 protein might be an early event in gastric carcinoma pathogenesis, and it tended to maintain stable throughout the progression of infiltration and metastasis.

Genetic alteration of cyclin D1 was observed in several kinds of human tumors such as breast carcinoma^[14], squamous cell carcinoma of the lung^[15], endometrial carcinoma^[16] and malignant gliomas^[17]. Yang *et al.*^[18] reported that a characteristic translocation, t(11:14)(q13;q32) involving rearrangement of cyclin D1 gene, was detected in centrocytic lymphoma and could be used in its diagnosis. In this study, cyclin D1 gene amplification accompanying positive expression of cyclin D1 protein and overexpression of cyclin D1 mRNA in advanced gastric carcinoma was observed in 7/42 (16.6%) cases. The expression rate of cyclin D1 protein (47.4%) was significantly higher than that of cyclin D1 gene amplification (16.6%). It was similar to the overexpression rate of cyclin D1 mRNA (42.1%). We considered that the expression of cyclin D1 protein was affected more directly by mRNA level rather than gene level. Besides gene amplification, other factors including alteration in cyclin D1 promoter or abnormal regulation by transcription factors could both up-regulate the expression of mRNA and induce more cyclin D1 protein production. The discrepancy between the expression rates of cyclin D1 mRNA and protein might be caused by stroma cells in tumor tissues, which make the overexpression rate of cyclin D1 mRNA lower.

Abstract

AIM: The conception of quality of life has been widely accepted by clinic doctors. Evaluations of the treatment effect of chronic diseases have been changed to depend not only on the survival time, but also on the quality of life of the patients. Fuzhou City and Changle County are high-incidence areas of the gastric cancer in Fujian Province. The aims of this research were to compare the quality of life of urban patients with that of rural patients and analyze the factors influencing quality of life of gastric cancer patients in Fujian Province.

METHODS: The samples were drawn with cluster sampling. The urban sample consisted of 162 patients aged 25 to 75 with 143 males and 19 females. The rural sample consisted of 200 patients aged 32 to 78 with 166 males and 34 females. The patients in both the urban and rural areas were investigated, and their scores on 21 items reflecting the quality of life were measured. The methods of *t* test and stepwise regression were used to analyze the data.

RESULTS: The average total scores of quality of life of the urban patients and rural patients were 64.11 and 68.69 respectively. There was a significant difference between the means of two samples ($P = 0.0004$). Seven variables in the regression model estimated by the urban sample and 4 variables in the model by the rural sample were at the level of significance $\alpha = 0.05$. Family income, nutrition and rehabilitative exercise were selected into both the urban and rural regression models.

CONCLUSION: Most of the gastric cancer patients have poor quality of life in Fujian Province and the rural patients have lower quality of life than that of urban patients. The patients having more family income have better quality of life, and enhanced nutrition and doing rehabilitative exercise are helpful in improving the quality of life of the gastric cancer patients.

INTRODUCTION

Along with the changes of medical pattern and health care practice, evaluations of the treatment effect of chronic diseases have been changed to depend not only on the survival time, but also on the quality of life of the patients. The quality of life of a person is his personal feeling in sections of physiology, psychology and society^[1,2]. The quality of life of the cancer patients can reflect not only treatment effect but also rehabilitation effect, so it has attracted much attention since 1980. Many studies have been done regarding the quality of life of the cancer patients in western countries and Japan^[3-8], and there also have been several relevant studies in China^[9-11]. Another important aspect of research on the quality of life is analyzing factors influencing the quality of life. Since many factors can impact on the quality of life of the cancer patients, it is important to analyze which factors may be related to the quality of life in order to improve the quality of life of the patients. Fuzhou City and Changle County are high-incidence areas of gastric cancer in Fujian Province. Every year, there are many new cases reported in the two areas^[12]. A lot of efforts have been made in prevention and treatment of gastric cancer. However, little attention has been paid to the quality of life of the gastric cancer patients and few studies have been done on how to improve the quality of life of the patients. In order to understand the levels of quality of life of the gastric cancer patients in Fujian Province, we made an epidemiological survey from May 1999 to July 1999. In this paper, we describe the levels of the quality of life of the urban patients and rural patients, compare the quality of life of the urban patients with that of the rural patients, and analyze the factors influencing the quality of life. The results of this research may be useful to doctors and nurses in the community health center to help improve the quality of life of the gastric cancer patients.

MATERIALS AND METHODS

Materials

The populations of the gastric cancer patients diagnosed between 1997 and 1998 were provided by the Tumor Registration Office of Fujian Province. The samples were drawn from the populations with cluster sampling. All of the gastric cancer patients in the urban sample were residents in Fuzhou City and diagnosed by the provincial-level hospitals. The patients in the rural sample were residents in Changle County and diagnosed by the county-level above hospitals. All of the patients in the two samples had survived for no less than one year.

Methods

The questionnaire was composed of two sections, one with 16 items related to the disease, treatment and rehabilitation of the gastric cancer patients (Table 1), and the other with 21 items related to the quality of life of the patients (Table 2). Each of the 21 items of survival quality was scored from 1 to 5 indicating the function from the worst to the best. The internal consistency and stability index, Cronbach $\alpha = 0.9866$, confirmed the reliability of the 21 items describing the quality of life. The investigators

Table 1 List of factors that may affect the quality of life of gastric cancer patients

Factor	Definition			
Gender	Male	1	Female	2
Age (yr)				
Marital status	Single	1	Married	2
	Divorced	3	Widowed	4
Education	Primary school	1	Middle school	2
	High school	3	University	4
Family income (per capita, Yuan)				
Medical insurance	Yes	1	No	0
Clinical stage of tumor	1-4			
Survival time (mo)				
Surgery	2/3 gastrectomy 1, 4/5 gastrectomy 2, total gastrectomy 3			
Number of chemotherapy programs				
Time from the latest chemotherapy to the enrollment (mo)				
Treatment of traditional Chinese medicine	Yes	1	No	0
Home nursing staff	Spouse	1	Other relatives	2
	Housekeepers	3	None	4
Chemotherapy	Yes	1	No	0
Enhanced nutrition	Yes	1	No	0
Rehabilitating exercise	Yes	1	No	0

visited the patient's family and asked the patient to complete the questionnaire except the contents of the disease stage and treatments which were collected from the medical records at the hospitals. The scores for the individual items shown in Table 2 were summed to produce a 'total score', representing the quality of life of each patient.

Numerical descriptive statistics were used in summarizing the total score of quality of life in urban patients and rural patients respectively, *t* test was used for testing the difference between the means of two samples and stepwise regression^[13] was used for analyzing the factors influencing quality of life. SAS software package was used for all analyses^[14].

Table 2 The 21 parameters of the quality of life

Items		Items	
1	Sleep	12	Knowledge of cancer
2	Range of activities	13	Mental status
3	Eating	14	Fear of disease
4	Ability of using traffic vehicles independently	15	Psychological pain
5	Ability of body movement	16	Connection with relatives and friends
6	Ability to live independently	17	Social contact
7	Housework	18	Disappointment
8	Pain	19	Confidence of fighting the disease
9	Recreational activities	20	Intellectual activities
10	Watching TV or listening to radio	21	Attitude towards treatment
11	Interest or hobby		

RESULTS

Description of samples

The urban sample consisted of 162 patients aged 25 to 75. There were 143 male and 19 female patients in the urban sample, about 88.3% and 11.7% of the urban sample size respectively. The rural sample consisted of 200 patients aged 32 to 78. There were 166 male and 34 female patients in the rural sample, about 83.0% and 17.0% of the rural sample size respectively. In the urban sample, the workers represented 42.6% and government functionaries took up 23.5%. All of the patients in the rural sample were peasants.

The quality of life

The distributions of total scores of urban patients and rural patients are shown in Table 3. Among the urban patients, the highest score was 96 and the lowest score 22, and 36.42% of the patients, the largest group, had total scores between 70 and 80 and 1.23%, the smallest group, had total scores between 90-105. Among the rural patients, the highest score was 81 and the lowest score 19, and 34.5% had total scores between 60 and 70 and none had a total score between 90-105. Table 4 shows the means and standard deviations of the total scores of the urban and rural patients. The difference of total scores between the urban and rural patients was significant ($P = 0.0004$). These results suggest that most of the gastric cancer patients had poor quality of life in Fujian Province and the qualities of life of rural patients were worse than those of urban patients.

Table 3 Distributions of total scores in urban patients and rural patients

Total score	Urban		Rural	
	<i>n</i>	Percentage (%)	<i>n</i>	Percentage (%)
<30	3	1.85	4	2.00
30-	3	1.85	6	3.00
40-	8	4.94	16	8.00
50-	17	10.49	54	27.00
60-	43	26.54	69	34.50
70-	59	36.42	41	20.50
80-	27	16.67	10	5.00
90-105	2	1.23	0	0.00

Table 4 Means and standard deviations of total scores in the two samples

	Number of the patients	mean	SD	95% confidence interval
Urban	162	68.69	12.98	66.69-70.69
Rural	200	64.11	11.29	62.54-65.67
		$t = 3.5885$	$P = 0.0004$	

Factors influencing the quality of life

The relationship between the total scores, also called dependent variables, and the factors shown in Table 1, also called independent variables, was analyzed by using method of stepwise regression.

Setting the level of significance $\alpha = 0.05$, we had the result

of regression analysis with urban patients (Table 5). Table 5 shows the factors influencing quality of life of gastric cancer patients and the regression coefficients. This result suggests that the factors related to the total score of urban patients were age ($P = 0.0001$), family income ($P = 0.0032$), clinical stage of the tumor ($P = 0.0375$), the time from the latest chemotherapy to the enrollment ($P = 0.0095$), home nursing staff ($P < 0.0001$), enhanced nutrition ($P = 0.0431$) and rehabilitative exercise ($P = 0.0115$). As indicated by the regression coefficients, the quality of life of elder patients was worse than that of the younger ones, the patient in the early stage of gastric cancer had a better quality of life than that in the late stage and patients with a longer time period from the latest chemotherapy to the enrollment had a better quality of life than one with a shorter time period.

Table 5 Results of stepwise regression with urban patients

Variable	Regression coefficient	SEM	<i>t</i>	<i>P</i>
Age (yr)	-0.10620	0.02654	-4.00	0.0001
Family income	1.11909	0.36949	3.03	0.0032
Clinical stage of the tumor	-1.10772	0.52498	-2.11	0.0375
Time from the latest chemotherapy to the enrollment	0.09199	0.03876	2.37	0.0095
Home nursing staff	-2.98233	0.57659	-5.17	<0.0001
Enhanced nutrition	1.80669	0.88221	2.05	0.0431
Rehabilitating exercise	1.01185	0.39245	2.58	0.0115

At $\alpha = 0.05$, the results of regression analysis of the rural patients are shown in Table 6. The results suggested that the factors related to the total score of rural patients were family income ($P = 0.0193$), surgical operation ($P < 0.0001$), enhanced nutrition ($P = 0.0488$) and rehabilitative exercise ($P = 0.0125$). Based on regression coefficients, patients with total gastrectomy had a worse quality of life than those with a partial gastrectomy.

Table 6 Results of stepwise regression with rural patients

Variable	Parameter estimated	SEM	<i>t</i>	<i>P</i>
Family income	1.0860	0.45974	2.36	0.0193
Surgery	-14.24462	2.77803	5.12	<0.0001
Enhanced nutrition	-2.73243	1.37834	1.98	0.0488
Rehabilitating exercise	-2.20909	0.87618	2.52	0.0125

Three factors: family income, nutrition and rehabilitative exercise, in both regression models, might be important for improving the quality of life of the gastric cancer patients. The patients having more economic incomes had a better quality of life, and increased nutrition and doing rehabilitative exercise are helpful in improving the quality of life of the gastric cancer patients.

DISCUSSION

Traditionally, the effects of treatments were evaluated by such quantitative indexes as survival rate, survival time and the volumes of tumors. The conception of quality of life is proposed, along with the changes of medical and health care practice patterns and progress of medical science. It is used to evaluate the effects of treatments for chronic diseases and cancers. The purpose of this study was to obtain the information about quality of life of gastric cancer patients in Fujian Province and explore which factors impacted on the quality of life of gastric cancer patients.

For most of gastric cancer patients, the prognosis and their qualities of life were poor since the cancers had been in advanced stages when they were diagnosed^[15,16]. Our results show that most of the gastric cancer patients have low quality of life in Fujian Province, and the quality of life of rural gastric cancer patients are worse than that of urban patients. It may be that the rural patients suffered more physical and psychological pain because of their lower levels of education and economic income compared with the urban patients.

Some researchers held that patient's nutritional status played a critical role in maintaining a positive quality of life from both physical and emotional points of view^[17-20]. Nutrient depletion adversely affects immune function, the patient's enjoyableness and social interactions with family and friends, which can further depress appetite^[17]. Low hemoglobin levels were associated with fatigue, poor overall quality of life, and decreased ability to work. Interventions that reverse fatigue and other anemia-related symptoms should have a positive effect on quality of life^[19]. Our results also showed that improved nutrition was one of the factors influencing quality of life both in rural and urban areas. This may suggest that appropriate nutritional care can help maintain the patient's body weight and protein status, reduce fatigue and improve quality of life.

Rehabilitating exercise has been thought to be a factor influencing quality of life of breast cancer patients. A review on 24 studies dealing with physical exercise and quality of life of cancer patients published between 1980 and 1997 demonstrated that physical exercise had a positive effect on quality of life including physical, functional, psychological, and emotional well-being^[21-27]. In our research, rehabilitating exercise was related to quality of life of gastric cancer patients, which is consistent with previous researches. Not only can taking rehabilitating exercise improve the patient's body function, but it can also please his mood, strengthen his confidence of defeating the disease and improve his ability of contacting society.

Our results also showed that the quality of life of urban patients could be affected by the home nursing staff and rural patients affected by the surgery. The psychological status of the nursing staff may have more influence on the physiological and psychological functions of the patient. Good nutritional care for the patient requires full support from the home nursing staff^[28-32]. Patients who have been given a partial gastrectomy achieved a better quality of life than those having a total gastrectomy. When the entire gastric is removed, the patients should adjust to a different eating schedule involving eating small quantities of food more frequently and high-protein foods, so the home nursing staff should be educated on providing cancer care and nutritional support. The family members should have adequate knowledge as to how to support the patient.

In summary, our data obtained by epidemiological survey show that most of the gastric cancer patients have poor quality of life in Fujian Province, and the quality of life of the rural patients are worse than that of the urban patients. The patients having more family income have better quality of life, and enhanced nutrition and doing rehabilitative exercise are helpful in improving the quality of life of the gastric cancer patients.

Abstract

AIM: To investigate the effect of schisandrin B (Sch B) on proliferation and apoptosis of human hepatoma SMMC-7721 cells *in vitro* and regulation of Hsp70 and Caspases-3, 7, 9 expression by Sch B.

METHODS: Human hepatoma cell line SMMC-7721 was cultured and treated with Sch B at various concentrations. Growth suppression was detected with MTT colorimetric assay. Cell apoptosis was confirmed by DNA ladder detection and flow cytometric analysis. The expression of Hsp70, Caspases-3, 7, 9 were analyzed by Western blot analysis.

RESULTS: Sch B inhibited the growth of hepatoma SMMC-7721 cells in a dose-dependent manner, leading to a 50% decrease in cell number (LC50) value of 23.50 mg/L. Treatment with Sch B resulted in degradation of chromosomal DNA into small internucleosomal fragments, evidenced by the formation of a 180-200 bp DNA ladder on agarose gels. FCM analysis showed the peak areas of subdiploid at the increased concentration of Sch B. The results of Western blot analysis showed that Hsp70 was down-regulated and Caspase-3 was up-regulated, while the activity of Caspases-7, -9 had no significant change.

CONCLUSION: Sch B is able to inhibit the proliferation of human hepatoma SMMC-7721 cells and induce apoptosis, which goes through Caspase-3-dependent and Caspase-9-independent pathway accompanied with the down-regulation of Hsp70 protein expression at an early event.

INTRODUCTION

Schisandrin B (Sch B, Figure 1) is a dibenzocyclooctadiene

compound isolated from *Fructus Schisandrae* (FS, the fruit of *Schisandra chinensis*), an herb commonly prescribed in tonic and sedative formulae in Chinese medicine^[1,2]. In clinical situations, FS was also found to produce beneficial effects on patients suffering from viral hepatitis^[3]. Recently, the pharmacological profile of FS, which includes the enhancement of liver functions and inhibitory/sedative effects on the central nervous system, has been established by laboratory investigations^[4-9]. We presented evidence that Sch B was able to inhibit the proliferation of human hepatoma SMMC-7721 cells and induce apoptosis *in vitro*.

Figure 1 Chemical structure of Schisandrin B.

Apoptosis is an essential physiological process required for normal development and maintenance of tissue homeostasis^[10,11]. Insufficient or excessive cell death can contribute to human diseases, including cancer, acquired immunodeficiency syndrome and some neurodegenerative disorders^[12]. Although many factors are involved in apoptotic program^[13-16], Caspases, a family of cysteine proteases have been shown to play a major role in the transduction of apoptotic signals and the execution of apoptosis in mammalian^[17-21], which has become recognized as key components of the apoptotic machinery^[22]. Most of the biochemical and morphological events of apoptosis are a direct result of Caspase-mediated cleavage of specific substrates^[23,24].

Inhibition of Caspases following treatment with apoptotic stimuli has been shown to prevent some features of apoptosis. The heat shock protein 70 (Hsp70) family of proteins has been demonstrated to be a potent inhibitor of apoptosis induced by a wide range of stimuli^[25,26]. It can protect against apoptosis at an early event in the apoptotic pathway. A role for Hsp70 in tumorigenesis has been suggested, based on the observations that many transformed cells have elevated levels of Hsp70 and overexpression of Hsp70 in transgenic mice results in T-cell lymphoma^[27-30].

In this study, Sch B induced human hepatoma SMMC-7721 cell apoptosis was confirmed by DNA ladder detection and flow cytometric analysis. At the same time, the modulation of Hsp70 and Caspases was observed to study the mechanism of Sch B induced apoptosis in human hepatoma SMMC-7721 cells.

MATERIALS AND METHODS

Reagents

Sch B was purchased from National Institute for the Control of Pharmaceutical and Biological Products, China (NICBPB). The drug was dissolved in dimethyl sulfoxide (DMSO) at a concentration of 10 g/L. For cell treatments, the samples were further diluted in culture medium with the final DMSO concentration <5 g/L. Antibodies to Hsp70, Caspases-3, 7, 9 were purchased from Boster Biotech, China. RPMI-1640 culture medium was obtained from Gibco Co. USA. Fetal calf serum was supplied by Si-Ji-Qing Biotechnology Co. (Hangzhou, China). 96-well plates and culture bottles were purchased from Costar Co. USA. All other chemicals were purchased from Sigma Chemical (St. Louis, MO, USA).

Cell lines and culture

Human hepatoma cell line SMMC-7721 and human hepatic cell line HL-7702 were purchased from American Type Culture Collection (ATCC). Human endothelial cell line ECV-304 was obtained from Tumor Institute, Zhejiang University. Primary human fibroblast cell line was derived from fresh muscle tissues by enzymatic dissociation. Human lymphocytes were derived from umbilical blood by Ficoll-Hyque separation method, and seeded in 96-well microplates with the concentration of phytoagglutinin (PHA). All the cell lines were grown as monolayers in RPMI 1640 medium supplemented with 100 mL/L fetal calf serum and antibiotics (100 unit/mL penicillin and 100 µg/mL streptomycin), incubated at 37 °C in a humidified incubator containing 50 mL/L CO₂ in air.

Assay of cell proliferation

SMMC-7721 cells (100 µL of cell suspension per well) were seeded at a density of 1.5×10^5 /mL in 96-well plates. Each group had three wells with a non-treated group as control. When the cells anchored to the plates, various concentrations of Sch B were added and the slides were incubated at 37 °C in humidified atmosphere containing 50 mL/L CO₂. When the cells described above were cultured for 48 h, 50 µL of MTT (2 mg/mL in PBS) was added to each well and cultured for another 4 h. After the supernatant was discarded, MTT formazan precipitates were dissolved in 100 µL of DMSO, shaken mechanically for 10 min and then read immediately at 570 nm in a plate reader. Cell proliferation inhibition rate (CPIR) was calculated using the following equation: CPIR = (1-average absorbance (A) value of experimental group/average A value of control group) × 100%.

Cell toxicity on primary cells or normal cell lines

HL-7702 cells, ECV-304 cells, primary human fibroblast cells, human lymphocytes (100 µL cell suspension per well) were seeded at a density of 1.0×10^5 /mL in 96-well plates. Following treatment at the concentration of 10, 20, 40, 80, 160 mg/L Sch B for 24 h, cell viability was estimated by trypan blue exclusion. Six wells were measured for each concentration of test compound. All toxicity experiments were repeated at least three independent occasions.

DNA ladder demonstration

After exposed to Sch B for 12 h, SMMC-7721 cells (5×10^6 /sample, both attached and detached cells) were collected and lysed with lysis buffer containing 50 mmol/L Tris-HCl buffer (pH 7.5), 20 mmol/L EDTA, and 10 g/L NP-40. Then 10 g/L SDS and RNase (5 µg/mL) were added to the supernatant, and incubated at 56 °C for 2 h, followed by incubation with proteinase K (2.5 µg/mL) at 37 °C for 2 h. After the DNA was precipitated by addition of both ammonium acetate (3.3 mol/L) and ethanol (995 mL/L), it was dissolved in a gel loading buffer. DNA fragmentation was detected by electrophoresis on 15 g/L agarose gels and visualized with ethidium bromide staining.

Flow cytometric analysis

SMMC-7721 cells were seeded in culture flasks. When the cells were anchored to the plates, various concentrations (0, 10 µmol/L, 20 µmol/L, 40 µmol/L) of Sch B were added and the cells were incubated at 37 °C in humidified atmosphere containing 50 mL/L CO₂ for 2 d. Then each group of cells were washed with PBS, trypsinized and fixed with 700 mL/L ethanol at -20 °C for 30 min, and they were stained with 1.0 µg/mL propidium iodide (PI, Boehringer Mannheim, Germany). The red fluorescence of DNA-bound PI in individual cells was measured at 488 nm with an Altra flow cytometer. The results were analyzed using the ExpoII software (Beckman Coulter, USA). Ten thousand events were analyzed for each sample.

Western blotting analysis

The cells were lysed in a lysis buffer (25 mmol/L hepes, 15 g/L Triton X-100, 10 g/L sodium deoxycholate, 1 g/L SDS, 0.5 mol/L NaCl, 5 mmol/L edetic acid, 50 mmol/L NaF, 0.1 mmol/L sodium vanadate, 1 mmol/L phenylmethylsulfonyl fluoride (PMSF) and 0.1 g/L leupeptin, pH7.8) at 4 °C with sonication. The lysates were centrifuged at 15 000 g for 15 min and the concentration of the protein in each lysate was determined with Coomassie brilliant blue G-250. Loading buffer (42 mmol/L Tris-HCl, containing 100 mL/L glycerol, 23 g/L SDS, 50 g/L 2-mercaptoethanol and 0.02 g/L bromophenol blue) was then added to each lysate, which was subsequently boiled for 3 min and then electrophoresed on a SDS-polyacrylamide gel. Proteins were transferred onto a nitrocellulose filter and incubated separately with antibodies against Hsp70, Caspases-3,7,9, then labeled with peroxidase-conjugated secondary antibodies. The reactions were visualized using the enhanced chemiluminescence reagent (Sigma). The results were approved by repeating the reactions twice.

Statistical analysis

All data were expressed as mean ± SD. Statistical analysis was performed by *t* test using software SPSS 11.0 for Windows. *P* < 0.05 was considered statistically significant.

RESULTS

Effect of Sch B on cell proliferation

Treatment of human hepatoma SMMC-7721 cells with Sch B resulted in a dose-dependent cytotoxicity. As shown in Figure 2, Sch B-mediated cytotoxicity occurred at a concentration greater than 20 mg/L for 48 h. A significant decrease in cell number was seen in the cells treated with Sch B at 20 mg/L. The concentration of Sch B leading to a 50% decrease in cell number (LC50) was about 23.5 mg/L.

Effect of Sch B on primary cells or normal cell line toxicity

As indicated in Figure 3, Sch B had little cytotoxic effect on primary human fibroblast cells and human lymphocyte cells even if at the concentration of 160 mg/L. Treatment of human HL-7702, ECV-304 with Sch B resulted in a dose-dependent cytotoxicity. But human hepatic HL-7702 cells were more resistant to the Sch B-mediated cytotoxicity than human endothelial cells, ECV-304 cells and human hepatoma SMMC-7721.

Detection of DNA fragmentation in SMMC-7721 cells treated with Sch B

As shown in Figure 4, treatment with Sch B resulted in degradation of chromosomal DNA into small internucleosomal fragments, evidenced by the formation of a 180-200 bp DNA ladder on agarose gels, hallmark of cells undergoing apoptosis. No DNA ladders were detected in the samples isolated from control cultures. These results indicated that Sch B induced an apoptotic cell death in SMMC-7721 cells.

Figure 2 Inhibition rate of Sch B on proliferation of SMMC-7721 cells. Cells were incubated at concentrations of Sch B for 48 h.

Figure 3 Cytocidal effect of Sch B on growth of human endothelial ECV-304 cells, human hepatic HL-7702 cells, primary human fibroblast cells and human lymphocyte cells. Cells were incubated at concentrations (10, 20, 40, 80, 160 mg/L) of Sch B for 48 h.

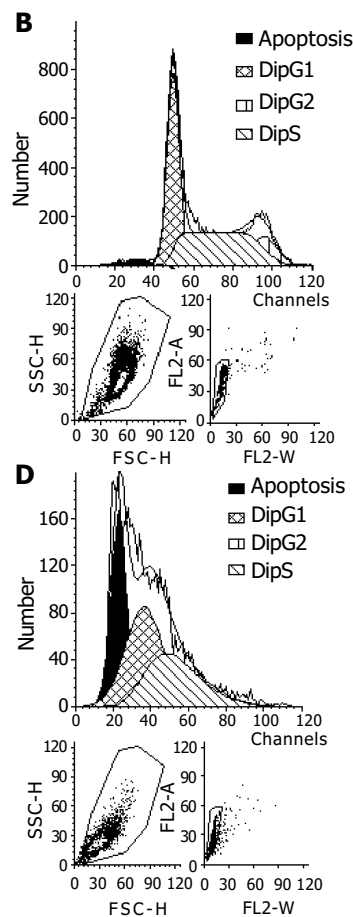

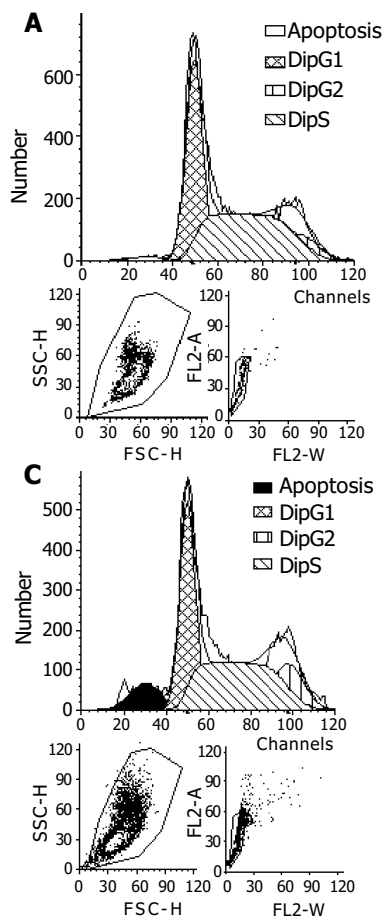

Figure 5 Cell apoptosis determined by flow cytometry. SMMC-7721 cells were treated with Sch B at various concentrations (0, 10, 20, 40 mg/L, respectively A to D) for 48 h.

Figure 4 DNA fragmentation in SMMC-7721 cells treated with Sch B for 12 h. M: size marker; C: control culture; lane 1: 20 mg/L Sch B treatment; lane 2: 40 mg/L Sch B treatment.

Flow cytometric analysis of cell apoptosis

SMMC-7721 cells were exposed to increased concentrations of Sch B (10 mg/L, 20 mg/L, 40 mg/L) for 48 h, and the growth of the cells was analyzed using flow cytometry (Figure 5). The peak value appearing before the G1 peak is called apoptotic peak. As shown in Figure 5 and Table 1, the apoptotic peak areas and rate increased with increased concentrations of Sch B.

Table 1 Apoptosis rate of SMMC-7721 cells induced by Sch B

Sch B concentration (mg/L)	Apoptosis rate (%)
0	0.95±0.17
10	3.44±0.21 ^a
20	10.73±1.17 ^b
40	30.25±1.76 ^b

Effects of Sch B on expression of Hsp70 and Caspases-3,-7,-9

Recent reports suggested that Hsp70 might help to protect cells from apoptosis at an early event in the apoptotic pathway. To elucidate whether Hsp70 was modulated during Sch B induced apoptosis, we examined the expression of Hsp70 by Western blot. Moreover, it was shown that Caspases were the main factor in the apoptotic pathway. We investigated whether Caspases were involved in inducing SMMC-7721 cell apoptosis treated with Sch B. SMMC-7721 cells treated with Sch B for 48 h were analyzed for the enzymatic activity by Western blot. The results showed that Hsp70 was down-regulated and Caspase-3 was activated, while the activity of Caspases-7,-9 had no significant change (Figure 6).

Figure 6 Effect of Sch B on expression of Hsp70, Caspases-3, -7, -9 proteins. SMMC-7721 cells were treated with Sch B for 48 h. After treatment, cell lysates were extracted, and the level of Hsp70, Caspases-3, -7, -9 proteins were analyzed by Western blot analysis. Beta-actin was used as an internal loading control. Lane 1: control; Lane 2: 20 mg/L Sch B treatment; lane 3: 40 mg/L Sch B treatment.

DISCUSSION

After human hepatoma SMMC-7721 cells were treated at various concentrations of Sch B for 48 h, MTT colorimetric analysis showed that Sch B could significantly inhibit the proliferation of SMMC-7721 cells, with LC50 value of 23.50 mg/L. While human hepatic HL-7702 cells were more resistant to the Sch B mediated cytotoxic activity than human endothelial ECV-304 cells and human hepatoma SMMC-7721 cells. It is interesting that Sch B had an unobvious cytotoxic effect on primary human fibroblast cells and human lymphocyte cells.

Current antineoplastic therapies, including chemotherapy and radiation-therapy, are likely to be affected by the apoptotic tendency of cells. During apoptosis, certain characteristic morphologic events, such as nuclear condensation, nuclear fragmentation, and cell shrinkage, and biochemical events, such as DNA fragmentation, would occur^[31-35]. In this study, we showed that Sch B induced human hepatoma SMMC-7721 cell apoptosis was confirmed by DNA ladder and cell cycle analyses.

The commitment of cell apoptosis requires the integration of numerous inputs involving multiple signal transduction pathways. Some cellular pathways and molecular regulators/ effectors of apoptosis have been identified. Many lines of evidence demonstrated that activation of Caspases is a central mechanism of apoptosis. So far, more than 15 members of Caspases have been reported in the literature, and most of them played a major role in apoptosis, participating in the initiation and execution of programmed cell death^[36,37]. Based on their structure and function, Caspases are classified into two groups: initiator Caspases (such as Caspases-2,-8 and-9) and executor Caspases (such as Caspases-3, -6 and -7)^[38,39]. In this study, Sch B-induced apoptosis of SMMC-7721 cells was accompanied with up-regulation of Caspase-3, but did not involve the regulation of Caspase-7 and Caspase-9 protein expression. These results suggested that Caspase-3 but not Caspase-7 was the "executors" of Sch B induced SMMC-7721 cell apoptosis that did not go through Caspase-9-dependent

pathway.

Recent results indicated that Hsp70 might help to protect cells from apoptosis. Jaattela *et al.*^[40] reported that Hsp70 exerted its anti-apoptotic function on downstream of Caspase-3. Creagh *et al.*^[41] revealed that Hsp70 acted on upstream of the Caspases. In the presence of Hsp70, Caspase-3 was not processed or activated and the release of cytochrome C from the mitochondrial intermembrane space, a major Caspase activating mechanism, was inhibited. In this study, the down-modulation of Hsp70 was observed, indicating that Sch B could help Caspase-3 to release from the blockade of Hsp70 so as to promote human hepatoma SMMC-7721 cells to apoptosis.

In conclusion, Sch B is able to inhibit the proliferation of human hepatoma SMMC-7721 cells and induce apoptosis, which goes through Caspase-3-dependent and Caspase-9-independent pathways accompanied with the down-regulation of Hsp70 protein expression at an early event. Further investigation will focus on the identification of other signal modulations in this apoptosis pathway.

Abstract

AIM: To assess the microscopic spread of low rectal cancer in mesorectum regions to provide pathological evidence for the necessity of total mesorectal excision (TME).

METHODS: A total of 62 patients with low rectal cancer underwent low anterior resection and TME, surgical specimens were sliced transversely on the serial embedded blocks at 2.5 mm interval, and stained with hematoxylin and eosin (HE). The mesorectum on whole-mount sections was divided into three regions: outer region of mesorectum (ORM), middle region of mesorectum (MRM) and inner region of mesorectum (IRM). Microscopic metastatic foci were investigated microscopically on the sections for the metastatic mesorectal regions, frequency, types, involvement of lymphatic vessels and correlation with the original rectal cancer.

RESULTS: Microscopic spread of the tumor in mesorectum and ORM was observed in 38.7% (24/62) and 25.8% (16/62) of the patients, respectively. Circumferential resection margin (CRM) with involvement of microscopic metastatic foci occurred in 6.5% (4/62) of the patients, and distal mesorectum (DMR) involved was 6.5% (4/62) with the spread extent within 3 cm of low board of the main lesions. Most (20/24) of the patients with microscopic metastasis in mesorectum were in Dukes C stage.

CONCLUSION: Results of the present study support that complete excision of the mesorectum without destruction of the ORM is essential for surgical management of low rectal cancer, an optimal DMR clearance resection margin should be no less than 4 cm, further pathologic assessment of the regions in extramesorectum in the pelvis is needed.

INTRODUCTION

Local tumor recurrence after surgical resection of rectal cancer remains a major problem. Since Heald *et al.*^[1] first reported evidence of isolated tumor deposits in the mesorectum, more authors have demonstrated that residual foci of the tumor within pelvis resulting from inadequate excision of the mesorectum were the cause of such recurrence^[2,3]. Further studies revealed that remnant of microscopic tumor nodules in the mesorectum, which cannot easily be detected by imaging preoperatively or by palpation intraoperatively, other than large nodules, contributes to most of local failures^[4,5].

Comparison of clinical outcomes between conventional surgery^[6,7] and total mesorectal excision (TME)^[1,8] showed that a proportion of microscopic tumor nodules of rectal cancer causing local pelvic collapse might settle in the outer region of mesorectum (ORM). Unfortunately, investigations on discrete tumor nodules spread in this region are rare. A comprehensive assessment of ORM in patients with low rectal cancer may provide further pathological evidence for supporting the TME procedure.

Although TME has been extensively employed as a standard procedure for surgical treatment of patients with low rectal cancer in western countries, conventional resection has been dominated in China due to little pathological information standing for TME. The present study investigated the regional spread of microscopic tumor nodules in mesorectum using whole-mount sections.

MATERIALS AND METHODS

Patients

Sixty-two consecutive patients with biopsy-proven adenocarcinoma of the rectum underwent TME at the Division of Gastroenterology Surgery of Affiliated West China Hospital of Sichuan University between November 2001 and June 2002, and specimens were examined prospectively by the same pathologist (Chen DY). Patients (30 males) had a mean age of 58 years (range, 21-78). Lesions were classified as upper or low rectal cancers based on the location of peritoneal reflection, and all diseases from our series were categorized as low rectal cancers with sigmoidoscopy preoperatively. Thirty-two patients had the lower board of primary tumors within 5 cm of anal verge, and another 30 patients had the lower board located not farther than 10 cm from anal verge and above the level of 5 cm from anal verge. None of the patients received any preoperative adjuvant therapy.

Surgical techniques

All patients were operated on by the same chief surgeon (Professor. Zhou ZG) and two assistants according to TME principles^[1]. The rectum and mesorectum were mobilized as a package enveloped within the fascia propria with the preservation of autonomic nerves. Under direct vision, electrocautery was used to divide the rectosacral ligament posterior, the peritoneum posterior to the seminal vesicle in the males and the peritoneal reflection in Douglas' pouch in the females anteriorly, lateral ligaments medial to the pelvic plexus laterally. Sharp dissection

was continued down to the pelvic floor in front of Denonvilliers' fascia anteriorly and along the fascia propria posteriorly. Eventually, over 2 cm of distal clearance margin of rectal wall and over 4 cm of mesorectum were attained by transecting the rectum without stretching the bowel wall^[9].

Whole-mount sections

Each specimen was straightened without stretching and pinned to a cork board, different from Quirke's method^[2]. The specimens were not opened longitudinally along the antimesenteric border, and fixed in 40 g/L buffered formaldehyde for 48 h. Serial longitudinal tissue blocks were cut at 5 mm intervals from the distal portion. Each block, consisting of the full thickness of the rectal wall with the mesorectum, was fixed in 40 g/L buffered formaldehyde for another 48 h, and then embedded in paraffin. Whole-mount sections of the bowel wall and mesorectum were sliced transversely on the embedded tissue blocks in 4 µm at 2.5 mm intervals, stained with hematoxylin and eosin (HE), and examined for discrete tumor nodules microscopically (Figure 1). Circumferential resection margin (CRM) involvement was assessed in the conventional manner^[10].

Parameters

The following pathological parameters were used for analysis, namely Dukes stage, differentiation grade, presence of microscopic tumor nodules, local metastasis of lymph nodes, outer region of mesorectum (ORM), distal mesorectum (DMR), CRM (involved ≤ 1 mm, or clear > 1 mm), and distant metastases. Microscopic metastatic nodules of rectal cancer were defined as tumor nodules ≤ 1 mm in diameter, which could not be detected either preoperatively or intraoperatively. Large metastatic nodules of rectal cancer were defined as tumor nodules > 5 mm in diameter, most of which could be easily detected by palpation during operation. The mesorectum on the transverse whole-mount section was divided into three regions (Figure 2).

Discrete tumor nodule spread in the mesorectum 1 mm or less away from the outermost board of CRM was recorded as involvement of CRM, and discrete tumor nodule spread in the mesorectum below the lowest board of primary tumor was defined as involvement of DMR.

Figure 1 Illustration for regions of mesorectum.

Figure 2 Transverse whole-mount sections of the specimen, HE staining, macroscopic view.

RESULTS

The clinicopathologic characteristics of the patients are summarized in Table 1. All the 62 patients underwent low anterior resection. In 52 patients (83.9%) the operation was potentially curative, while residual tumors in 2 patients (3.3%) were noticed to remain in pelvis on operation and distant metastases were observed in 8 patients (12.9%).

Table 1 Clinicopathologic characteristics of the 62 patients

Parameters	Results
Age (yr, range, mean)	20-78, 58
Sex (No. of patients)	
Male	30
Female	32
Dukes stage (No. of patients)	
A	2
B	10
C	42
D	8
Differentiation grade (No. of patients)	
High	4
Medium	34
Low	24
Distance of the primary tumor from anal verge (No. of patients)	
≤ 5 cm	32
> 5 cm	30
Diameter of the primary tumor (No. of patients)	
< 5 cm	24
≥ 5 cm	38

Microscopic spread types and involvement of mesorectum

Four types of microscopic spread of the tumor were observed in mesorectum: discrete microscopic tumor nodules, blood vessel invasion, lymphatic vessel invasion and perineural invasion (Figure 3). Microscopic spread in mesorectum was observed in 38.7% (24 of 62) of the patients (Table 2).

Table 2 Mesorectal regions with involvement of discrete tumor nodules (%)

	Involved mesorectal regions					
	MR	ORM	MRM	IRM	DMR	CRM
Tumor nodules	58.1 (36/62)	45.2 (28/62)	35.5 (22/62)	41.9 (26/62)	6.5 (4/62)	6.5 (4/62)
Microscopic tumor nodules	38.7 (24/62)	25.8 (16/62)	25.8 (16/62)	29.0 (18/62)	6.5 (4/62)	6.5 (4/62)

MR: mesorectum; ORM: outer region of mesorectum; MRM: middle region of mesorectum; IRM: inner region of mesorectum; DMR: distal mesorectum; CRM: circumferential resection margin.

Figure 3 Spread types of microscopic tumor nodules (→) in the mesorectum, HE, ×100. A: Discrete microscopic tumor nodules; B: Blood vessel invasion; C: Lymphatic vessel invasion; D: Perineural invasion.

Figure 4 Microscopic tumor nodule spread (→) in outer region of the mesorectum (ORM) (4a), CRM (4b) and DMR(4c), HE, ×100.

Microscopic spread of the tumor in outer region of mesorectum

Microscopic spread in ORM (Figure 4) occurred in 25.8% (16 of 62) of the patients (Table 2).

Microscopic spread of the tumor in circumferential resection margin

Four of 36 patients with tumor involvement of mesorectum and 2 of the 52 patients having potentially curative resections had microscopic spread in CRM.

Table 3 Mesorectal regional discrete microscopic tumor nodules involving lymph nodes or lymphatic vessels

	Involvement of MR	Involvement of ORM
L type (No. of patients)	16	14
NL type (No. of patients)	18	13

MR: mesorectum; ORM: outer region of mesorectum; L type: involving lymph nodes or lymphatic vessel; NL type: without involving lymph nodes or lymphatic vessels.

Microscopic spread of the tumor in distal mesorectum

DMR with involvement of microscopic tumor nodules was observed in 4 patients. The utmost spread was 3.0 cm or less from the low edge of primary carcinoma. The most extensive distal infiltration was seen in two cases of Dukes stage C.

Table 4 Correlation between mesorectal microscopic spread and primary tumors

Primary tumor	Spread in MR (No. of patients)	Spread in ORM (No. of patients)
Diameter: <5 cm/ ≥5 cm	10/14	8/8
Differentiation grade: high/medium/low	0/10/14	0/8/8
Dukes stage: A/B/C/D	0/2/20/2	0/2/12/2
From anal verge: ≤5 cm/>5 cm	12/12	8/8

MR: mesorectum; ORM: outer region of mesorectum.

Microscopic spread of the tumor in mesorectal lymph nodes or lymphatic vessels

Microscopic spread nodules without involvement of lymph nodes or lymphatic vessels in mesorectum were observed in 18 patients, and such a spread in ORM was found in 13 patients (Table 3).

Correlation between regional mesorectal microscopic spread and primary tumors

Most patients (20 of 24) with mesorectal microscopic spread in

MR and 12 of 16 microscopic spreads in ORM were Dukes C stage (Table 4).

Correlation between microscopic tumor nodules and large tumor nodules

Microscopic tumor nodules coexisting with large tumor nodules were observed in 14 of 24 (58.3%) patients with microscopic spread in mesorectum.

DISCUSSION

Whole-mount sections were used to facilitate the precise and effective assessment of rectal cancer, especially in mesorectal regional spread of discontinuous microscopic tumor nodules. All whole-mount sections showed that whole morphological features of the surgical specimen enclosing the primary tumor, bowel wall and the mesorectum, could be directly observed with naked eyes and by microscopy, which enabled the investigators to obtain valuable pathological outcomes on rectal cancer^[2,11].

The present study showed the incidence of discrete microscopic tumor nodules was 38.7% (24 of 62) of patients in mesorectum and 25.8% (16 of 62) of patients in ORM. The high frequency of microscopic tumor nodules in mesorectum (especial ORM) highlighted the importance of complete excision of mesorectum with fascia propria circumferentially intact for low rectal cancer. Disturbance of ORM during operation would predispose local recurrence because the undetected microscopic foci in the mesorectum, especially in ORM were easily left behind in pelvis^[4,12,13]. Frequency of CRM involvement after conventional resection was reported up to 27%^[2,11,14,15], compared with 6.5% after TME^[16,17], which is consistent with our findings. The decrease of CRM involvement rates after TME justified the theory: the frequency of microscopic spread in ORM could be very high, and destruction of ORM which often occurred in conventional resection, could easily lead to positive CRM.

Distal mesorectal spread can be evaluated pathologically after TME, after standard resection of the rectal cancer, the DMR remained inside pelvis^[18]. Frequency of discrete tumor cancer spread 3 cm or more from the primary lesions in DMR varied from 0 to 10% of the cases^[4,17,19-22], and discontinuous spread in DMR could be found even up to 5 cm beyond the lower margin of the primary tumor^[1,6], some patients with DMR spread had poor prognosis^[21-23]. The present study showed that four cases with tumor involvement of DMR had the spread within 3 cm of primary mural tumors, with a maximum of 3.0 cm. Therefore, we support a safe DMR resection margin of no less than 4 cm for lower rectal cancer, and consider that failure to adequate excision of the involved DRM would risk in leaving behind residual microscopic cancer foci in a significant percentage of patients. The most common pattern of pelvic recurrence is extramural diseases emanating from the sacral hollow or pelvic floor, which is entirely compatible with this hypothesis^[24]. But others argued that pathological evidence of DMR spread in itself did not necessarily justify total removal of DMR in all cases because the local recurrence rate and survival rate were not improved significantly even after TME^[4,17].

Cawthorn^[25] reported that mesorectal involvement of large tumor nodules (greater than 4 mm) was associated with significant poorer prognosis than that of small ones (less than 4 mm). However, the author cautioned that the poor prognosis might result from residual microscopic tumor nodules, which coexist with large nodules and can easily be overlooked and left behind during operation. Ueno *et al.*^[13] demonstrated that large tumor nodules and microscopic tumor nodules correlated closely, and that large tumor nodules had a predicting value for existence of microscopic tumor nodules. The present study showed that 58.3% (14/24) patients with microscopic tumor

foci involvement of the mesorectum had large tumor nodules (greater than 5 mm) in the mesorectum, which was lower than that reported by Ueno *et al.*

Kapiteijn *et al.* recently reported that standardized TME in combination with preoperative radiotherapy could significantly decrease the local recurrence rate in patients with rectal cancer, though its benefits in survival were not demonstrated because of a relatively short time of follow-up^[26]. Other authors also concluded that preoperative radiotherapy could improve the prognosis of patients with rectal cancer^[27]. In our series, no patients were treated with adjuvant therapy due to the high frequency of postoperative complications and its controversial impact on prognosis.

Extended lateral dissection beyond the extent of TME has been widely accepted in Japan as the improvement in survival rates was reported^[28,29], but some argued that it had a limited advantage in prognosis and the functional problems were considerable^[30,31]. Microscopic tumor nodule involvement of CRM after TME in our series suggested that a proportion of the patients had microscopic tumor spread in the extramesorectal regions in the pelvis. Further comprehensive pathological assessment of the extramesorectum is required to evaluate the curative value of TME in rectal cancer.

Abstract

AIM: The protective effects of sodium butyrate and NSAIDs (especially the highly selective COX-2 inhibitors) have attracted considerable interest recently. In this study, primary adenoma cells and HT-29 were used to investigate whether the above drugs would be effective for reducing proliferation and inducing apoptosis. Additionally, it was investigated whether NSAIDs would strengthen the effects of sodium butyrate and its possible mechanisms.

METHODS: *In vitro* primary cell culture of colorectal adenomas and HT-29 were used for this investigation. PGE₂ isolated from HT-29 cell culture supernatants was investigated by ELISA. MTT was employed to detect the anti-proliferative effects on both adenoma and HT-29 culture cells. FCM was used for apoptosis rate and cell cycle analysis. The morphology of apoptotic cells was investigated by means of electromicroscopy.

RESULTS: Sodium butyrate could stimulate the secretion of PGE₂, while NSAIDs inhibited it to below 30 pg/10⁶ cells. Both butyrate and NSAIDs could inhibit cell proliferation and induce apoptosis. The effects were time- and dose-dependent ($P < 0.05$). Aspirin and NS-398 could enhance the effects of sodium butyrate. The effects were stronger while sodium butyrate was used in combination with NS-398 than it was used in combination with Aspirin.

CONCLUSION: Butyrate and NSAIDs could inhibit cell proliferation and induce apoptosis respectively. NSAIDs could enhance the effects of sodium butyrate by down-regulating COX-2 expression. Selective COX-2 inhibitor is better than traditional NSAIDs.

INTRODUCTION

Colorectal cancer remains the major cause of cancer-related mortality in the developed countries. With improvement in economic status, the incidence of colorectal cancer is increasing in China. Prevention of the disease is a more attractive approach to dealing with the problem than treatment of existing disease

for both medical and fiscal reasons. Clinical evidences showed that removal of colorectal adenoma could attenuate 76-90% risk of colorectal cancer, but the yearly relapse rate has reached 10-15%. Therefore, the urgent task is to develop new strategies to prevent the disease. With regard to chemoprevention, butyrate sodium (sodium butyrate) and non-steroidal anti-inflammatory drugs (NSAIDs), especially selective COX-2 inhibitors have attracted more attention.

Evidences have shown that low fat and high dietary fiber diet could protect against colorectal cancer. Dietary fiber could be fermented by symbiotic bacteria in the large bowel and then a short chain fatty acid-butyrate, could be released. Clinical and laboratory studies showed that butyrate might be beneficial to the development of colorectal cancer and even in the early stage of its premalignant status^[1].

NSAIDs have shown its promising role in colorectal cancer chemoprevention in recent years. Epidemic studies demonstrated that it might reduce 40-50% risk of colorectal cancer in persons who took aspirin or other NSAIDs on a regular basis^[2]. The most recognized target for NSAIDs was cyclooxygenase (COX), because COX-2 showed 86% and 43% expression in colorectal adenoma and carcinoma tissues respectively^[17]. Furthermore, COX-2 selective inhibitors have attracted more attention because of their minimal risk of gastrointestinal side effects.

Although the precise mechanisms are unclear, sodium butyrate and NSAIDs are involved in chemoprevention of colorectal cancer. In this study, colorectal adenoma cells and HT-29 cells were used to investigate whether the above agents were effective in reducing proliferation and inducing apoptosis, and whether NSAIDs could strengthen the effects of sodium butyrate and its possible mechanisms.

MATERIALS AND METHODS

Materials

NS-398 was a gift from Dr. W Sternson (Washington University). EGF was from Dr. Ouyang Xueshong (Hong Kong University). Sodium butyrate, aspirin, collagenase type IV, hyaluronidase type IV were purchased from Sigma Chemical Co. Prostaglandin E₂ EIA kit was from Cayman Chemical. Arachidonic acid, insulin, FBS was from GIBCO Co.

Colorectal adenoma specimens were from resection through colonoscopy in the Endoscopic Center, First Hospital of Western China University of Medical Sciences. HT-29 was a gift from Immuno-Transplantation Laboratory, First Hospital of Western China University of Medical Sciences.

Methods

Cell cultures Adenoma specimens were washed at least 10 times in PBS containing penicillin (1 000 U/mL), streptomycin (1 000 U/mL), amphotericin B (3 µg/mL). The minced tissues were digested by DMEM containing collagenase type IV (1.5 mg/mL), hyaluronidase type IV (0.25 mg/mL) for 2 h until the tissues were dispersed into individual crypts, then they were incubated at 37 °C, 50 mL/L CO₂ in growth medium consisting of DMEM, 50 mL/L FBS, 0.5 µg/mL insulin, 1 µg/mL hydrocortisone, 5 µg/mL transferrin, 20 ng/mL EGF, 5 × 10⁻⁹ Na₂SeO₃, 0.1 µg/mL pentagastrin, 2 mmol/L glutamine, 200 U/mL penicillin, 200 U/mL

streptomycin. The culture cells were identified as epithelial origin by immunohistochemical staining and electro microscopy (data not shown). HT-29 was cultured in standard growth condition containing DMEM, 100 g/L LBS, 200 U/mL penicillin and streptomycin.

Preparation of drugs

Sodium butyrate was dissolved in culture medium. Aspirin and NS-398 were in DMSO, and the final concentration was less than 3.3 mL/L. The drugs below were used to measure PGE₂, MTT and FCM. Sodium butyrate: 2 mmol/L, 4 mmol/L, 6 mmol/L; Aspirin: 1 mmol/L, 5 mmol/L, 10 mmol/L, 20 mmol/L; NS-398: 0.1 μmol/L, 1 μmol/L, 10 μmol/L, 50 μmol/L; 2 mmol/L Sodium butyrate+10 mmol/L Aspirin; 2 mmol/L Sodium butyrate+10 μmol/L NS-398. For electro microscopy, 2 mmol/L Sodium butyrate, 10 mmol/L aspirin or 10 μmol/L NS-398 was used.

Prostaglandin E₂ (PGE₂) immunoassay

HT-29 cells were seeded at a density of 1×10⁶ cells/T25 flask for 48 h, and then treated with medicine for 24 h or 72 h separately. Aliquots of culture medium (1 mL) were stored at -70 °C until assayed (In NSAIDs treatments and control groups, an exogenous supply of 10 μmol/L AA was added to pre-treat for 30 min individually). Immunoassay was carried out according to the manufacturer's protocol. The sensitivity of the assay was 10 pg/mL.

Proliferation assays

Cell proliferation of both primary adenoma cells and HT-29 was assessed by MTT. After seeded at a density of 2×10⁴ cells/well for 96 well plates with 100 μL media for 48 h, the cells were treated with medicine for 24 h or 72 h separately. At the end of incubation, the medium was removed and 20 μL MTT solution was added to each well. Then DMSO was added to each well, the optical density of each well was read on the plate reader at 570 nm.

The inhibition rate = (1- tested group optical density/the control optical density)×100%.

Flow cytometric analysis

After HT-29 cells were harvested, they were fixed in 700 mL/L ethanol overnight at 4 °C, mixed with PI staining fluid for 20 min at 4 °C and then filtered. At last, the samples were examined by FCM.

Electro microscopy

The collected HT-29 cells were fixed in 30 g/L glutaraldehyde, then rinsed in 10 g/L osmium tetroxide for 30 min at 4 °C, dehydrated through a series of acetone, embedded in EPON polymerized at 60 °C, stained with uranyl acetate and Reynold lead citrate. Finally, the sections were examined under an electron microscope.

Statistical analysis

PGE₂ expression and growth inhibition were statistically analyzed by two-way ANOVA. Comparison among the groups was analyzed by L-S-D. The apoptotic rate was analyzed by χ^2 . All data were analyzed by SPSS.

RESULTS

PGE₂ production in HT-29 cells

With the increase of optical density, PGE₂ production was decreased in standard culture condition. Sodium butyrate 2 mmol/L was enough for stimulating the secretion of PGE₂ 1306 pg/10⁶ cells compared with control values of 69 pg/10⁶ cells in 24 h ($P<0.05$), but it was not time- and dose-dependent. 2 mmol/L\4 mmol/L\6 mmol/L sodium butyrate separately stimulated the secretion of PGE₂ 1306\1230\1385 (pg/10⁶ cells). And the same concentration of sodium butyrate had no statistical differential effects in 24 h and 72 h. In contrast, NSAIDs (aspirin and NS-398) could completely inhibit PGE₂ secretion in a time- and dose-independent manner ($P<0.001$). After incubated for 30 min with 10 μmol/L AA, PGE₂ production reached 1470 pg/10⁶ cells in control, while 1-20 mmol/L aspirin reduced the PGE₂ levels to below 30 pg/10⁶ cells and 0.1-50 μmol/L NS-398 reached 477 pg/10⁶ cells-25 pg/10⁶ cells. NS-398 was different in time- and concentration-dependence from aspirin. Sodium butyrate in combination with NSAIDs showed PGE₂ production inhibition (<30 pg/10⁶ cells) (Table 1).

Sodium butyrate and NSAIDs had dose- or time-dependent anti-proliferative effects on HT-29 and adenoma cells

The anti-proliferative effects on HT-29 and adenoma cells were obvious concentration- and time- dependent ($P<0.05$). 2-6 mmol/L sodium butyrate after 24 h showed 4.3-12.6% on HT-29 and 5.7-11.9% on adenoma cells. They reached 23.7-62.9% and 19-30.5% after 72 h. In agreement with NS-398 and aspirin, the effect was stronger on NS-398 than on aspirin with the same concentration. 1-20 mmol/L aspirin could inhibit the cell proliferation 18.5-57.1% after 24 h and 48.5-76.6% after 72 h, while 0.1-50 μmol/L NS-398 reached 4.5-24% after 24 h and 52.2-68.5% after 72 h. The effects were more obvious on the adenoma cells. Treatment with both Sodium butyrate and NSAIDs resulted in an increase in anti-proliferative effects compared with Sodium butyrate treatment alone for HT-29, and the effects were time-dependent (Table 2).

But for adenoma cells, the results were different in repeated experiments. Only treatment with Sodium butyrate and NS-398 for 72 h showed the synergistic effects on 28.6% adenoma specimens ($P<0.05$).

Moreover, HT-29 cell cycle distribution was analyzed by FCM. Both Sodium butyrate and NSAIDs could arrest the cell cycle in S phase compared with the control ($P<0.05$), but the response to G₁/G₁ or G₂ phase was different.

Induction of apoptosis effects was dose-dependent in HT-29

Normal primary culture cells and HT-29 showed irregular polygon-appearances. The cells treated with the drugs shrank and became round, then shad from the wall and floated in the fluid. The floating cells showed blue coloration by trypan blue staining, while the attached cells were achromatical.

As expected, the dose-dependent apoptotic effects on HT-29 cells treated with Sodium butyrate or NSAIDs could be seen

Table 1 PGE₂ (pg/10⁶ cells) production in HT-29 treated with Sodium butyrate and/or NSAIDs

Production of PGE ₂	2 mmol/L sodium butyrate	10 mmol/L aspirin	10 μmol/L NS-398	Sodium butyrate+aspirin	Sodium butyrate+NS-398
24 h	1306±5.6	13.2±4.1	35.2±3.5	14.9±1.9	45.9±2.9
72 h	1427±7.1	5.61±2.7	5.95±2.2	6.5±1.0	8.49±1.3

Table 2 Comparison of growth inhibition effects on HT-29 with Sodium butyrate alone or in combination with NSAIDs (%)

Time	2 mmol/L sodium butyrate	10 mmol/L aspirin	10 μmol/L NS-398	Sodium butyrate+aspirin	Sodium butyrate+NS-398
24 h	4.28	55	10.2	58.3	26
72 h	23.7	72.2	63.9	81.9	70.5

Table 3 Percentage of HT-29 apoptotic cell rate (%)

	Control				Aspirin (mmol/L)				NS-398 (μmol/L)				Sodium butyrate (mmol/L)		
Concentration	1	5	10	20	0.1	1	10	50	2	4	6				
Apoptotic rate	4.2±1.3	8.3±1.6	10.9±2.0	11.9±2.7	29.7±3.1	6±1.4	7.8±1.7	12.5±3.1	19.5±3.4	10.7±2.5	15.9±0.9	23.2±4.1			

($P < 0.05$) (Table 3). Sodium butyrate with NS-398 had more preferential apoptotic effects (14.7%) compared with Sodium butyrate alone (10.7%) or Sodium butyrate in combination with aspirin (13.3%).

To confirm the induction of apoptosis, the morphological appearances of HT-29 cells were examined by electron microscopy. Typical apoptotic appearances are shown in Figure 1, which included cell shrinkage, nuclear condensation, and formation of apoptotic bodies, etc.

DISCUSSION

In recent years, the incidence of colorectal cancer is increasing in China. Prevention of the disease is a more attractive approach in the early stage of adenoma-cancer progression. Butyrate and NSAIDs (especially highly selective COX-2 inhibitors) have attracted considerable attention recently.

As a byproduct of carbohydrates fermented by symbiotic bacteria, butyrate has been demonstrated its important role in inhibiting cell growth and in inducing apoptosis of colorectal cancer cells *in vitro*^[3]. Clinical case-control and cohort studies have shown a 40-50% reduction in colorectal cancer-related mortality in individuals taking aspirin and other NSAIDs on a regular basis compared with those not taking these agents^[2]. Aspirin serves as a typical representative of classical NSAID agents. As a highly selective COX-2 inhibitor, NS-398 showed higher selective effects than others. Its IC_{50} (COX-2/COX-1) was 0.0005, while L-745, 337 was 0.003, flosulide was 0.001^[4], rofecoxib was 0.0012^[5]. Although the precise mechanism underlying the protective effects of NSAIDs is unclear, COX-2 could play a key role in intestinal tumorigenesis^[6] and has been a widely recognized target because of its high expression in colorectal adenoma and cancer tissues^[7-10]. The COX-2-dependent mechanism involving in increased angiogenesis^[11-13], could reduce apoptotic susceptibility by inhibiting the cytochrome c-dependent apoptotic pathway^[14]. Down-regulation of bcl₂ and

CD44v6 expression and up-regulation of nm23 expression^[15] could inhibit death receptor 5 expression and confer resistance to tumor necrosis factor-related apoptosis-inducing ligand (TRAIL)-induced apoptosis^[16]. However, some COX-independent ways, such as lipoxigenase (LOX) another AA metabolic enzyme, could modulate sodium butyrate-induced apoptosis and cell differentiation^[17]. Leukotriene (LT) D₄/CysLT₁ (R) signaling could facilitate survival of colon cancer cells and LTs were accessible targets for pharmacologic treatment like COX-2^[18]. NF-KB/I-KB system^[19]. Activated Ras and TGF-β could collaborate to increase the invasive response^[20], etc, which have been shown to be involved in the protective mechanism. In this study, adenoma cells and HT-29 were investigated whether Sodium butyrate and aspirin/NS-398 were the effective adjuvants for the protective effects.

The relationship between PGE₂ (an AA metabolize product) and colorectal carcinogenesis is still disputed. Generally, PGE₂ could combine with the transcription factor PPAR_α, which activates the target gene transcription and promotes carcinogenesis^[21]. PGE₂ could also increase bcl-2 expression and inhibit cell apoptosis^[22] and was involved in the angiogenesis of cancers. So it has been implicated that PGE₂ inhibition is the main mechanism of anticarcinogenesis of NSAIDs. But a positive result showed that exogenous PGE₂ could not reverse the antineoplastic effects of sulindac sulfone^[23]. In this study, PGE₂ production was investigated to reflect the COX-2 enzyme activity indirectly. For HT-29, Sodium butyrate could stimulate its PGE₂ secretion in a time- and dose-independent manner, suggesting that it could increase its COX-2 enzyme activity. In contrast, NSAIDs inhibited PGE₂ production. Although previous evidence displayed that the expression of COX-2 was increased by some NSAIDs and TGF-β^[24], we proposed that the inhibited enzyme activity would still down-regulate the effects of NSAIDs.

Sodium butyrate could reduce cell proliferation and induce cell apoptosis in a time- and dose-dependent manner. The possible mechanism has been known to involve in a large number of parameters, including inhibition of histone deacetylase and induction of caspase-3 protease activity with a mitochondrial/cytochrome c-dependent pathway^[25], enhancement of Fas-mediated apoptosis^[26], inhibition of P53 expression^[25]. Down-regulation of GATA-6 and up-regulation of 15-LO-1 were observed after treatment with sodium butyrate (sodium butyrate), which was also involved in stimulating cell apoptosis and cell differentiation^[27]. NSAIDs had the same effects on both cell lines. This was not in a time- and dose-dependent manner. Therefore, it implied that anti-neoplastic mechanisms of NSAIDs were COX-2-dependent and COX-2-independent.

Compared with the effects on adenoma and carcinoma cells, NSAIDs had stronger inhibitory effects on carcinoma cells than on adenoma cells with MTT. Maybe the cause laid in the primarily cultured adenoma cells from different specimens, which resulted in the individual characterization of COX-2 expression and cell proliferation. Other studies gave the same conclusion that NSAIDs had stronger effects on HT-29 carcinoma cells (high COX-2 expression) than on S/KS cells (lack of COX-2 expression).

Previous studies revealed that COX-2 expression up-regulation would induce resistance to apoptosis induced by sodium butyrate. Because NSAIDs could down-regulate COX-2

expression, whether NSAIDs could sensitize the cells to the action of sodium butyrate and reduce the potential side-effects and increase the efficacy by using both drugs was investigated in this study. The data showed that NSAIDs inhibited the growth of HT-29 by sodium butyrate by down-regulating COX-2 expression. It was in agreement with the previous studies. In contrast, other studies reported that cooperation with the two agents was greatly dependent on the category of cell lines and NSAIDs, especially highly selective COX-2 inhibitors showed more preferential effects. Only HT-29 cell line was investigated in this study, so it was necessary to investigate other cell lines for more precise results. Cooperation with the two drugs could affect the two cell lines differently. The effects on HT-29 were completely shown, but only 28.6% was positive for primary adenoma specimens. The main cause depended on the adenoma samples. Additionally, treatment with NS-398 and sodium butyrate had more preferential effects than that with aspirin and sodium butyrate, suggesting that specific selective COX-2 inhibitor NS-398 had a more promising future in clinical application.

In summary, sodium butyrate and NSAIDs could inhibit the cell proliferation and induce cell apoptosis through a number of mechanisms. Combination of two kinds of agents would enhance the above effects by down-regulating COX-2 expression, which could serve as a promising chemoprevention for colorectal neoplasm.

Abstract

AIM: To develop an efficient animal colitis-associated carcinogenesis model and to detect the expression of β -catenin and p53 in this new model.

METHODS: Dysplasia and cancer were investigated in mice pretreated with a single intraperitoneal injection of 20 mg/kg body mass of 1,2-dimethylhydrazine prior to three repetitive oral administrations of 30 g/L dextran sulfate sodium to give conditions similar to the clinically observed active and remission phases. Immunohistochemical staining of β -catenin and p53 was performed on paraffin-embedded specimens of animals with cancer and/or dysplasia, those without dysplasia and the normal control animals.

RESULTS: At wk 11, four early-invasive adenocarcinomas and 36 dysplasia were found in 10 (90.9%) of the 11 mice that underwent 1,2-dimethylhydrazine-pretreatment with 3 cycles of 30 g/L dextran sulfate sodium-exposure. Dysplasia and/or cancer occurred as flat lesions or as dysplasia-associated lesion or mass (DALM) as observed in humans. Colorectal carcinogenesis occurred primarily on the distal portion of the large intestine. No dysplasia and/or cancer lesion was observed in the control groups with 1,2-dimethylhydrazine pretreatment or 3 cycles of 30 g/L dextran sulfate sodium exposure alone. Immunohistochemical investigation revealed that β -catenin was translocated from cell membrane to cytoplasm and/or nucleus in 100% of cases with dysplasia and neoplasm, while normal membrane staining was observed in cases without dysplasia and the normal control animals. Nuclear expression of p53 was not detected in specimens.

CONCLUSION: A single dose of procarcinogen followed by induction of chronic ulcerative colitis results in a high incidence of colorectal dysplasia and cancer. Abnormal expression of β -catenin occurs frequently in dysplasia and cancer. This novel mouse model may provide an excellent vehicle for studying colitis-related colon carcinogenesis.

INTRODUCTION

The incidence of colorectal cancer (CRC) has been increasing in patients with ulcerative colitis (UC) and the risk of CRC increases with increased extent and duration^[1-4]. The mechanisms underlying the frequent development of CRC in patients with UC are still unknown.

Through the study of animal models which do not allow experiments in humans, we could better understand the cause and mechanisms of various diseases. There are many animal ulcerative colitis models, but only a few of them are applicable to the study of dysplasia-cancer sequence. Among them, the most widely used is a mouse model with dextran sulfate sodium (DSS). DSS could be used to induce UC in mice. Acute colitis was observed by administration of 50-100 g/L DSS to mice for 4-9 d^[5-8]. A chronic colitis could be induced by feeding 30-50 g/L DSS in drinking water for 7 d followed by 7-14 d of water^[6,8-10]. In recent years, some researchers have described the occurrence of dysplasia and/or cancers in mice when they are subjected to repeated administration of DSS in a long term^[11-13]. Before the occurrence of cancer, the features of colitis in this model were very similar to those in patients in terms of both clinical and histopathological characteristics, i.e. diarrhea, occult blood, melena, mucosal inflammatory cell infiltration, crypt abscess formation, and mucosal erosion. But this kind of models needs a long period to be established and the incidence of induced tumors is relatively low.

1,2-dimethylhydrazine (DMH) is a toxic environmental pollutant which was reported as a specific colon procarcinogen. Animal studies showed that experimental colonic tumors induced by DMH were of epithelial origin with a similar histology, morphology and anatomy to human colonic neoplasms^[14]. This procarcinogen could thus provide an adequate model for studying colorectal cancer. However, multiple treatments with DMH (20-40 mg/kg body mass) and a long-term experimental period are needed to induce large bowel neoplasms^[15-17].

We present here a newly developed colitis-associated CRC mouse model in which dysplasia and cancer developed within 10 wk when mice were given a single, low dose of DMH followed by three repeated administrations of 30 g/L DSS in drinking water. We used DSS to induce recurrence-remission cycle of chronic colitis which was similar to humans and added a low dose of DMH, in order to shorten CRC development period since chronic exposure to a small amount of environmental carcinogens is also a main cause of human CRC. In addition, we found dysplasias and cancers in this model showed positive reactivity for β -catenin, but not for p53.

MATERIALS AND METHODS

Animals

Forty-five specific pathogen-free BALB/c male mice weighing 25-30 g (Slaccas Experimental Animal Co. Ltd. Shanghai, China), 7 wk of age, were used. They were housed in plastic cages (5 or 6 mice/cage) with wood shavings under standard laboratory conditions (24±0.5 °C temperature, 50±10% humidity, and 12 h of light from 06.00 to 18.00). All mice were permitted free access

to a commercial diet and DSS-supplemented or normal drinking tap water in bottles at the Animal Laboratory Center of our hospital.

Study design

The design for inducing colitis-associated dysplasia and/or cancer is shown in Figure 1. At the age of 8 wk, the animals were divided into one experimental group (group A) and 3 control groups (groups B-D), 10-12 mice each group. The animals in group A were subjected to three cycles of alternating administration of distilled water containing 30 g/L synthetic dextran sulfate sodium (DSS; mol mass 5000; Wako Pure Chemical Industries, Ltd. Japan) for 7 d followed by distilled water for the subsequent 14 d after intraperitoneal pretreatment with 20 mg/kg 1,2-dimethylhydrazine (DMH; Sigma-Aldrich Corp. St. Louis. MO. USA). For comparison, control groups B to D received each of the treatment alone or maintained as untreated control. Three mice from group A, B, and D were sacrificed during the experiment. Forty-two mice were anesthetized with ether and sacrificed at the age of 18 wk.

Figure 1 Experimental protocol for inducing colitis-related colon cancer in mice. ▼DMH, 20 mg/kg body mass, intraperitoneal injection; ▽ Saline 0.5 mL/mice intraperitoneal injection; 30 g/L ■ DSS in drinking water.

Observation of colitis

Changes in body weight were recorded every week throughout the experiment. Occult blood was examined on d 3 or 4 of DSS feeding, when DSS feeding was stopped, and once a week thereafter. Presence of gross blood and stool consistency were observed daily. The individuals who examined the mice were blinded as to the experimental group to which the animals belonged.

Histopathological evaluation

After death, the entire colorectum from the colocolic junction to the anal verge was examined. Their length was measured, and then the specimen was opened longitudinally and washed with saline. After colorectum was macroscopically inspected, it was immediately fixed in a 40 g/L formaldehyde buffer solution (pH 7.2).

Part of the colon was divided into three equal portions (proximal, middle and distal). Five-six pieces/portion and 14-17 pieces/colorectum were stained with hematoxylin and eosin (H&E) for histological processing.

The severity of UC of each colon was histologically graded on a scale from 0-4 and expressed using the pathological index corresponding to the following modified standard scoring system^[18]: 0, normal; 1, focal inflammatory cell infiltration including polymorphonuclear leucocytes; 2, gland loss with inflammatory cell infiltration or crypt abscess formation; 3, mucosal ulceration, or five or more foci of gland loss with inflammatory cell infiltration; 4, two or more areas of mucosal

ulceration.

Dysplasia (low and high grades) was scored according to the criteria described by Riddell *et al.*^[19]. Cancer was divided into early invasive and advanced cancer. Early invasive cancer was defined as cancer cells invading into muscularis mucosa and/or into submucosa. Advanced cancer was defined as cancer cells invading into muscularis propria or beyond.

A single experienced pathologist reviewed all cases blindly.

The evaluation of β -catenin and p53

To detect the expression of β -catenin and p53, we utilized the two step immunostaining technique. Four μ m thick tissue sections were dewaxed and rehydrated through changes of xylene and graded alcohol, then to water. Endogenous peroxidase activity was blocked by incubating the sections with 30 g/L hydrogen peroxidase for 15 min. Heat-mediated antigen retrieval was performed by heating the sections (immersed in 0.01 mol/L citrate buffer, pH 6.0) in a microwave oven (750 W) for 15 min. The slides were then washed with phosphate-buffered saline (PBS) before incubated with primary antibody overnight at 4 °C. The antibody to β -catenin (Santa Cruz Biotechnology, Inc. USA) was a mouse monoclonal IgG1 antibody corresponding to amino acids 680-781 and was used at a dilution of 1:800. p53 antibody (Santa Cruz Biotechnology, Inc. USA) was a rabbit polyclonal antibody that reacts with both wild-type and mutant p53 and was used at a dilution of 1:200. After washed with PBS, the slides were incubated for 30 min with the EnVision+peroxidase reagent (Zhongshan Biological Technology Co., LTD, Beijing, China). After further washed in PBS, the slides were developed with 3,3'-diaminobenzidine (DAB; Sigma-Aldrich Corp. St. Louis. MO. USA) for 5 min, and the reaction was terminated in water. The slides were then counterstained with hematoxylin, dehydrated in alcohol, and evaluated under a light microscope. Positive controls for β -catenin expression were normal human colonic epithelia. Human colonic adenocarcinoma were used as positive controls for p53 antibody. Omission of the primary antibody of β -catenin and p53 was used as a negative control.

Lesions were classified as positive for β -catenin if cytoplasmic/nuclear staining was detected (1+: \leq 50% cells positive, 2+: \geq 50% cell positive). Staining for p53 was considered positive if nuclear expression was detected in more than 10% of cells. Two experienced pathologists who were blinded to the specimen independently examined slides, and a high level of concordance (90%) was achieved. In case of disagreement, the slides were reviewed and a consensus view was achieved.

Statistical analysis

Statistical analysis was carried out by SPSS 11.5 for windows statistic software. Variance tests and One-way ANOVA test were used to compare the means of weight, length of large bowel in different groups, the number of neoplasms, and pathological index in different sites. $P < 0.05$ was considered statistically significant.

RESULTS

Body growth, fecal examination and colorectal length

At the end of the first DSS treatment period, 75.0% (18/24) mice in groups A and B had diarrhea and occult blood or gross blood in the feces, and these signs disappeared after the mice drank distilled water for 14 d. However, during the second and third administrations of DSS, only 45.5% (10/22) and 36.4% (8/22) mice had diarrhea or occult blood, respectively.

Body growth rate was slightly lower in the mice that received 3 cycles of DSS treatment. The mean body weight of group A and B at the end of study was significantly smaller than that of

group D ($P<0.05$, Table 1).

Although the colorectal length was not affected by DMH-treatment alone, it was shortened by DSS treatment. The mean length of colorectum of mice in groups A and B was significantly shorter than that of mice in group D ($P<0.01$, Table 1).

Table 1 Body mass and colorectal length (mean \pm SD)

Groups	A	B	C	D
Body mass (g)	24.09 \pm 2.02 ^a	25.9 \pm 2.020 ^a	31.00 \pm 2.10	30.01 \pm 1.02
Colon length (cm)	8.80 \pm 0.98 ^b	9.37 \pm 0.90 ^b	12.21 \pm 0.94	12.66 \pm 0.73

Significantly different from group D (^a $P<0.05$, ^b $P<0.01$).

Figure 2 Induced colorectal tumors. Gross polypoid lesions are evident on the distal and middle portions of the large intestine (arrows).

Figure 3 Histopathology showing dysplastic and cancer lesions developed in the colon of mice from group A. A: Whole-mount view of DALM with low-grade dysplasia, B: A slightly or non-elevated lesion diagnosed as high-grade dysplasia, C: whole-mount view of an early invasive cancer arising out of DALM. Hematoxylin and eosin stain. Original magnification, $\times 10$.

Incidence and distribution of dysplasia and cancer

Group A mice that received DMH pretreatment and repeated administrations of 30 g/L DSS developed multiple tumours in the colorectal region. Ten of 11 (90.9%) animals were detected to have at least one dysplasia and/or cancer lesion. Gross lesions were noted in 5 animals (all in group A). These lesions were dome shaped and ranged 2 to 4 mm in size, which appeared in the distal portion of the large intestine mainly, then in the middle portion, and none in the proximal part. (Table 2, Figure 2).

Most tumor tissues were tubular lesions with atypical severe cellular and structural high-grade dysplasia. A small number of lesions revealed relatively moderate dysplasia. Ten dysplasias were categorized as low-grade dysplasia (Figure 3A), and 26 dysplasias as high-grade dysplasia (Figure 3B), 22 out of 36 (61.1%)

dysplasia lesions were DALMs. Four out of 26 tumours on the distal portion of the large intestine were confirmed to be early invasive adenocarcinomas (Figure 3C), and 3 of them arose within a DALM. No signs of tumor development were detected in control groups B to D.

Among the animals with dysplasia and/or cancer, the incidence of dysplasia and/or cancer was 15.0% (6/40), 20.0% (8/40) and 65.0% (26/40) in the proximal, middle and distal colon segments, respectively, 4 of 10 (40.0%) animals with dysplasia and/or cancer had lesions limited to only one colon segment, 3 animals (30.0%) had lesions in two different segments, and 3 animals (30.0%) had lesions in all three segments. Of the 3 animals with cancers, one had two synchronous cancers.

Pathology score/cancer relationship

The mice that received repeated administrations of 30 g/L DSS showed mild colitis regardless of DMH pretreatment. Mice in group A and B demonstrated multiple foci of gland loss with inflammatory cell infiltration, but not many crypt abscess formations and mucosal ulcerations. Pathological scores in these two groups were statically significantly higher than those in group D (Table 2). However, there was no significant relationship between pathology scores among three portions of group A and B. This did not correlate well with the locations of CRC that developed mainly on the distal segment of colorectum.

Figure 4 Immunohistochemistry of β -catenin and p53 in dysplastic lesions found in the colon of mice from group A. A: Control colon. β -catenin was expressed exclusively on the cell membrane. No cytoplasmic or nuclear staining was observed, B: Dysplasia cells expressed strong cytoplasmic and partly nuclear staining of β -catenin while other adjacent dysplastic cells showed membrane pattern of β -catenin, C: Lesions of early invasive cancer showing strong nuclear and cytoplasmic staining of β -catenin, D: No nuclear expression of p53 in lesions with high-grade dysplasia was observed. Original magnification, $\times 40$.

β -catenin and p53 expression

Four cancers, 25 dysplasias (10 of low-grade, 15 of high-grade), 10 negative dysplasias and 10 control animals were studied for β -catenin and p53 expression, respectively.

In normal colon epithelial cells, β -catenin was mainly localized at the membranes of cell-cell borders (Figure 4A).

Table 2 Incidence of dysplasia/cancer and pathology score of UC (mean±SD)

Group number	Mice	Number of dysplasias/cancers			Pathology score of UC		
		Proximal	Middle	Distal	Proximal	Middle	Distal
A	11	0.55±0.82	0.73±0.79	2.36±1.12 ^a	1.82±0.40	1.72±0.46	1.82±0.40 ^c
B	11	0.0±0.0	0.0±0.0	0.0±0.0	2.00±0.63	1.82±0.40	2.09±0.54 ^c
C	10	0.0±0.0	0.0±0.0	0.0±0.0	0.0±0.0	0.0±0.0	0.0±0.0
D	10	0.0±0.0	0.0±0.0	0.0±0.0	0.0±0.0	0.0±0.0	0.0±0.0

^a*P*<0.05, significantly different from proximal and middle portion of group A; ^c*P*<0.05 significantly different from group D.

Strong (2+) β -catenin expression was seen in nuclei and cytoplasm of cancer cells of 4 specimens (Figure 4C). Although the intensity was relatively weaker than that in carcinoma cells, dysplastic cells showed positivity for β -catenin in their nuclei, cytoplasm, and cell membranes (Figure 4B). The intensity was greater in high-grade dysplasias (73.3% were 2+) than in low-grade dysplasias (30.0% were 2+). In addition, positive reaction against β -catenin antibody was found in vascular endothelia and infiltrated inflammatory cells. However, nuclear p53 staining was not seen in tumor cells and dysplastic cells (Figure 4D).

DISCUSSION

The results of our experiment indicate that neither DMH pretreatment nor repeated administration of 3% DSS induced any tumorous lesions in the colorectum. However, their combination induced 4 invasive adenocarcinomas and 36 lesions with dysplasia in 11 mice within the relatively short term of 10 wk. Therefore, a clear synergism between the two agents was established. The histopathology of dysplasia and cancer in this model was very similar to that seen in humans. First, the animals developed dysplasia in both flat mucosa and DALM identical to that seen in humans. Second, early invasive cancer was revealed in 4 out of 40 lesions, and the data provided evidence of a dysplasia-adenocarcinoma sequence in this experimental system. Finally, the distribution of dysplasia/cancer was also similar. Colon cancers in patients with UC developed mainly on the left side of the large intestine and transverse colon. In our experiment, DMH and DSS induced colitis-related tumors dominant in the distal part of colon followed by in the middle part. In human UC, dysplasia was found in two or more segments in 42-75% of the cases and the incidence of multiple synchronous cancers was reported to vary from 22-50%^[20-22]. In the current study, the result also showed that dysplasia was present in two or more segment in 60% of the animals and the incidence of synchronous cancers was 33.3%. However, we finished the experiment in 10 wk and only induced four early invasive cancers.

β -catenin played a role in both cell adhesion and intracellular signaling^[23,24]. Cytoplasmic/nuclear translocation of β -catenin was reported in human colitis-associated neoplasms^[25-27] and DSS-induced CRC mice models^[28,29]. In our study, we also found aberrant β -catenin expression immunohistochemical in dysplasia and cancer in mice treated with DMH and DSS. Furthermore, We noticed that carcinoma, high- and low-grade dysplasias had different intensities and distributions of β -catenin. However, we don't know whether the translocation of β -catenin was due to loss of APC function or a direct mutation of β -catenin itself. This change might be associated with the progression from dysplasia to cancer. Our model are dissimilar regarding the role of p53. Nuclear expression of p53 was a relatively early event in UC-related CRC compared with sporadic colon neoplasia^[30-32]. However, in the current study, p53 immunohistochemical expression was not detected in colonic dysplasia and cancer. This findings might be due to the absence or low frequency of p53 mutations in colitis-related cancer mouse model. It is also

possible that p53 mutations occurred at a later stage of cancer.

In conclusion, this study provides a novel colitis-associated mouse colon neoplasm model which features a single dose of procarcinogen followed by induction of chronic UC in a relatively short term. Further studies on molecular mechanism or chemopreventive agents of this model may help us better understand CRC in patients with UC.

ACKNOWLEDGEMENTS

The authors wish to thank Dr. Mei Jin, Department of Pathology, Sir Run Run Shaw Hospital, Zhejiang University, Hangzhou, China, for her technical assistance in immunohistochemical analysis. We are also very grateful to Ming-Juan Jin, Department of Epidemiology and Public Health Statistics, Medical College of Zhejiang University, Hangzhou, China, for her statistical analysis.

Abstract

AIM: Smoking may affect adversely the response rate to interferon- α . Our objective was to verify this issue among chronic hepatitis C patients.

METHODS: Over the year 1998, 138 chronic hepatitis C male Egyptian patients presenting to Cairo Liver Center, were divided on the basis of smoking habit into: group I which comprised 38 smoker patients (>30 cigarettes/d) and group II which included 84 non-smoker patients. Irregular and mild smokers (16 patients) were excluded. Non eligible patients for interferon- α therapy were excluded from the study and comprised 3/38 (normal ALT) in group I and 22/84 in group II (normal ALT, advanced cirrhosis and thrombocytopenia). Group I was randomly allocated into 2 sub-groups: group Ia comprised 18 patients who were subjected to therapeutic phlebotomy while sub-group Ib consisted of 17 patients who had no phlebotomy. In sub-group Ia, 3 patients with normal ALT after repeated phlebotomies were excluded from the study. Interferon- α 2b 3 MU/TIW was given for 6 mo to 15 patients in group Ia, 17 patients in group Ib and 62 patients in group II. Biochemical, virological end-of- treatment and sustained responses were evaluated.

RESULTS: At the end of interferon- α treatment, ALT was normalized in 3/15 patients (20%) in group Ia and 2/17 patients (11.8%) in group Ib compared to 17/62 patients (27.4%) in group II ($P=0.1$). Whereas 2/15 patients (13.3%) in group Ia. and 2/17 patients (11.8%) in group Ib lost viraemia compared to 13/62 patients (26%) in group II ($P=0.3$). Six months later, ALT was persistently normal in 2/15 patients (13.3%) in group Ia and 1/17 patients (5.9%) in group Ib compared to 9/62 patients (14.5%) in group II ($P=0.47$). Viraemia was eliminated in 1/15 patients (6.7%) in group Ia and 1/17 patients (5.9%) in group Ib compared to 7/62 patients (11.3%) in group II, but the results did not mount to statistical significance ($P=0.4$).

CONCLUSION: Smokers suffering from chronic hepatitis C tend to have a lower response rate to interferon- α compared

to non-smokers. Therapeutic phlebotomy improves the response rate to interferon- α therapy among this group.

INTRODUCTION

It has been reported that cigarette smoking causes a variety of life threatening disorders such as pulmonary, cardiovascular, neoplastic, secondary polycythemia and others^[1]. In addition, cigarette smoking has hepatotoxicity independent from alcoholic cirrhosis^[2,3] and chronic hepatitis B virus carriers^[4]. It increases the 5-year mortality rates of patients with alcoholic cirrhosis^[5]. Furthermore, tobacco consumption has been associated with an increased risk of hepatocellular carcinoma (HCC) in patients with viral hepatitis^[6-8]. A recent report has found that cigarette smoking was associated with increased fibrosis and histological activity in chronic hepatitis C (CHC) patients. It suggested that cigarette smoking could influence liver disease either by direct hepatotoxicity through its various constituents or secondary to erythrocytosis, immunological impact or synergistic effect with other factors such as alcohol^[9].

The spectrum of liver injury in patients with CHC is broad and many factors influence the severity and progression of the lesion such as age^[10], route of infection^[11], genotype^[12], concomitant chronic hepatitis B virus (HBV) infection^[13] and others. Furthermore, many factors influence the natural history of CHC, clinical picture, and response to therapy, yet not all identified factors^[12]. The adverse effects of heavy smoking particularly the response to therapy among CHC patients have been overlooked. Accordingly, we were motivated to study the impact of heavy smoking on clinical presentation, laboratory parameters and response to interferon- α (IFN- α) therapy in these patients.

MATERIALS AND METHODS

Over the year 1998, 138 CHC Egyptian male patients presenting to Cairo Liver Center for assessment of eligibility to interferon therapy were recruited. All patients met the following inclusion criteria: hepatitis C virus (HCV) antibody positive for ELISA, detectable HCV-RNA (Innolipa PCR) in serum, negative for HBsAg (Abbot ELISA), absent clinical and ultrasonographic evidence of cirrhosis, no ascites or hepatocellular carcinoma. No patient had received previous course of IFN- α therapy.

A standardized questionnaire to assess the smoking history was used^[14] and accordingly all patients were divided into: smokers (group I) which consisted of 38 patients who smoked >30 cigarettes/d and non-smokers (group II) which included 84 patients who never smoked. Sixteen patients who were irregular, mild and passive smokers as well as pipe water and cigar smokers were excluded owing to difficulty in calculating smoking index. All patients in both groups were residents away from known

districts of high carbon monoxide pollution. None of the patients received drugs causing haemolysis over the preceding 6 mo period. All patients in both groups were assessed for haemoglobin, haematocrit, serum iron, and liver profile before liver biopsy. Patients who had persistently normal transaminases or had thrombocytopenia (platelet count less than 80 000/mm³, 1 patient from group 1 and 16 patients from group 2) were considered non-eligible to interferon therapy and therefore excluded from the study.

Liver biopsy was performed using a true-cut needle to 37 patients from group I and 68 patients from group II scheduled for IFN- α therapy. All liver biopsy specimens were fixed in formalin, embedded in paraffin and routinely processed. The histological grade of disease activity and fibrosis was assessed using a reproducible scoring system^[15] as follows: A 1 to A 3 for the degree of necroinflammatory activity (A 1 = mild, A3 = marked) and stage F0 to F4 for the degree of fibrosis (F0 = no fibrosis, F4 = cirrhosis). Two patients from group 1 and 6 patients from group 2 who had F4 (established cirrhosis) were also eliminated from IFN- α therapy. Iron staining using Perl's stain was done to non-cirrhotic specimen in both groups and scored according to percentage of iron stained hepatocyte.

Phlebotomy at a 2-wk interval till achieving low normal serum iron level was performed to 18 randomly allocated cases in group I patients (Ia), whereas 17 smoker patients had no phlebotomy and formed group Ib. Before undergoing phlebotomy all patients were instructed about its possible complications and all gave informed consent. None of the patients developed serious complications and all continued their schedule of phlebotomy. On serial ALT follow up, persistent normalization of ALT was observed in 3 patients in group Ia and therefore they were excluded from interferon therapy.

Thirty two smoker patients (15 from group Ia and 17 from group Ib) and 62 non smoker patients from group II with persistent elevation of ALT received IFN- α therapy -3 MU TIW for 6 mo with serial evaluation of transaminases and test for HCV-RNA at the end of treatment and 6 mo later.

Statistical data was presented as mean \pm SD for the numeric variables. *t*-test was performed to compare both groups to each other. Response to therapy was categorized into responders and non-responders then presented into cross tables. χ^2 analysis was performed to assist the difference between the two groups. A *P* value of less than 0.05 was accepted as a level of significance.

RESULTS

Patients in group 1 had a significantly higher haemoglobin level ranging 16.1-19.1 g/dL with a mean of 16.9 \pm 0.54 g/dL compared to the patients in group 2 whose haemoglobin level ranged 13.5-16.3 g/dL with a mean of 15.3 \pm 0.59 g/dL. All patients in group 1 (100%) had a haemoglobin level exceeding 16 g/dL compared to 12/84 (14.3%) in patients of group 2.

The haematocrit level among group 1 patients ranged 56.1-61.4% with a mean of 56.3 \pm 0.86%, while group 2 patients had a haematocrit level ranging 45-55.9% with a mean of 54.8 \pm 1.16%, the difference was statistically significant (*P*<0.005). All patients in group 1 had a haematocrit value exceeding 55% compared to 14.3% of group 2 patients.

The mean serum iron level was significantly higher in group 1 (160.4 \pm 38.36 μ g/dL) with a range of 100.3-283 μ g/dL compared to group 2 (148.8 \pm 28.11 μ g/dL) with a range of 90-194.3 μ g/dL (*P*<0.05). Serum iron in 12 (31.5%) patients of group 1 was above normal level.

The mean serum uric acid level was 5.4 \pm 1.0 mg/dL in group 1 (range of 4-9 mg/dL) compared to 5.0 \pm 0.7 mg/dL (range of 3.8-6.9 mg/dL) in group 2, and the results were statistically significant (*P*<0.01).

Liver biopsy was performed to 37 patients from group 1 and 68 patients from group 2. Mild hepatitis was recorded in 10 (27%) patients of group 1 and 39 (57.4%) of group 2, whereas 17 patients (45.9%) of group 1 and 20 patients (29.4%) of group 2 had moderate hepatitis. Severe hepatitis was recorded in 8 patients (21.6%) of group 1 and 3 patients (4.4%) of group 2. Cirrhosis was recorded in 2 patients (5.4%) of group 1 and 6 patients (8.8%) of group 2. Iron staining using semiquantitative Perl's stain was positive with predominant periportal localization and associated steatosis in 3 (8.6%) patients of group 1 and 1 patient (1.5%) of group 2.

The end treatment biochemical response (ETBR) was reported in 5 patients (15.6%) of group 1 and 17 patients (27.4%) of group 2. Six months later only 3 patients (9.4%) of group 1 showed sustained normal ALT compared to 9 patients (14.5%) of group 2. The end treatment virological response (ETVR) was reported in 4 patients (12.5%) of group 1 and 3 patients (26%) of group 2. Six-months later, the sustained virological response (SVR) was reported in 2 patients (6.3%) of group 1 and 7 patients (11.3%) of group 2, but the differences did not reach statistical significance (*P*>0.05).

Among group I patients, ETBR in patients who had phlebotomy (group Ia) was recorded in 3 patients (20%) compared to 2 patients (11.8%) in those underwent no phlebotomy (group Ib). Two patients (13.3%) in group Ia had sustained biochemical response (SBR) compared to 1 patient (5.9%) in group 2b.

ETVR was found in 2 patients (13.3%) of group Ia compared to 2 patients (11.8%) of group Ib. SVR after 6 mo obtained in 1 patient of both groups (6.7% and 5.9%) respectively. Therefore, repeated phlebotomy increased both ETBR and SBR, but had no effect on virological responses (ETVR or SVR).

In group Ia repeated phlebotomy led to a significant decrease in mean ALT level from 167 \pm 50.3 to 112 \pm 37.7 IU/L (*P*<0.01).

DISCUSSION

Many studies have shown that smoking is an independent factor contributing to progression of HBV induced cirrhosis^[4], alcoholic cirrhosis^[1] and HCC development^[6-8]. A recent French study has shown similarly that smoking favors progression to cirrhosis in chronic HCV infection independent of other co-morbid conditions^[9].

The impact of smoking on various liver disorders has been extrapolated from experimental studies. It has been suggested that tobacco induced liver injury is ascribed to oxidative stress associated with lipid peroxidation^[16,17]. In patients with CHC, the reduction in the concentration of hepatic, plasmatic and lymphocytic glutathione could favor the hepatotoxic effect of smoking^[18]. Data from experimental studies suggest that nicotine, a major component of tobacco smoke, was rapidly absorbed through the lungs and released into circulation. Thereafter, it is mainly metabolized through the liver inducing lesions characterized by steatosis and focal or confluent necrosis^[19].

A recent study demonstrated that smoking was mainly related to increased inflammatory activity but not to the stage of fibrosis^[20], whereas Pessione *et al.*^[9] provided evidence that smoking could worsen the degree of fibrosis in CHC independent of other co-morbid conditions. Advanced fibrosis adversely affected the response to interferon therapy^[21,22], but this could not explain why smokers had lower response to interferon therapy compared to non-smokers as patients in both groups had comparable histopathological affection at entry of study. Cigarette smoking could increase generation of oxygen radicals. Chronic viral hepatitis patients who were cigarette smokers tended to have lower levels of natural anti-oxidants compared to non-smokers^[23].

Smoking could induce a secondary form of polycythemia.

Smoker's polycythemia was attributable to increased carbon monoxide. The latter interfered with oxygen transport and utilization^[24]. Secondary polycythemia may be associated with increased red cell turnover and subsequent rise of serum iron and tissue iron. In support of this hypothesis in our study, all smoker groups had higher hemoglobin and haematocrit compared to non-smoker group. In our study all HCV smoker patients had higher serum iron compared to HCV non-smoker patients as well.

It has long been recognized that hepatic iron overload could promote hepatic fibrosis in hereditary haemochromatosis^[25]. Serum iron stores were frequently increased in patients with CHC^[26]. Enhanced liver fibrosis has been reported in HCV infected patients with stainable iron in liver biopsy compared with controls with no detectable liver iron^[27]. The mechanism by which iron accumulates in CHC patients has not been established but might in part be the result of iron release from damaged hepatocytes^[28].

Another possible mechanism is that smoker polycythemia contributes to increased serum iron by increased cell turnover.

In support of this point of view, it was found that phlebotomy ameliorated not only symptoms related to smoker's polycythemia, but also transaminase level and resulted in persistent normalization of ALT level in 3/38 smoker patients. In our study, non-smoker patients had a better-sustained virological response rate compared to smoker patients. Although, phlebotomy resulted in a slight amelioration response rate, but results did not reach statistical significance. Many reports^[29,30] showed significant improvement in serum ALT levels in interferon non-responders when they underwent iron reduction by therapeutic venesection. Three prospective, randomized controlled trials showed that iron reduction could increase the response rate to interferon therapy. While another multi-center trials showed no significant improvement in response of CHC to iron reduction treatment, although, histological improvement was documented even in patients with iron therapy alone^[31].

This could be explained by other possible mechanisms such as immune alterations. Cigarette smoking may induce immune impairment by increasing apoptosis of lymphocytes, and counteracting interferon effect^[32]. It was shown that tobacco smoking had a suppressive effect on human immunity as a result of decreased serum concentration of immunoglobulins and lysosome decreased absolute number of (CD16+) NK-cells and elevated population of (CD8+) T-cytotoxic lymphocytes entailing a decrease in CD4+/CD8+ ratio^[33]. Cigarette smokers exhibited impaired NK cytotoxic activity and unbalanced production of pro- and anti-inflammatory cytokines^[34]. Smoking could alter immune response either directly through impairment of antigen receptor mediated signal transduction pathways leading to T cell anergy^[35] or indirectly through brain immune interactions^[36].

In conclusion, smokers suffering from CHC tend to have lower response to IFN- α compared to non-smokers. Therapeutic phlebotomy improves the response rate to IFN- α therapy among this group. This deserves further evaluation in prospective study. Chronic hepatitis C patients should be advised to avert smoking before embarking on interferon therapy.

Abstract

AIM: RNA interference (RNAi) is a newly discovered phenomenon provoked by dsRNA. The dsRNA is initially cleaved by Dicer into 21-23 nt small interfering RNA (siRNA) and can then specifically target homologous mRNA for degradation by cellular ribonucleases. RNAi has been successfully utilized to down-regulate the endogenous gene expression or suppress the replication of various pathogens in mammalian cells. In this study, we investigated whether vector-based siRNA promoted by U6 (pSilencer1.0-U6) could efficiently inhibit HBV replication in cell culture.

METHODS: pSilencer vectors with inserts targeting on different regions of HBV genome were constructed. These plasmids were co-transfected with pHBV3.8 into Huh-7 cells via lipofection and viral antigens were measured by ELISA. Viral RNA was analyzed by Northern blot. The mRNA of Mx_A and 2'-5'OAS was reverse transcribed and quantified by real-time PCR.

RESULTS: Vector-based siRNA could potentially reduce hepatitis B virus antigen expression in transient replicative cell culture. Furthermore, Northern blot analysis showed that viral RNA was effectively degraded, thus eliminating the messengers for protein expression as well as template for reverse transcription. Real-time PCR analysis of cellular Mx_A and 2'-5'OAS gene expression revealed that vector-based siRNA did not provoke the interferon pathway which reassured the specificity of the vector-based RNA interference technique.

CONCLUSION: Our results indicate that RNA interference may be a potential tool to control HBV infection.

INTRODUCTION

Hepatitis B virus is a severe infectious pathogen causing chronic liver diseases and increasing risk of hepatocellular carcinoma^[1]. Although recombinant vaccines are widely available^[2], HBV infection is still a big challenge to the societies

all over the world. Until now, interferon- α and nucleoside analogs, such as lamivudine, are of the few drugs capable of inhibiting HBV replication. However, interferon treatment usually results in a limited percentage of complete response and relapses generally occur without further treatment. Lamivudine, a strong inhibitor of HBV's reverse-transcriptase, has been proved to be highly effective in blocking its genome replication. Nevertheless, a significant portion of patients relapsed after cessation of treatment. With prolonged treatment, escape mutants would develop^[3].

RNA interference is a newly discovered phenomenon present in almost all eukaryotes^[4,5]. It is activated by dsRNA, which is subsequently cleaved by Dicer into 21-23 nt small interfering RNAs (siRNA). The siRNAs are then unwound by RISC (siRNA induced silencing complex) in the presence of ATP. The activated RISC binds to and degrades target mRNA guided by the single strand siRNA. In mammals, long dsRNA can activate protein kinase R (PKR) and RNaseL, which are key components of the interferon signaling pathway, thus causing unspecific effects, whereas 21-23 nt siRNAs are short enough to bypass them^[6]. Many studies have been carried out to silence a number of RNA viruses by RNA interference, such as human immunodeficiency virus (HIV), hepatitis C virus (HCV) and poliovirus, *etc*^[7-11]. As hepatitis B virus (HBV) utilizes pregenomic RNA for synthesis of viral DNA via reverse transcription, it is also an ideal candidate for RNAi. Recently, vector-based RNAi technique, which uses endogenous U6 or H1 promoter to generate small interfering RNA (siRNA) *in vivo*, has become a new and economical system to achieve gene silencing^[12,13]. In this study, we investigated whether vector-based siRNA promoted by U6 (pSilencer1.0-U6) could efficiently inhibit HBV replication in cell culture.

MATERIALS AND METHODS

Materials

TRIzol reagent, Dulbecco's modified Eagle's medium (DMEM), fetal calf serum and antibiotics were from GIBCO BRL. Restriction endonucleases were supplied by MBI Fermentas. SuperScript II reverse transcriptase was from Invitrogen, Carlsbad. DNA sequence primers were synthesized by CASarray, Shanghai. pSilencer 1.0-U6 was from Ambion, Austin. HBsAg and HBeAg ELISA kit were purchased from Shanghai SIIC Kehua Biotech. pHBV3.8 plasmid encoding the whole transcript of HBV DNA (adr subtype) from the core promoter to the polyA signal region (nucleotides 1403-3215 plus 1 to 1987), was constructed as a 1.2 copy insert of the full-length HBV genome into vector pBS+ (Stratagene) via restriction enzyme *EcoRI* and *PstI* sites (kindly provided by Professor. Yuan Wang, Institute of Biochemistry, Academia Sinica, Shanghai). After transfected into Huh-7 cells, the pHBV3.8 could express both HBV surface antigen (HBsAg) and E antigen (HBeAg), and the replication of HBV could be initiated. Plasmid pcDNA-CAT containing the chloramphenicol acetyltransferase (CAT) gene under control of the CMV promoter was co-transfected as internal control. The expression of CAT could be measured by CAT ELISA kit (Roche, Mannheim, Germany).

Cell culture and transfection

Huh-7 cell line was maintained in Dulbecco's modified Eagle's

medium supplemented with 100 mL/L fetal calf serum, 2 mmol/mL L-glutamine, 100 µg/mL penicillin and 100 units/mL streptomycin (GIBCO BRL). The cells were incubated in a humidified incubator at 37 °C containing 50 mL/L CO₂. Cell viability was estimated by the trypan blue dye exclusion method. Huh-7 cells were transfected using FuGENE6 cationic liposome (Roche, Mannheim, Germany), and cells were harvested 48 h and 72 h after transfection, respectively. Experiments were performed in triplicate.

Target sequence selection and insertion sequence synthesis

By aligning different subtypes of HBV genome and using the Ambion web-based software, we selected 3 regions of high conservation designated as si-HBV1, 2 and 3 to be the target sequence. The target sequence of si-HBV1 was located in S region as well as P region of the HBV genome (nt 310 to 328), si-HBV2 and 3 were both in the C region (nt 1868 to 1886 for HBV2, nt 2373 to 2391 for HBV3). si-HBV1, 2 and 3 had the siRNA sequences completely identical to the target sequence of pHBV3.8. To create pSilencer plasmids, we used the primers: 5'-TTCGACAGTCCCCAACCTCCTTCAAGAGAGGAGGTTGGGACTGCGAATTTTTT-3' (sense) and 5'-AGCTAAAAAATTCGAGTCCCCAACCTCCTTCTTGAAGGAGGTTGGGACTGCGAAGGCC-3' (antisense) for pSi-HBV1; 5'-GCCTCCAAGCTGTGCCTTGTTCAAGAGACAAGGCACAGCTTGGAGGCTTTT-3' (sense) and 5'-AGCTAAAAAAGCCTCCAAGCTGTGCC TTGTCTCTTGAACAAGGCACAGCTTGGAGGCGGCC-3' (antisense) for pSi-HBV2; 5'-GAAGAACTCCCTCGCCTCGTTCAAGAGACGAGGCGAGGGAGTTCTTCTTTTTT-3' (sense) and 5'-AGCTAAAAAAGAAGAACTCCCTCGCCTCGTCTCTTGAACGAGGCGAGGGAGTTCTTCGGCC-3' (antisense) for pSi-HBV3.

Figure 1 Design of siRNAs specific for HBV genome. A: Downward arrows show the target sites within the RNA transcripts. The HBV ORFs are shown below aligned with HBV mRNA. B: Schematic presentation of U6 promoter constructs. The inverted 19 nt sequences are separated by a 9 nt loop, transcription ends with 5Ts. The resulting shRNA (short hairpin RNA) are predicted to fold back to form a hairpin RNA.

In this study, the target sequences used by Shlomai *et al.*^[14] for pSuper core1 (nt 2191 to 2209) and pSuper X (nt 1649 to 1667)

were also included for comparison (Figure 1) with slight modifications to suit the DNA sequence of pHBV3.8. The oligo sequences were: 5'-AATCAGACAACACTACTGTGGTTCAAGAGACCACAGTAGTTGTCTGATTTTTTTT-3' (sense) and 5'-AGCTAAAAAAATCAGACAACACTACTGTGGTCTCTTGAACCACAGTAGTTGTCTGATTGGCC-3' (antisense) for pSi-core1; 5'-GGTCTTACATAAGAGCACTTTCAAGAGAAGTGCTCTTATGTAAGACCTTTTTT-3' (sense) and 5'-AGCTAAAAAAGGTCTTACATAAGAGCACTTCTTGAAGAGTGCTCTTATGTAAGACCGGCC-3' (antisense) for pSi-X.

pSi-EGFP-h was a control vector with insertion sequence targeting on EGFP gene. The synthesized oligos were: 5'-GACGTAAACGGCCACAAGTTTCAAGAGAAGTTGTGGCCGTTTACGTCTTTTTT-3' (sense) and 5'-AGCTAAAAAAGACGTAAACGGCCACAAGTTCTTCTTGAAGTTGTGGCCGTTTACGTTCGCC-3' (antisense).

Plasmid constructs

The oligos were annealed and cloned into *ApaI*-*HindIII* sites of pSilencer as described in the pSilencer 1.0 U6 manual (Ambion). All the plasmids constructed were confirmed by DNA sequencing.

Quantitation of HBsAg and HBeAg

The HBsAg and HBeAg secreted into the culture media were measured by diagnostic ELISA kit (Shanghai SIIC Kehua Biotech).

Northern blot analysis of viral RNA

Total RNA was extracted directly from transfected cells using TRIzol reagent (Gibco BRL). After 30 min of DNaseI digestion of remaining DNA, total RNA was re-extracted by TRIzol, precipitated and dissolved in DEPC-H₂O. Ten micrograms of total RNA was electrophoresed on 10 g/L formaldehyde-agarose gel and then transferred to nylon membranes (Roche, Mannheim, Germany). After fixation at 120 °C for 30 min, the membrane was prehybridized for 6 h at 42 °C in 5×SSC, 5×Denhardt's solution, 10 g/L SDS, 50 g/L formaldehyde, 0.1 mg/mL salmon sperm DNA, followed by hybridization with full-length HBV DNA probes labeled with [α -³²P] dCTP by hexamer random labeling kit (Roche, Mannheim, Germany) under the same condition of prehybridization at 42 °C for 16 h. After a stringent washing process at 68 °C, the signals were detected by autoradiography, then the blots were quantified by densitometry. The 28 s and 18 s rRNA were visualized under ultraviolet light for equal loading control. The values of HBV blots were normalized by monitoring the expression of an internal control CAT by CAT ELISA (Roche, Mannheim, Germany).

Quantitative real-time PCR

Huh-7 cells in 6-well plates were transfected with 2 µg of various plasmids. After 48 h of transfection, total RNA was extracted as described above. RNA was denatured for 5 min at 65 °C in the presence of random hexamer, immediately cooled in ice water, then reverse transcribed using SuperScript II reverse-transcriptase according to the manufacturer's instructions. Real-time PCR (iCycler, Bio-Rad) was performed as instructed by iCycler resource guide. Reactions with no reverse transcriptase enzyme added were performed in parallel. Briefly, reactions were carried out in 25 µL volume containing 2 µL of template (cDNA or RNA), 400 nmol/L of each forward and reverse primer and 1X SybrGreenI PCR Master Mix (Roche). To quantitate cellular transcripts, dilutions of plasmids containing the human GAPDH gene were run in parallel. The experiment was performed twice. The primer sequences used included: 5'-GGTATCGTGGAAGGACTCATGAC3' (sense) and 5'-ATGCCAGTGAGCTTCCCGTTCAGC3' (antisense) for GAPDH; 5'-GCTACACACCGTGACGATATGG3' (sense) and 5'-CGAGCTGGATTGGAAAGCCC3'

(antisense) for MxA; 5'-TCAGAAGAGAAGCCAACGTGA-3' (sense) and 5'-CGGAGACAGCGAGGGTAAAT-3' (antisense) for 2'-5'OAS.

RESULTS

Inhibition of HBV gene expression in transiently transfected Huh-7 cells by RNAi

pSilencer, pSi-EGFP-h and other derivatives targeting on different regions of HBV genome were co-transfected with pHBV3.8 in the ratio of 10:1 into Huh-7 cells. pcDNA-CAT was also transfected as internal control. The secreted viral antigens, HBsAg and HBeAg in the culture media were quantified 48 h and 72 h after transfection. Transfection efficiencies were standardized by measurement of CAT using CAT ELISA Kit. Compared with control vector, HBsAg and HBeAg expressions were reduced by about 60% in average when measured 48 h after transfection (Figure 2). When the antiviral effect of siRNA was assessed 72 h post-transfection, the silencing effect was still apparent, indicating the stability of the transcribed RNAi. Among all the siRNAs used, pSi-HBV1 targeting on S gene as well as P gene of HBV genome was most potent, as HBsAg and HBeAg were reduced 86% and 83% 72 h after transfection, respectively.

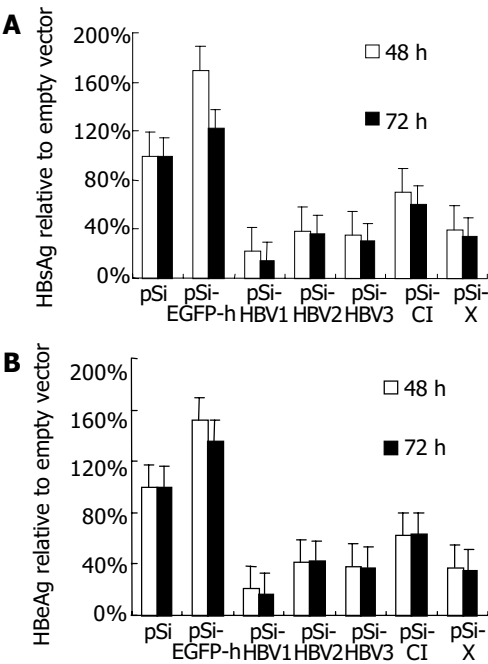

Figure 2 Effect of RNAi on HBV protein expression in transiently transfected Huh-7 cells.

Reduction of HBV viral transcripts by RNAi

To determine whether viral pregenomic RNA and other transcripts were efficiently degraded by siRNA, Northern blot assay was carried out using ³²P-labeled full length HBV fragment as the probe generated with a random-primed labeling kit. Compared with control vector pSi-EGFP-h, significant reduction of all the viral transcripts was observed when pSilencer vectors targeting on specific HBV RNA were used (Figure 3). Among them, pSi-HBV1 and pSi-HBV2 were much more efficient with over 90% reduction in viral RNAs.

Vector-based siRNA could not activate interferon response

To rule out the possibility that inhibition of HBV gene expression and replication by vector-based siRNA was due to the dsRNA-induced activation of IFN pathway, we compared the mRNA

levels of IFN-induced genes 2'-5'OAS and MxA by quantitative real-time PCR 48 h after transfection of siRNA generating plasmids. Compared with mock-transfected Huh-7 cells, IFN induced about 10 000 and 100-fold increase in 2'-5'OAS and MxA mRNA levels, respectively. While the transfection of pSi-HBV plasmids only led to 1.67-fold and 0.71-fold (in average) induction of MxA and 2'-5'OAS, respectively, thus eliminating the non-specific effect of siRNAs (Figure 4).

Figure 3 Effect of RNAi on HBV gene transcription detected by Northern blot. A: Northern blot experiment of HBV transcripts. The 28 s and 18s rRNAs were visualized under ultraviolet light for equal loading control. B: The hybridization signal was quantitatively evaluated by Smartview™ image analysis software (Shanghai Fu-ri Inc).

Figure 4 Effect of RNAi on IFN-induced genes. Real-time PCR quantification of MxA and 2'-5'OAS. The copy number of MxA and 2'-5'OAS were normalized with GAPDH. The relative fold induction of each gene compared with mock transfection is shown.

DISCUSSION

Numerous reports have demonstrated that RNAi can block replication of various types of mammalian viruses, including

two retroviruses, human immunodeficiency virus (HIV)^[7,15-17] and Rous sarcoma virus^[18]; a negative-strand RNA virus, respiratory syncytial virus (RSV)^[19], two positive-stranded RNA virus, hepatitis C virus (HCV)^[9,20,21] and poliovirus^[10]; and a DNA virus, human papillomavirus^[22]. Although HBV is a DNA virus, its replication requires a key step of reverse transcription for synthesis of viral DNA from pregenomic RNA, which is quite different from other DNA viruses. Therefore, HBV is assumed to be susceptible to siRNA not only at the level of post-transcription, but also at the level of replication.

In this study, we demonstrated that vector-based siRNA could significantly inhibit HBV antigen expression (both HBsAg and HBeAg) in hepatocytes. Furthermore, Northern blot analysis revealed that HBV pregenomic RNA and other shorter transcripts were diminished in the presence of specific siRNAs. Our results were different from a previous report^[14], which demonstrated that pSuper-core1 and pSuper-core2 did not inhibit HBsAg and resulted in only a minor reduction of about 13% in the 3.5-kb transcript whereas pSuper-X reduced both HBsAg and HBeAg, and resulted in a significant reduction of about 68% at the level of all the viral transcripts. However, they were consistent with McCaffrey *et al.*^[23] that siRNA targeting on the pregenomic RNA in the overlap region of the C and P open reading frames (ORF) reduced the levels of 2.4- and 2.1-kb RNAs and serum HBsAg even though it did not directly target on these RNAs. It can be assumed that HBV-specific siRNA first recognizes and degrades the corresponding sequence of viral pregenomic RNA, consequently depleting template for reverse transcription. Decreased synthesis of viral DNA then further influences the life cycle of HBV genome, especially in transcription and translation, thereby resulting in the overall inhibition of viral RNA and proteins.

Among the selected siRNAs, si-HBV1 is the most potent in inhibiting HBV replication. As si-HBV1 targeted on S region of the virus, multiple viral RNAs would be inhibited. Besides, it could also down-regulate the expression of P gene (the S ORF is within the P ORF), thus inhibiting viral replication *in trans*. These factors might explain, at least in part, why si-HBV1 has the highest efficacy.

Compared with the general nonspecific shutdown of cellular protein synthesis by double-stranded RNA (dsRNA) mediated primarily by IFN- α/β through the induction of protein kinase R (PKR) and RNaseL, the main known advantage of RNAi strategies is its high specificity on gene silencing. Attention has been paid to the potential non-specific effects of RNAi recently. Bridge *et al.*^[24] found that a substantial number of siRNA vectors could trigger an interferon response. Sledz *et al.*^[25] reported that transfection of siRNA resulted in interferon mediated activation of the Jak-Stat pathway and global up-regulation of IFN-stimulated genes. Although Kapadia *et al.*^[20] and we did not detect the activation of known IFN-inducible pathways after transfection of siRNA or siRNA generating plasmids, the overall inhibition of viral RNAs by RNAi in our study and others still raise the possibility that RNAi may have some sequence-independent antiviral effects at certain doses. Overdose of siRNA or accumulation of unprocessed or aberrantly processed Pol III transcripts may trigger interferon response. Hence, further studies are required to optimize the dose and structure of short-hairpin RNA as well as the delivery strategy to minimize the non-specific effects.

Taken together, our data show that RNAi is an attractive new strategy to inhibit the replication of hepatitis B virus. But to really apply this phenomenon to medical therapy, many problems are yet to be solved. One major problem is the selection of target sequence. Although there have been some online tools to help select the target sequence, the result is not always satisfactory. Recently, a theory has been proposed that siRNAs with relative stability at the 5' end of the sense strand, relative

instability at the 5' end of the antisense strand and the cleavage site will most probably be the most effective ones^[26-28]. These findings have significantly enlarged our knowledge of target selection, but the best siRNA should still be selected empirically. Therefore, a simple method of finding out the best target is urgently needed. Another major problem is how to efficiently and specifically deliver the siRNA-expressing vectors to the target cell types^[29]. At present, retroviral or lentiviral vectors containing RNAi cassettes seem to be a good delivery system in carrying out gene silencing *in vivo*^[30,31]. Chemically modified synthetic siRNA, which could be delivered into cells without cationic lipid carrier also holds promise for a future therapeutic agent^[8]. With the advance in newly established techniques, RNAi may provide an effective therapeutic solution for HBV infection in the near future.

Abstract

AIM: To explore the role of hepatitis C virus (HCV) envelope protein 2 (E2) in the induction of apoptosis.

METHODS: A carboxyterminal truncated E2 (E2-661) was transiently expressed in several cultured mammalian cell lines or stably expressed in Chinese hamster ovary (CHO) cell line. Cell proliferation was assessed by ³H thymidine uptake. Apoptosis was examined by Hoechst 33258 staining, flow cytometry and DNA fragmentation analysis.

RESULTS: Reduced proliferation was readily observed in the E2-661 expressing cells. These cells manifested the typical features of apoptosis, including cell shrinkage, chromatin condensation and hypodiploid genomic DNA content. Similar apoptotic cell death was observed in an E2-661 stably expressing cell line.

CONCLUSION: HCV E2 can induce apoptosis in cultured mammalian cells.

INTRODUCTION

Hepatitis C virus (HCV) is the major causative agent of post-transfusion and community-acquired hepatitis. HCV has been classified in the Hepacivirus genus within the *Flaviviridae* family that includes flaviviruses, such as yellow fever and dengue viruses, and animal pestiviruses, such as bovine viral diarrhea virus (BVDV). Infection with HCV usually leads to chronic hepatitis. Although the mechanism for virus persistence is poorly understood, the high mutation rate of viral envelope proteins^[1,2] and the suppression of the host immune system^[3-5] are believed to contribute to the chronic infection. Analysis of peripheral blood mononuclear cells and liver biopsies from chronic patients suggested that HCV infection could induce apoptosis, which may help the virus escape the immune surveillance and causes liver injuries^[6-11]. *In vitro* studies with

either HCV full length RNA^[12] or cDNA^[13] have demonstrated that apoptosis could be induced by viral proteins. Several independent studies suggested that the viral core protein could induce apoptosis in cultured mammalian cell lines^[14,15], while others using similar systems obtained different results^[16-18]. Therefore, the viral molecule (s) responsible for the induction of apoptosis has not been clearly identified.

Some members in the *Flaviviridae* family, e.g. dengue and Langkat viruses, could induce apoptosis during infection^[19-22]. Duarte dos Santos *et al.* showed that determinants in the envelope protein of dengue type 1 virus could influence the induction of apoptosis^[21]. Prikhod'ko *et al.* demonstrated that apoptosis could be induced by Langkat flavivirus infection. Moreover, expression of the viral envelope protein alone was sufficient to induce apoptosis in cultured mammalian cells^[22].

Since HCV envelope protein 2 (E2) displays a similar genetic organization as the envelope proteins of these viruses^[23], it is possible that E2 may also induce apoptosis. It has been reported that a carboxyterminal truncated E2 (E2-661) without the transmembrane domain is properly folded in cultured mammalian cells^[24,25] and has since been used in HCV studies, such as E2-CD81 binding analysis^[26] and post-translational processing of E2^[27]. In this study, we observed reduced cell proliferations of several cultured mammalian cell lines transiently expressing E2-661. These cells showed the typical features of apoptosis, including cell shrinkage, chromatin condensation and hypodiploid genomic DNA content. Similar apoptotic cell death was observed in an E2-661 stably expressing cell line. This is the first report that HCV E2 can induce apoptosis in cultured mammalian cells.

MATERIALS AND METHODS

Plasmid

pSecTagB/sE2 and pSecTagB/sS1E2 containing the insert of E2-661 (aa384-661 of the HCV polyprotein) coding sequence downstream to a signal sequence of Igk and under the control of the CMV promoter (Figure 1A) were used in the study. To construct pSecTagB/sE2, E2-661 was PCR-amplified from pUC18/E (a gift from Dr. Wang *et al.*^[28], Beijing University, GenBank accession# D10934) with primers 5'-GGCGTTAAGCTTAA CACCTACG TG-3' (*Hind*III site underlined) and 5'-CAG GAATTCTCACTCTGATCTATC-3' (*Eco*RI site underlined). The PCR product was digested with *Hind*III/*Eco*RI and cloned in the pSecTagB (Invitrogen). pSecTagB/sS1E2 was constructed by the insertion of a short tag derived from hepatitis B virus (HBV) preS1 polypeptide (aa21-47) upstream to the E2-661 coding sequence in pSecTagB/sE2. These constructs were verified by sequencing.

Cell culture

Human liver carcinoma Huh7 and hepatoma HepG2, human cervical carcinoma HeLa and baby hamster kidney BHK-21 cell lines were grown in DMEM supplemented with 100 mL/L fetal calf serum (FCS). Chinese hamster ovary (CHO) cells were grown in DMEM/F12 (1:1) supplemented with 100 mL/L FCS. The stable E2-661 expressing cell line, CHO/sS1E2 was constructed by transfection

of CHO cells with pSecTagB/sS1E2 and selection in DMEM/F12 (1:1) medium containing 400 µg/mL Zeocin (Invitrogen)^[24].

Transient expression

Expression plasmids or empty vectors were introduced into cells grown to 60% confluence with LipofectAMINE (Gibco). Transfection efficiency was monitored by co-transfection of pEGFP-C2 (Clontech) which encodes an enhanced green fluorescent protein. Two days after transfection, cells were subjected to Western blot, cell proliferation and apoptosis analysis.

Western blot analysis

Proteins were resolved on 100 g/L SDS-polyacrylamide gels and electroblotted onto nitrocellulose membranes. Membranes were blocked with 50 mL/L skimmed milk in PBS, followed by incubation with rabbit polyclonal anti-E2 antibody RE2116^[29]. The blots were then incubated with horseradish peroxidase conjugated anti-rabbit IgG (Dako) and developed with SuperSignal West Pico stable peroxide solution (Pierce).

Immunofluorescence analysis

CHO and CHO/sS1E2 cells were fixed in ice-cold CMA solution (chloroform: methanol: acetone=1:2:1), incubated with anti-preS1 monoclonal antibody 12SE11^[30] 1 000-fold diluted in 10 g/L BSA (prepared in PBS) and followed by incubation with FITC conjugated anti-mouse IgG (Santa Cruz). Fluorescence was viewed under a fluorescence microscope.

Deglycosylation analysis

CHO and CHO/sS1E2 cells were washed twice with PBS and then harvested. Cells were lysed by boiling in the denaturing buffer provided by the manufacturer. Cell lysates were then digested with PNGase F or Endo H (NEB) for 2 h at 37 °C. To analyze the secreted expression products, CHO and CHO/sS1E2 cells were grown in serum free OptiMEM/F12 (1:1) for 12 h. Medium was clarified by centrifugation at 20 000 g for 30 min at 4 °C. Expression products were precipitated by an equal volume of ice-cold ethanol, resuspended in a small volume of PBS and subjected to Western blot analysis.

Cell proliferation analysis

Cell proliferation was measured by ³H thymidine uptake according to a standard protocol^[31]. Cells were incubated with 0.05 µCi ³H thymidine (Amersham Pharmacia) for 4 h in complete medium with 100 mL/L FCS. Cells were then washed once with PBS and 100 mL/L trichloroacetic acid (TCA) followed by incubation in 100 mL/L TCA for 10 min at 37 °C. After TCA was removed from the culture dishes, cells were lysed in the lysis buffer containing 0.33 mol/L NaOH and 10 g/L SDS. ³H thymidine incorporation in the cell lysates was measured by liquid scintillation counting.

Apoptosis analysis

Apoptosis in stable and transient E2 expressing cells was analyzed by three methods: (1) Hoechst 33258 staining: Cells were seeded on sterile cover glasses placed in the 6-well plates the day before transfection. Two days after transfection, cells were fixed, washed twice with PBS and stained with Hoechst 33258 staining solution according to the manufacturer's instructions (Beyotime). Stained nuclei were observed under a fluorescence microscope. For the stable cell lines, similar staining procedures were performed without DNA transfection. (2) Flow cytometry: Cells were washed twice with PBS, trypsinized, and resuspended in complete medium with 100 mL/L FCS. Cells were then washed twice again with PBS and fixed with ice-cold 700 mL/L ethanol at 4 °C for 1 h. After the removal of ethanol, cells were incubated in PBS containing 250 µg/mL RNase A

and 50 µg/mL propidium iodide (Sigma) at room temperature for 15 min, and stored in the dark at 4 °C until further analysis. Ten thousand cells per sample were analyzed with a FACSCalibur flow cytometer (Beckton-Dickinson). (3) DNA fragmentation: CHO and CHO/sS1E2 cells were washed twice with PBS and harvested. Cells were incubated in lysis buffer [10 mmol/L Tris, 1 mmol/L EDTA, 100 mmol/L NaCl, 5 g/L SDS, 1 µg/µL RNase A, pH8.0] at 37 °C for 30 min. At the end of incubation, proteinase K was added to a final concentration of 0.1 mg/mL and the incubation was continued at 55 °C for 4 h. DNA was extracted with phenol/chloroform and precipitated with ethanol. DNA pellets were dissolved in TE buffer and analyzed on a 20 g/L agarose gel.

Statistical analysis

Statistical analysis was performed with unpaired 2-sided Student *t* test. *P*<0.05 was regarded as statistically significant.

RESULTS

Transient expression of E2-661 in mammalian cells

DNA fragments encoding aa384-661 of the HCV polyprotein (E2-661) were cloned in the expression vector pSecTagB to generate pSecTagB/sE2 and pSecTagB/sS1E2 (Figure 1A). Compared to pSecTagB/sE2, E2-661 expressed by pSecTagB/sS1E2 had a small 27-aa preS1 tag located at the N-terminus to facilitate the characterization of the expression products. The above plasmids were used to transfect Huh7, HepG2, HeLa and BHK-21 cells. Cell lysates were analyzed by Western blot with anti-E2 antibody. E2-661 was detected in E2-661 transient expressing cells (Figure 1B). The expressed protein exhibited a heterogeneous pattern typical of a glycoprotein. The expression of E2-661 could also be detected in the cells (transiently) transfected with pSecTagB/sS1E2 (see below).

Figure 1 Transient expression of E2-661 in mammalian cells. A: Schematic representation of plasmids encoding E2-661. HBV preS1 (21-47) tag and HCV E2-661 (384-661) signal peptide are indicated. Numbers refer to amino acids of the HCV polyprotein. B: Western blot analysis of E2-661 expressed in mammalian cells with a rabbit polyclonal anti-E2 antibody RE2116. Lanes on the left of all blots were transfected with the empty vector while those on the right were transfected with pSecTagB/sE2. 1-2, BHK-21; 3-4, HeLa; 5-6, Huh7 and 7-8, HepG2. E2-661 was indicated by arrowhead.

E2 expressing cells showed reduced cell proliferation

Cells transfected with pSecTagB/sE2 showed significant cell death upon microscope observation (Figure 2A). Reduced cell

density, cell rounding and cell shrinkage were the common features of all the cell lines transfected with pSecTagB/sE2. The effect of E2 expression on the cell proliferation was further analyzed by ^3H thymidine uptake assay (Figure 2B). Reductions in ^3H incorporation were observed with all the cell lines assayed ($P<0.05$ for HepG2, $P<0.001$ for Huh7, HeLa and BHK-21). Transfection efficiencies were monitored by cotransfection with pEGFP-C2. Since a similar amount of EGFP expressing cells were observed between pSecTagB and pSecTagB/sE2 transfected cells (data not shown), the reduced cell proliferation

of E2 expressing cells was not due to the transfection procedure (e.g. transfection reagent and EGFP expression). Similar results were observed with the E2 expressing plasmid pSecTagB/s1E2 (data not shown). These results suggested that the expression of E2 was responsible for the reduction in cell proliferation.

Apoptosis induced by transient expression of E2

The reduced proliferation might be due to various reasons. To determine if apoptosis contributed to the reduced cell proliferation of E2 expressing cells, cells transfected with pSecTagB/sE2 or

Figure 2 Reduced cell proliferation in E2 expressing cells. A: Morphology of Huh7, HepG2, HeLa, BHK-21 cells 48 h after transfection with pSecTagB or pSecTagB/sE2 (original magnification 40 \times). B: Reduced ^3H thymidine uptake by E2 expressing cells. $P<0.05$ between all the cells tested.

Note the bright nuclei among cells transfected with pSecTagB/sE2. Photograph is a representative experiment repeated three times (original magnification 400×). B: Flow cytometry analysis of PI stained cells 48 h after transfection with pSecTagB or pSecTagB/sE2. The percentage of cells with hypodiploid genomic DNA are indicated on each of the histogram. Results were a representative experiment repeated twice.

Figure 4 Expression of E2-661 in CHO/sS1E2 cells. A: Immunofluorescence of E2 in CHO/sS1E2 cells analyzed with a monoclonal anti-preS1 antibody 125E11 (original magnification 400×). B: Western blot analysis of the E2 products from CHO/sS1E2 cells. Cell lysates and proteins precipitated from culture medium were analyzed with anti-E2 polyclonal antibody RE2116 after N-glycosidase treatment. Lanes 1, 2, 5, 6: cell lysates from CHO cells; lanes 3, 4, 7, 8: cell lysates from CHO/sS1E2 cells; lanes 9, 10, 13, 14: culture medium from CHO cells; lanes 11, 12, 15, 16: culture medium from CHO/sS1E2 cells; lanes 1, 3, 9, 11: samples incubated with Endo H digestion buffer; lanes 2, 4, 10, 12: samples digested with Endo H; lanes 5, 7, 13, 15: samples incubated with PNGase F digestion buffer; lanes 6, 8, 14, 16: samples digested with PNGase F.

pSecTagB were stained with Hoechst 33258, respectively (Figure 3A). Condensed bright apoptotic nuclei were readily observed amidst the pSecTagB/sE2 transfected cells. The presence of apoptotic cells in E2 expressing cells was further confirmed by flow cytometry. Huh7, HepG2, BHK-21, HeLa cells transfected with pSecTagB/sE2 or control pSecTagB were stained with PI and analyzed by flow cytometry (Figure 3B). Hypodiploid DNA appeared in the sub-G0/G1 region, which

represented dead cells. A higher percentage of dead cells was observed in all the four cell lines transfected with pSecTagB/sE2.

Apoptosis in a CHO cell line stably expressing E2

E2 induced apoptosis was also investigated in a CHO cell line CHO/sS1E2 stably expressing E2-661. This cell line showed the expression of E2-661 as detected by indirect fluorescence assay with the monoclonal antibody against the preS1 tag (Figure 4A).

The fluorescence in CHO/sS1E2 cells suggested the localization of expressed proteins in the cytoplasm. In further characterization by Western blot analysis, cell-associated and secreted E2 proteins (from 10^5 and 10^7 cells) were detected with the E2 polyclonal antibody (Figure 4B). The cell-associated E2 protein was sensitive to Endo H (lane 4), suggesting that the glycans carried on it were ER-restricted. On the other hand, secreted E2 was resistant to Endo H (lane 12), suggesting that the glycans on this species of E2 underwent the modification by Golgi enzymes.

Similar to cells transiently transfected with pSecTagB/sE2, the morphology of CHO/sS1E2 was different from that of the original CHO cell line (Figure 5A). There were obvious differences in cell size and shape between these two cell lines. A significant number of dead cells were readily observed for CHO/sS1E2 and cells could hardly grow to 100% confluency. Similar morphology and growth curve were also observed in other CHO/sS1E2 clones (data not shown), suggesting that they are not the result of clonal selection. ^3H incorporation analysis showed that there was a significant reduction (72.0%, $P < 0.001$) of cell proliferation for CHO/sS1E2 in comparison with CHO

cells (Figure 5B).

Hoechst 33258 staining of CHO/sS1E2 showed condensed bright nuclei typical of apoptotic dead cells which reached about 14% of the total cells, while almost no apoptotic nuclei were observed in control CHO cells (Figure 6A). Flow cytometry analysis confirmed that there were a significant number of dead cells for CHO/sS1E2 (Figure 6B).

Since the cleavage of chromosomal DNA into fragments of oligonucleosomal size is a biochemical hallmark of apoptosis^[32], DNA fragmentation in CHO/sS1E2 was examined by DNA laddering assay. With the freshly seeded CHO/sS1E2 cells, no obvious DNA fragmentation was observed, while clear DNA laddering in -180 bp interval was detected 48 h after cell seeding. No apoptotic DNA fragmentation was observed in CHO cells at either time points (Figure 6C).

DISCUSSION

In this study, HCV E2 was transiently expressed in several mammalian cells. All tested cells showed shrinkage in morphology and reduced cell proliferation due to the expression

Figure 5 Reduced cell proliferation in CHO/sS1E2 cells. A: Morphology of CHO and CHO/sS1E2 cells (original magnification 40 \times). B: Reduced ^3H thymidine uptake by CHO/sS1E2 cells. CHO and CHO/sS1E2 cells were subjected to ^3H thymidine uptake assay 24 h after seeding. Each sample was done in quadruplicates. The differences in ^3H incorporation between CHO and CHO/sS1E2 cells were significant ($P < 0.001$).

Photograph is a representative experiment repeated three times (original magnification 400 \times). The percentage of condensed and fragmented nuclei is indicated at the bottom of each photo. Numbers are presented as mean \pm SD. B: Flow cytometry analysis of PI stained cells 24 h after seeding. The percentage of cells with hypodiploid genomic DNA is indicated on each of the histogram. Results were a representative experiment repeated twice. C: Fragmentation of CHO/sS1E2 cell DNA. Lane 1: CHO cells 48 h post-seeding; lane 2: CHO cells freshly seeded; lane 3: CHO/sS1E2 cells 48 h post-seeding; lane 4: CHO/sS1E2 cells freshly seeded; lane 5: DNA size marker.

of E2. Further evidences, such as condensed chromatin, demonstrated that apoptosis contributed, at least in part, to the cell death induced by E2. E2 induced apoptosis was also observed in a stable E2 expressing cell line CHO/sS1E2. Again there was a significant reduction in cell proliferation of CHO/sS1E2 in comparison to CHO cells. Hoechst 33258 staining, flow cytometry analysis and DNA laddering assay demonstrated that apoptosis contributed to the reduced cell proliferation. Apoptosis in CHO/sS1E2 was not due to the expression of the small preS1 tag because toxicity was not observed when preS1 was transiently expressed in cultured mammalian cells^[33]. In conclusion, our results demonstrate that the expression of HCV E2 could induce apoptosis in cultured mammalian cells.

It has been reported that apoptosis is involved in the pathogenesis of hepatitis C. Immunohistochemical study suggested that the Fas system played an important role in liver injuries of viral hepatitis^[34]. There is evidence that immune response (cytotoxic T lymphocyte) might be involved in the apoptosis of hepatocytes in HCV infected patients^[35]. Recent studies suggested that apoptosis of hepatocytes might also be due to the cytopathic effect of viral proteins^[13,14]. Our result that E2 expression induced apoptosis in cultured mammalian cells including human hepatic cells supports this hypothesis. On the other hand, E2-induced apoptosis may also partly contribute to the escape of HCV from the host immune surveillance. It awaits further investigation whether the expression of E2 can induce apoptosis in lymphocytes.

Studies of Langkat flavivirus^[22] demonstrated that expression of envelope (E) protein could induce apoptosis via the Caspase 3 pathway. Since HCV E2 and the E protein of Langkat flavivirus share similar genetic organization and hydropathy profile^[23], it is possible that E2 could induce apoptosis through a similar mechanism. Increased Fas expression observed in HCV patients^[7] also suggested the involvement of the caspase-3 pathway. However, comparing the expression levels of secreted and cell-associated E2, we found that in our system, E2 was mainly cell-associated and localized in the cytoplasm. By glycosidase digestion analysis, we found that most of the cell-associated E2 were high-mannose type glycoproteins, which suggested the localization of E2 to the endoplasmic reticulum (ER). Many other mammalian expression systems also showed the ER localization of the expressed HCV E2, and a large portion of them formed disulfide-linked aggregates^[36-38]. The accumulation of large amount of proteins in the ER might induce ER stress and apoptosis could be triggered via the Caspase 12-mediated apoptosis pathway^[39]. Further study is required for understanding the possible pathway of HCV E2 induced apoptosis.

ACKNOWLEDGEMENTS

The authors thank Professor Jia-Rui Wu for providing CHO cell line and Professor Yu Wang for the HCV cDNA for this study.

Abstract

AIM: To design and construct an exogenous multiple epitope of helper T lymphocytes (HTL), and to evaluate its effect on anti-HBs response through DNA immunization.

METHODS: Artificial HTL epitope, PADRE and four other HTL epitopes from different proteins were linked together using splicing by overlap extension to generate exogenous multiple epitopes of HTL, MTE5. pcMTE5 and pcHB were generated by cloning MTE5 and fragments of HBV pre-S2/S gene into mammalian expression plasmid pcDNA3. Four chimeric plasmids were constructed by cloning MTE5 into the region of pre-S2 gene (*Bam* HI), 5' terminal of S gene (*Hinc*II, *Xba* I) and 3' terminal of S gene (*Acc* I) of pcHB respectively. BALB/c mice were used in DNA immunization of the recombinant plasmids. Anti-HBs was detected using Abbott IMx AUSAB test kits.

RESULTS: The sequences of MTE5 and the 6 constructs of recombinant plasmids were confirmed to be correct by DNA sequencing. The anti-HBs response of the co-inoculation of pcHB and pcMTE5 was much higher than that of the inoculation of pcHB only (136.7 ± 69.1 mIU/mL vs 27.6 ± 17.3 mIU/mL, $P < 0.01$, $t = -6.56$). Among the 4 chimeric plasmids, only the plasmid in which MTE5 was inserted into the pre-S2 region had good anti-HBs response (57.54 ± 7.68 mIU/mL), and had no significant difference compared with those of pcHB and the co-inoculation of pcHB and pcMTE5.

CONCLUSION: Exogenous multiple epitopes of HTL had immune enhancement when they were co-inoculated with pre-S2/S gene or inoculated in the chimeric form at a proper site of pre-S2/S gene of HBV. It might suggest that it was possible to improve hepatitis B vaccine using exogenous multiple epitopes of HTL. The antibody responses were very low using DNA immunization in the study. Thus, the immune enhancement effect of exogenous multiple epitopes of HTL has to be confirmed and the effect on overcoming the drawback of the polymorphism of HLA II antigens should also be evaluated after these chimeric plasmids are expressed in mammalian cell lines.

INTRODUCTION

There are more than 300 millions of HBsAg carriers all over the world. Most of them have active infection of hepatitis B virus. Chronic hepatitis B virus infection may cause significant incidence of chronic hepatitis, cirrhosis, and hepatocellular carcinoma^[1,2]. Hepatitis B vaccine inoculation is an important measure for prevention of HBV infection. Considerable variability exists, however, in response to hepatitis B vaccines, and 5-10% of healthy young adults demonstrate no or inadequate responses following a standard vaccination schedule^[3-8]. The frequency of non- and low-responders is up to 40-50% in vaccinated subjects with depressed immune responses, such as patients on maintenance hemodialysis. Only some of the non- or low-responders to hepatitis B vaccine are responsive to the novel recombinant triple antigen hepatitis B vaccine (pre-S1/S2 and HBsAg)^[9]. These non- or low-responders usually carry specific type of class II human leukocyte antigens (HLA II antigens), such as DRB1*3, DRB1*7, DQB1*20 or DPB1*1101^[10-13]. The antigen presentation is blocked because these HLA II antigen molecules on the surface of helper T lymphocytes (HTL) cannot combine efficiently with the epitope of HTL on the vaccine protein, hepatitis B surface antigen (HBsAg)^[14,15]. Adding exogenous multiple epitopes of HTL, which can combine with much more types of HLA II antigens to hepatitis B vaccine may be a good way to solve this problem. Conducting HTL epitopes from tetanus toxoids (aa73-99, aa830-845) and artificial epitopes of PADRE into HBsAg can enhance the immunogenicity of HbsAg^[16,17]. Adding exogenous HTL epitopes to HBsAg can let natural non-responder mice respond to HbsAg^[18]. These data suggest that it is possible to use exogenous HTL epitopes to improve hepatitis B vaccine. For these reasons, an exogenous multiple epitope of HTL, MTE5, consisting of five HTL epitopes from different origins was designed and constructed. Its effect on anti-HBs response was evaluated through DNA immunization after it was inserted in different loci of HBV pre-S2/S gene.

MATERIALS AND METHODS

Reagents

pTZ19U-HBV containing double copies of HBV DNA (adw) was a gift from professor Zhi-Min Huang, Sun Yat-Sen University. T4 DNA ligase and pfu DNA polymerase were purchased from Promega Company (USA). DNA gel extraction kits and plasmid isolation kits were purchased from Qiagen Company (German). Polyclonal antibodies of anti-HBs and LSAB test kit for immunohistochemistry were purchased from DAKO Company (USA). Primers and oligonucleotide fragments shown in Table 1 were synthesized in Bioasia Biological Engineering Company (Shanghai, China).

Animal

Eight to 12 week-old female inbred BALB/c mice were obtained from Guangzhou Traditional Chinese Medicine University.

MTE5 splicing and cloning MTE5 was designed to consist of HTL epitopes from heat shock protein 65 of *mycobacterium tuberculosis* (aa1-20), E2 polypeptide of *rubella* virus (aa54-65), artificial epitope (PADRE), heat shock protein 60 of *chlamydia trachomatis* (aa35-48) and tetanus toxoid (aa830-843). These epitopes were translated into a 219-bp fragment of DNA sequence. Then, it was synthesized in four oligonucleotide fragments, which were linked together at last using splicing by overlap extension^[19,20]. The oligonucleotide fragments F1 and F2, F3 and F4 were spliced by PCR respectively at first. Their purified products were spliced together again to generate MTE5. The construct of pUMTE5 was generated by cloning MTE5 into plasmid pUC18 at the site between restriction endonucleases *Bam* HI and *Xba* I. pcMTE5 then was obtained by sub-cloning MTE5 from pUMTE5 into mammalian expression plasmid, pcDNA3. The sequence of MTE5 in pcMTE5 was confirmed using automatic DNA sequencing in Bioasia Biological Engineering Company.

HBV pre-S2/S gene cloning Pre-S2/S fragment of HBV was obtained using pTZ19U-HBV as template, and HBV-P1 and HBV-P2 as primers. The purified product was then cloned into pUC18 at the site between the restriction endonucleases *Hind* III and *Eco* RI to generate recombinant plasmid pUHB. pCHB was constructed by sub-cloning the fragment of HBV pre-S2/S gene into pcDNA3. pCHB was denominated after its sequence was confirmed by automatic DNA sequencing.

Construction of chimeric plasmids of MTE5 and HBV pre-S2/S gene MTE5 was designed to insert into the region of pre-S2 gene (*Bam* HI), 5' terminal of S gene (*Hinc* II, *Xba* I) and 3' terminal of S gene (*Acc* I) respectively. All the inserting sites were far from the α determinant to avoid decreasing the antigenicity of HBsAg. In order to obtain these chimeric plasmids, four fragments of MTE5 with different types of restriction endonuclease site in its two terminals were generated through PCR with different primers at first. Then four chimeric plasmids, pCHB-MTEB, pCHB-MTEH, pCHB-MTEX and pCHB-MTEA were constructed by cloning MTE5 into pUHB at first since pcDNA3 had some similar restriction endonuclease sites of its own, and then by sub-cloning the chimeric fragment of MTE5 and pre-S2/S into pcDNA3. The sequences of these recombinant plasmids were confirmed by automatic DNA sequencing.

Large-scale DNA preparation, DNA immunization Large-scale plasmid DNA of recombinant plasmids was prepared using

Qiagen's Max-Prep kits. Plasmid DNA of pcDNA3 was used as control. Plasmid DNA was adjusted to 1 μ g/mL in normal saline. Seventy BLBA/c mice were randomly divided into 8 groups. Every mouse was injected a total 100 μ L of plasmid DNA which was distributed over five different sites into the anterior tibialis muscle 5 d after the injection of an equal volume of 2 g/L Bupivacaine. Boost injection was carried out every 3 wk for 3 times with an equal amount of plasmid DNA. Four weeks after the last boost injection, all mice were put to death for serum.

Detecting anti-HBs in serum Anti-HBs in serum was detected using AUSAB kits (Abbott Laboratory, USA). The tests were carried out following the manufacturer's instructions.

Pathological examination and HBsAg detection in muscle cell Pathological examination and HBsAg detection using immunohistochemistry in the mouse muscle of inoculation site from all groups were carried out after the samples were routinely embedded by paraffin in our laboratory. The muscles from the opposite leg were used as negative controls.

Statistical analysis For anti-HBs level, geometric mean titer (GMT) for each group was calculated at first. Then Student-Newman-Keuls-q was used for statistical analysis. For positive rate, Fisher's exact probability analysis was used. SPSS 10.0 for Windows was used for all statistical analyses.

RESULTS

MTE5 splicing and cloning

The theoretical products of the first and second round splicing were 120 bp and 219 bp, respectively. The actual products shown in Figure 1 were same as the design. Restriction fragment length polymorphism (RFLP) analysis was used to identify the positive clones after the 219-bp fragment was inserted into pUC18 to generate recombinant plasmid pUMTE5, which is shown in Figure 2. Two correct clones were selected by DNA sequencing among 13 positive clones of pUMTE5. The rest clones usually carried deletions or mismatches in the region longer than 50 bp of the synthesized oligonucleotide fragments, which implied that the synthesized DNA oligonucleotide fragment longer than 50 bp would not be reliable. The DNA sequence and amino acid sequence of MTE5 are shown in Figure 3. MTE5 was successfully cloned into pcDNA3 to generate pcMTE5 at last.

HBV pre-S2/S gene cloning

The theoretical base pair number of PCR products of HBV pre-S2/S fragment was about 847 bp. It was cloned into pUC18 to

generate recombinant plasmid pUHB. Then, the fragment of pre-S2/S was sub-cloned into pcDNA3 to generate recombinant plasmid pcHB. RFLP analysis was used to identify the positive clones of pcHB, which is shown in Figure 4A. After its sequence was confirmed by DNA sequencing, the recombinant plasmid was denominated as pcHB.

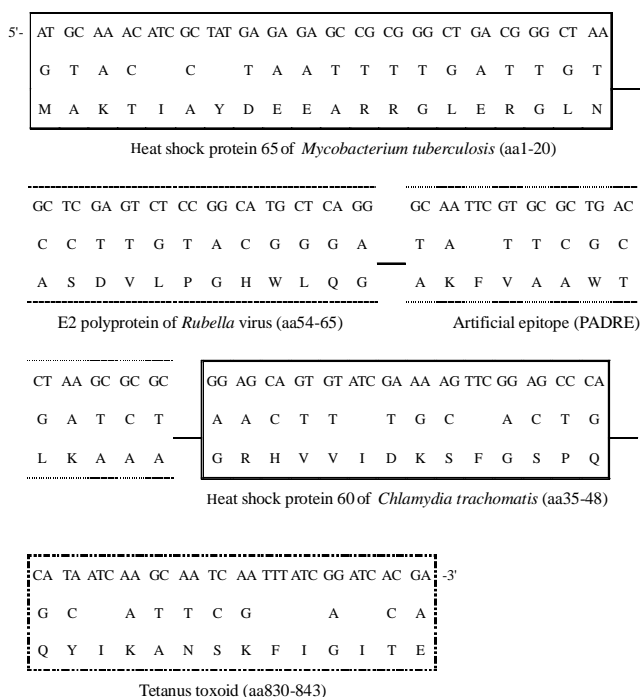

Figure 3 DNA and amino acid sequences of MTE5.

Construction of chimeric plasmids of MTE5 and HBV pre-S2/S gene

Four fragments of MTE5 with different types of restriction endonuclease site in its two terminals were successfully obtained by PCR. They were cloned into pUHB to generate their recombinant plasmids at first. The chimeric fragments of MTE5 and pre-S2/S were sub-cloned into pcDNA3 to generate their mammalian expression plasmids at last. RFLP analysis was used to identify positive clones. The results of RFLP analysis of the recombinant plasmid pcHB-MTEX with MTE5 inserted in site of *Xba* I is shown in Figure 4B as an example. The sequence of all chimeric plasmids was confirmed to be correct by DNA sequencing.

Anti-HBs responses

All mice were alive after the inoculation schedule was finished. The anti-HBs levels are shown in Table 2. The anti-HBs level was negative in groups of normal saline and plasmid pcDNA3. The anti-HBs response to co-inoculation of pcHB and pcMTE5 was much higher than that to inoculation of pcHB only (136.7 ± 69.1 mIU/mL vs 27.6 ± 17.3 mIU/mL, the positive rate was $8/10$ vs $6/10$, $P < 0.01$, $t = -6.56$). Among the 4 chimeric plasmids, only pcHB-MTE-B with MTE5 inserted into pre-S2 region had a good anti-HBs response, which was 57.54 ± 7.68 mIU/mL, and

slightly higher than that of pcHB, and lower than that of the co-inoculation of pcHB and pcMTE5. However, the difference was not statistically significant ($P>0.05$).

Table 2 Effect of MTE5 on anti-HBs response of HBV pre-S2/S gene

Group	Anti-HBs		Enhancement
	Positive ratio	MIU/L (GMT±SE)	
Empty control	0/5	-	-
PcDNA3	0/5	-	-
PcHB	6/10	27.60±17.3	-
PcHB/pcMTE5	8/10	136.70±69.1 ^b	4.95
PcHB-MTEB	7/10	57.540±7.68	2.09
PcHB-MTEX	0/10	-	-
PcHB-MTEH	1/10	1.50	-
PcHB-MTEA	0/10	-	-

GMT: Geometric mean titer; Enhancement: GMT ratio of given group to pcHB, immune enhancement was considered when the ratio was larger than 1. “-” means anti-HBs negative or the enhancement could not be detected. ^b $P<0.01$, $t = -6.56$ vs pcHB group.

Histological findings and HBsAg in mouse muscle cells

Compared with the control groups and the sample from the opposite leg, all experimental groups had obvious inflammation cell filtration in the inoculation sites and HBsAg expression in muscle cells with disassembling and rupture. HBsAg was prominently expressed in cytoplasm of cells. Some cells had membrane expressions simultaneously. The positive signal of HBsAg was usually expressed in cytoplasm, and inflammation was more obvious in non- or low-anti-HBs response groups of chimeric plasmids.

DISCUSSION

The simple way for a given protein to obtain exogenous multiple epitopes was to link them to a higher molecular weight protein. The immune responses were not always good enough because of the interfering effects of immune responses of the carrying protein^[21]. The spliced exogenous multiple epitopes of HTL used in this study, however, might not have immune responses of its own, and were thus preferable. The exogenous multiple epitopes of HTL, MTE5, constructed in this study consisted of 2 universal HTL epitopes and 3 unique HTL epitopes. Two universal epitopes of tetanus toxoid (aa830-843) and artificial epitope PADRE were both effective for 95% individuals of the population^[22-26]. They might cover more individuals when used together. Three unique epitopes from *Mycobacterium tuberculosis* (aa1-20), E2 polypeptide of *rubella* virus (aa54-65) and heat shock protein 60 of *Chlamydia trachomatis* (aa35-48) were selected for HLA-DRB1*3, HLA-DRB1*7 and HLA-DR4 respectively^[27-29]. They could improve the anti-HBs responses of hepatitis B vaccine in individuals who carried these types of HLA II antigens. Thus, the overall response rate of HB vaccine in population could rise dramatically. During the course of splicing, many deletions or mismatches were found in the spliced sequences, especially in the region of synthesized oligonucleotide fragments longer than 50 bp. It implied that synthesized DNA oligonucleotide fragments shorter than 50 bp would be preferable.

A satisfactory anti-HBs response was obtained when MTE5 and pre-S2/S were co-inoculated through DNA immunization, suggesting that MTE5 had immune enhancement. Among the 4 chimeric plasmids, only the recombinant plasmid with MTE5 inserted into the region of pre-S2 had a detectable anti-HBs

response, suggesting that the insertion location of MTE5 was critical for anti-HBs response. The insertion was far from the antigen determinant of HBsAg. Thus, the non-response cause of the rest chimeric plasmids was not clear. HBsAg could be detected in muscle cells at the inoculation site, suggesting that the construction of recombinant plasmids was successful. HBsAg positive signals were mainly located in cytoplasm, suggesting that the poor anti-HBs response might result in failure to secrete the large particles like HBsAg^[30-32].

The chimeric plasmid of pcHB-MTEB had an equal or better anti-HBs response as comparing with that of pcHB, and might be a good candidate for new hepatitis B vaccine in further research. DNA immunization is a simple and quick way to evaluate recombinant plasmids. The response rate of recombinant plasmids, however, was very low in this study. A considerable portion of mice did not develop anti-HBs at all. Its reason is not clear. It might be the nature of DNA immunization because this phenomenon also occurred in other researches^[31]. The exact value should be evaluated after purified recombinant protein is obtained through mammalian expression. The effect on overcoming the drawback of the polymorphism of HLA II antigens should also be evaluated in the future.

Abstract

AIM: To assess the effect of artificial liver support system (ALSS) on patients with severe viral hepatitis, who were divided into treatment group and control group.

METHODS: Four hundred in-hospital patients enrolled during 1995-2003 who received ALSS therapy were studied as the treatment group. Four hundred in-hospital patients enrolled during 1986-1994 who received other medical therapies served as the control group. The methods of ALSS used included plasma exchange, hemoperfusion, hemofiltration, continuous hemodiafiltration (CHDF). The effect of ALSS treatment was studied in patients at different stages of the disease.

RESULTS: The cure rate of acute and subacute severe hepatitis in the treatment group was 78.9% (30/38), and was 11.9% (5/42) in the control group. The improved rate of chronic severe hepatitis in the treatment group was 43.4% (157/362), and was 15.4% (55/358) in the control group. We found that patients treated with ALSS in the early or middle stage of the disease had much higher survival rates than patients in the end stage of the disease.

CONCLUSION: ALSS is an effective and safe therapy for severe viral hepatitis.

INTRODUCTION

Severe viral hepatitis is the main cause of hepatic failure in China because of the great population of hepatitis B patients, which is different from the Western countries where drugs or alcohol usually is the major cause. Despite a combination of all available treatments, the mortality of hepatic failure is more than 70%^[1,2].

It is believed that damaged liver has the ability to regenerate

and restore normal function of metabolism, synthesis and biotransformation. Liver transplantation remains the only effective therapeutic modality for chronic patients in end-stage^[3-5]. There is also a need to develop a liver support system that can serve as a bridge to transplantation^[6,7], so that patients can be supported until a liver becomes available or the condition of patients is improved. ALSS has been used to treat hepatic failure and has significantly decreased the mortality^[8-11].

We designed an artificial liver support system for severe hepatitis patients. In this report, we described 400 patients with hepatic failure treated with ALSS in our hospital. Data such as concentrations of endotoxin and blood HBV, and serum amino acid spectrum were recorded. The effect of ALSS treatment was also compared in patients at different stages of the disease.

MATERIALS AND METHODS

The treatment group consisting of 400 viral severe hepatitis patients was treated with ALSS at the First Hospital of College of Medicine, Zhejiang University during 1995 to 2003. Two hundred and ninety-five were males and 105 were females. The age ranged from 20 to 64 years, with an average of 34.3 ± 16.5 years. The control group consisting of 400 viral severe hepatitis patients was treated in Department of Internal Medicine at the same hospital during 1986 to 1994, of them 273 were males and 127 were females. The age ranged from 19 to 68 years, with an average of 32.5 ± 18.8 years.

The patients were diagnosed according to the criteria established in the 1995 National Infectious Disease Meeting in Beijing^[12]. Type A hepatitis was diagnosed by the identification of HAV-RNA and/or IgM anti-HAV. The diagnosis of hepatitis B was based on positive HBsAg. Acute type B hepatitis was diagnosed by the presence of HBsAg and/or IgM anti-HBc antibody. Three patients among them were negative for HBsAg but had positive IgM anti-HBc and they were diagnosed as type B hepatitis. All were positive for HBV DNA by PCR. An acute exacerbation of HB in a HBV carrier was diagnosed by a history of known HBsAg positivity for more than 6 mo, the presence of HBV-DNA and a markedly elevated IgG anti-HBc level. Type C hepatitis was diagnosed by the presence of either HCV RNA or anti-HCV antibody. Type B+D hepatitis was diagnosed by the presence of HBsAg and HDV-RNA. Type E hepatitis was diagnosed by the identification of IgM anti-HEV antibody.

Three types of severe viral hepatitis have been found in our country: acute, subacute and chronic severe hepatitis. Violent symptoms of acute severe hepatitis occurred within 10 d after the appearance of clinical manifestations, including malignant jaundice, hepatic encephalopathy (above phase II) and prolonged prothrombin time (PTA<40%). These patients were usually accompanied with shrinking live dullness, rapidly rising blood bilirubin (TB>171 $\mu\text{mol/L}$) and obvious abnormal liver functions. Subacute severe hepatitis patients were those who had prolonged prothrombin time (PTA<40%) after the occurrence of manifestations for more than 10 d, and meanwhile, they had any one of the following symptoms, namely hepatic encephalopathy (above phase II⁰), rapid rising of blood bilirubin (blood TB more than 171 $\mu\text{mol/L}$ within several days), severe damage of liver functions, extremely fatigue, loss of appetite,

nausea, abdominal distention or hydroperitoneum, sometimes with a tendency to bleed. Chronic severe hepatitis was clinically similar to acute or subacute severe hepatitis, but was distinguished by a known history of HBV carriage, chronic hepatitis or cirrhosis, or by the results of imaging, endoscopy or biopsy showing the existence of chronic hepatitis. Subacute and chronic severe hepatitis was classified into early, middle and end stages. Symptoms of the early stage included fulminant liver failure but without hepatic encephalopathy or ascites. The serum level of bilirubin (TB) was above 171 $\mu\text{mol/L}$, while the prothrombin time rate (PTA) was less than 40%. Liver biopsy was also taken into account when available. In addition, patients in the middle stage had hepatic encephalopathy (II^o above), ascites, or a tendency to bleed with a PTA $\leq 30\%$. End stage patients had severe complications such as hepatorenal syndrome, infection, hepatoencephalopathy (II^o above), electrolytic disturbance, with a PTA $\leq 20\%$.

In the treatment group there were 38 cases of acute or subacute severe hepatitis (6 type A, 8 type A+B, 5 type B+E, 17 type B, 2 type E), while the other 362 were cases of chronic severe hepatitis (310 type B, 18 type A+B, 14 type C, 12 type B+D, 7 type B+E, 1 type B+C+D). The average prothrombin time of the patients on admission was 31.8 ± 7.2 s (the normal was 12 s). Sixty-eight cases were treated with ALSS in the early stage, 186 in the middle stage and 146 in the end stage. In the control group there were 42 cases of acute or subacute severe hepatitis (8 type A, 9 type A+B, 3 type B+E, 20 type B, 1 type E, 1 type B+C+D), while the other 358 were cases of chronic severe hepatitis (313 type B, 16 type A+B, 10 type C, 13 type B+D, 5 type B+E, 1 type B+C+D) (Table 1). The average prothrombin time of the patients in control group on admission was 30.9 ± 8.4 s. Seventy-four patients were diagnosed as early stage, 168 cases as middle stage and 158 as end stage acute or subacute severe hepatitis, respectively. There were no significant differences in sex, ages, etiology and conditions between two groups.

Table 1 Types of severe hepatitis in two groups

Types	Treatment group		Control group	
	Acute and subacute	Chronic	Acute and subacute	Chronic
A	6	0	8	0
B	17	310	20	313
C	0	14	0	10
E	2	0	1	0
B+D	0	12	0	13
A+B	8	18	9	16
B+E	5	7	3	5
B+C+D	0	1	1	1
Total	38	362	42	358

The methods of ALSS included plasma exchange, hemoperfusion, hemofiltration, continuous hemodiafiltration (CHDF). We chose therapy based on the condition of patients. The ALSS treatment room was thoroughly sterilized by UV light before each treatment. The external circulation system and the separator were connected under sterile condition, washed with 0.9% saline solution at 38 °C to remove the micro bubbles in the line, and then filled with 2 mg/500 mL heparin saline solution. The main parts of ALSS were 160-200 g activated carbon absorber, membrane plasma separator, bilirubin absorbent, dialyser, *etc.* Plasma exchange was performed by using a membrane separation method marketed as Plasmacure PS-06 (Kuraray Co., Japan) (Figure 1). Fresh frozen plasma (FFP) was supplied by the Hangzhou Blood Center, Chinese Red Cross. Filtration was performed at a flow rate of 4-6 liters/h using a

bicarbonate buffer, pH 7.4, having a potassium concentration of 4.0 mmol/L. The volume of substitution fluid was adjusted over a range of 6-30 L, depending on the patient's response (Figure 3). Dialysis was performed concurrently at a flow rate of 500 mL/min using a conventional acetate buffer.

Figure 1 Circuit diagram of plasma exchange.

Figure 2 Circuit diagram of plasmapheresis plus plasma absorption. Special absorbers could be used to treat patients with hyperbilirubinemia or hepatic encephalopathy such as bilirubin and carbon absorbers.

Figure 3 Continuous hemofiltration and hemodiafiltration with aid of a blood pump. A: Continuous hemofiltration with aid of a blood pump; B: Continuous hemodiafiltration with aid of a blood pump.

Before ALSS therapy, blood access was established with a double-lumen catheter inserted into the patient's jugular or femoral vein, and heparin was then used to block the catheter after each session. The circuit diagrams for plasma exchange and perfusion are shown in Figures 1, 2. During each session of ALSS therapy which was lasted for 4-6 h, the total volume of exchanged plasma was about 3 500 mL, and the exchange rate of plasma was 25-30 mL/min. A total of 3 000-4 500 mL of fresh frozen plasma and its substitute fluid, and 20-40 g albumin were supplied. The flow rate of blood was adjusted to 60-130 mL/min, and blood pressure and pulse were recorded continuously during treatment. Prophylactic antibiotics were used before and after therapy. Five mg dexamethasone and 10-20 mg heparin were injected routinely before therapy. During the session, the prothrombin time was tested constantly to allow the dose of heparin to be adjusted. A total of 10-108 mg heparin was used for each session. At the end of each ALSS treatment heparin was neutralized by injection of 10-50 mg of protamine sulphate. ALSS therapy was carried out two or three times in the first or second week, then one time each week till the patient's condition was stable.

Liver function and endotoxin levels were monitored during the therapy. Amino acid spectra were determined for 25 subjects by auto amino acid analyzing system, performed at the Analyzing Center of the Second Medical University in Shanghai. Endotoxin level was measured by quantitative Azo color test. HBV-DNA concentration in 10 cases was measured by chiron branched chain DNA assay, performed at the Virus Center of Luebrek Medical University, Germany.

Statistical analysis

All data were presented as mean±SE. The data were analyzed by SPSS 10.0. The Student's *t* test or Fischer's exact test was used to determine the level of significance between groups. A *P*-value <0.05 was considered statistically significant.

RESULTS

Nearly 90% patients experienced an improvement in symptoms such as fatigue or abdominal distention after each treatment. Results of liver function tests improved significantly in all subjects. The serum ALT, AST and TBA levels declined significantly (*P*<0.001), the level of serum bilirubin decreased from 511.36±192.81 μmol/L to 257.38±123.48 μmol/L (*P*<0.001), while the prothrombin time decreased from 31.8±7.2 s to 23.6±6.8 s (Table 2). The serum endotoxin levels before therapy in all hepatic failure patients were above the upper limit of normal which was 40 ng/L. After ALSS therapy, serum endotoxin levels declined from 58.2±12.3 ng/L to 32.4±7.8 ng/L (*P*<0.001). In the 10 patients tested, the HBV-DNA concentration declined from an average of 2 588±1 534 copies/mL to 1 815±620 copies/mL (*P*<0.05) as a result of ALSS therapy. The serum level of aromatic amino acids (AAA), such as methionine, tyrosine, phenylalanine, cysteine, arginine, especially methionine declined significantly (*P*<0.05) in 25 subjects. Meanwhile, the ratio of branched-chain amino acid/aromatic amino acid (BCAA/AAA) increased significantly (*P*<0.05) (Table 3). No significant difference in TNF, rIL-2R and IL-2 levels before and after the ALSS treatment was observed (Table 4). There was no disturbance of electrolytes after ALSS therapy.

Seventeen candidates for orthotopic liver transplantation (OLT) received 2-3 runs of ALSS and were "bridged" successfully to OLT. After OLT, ALSS was used to replace liver function in non-function period. Twelve of 17 patients were completely recovered and 3 died of infection, acute rejection and abdominal bleeding.

Among the 38 patients with acute or subacute severe hepatitis treated with ALSS 3-5 times, 30 of them (78.9%)

survived for at least half a year but 8 died in 1 mo. One hundred and fifty-seven of 362 patients with chronic severe hepatitis were cured or greatly improved, 107 patients were discharged as their own will, and 98 patients died in the next 3 months, so the cure rate was 43.4%. In the control group, the cure rate of acute and subacute severe hepatitis was 11.9% (5/42), while cure and improved rate of chronic severe hepatitis was only 15.4% (55/358) (Table 5). There were significantly differences in the cure rate between two groups (*P*<0.001). More importantly, in the treatment group, the cure rate of patients in early or middle stage (76.5% and 61.8%, respectively) was much higher than that those in end-stage (13.7%, Table 6).

Table 2 Result of liver function test before and after ALSS therapy (mean±SE)

Liver function	Pre-treatment	Post-treatment	<i>P</i>

DISCUSSION

In acute liver failure, the liver parenchyma injured by viral, toxic, or some other insults failed to function sufficiently. Temporary support of normal liver function would promote the damaged liver to restore its normal function. Artificial liver support system could serve this purpose. Moreover, when the liver lost its ability to function normally, then an artificial liver support system might be used as a “bridge” to liver transplantation^[6,7]. Although various liver assistant devices have been introduced during the past 40 years, a complete artificial liver system that can support patients with severe hepatic failure till the damaged liver restores its normal function has not yet been developed^[8].

We modified the artificial liver support system for treatment of patients with severe hepatic failure. We substituted the usual 50 g activated carbon absorber with 160-200 g one to remove toxic substances of intermediate molecular weight from blood. The 160-200 g carbon absorber proved to be appropriate, as a larger carbon absorber might destroy blood cells and cause side effects. The bilirubin absorbent could absorb excess bilirubin from the plasma, so that the cleaned plasma could be retransmitted to patients directly. The membrane plasma separator could separate and discard plasma containing toxic substances, and supply normal fresh plasma containing albumin and coagulation factors for patients. The volume exchanged

utilizing this method was about 3 500 mL each time, much more than that utilizing traditional centrifugation methods, which exchanged only 800-1 000 mL each time. Continuous hemodiafiltration (CHDF) could eliminate middle and small molecular toxic substances, and keep the balance of internal environment^[13]. These methods were used in different combinations based on the symptoms of patients (Figures 1-3). For example, when patients had hepatic encephalopathy, we performed plasma exchange in combination with plasma perfusion. For patients with hepatorenal syndrome, we chose plasma exchange and hemodialysis or hemofiltration or CHDF. For those with hyperbilirubinemia, plasma bilirubin absorption in combination with hemoperfusion was used. When the balance of water or electrolytes was disturbed, we used plasma exchange and hemofiltration or CHDF. Sometimes, more than three methods were used together for one patient. In addition, we carefully adjusted the dose of heparin and protamine according to PT, and maintained fluid balance to decrease complications such as bleeding, hemolysis, hypotension. This was crucial to decrease the mortality of hepatic failure.

Changes in the spectrum of amino acids might be another benefit of ALSS therapy. It has been shown that the concentration of aromatic amino acids (AAA) was increased in patients with fulminant hepatitis failure^[14,15]. Moreover, the concentration of methionine was a sensitive indicator of liver injury because methionine was released while liver necrosis^[16]. Methionine was toxic to the central nervous system, and one of the main causes of hepatic encephalopathy^[17]. After ALSS therapy, the serum level of aromatic amino acids, especially methionine declined and the ratio of BCAA/AAA was significantly increased.

In this study, we found that the cure rate of treatment group was significantly higher than that of the control group, indicating that ALSS is an effective therapy in treating patients with severe hepatitis. We also compared the efficiency of ALSS therapy in different stages of severe liver disease and concluded that the cure rate of early or middle stage severe hepatitis was much higher than that of end stage severe hepatitis (76.5%, 61.8% vs 13.7%, respectively). It is possible that ALSS may provide a favorable internal environment for hepatocytes to regenerate and restore normal function in patients at early or middle stage. However, there was massive necrosis of hepatocytes in hepatitis patients at end stage, and liver regeneration was not sufficient to recover liver function. Our data suggested that ALSS therapy might be an effective method to treat hepatitis patients at early stages.

Liver transplantation could provide good results in the treatment of hepatic failure, with a 5-year survival rate of 60%^[6,18]. However, its use has been greatly limited because of the lack of sufficient liver donors. Therefore, a system that can serve as a “bridge” to eventual OLT would greatly extend the survival rate^[19,20]. Based on our data, the artificial liver support system could serve as an effective “bridge” to OLT. Plasmapheresis was also beneficial, as the levels of coagulation factors and albumin could be increased by several plasma exchanges^[19]. Hemoperfusion was effective in improving the neurologic status

of patients with hepatic failure^[8,21]. Hemodialysis, hemofiltration or CHDF could correct the disturbance of water or electrolytes of patients^[13,22]. So ALSS could improve the condition of patients until a donor liver was available. Complications of the transplantation included acid-base imbalance, hyperbilirubinemia, disturbance of electrolytes, dysfunction of blood coagulation, acute rejection, *etc.*^[23]. ALSS treatment could improve the internal environment to support patients in pre- and post-transplantation periods. In addition ALSS could therefore improve the result of OLT in patients with severe liver disease. Further appropriately controlled trials are being initiated to confirm this observation.

Abstract

AIM: Immune escape mutations of HBV often occur in the dominant epitope, the second-loop of the α determinant of hepatitis B surface antigen (HBsAg). To let the hosts respond to the subdominant epitopes in HBsAg may be an effective way to decrease the prevalence of immune escape mutants. For this reason, a man-made clone of HBV S gene with the second-loop deletion was constructed. Its antigenicity was evaluated by yeast expression analysis and DNA immunization in mice.

METHODS: HBV S gene with deleted second-loop, amino acids from 139 to 145, was generated using splicing by overlap extension. HBV deleted S gene was then cloned into the yeast expression vector pPIC9 and the mammalian expression vector pcDNA3 to generate pHB-SDY and pHB-SD, respectively. The complete S gene was cloned into the same vectors as controls. The deleted recombinant HBsAg expressed in yeasts was detected using Abbott IMx HBsAg test kits, enzyme-linked immunosorbent assay (ELISA) and immune dot blotting to evaluate its antigenicity *in vitro*. The anti-HBs responses to DNA immunization in BALB/c mice were detected using Abbott IMx AUSAB test kits to evaluate the antigenicity of that recombinant protein *in vivo*.

RESULTS: Both deleted and complete HBsAg were successfully expressed in yeasts. They were intracellular expressions. The deleted HBsAg could not be detected by ELISA, in which the monoclonal anti-HBs against the α determinant was used, but could be detected by Abbott IMx and immune dot blotting, in which multiple monoclonal anti-HBs and polyclonal anti-HBs were used, respectively. The activity of the deleted HBsAg detected by Abbott IMx was much lower than that of complete HBsAg (the ratio of sample value/cut off value, 106 ± 26.7 vs $1\ 814.4 \pm 776.3$, $P < 0.01$, $t = 5.02$). The anti-HBs response of pHB-SD to DNA immunization was lower than that of complete HBV S gene vector pHB (the positive rate $2/10$ vs $6/10$, 4.56 ± 3.52 mIU/mL vs 27.60 ± 17.3 mIU/mL, $P = 0.02$, $t = 2.7$).

CONCLUSIONS: HBsAg with deleted second-loop of the α determinant still has antigenicity, and can also raise weak anti-HBs response in mice to DNA immunization, suggesting

that it is possible to develop a subdominant vaccine for preventing infections of immune escape mutants of HBV.

INTRODUCTION

The prevalence of hepatitis B virus (HBV) is still high in some areas of the world^[1,2]. Universal inoculation of hepatitis B vaccine helps to sharply decrease the prevalence of HBsAg carriers from about 10% to 2% among the urban children in China^[3]. However, there are about 5-10% of healthy individuals demonstrating no or inadequate responses following a standard vaccination schedule^[4,5]. A portion of these non-responders may be with a breakthrough infection of immune escape mutants^[6,7]. The escape mutant infections were also frequently occurred in liver transplant recipients under hepatitis B immunoglobulin prophylaxis^[8,9]. The prevalence of the mutants, usually as occult HBV infections, will progressively increase in the future since certain mutants are stable enough to be horizontally transmittable^[10,11] and have a potential to be transmitted through blood transfusion because of escaping the routine screening assays. The second-loop from aa139 to aa147 of the α determinant of HBsAg is the dominant epitope. The escape mutants usually have mutations in this region, including K141E, P142S, D144E and G145R^[8,9,12-16], though there are mutations in the rest part of HBsAg^[17,18], and induce an altered immunity against the second-loop so that the mutants can escape vaccine-raised antibodies or rabbit polyclonal antibodies to some extent^[19,20]. Fortunately, recent researches suggested that weak epitopes, such as subdominant epitopes, might not be escaped^[21,22]. To let hosts respond to subdominant epitopes or to both dominant and subdominant epitopes may be an effective way for the prevention of escape mutant infections. For these reasons, a man-made clone of HBV S gene with the second-loop deletion of the α determinant region was constructed in order to destroy the dominant epitope and let the subdominant epitopes be responded by the hosts. The antigenicity of that deleted S gene was evaluated by means of yeast expression analysis and DNA immunization in mice.

MATERIALS AND METHODS

Reagents

pTZ19U-HBV containing double copies of HBV DNA (adw) was presented from professor Zhi-Min Huang, Zhongshan University, Guangzhou, China. pcDNA3 and pPIC9 were purchased from Invitrogen Company (the United States of America). T4 DNA ligase and pfu DNA polymerase were purchased from Promega Company (the United States of America). DNA gel extraction kits and plasmid isolation kits were purchased from Qiagen Company (Germany). Primers shown in Table 1 were synthesized by Bioasia Biological

Engineering Company (Shanghai, China). ELISA HBsAg kit was purchased from Zhongshan Biological Engineering Company (Guangdong, China). Abbott IMx HBsAg and AUSAB test kits were purchased from Abbott Laboratory (the United States of America). Sheep polyclonal anti-HBs and labeled streptavidin biotin detecting kit were purchased from DAKO Company (the United States).

Animal

Eight to twelve week-old inbred BALB/c female mice were obtained from Guangzhou Traditional Chinese Medicine University.

Construction of HB-SD and HB-SDY fragments

HB-SD was the fragment of HBV S gene with deletion of seven amino acid residues from 139 to 145 of the second-loop of the α determinant. In order to construct HB-SD, Two fragments of HBV S gene from codon 1 to codon 138 and from codon 146 to codon 226 were obtained by polymerase chain reaction (PCR) using HBS-SD1/HBS-SD2 and HBS-SD3/HBS-SD4 as primers, respectively, and pTZ19U-HBV as template. The fragments were then connected using splicing by overlap extension after the PCR products were run on 20 g/L agarose gel and a given band was extracted using DNA gel extraction kit^[23]. HB-SD was obtained at last by purifying the spliced products. HB-SDY was obtained by PCR using HB-SD as template and HBSPIC9-1/HBSPIC9-2 as primers. The control fragments of complete HBV S gene were obtained using pTZ19U-HBV as template, and HBS-SD1/HBS-SD4 or HBSPIC9-1/HBSPIC9-2 as primers.

Construction of recombinant vector pHB-SDY and pHB-SD

For construction of pHB-SDY, the fragments of HB-SD and pPIC9 were digested by restriction endonucleases *Eco*RI and *Not* I, respectively. For construction of pHB-SD, the fragment of HB-SD was digested by restriction endonucleases *Hind* III and *Eco* RI, respectively as well as pcDNA3. Digested DNA fragment and vector DNA were ligated using T4 DNA ligase after purification. Plasmid DNA was obtained after *Escherichia coli* was transformed by ligated products. Candidate recombinant plasmids were selected by restriction fragment length polymorphism (RFLP) analysis and automatic DNA sequencing by Bioasia Biological Engineering Company. Control vectors pHB and pHBV were generated using the control fragments of complete HBV S gene in the same way.

Expression of pHB-SDY in yeast

The recombinant vector DNA of pHB-SDY and pHBV was prepared from transformed bacteria using Qiagen's Max-Prep kits. Yeast cells from a single colony of *Pichia pastoris* GS115 strain were cultivated using YPD culture. Vector DNA was transformed into yeast cells by lithium chloride transformation method. Transformants were grown on minimal dextrose and minimal methanol plates to screen Mut⁺ and Mut^S phenotypes. PCR using AOX1 primers was utilized to screen integrants. Mut^S strain was cultivated in BMGY culture and induced using 5 mL/L methanol. Protein expression of the supernatants and cell pellets

was analyzed by Coomassie-stained SDS-PAGE, ELISA, Abbott IMx and immune dot blotting assay. ELISA and IMx tests were carried out as the manufacturer's protocol. Immune dot blotting was carried out using sheep polyclonal anti-HBs as first antibody and LSAB kit to demonstrate the results.

DNA immunization analysis of pHB-SD

Large scale plasmid DNA of recombinant plasmids pHB-SD and pHB was prepared using Qiagen's Max-Prep kits. Plasmid DNA of pcDNA3 was also prepared to be used as control. Plasmid DNA was adjusted to 1 μ g/ μ L in normal saline. Thirty BLBA/c mice were randomly divided into 4 groups. Each mouse was injected 100 μ L of plasmid DNA which was distributed over five different sites into the anterior tibialis muscle 5 d after the injection of an equal volume of 2 g/L bupivacaine. Boost injection was carried out 3 times every 3 wk with equal amount of plasmid DNA. Four weeks after the last boost injection, all mice were put to death for serum. Anti-HBs in serum was detected using Abbott AUSAB kits.

Statistical analysis

For anti-HBs level, geometric mean titer (GMT) for each group was calculated at first. Then Student-Newman-Keuls-q was used for statistical analysis. For positive rate, Fisher exact probability analysis was used. SPSS 10.0 for Windows was used for all statistical analysis. $P < 0.05$ was considered statistically significant.

RESULTS

Construction of HB-SD and HB-SDY

Two fragments for constructing HB-SD fragment (Figure 1) were successfully obtained with base pair number as expected. The base pair number of spliced HB-SD fragment (Figure 1) was just a little smaller than that of HB fragment (Figure 1), which was the PCR fragment of complete HBV S gene with 711 bp in length. That was conformed to the fact that HB-SD fragment was only 21 bp smaller than HB fragment. HBV and HB-SDY fragments are shown in Figure 1. Their base pair numbers were the same as designed.

Construction of pHB-SD and pHB-SDY

HB-SD fragment was inserted into the vector of pcDNA3 between restriction endonucleases *Hind* III and *Eco*RI. When recombinant plasmids were digested with the two restriction endonucleases, the molecular weight of the small restriction fragment was the same as that of HB-SD (Figure 2). After its sequence was confirmed by DNA sequencing, the recombinant plasmid was denominated as pHB-SD. The HB fragment was cloned into the same vector to obtain a recombinant plasmid of pHB as control. HB-SDY fragment was inserted into the vector of pPIC9 between restriction endonucleases *Eco* RI and *Not* I. The digested fragment shown in Figure 2 was the same as designed in base pair numbers. The recombinant vector was denominated as pHB-SDY after its sequence was confirmed by DNA sequencing. HBV fragment was cloned into the pPIC9 to obtain recombinant vector of pHBV as control.

Expression of recombinant plasmid pHB-SDY in yeast

Mut^s transformants for pHB-SDY and its control pHBY were successfully selected though growing on plates of minimal dextrose and minimal methanol. The integrant screening results of transformants are shown in Figure 3. The PCR product of Mut⁺ transformants without gene of interest was 2.2 kb (Figure 3A). The PCR product of pPIC9 alone was 492 bp (Figure 3A). The PCR products of integrants of pHBY and pHB-SDY were 1 200 bp and 1 179 bp respectively. These transformants shown in Figure 3A were recombinants with the genes of interest, and belonged to Mut^s transformants since they had no bands of wild-type *AOX1* gene. The results of Coomassie-stained SDS-PAGE analysis of the protein expression of Mut^s transformants with pHBY and pHB-SDY are shown in Figure 3B. No recombinant protein was visible. The results of HBsAg antigenicity detection using ELISA and immune dot blotting are shown in Figure 4. The expression of transformants with pHBY was intracellular. The recombinant protein of pHB-SDY could not be detected by ELISA, and only weakly demonstrated by immune dot blotting assay. The IMx results are shown in Table 2. The ratio of sample value/cut off value of pHB-SDY was much lower than that of pHBY ($P < 0.01$, $t = 5.02$).

DNA immunization

All mice were alive after the inoculation schedule was finished. The anti-HBs levels are shown in Table 2. The anti-HBs was

negative in groups of normal saline and plasmid pcDNA3. The positive rate of anti-HBs was 2/10 in pHB-SD group and 6/10 in pHBY group. The amount of anti-HBs induced in groups of HBV S gene with deleted second-loop of the α determinant was less than that in the complete HBV S gene groups ($P = 0.02$, $t = 2.7$).

Table 2 Antigenicity of HBsAg with second-loop deletion of α determinant

Groups	HBsAg titer by IMx S/CO value	Anti-HBs responses in DNA immunization	
		Positive rate	mIU/L (GMT \pm SE)
Empty control	-	0/5	-
pcDNA3	-	0/5	-
pHB	1 589 \pm 234.5 ^b	6/10	27.60 \pm 17.3 ^c
pHB-SD	106 \pm 26.8	2/10	4.56 \pm 3.52

S/CO: the ratio of sample against cut off value. GMT: geometric mean titer. ^b $P < 0.01$, $t = 5.02$ vs groups of pHB-SD; ^c $P = 0.02$, $t = 2.7$ vs groups of pHB-SD.

DISCUSSION

The hosts usually do not respond to the subdominant epitopes in both vaccinated individuals and patients because of the dominant negative mechanism. Since they usually have no escape mutations and are not tolerant in patients, the subdominant epitopes have been widely used to overcome immunological tolerance in the fields of tumor and chronic infections^[24-27]. Many subdominant epitopes were successfully responded by the hosts with chronic infections or tumor carrying patients^[24-29]. However, the most data were limited in CD8+ cells or cytotoxic T lymphocytes. There are few such literatures about the epitopes of B lymphocytes. As a protective antigen, HBsAg is of great significance for prevention of HBV infection. It has been confirmed that there are more than three B-lymphocyte epitopes in HBsAg. The second-loop of α determinant is the strongest one among them^[30]. It is the dominant epitope, and the rest ones are the subdominant epitopes.

To completely destroy the dominant epitope may be able to eliminate the dominant negative mechanism, and let the subdominant epitopes be responded by the hosts. In our study even after deletion of the second-loop of HBsAg α determinant, the recombinant protein expressed in yeasts still had a weak antigenicity. Though it escaped the monoclonal anti-HBs derived from the α determinant, the recombinant protein might react with polyclonal anti-HBs or monoclonal anti-HBs derived from other parts of HBsAg because it could be detected by immune dot blotting and Abbott IMx kits, in which the demonstrating antibodies consisted of monoclonal anti-HBs derived from α determinant and the rest part of HBsAg^[31]. These results are similar to that of the α determinant variants that could be detected by monoclonal antibody from the rest part of HBsAg too^[22]. Mammalian expression vector with deleted HBV S gene could raise a weak anti-HBs response to DNA immunization. It was not sure that this anti-HBs was protective. However, it might be able to react with HBV particles since the anti-HBs derived from the first-loop of the α determinant of HBsAg could be accessible on native HBsAg^[21]. These suggested that it was possible to develop a subdominant vaccine for the prevention of immune escape mutant infections of HBV.

The response rate of recombinant plasmids was very low in our study. It might be the nature of DNA immunization because this phenomenon also occurred in researches of other scientists^[32]. The deleted HBV S gene was successfully expressed in yeasts. However, the expression conditions need to be improved. The exact value of deleted HBsAg should be evaluated after purified recombinant proteins are obtained in the future. The effect of anti-HBs raised by subdominant epitopes of HBsAg on the infectivity of HBV should also be evaluated in the future.

HBsAg with deleted second-loop of the α determinant still has antigenicity, and can also raise weak anti-HBs response in mice to DNA immunization, suggesting that it is possible to develop a subdominant vaccine for preventing infections of immune escape mutants of HBV.

Abstract

AIM: γ -glutamyl transpeptidase (GGT) has been reported as a virulence and colonizing factor of *Helicobacter pylori* (*H pylori*). This study examined the effect of GGT on the growth of *H pylori*.

METHODS: Standard *H pylori* strain NCTC 11637 and 4 clinical isolates with different levels of GGT activity as measured by an enzymatic assay were used in this study. Growth inhibition and stimulation studies were carried out by culturing *H pylori* in brain heart infusion broth supplemented with specific GGT inhibitor (L-serine sodium borate complex, SBC) or enhancer (glutathione together with glycyl-glycine), respectively. The growth profiles of *H pylori* were determined based on viable bacterial count at time interval.

RESULTS: Growth was more profuse for *H pylori* isolates with higher GGT activity than those present with lower GGT activity. However, in the presence of SBC, growth of *H pylori* was retarded in a dose dependent manner ($P = 0.034$). In contrast, higher growth rate was observed when GGT activity was enhanced in the presence of glutathione and glycyl-glycine.

CONCLUSION: Higher GGT activity provides an advantage to the growth of *H pylori* *in vitro*. Inhibition of GGT activity by SBC resulted in growth retardation. The study shows that GGT plays an important role on the growth of *H pylori*.

INTRODUCTION

Helicobacter pylori (*H pylori*) is a gram-negative spiral bacterium that causes chronic infection of the human stomach in adults^[1-5] as well as children^[6]. The chronic *H pylori* infection may lead to peptic ulceration^[7-9] and may be a potential risk factor for gastric carcinoma^[10-12].

The exact mechanism on how *H pylori* promotes gastric neoplasia is not known but is hypothesized to have occurred through the production of reactive oxygen species leading to oxidative stress and DNA damage in gastric epithelial cells^[13-15].

The level of reduced form of the tripeptide thiol, glutathione (GSH), one of the major endogenous defense mechanisms against oxidative stress, was shown to be decreased in gastric mucosal after *H pylori* infection^[16,17]. Furthermore, it has been well established that GGT plays a major role in glutathione metabolism. This enzyme catalyses transpeptidation reaction in which a γ -glutamyl moiety is transferred from γ -glutamyl compounds, such as glutathione, a non-protein sulphhydryl molecule, to amino acids. In addition, GGT can use γ -glutamyl peptides as substrates in the reciprocal hydrolysis reaction, thus playing a role in the synthesis of glutathione^[18,19].

It has been reported that GGT activity could be inhibited by the presence of inhibitors like L-serine sodium borate complex (SBC)^[20] and acivicin^[21]. Although acivicin is a more effective GGT inhibitor, it is nonspecific and inhibits a number of glutamine amino-transferase^[21]. In contrast, SBC is a highly specific GGT inhibitor but substantially higher concentration of SBC as compared to acivicin is needed for an effective inhibition of GGT activity^[20].

GGT being a constitutive enzyme of *H pylori* was shown to participate in the colonization of *H pylori* in Swiss specific pathogen-free mice^[22]. However, a later study using a different animal model demonstrated that GGT was not essential for colonization but acted as a virulence factor^[23]. The present study examined the effect of GGT on *H pylori* growth *in vitro* in the presence of GGT inhibitor as well as enhancer.

MATERIALS AND METHODS

Bacterial strains and culture conditions

A standard *H pylori* strain NCTC 11 637 and 4 clinical isolates with different levels of GGT activity were used in this study. Strains 712 and 1 018 showed high GGT activity (>1 U/mg protein) while strains 1 082 and 888 had low GGT activity (<0.4 U/mg protein).

H pylori was grown for 3 d at 37 °C on chocolate blood agar containing 40 g/L blood agar base No.2 (Oxoid) and 50 mL/L horse blood (Gibco) in a humidified incubator (Forma Scientific) supplied with 50 mL/L CO₂^[24]. The bacterial cells were harvested and washed with PBS buffer (pH 7.4) to give a suspension of ca. 5×10^7 CFU/mL ($A_{600} = 0.2$) in either PBS or brain heart infusion (BHI, Gibco) broth.

Inhibitory effect of SBC on *H pylori* GGT activity

A bacterial population of 3 d old 10^7 CFU/mL *H pylori* NCTC 11 637 was incubated in BHI broth containing various concentrations (2-10 mmol/L) of SBC (Sigma) at 37 °C for 30 min. GGT activity of *H pylori* cells was then measured by an enzymatic assay as described by Meister *et al.*^[25].

Growth inhibition and stimulation studies

H pylori NCTC 11 637 was suspended in fresh BHI broth at a final cell concentration of approximately 5×10^5 CFU per ml. For growth inhibition study, appropriate volumes of filter-sterilized (pore size, 0.2 μ m; Nalgene sterile syringe filter) SBC stock solution (100 mmol/L) were added to sterile BHI broth to provide final concentrations of SBC in BHI in the range of 2-10 mmol/L. For growth stimulation study, filter-sterilized glycyl-glycine

(Sigma) and GSH (Sigma) were added to BHI broth at a final concentration of 1 mmol/L and 0.1 mmol/L, respectively.

Growth inhibition and stimulation curves were constructed based on viable bacterial count at different time interval.

Growth of various *H pylori* strains that expressed different levels of GGT activity

Two strains each with high GGT activity (strains 1 018 and 712) and low GGT activity (strains 1 082 and 888) were grown in BHI broth at 37 °C over a period of 3 wk. The bacterial populations of the various strains were enumerated at time interval.

Statistical analysis

Data was analyzed using one-way ANOVA test (SPSS). A value of $P \leq 0.05$ was considered statistically significant.

RESULTS

SBC inhibits GGT activity of *H pylori*

Figure 1 shows that *H pylori* strain NCTC 11 637 GGT activity was inhibited in a dose dependent manner upon exposure to a range of SBC concentrations (2–10 mmol/L) for 30 min at 37 °C, where >90% GGT activity was inhibited by ≥ 4 mmol/L SBC. The maximum inhibitory effect of 96% of GGT activity was achieved at the concentration of 10 mmol/L SBC.

Effect of GGT on *H pylori* growth

Since SBC has inhibitory effect on *H pylori* GGT activity, *H pylori* NCTC 11 637 was cultured in BHI broth supplemented with different concentrations of SBC (2–10 mmol/L). Figure 2 shows that the *H pylori* cultured in the presence of various concentrations of SBC (2–10 mmol/L) over 3 wk displayed marked inhibition on the growth of *H pylori* in a dose dependent manner (ANOVA, $P = 0.034$). A >99% decrease in viability of the bacterial population was observed within 72 h after culturing *H pylori* in the presence of 10 mmol/L SBC. In contrast, *H pylori* proliferated at twice the normal growth rate in the presence of GSH and glycyl-glycine with increased GGT activity as compared to the control. And this acceleration in growth lasted over a period of more than two weeks. Similar growth profile was observed with another *H pylori* strain SS1 (data not shown).

Growth of different *H pylori* strains

Growth of the four *H pylori* strains with disparate GGT activities was followed over a period of 3 wk. Figure 3 shows that *H pylori* isolates with higher GGT activity (strains 1 018 and 712) grew better and more abundant than those with lower GGT activity (strains 1 082 and 888) by 10–100 folds depending on the age of culture. However, all 4 cultures showed similar growth rate at 3 wk-old.

Figure 1 Inhibitory effect of SBC on *H pylori* GGT activity. Inhibition of 85%, 92%, 94%, 95% and 96% were obtained by incubating *H pylori* in 2, 4, 6, 8 and 10 mmol/L SBC, respectively at 37 °C for 30 min.

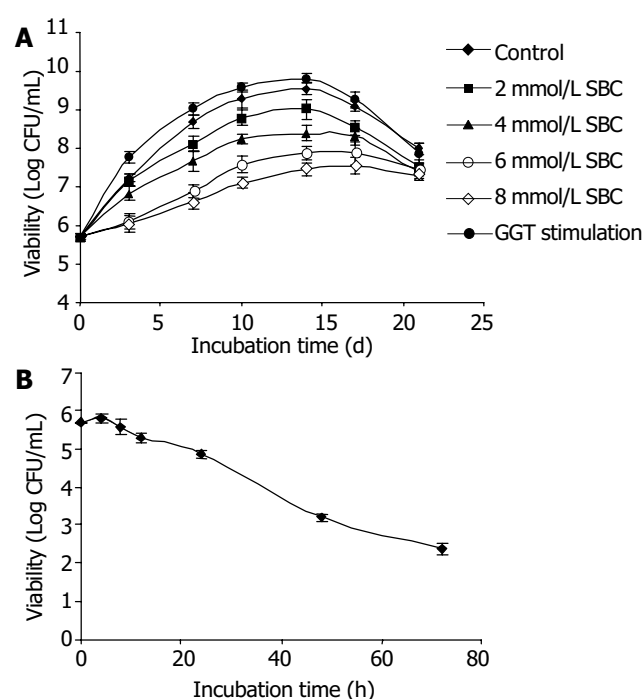

Figure 2 Effect of GGT on the growth of *H pylori*. *H pylori* strain NCTC 11 637 was cultured microaerobically in BHI broth medium supplemented with 10% fetal bovine serum at 37 °C and in the presence of either different concentration of GGT inhibitor or stimulator. A: Effect of 2 mmol/L (■ square), 4 mmol/L (▲ triangle), 6 mmol/L (× cross), 8 mmol/L (* star) SBC and GGT stimulation (0.1 mol/L GSH+1 mol/L glycyl-glycine, ● circle) on NCTC 11 637 over 21 d. Control (◆ diamond). B: Effect of 10 mmol/L SBC on NCTC 11 637 over 72 h. Viability was determined continuously at time intervals. (CFU: colony-forming units).

Figure 3 Growth of 4 *H pylori* strains with different levels of GGT activity. *H pylori* strains 1 018 and 712 expressed high GGT activity (>1 U/mg protein) while strains 888 and 1 082 produced low GGT activity (<0.4 U/mg protein). *H pylori* strains 1 018 (diamond), 712 (■ square), 888 (△ triangle), and 1 082 (× cross) were cultured in BHI medium microaerobically over 3 wk. Viability was determined continuously at time intervals.

DISCUSSION

Inhibition of GGT activity by SBC was caused by competition with respect to γ -glutamyl substrate, and it was suggested that a serine-borate complex is formed which may bind to the active site of the enzyme by interacting with a carbohydrate residue of the enzyme^[20]. Although acivicin is 20 times more effective in inhibiting GGT activity as compared to SBC (data not shown), it was not used for the growth inhibition study because it is a non-specific GGT inhibitor^[21]. In this study, more than 90% of GGT activity was suppressed by 4 mmol/L SBC. Inhibition of

GGT activity by SBC resulted in retarding the growth of *H pylori* in a dose dependent manner indicating that GGT is an essential enzyme in the growth of *H pylori*. In contrast, when physiological concentration of GSH and glycyl-glycine^[26,27] were supplemented into the culture medium, growth of *H pylori* was accelerated by more than two folds. The results show that the growth of *H pylori* was enhanced under GGT stimulation condition demonstrating the possibility of such event in *in vivo* situation.

In this study, it is interesting to note that *H pylori* with higher GGT activity (>1 U/mg protein) grows better than those with lower GGT activity (<0.4 U/mg protein). However, in the presence of SBC, a specific GGT inhibitor, the growth of *H pylori* was shown to be retarded. This finding that GGT is vital for the growth of *H pylori* could possibly explain why there was a reduction in the recovery of GGT isogenic mutant in the postinfected mice in the *in vivo* study carried out by McGovern *et al.*^[23], while no *ggt* mutant *H pylori* were recovered in the animal model of Chevalier *et al.*^[22]. The explanation supports the role of GGT activity in the ability of *H pylori* to proliferate in *in vivo* condition. However, the variation could also be due to the difference in animal model as suggested by McGovern *et al.*^[23], or owing to strain difference in terms of the level of GGT activity expressed as demonstrated in this study.

It has been reported that GGT plays a significant role in *H pylori*-mediated apoptosis^[28]. It was therefore suggested that *H pylori* induces apoptosis by GGT and that the bacteria gain essential nutrients from the apoptotic cells, thus establishing a permanent colony *in vivo*^[28,29]. The results of earlier studies^[22,23,28] indicated that GGT is an important enzyme for the growth and survival of *H pylori in vivo* while our findings that growth of *H pylori* is relative to the level of bacterial GGT activity and that higher GGT activity favors its growth *in vitro*. It is therefore proposed that GGT has a vital and prominent role to play on the growth of *H pylori*.

Abstract

AIM: To study the diagnosis of *Helicobacter pylori* (*H pylori*) infection through the determination of serum levels of anti-*H pylori* IgG and IgA antibodies, and the levels of anti-*H pylori* IgA antibodies in duodenal fluid.

METHODS: Data were collected from 93 patients submitted to upper digestive endoscopy due to dyspeptic symptoms. The patients were either negative (group A) or positive (group B) to *H pylori* by means of both histological detection and urease tests. Before endoscopy, peripheral blood was collected for the investigation of anti-*H pylori* IgG and IgA antibodies. To perform the urease test, biopsies were obtained from the gastric antrum. For the histological evaluation, biopsies were collected from the gastric antrum (greater and lesser curvatures) and the gastric body. Following this, duodenal fluid was collected from the first and second portions of the duodenum. For the serological assaying of anti-*H pylori* IgG and IgA, and anti-*H pylori* IgA in duodenal fluids, the ELISA method was utilized.

RESULTS: The concentration of serum IgG showed sensitivity of 64.0%, specificity of 83.7%, positive predictive value of 82.0%, negative predictive value of 66.6% and accuracy of 73.1% for the diagnosis of *H pylori* infection. For the same purpose, serum IgA showed sensitivity of 72.0%, specificity of 65.9%, positive predictive value of 72.0%, negative predictive value of 67.4% and accuracy of 69.8%. If the serological tests were considered together, i.e. when both were positive or negative, the accuracy was 80.0%, sensitivity was 86.6%, specificity was 74.2%, positive predictive value was 74.2% and negative predictive value was 86.6%. When values obtained in the test for detecting IgA in the duodenal fluid were analyzed, no significant difference ($P = 0.43$) was observed between the values obtained from patients with or without *H pylori* infection.

CONCLUSION: The results of serum IgG and IgA tests for *H pylori* detection when used simultaneously, are more efficient in accuracy, sensitivity and negative predictive value, than those when used alone. The concentration of IgA antibodies in duodenal fluid is not useful in identifying patients with or without *H pylori*.

INTRODUCTION

Knowledge about peptic ulcers has changed profoundly since Warren and Marshall^[1] managed to cultivate *Helicobacter pylori* (*H pylori*) from gastric biopsies. This raised great interest in the study of how it colonized the upper gastrointestinal tract and more specifically, in its direct relationship with peptic disease^[1-3].

In epidemiological studies, serum tests could offer high sensitivity and specificity^[4]. Serum assaying of anti-*H pylori* IgG and IgA antibodies could be used for the determination of prevalence of acute and chronic infections^[5-7]. In general, the serum levels of anti-*H pylori* IgG antibodies were increased in the presence of infection and could be used as a marker. On the other hand, anti-*H pylori* IgA antibodies were less appropriate for this purpose^[8,9], nevertheless serological findings of anti-*H pylori* IgA antibodies in symptomatic patients might have significant clinical values for the diagnosis of infection, especially if the patient was seronegative for IgG^[10].

In treatment of peptic diseases among *H pylori*-infected patients, local immune responses of the host, as well as the inherent factors of the microorganism, such as the presence of cytotoxin-associated gene A (*cagA*) were important^[11,12]. Few studies have analyzed the effect of local immune response on diseases induced by *H pylori*^[13,14].

H pylori infection could result in a major increase in cells secreting IgA in human gastroduodenal mucosa^[15,16] and usually induce high serum levels of anti-*H pylori* antibodies. Moreover, significant concentrations of antibodies were demonstrated in saliva, gastric fluid and feces^[17]. Despite the antibody response, this microorganism has been rarely eliminated from the stomach and when it was not treated adequately the infection generally persisted in the rest of an individual's life^[18].

However, the use of serological tests based on the determination of serum levels of anti-*H pylori* IgG and IgA antibodies to clinically diagnose *H pylori* infection has not yet been fully clarified^[5,7,10,16].

The objective of the present study was to analyze the use of serum levels of anti-*H pylori* IgG and IgA antibodies, and the levels of anti-*H pylori* IgA antibodies in duodenal fluid for the diagnosis of *H pylori* infection.

MATERIALS AND METHODS

Patients

Examinations were done on 93 patients with peptic symptoms from November 2000 to September 2001.

The inclusion criteria were: adult patients with a normal endoscopic examination or showing a peptic disease^[19,20]. The followings were considered to be exclusion criteria: presence of malignant disease of the upper digestive tract, previous gastrectomy, use of hormonal or non-hormonal anti-inflammatory medications, proton pump inhibitors, histamine H₂ receptor

blockers or antibiotics or antacids over the past twelve months, previous treatment for the elimination of *H pylori* over the past twelve months, presence of intestinal inflammatory disease or immunodeficiency of any nature, and pediatric age.

The patients ($n = 93$) were divided into two groups. Group A ($n = 43$) that had urease test and was histology negative for *H pylori*, and group B ($n = 50$) that had urease test and was histology positive for *H pylori*. These criteria (patients simultaneously positive or negative in histological and urease tests) were used for diagnosis of *H pylori*. In group A, 22 (51.2%) patients were males and 21 (48.8%) were females, the mean age was 34.77 ± 12.89 years (range: 17 to 71 years). In group B, 25 (50.0%) patients were males and 25 (50.0%) were females, the mean age was 41.6 ± 14.6 years (range: 21 to 71 years).

Methods

Endoscopic examination, biopsies of gastric mucosa and sampling of duodenal fluid To perform urease test, two biopsies were obtained from the gastric antrum (greater and lesser curvatures) at least 2 cm from the pylorus. For the histological analysis, four biopsies were collected, two of which from the gastric antrum (greater and lesser curvatures), and two of which from the gastric body on the anterior and posterior walls. Following this, a minimum of 2 mL of secreted duodenal fluid was collected from the first and second portions of the duodenum.

Processing of biopsy material The material collected from the gastric biopsies was placed in flasks containing 40 g/L buffered formaldehyde for fixation and then sent for histological examination. Slides were stained with hematoxylin and eosin and the modified Giemsa method (1% Lugol's solution and 25 g/L gentian violet solution). The four biopsy fragments removed from the gastric antrum were placed in flasks containing urease medium (Probac, Sao Paulo, Brazil), with 2 mL of solution in each. The flasks were maintained at 37°C and read by the main author 6 and 12 h later.

Determination of serum levels of anti-*H pylori* IgG and IgA and anti-*H pylori* IgA in duodenal fluid Before endoscopy, peripheral blood was collected to determine the serum levels of anti-*H pylori* IgG and IgA. Two-milliliter aliquots from duodenal fluid were diluted with distilled water until a final volume of 10 mL was reached. This solution was centrifuged at 1 500 r/min for 10 min and the supernatant was stored at -20°C .

ELISA method (Accubind®, Monobind, Inc., Costa Mesa, California, USA) was used to determine the levels of serum anti-*H pylori* IgG and IgA and anti-*H pylori* IgA in the duodenal fluid. The serum samples were diluted to 1/100 while the samples of duodenal fluids were diluted to 1/1 000. Other steps were performed according to the instructions of manufacturer.

For both the anti-*H pylori* IgG and IgA serum antibodies, optical density values greater than 20 U/mL were considered as positive results. For the anti-*H pylori* IgA antibodies in the duodenal fluid, no reference optical density value for a positive or negative test was available. Thus, a receiver operating characteristic (ROC) curve was constructed, taking the results obtained in ELISA test versus the gold standard.

Statistical analysis

Statistical analysis was performed by the Mann-Whitney, Fisher's exact and Kruskal-Wallis tests. The ROC curve was constructed in order to assess the sensitivity and specificity of anti-*H pylori* IgA assays in the duodenal fluid at different cutoff levels. An alpha value less than or equal to 5% was adopted for rejection of the null hypothesis. The results were expressed as mean \pm SD to illustrate the distribution of variables.

RESULTS

Findings of endoscopic and histological examination

The findings of endoscopic and histological examination were

gastritis alone in 32 (34.4%) patients, gastritis in association with duodenal peptic ulcer and/or moderate to severe enanthematic or erosive bulboduodenitis in 18 (19.4%), gastritis in association with hiatal hernia and/or esophagitis in 16 (17.2%), gastritis and slight bulboduodenitis in 11 (11.8%), gastritis in association with gastric ulcer and duodenal ulcer simultaneously in 4 (4.3%) and gastritis and gastric polyps in one (1.0%). Eleven (11.8%) patients presented normal endoscopic and histological examination of the gastric mucosa.

Value of serum tests for diagnosis of *H pylori* infection

The sensitivity, specificity, positive and negative predictive values and accuracy of the serum tests for anti-*H pylori* IgG and IgA were analyzed in relation to the gold standard. The accuracy of serum IgG levels was 73.1%, the sensitivity was 64.0%, specificity was 83.7%, positive predictive value was 82.0% and negative predictive value was 66.6%. With regard to serum IgA levels, the accuracy was 69.8%, sensitivity was 72.0%, specificity was 65.9%, positive predictive value was 72.0% and negative predictive value was 67.4%. If the serological tests were considered together, i.e. when both were positive or negative in comparison with the gold standard (Table 1), the accuracy was 80.0%, sensitivity was 86.6%, specificity was 74.2%, positive predictive value was 74.2% and negative predictive value was 86.6%.

Table 1 Frequency of patients positive or negative for serum anti-*H pylori* IgG, positive or negative for serum anti-*H pylori* IgA and negative or positive simultaneously for serum anti-*H pylori* IgG and IgA in comparison to the gold standard

	IgG (+) <i>n</i>	IgG (-) <i>n</i>	IgA (+) <i>n</i>	IgA (-) <i>n</i>	IgG and IgA (+) ^f <i>n</i>	IgG and IgA (-) ^f <i>n</i>
Histology and urease (+)	32 ^b	18 ^b	36 ^d	14 ^d	26 ^f	4 ^f
Histology and urease (-)	7	36	14	29	9	26

n: Number of patients; ^b $P < 0.0001$, ^d $P = 0.0002$, ^f $P < 0.0001$ vs histology and urease (-) group.

Figure 1 Sensitivity and specificity of anti-*H pylori* IgA in duodenal fluid for diagnosis of infection determined by ROC curve.

Compared with the frequencies of individuals with positive or negative results in the serological test for identifying anti-*H pylori* IgG and IgA antibodies, the serological tests were efficient in the diagnosis of the presence or absence of *H pylori* infection. The difference in the frequencies of positive and negative test results between the groups was highly significant (Table 1). With regard to the ELISA serological tests for anti-*H pylori* IgG and IgA considered together (Table 1), the difference between the frequencies of patients in each group was highly

significant ($P < 0.0001$).

In comparison between the values obtained in the ELISA tests in patients positive or negative for *H pylori*, the difference was significant in relation to anti-*H pylori* serological IgA and IgG.

Value of anti-*H pylori* IgA antibodies in duodenal fluid for diagnosis of *H pylori* infection

Sensitivity, specificity and false positive ratio for IgA in the duodenal fluid were defined by the ROC curve at different cutoff levels, as compared to the gold standard (Figure 1).

When values obtained in the ELISA test for determination of anti-*H pylori* IgA antibodies in the duodenal fluids were analyzed, no significant difference ($P = 0.43$) was observed between the patients with or without *H pylori* infection.

DISCUSSION

Martin-de-Argila *et al.*^[21] concluded that ELISA serum test for the detection of anti-*H pylori* IgA and IgG antibodies was sensitive and specific and should preferentially be utilized in population-based studies. Peura^[22] found that the sensitivity and specificity of ELISA test ranged from 75% to 95%. Perez-Perez *et al.*^[23] examined the detection of anti-*H pylori* IgA and IgG in serological samples from patients with positive cultures for *H pylori* and a histological diagnosis of gastritis, and verified that tests using both antibodies simultaneously had a sensitivity of 93.1% and a specificity of 94.4%. In our study, if the serological tests were considered together, the sensitivity was 86.6% and specificity was 74.2%. A possible explanation for this difference could be the different methods utilized as the gold standard. Indeed, the *H pylori* culture method performed by those authors could possibly have revealed smaller quantities of bacteria in the gastric mucosa. With few bacteria in the mucosa, the urease test and histology could give a false negative result.

Our results also pointed to an increased sensitivity when both anti-*H pylori* IgG and IgA were considered together, in relation to IgG or IgA alone, but the improvement in specificity occurred only in relation to IgA, and it was reduced in comparison with IgG alone. The association between IgG and IgA resulted in a marked improvement of the negative predictive value in comparison with the two assays alone, but did not offer advantages in relation to the positive predictive value.

Certainly, other variables than these might be responsible for the differences observed between the various studies, such as the severity and staging of peptic disease and the different strains of microorganism might also play a role. Strains with cytotoxin-associated gene A (cagA) exhibited more intense immunological responses^[11,16,23,24].

Watanabe *et al.*^[14] found that patients who presented high titers of anti-*H pylori* IgA in the gastric secretion presented a lower degree of neutrophilic infiltration on histological examination. These results suggest that anti-*H pylori* IgA antibodies have a protective function, even though this is insufficient to completely eliminate the organism.

In the present study, when the titers of anti-*H pylori* IgA in the duodenal fluid in patients with and without *H pylori* were analyzed, no significant difference was found in these values. The ROC curve, constructed using the values obtained from the determination of duodenal anti-*H pylori* IgA, compared to the gold standard, showed that the levels of this immunoglobulin in the duodenal fluid presented high sensitivity and low specificity, or even the opposite, depending on the cutoff level considered. Thus, if a cutoff level of 1.0 is adopted, it can be predicted that an individual will be negative for *H pylori* if the anti-*H pylori* IgA values in the duodenal fluid are below this reference level (sensitivity 82.4%). However, at this cutoff level,

individuals with anti-*H pylori* IgA above this value will be at increased risk of being considered as false positive, i.e. with a specificity of 14.5%, the number of false positives will reach 85.4%.

Crabtree *et al.*^[24], using ELISA method, evaluated the local immunological response of anti-*H pylori* IgA and IgG antibodies in patients with duodenitis. These authors observed that the local immunological response of anti-*H pylori* IgA antibodies was greater than that of anti-*H pylori* IgG antibodies. They also noted that there was a direct relationship between the titers of anti-*H pylori* antibodies and the severity of the inflammatory process found, or in other words, the more severe the duodenitis, the higher the levels of local antibodies and especially those of IgA. However, their investigation into these antibodies was done by evaluating the supernatant material from *in vitro* culture of biopsies taken from the first and second portions of the duodenum. In our study, duodenal fluid was collected from these same locations for investigating the anti-*H pylori* IgA antibodies. Often, studies performed *in vitro* could not be directly correlated with *in vivo* results because of the absence of other conditions frequently encountered *in vivo*, such as the presence of proteolytic enzymes in the intestine that could change the concentration of secreted IgA, although this immunoglobulin is very resistant to the action of these enzymes^[14]. Our results expressed the concentration of IgA in the duodenal fluid, but the total amount of IgA in this fluid was unknown, because the quantity of fluid in the first and second portions of the duodenum varied between patients. Crabtree *et al.* studied anti-*H pylori* antibodies in the duodenal mucosa, and observed notable differences in antibody concentrations between the first and second portions of the duodenum. These authors observed that, in the second portion of the duodenum, the concentrations of anti-*H pylori* IgA and IgG antibodies were lower than those in the first portion. This could have had a decisive influence on our results, since the duodenal fluid presented a greater volume in the second portion of the duodenum and it was often difficult to obtain samples of duodenal fluid from the first portion.

In conclusion, the results from the present investigation demonstrate that anti-*H pylori* IgA and IgG serum immunoglobulins are useful in distinguishing between patients with and without *H pylori* infection, whereas the concentration of anti-*H pylori* IgA in the duodenal fluid is not useful in identification of infected or uninfected patients.

Abstract

AIM: To investigate the dynamic expression of focal adhesion kinase (FAK) protein and FAK mRNA in fibrotic rat liver tissue, and the relationship between FAK and hepatic stellate cell (HSC) proliferation.

METHODS: Rat hepatic fibrosis was induced by bile duct ligation (BDL). Histopathological changes were evaluated by hematoxylin and eosin staining, and by Masson's trichrome method. FAK mRNA in the rat livers was determined by reverse transcription-polymerase chain reaction (RT-PCR), and the distributions of FAK were assessed immunohistochemically. The number of activated HSCs was quantified after alpha smooth muscle actin (α -SMA) staining.

RESULTS: With the development of hepatic fibrosis, the positively stained cells of α -SMA increased obviously, which were mainly resided in the portal ducts, fiber septa and perisinuses accompanied with proliferating bile ducts. The positively stained areas of the rat livers in model groups 1 to 4 wk after ligation of common bile duct ($12.88 \pm 2.63\%$, $22.65 \pm 2.16\%$, $27.45 \pm 1.86\%$, $35.25 \pm 2.34\%$, respectively) were significantly larger than those in the control group ($5.88 \pm 1.46\%$) ($P < 0.01$). The positive staining for FAK significantly increased, which was mainly situated in portal ducts, fiber septa and around the bile ducts, vascular endothelial cells and perisinusoidal cells. The expression of FAK was positively correlated with α -SMA expression ($r = 0.963$, $P < 0.05$). FAK mRNA expression was obviously up-regulated in the model groups compared to the control group.

CONCLUSION: These data suggest that expressions of FAK protein and mRNA are greatly increased in fibrotic rat livers, which may play an important role in HSC proliferation and hepatic fibrogenesis.

INTRODUCTION

Focal adhesion kinase (FAK) is a cytoplasmic protein tyrosine kinase that has been implicated to play an important role in integrin-mediated signal transduction pathways. Furthermore, some lines of evidence indicate FAK as a point of convergence of other signaling pathways. The *in vitro* expression of FAK and its level of phosphorylation appear to be related to several physiological phenomena, including cell adhesion, spreading, migration, cytoskeleton organization, proliferation and apoptosis^[1-3]. It has been accepted that hepatic stellate cells (HSCs) represent the pivot of fibrotic process^[4-9]. In healthy livers, HSCs are perisinusoidal mesenchymal elements with characteristic intracytoplasmic lipid droplets rich in retinyl esters. In contrast, in chronic liver injury, HSCs undergo a process of activation from the resting fat-storing phenotype towards a myofibroblast-like phenotype^[10].

Current evidence indicates that activated HSCs are responsible for the majority of extracellular matrix protein depositions in liver fibrosis^[11]. Although a recent study has focused on the roles of FAK in cultured cells^[12], little is known about its regulation *in vivo* or its relevance to HSC proliferation. In addition, it is not known whether FAK is up-regulated in response to liver injury by bile duct ligation (BDL). To assess whether FAK was associated with fibrogenesis or the survival of HSCs in biliary fibrosis, we investigated the expression of FAK in liver tissues from rats with BDL-induced biliary fibrosis using immunohistochemistry and reverse transcription-polymerase chain reaction (RT-PCR), we also used immunohistochemistry method to examine the expression of α -smooth muscle actin (α -SMA) as a marker of activated HSCs.

MATERIALS AND METHODS

Reagents

Monoclonal antibodies against FAK and α -SMA were products of Santa Cruz Biotech Inc. Streptavidin peroxidase (SP) immunohistochemical kit was purchased from Zhongshan Biological Technology Co. (Beijing). Trizol reagent was obtained from Life Technologies, Inc (USA). One tube RT-PCR kit was from Promega Co (USA). Primers for rat FAK and β -actin were designed by ourselves in accordance with gene sequence in GeneBank, synthesized and purified by Bao Biological Engineering Co. (Dalian). All other reagents were analytically pure.

Animal model and experimental protocol

A total of 80 adult male Sprague-Dawley rats weighing 350-400 g were purchased from the Experimental Animal Center of Hebei Medical University (Clearing Grade, Certificate No. 04057). All rats were housed in plastic cages and allowed free access to food and water. For the purpose of this study, rats were randomly divided into eight groups (ten rats in each group) as follows: Control group (sham-operated group), with BDL for 2 h, 6 h, 2 d, 1 wk, 2 wk, 3 wk and 4 wk, respectively. The rats were subjected to laparotomy with their common bile ducts completely ligated while they were intraperitoneally injected with ketamine hydrochloride at a dose of 100 mg/kg^[13]. Under deep anaesthesia, the peritoneal cavity was opened and the common bile duct

was double-ligated with 3-0 silk and cut between the ligatures. Control animals underwent a sham operation that consisted of exposure but not ligation of the common bile duct. At various intervals postoperation, animals were anaesthetised and the livers were harvested. Liver tissue specimens were routinely fixed in 40 g/L phosphate-buffered formaldehyde and embedded in paraffin. Some liver tissue specimens were used for light microscopy and immunohistochemistry using anti α -SMA and FAK, while others were snap-frozen in liquid nitrogen and stored at -80 °C for RNA analysis. In addition, control livers were harvested 4 wk after sham operation.

Histopathology

For light microscopic examination, liver specimens were routinely fixed overnight in 40 g/L phosphate-buffered formaldehyde, embedded in paraffin. Tissue sections (5- μ m thick) were stained with haematoxylin and eosin (HE) for morphological evaluation and Masson's trichrome for assessment of fibrosis.

Immunohistochemical detection of α -SMA and FAK

All immunohistochemical studies using the streptavidin-peroxidase technique were performed on 5- μ m thick sections of paraformaldehyde-fixed and paraffin-embedded liver block tissue mounted on APES-coated slides. Slides were deparaffinised in xylene, and rehydrated in graded ethanol. Endogenous peroxidase activity was quenched with a 30 mL/L hydrogen peroxide solution in methanol at room temperature for 30 min, followed by rinsing in pH 6.0 phosphate-buffered saline (PBS). After antigen retrieval in a water bath set in a 10 mmol/L citrate buffer (pH 6.0) at 94 °C for 8 min, 10 min, respectively, the slides were immediately cooled for 20 min at room temperature. Non-specific binding sites were blocked by incubation with washing buffer containing 100 mL/L normal goat serum at 37 °C for 30 min. Sections were then incubated at 4 °C with a mouse monoclonal antibody directed against α -SMA or FAK at a dilution of 1:100. The secondary antibody bindings were localized using a biotin conjugated rabbit anti-mouse IgG (1:100 dilution), followed by incubation with streptavidin-peroxidase complex (1:200 dilution). Peroxidase conjugates were subsequently visualised using diaminobenzidine (DAB) solution in hydrogen peroxide as a chromogen yielding a brown reaction product. Sections were then counterstained in Mayer's hematoxylin and mounted over cover slips. All incubations were performed in a moist chamber. Furthermore, between each incubation step, the slides were washed three times with PBS for 5 min. To ensure antibody specificity, negative control samples were processed in parallel under the same conditions but with omission of the first antibody, which was replaced by an equal volume of PBS. The α -SMA-positive parenchyma and the FAK-positive parenchyma were measured by a video-image analysis system and expressed as a percentage of area occupied by the signal.

RNA extraction and RT-PCR assay

Expression of FAK mRNA was evaluated with RT-PCR. Total RNA from liver specimens (100 mg) was isolated using a monophasic solution of phenol and guanidine thiocyanate (Trizol), precipitated in ethanol and resuspended in sterile RNAase-free water for storage at -80 °C until use, as recommended by the suppliers. Total RNA was quantified spectrometrically at 260 nm, and the quality of isolated RNA was analysed on agarose gels under standard conditions. One-step RT-PCR was performed according to the manufacturer's instructions. Two micrograms of RNA was added to each reaction and RT-PCR was routinely performed using 5 units of AMV reverse transcriptase, 5 units of *Tfl* DNA polymerase, 10 pmol of each oligonucleotide primer, 10 pmol of dNTP mix and 25 mmol/L $MgSO_4$ in a final reaction volume of 50 μ L. Primer sequences were as follows:

FAK, forward 5'-ACT TGG ACG CTG TAT TGG AG-3' and reverse 5'-CTG TTG CCT GCT TTC TGG AT-3', fragment length 833 bp; β -actin, forward 5'-AGC TGA GAG GGA AAT CGT GCG-3' and reverse 5'-GTGCCACCA GAC AGC ACT GTG-3', fragment length 300 bp. RT-PCR was performed in the following steps: reverse transcription was performed at 41 °C for 45 min, pre-denaturation at 94 °C for 2 min; then amplification was performed in a thermal controller for 35 cycles (denaturation at 94 °C for 40 s, annealing at 52 °C for 1 min and extension at 72 °C for 1.5 min), and a final extension at 72 °C for 10 min after the last cycle. A 10 μ L of the PCR products was analyzed on 1.5 g/L agarose gel containing ethidium bromide with TAE buffer at 80 V for 40 min and photographed under UV illumination. The band intensities were quantified by densitometry. FAK/ β -actin quotient indicated the relative expression of FAK. Experiments were performed at least three times with similar results.

Statistical analysis

The data were expressed as mean \pm SD. The mean values were compared by using analysis of variance, followed by the Student-Newman-Keuls test if the former was significant. The correlation between the expressions of FAK and α -SMA was analyzed for statistical significance by the simple linear regression analysis. *P* values less than 0.05 were considered statistically significant.

RESULTS

Histology of progressive fibrotic liver injury

In accordance with previous reports^[13], a marked liver fibrosis was apparently observed in the SD rats after BDL. In the present study, the results of HE and Masson's trichrome staining confirmed spotted (or scattered) perivenular degeneration of hepatocytes, an increase in the inflammatory infiltrates in the necrotic areas and bile ductular proliferation in the portal triads after 1 wk of BDL. After 2 wk of BDL, all rats showed expanded portal tracts with fibrous tissues, portal-to-portal fibrous bridging, nodular transformation and widespread proliferating bile ductules that extended into the parenchyma in places without clear-cut cirrhosis. After BDL for 3-4 wk, the animals developed severe fibrosis associated with proliferating bile ducts that formed a continuous meshwork of connective tissues with complete distortion of lobular architecture, whereas there was no notable histological abnormality or evidence of stainable collagen in any of the shamly operated control livers (Figure 1A-D).

Identification of proliferating and activated HSC

Since α -SMA was expressed in activated HSCs, immunostaining for this protein was used to detect and quantify the numbers of activated HSCs. A weak staining for α -SMA positive cells in the shamly operated control livers was observed in vascular smooth muscle cells and sinusoids. With the development of hepatic fibrosis, the positive stainings for α -SMA were greatly increased in the cells of portal ducts, fibrotic septa, perisinuses and around the proliferated bile ducts. The positively stained areas of the rat livers in model groups 1 to 4 wk after ligation of common bile duct ($12.88 \pm 2.63\%$, $22.65 \pm 2.16\%$, $27.45 \pm 1.86\%$, $35.25 \pm 2.34\%$, respectively) were significantly larger than that in control group ($5.88 \pm 1.46\%$) ($P < 0.01$, Figure 2 A-C).

Distribution of FAK protein in common bile duct ligated rat liver

To explore the distribution of FAK, the sections of rat livers in sham operation and BDL groups were immunostained using specific monoclonal anti-FAK antibody. In the sections from sham operation group, expression of FAK was found in vascular smooth muscle cells and perisinusoidal cells. In contrast, the positive staining of BDL rat liver was obviously visible in and

around α -SMA-positive areas, which were prevailing detected in portal ducts, fibrotic septa, perisinusoidal cells and cells around the bile ducts as well as vascular endothelial cells. The positive areas of the rat livers in model groups 1 to 4 wk after

ligation of common bile duct ($13.05 \pm 1.32\%$, $18.43 \pm 2.18\%$, $23.45 \pm 2.73\%$, $31.00 \pm 2.77\%$, respectively) were significantly larger than that in control group ($3.98 \pm 1.27\%$) ($P < 0.01$, Figure 3A-C).

Figure 1 Histopathological changes in liver tissue (100 \times) A: Normal hepatic lobular architecture in sham operation group (HE); B: Few ECM deposition in sham operation group (Masson trichome); C: Extensive ductular proliferation and ECM deposition 4 wk after BDL (HE); D: Extensive connective tissue deposition 4 wk after BDL (Masson trichome).

Figure 2 α -SMA protein expression in liver tissue stained by immunohistochemistry (SP 200 \times) A: Few α -SMA expressions in sham operation group; B: Positive cells of α -SMA resided in portal ducts, fiber septa, perisinuses and around proliferated bile ducts after 2 wk BDL; C: Positively stained areas of α -SMA expression in model groups 1 to 4 wk after common bile duct ligation.

Figure 3 FAK protein expression in liver tissue stained by immunohistochemistry (SP 200 \times) A: FAK protein expression in sham operation group; B: FAK protein expression 2 wk after BDL; C: Time course of FAK expression in hepatic fibrogenesis stained by immunohistochemistry.

Figure 4 RT-PCR analysis of mRNA encoding FAK in hepatic fibrogenesis. A: RT-PCR analysis of mRNA encoding FAK in hepatic fibrogenesis at different time points. Lane 1: sham operation group; lane 2: BDL 2 h; lane 3: BDL 6 h; lane 4: BDL 2 d; lane 5: BDL 1 wk; lane 6: BDL 2 wk; lane 7: BDL 3 wk; lane 8: BDL 4 wk; lane 9: Marker B: Band intensities were quantified by densitometry. FAK/ β -actin quotient indicated the relative expression of FAK.

FAK mRNA expression in common bile duct ligated rat livers

Although it was shown that FAK protein was produced by liver tissues *in vivo*, it was not clear whether the FAK mRNA level under fibrogenic response was increased *in vivo*. Therefore, we investigated the production of FAK mRNA in the liver. RT-PCR results revealed faint bands for FAK mRNA in the sham operation group, whereas obvious and specific bands for FAK mRNA in fibrotic liver of BDL groups. Moreover, FAK mRNA expression was initially up-regulated and reached the peak level 4 wk after BDL. The levels housekeeping gene, β -actin, did not show any significant differences between normal and BDL rat liver tissues (Figure 4A, B).

Correlation between FAK and α -SMA

Immunohistochemistry experiments were performed to analyze whether FAK protein distribution was correlated with α -SMA between sham operation group and BDL group. The results indicated that FAK was positively correlated with α -SMA ($r=0.963$, $P<0.05$).

DISCUSSION

HSCs, a principal cellular source of extracellular matrix during chronic liver injury, undergo a transition into α -SMA-expressing myofibroblast-like cells in response to injury. Furthermore, HSC activation is associated with stellate cell proliferation, increased contractility, enhanced matrix production, and expression of a number of fibrogenic and proliferative cytokines and their cognate receptors. Therefore, HSCs could play a pivotal role in cellular and molecular events that lead to fibrosis^[14-17]. As above, expressing α -SMA is one of the characteristics of activated HSCs. Cassiman *et al.*^[18] and α -SMA-positive cells mainly reside in the portal triads and fibrotic septa accompanied with proliferating bile ducts. Namely, α -SMA-positive cells was coincident with collagen deposition. The results of the present study verified that the positive cells of α -SMA, which mainly reside in portal ducts, fibrotic septa, perisinuses and around the proliferated bile ducts, were greatly increased with the development of hepatic fibrosis compared with sham operation group. Thus, our results are consistent with the others mentioned above.

Various factors and signal transduction pathways have been shown to regulate the activation and proliferation of HSCs^[8,9,19-21]. However, the mechanism by which *in vivo* factors impact HSC activation is not clear as yet. To better understand the mechanism by which FAK is generated in liver tissues might influence HSC activation, proliferation, and hepatic fibrogenesis, we performed the current research.

FAK, a 125 kD molecule, is a cytoplasmic nonreceptor tyrosine kinase that has been shown to play a key role in the

regulation of cell adhesion, spreading, migration, cytoskeleton organization, proliferation and apoptosis. Furthermore, some lines of evidence has indicated FAK is a point of convergence of many signaling pathways^[22]. The co-localization of FAK with integrins in focal adhesion plaque (FAP) is a trigger for cell adhesion-dependent activation of FAK signals^[22]. Subsequently, its autophosphorylation at Tyr397 in the N-terminal domain is prerequisite, which may initiate a number of signaling pathways. Among them, RAS-dependent mitogen-activated protein kinase (MAPK) pathway is the clearest. It has been found that the RAS-RAF-MEK (ERK kinase)-ERK (extracellular signal-regulated kinase) pathway is involved in many cellular behaviors^[22,23], such as proliferation, apoptosis. FAK knockout mice showed extensive mesodermal defects and embryonic death^[24]. Moreover, the monoclonal antibody specific for FAK microinjected into fibroblasts could inhibit FAK activity and give rise to apoptosis of fibroblasts^[25]. The results presented herein demonstrated that FAK protein was obviously expressed in portal ducts, fibrotic septa, perisinusoidal cells in BDL rat livers, which was in accordance was the distribution α -SMA-positive loci. In addition, FAK mRNA expression was also elevated with the progression of hepatic fibrosis. Importantly, FAK protein distribution was positively correlated with α -SMA. So, we suggested that activation of FAK in BDL rat liver tissues might activate downstream signal molecules, which could modulate gene expression of HSCs and give rise to hepatic fibrosis.

To date, the mechanism of FAK elevation during hepatic fibrogenesis remains unknown. But increasing *in vitro* evidence supports that HSCs are a major cell source of FAK. First, extracellular matrix components, including collagen and fibronectin could activate FAK in HSCs via integrin signal pathway^[26-28]. Second, cytokines such as platelet derived growth factor (PDGF), endothelin (ET), insulin-like growth factor-1 (IGF-1) and tumor necrosis factor (TNF), could increase the production of FAK^[29]. Third, reactive oxygen species (ROS) like H_2O_2 could also elevate the expression of FAK^[30,31]. In contrast, antioxidants such as *Salvia Miltiorrhiza*, might have opposite effects on FAK expression in HSCs^[32,33].

In conclusion, FAK-mediated activation of HSCs can result in hepatic fibrogenesis. Inhibition of FAK activity by various methods would be expected to attenuate liver fibrosis and, therefore, deserve further study.

Abstract

AIM: To analyze the tissue morphologic phenotype and liver gene expression profile of hB1F transgenic mice.

METHODS: Transgene expression was analyzed with RT-PCR and Western blotting. For one of the transgenic mouse lines, tissue expression pattern of the transgene was also examined with immunochemical methods. Pathological analysis was used to examine the tissue morphologic phenotype of established transgenic mice. The liver gene expression profile of transgenic mice was analyzed with microchip, and some of the differentially expressed genes were verified with RT-PCR.

RESULTS: The expressions of hB1F were shown in livers from 6 of 7 transgenic mouse lines. The overexpression of hB1F transgene did not cause pathological changes. Expressions of three genes were up-regulated, while down-regulation was observed for 25 genes.

CONCLUSION: The overexpression of hB1F transgene may cause changes of gene expression profiles in the liver of transgenic mice.

INTRODUCTION

Human hepatitis B virus enhancer II B1 binding factor (hB1F, also known as LRH-1, hFTF, CPF) belongs to the *fushi tarazu* factor 1 (FTZ-F1) nuclear receptor subfamily, which was formally designated as NR5A2^[1-3]. Like other FtsTZ-F1 receptors, hB1F contains a particular FTZ-F1 box which is located at the C-terminus of the DNA-binding domain (DBD) and binds to the response element as monomer^[1]. The biological function of

hB1F is just being unveiled. It has been reported that hB1F and/or its rodent homologs play an important role in regulating the liver-specific expression of several genes^[4,5]. Recent findings pinpoint hB1F as a critical transcription regulator in bile acid biosynthesis^[2,6,7], cholesterol homeostasis^[8-10], sex hormone biosynthesis^[11-13], and lipid metabolism^[14].

To facilitate the study on the function of hB1F, we have established 7 transgenic mouse lineages carrying hB1F transgene^[15]. In this study, we analyzed the expression of the transgene in livers of these transgenic mouse lines with RT-PCR and Western blotting. Tissue expression pattern of the transgene in one of the transgenic mouse lines was also examined with immunochemical methods. The results of pathological analysis demonstrated that the overexpression of hB1F transgene did not cause pathological changes. We then analyzed the gene expression profile in the liver of transgenic mice with microchip and found that the expression of 3 genes was up-regulated while the expression of 25 genes was down-regulated. Some of the differentially expressed genes were verified with RT-PCR. The expression of farnesyl pyrophosphate synthase, a key enzyme in cholesterol biosynthesis, was inhibited in hB1F transgenic mice.

MATERIALS AND METHODS

Animals

C57 mice were maintained by Shanghai Nanfang Research Center for Model Organisms (SNRCMO). hB1F transgenic mice were produced in SNRCMO, maintained and bred in the Laboratory Animal Center of the Second Military Medical University.

Expression of the transgene

Total RNA was isolated from tissues with the TRIzol reagent (Invitrogen) according to the manufacturer's instructions. Semiquantitative RT-PCR reactions were performed with primer pair sets 5'-CCGACAAGTGGTACATGGAA-3' and 5'-CTGCTGCGGG TAGTTACA CA-3' for hB1F cDNA, and 5'-AACTTTGGCATTGTGGAAGG-3' and 5'-TGTGAGGGAG ATGCTCAGTG-3' for mouse glyceraldehyde-3-phosphate dehydrogenase (GAPDH) cDNA, which resulted in the generation of 300 bp and 600 bp products, respectively. PCR reactions were performed 30 cycles at 94 °C for 1 min, at 57 °C for 1 min, and at 72 °C for 1 min. PCR products were electrophoresed on 15 g/L agarose gels.

For Western blotting, protein samples from tissues were prepared according to the protocol from Santa Cruz Biotechnology, Inc. Each protein sample (50 µg) was electrophoresed on 100 g/L SDS-polyacrylamide gel and transferred to PVDF membrane. Membranes were blocked with 50 g/L non-fat milk in Tween-TBS (TBST) overnight at 4 °C and incubated with the anti-Flag antibody (Sigma) at a dilution of 1:500 in TBST for 2 h at room temperature. Membranes were washed three times with TBST and incubated with a horseradish peroxidase-conjugated anti-mouse IgG at a dilution of 1:2 000 at room temperature for 1 h. Immunodetection was carried out with an enhanced chemiluminescence kit (Amersham Pharmacia Biotech) according to the manufacturer's instructions.

Immunohistochemistry and pathological analysis

Tissue samples were fixed in 10% (vol/vol) neutral formalin,

embedded in paraffin, and sectioned for staining. Immunohistochemistry was performed on deparaffinized sections. Tissue sections were permeabilized with 3 g/L Triton X-100 in PBS for 30 min. After washed with PBS, sections were saturated for 30 min at room temperature with PBS containing 50 mL/L milk and then incubated for 1 h at room temperature with the anti-Flag antibody (1/250 dilution). This incubation was followed by five washes for 5 min in PBS-10 mL/L milk and then incubated with a sheep anti-mouse IgG (1/100 dilution) in PBS-milk for 1 h at room temperature. Sections were then washed five times for 5 min in PBS and coverslipped with 500 mL/L glycerol in PBS and examined under a microscope and photographed. Immunohistochemistry and pathological analyses were carried out at the Department of Pathology, Changhai Hospital of the Second Military Medical University.

Microchip analysis of gene expression profile change

RNAs were isolated from livers of two male transgenic mice (TGM-4) and a male C57 mouse. Expressions of 8,315 genes of the mice were analyzed by using BiostarM-80s cDNA arrays (Biostar genechip Inc., Shanghai, China). Control C57 mouse liver cDNA was labeled with fluorescence Cy3 and TGM-4 liver cDNA was labeled with fluorescence Cy5. Cy3 intensity values were adjusted to Cy3* by multiplying a normalization coefficient. The ratios of Cy5/Cy3* were calculated and genes were identified as either up-regulated when the ratio >2, or down-regulated when the ratio <0.5.

Semi-quantitative RT-PCR analysis

Primers used in PCR for CBG gene were 5'-TGTCGTCGCTGCACTTAATC-3' and 5'-AGCACATTCCCTTCATCCAG-3', and

for FPPS gene 5'-GGCCATGTGGATCT TGGTAG-3' and 5'-GAGGAGAGGCTCGTAGCAGA-3', which resulted in generations of 255 bp and 301 bp products, respectively. The cycling parameters were at 94 °C for 5 min, followed by 30 cycles at 94 °C for 1 min, at 57 °C for 1 min, and at 72 °C for 1 min. The PCR products were separated on 1.5% agarose gels. Signals were quantified by density analysis of the digital images using Alpha image software (Alpha Co., Ltd).

Statistical analysis

Differences in CBG and FPPS mRNA expressions (comparing CBG/GAPDH or FPPS/GAPDH ratios) were analyzed using one-way ANOVA and by the Student-Newman-Keuls multiple range test.

RESULTS

Transgene expression in livers of transgenic mice

Since the liver is the main organ that expresses hB1F which is involved in the regulation of the liver-specific expression of several important genes, the overexpression of hB1F transgene in mouse liver may serve as an *in vivo* model to study the function of hB1F in liver. We examined the expression of hB1F transgene in livers of seven transgenic mouse lines. RT-PCR results showed that except TGM-2, six out of seven transgenic mouse lines examined had expression of the transgene (Figure 1). Western blot results demonstrated the expression of the transgene was found in livers of all lines with a relatively higher expression in lines TGM-3, TGM-6, and TGM-7 (Figure 2).

expression of hB1F transgene might cause any pathological changes in tissues of the transgenic mice. As shown in Figure 3, no obvious pathological change was observed in all tissues from the transgenic mouse line TGM-4. Therefore, as far as the tissues were examined, the expression of hB1F transgene did not result in pathological consequences in TGM-4. Similar results were obtained with other lines (data not shown).

Gene expression profile in livers of TGM-4

Microchip analysis was performed to investigate whether the gene expression profile of the host mice might be altered in the transgenic lines due to the expression of hB1F transgene. The gene expression profiles of cells from the livers of two independent TGM-4 mice were compared with that of the non-transgenic control mouse. Figure 4 represents a visual demonstration of the comparison of gene expression profiles between TGM-4 and C57. The expressions of 28 genes in the livers of TGM-4 mice were found to have changed compared with the C57 control mouse. Among them, 25 genes were down-regulated and 3 genes were up-regulated (Table 1).

RT-PCR analysis of differentially expressed genes

Based on the results of the microchip analysis, some of the differentially expressed genes including corticosteroid-binding globulin (CBG) and farnesyl pyrophosphate synthase (FPPS) were subjected to further analysis. Semi-quantitative RT-PCR was performed with samples used in the microchip analysis and also with additional samples from other transgenic lines, TGM-1, TGM-3, TGM-6, and TGM-7. The corticosteroid binding globulin (serine/cysteine proteinase inhibitor) gene was up-regulated in the liver of TGM-4 (Figure 5) and the farnesyl

Figure 6 Semi-quantitative RT-PCR results of FPPS expression in livers of TGMs and C57 control mouse. A: lane 1: DNA molecular weight marker DL2000; lane 2: TGM-1; lane 3: TGM-3; lane 4: TGM-4; lane 5: TGM-6; lane 6: TGM-7; lane 7: C57 control mouse. B: The ratio of FPPS/GAPDH was calculated for each sample and used as an indication for the relative expression of FPPS. The average value for the control was taken as 1. pyrophosphate synthase gene was down-regulated in all transgenic mouse lines (Figure 6). These results were well consistent with the microchip analysis data.

DISCUSSION

In this report, we verified the expression of hB1F transgene in several transgenic lines we have constructed previously. Results from RT-PCR and Western blotting analysis indicated that hB1F transgene was expressed in livers of all transgenic lines but with different expression levels. Besides liver, the transgene was also expressed in other organs such as stomach and testis (data not shown). The tissue expression pattern of hB1F transgene was expected since the transcription of the transgene was under the control of the CMV early promoter which has a relative broad tissue expression range. Although hB1F was thought previously to be present mainly in liver and pancreas, recent data revealed that it could be expressed in many types of tissues, such as intestine^[10,16], ovary^[17], adrenal gland^[12], and preadipocytes^[11,18]. Therefore, the transgenic lines established and verified in this study would provide a valuable animal model for studying the function of hB1F in multiple tissues.

Given that hB1F plays an important role in cholesterol homeostasis and bile acid biosynthesis, it is somewhat unexpected that no discernable pathological changes resulting from the overexpression of hB1F transgene have occurred in these transgenic lines. It is possible that the overexpression of hB1F might negatively feedback on the expression of the endogenous mouse counterpart of hB1F, mLRH-1. It remains to determine whether the expression of the endogenous mLRH-1 changes in cells overexpressing hB1F. On the other hand, it is apparent from the microchip analysis that the expression of some genes were altered in livers of these transgenic lines. Since disturbance to metabolic pathways such as the cholesterol homeostasis might require a long incubation time before any pathological phenotypes could be observed, it is necessary to perform a long term follow-up investigation on the possible pathological changes.

Among the genes identified to exhibit altered expressions in hB1F transgenic mice, the gene that encodes the farnesyl pyrophosphate synthase (FPPS) is the most interesting one. FPPS could catalyse the formation of farnesyl pyrophosphate (FPP) through the condensation of dimethylallyl pyrophosphate with two molecules of isopentenyl pyrophosphate. FPP is a key cellular intermediate for the biosynthesis of isoprenoids and a precursor of cholesterol, steroid hormones, dolichols, haem A and ubiquinone. Furthermore, it has been found that FPP and its derivative geranylgeranyl pyrophosphate are involved in prenylation, a post-translational modification of a variety of cellular proteins that influence their proper cellular

localizations and biological functions^[19]. The semi-quantitative RT-PCR results confirmed the down-regulated expression of FPPS in all transgenic lines, suggesting that inhibition of the expression of FPPS has a general effect on hB1F transgenic mice, unrelated to other reasons such as the position effect due to the integration of the transgene. Given the complexity of the regulatory network for the cholesterol homeostasis, it is still early to speculate on the molecular mechanism underlying the inhibition of expression of FPPS in hB1F transgenic mice. Whether hB1F directly or indirectly inhibits the expression of FPPS awaits future study.

Abstract

AIM: To construct a *pEgr-IFN γ* plasmid and to investigate its expression properties of interferon- γ (INF- γ) induced by irradiation and the effect of gene-radiotherapy on the growth of melanoma.

METHODS: A recombinant plasmid, *pEgr-IFN γ* , was constructed and transfected into B16 cell line with lipofectamine. The expression properties of *pEgr-IFN γ* were investigated by ELISA. Then, a B16 melanoma-bearing model was established in mice, and the plasmid was injected into the tumor tissue. The tumor received 20 Gy X-ray irradiation 36 h after injection, and IFN- γ expression was detected from the tumor tissue. A tumor growth curve at different time points was determined.

RESULTS: The eukaryotic expression vector, *pEgr-IFN γ* , was successfully constructed and transfected into B16 cells. IFN- γ expression was significantly increased in transfected cells after X-ray irradiation in comparison with 0 Gy group (77.73-94.60 pg/mL, $P < 0.05-0.001$), and was significantly higher at 4 h and 6 h than that of control group after 2 Gy X-ray irradiation (78.90-90.00 pg/mL, $P < 0.01-0.001$). When the transfected cells were given 2 Gy irradiation 5 times at an interval of 24 h, IFN- γ expression decreased in a time-dependent manner. From d 3 to d 15 after IFN γ gene-radiotherapy, the tumor growth was significantly slower than that after irradiation or gene therapy alone.

CONCLUSION: The anti-tumor effect of *pEgr-IFN γ* gene-radiotherapy is better than that of gene therapy or radiotherapy alone for melanoma. These results may establish an important experimental basis for gene-radiotherapy of cancer.

INTRODUCTION

Radiotherapy is one of the treatments for cancer. However, its therapeutic effect is still unsatisfactory, and thus new therapeutic

strategy must be adopted. Gene therapy in combination with radiotherapy is one of the most important advances^[1-4]. The introduction of Egr-1 promoter induced by irradiation has provided a possible approach to this combination therapy^[5-6].

IFN γ is the first cytokine produced by gene engineering and used for treatment of carcinoma, and has anti-tumor effects. Its antitumor mechanism includes direct inhibition of tumor cell proliferation, and indirect action by activating cytotoxic activities^[7-18]. In the present study we constructed the *pEgr-IFN γ* plasmid by connecting IFN γ cDNA to Egr-1 promoter to investigate its expression properties in B16 cells and its antitumor effect in mice.

MATERIALS AND METHODS

Construction of *pEgr-IFN γ* Plasmid

The expression vector for *pEgr-IFN γ* is shown in Figure 1.

Cell line and transfection

B16 cell line was cultured in MH Radiobiology Research Unit of Jilin University and maintained in RPMI 1640 (Life Technologies) with 100 mL/L fetal bovine serum (Hyclone Laboratories), L-glutamine, 100 μ g/mL of streptomycin, and 100 U/mL of penicillin. The cell line was incubated at 37 °C in 50 mL/L CO₂.

B16 cells were transfected in a 6-well plate when the cells reached 70% confluence. Solution A was prepared by addition of 10 μ g of *pEgr-IFN γ* or pcDNA3.1⁺ to 100 μ L serum-free medium (SFM), and solution B by addition of 10 μ L liposome to 100 μ L SFM. Solutions A and B were mixed at room temperature for 30 min, then mixed with 0.8 mL SFM, the mixture was added to the rinsed cells. The medium was replaced with fresh and complete medium 6 h after transfection.

Protein determination

Supernatants from different groups were collected for detection of the IFN γ expression with ELISA kit (Genzyme).

Establishment of B16 melanoma-bearing model

Adult female Kunming mice were provided by the Experimental Animal Center of Jilin University, with an average weight of 18 \pm 2 g.

A melanoma-bearing model was established by subcutaneous injection at right hind limb with 0.1 mL B16 cells (5 \times 10⁶/mL), 10 d later, tumor tissue received multi-focus injection of plasmids packaged with liposome (20 μ g plasmid and 0.1 mL liposome per mouse) for the experimental groups.

Tumor size was measured. Then, tumor volume (V) was calculated according to the formula: $V \text{ (mm}^3\text{)} = L \times W^2 / 2$, where, L: the longest diameter of tumor; W: the diameter at right angles on the largest horizontal section. Tumor growth rate (f) was the ratio of the volume at different time points over the initial volume (V₀).

Ionizing irradiation

X-rays of 200 kV and 10 mA with 0.5 mm copper and 1.0 mm aluminum filter were given at a dose-rate of 0.8639 Gy/min for a total dose of 2--20 Gy.

Figure 1 Construction of plasmid pEgr-IFN γ .

B16 cells were seeded in a 6-well plate and randomly divided into different groups. The experiment groups received X-ray irradiation of various doses or at different time points, control groups received sham irradiation simultaneously.

Mice bearing B16 xenografts ($n = 40$) were randomly divided into five groups: control group, 20 Gy group, pcDNA3.1+20 Gy group, pEgr-IFN γ group and pEgr-IFN γ +20 Gy group. Thirty-six hours before irradiation, melanoma tissue was injected with plasmids or buffer at 5 separate sites. Tumor beds were given 20 Gy X-ray irradiation. Animals of 20 Gy group, pcDNA3.1+20 Gy group and pEgr-IFN γ +20 Gy group were shielded with lead except for the tumor-bearing hind limb, animals in the other 2 groups were given sham-irradiation at the same time. Tumors were measured and recorded as previously described.

RT-PCR

Total RNA were extracted from EC9706 cells and tumor tissue for RT-PCR. GAPDH was used as an internal reference. Primers were as follows: GAPDH, forward primer 5'-TGCACCACCAAC TGCTTAGC -3' and reverse one 5'-GGCATGGACTGTGG TCATGAG-3', mouse IFN γ cDNA, forward primer 5'-GATCCT TTGGACCCTCTG ACTT-3' and reverse one 5'-AGACAGTGA TAAACTATAAATGAGCG-3'.

RT-PCR was performed as following: denaturation at 95 °C for 3 min, 30 cycles at 95 °C for 45 s, at 56 °C for 45 s, at 72 °C for 40 s and extension at 72 °C for 10 min.

Statistical analysis

Student's *t* test was used to determine comparability between groups. *P* values less than 0.05 were considered statistically significant.

RESULTS

B16 cell line transfected with pEgr-IFN γ plasmid

Pre- and post-transfection of B16 cells are shown in Figure 2.

IFN γ expressions in B16 cells transfected with pEgr-IFN γ after different doses of X-irradiation

After transfection B16 cells received different doses of X-ray irradiation. The cells of control group were transfected with pcDNA3.1+ plasmid. Six hours after irradiation IFN γ expression and mRNA level were detected.

The results showed that IFN γ expression in 2-20 Gy groups was significantly higher than that in 0 Gy group ($P < 0.05-0.01$) (Figure 3).

B16 cells before transfection

B16 cells after transfection

Figure 2 Pre- and post-transfection of B16 cells.

Figure 3 Expression of IFN γ in B16 cells after different doses of X-ray irradiation. (mean \pm SD, $n = 3$) ^a $P < 0.05$ and ^b $P < 0.01$ vs 0 Gy group.

After irradiation IFN γ mRNA could be detected in B16 cells (Figure 4). The level of IFN γ mRNA was compared with that of GAPDH, and their ratios are shown in Table 1. The IFN γ mRNA levels in 2-20 Gy groups were higher than that of 0 Gy group.

IFN γ expressions in B16 cells transfected with pEgr-IFN γ at different time points after 2Gy irradiation

After transfection B16 cells received 2 Gy of X-ray irradiation while the control group received sham irradiation. IFN γ protein was detected at different time points after irradiation. ELISA results showed that the IFN γ expression increased with time from 2 h to 6 h in a time-dependent manner, and peaked at 6 h, about 1.8 times of that in control group ($P < 0.001$). However,

from 8 h to 48 h post-radiation IFN γ expressions were not significantly different from that in control group (Figure 5).

Table 1 IFN γ mRNA level in B16 cells after irradiation with different doses

Dose (Gy)	Ratio of IFN γ mRNA level
0	0.819
2	0.972
5	1.347
10	1.950
20	2.144

Figure 5 Expression time course of IFN γ in B16 cells after 2 Gy X-ray irradiation (mean \pm SD, $n = 3$) ^b $P < 0.01$ and ^d $P < 0.001$ vs control group.

Expression of IFN γ in B16 cells at different time points after X-ray irradiation

After transfection B16 cells received 2 Gy irradiation while the

control group received sham irradiation. IFN γ expression was detected 6 h later. Irradiation and detection were repeated 5 times at an interval of 24 h.

The result showed that the IFN γ expression after the first irradiation was the highest, then decreased in a time-dependent manner. The expressions after the first 2 times of irradiation were higher than that in control group ($P < 0.01-0.001$) (Figure 6).

Figure 6 Expression of IFN γ in B16 cells at different time points after X-ray irradiation (mean \pm SD, $n = 3$) ^b $P < 0.01$ and ^d $P < 0.001$ vs 0 Gy groups.

Effect of gene-radiotherapy on tumor growth

Melanoma-bearing mice of different groups were shown in Figure 7.

Tumor growth rate of pEgr-IFN γ group was significantly slower than that of control group ($P < 0.001$) between 6 d and 15 d after irradiation (Table 2), so was pEgr-IFN γ plus 20 Gy group compared with control and 20 Gy groups between 3 d and 15 d after irradiation ($P < 0.001$).

Table 2 Tumor growth rate after gene-radiotherapy (mean \pm SD, $n = 8$)

Group	f (V/V ₀) on days after irradiation				
	3 d	6 d	9 d	2 d	15 d
Control	1.23 \pm 0.37	3.11 \pm 1.5	12.29 \pm 4.83	20.21 \pm 7.62	22.80 \pm 8.50
20 Gy	1.57 \pm 0.19	2.34 \pm 0.40	3.28 \pm 0.68 ^b	4.18 \pm 0.66 ^b	6.18 \pm 1.40 ^b
PcDNA3.1+20 Gy	1.86 \pm 0.54	1.67 \pm 0.40 ^{ad}	2.26 \pm 0.50 ^{bd}	2.86 \pm 0.58 ^{bd}	5.19 \pm 0.66 ^b

^a $P < 0.05$, ^b $P < 0.001$ vs control group; ^d $P < 0.01$, ^f $P < 0.001$ vs 20 Gy group.

Figure 7 Melanoma-bearing mice 15 d after treatment.

RT-PCR analysis of IFN γ in tumor tissue

Melanoma-bearing mice were injected with plasmids, and the tumor received 20 Gy X-ray irradiation, 3 d later total RNA from tumor tissue was extracted for RT-PCR.

GAPDH bands were shown in all groups, but IFN γ cDNA bands were shown only in pEgr-IFN γ and pEgr-IFN γ +20 Gy groups (Figure 8).

Figure 8 RT-PCR analysis of intratumor IFN γ . Lane 1: DL2000 Marker; Lane 2: control; Lane 3: 20 Gy; Lane 4: pcDNA3.1+20 Gy; Lane 5: pEgr-IFN γ ; Lane 6: pEgr-IFN γ +20 Gy.

DISCUSSION

In 1992 Weichselbaum put forward the new therapeutic strategy that took advantage of the dual tumor-killing effects of genetherapy and radiotherapy, namely, to choose certain exogenous genes that could be activated by irradiation and then transcript some cytotoxic proteins to kill the tumor cells. They also established the techniques that might be used for target gene therapy of carcinomas^[19-25].

It had been reported that Egr-1 was transcriptionally induced by exposure to irradiation, and its induction by irradiation was conferred by serum response or CC (A/T) rGG elements in its promoter region^[26-30]. Based on this finding, we firstly connected IFN γ cDNA with Egr-1 promoter to construct pEgr-IFN γ plasmid to investigate the expression properties in B16 melanoma cells. Furthermore, a melanoma model was established by subcutaneous injection of B16 cells, and then plasmids were injected to observe its antitumor effect *in vivo*.

Firstly, B16 cells transfected with pEgr-IFN γ received different doses of X-ray irradiation and the IFN γ expression was detected. The results showed that the IFN γ expression level in B16 cells post-transfection induced by irradiation was higher than that of sham-irradiation group ($P < 0.05-0.01$). Time-course studies revealed that IFN γ expression reached its peak at 6 h after 2Gy irradiation, and the maximal level was 1.8 times of that in control group ($P < 0.01$). Furthermore, after repeated irradiation the IFN γ expression in B16 cells post-transfection reached the peak level just after the first irradiation, and then decreased in time-dependent manner. All of these demonstrated that pEgr-IFN γ plasmid could enhance IFN γ expression.

Secondly, the results of *in vivo* experiments showed that the proliferation of melanoma was significantly inhibited in pEgr-IFN γ group in comparison with control group between 6 and 15 d after irradiation ($P < 0.001$). So was pEgr-IFN γ gene-radiotherapy group compared with control and 20 Gy groups between 3 and 15 d after irradiation ($P < 0.001$). IFN γ expression was detected in melanoma tissue having received injection of pEgr-IFN γ plasmid. These results demonstrated that injection of pEgr-IFN γ improved antitumor effect, and combined pEgr-IFN γ and irradiation showed the most optimal effect.

This study combined pEgr-IFN γ plasmid and irradiation, and demonstrated much more enhanced antitumor efficacy than either one in the melanoma model. It was very easy to administer directly the plasmid into melanoma tissue, and therapeutic dose could also be administered as required. The tumor could be effectively exposed to radiation with external beam or intratumoral

sources, or both, to enhance local IFN γ expression and boost local tumor control. Increased IFN γ levels might elicit systemic mediators, such as cytokines and matrix proteinases, which target occult distant metastases and thereby further enhance the therapeutic ratio. The absence of systemic toxicities with intratumoral administration of IFN γ supports the safe addition of pEgr-IFN γ gene radiotherapy to current antitumor protocols.

Abstract

AIM: To explore the possibility of marrow mesenchymal stem cells (MSC) *in vitro* differentiating into functional islet-like cells and to test the diabetes therapeutic potency of Islet-like cells.

METHODS: Rat MSCs were isolated from Wistar rats and cultured. Passaged MSCs were induced to differentiate into islet-like cells under following conditions: pre-induction with L-DMEM including 10 mmol/L nicotinamide+1 mmol/L β -mercaptoethanol+200 mL/L fetal calf serum (FCS) for 24 h, followed by induction with serum free H-DMEM solution including 10 mmol/L nicotinamide+1 mmol/L β -mercaptoethanol for 10 h. Differentiated cells were observed under inverse microscopy, insulin and nestin expressed in differentiated cells were detected with immunocytochemistry. Insulin excreted from differentiated cells was tested with radioimmunoassay. Rat diabetic models were made to test *in vivo* function of differentiated MSCs.

RESULTS: Typical islet-like clustered cells were observed. Insulin mRNA and protein expressions were positive in differentiated cells, and nestin could be detected in pre-differentiated cells. Insulin excreted from differentiated MSCs (446.93 ± 102.28 IU/L) was much higher than that from pre-differentiated MSCs (2.45 ± 0.81 IU/L ($P < 0.01$)). Injected differentiated MSCs cells could down-regulate glucose level in diabetic rats.

CONCLUSION: Islet-like functional cells can be differentiated from marrow mesenchymal stem cells, which may be a new procedure for clinical diabetes stem-cell therapy, these cells can control blood glucose level in diabetic rats. MSCs may play an important role in diabetes therapy by islet differentiation and transplantation.

INTRODUCTION

Diabetic mellitus (DM), one of the leading causes of morbidity and mortality in many countries, is caused by an absolute insulin

deficiency due to the destruction of insulin secreting pancreatic cells (type 1 DM) or by a relative insulin deficiency due to decreased insulin sensitivity, usually observed in overweight individuals (type 2 DM). In both types of the disease, an inadequate mass of functional islet cells is the major determinant for the onset of hyperglycemia and the development of overt diabetes. Islet transplantation has recently been shown to restore normoglycemia in type 1 DM^[1]. However, a limited supply of human islet tissues prevents this therapy from being used in patients with type 1 DM. Alternatively, much effort has been made to increase β cell mass by stimulating endogenous regeneration of islets or *in vitro* differentiated islet-like cells^[2-5]. Multipotent stem cells have been described within pancreatic islets and in nonendocrine compartments of the pancreas^[6-12], and these cells have the capacity of differentiating into pancreatic islet-like structures. Furthermore, cells that do not reside within the pancreas, such as embryonic stem cells (ESC), hepatic oval cells, cells within spleen, have been differentiated into pancreatic endocrine hormone-producing cells *in vitro* and *in vivo*^[13-21]. However, despite their differentiating potency, differentiation of various stem cells into islet cells has two major obstacles preventing clinical application: One is that these stem cells do not originate from DM patients, transplanting them would unavoidably be rejected by DM recipients. The other is that the source is not enough to provide abundant stem cells. The current article reports a potential means to generate insulin-producing cells, islet differentiation from bone marrow-derived stem cells. We suggest that cells within the adult bone marrow (mesenchymal stem cells MSC) are capable of differentiating into functional pancreatic β cell phenotypes.

MATERIALS AND METHODS

Materials

Wistar rats were bought from Animal Center, Tongji Medical College. All procedure was accordant with animal experiment guideline of the university. Cell culture medium L-DMEM (4.5 mmol/L glucose), H-DMEM (23 mmol/L glucose) and fetal calf serum (FCS) were bought from GIBCO Co. Nicotinamide, β -mercaptoethanol, B27 were from Sigma Co. Anti-nestin, anti-insulin monoclonal antibodies were bought from Santa Cruz Co. RT-PCR kit and primers were purchased from GIBCO Co. Radioimmunoassay (RIA) kit was purchased from Beijing North Biotechnology Co.

Differentiation of rat marrow mesenchymal stem cells into functional islet β cells

Bone marrow was isolated from femoral bone under aseptic condition and dispersed into single cell suspension, L-DMEM cells were cultured in a density of 1×10^5 /L at 37 °C, 50 mL/L CO₂ for 48 h. Suspended cells were disposed and adherent cells were cultured in L-DMEM with 200 mL/L FCS for about 10 d, culture medium was changed at 3-d intervals. These cells were digested with 2.5 g/L trypsin and passed for 2-3 generations when the confluence reached 70-90%. Then, cells with 70-80% confluence were induced to differentiate into functional pancreatic cells. Cells were pre-induced with 10 mmol/L nicotinamide and 1 mmol/L

β -mercaptoethanol in L-DMEM for 24 h, and re-induced with 10 mmol/L nicotinamide and 1 mmol/L Mercaptoethanol in serum-free H-DMEM for another 10 h. Cells induced without nicotinamide or β -mercaptoethanol were used as controls.

Function assessment of differentiated cells

Cell morphology changes were investigated under converted microscope. Insulin-1 mRNA or protein expression was detected with immunocyto-chemical procedure and reverse transcription polymerase chain reaction (RT-PCR), and insulin level in culture suspension secreted from differentiated cells was detected with radio-immunological assay (RIA).

RT-PCR

Total RNA from 5×10^6 pre-treated or post-treated MSC cells was isolated according to a Qiagen protocol including DNase treatment. Reverse transcription was carried out using the Superscript protocol. Taq-man RT-PCR was performed using the Master Mix (Applied Biosystems). Insulin-1 primers were designed using the primer express program (Applied Biosystems) according to gene bank sequences. The following primers were used for Insulin-1: forward: 5'-GGGGAACGTGGT TTCTTCTA-3', backward: 5'-TAGACGAGGGAGATGGTTGA CC-3'. 35 cycles of 94 °C \times 30 s, 55 °C \times 30 s, 72 °C \times 30 s were performed and the PCR product for Insulin-1 was 187 bp. GAPDH was used as internal control with the following primers: forward: TGGTATCGTGGAAGGACTCATGA. backward: ATGCCAGTGAGCTTCCCGTTCAGC. Products were tested with 15 g/L gel electrophoresis.

Immunohistochemistry

Cells adherent to slides were fixed with 40 g/L para-formaldehyde. After washed, the slides were incubated with a biotin-goat anti- rat insulin or nestin monoclonal antibodies (Santa Cruz Co, USA) diluted 1:200 in 50 mL/L normal goat serum for 20 min at room temperature. Immuno-reactive cells were visualized using the Vectastain Elite ABC Kit (Vector Labs, USA) with 3'3 diaminobenzidine tetrachloride (DAB) (Boehringer-Mannheim) as the chromogen. All sections were counterstained with hematoxylin.

Radioimmunoassay

The amounts of immunoreactive insulin in supernatants secreted from differentiated cells 48 h after treatment and cells 24 h before treatment were determined by RIA using a commercially available RIA kit according to the manufacturer's instructions. Briefly, to each polypropylene RIA tube 100 μ L each of anti-Insulin, 125 I- insulin, and insulin or the samples were added. Immune complexes were precipitated 24 h later with 1 mL of 160 mL/L polyethylene glycol solution, and a gamma counter was used to determine the radioactivity in the precipitates. There was no nonspecific interference of the assay with the components of the samples. Determinations were carried out in triplicate and the means and standard deviations were obtained.

Primitive glucose controlling role of differentiated MSCs on STZ-diabetic rats

Diabetic animal models were made according to the standard procedure with modifications. Briefly, 10 Wistar rats (weighting about 200 grams) were intravenously injected with 50 mg/L streptozotocin (STZ) from caudal veins, and glucose levels were tested 1 week later with Roche ACCU-CHEK glucose tester. Two rats died and were excluded. After stable hyperglycemia level was achieved, 3 animals were subcutaneously injected with 5×10^6 differentiated cells, while 2 others received the same amount of un-differentiated cells, the remaining 1 did not receive any cells. One week after cell injection, animal glucose level

was recorded.

Statistical analysis

Data were analyzed with Student's *t* test, $P < 0.05$ was considered statistically significant.

RESULTS

Morphological changes of MSC differentiation

Under inversed microscope, undifferentiated MSCs were typical of adherent spindle and fibrocyte- like. However, under differentiation, these spindle-like cells changed rapidly into round or oval types with confluence. These cells were abundant in endocrinal granules, similar to those differentiated islet cells from ES cells. These grape-like cells lasted for at least 2 wk. Some cells changed into neuron-like cells with typical processes.

Figure 1 Islet-like grape-shaped cells isolated from marrow mesenchymal stem cells.

Insulin-1 transcription in differentiated cells

To assess insulin-1 mRNA expression in differentiated cells, RT-PCR was applied on MSCs shortly after bone marrow isolation (Neg), 24 h before nicotinamide and β -mercaptoethanol treatment (Pre), 48 h (Islet1) and 1 week after Nicotinamide and β -mercaptoethanol treatment (Islet2). There were no pre-differentiated MSCs (Figure 2). However, 48 h after treatment, insulin-1 mRNA transcription could be detected and continued for at least 1 wk. Since we did not observe any pancreatic islet-like cells in control group, RT-PCR was not performed on this group of cells.

Figure 2 Insulin transcription in pre-differentiated MSCs shown in RT-PCR. Neg: MSCs undifferentiated; Pre: MSCs 24 h before differentiation; Islet1: cells 24 h after differentiation; Islet2: cells 1w after differentiation.

Insulin and nestin protein expression in different stages of MSCs

Immunocytochemistry was performed to test insulin or nestin protein expressions in MSCs. Insulin could be observed obviously in those grape-like cells (Islet-like), and in unchanged spindle-like cells not positively stained. Nestin was regarded

as an important pre-marker for islet cell differentiation, and its expression was tested. Immunocytochemistry showed nestin positivity in pre-differentiated spindle-like cells (Figure 4), while no nestin positivity in differentiated islet-like cells.

To further clarify the function of these differentiated cells, RIA was used to assess the insulin excretion from these cells in 6 independent cell cultures. As shown in Table 1, pre-differentiated MSCs seldom secreted insulin into their supernatant if any. However, 48 h after differentiation, these islet-like cells produced much insulin and secreted insulin in extra-cellular medium.

Figure 3 Insulin staining for islet -like cells. Strong brown staining indicates insulin positivity in differentiatly arranged grape shape cells.

Figure 4 Positive nestin in pre-differentiated MSCs.

Table 1 Insulin excretion changes in pre- and differentiated MSCs (RIA) (IU/L)

Group	Insulin excretion in pre-treated MSCs	Insulin excretion in treated islet-like cells
1	1.67	410.79
2	2.53	383.21
3	1.53	465.81
4	3.36	308.28
5	2.20	516.45
6	3.40	597.02

In supernatant of pre-differentiated MSC cells, there was no obvious insulin excretion (2.45 ± 0.81 IU/L). Forty-eight h after differentiation, cells excreted more insulin into supernatant, the insulin level was as high as 446.93 ± 102.28 IU/L ($t = 10.65$ $^bP<0.01$).

To test if these MSC-differentiated islet-like cells could exert glucose-controlling function, 6 diabetic Wistar rat models were included. Each of 3 rats was administered subcutaneously 5×10^6 differentiated cells, 2 received similar un-differentiated MSCs injection, while the last one received none. Glucose levels of these 6 rats at different times are shown in Table 2. Although lack of statistical analysis, it could be suggested that MSC-

differentiated islet-like cells could change diabetic glucose level.

Table 2 Blood glucose level (mmol/L) changes in STZ-diabetic rats

Types of cells injected	Glucose level 24 h before injection	Glucose level 1 w after injection
Islet1	>33.3	25.4
Islet2	>33.3	21.4
Islet3	25.3	19.7
MSC1	>33.3	>33.3
MSC2	28.9	29.7
Non	>33.3	>33.3

Islet1, Islet1, Islet3: different STZ-diabetic rats received islet cell injection; MSC1, MSC2: STZ-diabetic rats received undifferentiated MSC injection; Non: STZ-diabetic rats did not receive cell injection.

DISCUSSION

Multipotent stem cells within pancreas and outside could develop into insulin-secreting islet cells^[7-21]. However, differentiation of various stem cells into islet cells has two major obstacles preventing clinical application. As these stem cells do not originate from DM patients, these cells transplanted would be rejected by DM recipients. The source is not enough to provide abundant stem cells.

Bone marrow mesenchymal cells (MSC) reside in bone marrow and are multipotent, and can differentiate into lineages of mesenchymal tissues, such as bone, cartilage, fat, tendon, muscle, adipocytes, chondrocytes, osteocytes^[22-24]. MSCs could differentiate into endodermal and epidermal cells, such as vascular endothelial cells, neurocytes, lung cells and hepatocytes^[25-27]. MSCs as differentiation donors are of advantages compared with other stem cells as ESC or stem cells from organs. MSCs are of great multiplication potency. Cell-doubling time is 48-72 h, and cells could be expanded in culture for more than 60 doublings^[28]. Functional cells differentiated from MSCs transplanted into MSC donors (autologous transplantation) would not cause any rejection.

Differentiation of MSCs into functional pancreatic islet cells is not yet reported. Ianus *et al.*^[29] reported, using a CRE-LoxP system, bone marrow from male mice with an enhanced green fluorescent protein (GFP) replacing insulin expression was transplanted into lethally irradiated recipient female mice. After 4-6 wk, recipient mice revealed both Y chromosome and GFP positivity in pancreatic islets. These GFP positive cells expressed insulin, glucose transporter-2 and other islet β cell related markers. Cells from bone marrow were able to differentiate into islet cells. MSCs could differentiate into hepatocytes^[25,27], precursor cells of hepatocytes could differentiate into pancreatic islet cells, adult hepatic stem cells could trans-differentiate into pancreatic endocrine hormone-producing cells^[19,20]. These reports indicated that, MSCs had the capacity of differentiating into pancreatic islet cells.

We found that MSCs could successfully differentiate into pancreatic islet β -like cells. These cells were morphologically similar to pancreatic islet cells. More importantly, they could also transcript, translate and excrete insulin. Cells were injected subcutaneously into NOD rat models, although lack of statistical data, these MSC-derived cells could regulate NOD blood glucose level. Nestin was regarded as a marker of precursors of pancreatic islet cells^[10,14]. In our study, nestin was also positive in pre-pancreatic islet MSCs, suggesting that MSCs could differentiate into islet cells. High glucose concentration was considered as a potent inducer for pancreatic islet differentiation. Nicotinamide was used to preserve islet viability and function through poly

(ADP-ribose) polymerase (PARP)^[30], β -mercaptoethanol was commonly used as a neurocyte inducer. In our primary experiment, high glucose alone could not effectively induce MSC to differentiate into islet-like cells. After nicotinamide was added, they could effectively transform MSCs into islet-like cells. This may imply that nicotinamide could be an effective inducer, or it could protect differentiated cells from dying or transforming into other cell types. β -mercaptoethanol increased the potency of nicotinamide in our experiment. Considering nestin expression in pre-differentiated MSCs, MSCs might differentiate into pancreatic islet-like cells through intermediate neurocyte stage. We did not test the insulin secretion based on the number of cells, the increased insulin in supernatant might be mainly from increased insulin excretion by islet-like cells.

Bone marrow stem cells are non-endodermal cells with no immediate relationship to putative pancreatic stem cells that are resident in tissues of endodermal origin or developmental neuro-endocrine stem cells derived from the endoderm. Alternatively, stem cells in bone marrow may be derived from sites of endodermal origin. Regardless of their germ layer of origin, these cells represent multi-potent cells mediated by circulating signals, and can be recruited to neuro-endocrine compartments of the pancreas. Once homing of these cells to pancreatic islets has occurred, local cell-cell interaction as well as paracrine factors may initiate differentiation.

There was an argument^[31] that Islet-like cells differentiated from ESC were falsely insulin positive from insulin-uptake. These insulin-positive cells which do not transcribe insulin mRNA, are TUNEL+. Bone marrow cells could also fuse with other cells and adopt the phenotypes of these cells^[32,33]. However, cell differentiation in our report was not the case. Islet cells expressed insulin at both mRNA and protein levels, the excreting insulin level was far more higher than that in culture media and that of pre-differentiated cells. Further more, these MSCs-derived cells could down-regulate glucose level in diabetic rats.

In conclusion, MSCs can differentiate into functional pancreatic islet-like cells *in vitro*. If human MSCs, especially MSCs from diabetes patients themselves can be isolated, proliferated, differentiated into functional pancreatic islet-like cells, and transplanted back into their donors (autologous transplantation), their high proliferation potency and rejection avoidance will provide one promising therapy for diabetes.

Abstract

AIM: To evaluate the therapeutic effect of adenoviral-vector-delivered human interleukin-10 (hIL-10) gene on severe acute pancreatitis (SAP) rats.

METHODS: Healthy Sprague-Dawley (SD) rats were intraperitoneally injected with adenoviral IL-10 gene (AdvhIL-10), empty vector (Adv0) or PBS solution. Blood, liver, pancreas and lung were harvested on the second day to examine hIL-10 level by ELISA and serum amylase by enzymatic assay. A SAP model was induced by retrograde injection of sodium taurocholate through pancreatic duct. SAP rats were then administered with AdvhIL-10, Adv0 and PBS solution by a single intraperitoneal injection 20 min after SAP induction. In addition to serum amylase assay, levels of hIL-10 and tumor necrosis factor- α (TNF- α) were detected by RT-PCR, ELISA and histological study. The mortality rate was studied and analyzed by Kaplan-Meier and log rank analysis.

RESULTS: The levels of hIL-10 in the pancreas, liver and lung of healthy rats increased significantly after AdvhIL-10 injection (1.42 ng/g in liver, 0.91 ng/g in pancreas); while there was no significant change of hIL-10 in the other two control groups. The concentration of hIL-10 was increased significantly in the SAP rats after AdvhIL-10 injection (1.68 ng/g in liver, 1.12 ng/g in pancreas) compared to the other two SAP groups with blank vector or PBS treatment ($P < 0.05$). The serum amylase levels remained normal in the AdvhIL-10 transfected healthy rats. However, the serum amylase level was significantly elevated in the other two control SAP rats. In contrast, serum amylase was down-regulated in the AdvhIL-10 treated SAP groups. The TNF- α expression in the AdvhIL-10 treated SAP rats was significantly lower compared to the other two control SAP groups. The pathohistological changes in the AdvhIL-10 treated group were better than those in the other two control groups. Furthermore, the mortality of the AdvhIL-10 treated group was significantly reduced compared to the other two control groups ($P < 0.05$).

CONCLUSION: Adenoviral hIL-10 gene can significantly attenuate the severity of SAP rats, and can be used in the

treatment of acute inflammation process.

INTRODUCTION

The pathogenesis of severe acute pancreatitis (SAP) is complicated. Studies have indicated that the explosive production and release of pro-inflammatory cytokines play an important role in its pathogenesis. There is evidence that TNF- α and interleukin-1 (IL-1) are very important inflammatory cytokines in this process^[1,2]. Although pro-inflammatory cytokines are necessary for protecting against inflammation in the early phase, uncontrolled and adverse inflammatory effects of the systemic cytokine response could also be harmful. Thus, inhibiting the synthesis of pro-inflammatory cytokines and altering the balance between pro- and anti-inflammatory cytokines might significantly affect the severity of pancreatitis and the survival rate^[3,4]. IL-10 is a major anti-inflammatory cytokine. It has been shown to be down-regulated the expression of TNF and other inflammatory cytokines from activated macrophages. IL-10 could block the release of oxygen free radicals and nitrogen oxide. In consequence^[5], it could decrease the mortality^[6-8]. These findings suggested that administration of IL-10 could be useful in blocking these pro-inflammatory cytokines during the initiation of acute pancreatitis.

Gene therapy as a novel drug delivery system to express proteins in individual tissues has been used in inflammatory diseases^[9]. The use of deficient adenovirus vectors might be a useful tool for this gene therapy due to its high infectious activity and high protein expression ability. Gene therapy has been proposed in many inflammation diseases to produce anti-inflammatory cytokines at local sites^[10,11]. However, transfection of SAP rats with an adenoviral vector has not been previously reported.

In this paper, we reported a successful gene therapy for SAP rats. Our experiments showed that human IL-10 expression in tissues could block the development of SAP and improve the survival rate. The results suggest a novel potential therapeutic approach for the treatment of patients with acute pancreatitis.

MATERIALS AND METHODS

Materials

Adenovirus expression system (Adenoviral Gateway Expression Kit, 293A Cell Line, Gateway LR Clonase Enzyme Mix, Lipofectamine 2000) and TRIzol reagent were provided by Invitrogen (San Diego, CA). pcDNA3IL-10 plasmid was generously donated by professor XY Liu (Shanghai Institute for Biological Sciences, Chinese Academy of Sciences, Shanghai, China). Restriction enzyme (*Hind*III, *Eco*RI, *Bam*HI, *Sal*I) was obtained from Promega (Madison, WI, USA). Sodium taurocholate was purchased from Sigma Chemical Company

(St Louis, MO). Amylase enzyme assay kits were obtained from Shanghai Kehua-Hualing Diagnosis Kit Co (Shanghai, China). An ELISA kit specific for human IL-10 was purchased from Diaclone Research International (BESANÇON Cedex, French).

Adenoviral vectors

Human IL-10 cDNA was cloned into the *Bam*HI and *Eco*RI sites of pEntr 1A vector. Then the IL-10 cDNA was moved into the adenoviral destination vector from pEntr 1A vector by Gateway LR Clonase. The recombinant E1 deleted type 5 adenoviral vector encode hIL-10 under the transcriptional control of the cytomegalovirus promoter and contained the bGHP(A) sequence. Adenovirus hIL-10 vector was transfected into 293A human embryonic kidney cell line with Lipofectamine 2000. After transfection, cells were fed with fresh DMEM solution until the onset of cytopathic effect. Viruses were propagated in the 293A and purified by ultra centrifugation through two caesium chloride gradients. The titer of adenoviral vectors was determined by plaque assay on 293A cells. Viral stocks were aliquoted and stored in 100 mL/L glycerol at -80 °C until use.

Adenovirus IL-10 gene transfection into healthy rats

Sprague-Dawley (SD) rats were purchased from Shanghai BK Experimental Animal Company (Shanghai, China) and maintained in filter-top cages under specific pathogen-free conditions. The Animal Study Ethics Committee of Shanghai Second Medical University approved all experiments. The experiments were conducted in 6-7 week-old male rats, weighing 170-180 g. Adult healthy male SD rats ($n = 20$) were given a single intraperitoneal injection of adenovirus PBS solution containing 10^{10} pfu of the AdvhIL-10. All injections were performed with a sterile 25-gauge needle in the left lower quadrant of the abdomen. Rats were anesthetized using sodium pentobarbital (40 mg/kg injection, intraperitoneal) and killed 24, 48, 96, and 168 h after transfection. Blood samples were obtained from the celiac artery. The samples were separated and stored at -70 °C for determination of amylase. Pancreas, liver and lung were immediately dissected from their attachments and divided for isolation of total RNA and total protein. some samples were fixed in 40 g/L buffered formaldehyde for histopathological test. PBS control group ($n = 5$) received an intraperitoneal injection of PBS solution, and the empty vector control group ($n = 5$) was given a single intraperitoneal injection of empty vector (Adv0) containing 10^{10} pfu viruses. Tissues of both control groups were harvested 24 h later as previously described.

Adenovirus IL-10 gene therapy in SAP rats

SD rats ($n = 80$) were randomly divided into four groups: normal, AdvhIL-10, Adv0, and PBS groups. After laparotomy, SAP model was induced through injection of 0.5 mL of 30 g/L sodium taurocholate via the pancreatic duct. Twenty minutes after sodium taurocholate injection, AdvhIL-10 group received 0.5 mL single intraperitoneal injection of AdvhIL-10 containing 10^{10} pfu of AdvhIL-10. Two control groups received 0.5 mL single intraperitoneal injection of Adv0 (containing 10^{10} pfu viruses) or PBS solution, respectively. In each group, 5 rats were sacrificed by dislocation of the cervical vertebra 24 and 48 h after induction of SAP, respectively. Blood samples were obtained as previously described for determination of amylase. Pancreas, liver, and lungs were harvested as previously described and prepared for RT-PCR, ELISA, and histopathological test. Mortality was observed among the rats 7 d after the initiation of pancreatitis.

Assay

Serum amylase levels were measured at 37 °C by an enzymatic assay using a Beckman nucleic acid and protein analyzer DU

640 (BECKMAN, USA) standardized for these rat proteins. All serum samples were assayed in duplicate, and the results were averaged at the end of the experiment. Rat TNF- α , hIL-10 levels in the homogenates were determined using commercially available enzyme-linked immunosorbent assay (ELISA) kits from Diaclone Research International.

IL-10 and TNF- α mRNA expression

Total RNA was extracted from homogenized liver, pancreas, and lung with TRIzol reagent following the manufacturer's instructions. Aliquots of 5 μ g of total RNA were reverse-transcribed by using a first-strand cDNA synthesis kit (Promega A3500). The cDNA was then amplified by polymerase chain reaction using primers specific for hIL-10 or TNF- α with β -actin primers serving as controls. The primer sequences and sizes of amplification products were as follows: hIL-10 sense, 5'-GAGCG, GATCC, ATGAA, GTGGG, TAACC, TTTC-3'; antisense, 5'-ATACG, AATTC, CTGCA, GCGGC, CGCCA, CT-3' (540 base pairs); TNF sense, 5'-TGCCT, CAGCC, TCTTC, TCATT-3'; antisense, 5'-ACACC, CATTG, CCTTC, ACAGA-3' (446 base pairs); β -actin sense, 5'-TTGTA, ACCAA, CCTGGG, ACGAT, ATGG-3'; antisense, 5'-TGGAA, GACTC, CTCCC, AGGTA-3' (515 base pairs). Following an initial denaturation at 94 °C for 5 min, the samples were amplified by 27 cycles of denaturation at 94 °C for 40 s, annealing at 58 °C for 50 s, extension at 72 °C for 90 s, and ended by extension at 72 °C for 15 min. The PCR reaction products were separated on 20 g/L agarose gels. Photo-micrographs of ethidium bromide stained gels were taken. Relative mRNA levels of hIL-10, TNF- α and β -actin were determined by computer-assisted densitometric scanning.

Histopathological analysis

Pancreas samples were fixed in 40 g/L buffered formaldehyde and embedded in paraffin. Then the samples were cut into 5 μ m thick sections, and stained with haematoxylin and eosin for light microscopic examination. Histological assessment was performed by an investigator blinded to the treatment group. The severity of pancreatitis was determined by the degree of edema, hemorrhage, inflammation and necrosis^[11].

Statistical analysis

Results were expressed as mean \pm SD. Differences between groups were compared by two-way ANOVA. $P < 0.05$ was considered statistically significant. Mortality was assessed by Kaplan-Meier and log rank analysis. All data processing was done with a statistical program, SPSS 11.0.

RESULTS

hIL-10 levels in pancreas, liver, and lung at 24 h post-transfection in healthy rats

Twenty-four h after transfection, The normal and two control groups did not show hIL-10 protein expression.

hIL-10 protein was effectively measured in healthy rats after AdvhIL-10 administration. The hIL-10 level in pancreas, liver, and lung increased and reached its peak at 24 h post-transfection, then decreased gradually 4 d after transfection. The hIL-10 level in the tissues was undetectable 7 d post-transfection, and was the highest in the liver among the three observed organs (Figure 1A).

Serum amylase levels and histological changes in healthy rats

There were no significant differences in serum amylase level among the rats effectively transfected with AdvhIL-10 and Adv0 and PBS treated rats in the duration of the experiment (Figure 6, $P > 0.05$). In addition, no detectable histology alternation of the pancreas, liver, and lungs was observed in the transfected rats.

Pancreatic edema, hyperemia, exudation and necrosis were not detected. These findings indicated that adenovirus gene transfer could be performed safely.

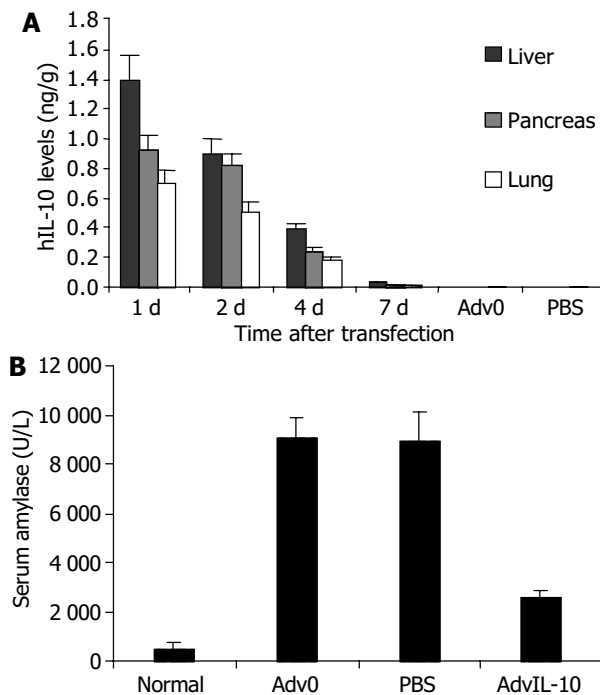

Figure 1 hIL-10 levels and serum amylase levels in pancreas, liver, and lung after administration of AdvIL-10, Adv0, and PBS in healthy and SAP rats. A: hIL-10 levels in pancreas, liver and lung after administration of AdvIL-10, Adv-0 and PBS in healthy rats. B: Serum amylase levels in pancreas, liver and lung after administration of AdvIL-10, Adv-0 and PBS in SAP rats.

Serum amylase in SAP rats

The SAP rats treated with Adv0 and PBS showed a significant increase in serum amylase level compared to normal rats ($P < 0.05$). Transfection with AdvhIL-10 after induction of pancreatitis decreased the severity of SAP, as evidenced by markedly attenuated amylase production compared to the two control SAP groups (Figure 1B, $P < 0.05$).

Figure 2 Expression of IL-10 and TNF- α in SAP rat tissues 24 h post-transfection with AdvhIL-10 and PBS. Lanes a, b and c: IL-10 expression in liver, pancreas, and lung, respectively, in AdvIL-10 treated SAP rats; Lanes d, e and f: IL-10 expression in liver, pancreas, and lung, respectively, in the PBS treated SAP rats; Lanes 1, 2, and 3: TNF- α expression in liver, pancreas, and lung, respectively, in PBS treated SAP rats; Lanes 4, 5, and 6: TNF- α expression in liver, pancreas, and lung, respectively, in AdvIL-10 treated SAP rats. β -actin served as control.

IL-10 and TNF- α mRNA expression in SAP rats

HIL-10 mRNA was strongly expressed in the AdvhIL-10 treated pancreatitis rats 24 h post-transfection. The levels of hIL-10 in pancreas, liver, and lung did not show significant difference. A

weak expression of hIL-10 was observed in Adv0 and PBS treated pancreatitis rats 24 h post-transfection. TNF- α gene in the normal rats was not detected. The expression of TNF- α gene was significantly higher in the pancreatitis rats treated with Adv0 and PBS than that in those treated with AdvhIL-10 ($P < 0.05$, Figure 2). In the AdvhIL-10 group, the level of TNF- α gene was moderate in pancreas and weak in the liver and lung (Figure 3).

Levels of hIL-10 and TNF- α proteins in SAP rats

The levels of IL-10 in pancreas, liver and lung in the AdvhIL-10 group were markedly higher than those in the two control groups 24 and 48 h post-transfection ($P < 0.05$). No significant difference was observed between the two control groups (Figure 3A). In normal rats, TNF- α expression was undetectable. Twenty-four h after induction of pancreatitis, TNF- α level was significantly higher in Adv0 and PBS groups than that in AdvIL-10 group ($P < 0.05$, Figure 3B).

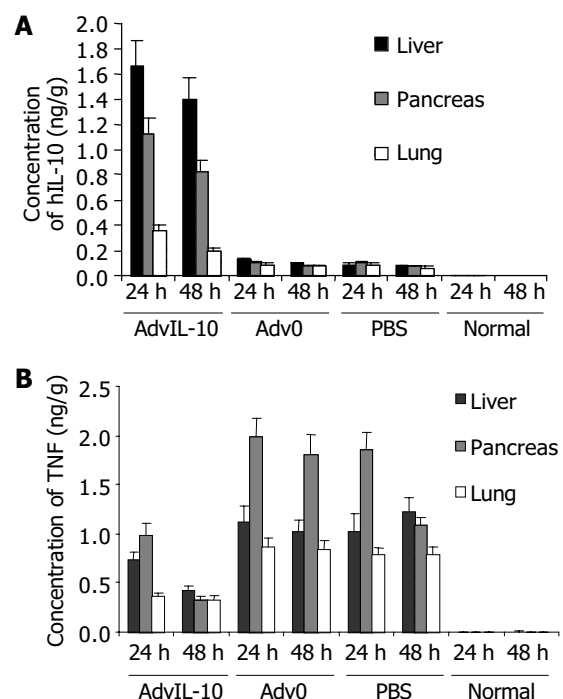

Figure 3 hIL-10 and TNF- α levels in liver, pancreas, and lungs of SAP rats after treatment with AdvIL-10, Adv0, and PBS. A: hIL-10 levels in liver, pancreas and lungs of SAP rats after treatment with AdvIL-10, Adv-0 and PBS. B: TNF- α levels in liver, pancreas and lungs of SAP rats after treatment with Adv-10, Adv-0 and PBS.

Histopathological changes

Hematoxylin and eosin-stained sections of pancreas from pancreatitis rats treated with Adv0 and PBS showed an increase in inflammation, hemorrhage, and necrosis after injection of sodium taurocholate. The histological changes in the AdvIL-10 treated pancreatitis rats were mild compared with the control groups. Most of the pathological parameters of pancreatic injury were significantly decreased in pancreatitis rats transfected with AdvIL-10 gene compared to the pancreatitis rats treated with Adv0 and PBS ($P < 0.05$, Table 1, Figure 4).

Mortality

No significant difference in mortality was observed between the two control SAP groups within 7 d after SAP induction, 90% of the rats were died in the Adv0 and PBS treated groups, while only 20% of the rats were died in the AdvIL-10 gene therapy group (Figure 5).

Figure 4 Histological sections of rat pancreas (HE, 200 \times). A: Normal rat pancreas; B: Severe necrotizing acute pancreatitis with hemorrhage and necrosis 24 h after induction with sodium taurocholate; C: Acute pancreatitis in rats treated with AdvhIL-10; D: Acute pancreatitis in rats treated with PBS (the pathology changes in the Adv0 group were completely the same as PBS group).

Figure 5 Survival rate of SAP rats after treatment.

Figure 6 Serum amylase levels in healthy rats 24 h after transfection with Adv0, PBS and AdvIL-10.

Table 1 Histological scores of pancreas from rats with SAP (mean \pm SD)

	Normal	PBS (or Adv0)	hIL-10 transfected
Edema	0 \pm 0	2.26 \pm 0.13	1.74 \pm 0.13
Necrosis	0 \pm 0	2.56 \pm 0.21	0.51 \pm 0.13

Hemorrhage	0 \pm 0	2.31 \pm 0.17	0.13 \pm 0.11

DISCUSSION

IL-10 gene therapy has been widely explored for the treatment

of many diseases, including intestinal transplantation immune regulation, bronchiolitis, endotoxemia, and rheumatoid arthritis^[12-15]. In the present report, we explored the tissue levels, distribution, and biological responses of hIL-10 mediated by adenoviral vectors in healthy and pancreatitis rats. Adenovirus vector has many advantages. Adenovirus genomes did not integrate into the host cell chromosome and had a high efficiency gene transfer than cationic liposome regardless of the proliferative state of tissues. Although the duration of gene expression was short, the level of therapeutic gene expression was much higher^[16]. Adenoviral vectors could bind to cell surface integrins and gain entry by receptor mediated endocytosis using receptors such as Coxsackie virus and adenovirus receptor^[17]. Thus, adenoviral vector could offer the opportunity to target specific tissues for highly local expression, owing to special tropism for pulmonary epithelial cells, hepatocytes, and pancreatic epithelial cells^[18-20]. Expression of adenoviral vector was rapid, protein appearance usually occurred within hours and peak concentration appeared within 1-2 d after adenoviral administration^[21]. Furthermore, adenovirus vectors could be prepared at a much higher titre.

Norman James^[22] reported that with very few exceptions, cytokines were not constitutively produced. The results of our experiment is consistent with Norman James's results. We explored the use of adenovirus based gene therapy to deliver hIL-10 gene intraperitoneally to healthy and pancreatitis rats. Tissue hIL-10 protein was highly produced 24, 48 h after AdvhIL-10 was injected into peritoneal cavity of healthy rats. The current study demonstrated that the current adenovirus delivery system could offer a highly efficient transfection and well-correlated tissue accumulation. We also found that highly efficient transfection with AdvhIL-10 did not result in an increase in amylase and lipase or any alteration in pancreatic histopathology. Therefore, adenoviral vector mediated hIL-10 gene delivery in healthy rats was well tolerable and safe. In SAP rats, AdvhIL-10 attenuated the release of serum amylase and decreased histologic injury significantly. In addition, the action of TNF- α could also be diminished by IL-10. The important factor of our experiment was the increase of survival rate resulted from adenoviral vector mediated hIL-10 gene delivery in rats with lethal acute pancreatitis. These results are consistent with several previous reports on adenoviral vector-mediated gene therapy in pancreatitis and acute lung inflammation^[9,23,24].

There is sufficient evidence (immunological, pathophysiological, and biochemical) that SAP is a systemic rather than a local critical condition. The severity of the process varied from a limited local inflammation of the pancreas to a systemic multi-organ failure. SAP was characterised by enzyme activation, interstitial edema, hemorrhage and necrosis^[25]. Many pro- and anti- inflammation cytokines are involved in the initiation of acute pancreatitis. IL-10, produced by TH2 cells, macrophages, stellate cells and hepatocytes, has been reported to play an important role in inflammatory diseases^[26]. It has been reported the deficiency of IL-10 gene could prompt colitis and fibrosis probably by its failure in inhibiting the overproduction of tumor growth factor- β_1 and TNF^[27,28]. The later is secreted by macrophages and can enhance inflammation in a local site. In animals, IL-10 is endogenously released during inflammatory diseases, and its blockade could result in higher elevations of TNF as well as more severe histologic injury^[10]. Production of large quantities of exogenous IL-10 in local sites of inflammation could change the balance of pro- and anti- inflammation cytokines and block the production and release of TNF and other pro-inflammation cytokines. IL-10 administration could improve of local and systemic conditions. In the current study, exogenous hIL-10 was found to be able to inhibit the progress of acute pancreatitis in rats. Similar results were also reported by previous studies^[10,11].

The time to administrate AdvIL-10 seems to be very important, since it takes time to transfect and express protein. Thus, early administration of AdvIL-10 might block the induction of TNF and IL-1^[5]. Kato *et al.* reported that the time to administrate hIL-10 should be in the early period of sepsis. In the current study, hIL-10 gene was administrated 20 min after the induction of SAP, and the highest level of IL-10 protein was observed 24 h after administration, which was very similar to a previous study by Denham *et al.*^[10].

In conclusion, human genes can be effectively transfected into rat pancreas, livers, and lungs using a adenoviral vector-mediated delivery system. Transfection of hIL-10 gene can decrease the severity of pancreatitis and improve the survival rate. As gene therapy is becoming a more acceptable method of treatment, it is anticipated that adenovirus-based gene therapy will become available as a drug delivery system. Cytokine modulating therapies, like IL-10, represent an attractive therapeutic approach for the treatment of acute pancreatitis patients in clinic.

Abstract

AIM: To study changes of inflammation-associated cytokine expressions during early phase of endotoxic shock in macaques.

METHODS: Experiments were performed in *Macaque mulatta* treated with LPS 2.8 mg/kg in shock model group or with normal saline in control group. Blood samples were collected before, or 60 min, or 120 min after LPS injection, respectively. Liver and spleen tissues were obtained at 120 min after LPS injection. The plasma levels of TNF- α , IL-1 β , IL-10 and IL-12P40 were determined by double-antibody sandwich ELISA with antibodies against human cytokines. The mRNA levels of TNF- α , IL-1 β , and IL-18 in peripheral blood mononuclear cells (PBMCs), liver and spleen were examined by real-time fluorescence semi-quantitative RT-PCR with the primers based on human genes.

RESULTS: Mean systemic arterial pressure (MAP), systemic vascular resistance index (SVRI) and left ventricular work index (LVWI) of macaques were significant declined in shock model group on average 60 min after LPS injection. The plasma levels of TNF- α and IL-10 were significantly increased 60 min after LPS injection and then decreased. The plasma levels of IL-1 β and IL-12P40 were significantly increased at 120 min after LPS injection. The mRNA levels of TNF- α and IL-1 β were significantly increased 60 min after LPS stimulation in PBMCs and 120 min after LPS stimulation in livers. The mRNA level of IL-18 was significantly increased 120 min after LPS stimulation in PBMCs and livers. But in spleen, only TNF- α mRNA level in LPS group was significantly higher 120 min after LPS stimulation, compared with that in control group.

CONCLUSION: An endotoxic shock model of *Macaque mulatta* was successfully established. Both antibodies for ELISA and PCR primers based on human cytokine assays were successfully applied to detect macaque cytokines. In the model, inflammatory cytokines, such as TNF- α , IL-1 β , IL-12 and IL-18 as well as anti-inflammation cytokine IL-10, were released at very early phase of endotoxic shock within 120 min after LPS injection. PBMCs and liver cells might be the important sources of these cytokines.

INTRODUCTION

Endotoxin-induced shock mostly occurs during serious infection with Gram-negative bacteria. Lipopolysaccharide (LPS), residing in the outer membrane of all Gram-negative bacteria and being the major component of Gram-negative bacteria cell walls and the toxic component of endotoxin, is considered as an important initiating factor of the Gram-negative septic syndrome in human. Gram-negative sepsis has aroused great concern in clinic because of its high mortality. But LPS is not the direct causative factor. It is well known that LPS activates immunocytes, such as monocyte-macrophage and lymphocyte, and induces these cells to excessively release a series of potent inflammatory cytokines, including TNF- α , IL-1 β , IL-6, IL-8 and IL-18. It is the excessive cytokines, such as TNF- α , IL-1 β , IL-6 and IL-18, that result in high fever, hypotension, vascular endothelial cell damage and disseminated intravascular coagulation, blood capillary leak syndrome, and multiple organ failure. On the other hand, in patients with primary liver injury, such as viral hepatitis, LPS plays an important role in intestinal endotoxemia, which in turn induces secondary liver injury and liver failure^[1]. New therapeutic concepts for the treatment of endotoxic shock or endotoxemia with anti-inflammatory cytokines have been developed. Although knowledge about the changes of inflammation-associated cytokines during endotoxemia and endotoxic shock has been well addressed, the change pattern of inflammatory cytokines just during the early phase of endotoxemia and endotoxic shock is still not clear and worth working on, because it can help the selection of new therapeutic targets. The therapies in early phase are more effective.

The aim of the present study was to investigate the changes of TNF- α , IL-1 β , IL-10, IL-12 and IL-18 expressions during early phase (within 120 min) of endotoxic shock in macaques.

MATERIALS AND METHODS

Animals

Totally 25 macaques (*Macaca mulatta*) of 5-8 years old, weighing 4.8-9.2 kg (6.17 ± 1.1 kg), were obtained from Shanghai Laboratory Animal Center, Chinese Academy of Sciences. All animal studies were carried out in accordance with the institutional regulations concerning animal experimentation of the Ministry of Health of China. The animals were housed at 10-25 °C with light, around 8-10 h per day for, at least, a week before experiment. One of 25 macaques was used in preliminary experiment for the optimal dose of LPS at which hypotension and shock should be induced. The other 24 macaques were divided into two groups: 19 in LPS group and 5 in normal saline (NS) group.

Agents

LPS, derived from *E. coli* O127: B8 and prepared by phenol

extraction, was purchased from Sigma Co. (Saint Louis, USA). ELISA kits for detecting human TNF- α , IL-1 β , IL-10 and IL-12 P40/ P70 were from Pharmingen (San Diego, USA). TriZol RNA extraction kit was from Gibco (Grand Island, USA). Moloney murine leukemia virus (M-MLV) reverse transcriptase, RNase inhibitor, PCR kit and PGEM-T vector were all from Promega (Shanghai, China). PCR product purification kit was from Boehringer Mannheim Co. (Mannheim, Germany). Plasmid DNA extraction kit was from Scientz Bio Co. (Shanghai, China).

PCR primers

In order to determine the mRNA expression levels of inflammatory cytokines by RT-PCR, some pairs of primers based on specific sequences published previously were used. These primers, synthesized in ShengGong Biotech Co. (Shanghai, China), are shown in Table 1.

Establishment of endotoxic shock model

In the pilot experiment, one macaque was used to find out optimal dose of LPS. Intravenous injection of LPS of 2.8 mg/kg resulted in reduction of mean arterial pressure (MAP) from 17.55 to 10.80 kPa. This dosage was applied to establish macaque model of endotoxic shock in this experiments. After being fasted overnight, macaques were anesthetized with ketamine (15 mg/kg, intramuscularly), then they were mechanically ventilated with a ventilator (SERVE900c, Siemens- Elama) through trachea intubator. Tidal volume was set at 12 mL/kg and the respiratory rate at 20 beat/min during experiment. A value of 5 cm H₂O (1 cm H₂O = 0.098 kPa) of positive end-expiratory pressure was applied to maintain end-expiratory lung volume. Anesthesia was maintained with repeated intravenous injection of sodium γ -hydroxybutyl acid (200 mg/kg·h) and intramuscular injection of fentanyl citrate (a bolus of 6 μ g/kg·30 min). A pulmonary artery catheter was placed in the jugular vein for detecting hemodynamic parameters by thermodilution (Siemens,). After percutaneous puncture, the catheter was introduced into the femoral artery and forwarded into the abdominal aorta for measuring blood pressure. Nineteen animals in the shock group were given a dose of 2.8 mg/kg LPS i.v., while 5 animals in the control group were given 1 mL/kg normal saline. Occurrences of endotoxic shock were confirmed by reduction of MAP by 30% and by other hemodynamic changes, such as the reduction of systemic vascular resistance index (SVRI) or left ventricular work index (LVWI), in LPS group. It took 60 min on average to establish shock after LPS injection. Venous blood of 18 animals in LPS group and 5 animals in NS control group were collected at 0, 60 and 120 min after LPS or NS injection for detection of inflammation-associated cytokines. Then, the macaques were sacrificed for detecting myocardial damages in another sub-study of this project. At the same time, a small portion of liver and spleen tissues were sliced and stored at -80 °C after being rapidly frozen in liquid nitrogen for mRNA assays.

Blood processing

Blood from the macaques, anticoagulated with EDTA-Na₂, were centrifuged, at 1 500 r/min×10 min, to separate plasma from cells. The plasma were stored at -20 °C for cytokines detection. The sedimentary cells were resuspended with Hanks' solution and the cell suspension was centrifuged with Ficoll-Hypaque lymphocyte separating medium, at 2 000 r/min×20 min, to get peripheral blood mononuclear cells (PBMCs). After being rapidly frozen in liquid nitrogen, PBMCs from the macaques were stored at -80 °C for mRNA assays.

Plasma cytokines detection

The levels of TNF- α , IL-1 β , IL-10 and IL-12P40/P70 in plasma were determined by double-antibodies sandwich ELISA using the kits. The assays were performed according to the kit protocol.

Test for intracellular cytokine mRNA

PBMCs of 10⁶ and liver or spleen tissue of 0.1 g were used to extract total cytoplasmic RNA according to the TriZol method. The total RNA was converted to complementary DNA (cDNA) by a reverse transcription step with M-MLV reverse transcriptase, OligodT primer, RNase inhibitor and dNTPs. Using the cDNA, specific primers, SYBR-Green I and PCR kit, a series of real-time semi-quantitative PCR were performed with a DNA amplifier (PE5700) to determine levels of mRNA coding for TNF- α , IL-1 β and IL-18, as well as β -actin which was used in the assay as an internal control, in PBMCs, liver and spleen. cDNA samples were amplified for 40 cycles: denaturation at 94 °C for 30 s, annealing at 60 °C for 60 s and extension at 68 °C for 120 s. The ratio of fluorescence intensity of cytokine-specific product to that of the internal control product represents relative levels of cytokine mRNA expression. After PCR, the products were cloned into PGEM-T vector, which was then used to transform JM109 *E. coli*. The plasmid DNAs of positive clones were extracted for sequencing.

Statistical analysis

All results were expressed as mean±SD. The significances of differences between LPS shock group and NS control group were evaluated by *t*-test. Testing standard was set at $\alpha = 0.05$. *P*<0.05 indicates a significant difference, and *P*<0.01 indicates a remarkably significant difference.

RESULTS

Change of TNF- α within 120 min after LPS administration

Plasma concentration of TNF- α in LPS group increased earlier and was significantly higher than that in NS group at 60 min after LPS administration, then decreased to a level similar to that in NS group. This result is shown in Figure 1A. The dynamics for TNF- α mRNA expression by PBMCs in LPS group was similar to that for plasma TNF- α concentration. The result is shown in Figure 1B.

The expression levels of TNF-α mRNA in liver and spleen in LPS group were remarkably higher than those in NS control group at 120 min after LPS challenge. The results were presented in Figure 2.

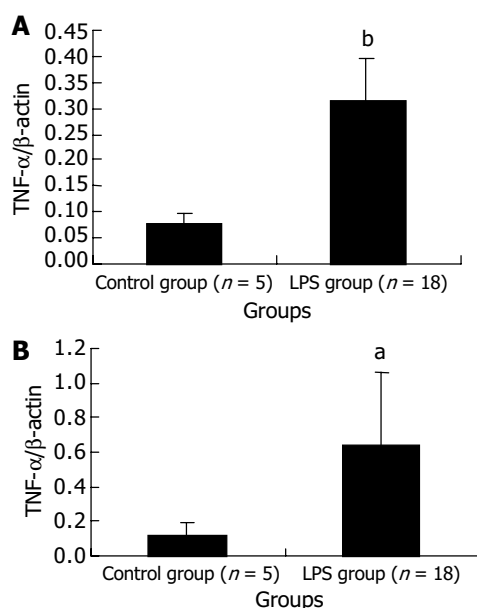

Figure 2 Transcript levels of TNF-α mRNA in liver (A) and spleen (B) at 120 min after LPS administration. ^a $P < 0.05$ vs control group, ^b $P < 0.01$ vs control group.

Change of IL-1 β within 120 min after LPS administration

The plasma IL-1 β level in LPS group began to rise at 60 min after LPS challenge and was significantly higher at 120 min after LPS challenge, compared with that in NS control group. Whereas the IL-1 β transcription level in PBMCs rose earlier than plasma IL-1 β level. The transcription level of IL-1 β in PBMCs of LPS group was significantly higher than that in control group at 60 min after LPS injection, and then dropped to a level similar to that in control group after another 60 min. Figure 3 shows the changes of plasma level and transcription

level of IL-1 β within 120 min after LPS injection.

The transcript level of IL-1 β mRNA in the liver of LPS group remarkably increased at 120 min after LPS administration. But the level in the spleen did not show a significant increase. These results are shown in Figure 4.

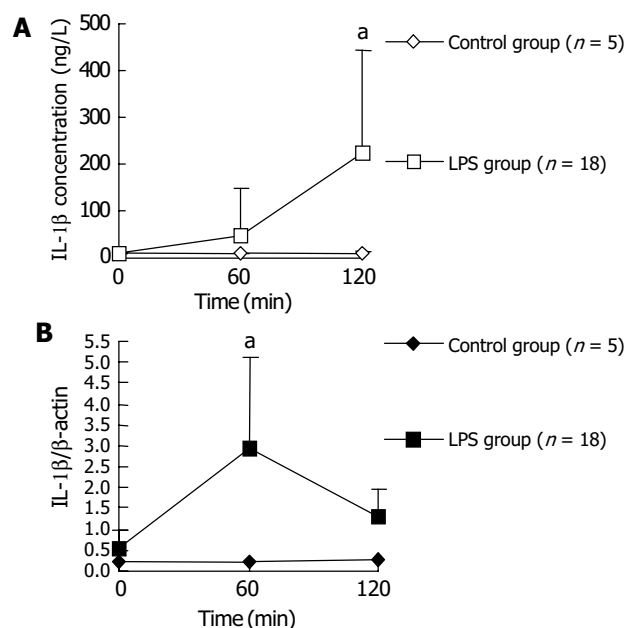

Figure 3 Dynamics of IL-1 β expression in macaque plasma (A) and PBMCs (B) within 120 min after LPS challenge. ^a $P < 0.05$ vs control group.

Figure 4 Transcript levels of IL-1 β mRNA in liver (A) and spleen (B) at 120 min after LPS administration. ^a $P < 0.05$ vs control group.

Changes of IL-18 mRNA expression in PBMCs, liver and spleen within 120 min after LPS administration

The expression level of IL-18 mRNA in PBMCs gradually increased with LPS challenge and a statistical significance could be found at 120 min after LPS challenge. The results are presented in Figure 5. Data in Figure 6 indicate at 120 min after LPS challenge, the expression levels of IL-18 mRNA in LPS group were significantly higher in liver cells, not in spleen cells, compared with those in control group after NS injection.

Figure 5 The change of IL-18 mRNA transcript level in PBMCs within 120 min after LPS challenge. ^a $P < 0.05$ vs control group.

Figure 7 Change of plasma IL-12 levels within 120 min after LPS challenge. ^a $P < 0.05$ vs control group.

Change of plasma IL-12 levels within 120 min after LPS challenge

Sixty minutes after LPS challenge, plasma IL-12P40/P70 level of macaques in LPS group gradually rose and was significantly higher than that in control group at 120 min after LPS challenge. Data are supplied in Figure 7.

Change of plasma IL-10 levels within 120 min after LPS administration

Immediately after LPS administration, plasma IL-10 level of macaques in LPS group increased slightly, and showed a statistically significant rise at 60 min after LPS injection, compared with control group. Thereafter the level gradually declined to normal level. The results are shown in Figure 8.

Figure 8 Change of plasma IL-10 level within 120 min after LPS injection. ^a $P < 0.05$ vs control group.

DISCUSSION

Endotoxic shock model

A series of endotoxic shock animal models have been established for studies. *Macaque Mulatta* belongs to primate animals. The physiological functions and anatomical features are similar among primates, including humans. Therefore, it is important to study primate model of endotoxic shock in order to understand septic shock in human. In the present study, an endotoxic shock model of macaque was established to study about changes of inflammation-associated cytokines during early phase of endotoxic shock.

In human volunteers, an intravenous injection with endotoxin bolus of 2-4 ng/kg caused pyrexia, cytokine release and mild decline of MAP^[6,7]. In non-human primate, however, LPS sensitivities were quite different: chimpanzee shared the sensitivity of human to LPS, while baboons and rhesus macaques were insensitive to LPS like rodents^[8,9]. Chimpanzee is too precious to be commonly used in research, baboon and macaque are used as primate model more commonly. The injection bolus of LPS of 10-20 mg/kg, or continuous infusion of LPS of 10 mg/(kg·h) was applied in several studies with rhesus macaques^[10,11]. A bolus injection of LPS 3.0 mg/kg for *Macaque mulatta* model had been reported previously by Hajek^[12]. In the present study, we successfully established an endotoxic shock model of *Macaque mulatta*, which was proved by the decline of MAP, SVRI and LVWI. The LPS dose we used was 2.8 mg/kg and consistent with the previous report in *Macaque mulatta* model^[12].

Methodology of detection for macaque cytokines

Unfortunately, no standard and commercial ELISA kits for detection of macaque cytokines are available. Nevertheless, it is reasonable to try application of human cytokine kits to detect macaque cytokines, because there is a high homology in genome between human and primate animals such as macaque^[2] and it was reported that IL-2 receptor on the surface of rhesus monkey cells reacted with antibody against human IL-2 receptor^[13] and IL-1, IL-2 and TNF- α from monkey cells could bind to antibodies against human IL-1, IL-2 and TNF- α in ELISA^[13,14]. In this experiment, we tried to use ELISA kits for detection human cytokines to determine the levels of TNF- α , IL-1 β , IL-12P40/P70 and IL-10 of *Macaque mulatta* and successfully obtained useful data.

Similarly, we used the primers based on human TNF- α , IL-1 β , IL-18 and β -actin genes to amplify the cDNA segments of macaque TNF- α , IL-1 β , IL-18 and β -actin by RT-PCR methods and successfully obtained the expected products such as 702-bp segment of TNF- α , 810-bp segment of IL-1 β , 341-bp segment of IL-18 and 225-bp segment of β -actin (Figure 9). The PCR products from one macaque were sequenced for homology comparison with human homologue. The results indicated that the identity of TNF- α or IL-18 gene segment between macaque and human was 97%, IL-1 β was 93% (Figure 10).

Figure 9 Identification of amplified products by RT-PCR with the method of agarose gel electrophoresis. A: 702 bp from TNF- α gene; B: 810 bp from IL-1 β gene; C: 341 bp from IL-18 gene; D: 225 bp from β -actin gene.

Figure 10 Differences of cDNA fragments from TNF- α (A), IL-1 β (B) and IL-18 (C) gene between macaque and human according to GenBank.

quantitative analysis. Moreover, a two step strategy of reverse transcription first and then PCR was applied to ensure the consistency of amplification efficiency between cytokine and control mRNA. On the other hand, a real-time PCR was performed to find the cycle number of exponential phase of target DNA. Because the cycle number of exponential phase of cellular target DNA is different from that of primer-dimer DNA, it is possible to exclude primer-dimer interference with target DNA quantitative analysis when the product of cellular target DNA is collected within its exponential phase. In our experiment,

the cycle numbers of exponential phase of cellular target DNA were all less than 40, while that of primer-dimer was far more than 40. So the PCR was carried out for 40 cycles.

Expression changes of inflammation-associated cytokines during early phase of endotoxic shock model of macaques

TNF- α is one of the most important inflammatory cytokines and has a lot of cellular origins such as monocyte-macrophages, lymphocytes and endothelial cells. The present study demonstrated the level of plasma TNF- α peaked at 60 min after LPS injection and then gradually decreased. The change of mRNA expression level in PBMCs was nearly synchronous, which indicated PBMCs were one of main sources of plasma TNF- α . After LPS challenge, expression levels of TNF- α mRNA both in liver and in spleen increased, suggesting that liver and spleen were also the sources of plasma TNF- α . TNF- α releases firstly during infection or inflammatory reaction. In endotoxic shock models of rats, rabbits and monkeys, plasma TNF- α levels were reported to increase at 30 min after LPS injection and reach the peak about 60-120 min after LPS injection^[15], which was in great agreement with our results. Kupffer cells in liver were an important source of TNF- α . It was reported in endotoxin-induced liver injury model of mice, there were two expression peaks of TNF- α mRNA in liver, one happened within 2 h after LPS injection and the other happened 5 h after LPS injection. The first peak, during which TNF- α was derived from LPS-activated kupffer cells, was not as high as the second one. The second peak was induced by other inflammatory cytokines such as INF- γ and IL-18, and was the main factor inducing liver injury^[16]. In the present experiment, the increase of TNF- α mRNA in liver at 120 min after LPS injection should be the first peak. We found the expression level of TNF- α mRNA in spleen cells also increased after LPS injection. There are few studies on TNF- α production by spleen in endotoxic shock models, which needs more investigations.

IL-1 β , produced by activated monocyte-macrophages, is also an important inflammatory cytokine that is released early. Leturcq^[17] reported that the peak of plasma IL-1 β level in endotoxic shock model of cynomolgus monkeys appeared at 2 h after LPS stimulation which was slightly later than that of plasma TNF- α . This is similar to our result. We observed that IL-1 β plasma level increased in 2 h after LPS injection, but later than TNF- α level did. The fact that expression level of IL-1 β mRNA in PBMCs increased significantly at 60 min after LPS injection and quite earlier than plasma level suggested that PBMCs were the main source of circulating IL-1 β . PBMCs synthesized and released IL-1 β firstly and IL-1 β accumulated in plasma sequentially. The liver cells were also one of IL-1 β sources, but spleen cells the not.

IL-18, produced mainly by kupffer cells and other macrophages, is another important inflammatory factor. IL-18 activates cytokine network of liver and inflammatory reaction. By inducing INF- γ , IL-18 causes the second peak of TNF- α and sequential increase of FasL which induces apoptosis of liver cells^[16-18]. IL-18 was found to be expressed basically in fresh-separated human PBMCs and to increase significantly in 1 h after LPS stimulation^[4]. In LPS-induced acute liver injury model in *Propionibacterium acnes*-primed INF- γ -deficient mice, IL-18 was found to show a basic expression in liver followed by a remarkably increased expression within 2 h after stimulation with *Propionibacterium acnes* and LPS^[19]. In this study, we found in endotoxic shock model of macaques, IL-18 mRNA expression in PBMCs began to increase after LPS stimulation and showed a statistically significant increase 2 h later. We also demonstrated a significant increase of IL-18 transcription in liver cells after LPS stimulation. These discoveries in macaque models were not reported here before.

IL-12, produced mainly by macrophages, kupffer cells and dendritic cells, activates neutrophilic granulocytes and promotes release of inflammatory cytokines such as INF- γ , TNF- α etc.^[20,21], while inhibits the release of anti-inflammation cytokines such as IL-10^[22]. So, IL-12 is also closely related to inflammatory responses. Reports about the change of IL-12 expression in endotoxic shock was quite few except for Tsuji's work, in which plasma IL-12 level of acute liver injury model mice was reported to reach a peak within 3 h after LPS stimulation, following the first peak of TNF- α ^[19]. In Trinchieri's opinion, the observation of dynamics of inflammatory cytokines in above model mice suggested that the order of activation for these cytokines was: the first peak of TNF- α , IL-12, IL-18, INF- γ , the second peak of TNF- α and FasL^[23]. Our observation indicated in macaque mulatta, the plasma IL-12 concentration significantly increased in 120 min after LPS stimulation. To our knowledge, there were few reports about IL-12 dynamics in endotoxic shock primate model. Our results in macaque were compatible with Trinchieri's description.

IL-10, originated from Th1, Tr (regulator) or Th3 cells and B lymphocytes as well as monocyte-macrophages, is an anti-inflammation cytokine, inhibiting the release of inflammation cytokines such as TNF- α , IL-1 β , IL-6, IL-8, IL-12 and IL-18^[24,25]. It is one of the cytokines produced very early after LPS injection in mice model, like TNF- α . Dynamics curves showed two peaks of plasma IL-10 in mice model: plasma IL-10 level reached the first peak in 1-5 h after LPS injection and then declined; the second peak appeared in 8-12 h after LPS injection. Plasma IL-10 originated from kupffer cells in liver during the first peak, while it originated from peripheral blood lymphocytes during the second peak^[26]. The amount of IL-10 in the first peak during early phase of endotoxic shock was not enough to suppress the increases of inflammatory cytokines and hence effectively stop inflammation. So it is necessary to use exogenous recombinant IL-10 as a therapeutics in early phase of endotoxic shock to interrupt the chain release of inflammatory cytokines and to stop shock development^[27]. In the present study, we observed IL-10 level in shock model of macaques increased slightly, and significantly in 60 min after LPS injection and formed a smaller peak, and about 60 min later it returned nearly to the value of control group. Our result in macaque model was quite consistent with that in mouse model. The rise of IL-10 level we observed in early phase of endotoxic shock in macaque models should correspond to the first peak.

It is necessary to mention Kupffer cells for understanding the dynamics of inflammatory cytokine release induced by LPS. LPS is the main activator of Kupffer cells, while Kupffer cells are the major source of inflammatory cytokines, such as TNF- α , IL-12 and IL-18, which are produced in response to LPS. TNF- α is the key factor in systemic inflammation (for example, endotoxic shock and septic syndrome), and it is Kupffer cells that are the major source of TNF- α in the liver. So Kupffer cells play an important role in systemic inflammatory reaction caused by Gram-negative bacteria. On the other hand, Kupffer cells are the main scavengers of LPS and also play an important role in removing circulatory LPS and relieving the stimulation and injury caused by LPS^[28].

Abstract

AIM: To evaluate the value of MR cholangiopancreatography (MRCP) in patients in whom endoscopic retrograde cholangiopancreatography (ERCP) was unsuccessfully performed by experts in a tertiary center.

METHODS: From January 2000 to June 2003, 22 patients fulfilled the inclusion criteria. The indications for ERCP were obstructive jaundice ($n = 9$), abnormal liver enzymes ($n = 8$), suspected chronic pancreatitis ($n = 2$), recurrent acute pancreatitis ($n = 2$), or suspected pancreatic cancer ($n = 1$). The reasons for the ERCP failure were the postsurgical anatomy ($n = 7$), duodenal stenosis ($n = 3$), duodenal diverticulum ($n = 2$), and technical failure ($n = 10$). MRCP images were evaluated before and 5 and 10 min after i.v. administration of 0.5 IU/kg secretin.

RESULTS: The MRCP images were diagnosed in all 21 patients. Five patients gave normal MR findings and required no further intervention. MRCP revealed abnormalities (primary sclerosing cholangitis, chronic pancreatitis, cholangitis, cholecystolithiasis or common bile duct dilation) in 10 patients, who were followed up clinically. Four patients subsequently underwent laparotomy (hepaticojejunostomy in consequence of common bile duct stenosis caused by unresectable pancreatic cancer; hepaticotomy+Kehr drainage because of insufficient biliary-enteric anastomosis; choledochojejunostomy, gastrojejunostomy and cysto-Wirsungo gastrostomy because of chronic pancreatitis, or choledochojejunostomy because of common bile duct stenosis caused by chronic pancreatitis). Three patients participated in therapeutic percutaneous transhepatic drainage. The indications were choledocholithiasis with choledochojejunostomy, insufficient biliary-enteric anastomosis, or cholangiocarcinoma.

CONCLUSION: MRCP can assist the diagnosis and management of patients in whom ERCP is not possible.

INTRODUCTION

The most sensitive diagnostic modality in suspected biliopancreatic diseases is endoscopic retrograde cholangiopancreatography (ERCP)^[1-4]. However, the success rate of the examination mainly depends on the experience of the endoscopist, and does not exceed 95-98% even in the largest specialized centers. Previous operations (Billroth II, Roux-en-Y or biliary-enteric anatomy), duodenal stenosis, or duodenal diverticulum make cannulation of the ducts difficult or even impossible, and increase the risk of complications^[5-7]. If ERCP fails, intravenous (iv) or percutaneous transhepatic cholangiography (PTC) is the alternative method. Since the diagnostic accuracy of iv cholangiography is very low, it is no longer used. PTC is invasive, may be associated with severe complications, and can successfully be applied if the intrahepatic biliary tree is dilated. PTC and iv cholangiography are both unable to visualize the pancreatic duct^[8-10]. There is clearly a need for a noninvasive, sensitive and specific diagnostic modality for patients with suspected biliopancreatic disease if ERCP fails^[11]. Magnetic resonance cholangiopancreatography (MRCP) is a new noninvasive diagnostic modality capable of producing high-quality images of the pancreatobiliary tree. It has been emphasized that its sensitivity (81-100%), specificity (94-98%), positive (86-93%) and negative (94-98%) predictive values and diagnostic accuracy (94-97%) are as high as those of ERCP, which makes MRCP a promising alternative to diagnostic ERCP^[12-16]. Moreover, MRCP has the following advantages over ERCP. It is noninvasive, there are no complications, no radiation, no need for any contrast agent. It causes less discomfort for the patients, and can provide useful information on the parenchymatous organs in this region in combination with conventional cross-sectional MR sequences.

The aim of our study was to assess the value of MRCP in the management of patients with biliopancreatic diseases in whom ERCP was failed.

MATERIALS AND METHODS

Between January 2000 and June 2003 a prospective study was conducted. Twenty-two patients were enrolled, in whom ERCP performed by experts at our endoscopic unit failed to adequately visualize the clinically relevant duct(s). Failure meant two unsuccessful ERCP attempts by precut papillotomy with a needle knife when the ducts were not cannulated with the conventional approach. There were 10 males and 12 females, with a mean age of 51.2 years, range 24-82 years. The indications for ERCP were obstructive jaundice ($n = 9$), abnormal liver enzymes ($n = 8$), suspected chronic pancreatitis ($n = 2$), recurrent acute pancreatitis ($n = 2$), or suspected pancreatic cancer ($n = 1$). The reasons for the ERCP failure were the postsurgical anatomy ($n = 7$), duodenal stenosis ($n = 3$), duodenal diverticulum ($n = 2$), or technical failure ($n = 10$) (Table 1). All patients gave their informed consent after receiving a detailed explanation of the complete examination procedure.

MRCP

All patients underwent MR imaging (Signa Horizon LX 1.0 T-Scanner, General Electric, USA). T1-weighted and T2-weighted

axial plane fast spoiled gradient (FSPGR) images were acquired. These images were used to evaluate the liver and pancreas parenchyma and also to plan the MRCP data collection. The heavily T2-weighted MRCP images were taken in two sets. With a single shot technique, one 30.0–70.0-mm-thick slice was first acquired at TR 5 000 ms, TE 500 ms, with a 320×320 matrix and 40×36 FOV. In the second set, 9–13 thin (5.0 mm) slices with a 2-mm gap were taken from the same region. The breath-hold technique was used for all sequences. “Dualflex” flexible body coil was applied. MRCP images were evaluated before and 5 and 10 min after the iv administration of 0.5 IU/kg secretin (Secretolin, Hoechst, Frankfurt am Main, Germany)^[17]. The administration of secretin induced the secretion of bile and pancreatic juice. Consequently, the ductal filling was increased, and the visualization of the biliary and pancreatic ducts and the image quality were therefore improved^[18].

RESULTS

The MRCP images were of diagnostic quality in all but 1 patient. MRCP furnished normal findings in 5 cases and revealed abnormalities in 17 patients (Table 1). Conservative medical treatment was applied in 10 cases. MRCP demonstrated mild bile duct dilation caused by chronic pancreatitis in 3 patients. Since they were mainly asymptomatic, surgical intervention was not indicated. Primary sclerosing cholangitis was indicated by MRCP in 3 patients, the cholestasis was improved after treatment with ursodeoxycholic acid. Gallbladder stones were found in an 82-year-old female patient, operation was not recommended because of her age. In a 77-year-old female patient who had previously undergone choledochoduodenostomy, the extrahepatic biliary tree exhibited caliber changes. This finding was considered to correspond to cholangitis, the abnormal liver function was normalized by antibiotic therapy. In 2 patients with previous cholecystectomy and abnormal liver enzymes, MRCP revealed mild extrahepatic bile duct dilation (postcholecystectomy syndrome?). The liver function normalized without treatment in 1 patient, and in response to ursodeoxycholic acid treatment in the other (Table 1).

Figure 1 MRCP of a 78-year-old female patient. The common bile duct is dilated with a stricture at the level of the papilla of Vateri (open arrow), with multiple stones in the gallbladder (solid arrow). The Wirsung duct is not visible.

Seven patients required therapeutic interventions. Four of these 7 patients underwent surgery. The indication for operation was based on the MRCP findings, which were confirmed at surgery in 3 of the 4 cases. In 1 patient (No. 10, Figure 1), MRCP revealed only the site, but not the cause of the bile duct obstruction. This patient was referred to the endoscopy unit because of obstructive jaundice. MRCP demonstrated a prepapillary common bile duct obstruction. The Wirsung duct was not visible. These findings, the clinical picture and the result of duodenoscopy led to a suspicion of pancreatic head carcinoma. The patient was operated

on, and the surgery confirmed the suspicion. Curative resection was not possible because of the local invasiveness of the tumor, bilio-enteric anastomosis was performed.

Figure 2 MRCP of a 58-year-old female patient in whom ERCP failed because of a previous Billroth II resection. The intrahepatic biliary tree is markedly dilated with stones (open arrows), and the choledochojejunostomy anastomosis is narrowed (solid arrow). The patient underwent hepaticotomy and Kehr drainage.

In 1 patient in whom ERCP was failed because of a previous Billroth II resection, MRCP demonstrated a stricture of the choledochojejunostomy anastomosis as the cause of a bile duct obstruction (No. 1, Figure 2). The intrahepatic biliary tree was markedly dilated and contained secondary stones. The patient subsequently underwent hepaticotomy and Kehr drainage.

Figure 3 MRCP of a 63-year-old male patient in whom ERCP failed because of duodenal stenosis. The calcified pancreatic head obstructs the Wirsung duct and the common bile duct (arrow) with an upstream dilation, causing the “double duct sign”. The intrahepatic biliary tree and the cystic duct are also dilated. The patient underwent choledochojejunostomy, gastrojejunostomy and Wirsungogastrostomy.

In a patient with chronic pancreatitis, whose disease was not followed up regularly, ERCP was indicated because of obstructive jaundice, but it failed in consequence of duodenal stenosis. MRCP showed obstruction of the Wirsung duct and the common bile duct by the calcified pancreatic head, with an upstream dilation in both ducts, causing the “double duct sign” (No. 11, Figure 3). The intrahepatic biliary tree and the cystic duct were also dilated. The patient underwent choledochojejunostomy, gastrojejunostomy and Wirsungogastrostomy. Similarly, in a patient with chronic pancreatitis in whom a previous Billroth II resection precluded ERCP, MRCP demonstrated an intrapancreatic bile duct obstruction. Choledochoenterostomy was performed (No. 19).

In 3 patients of advanced age in a moribund physical status, the bile duct obstruction was treated with percutaneous transhepatic drainage (PTD). MRCP indicated common bile duct stones in a patient who had previously undergone choledochojejunostomy

Table 1 Indications for ERCP, reasons for ERCP failure, MRCP findings, and management of patients

Patient	Indication for ERCP	Reason for ERCP failure	MRCP findings	Management of patients
1	Obstructive jaundice	Billroth II anatomy (choledochojejunostomy anatomy)	stricture of choledochojejunostomy	hepaticotomy +Kehr drainage
2	Obstructive jaundice	Billroth II anatomy (choledochojejunostomy anatomy)	cholangitis	antibiotic treatment
3	Obstructive jaundice	choledochojejunostomy anatomy	choledocholithiasis	PTD
4	Obstructive jaundice	Roux and Y anatomy hepaticojejunostomy anatomy	stricture of hepaticojejunostomy	PTD
5	Cholestasis biliary pancreatitis	technical	cholecystolithiasis	follow-up
6	Cholestasis	technical	mild CBD dilatation	follow-up
7	Suspected pancreatic cancer	duodenal stenosis	chronic pancreatitis	follow-up

9	Cholestasis	technical	PSC	follow-up
10	Obstructive jaundice	technical	distal stricture of CBD	hepaticojejunostomy unresectable pancreas carcinoma
11	Obstructive jaundice chronic pancreatitis	duodenal stenosis	"double duct sign"	choledochojejunostomy gastrojejunostomy Wirsungogastrostomy
12	Obstructive jaundice chronic pancreatitis	technical	intrapancreatic stricture of CBD, chronic pancreatitis	follow-up
13	Cholestasis	technical (choledocho-duodenostomy anatomy)	normal	follow-up
14	Cholestasis	duodenal diverticulum	PSC	follow-up
15	Cholestasis	technical	PSC	follow-up
16	Obstructive jaundice	duodenal diverticulum	normal	follow-up
17	Recurrent pancreatitis	technical	normal	follow-up
18	Recurrent pancreatitis	technical	normal	follow-up
19	Obstructive jaundice	Billroth II anatomy	intrapancreatic stricture of CBD, chronic pancreatitis	choledochoenterostomy cholecystectomy
20	Cholestasis	technical	mild CBD dilation	follow-up
21	Obstructive jaundice	duodenal stenosis	intrapancreatic stricture of CBD, chronic pancreatitis	follow-up
22	Cholestasis	Billroth II anatomy	normal	follow-up

CBD: common bile duct; PSC: primary sclerosing cholangitis; PTD: percutan transhepatic drainage.

(No. 3), another with a hepaticojejunostomy anastomotic stricture (No. 4) and one with prepapillary cholangiocarcinoma (No. 8, Figure 4). These findings were confirmed by PTC and the patients subsequently underwent biliary drainage.

Figure 4 Normal Wirsung duct and bilateral renal cysts in an 81-year-old female patient. The intraluminal focus with low signal intensity in the distal common bile duct (arrow) proved to be cholangiocarcinoma. The biliary tree is dilated. With regard to her age and physical status, the patient underwent biliary stent implantation to ensure bile flow.

DISCUSSION

ERCP is the most sensitive and specific technique currently available for visualization of the biliary tree and pancreatic duct. Beside the establishment of a diagnosis, this examination at the same time offers therapeutic options. However, ERCP is invasive, and may be associated with complications, and patients who undergo ERCP need sedation. Another disadvantage is that it affords no information on extraductal lesions, and does not opacify the obstructed segment in the event of total duct obstruction. It was unsuccessful in 3-10% of the cases, even in the largest endoscopic centers^[5-7]. Inexperience of the endoscopist and anatomic factors such as previous gastroentero-anastomosis, duodenal stenosis, or periampullary diverticulum might lead to higher rates of unsuccessful ERCP^[19,20]. When the papilla of Vater is in the visual field of the duodenoscope, but conventional cannulation fail, precut papillotomy could be performed with a needle knife, and cannulation could subsequently be achieved. However, precut papillotomy could increase the frequency and severity of complications as compared with conventional ERCP (6-12% vs 1-5%)^[21,22]. Iv cholangiography or PTC examinations are the alternative choices for visualization of the biliary tree. However, iv cholangiography has been no longer used, because its

diagnostic accuracy was limited^[8]. PTC is a sensitive method of detecting biliary abnormalities, but it was invasive, might be associated with severe complications, and could successfully be applied if the intrahepatic biliary tree was dilated. In addition, neither PTC nor iv cholangiography was able to visualize the pancreatic duct^[9,10].

The need for a safe and noninvasive technique for examination of the biliary tree and pancreatic duct resulted in the development of MRCP. A number of studies have demonstrated that the sensitivity, specificity, positive and negative predictive values and diagnostic accuracy of MRCP in the detection of biliopancreatic diseases are as high as those of ERCP^[12-16]. Despite these data, the actual role of MRCP in the diagnostic work-up of patients with suspected biliopancreatic disease is not clear. Besides its advantages, MRCP has certain drawbacks. Most importantly, it does not allow simultaneous therapeutic intervention. While ERCP offers a therapeutic option in the same session after the diagnosis is made (papillotomy, removal of choledocholithiasis, stenting of a biliary stricture, *etc.*), MRCP yields only the diagnosis. Clips, stents, pneumobilia, hemobilia and ascites might result in artifacts and impede interpretation of the MRCP image. Despite the new technological advances in MR imaging, its resolution has remained behind that of ERCP^[23].

In the present study we assessed the value of MRCP in the management of patients in whom ERCP was unsuccessful. MRCP prevented an invasive procedure in 15 of 22 cases and guided therapy in the remaining 7. Ten patients were treated conservatively. They did not require further diagnostic examinations or therapeutic interventions; they were asymptomatic or responded well to the medical therapy during the follow-up. In 7 patients, therapeutic intervention was indicated by the MRCP findings. The information provided by MRCP was sufficient for the decision-making, and a further diagnostic work-up was required in only 1 patient. This patient (No. 10) was referred to the endoscopy unit because of obstructive jaundice. Duodenoscopy revealed an enlarged papilla of Vater with an irregular surface, which was suspicious of malignancy. Cannulation of the biliary or the pancreatic duct was impossible, even after precut papillotomy. The histological examination of the biopsy specimens taken from the papilla indicated no malignancy. MRCP demonstrated a dilated biliary tree with a severe prepapillary stricture (Figure 1). The pancreas was not separated well from its surroundings in the conventional axial plane MR images, because of the lack of peripancreatic fatty tissue. The Wirsung duct was not depicted or could not be identified among the fluid-filled bowels, despite the use of secretin. The evaluation of the MR images was hampered by the technical artifacts. These findings and the clinical picture together suggested pancreatic head carcinoma. The patient was operated on. The surgery confirmed the suspicion, but a curative resection was impossible as a result of the local invasiveness of the tumor. Biliary-enteric anastomosis was performed.

The sensitivity, specificity, positive and negative predictive values and diagnostic accuracy of MR imaging in the detection of pancreatic cancer were at least as high as those of computer tomography or ERCP^[24,25]. The combination of conventional MR imaging with MRCP and MR angiography could increase the accuracy in the diagnosis, the staging of pancreatic malignancies and the assessment of respectability^[26-29]. With this combined MR imaging technique, the biliary tree and pancreatic duct with the surrounding vessels and parenchymatous organs could be depicted in one examination, which makes it cost-effective. In our case, the poor quality of the MR imaging with significant amount of artifacts might explain why it was unable to diagnose the cause of the biliary obstruction.

Four patients underwent surgery without further diagnostic

examinations. In 3 cases the diagnosis made by MR was confirmed by the surgical findings. In 1 case (No. 10), the MR revealed only the site, but not the cause (i.e. pancreatic cancer) of the bile duct obstruction, which was diagnosed during the operation. In 3 patients, surgery was not recommended because of their moribund physical status. PTC was performed and in each case confirmed the results of MRCP. These patients subsequently underwent biliary drainage.

Seven out of 22 patients required intervention after MRCP. This points the major drawbacks of MRCP. It is unable to combine therapy with diagnosis. It could be argued that the 3 patients with obstructive jaundice who required PTC and PTD after MRCP might have better served by proceeding to this modality directly. However, the fact that MRCP is noninvasive is a powerful point in its favor. It can identify those patients where therapeutic intervention is needed.

Our results suggest that MRCP is a feasible and valuable diagnostic modality in patients in whom ERCP fails. MRCP facilitates the management of these patients. It differentiates patients who require invasive therapy from those who can be treated conservatively, and provides information necessary for the planning of surgical or radiological interventions.

Abstract

AIM: Cardiovascular autonomic and peripheral sensory neuropathy is a known complication of chronic alcoholic and non-alcoholic liver diseases. We aimed to assess the prevalence and risk factors for peripheral sensory nerve and autonomic dysfunction using sensitive methods in patients with primary biliary cirrhosis (PBC).

METHODS: Twenty-four AMA M2 positive female patients with clinical, biochemical and histological evidence of PBC and 20 age matched healthy female subjects were studied. Five standard cardiovascular reflex tests and 24-h heart rate variability (HRV) analysis were performed to define autonomic function. Peripheral sensory nerve function on median and peroneal nerves was characterized by current perception threshold (CPT), measured by a neuroselective diagnostic stimulator (Neurotron, Baltimore, MD).

RESULTS: Fourteen of 24 patients (58%) had at least one abnormal cardiovascular reflex test and thirteen (54%) had peripheral sensory neuropathy. Lower heart rate response to deep breathing ($P = 0.001$), standing ($P = 0.03$) and Valsalva manoeuvre ($P = 0.01$), and more profound decrease of blood pressure after standing ($P = 0.03$) was found in PBC patients than in controls. As a novel finding we proved that both time domain and frequency domain parameters of 24-h HRV were significantly reduced in PBC patients compared to controls. Each patient had at least one abnormal parameter of HRV. Lower CPT values indicated hyperaesthesia as a characteristic feature at peroneal nerve testing at three frequencies (2000 Hz: $P = 0.005$; 250 Hz: $P = 0.002$; 5 Hz: $P = 0.004$) in PBC compared to controls. Correlation of autonomic dysfunction with the severity and duration of the disease was observed. Lower total power of HRV correlated with lower CPT values at median nerve testing at 250 Hz ($P = 0.0001$) and at 5 Hz ($P = 0.002$), as well as with those at peroneal nerve testing at 2000 Hz ($P = 0.01$).

CONCLUSION: Autonomic and sensory nerve dysfunctions are frequent in PBC. Twenty-four-hour HRV analysis is more sensitive than standard cardiovascular tests for detecting of both parasympathetic and sympathetic impairments. Our novel data suggest that hyperaesthesia is a characteristic feature of peripheral sensory neuropathy and might contribute to itching in PBC. Autonomic dysfunction is related to the duration and severity of PBC.

INTRODUCTION

Autonomic neuropathy (AN) is frequent complication of both alcoholic and non-alcoholic chronic liver diseases^[1]. Cardiovascular AN represents a serious complication as it carries a 5-fold risk of mortality in patients with chronic liver diseases^[2]. In a 10-mo long follow-up study in patients awaiting for liver transplantation the mortality was significantly higher in patients with AN (27%) compared to those without AN (0%), suggesting that AN should be taken into consideration for early liver transplantation in patients with advanced liver disease^[3]. Up to now the precise explanation of increased mortality associated with AN has not been identified. Beside the most severe complications of AN-silent myocardial ischaemia and infarction, cardiorespiratory arrest, major arrhythmias^[4] -the attenuation of circadian variation of blood pressure and heart rate may contribute to the higher death rate^[5,6]. Prolongation of the QT-interval is also involved in the poor prognosis of AN accompanying chronic liver disease^[7,8]. Autonomic neuropathy may also be regarded as a potential etiologic factor of hyperdynamic circulation and portal hypertension^[9].

Recently, attention has been focused on the importance of 24-h heart rate variability (HRV). It has been confirmed that HRV is a strong and independent predictor of mortality after an acute myocardial infarction^[10]. Time and frequency domain analysis of HRV proved to be a reliable, noninvasive tool to provide quantitative information on cardiovascular autonomic function differentiated into vagal and sympathetic components^[11]. Additionally, assessment of HRV is a sensitive method for early detection of autonomic neuropathy even if the standard cardiovascular reflex tests are normal^[12]. Depressed HRV has been described not only in cardiovascular disorders, but also in chronic liver diseases^[5,13-15]. Although autonomic and sensory neuropathy is known as a common extrahepatic manifestation in chronic liver diseases^[1,3,7,13], there are only few data on risk factors of neuropathy in PBC^[16,17].

The aim of our study was to assess the frequency and predisposing factors of autonomic and peripheral sensory neuropathy in PBC.

MATERIALS AND METHODS

Patients

Twenty-four female patients with PBC (mean age: 60.4 ± 7.1 years; range: 45-73 years) from the Hepatological Outpatient Unit of Semmelweis University, Budapest and 20 age-matched healthy female controls (mean age: 59.3 ± 6.8 years; range: 44-72 years) were recruited for this cross sectional study. The diagnosis of PBC was based on characteristic clinical and laboratory data, AMA M2 positivity and liver biopsy. The severity of liver disease was assessed by histologic classification. Stage I: 2, stage II: 5, stage III: 12 and stage IV: 5 patients. Full medical history was taken, followed by thorough physical and neurologic

examination in each patient and control. Patients were only included if they were normotensive, ie. no history of hypertension, and at the time of inclusion visiting office blood pressure <140/90 mmHg calculated by the mean of three measurements using Korotkov's technique and no evidence of disease known to affect autonomic function (e.g. other hepatic disease, cardiovascular, kidney, endocrinologic, neurologic and psychiatric disorders including alcoholism). None was taking any antihypertensive drugs or other medications, apart from ursodeoxycholic acid, vitamin D and calcium supplementation^[18], and none had ascites. The healthy controls were recruited from the staff of our institution and their family members. Every participant was asked to refrain from consuming caffeine and alcoholic beverages, and tobacco products 12 h before autonomic testing.

Methods

The autonomic function was explored by the *five standard cardiovascular reflex tests*^[19]. Heart rate tests (heart rate responses to deep breathing, the 30/15 ratio and the Valsalva ratio) mainly reflect parasympathetic function while blood pressure responses to sustained handgrip and standing primarily allow the assessment of sympathetic integrity. Patients with at least one abnormal or two borderline cardiovascular tests were considered to have autonomic neuropathy. The same research assistant using a computerized ECG-recording-analyzing system developed by Innomed Inc, Budapest, Hungary, performed all reflex tests.

Two channel 24-h ECG recordings were done by CardioTens equipment (Meditech, Budapest, Hungary). This device complies with the requirements of the British Hypertension Society and the Association for the Advancement of Medical Instrumentation protocols. Automatic filters were used to continuously restore baseline and filter background and muscle noise. Analysis of stored data was done by Medibase software. The recording was also edited using visual control and manual corrections were made to omit ectopic beats, arrhythmic events and noise effects and only normal-to-normal beats (NN intervals) were used for further analysis. Ratio of normal beats to total number of beats was >95% in both groups.

To characterize 24-h HRV, time domain and frequency domain methods were used. Since there were several parameters cited in the literature to assess HRV, we selected a limited number of parameters according to the recommendations of the European Society of Cardiology and the North American Society of Pacing and Electrophysiology^[11]. Statistical time domain parameters could be calculated from either the direct measurements of NN intervals or from the differences between NN intervals. The following parameters were calculated from direct measurements of NN intervals: standard deviation of all NN (SDNN) intervals reflecting all the cyclic components responsible for variability and standard deviation of the averages of NN (SDANN) intervals in all 5-min segments of the entire recording, an estimate of the changes in heart rate due to cycles longer than 5 min.

Statistical time domain parameters deriving from NN interval differences are RMSSD and pNN50. RMSSD (the square root of the mean of the sum of the squares of differences between adjacent NN intervals) is an estimate of short-term components of HRV. PNN50 (the proportion of adjacent NN intervals differ by more than 50 ms) was considered to reflect the vagal tone of the heart.

A simple geometric time domain parameter, HRV triangular index (HRVTI) was also computed. HRVTI is the integral of the density distribution (the number of all NN intervals) divided by the maximum of the density distribution. HRVTI represents overall HRV.

In the frequency domain analysis (power spectral density analysis) of heart period oscillations low- (0.04-0.15 Hz) and high- (0.15-0.4 Hz) frequency bands of the power (i.e. variance)

spectrum (power distribution as function of frequency) was performed. The following frequency domain measures were computed: TP (total power: variance of all NN intervals), LF (power in the low frequency range) which is under both sympathetic and parasympathetic influences, HF (power in the high frequency range) which is an acknowledged measure of the parasympathetic (i.e. vagal) modulations.

Peripheral sensory function was characterized by the evaluation of the current perception threshold (CPT) with a neuroselective diagnostic stimulator (Neurotron, Baltimore, MD, USA), which permits transcutaneous testing at three sinusoidal frequencies (2000 Hz, 250 Hz and 5 Hz). The intensity of the stimulating current was changed within the range from 0.01 to 9.99 mA. The neurometer is the first instrument designed for the overall assessment of all types of sensory fibres. As demonstrated by the results of comparative trials conducted earlier^[20], CPT values measured during high frequency stimulation correlated best with tests of large fibre function and low frequency CPT values correlated with tests of small fibre function. Median and peroneal nerves (digital branches) were studied.

The Local Regional Committee of Science and Research Ethics approved the study. Written informed consent was obtained.

Statistical analysis

All analyses were performed using Statistica Software. Data are expressed as mean±SD and were compared between groups by Student's *t*-test. Correlations between variables were analysed by partial correlation coefficient calculation adjusted for age. *P*<0.05 was regarded as statistically significant.

RESULTS

Autonomic function

Using standard cardiovascular tests^[18], 14 PBC patients (58%) had at least one abnormal autonomic function test. Among these patients parasympathetic neuropathy was found in 8 (57.1%) patients, sympathetic nerve dysfunction was observed in 2 patients, and 4 subjects had both parasympathetic and sympathetic damage.

As a novel finding we proved that both time domain and frequency domain parameters of HRV were significantly reduced in PBC patients compared to controls. Each patient had at least one abnormal parameter of HRV.

Results of cardiovascular reflex tests and HRV parameters are presented in Table 1. The heart rate response to deep breathing (*P* = 0.001), as well as to standing (*P* = 0.03) and Valsalva manoeuvre (*P* = 0.01) was significantly lower in PBC patients than in age matched control subjects. A more profound decrease of systolic blood pressure after standing (*P* = 0.03) was found in patients compared to healthy controls. By HRV analysis most of the time-domain indices were significantly lower in patients than in controls (PNN50: *P* = 0.0008; HRVTI: *P* = 0.004; RMSSD: *P* = 0.006 and SDNN: *P* = 0.015). PBC patients also showed significantly lower total power (*P* = 0.0001), power of LF band (*P* = 0.00007) and of HF band (*P* = 0.004).

Peripheral sensory nerve function

At least one abnormal sensory parameter was detected in 13 patients (54%), of whom 12 had hyperaesthetic type, and only one had hypoaesthetic type sensory nerve dysfunction. Among patients with sensory neuropathy the lower extremities were affected in all 13 patients, while 3 patients had abnormal CPT values at upper extremities testing. Lower CPT values, indicating hyperaesthesia, were found in PBC patients compared with age matched controls at peroneal nerve testing at all three frequencies (*P*<0.01) as well as at median nerve testing at 250 Hz (*P* = 0.03). The CPT values of patients and controls are shown in Table 2.

Table 1 Results of cardiovascular reflex tests and 24-h heart rate variability (HRV) parameters in patients with PBC and age matched healthy controls

	Patients with PBC (n = 24)	Age-matched controls (n = 20)	P value
Cardiovascular reflex tests			
Deep breathing test (beats/min)	11.3 (4.4)	17.5 (6.6)	0.001
30/15 ratio	1.18 (0.1)	1.29 (0.2)	0.03
Valsalva ratio	1.32 (0.1)	1.48 (0.2)	0.01
Orthostatic test (mmHg)	-7.1 (8.6)	-1.5 (3.7)	0.03
Handgrip test (mmHg)	20.4 (8.1)	22.3 (4.4)	NS
Time domain parameters of HRV			
SDNN (ms)	119 (42)	151 (37)	0.015
SDANN (ms)	142 (102)	165 (66)	NS
RMSSD (ms)	23 (10)	38 (22)	0.006
PNN50 (%)	2.4 (4)	11 (10)	0.0008
HRVTI	28 (8)	38 (13)	0.004
Frequency domain parameters of HRV			
TP (ms ²)	1506 (701)	4032 (2787)	0.0001
LF (ms ²)	299 (176)	1213 (977)	0.00007
HF (ms ²)	150 (148)	525 (565)	0.004

Table 2 Current perception threshold (CPT) values in PBC patients and controls at median and peroneal nerve testing at three different frequencies

	Patients with PBC (n = 24)	Age-matched controls (n = 20)	P value
CPT (mA)-Median nerve			
2000 Hz	2.45 (0.75)	2.94 (0.87)	0.076
250 Hz	0.81 (0.33)	1.10 (0.46)	0.030
5 Hz	0.42 (0.23)	0.50 (0.17)	0.242
CPT (mA)-Peroneal nerve			
2000 Hz	2.91 (0.71)	3.61 (0.66)	0.005
250 Hz	1.01 (0.39)	1.40 (0.26)	0.002
5 Hz	0.68 (0.40)	1.06 (0.28)	0.004

Associations of autonomic function with clinical and biochemical characteristics

After adjustment for age, the longer duration of the disease was associated with less prominent increase of diastolic blood pressure during sustained handgrip test ($r = -0.52$, $P = 0.01$). Duration of the disease also correlated with reduced SDNN and SDANN ($r = 0.47$ and $r = -0.45$, $P < 0.05$, for both). The severity of PBC (stage) was found to negatively correlate with lower HRVTI ($r = -0.6$, $P = 0.01$) and lower SDANN ($r = -0.49$, $P = 0.04$) as well.

Partial correlation analysis revealed that lower prothrombin activity was associated with lower heart rate response to standing ($r = 0.79$, $P = 0.006$) as well as to deep breathing ($r = 0.63$, $P = 0.04$). The serum albumin positively correlated with SDNN and HRVTI ($r = 0.47$ and 0.57 , $P < 0.05$, for both). Serum AST and ALT levels negatively correlated with SDNN ($r = -0.54$, $P = 0.01$, for both). Positive correlations of SDNN ($r = 0.62$, $P = 0.004$) and Valsalva ratio ($r = 0.51$, $P = 0.02$) with serum triglyceride levels were found. These relationships remained significant after age adjustment.

Correlations of peripheral sensory nerve function with clinical and chemical characteristics

Negative correlations of serum ALT with CPT values at median nerve testing at 250 Hz ($r = -0.56$, $P = 0.005$) as well as with CPT at peroneal ($r = -0.48$, $P = 0.03$) and median nerve ($r = -0.45$, $P = 0.02$) at 5 Hz were revealed. AST and ALP levels were inversely related to CPT values at peroneal nerve testing at all three frequencies, as well as to those at median nerve testing at 250 Hz and 5 Hz. An inverse relationship was also found

between serum bilirubin levels and CPT values at median nerve testing at 5 Hz ($r = -0.43$, $P = 0.04$). None of these relationships was altered by adjustment for age.

Interestingly no correlation was found between peripheral sensory nerve function and duration and severity of PBC. Furthermore, no association was found between sensory nerve function and serum lipid levels, prothrombin activity and serum albumin levels.

Associations between autonomic and peripheral sensory nerve function

Reduced total power was associated with lower CPT values testing median nerve at 250 Hz ($r = 0.69$, $P = 0.0001$), and at 5 Hz ($r = 0.62$, $P = 0.002$), as well as with those testing peroneal nerve at 2000 Hz ($r = 0.53$, $P = 0.01$). HF-power was positively related to CPT values at peroneal nerve testing at 2000 Hz ($r = 0.51$, $P = 0.01$), LF-power correlated positively with CPT values testing median nerve at 250 ($r = 0.53$, $P = 0.01$), as well as at 5 Hz ($r = 0.47$, $P = 0.03$). A significant positive correlation was observed between the SDNN and the CPT values testing the median nerve at 2000 Hz ($r = 0.60$, $P = 0.003$), as well as at 250 Hz ($r = 0.53$, $P = 0.01$) and at 5 Hz ($r = 0.50$, $P = 0.02$). Lower SDANN values were associated with lower CPT values at the median nerve at 2000 Hz ($r = 0.52$, $P = 0.01$). The PNN50 values correlated positively with CPT values testing the peroneal nerve at 2000 Hz ($r = 0.50$, $P = 0.02$) and the beat-to-beat variation was also positively related to CPT values at the peroneal nerve at 250 Hz ($r = 0.47$, $P = 0.02$), even after adjustment for age.

DISCUSSION

Somatic neuropathy accompanying advanced stage primary biliary cirrhosis, was described as early as 1964 by Walker and Thomas^[21]. In the last two decades, autonomic neuropathy has been found as a common complication of this type of liver disease^[1,16,17,22]. The poor prognosis of neuropathy has been widely known even in chronic liver diseases, primarily as regards the impairment of autonomic functions^[2,3]. During the 4-year follow-up study of Hendrickse *et al.*, mortality was 30% among patients with autonomic neuropathy and 6% in those without AN^[2]. As suggested by the description of clinical features, the prognosis of sensory neuropathy was rather poor. In their 14-year follow-up study conducted on diabetic patients, Coppini *et al.* showed that sensory neuropathy was an independent predictor for mortality^[23].

There are only few studies on the prevalence of autonomic and sensory neuropathy in PBC, and the characteristics of the study population have a strong impact on prevalence data. Nevertheless, our data are consistent with previous findings showing that autonomic and sensory neuropathy were frequent complications in patients with PBC^[1,16,17].

Sensory neuropathy has also been found as a common complication in chronic liver diseases, yet there are no data on its prognostic importance.

Although many studies have been published on autonomic and sensory neuropathy in chronic liver diseases, some of the results were conflicting. To our knowledge this is the first study in PBC conducted on the evaluation of autonomic function assessed both by the standard cardiovascular reflex tests and by 24-h HRV analysis. HRV analysis could indicate the synchronic impairment of the parasympathetic and sympathetic systems in PBC. To date only one systematic study has assessed the factors that predispose to autonomic and sensory nerve dysfunction in PBC^[17], but in their study the autonomic function was only evaluated by the standard tests. We confirmed previous data showing that autonomic dysfunction was related to the severity of liver damage^[1,14,15,24], contrary to Oliver^[25] who did not show similar results. As a novel finding not only the severity, but also the duration of PBC was related to autonomic dysregulation. It would be worthy to investigate neuropathy in asymptomatic PBC population^[26]. We have also found a close correlation between decreased serum albumin and prothrombin activity with the autonomic dysfunction, which differed from the data of Lazzeri *et al.*^[5], but these results were consistent with two other studies^[3,15]. Moreover, in our study the serum AST and ALT levels were inversely related to the autonomic function. The markers of cholestasis did not correlate with the autonomic function, in keeping with the data of Coelho^[15]. An interesting finding in our study was that lower serum triglyceride level was associated with impaired autonomic function. This is of interest, since PBC related somatic neuropathy was originally attributed to lipid deposition^[21]. Later, however, no significant association of hyperlipidaemia with autonomic and sensory neuropathy was demonstrated^[17], which is consistent with our data regarding the serum cholesterol level.

Sensory impairment might involve both large myelinated fibres and small sensory fibres as demonstrated by Kempler^[16]. These data are consistent with the present results showing abnormal CPT values at all types of sensory fibres, testing both median and peroneal nerves. Abnormal CPT values were more frequent on the lower extremities, which were in accordance with previous observations that longer fibres were damaged earlier^[27]. The present data extended previous results by analysing which type of sensory nerve dysfunction was specific for PBC. Our data provide the first evidence that hyperaesthesia is a feature of peripheral sensory neuropathy in PBC. In this phase of neuropathy the degeneration and regeneration of non-myelinated small fibres occur concomitantly. These processes

were inaccessible to earlier methods for sensory testing, but the neurometer could permit the detection of this early phase of sensory nerve impairment^[28]. Evaluating the current perception threshold by neurometer seems a simple and comprehensive way of assessing even early abnormalities of peripheral sensory nerve function in patients with PBC. Recent studies have demonstrated that itching, a characteristic symptom in PBC, could be evoked by activation of peripheral unmyelinated C-fibers^[29,30]. In our study, patients with hyperaesthesia at 5 Hz had itching. Considering that 5 Hz CPT values demonstrate the unmyelinated C-fibre function, our results support the possible role for unmyelinated C-fibre damage in hyperaesthesia in the pathogenesis of pruritus in PBC.

Serum bilirubin and albumin were found to be associated with peripheral nerve function in the only one study published on correlation of sensory nerve dysfunction in PBC^[17]. Our results confirmed these data regarding serum bilirubin, but not serum albumin. Moreover, in our study not only elevated serum bilirubin, but higher serum AST, ALT and ALP were also related to lower CPT values.

Our results were consistent with those of Hendrickse^[17], showing that peripheral sensory nerve function correlates with cardiovascular autonomic function in patients with PBC. Prospective studies are required to evaluate the prognostic importance of sensory neuropathy in PBC.

In summary, autonomic and sensory nerve dysfunctions are frequent complications in patients with PBC and seem to be mutually related. The novel findings of reduced time and frequency domain parameters of 24-h HRV analysis indicate the synchronic impairment of parasympathetic and sympathetic systems. HRV analysis is more sensitive than standard cardiovascular tests for detecting autonomic neuropathy. This study provides the first evidence that hyperaesthesia involving all types of fibres is characteristic for sensory neuropathy in PBC. Hyperaesthesia of unmyelinated fibres might partly be responsible for itching, a characteristic symptom in PBC. Our data suggest that autonomic neuropathy is related to the severity and duration of liver disease as well as to the markers of hepatocellular dysfunction.

Abstract

AIM: To investigate the expression of three types of mucin (MUC1, MUC2, MUC5AC) and E-cadherin in human gastric carcinomas and their clinical significance.

METHODS: Ninety-four gastric cancer specimens were classified according to WHO criteria and detected by immunohistochemical assay of expression of mucins and E-cadherin.

RESULTS: The positive expression rates of MUC1, MUC2, MUC5AC and E-cadherin were 82% (77/94), 84% (79/94), 40% (38/94) and 56% (53/94) respectively. MUC1 expression was significantly correlated with the types of cancer (the positive rates of MUC1 in well and moderately differentiated tubular adenocarcinoma, poorly differentiated adenocarcinoma, signet-ring cell carcinoma and mucinous carcinoma were 91%, 87%, 71%, 71%, respectively, $P < 0.05$), age of patients (the positive rates of it among the people who are younger than 40 years, between 40-60 years and over 60 year were 74%, 81%, 89%, $P < 0.05$), lymph nodes involvement (the positive rates in the non-interfered group and the interfered group were 78%, 85%, $P < 0.05$) and tumor size (the positive rates in the tumors with the size less than 3 cm, 3-6 cm and larger than 6 cm were 69%, 92%, 69%, $P < 0.05$); MUC2 expression was significantly associated with types of cancers and had the strongest expression in mucinous carcinomas (the positive rates of MUC2 in well and moderately differentiated tubular adenocarcinoma, poorly differentiated adenocarcinoma, signet-ring cell carcinoma and mucinous carcinoma were 94%, 70%, 81%, 100%, $P < 0.05$), but it had no obvious relation to age, gender, tumor location, lymph nodes involvement, depth of invasion and metastasis to extra-gastric organs ($P > 0.05$); MUC5AC expression was not related to any of the characteristics investigated except that it had relation to gender, whereas MUC5AC showed the tendency to higher expression in less invasive lesions and lower expression in advanced stage cancers ($P > 0.05$); No significant difference was found for E-cadherin expression. There were strong positive relationships between the expression of MUC1 and E-cadherin, MUC2 and E-cadherin, MUC1 and MUC2 ($R = 0.33$, $R = 0.22$, $R = 0.32$, respectively, $P < 0.05$). According to the COX proportional hazards model, older patients,

involvement of lymph nodes, different types of gastric cancer and MUC2 expression were significantly associated with poorer outcome of gastric carcinoma patients ($\beta = 0.08$, $\beta = 3.94$, $\beta = 1.33$, $\beta = 0.75$, respectively, $P < 0.05$).

CONCLUSION: MUC1 and MUC2 are good markers of different types of gastric cancer. MUC2 is especially a good marker of mucinous carcinoma. MUC1, MUC2 may interfere with the function of E-cadherin in gastric carcinomas, and have synergic effect on progression of gastric cancers.

INTRODUCTION

Mucins, the high molecular weight glycoproteins that contain oligosaccharides, are the major components of the mucous gel covering the surface of epithelial tissue. Their main functions are thought to be lubrication and protection of the epithelial surface^[1,2]. To date, at least thirteen mucins have been found^[3].

MUC1, an epithelial mucin glycoprotein, is highly expressed in lactating mammary glands^[4]. Under pathological conditions, such as colon adenocarcinoma and pancreas adenocarcinoma or stomach adenocarcinoma, MUC1 would change its expression fashion and rate^[5]. MUC2, a gel-forming mucin, highly expresses in normal intestinal tissues and has no expression in normal gastric mucosa. However, it had *de novo* expression in stomach when the mucosa underwent metaplasia and carcinoma^[6]. MUC5AC, a gastric type mucin in gastric cardia and body mucosa, is decreased when the tissue has cancers^[7]. E-cadherin is a calcium-dependent cell-cell adhesion molecule and its expression decreases in the carcinoma tissues thus contributing to cancer progression and correlate with patients' prognosis^[8].

Despite many studies have been done in gastric carcinoma tissue, the results are still in contradiction. Some reported that MUC1 could well predict the patients' prognosis, while others thought not. MUC2 showed the same result^[9,10]. MUC5AC is a relatively less studied molecule, and its expression decreases in advanced cancers than in early cancers^[11]. Study on E-cadherin also remains contradictory^[12,13]. What's more, few studies have been done about their relationships, especially between E-cadherin and the mucins. The present study was designed to provide some useful information on these molecules.

MATERIALS AND METHODS

Materials

Ninety-four patients with gastric adenocarcinomas confirmed pathologically and underwent gastrectomy in our hospital from January 1989 to December 2000 were Systemically selected for the study. Patients' age, gender, tumor location, depth of invasion, local lymph nodes involvement, metastasis, tumor size were all obtained from the original records. Specimens were

histologically classified according to WHO criteria by two experienced pathologists. Among these subjects, there were 33 moderately and highly-differentiated tubular carcinomas, 23 poorly differentiated adenocarcinomas, 31 signet-ring cell carcinomas and 7 mucinous carcinomas. There were 64 male and 30 female patients with a mean age of 52.1 ± 12.1 years (range 25-75 years). The mean tumor size was 4.5 ± 2.0 cm in diameter (range 1-10 cm). A total of 48 patients provided full information during follow-up.

Reagents and methods

Antibodies against MUC1, MUC2 and MUC5AC were purchased from Shenzhen Jingmei Biotechnology, Inc., and the antibody against E-cadherin was from Fujian Maixin Co, Ltd. All the 94 formalin-fixed, paraffin-embedded specimens were sliced sequentially with a thickness of 4 μ m. According to the protocol, these tissue sections were dewaxed, rehydrated, incubated with 30 mL/L hydrogen peroxide in methanol for 30 min to block endogenous peroxidase, and then washed with PBS (phosphate buffered saline, pH 7.4). After that, they were incubated with non-immunized horse serum for 30 min at room temperature, washed again, and incubated with the specific antibodies overnight at 4 °C or 1 h at 37 °C. They were washed again, incubated with the secondary antibody (Biotin labeled goat anti-rabbit antibody) and streptavidin-biotin peroxidase for 30 min separately, visualized with 3,3'-diaminobenzidine tetra-hydrochloride and H₂O₂, counterstained with haematoxylin. Primary antibodies were replaced with PBS buffer as negative control.

In order to obtain a more precise relation between mucins and the clinical indicators, a semiquantitative analysis was performed to evaluate positively stained cells in carcinoma tissues as +++, ++, + or -. We examined 10 fields of each cancerous tissue at high magnification ($\times 400$) and scored the intensity of color as 0 for non-stained, 1 for the color of yellow, 2 for brown-yellow, 3 for brown; the rate of positive cell was judged as negative (0) if it was less than 5%, 1 for 5-25%, 2 for 26-50%, 3 for over 50%. The mean intensity scores were multiplied by the rate scores. Negative group (-) was defined when the result was 0, 1-3 was mild-positive (+), 4-5 was moderate-positive (++) and equal or greater than 6 was strong positive (+++).

Statistical analysis

χ^2 test, the hazards proportional analysis (COX) and the correlation analysis were used to determine differences between groups using SPSS 10.0 software. Statistical significance was established at $P < 0.05$.

RESULTS

Expression and distribution of MUC1, MUC2, MUC5AC and E-cadherin

The positivity rate of MUC1 was 82% in the cancerous tissues. It expressed in the cytoplasm diffusely or stained on the membrane of the cells. There were significant differences in its expression among different types of the cancer ($P < 0.05$) with the highest expression rate in well and moderately differentiated tubular

adenocarcinomas (91%). Moreover, its expression level had significant relationship with patients' age, local lymph nodes involvement and tumor size ($P < 0.05$). MUC2 had a positive expression rate of 84%, with the highest expression level in mucinous carcinomas (100%) and lowest expression level in signet-ring cell carcinoma (19%). Furthermore, it also showed significant differences in expression among different types of cancer ($P < 0.05$). MUC5AC had a positive expression rate of 40% and the lowest expression level in mucinous carcinoma (14%), but no significant differences in expression levels among different types of cancer were found ($P > 0.05$). It expressed mainly in the cytoplasm. E-cadherin had a positive expression rate of 56% with the highest expression in well and moderately differentiated cancers (70%) and the lowest in mucinous type (29%). There was no significant difference of expression level among different types of cancer ($P > 0.05$). Its positive expression was on the membrane and in the cytoplasm of cancerous cells. The expression of MUC2, MUC5AC, E-cadherin were not significantly different with regards to clinicopathological characteristics (Table 1, Figure 1).

Relationship between proteins' expression and prognostic factors

There were significantly positive relationships between MUC1 and MUC2, MUC1 and E-cadherin, MUC2 and E-cadherin ($P < 0.05$). According to COX analysis, patients' age, lymph node involvement, types of the cancer and the level of MUC2 expression were the factors related to patients' survival after operation (figures not shown).

DISCUSSION

We confirmed that mucin expression was associated with differentiation characteristics of gastric carcinoma. MUC1 was expressed in most of the studied gastric cancerous specimens (82%), being consistent with other studies^[10]. MUC1 expression related to clinical characteristics such as patients' age, tumor size and local lymph nodes involvement. MUC1 expressed higher in older patients with larger tumor or with more lymph nodes involvement. On the other hand, though the expression

of MUC1 was not significantly associated with the metastasis and depth of invasion ($P > 0.05$), it still had the tendency toward higher expression in advanced stage of cancer. However, we failed to find that MUC1 had the prognostic role in gastric cancer patients, which is different with Utsunomiya's conclusion^[9], but consistent with Reis's conclusion^[14]. These contradictory results might be due to our relatively small number of follow-up patients after operation.

MUC2, the intestinal mucin, expressed in most of the studied cases (86%), higher than that in other studies^[15]. However our result was in accordance with other results concerning its overwhelming expression in mucinous carcinomas^[15,16]. Contradictory to some reports that MUC2 indicated good prognosis^[9], our study found that MUC2 could predict poor outcome. Our *in vitro* study used anti-sense oligonucleotide of MUC2 to inhibit the growth of gastric cancer cells, while Sternberg used the anti-sense oligonucleotide of MUC2 in colon cells *in vitro* and *in vivo* and found that it decreased the adherence ability of cells to E-selectin and resulted in inhibition of liver metastasis^[17]. Both supported our conclusion that MUC2 might contribute to gastric cancer progress.

MUC5AC was thought to be gastric mucin and expressed higher in early stage of cancers than in the advanced stage^[18]. MUC5AC rarely expressed in mucinous carcinoma except in one case. Between different sex groups, MUC5AC had significant difference ($P < 0.05$).

E-cadherin is a calcium-dependent molecule, and acts as a tumor-inhibitory factor. Some studies have shown that the lower expression level it had, the faster the tumor progressed^[12]. But we could not draw a conclusion like this despite the tendency shown at present. While we noted its highest expression in the well and moderately differentiated tubular carcinoma which supported the view on its contribution to tubular structure formation^[19].

Although some studies showed that MUC1 expression in gastric cancers was negatively correlated with the expression of E-cadherin^[20], we found the positive relationships between them, what's more, the correlation of MUC1, MUC2 and E-cadherin were first studied by us. Both MUC1 and MUC2 might contribute to the progress of gastric cancer, and they might

restrain the role of E-cadherin.

In summary, MUC1 may contribute to gastric cancers progress, larger tumor size and metastasis to lymph nodes, at the same time, it may inhibit E-cadherin. MUC2 had the same role as MUC1, besides, it may be an indicator for prognosis of gastric cancer patients and good marker for mucinous cancers. E-cadherin could not be used a tangible marker to indicate gastric cancers progress but may play a role in the tubular formation. The role of MUC5AC in gastric cancers needs more investigation.

ACKNOWLEDGEMENTS

The authors express their gratitude to Dr. Jie Chen and Dr. Fu-Sheng Liu for their precious advice and suggestions. We thank Mr. Da-Hai Sun for his assistance in preparation of the manuscript.

Abstract

AIM: To study the anti-tumor effect of resveratrol and in combination with 5-FU on murine liver cancer.

METHODS: Transplantable murine hepatoma₂₂ model was used to evaluate the anti-tumor activity of resveratrol (RES) alone or in combination with 5-FU *in vivo*. H₂₂ cell cycles were analyzed with flow cytometry.

RESULTS: Resveratrol could inhibit the growth of murine hepatoma₂₂, after the mice bearing H₂₂ tumor were treated with 10 mg/kg or 15 mg/kg resveratrol for ten days, and the inhibition rates were 36.3% ($n = 10$) and 49.3% ($n = 9$), respectively, which increased obviously compared with that in control group (85 ± 22 vs 68 ± 17 , $P < 0.01$). RES could induce the S phase arrest of H₂₂ cells, and increase the percentage of cells in S phase from 59.1% ($n = 9$) to 73.5% ($n = 9$) in a dose-dependent manner ($P < 0.05$). The enhanced inhibition of tumor growth by 5-FU was also observed in hepatoma₂₂ bearing mice when 5-FU was administered in combination with 10 mg/kg resveratrol. The inhibition rates for 20 mg/kg or 10 mg/kg 5-FU in combination with 10 mg/kg resveratrol were 77.4% and 72.4%, respectively, compared with the group of 20 mg/kg or 10 mg/kg 5-FU alone, in which the inhibition rates were 53.4% and 43.8%, respectively ($n = 8$). There was a statistical significance between the combination group and 5-FU group.

CONCLUSION: RES could induce the S phase arrest of H₂₂ cells and enhance the anti-tumor effect of 5-FU on murine hepatoma₂₂ and antagonize its toxicity markedly. These results suggest that resveratrol, as a biochemical modulator to enhance the therapeutic effects of 5-FU, may be potentially useful in cancer chemotherapy.

INTRODUCTION

Liver cancer is common in the world, especially in China^[1-10].

Since the introduction of 5-FU for the treatment of liver cancer, the prognosis of liver cancer patients has been greatly improved. However, the serious side effects of 5-FU restrict its extensive clinical application. Searching for some new types of drugs to substitute or combine with 5-FU is necessary. Recently, scientists have found that resveratrol (3,4,5-trihydroxy-trans-stilbene, RES), a kind of phytoalexin found in root extract of the weed *Polygonum cuaspidatum* and in grape skins as well as red wine, has comprehensive pharmacological effects. Studies demonstrated that RES could alter the synthesis and secretion of lipids and lipoproteins by liver cells, block human platelet aggregation and inhibit the synthesis of proaggregatory and proinflammatory eicosanoids by platelets and neutrophils^[11-15]. Some reports indicate that RES could prevent tumor growth and metastasis in human lung carcinoma, pancreatic cancer, prostate cancer, bronchial epithelium cancer and breast cancer models^[16-20]. The present investigation evaluated the potency of RES and in combination with 5-FU on tumor cell growth and proliferation and on cell cycle distribution in a transplantable murine hepatoma₂₂ model.

MATERIALS AND METHODS

Materials

Resveratrol was purchased from Sigma Co (USA), dissolved and sterilized in dimethyl sulfoxide (DMSO) first and then diluted to the required working concentrations in RPMI 1640 (Gibco, USA) containing 100 mL/L calf serum (Sijiqing Co, Hangzhou, China). Mouse hepatocellular carcinoma cell line H₂₂ was purchased from the Department of Pathology, Fourth Military Medical University. Male BALB/c mice, 6-8 wk old, weighing 20 ± 2 g, were purchased from the Animal Center of Xi'an Jiaotong University.

Suppressive effect of RES on transplanted liver cancer

H₂₂ cells were first subcultured in RPMI 1640 containing 100 mL/L fetal bovine serum, and then washed twice and resuspended in RPMI 1640 culture medium (1×10^{11} /L). About 0.2 mL cell solution (including 2×10^7 cells) was taken and injected into the right groin of 5 Balb/c mice. After 14 d, when the tumors of 3-5 mm in diameter formed in the right groin of these mice, they were taken out and cut into small pieces of 1 mm³ under sterile condition. Fifty Balb/c mice were anesthetized using coeliotomy injection of pentobarbitone (70 mg/kg) and laparotomy was performed. Under sterile condition their middle lobes of liver were punctured to form a 3 mm-long sinus tract and a small piece of tumor tissue was put into each sinus tract. Then these mice were randomly divided into 5 groups: control group, 5-FU group and 3 experimental groups. The experimental groups were injected with RES (dissolved in DMSO and diluted to the working concentration of 25 mmol/L in RPMI 1640 containing 100 mL/L calf serum) at 5, 10 or 15 mg/kg body mass, respectively, while the control group was given the same volume of the solution as for the experimental group without RES and the 5-FU group was injected with 5-FU at 20 mg/kg body mass. Twenty-four hours following liver tumor transplantation, each mouse was injected a corresponding dosage of RES into its abdominal cavity once a day for 10 d. These mice were then

sacrificed on the following day after the last injection. After the maximum diameter and transverse length of tumor were measured, hepatocellular carcinoma tissues were sampled. The tumor volume was calculated by using the formula $V = 1/2$ (maximum diameter \times transverse length²). The suppressive rate of tumor growth was calculated as [(mean V of tumor in control group - mean V of tumor in experimental group)/mean V of tumor in control group] $\times 100\%$.

H₂₂ cell cycle in transplanted liver cancer

Fresh hepatocellular carcinoma tissues with a size of 0.5-0.7 cm³ were washed twice in saline and then single cells were isolated from sampled tissues using 21 g/L citric acid 5 g/L Tween 20 according to the method of Otto^[21]. After this, cells were first washed with PBS (pH 7.4) three times, then adjusted to the density of 1×10^9 /L in RPMI 1640, and 0.2 mL cell suspension was taken and stained with 0.2 mL PI compound dye for 20 min at room temperature. Then, cell suspension was centrifuged at 800 r/min for 10 min and washed twice in PBS at pH 7.4. Finally, the cells were added to 1 mL PBS followed by slight shaking at room temperature and cell cycle analysis was performed using flow cytometer (Coulter, Epice Elite, ESP, USA). By using the multicycle software program it was possible to calculate the proportion of H₂₂ cells in S and G₂/M phases in tumor.

Synergistic anti-tumor effects of RES and 5-FU

A total of 128 tumor-bearing BALB/c mice were randomly divided into 8 groups: control group, RES group, three 5-FU groups and three experimental groups. The RES group was injected with RES at 10 mg/kg body mass (this dosage was proven to have obvious anti-tumor effect in our preliminary study.) and the 5-FU groups were injected with 5-FU at 5, 10, or 20 mg/kg body mass, respectively, and 3 experimental groups were injected with RES at 10 mg/kg body mass+5-FU at 5, 10, or 20 mg/kg body mass, respectively. The control group was given the same volume of the solution as for the experimental group without RES and 5-FU. Twenty-four hours after liver tumor transplantation, each mouse was injected with a corresponding drug at respective dosage into its abdominal cavity once a day for 10 d. Half of the mice in each group were then sacrificed on the following day after the last injection and the maximum diameter and transverse length of tumor were measured. The tumor tissues of mice treated with various dosages of 5-FU alone or in combination with RES were observed and photographed with an Olympus BH-I microscope. The rest mice were kept on feeding and their survival time and changes of body mass were recorded and their tumor metastasis conditions in lung or abdominal cavity were observed.

Statistical analysis

Student's *t* test was used to evaluate the significance of the difference between experimental groups and control group, between combination groups and corresponding sole drug groups.

RESULTS

Suppressive effect of RES on transplanted liver cancer and distribution of H₂₂ cell cycles

Except 3 Balb/c mice (each in control group, 15 mg/kg RES group and 20.0 mg/kg 5-FU group), all the mice inoculated with hepatocarcinoma cell line H₂₂ were successively transplanted with liver cancer. After treatment of the tumour bearing mice with 5, 10 or 15 mg/kg RES for 10 d, the tumour size was reduced from 134 ± 40 mm³ in control group to 105 ± 14 mm³, 85 ± 22 mm³ and 68 ± 17 mm³ in three experimental groups, the inhibition rate of tumour growth was 21.6 %, 36.3 % and 49.3 %, respectively.

The inhibitory effect on the latter 2 therapeutic groups was significant higher than that on control group ($P < 0.01$). Though the inhibition rate of tumour growth of 5-FU was rather high (53.0%), its toxicity was serious and the concrete manifestations included poor ingestion, diarrhea, and decrease in body mass, while the mice in RES groups showed no evident toxicity and were alive at the end of treatment (Table 1).

The cell cycles were analysed using flow cytometer to calculate the number of H₂₂ cells in each phase in tumor under the action of various dosages of RES (5, 10, or 15 mg/kg body mass). The results showed that the number of H₂₂ cells in S phase increased from 0.60 in control group to 0.75 in 15.0 mg/kg RES group, while the number of H₂₂ cells in G₂ phase decreased from 0.11 to 0.00 and the effect was dose-dependent (Table 2, Figure 1).

^a*P*<0.05, ^b*P*<0.01, vs control.**Suppressive effect of RES in combination with 5-FU on transplanted liver cancer**

RES in combination with 5-FU had synergistic suppressive effects on transplanted liver cancer of mouse (Figure 2). When 10 mg/kg RES in combination with 5, 10 or 20 mg/kg 5-FU, the inhibition rate was 50.0%, 72.4%, and 77.4%, respectively. When the group administered 5, 10 or 20 mg/kg 5-FU alone, the inhibition rate was 28.4%, 43.8%, and 53.4%, respectively. There was a statistical significance between the combination group and the 5-FU alone group (Table 3). Morphologic observation showed that more cellular necrosis was found in the combination group than in control group (Figure 3).

**Figure 2** Tumor size of mice treated with 10.0 mg/kg RES+20.0 mg/kg 5-FU (tumor A: 3.5×3.1×2.6 mm) and RPMI-1640 (tumor B: 4.8×4.7×4.2 mm; tumor C: 5.3×5.2×4.8 mm).**Effect of RES in combination with 5-FU on survival time and tumor metastasis**

When the mice were administered 10 mg/kg RES in combination with 5, 10 or 20 mg/kg 5-FU, the survival time of tumor bearing mouse was 30.6±8.0 d, 36.3±9.4 d, and 44.6±11.6 d, respectively. When group administered 5, 10 or 20 mg/kg 5-FU alone, the survival time was 19.4±4.4 d, 23.9±5.4 d, and 32.1±9.7 d, respectively (Figure 6). There was a statistical significance between the combination group and the 5-FU alone group. In

the beginning of the study, there was no statistical difference in the body mass of mouse among various groups. However, at the end of the investigation, the body mass of mouse in combination group was significantly heavier than that in sole drug group (*P*<0.01), showing that RES might antagonize the toxicity of 5-FU markedly (Table 4). Two Balb/c mice in control group had lung and celiac lymph node metastases, one in 5 mg/kg 5-FU therapeutic group had celiac lymph node metastasis. Except these 3 groups, all the mice inoculated with hepatocarcinoma cell line H₂₂ showed no signs of tumor metastasis.

**Figure 3** Morphologic observation of tumor tissues of mice treated with RPMI-1640 (A) or 10.0 mg/kg RES+20.0 mg/kg 5-FU (B).

Figure 4 Kaplan-meier curves of survival rates of tumor bearing mice when administered RPMI-1640, 10 mg/kg RES, 20 mg/kg 5-FU, and 5-FU (20.0 mg/kg)+RES (10.0 mg/kg).

DISCUSSION

Great attention has been paid to the chemopreventive activities and low toxicities of dietary polyphenolic compounds like RES^[22]. The function of RES might be mediated via different mechanisms in different cells, and the ability of RES to inhibit cellular events associated with tumor initiation, promotion, and progression might be attributed to its anticyclooxygenase activity, inducing apoptosis of tumor cells, antagonism to mutation, antioxidation and anti-free radical activity and effect on cell cycles^[23-28]. Ahmad *et al.*^[29] proved that resveratrol treatment of human epidermoid carcinoma A431 cells caused an induction of WAF1/p21 inhibiting cyclin D1/D2-cdk6, cyclin D1/D2-cdk4, and cyclin E-cdk2 complexes, thereby imposing an artificial checkpoint at the G1-S transition of the cell cycle, which resulted in a G1 phase arrest of the cell cycle and subsequent apoptotic death of cancer cells. Our previous studies demonstrated that RES could suppress the growth of murine transplanted liver tumor H₂₂ and the anti-tumor mechanism of RES might prevent mitosis of tumor cells by suppressing the protein expression of cyclin B1 and p34cdc2, thus interfering with the process of tumor cells from S stage to G2/M stage^[30,31].

One main role of 5-fluorouracil is to affect the biosynthesis of nucleic acids. Inside cells, 5-FU is converted to 5-fluorouracil deoxynucleotide (5F-dUMP) and inhibits the function of deoxythymidylic acid synthetase, blocks the methylation of uracil deoxyribonucleotide into deoxythymidylic acid, thus affecting the synthesis of DNA. As a result, 5-FU can prevent the tumor cells from splitting and proliferating and its cardinal acting period is S phase. Besides that, after the conversion of 5-FU into 5-fluorouracil uridine (5-FUR) *in vivo*, it also can be added into RNA to interfere with the synthesis of proteins, so it can affect the cells in other phases. Therefore, RES can enhance the anti-tumor effect of 5-FU by inducing the S phase arrest of H₂₂ cells, a stage in which 5-FU can exert its max tumor cell killing function, and this synergism was proved in our *in vitro* experiments.

In the present investigation, RES was administered into murine abdomen, its potency on growth and proliferation of H₂₂-innoculated tumors and its synergism with 5-FU were evaluated by measuring the size of hepatoma and examining the distributions of H₂₂ cell cycles and observing the survival time of mice. The tumor size was reduced by each dosage of 5, 10 or 15 mg/kg of RES for 10 d. When the larger dosage of RES was applied, the tumor size was significantly reduced, the inhibition rate of tumor growth by 10 or 15 mg/kg reached to 36.3% and 49.3%, respectively ($P < 0.01$). It was also found that RES could induce the S phase arrest of H₂₂ cells. RES could increase the percentage of cells in S phase from 59.1% to 73.5% in a dose-dependent manner ($P < 0.05$). The enhanced inhibition

of tumor growth by 5-FU was also observed in hepatoma₂₂ bearing mice when 5-FU was administered in combination with 10 mg/kg RES. The inhibition rate of 10 mg/kg or 20 mg/kg 5-FU in combination with 10 mg/kg RES was 72.4% and 77.4%, respectively. The inhibition rate was 43.8% and 53.4%, when the group administered 10 mg/kg or 20 mg/kg 5-FU alone. There was a statistical significance between the combination group and the 5-FU alone group ($P < 0.01$). In addition to that, when RES was administered in combination with a smaller dosage of 5-FU, the therapeutic effect was similar to that of a larger dosage of 5-FU but without severe side effects of 5-FU, therefore the survival time of mice was elongated.

In short, the data suggest that RES can induce the S phase arrest of H₂₂ cells and enhance the anti-tumor effect of 5-FU on murine hepatoma₂₂ and antagonize its toxicity markedly. Resveratrol, a biochemical modulator to enhance the therapeutic effects of 5-FU, may be potentially useful in cancer chemotherapy.

Abstract

AIM: To study the localization of the solitary metastases in relation to the primary gastric cancers and the feasibility of sentinel lymph node (SLN) concept in gastric cancer.

METHODS: Eighty-six patients with gastric cancer, who had only one lymph node involved, were regarded retrospectively as patients with a possible sentinel node metastasis, and the distribution of these nodes were assessed. Thirteen cases with jumping metastases were further studied and followed up.

RESULTS: The single nodal metastasis was found in the nearest perigastric nodal area in 65.1% (56/86) of the cases and in 19.8% (17/86) of the cases in a fairly remote perigastric area. Out of 19 middle-third gastric cancers, 3 tumors at the lesser or greater curvatures had transverse metastases. There were also 15.1% (13/86) of patients with a jumping metastasis to N2-N3 nodes without N1 involved. Among them, the depth of invasion was mucosal (M) in 1 patient, submucosal (SM) in 2, proper-muscular (MP) in 4, subserosal (SS) in 5, and serosa-exposed (SE) in 1. Five of these patients died of gastric cancer recurrence at the time of this report within 3 years after surgery.

CONCLUSION: These results suggest that nodal metastases occur in a random and multidirectional process in gastric cancer and that not every first metastatic node is located in the perigastric region near the primary tumor. The rate of "jumping metastasis" in gastric cancer is much higher than expected, which suggests that the blind examination of the nodal area close to the primary tumor can not be a reliable method to detect the SLN and that a extended lymph node dissection (ELND) should be performed if the preoperative examination indicates submucosal invasion.

INTRODUCTION

The sentinel lymph node (SLN) which refers to the first lymph node to receive drainage from the primary tumor has been successfully introduced in the patients with breast cancer^[1] and malignant melanoma^[2] to assess tumor involvement in regional lymph nodes with less morbidity but equal accuracy to complete lymphadenectomy. But the feasibility of sentinel node mapping of gastric carcinoma is still unclear and controversial. To explore the applicability of sentinel node concept to gastric cancer and provide useful information for establishing a novel method to detect sentinel nodes during operation, we retrospectively investigated solitary lymph node metastases that hypothesized to represent sentinel lymph node.

MATERIALS AND METHODS

Patients

Between January 1997 and December 2003, 1 698 patients with gastric cancer underwent gastrectomy with lymph node dissection (more than D1) at the Department of General Surgery, Guangzhou General Hospital of PLA, Nanfang and Zhujiang Hospitals of First Military Medical University. Among them, 86 (5.1%) patients were rolled in this study by the following criteria: (1) the lesion was solitary and limited to one part of the stomach; (2) a curative gastrectomy with ELND was performed; and (3) the histological examination of all resected lymph nodes revealed only one lymph node involved. These patients were subdivided according to the primary site of gastric cancer: 16 upper-third (U) tumors; 19 middle-third (M) tumors; and 51 lower-third (L) tumors. According to the depth of wall invasion, mucosal (M) lesions, submucosal (SM) lesions, proper-muscular (MP) lesions, and subserosal (SS) lesions were observed in 2, 7, 47, and 30 patients, respectively. Regarding their histologic grades, 23 of high-differentiated cases, 55 of middle- differentiated cases, 7 of low- differentiated cases, and 1 of non-differentiated case were proven to have only one lymph node involved. Total gastrectomy, proximal subtotal gastrectomy and distal subtotal gastrectomy were carried out in 29, 6 and 51 cases, respectively.

Methods

The resected specimens and the lymph nodes were stained conventionally with hematoxylin and eosin (HE) and examined by pathologists. The clinicopathological data were evaluated according to the General Rules by the Japanese Research Society for Gastric Cancer^[3]. In the present study, to express the group and station number of each lymph node, No. and N were inserted in front of the number, i.e., No. 4 means group 4 lymph node and N1 means station 1 lymph node. If patients were histologically verified to have distant lymph nodes (N2 or N3) involved without perigastric node metastasis (N1), they were defined to have either jumping or skip metastases. If the tumors at the lesser or greater curvatures had metastasized to the lymph nodes located in the opposite curvatures, they were then defined to have transverse metastases. Ten of 13 patients with skip metastases were followed up for 1-5 years until December 2003.

RESULTS

Upper-third (U) tumors

In 13 out of 16 U tumors, the solitary node metastasis was found in perigastric area close to the tumor (N1). In 3 cases, the metastasis was found in N2 area. Among them, 2 nodes were along the left gastric artery (LGA) (No.7), the other 1 along common hepatic artery (CHA) (No.8a).

Middle-third (M) tumors

In 9 out of 19 M tumors, the single node metastasis was found either in the lesser (No.3) or greater curvature (No.4) perigastric area close to the primary tumor. Among them, 2 tumors at the lesser curvature and 1 tumor at the greater curvature had transverse metastases. In 6 cases, the metastasis was found in the remote perigastric area (No.1, 5 and 6), and another 4 cases in the N2 or N3 area (No.7, 8a and 12) were without N1 involvement.

Lower-third (L) tumors

Of 51 patients with L tumors, 34 had the single metastasis in the perigastric node close to the tumor (No.3 and 4), 11 had metastasized to the surpyloric (No.5) or infrapyloric (No.6), both of which were N1 but somewhat remote from the primary tumor. In the other 6 cases, the metastasis was found in the N2 or N3 area (No.1, 4 s, 7 and 11 p) without N1 involvement.

Invasion and survival of patients with jumping metastasis

Among 13 cases with jumping metastasis, the depth of invasion was M in 1, SM in 2, MP in 4, SS in 5, and SE in 1. Among 6 out of 10 patients who received a follow-up, 5 died of tumor recurrence and 1 of other disease within 3 years after operation. The other 4 were alive at the time of this report for more than 3-5 years after surgery.

Metastasis of tumors

A total of 1376 lymph nodes were harvested in this group of 86 patients with D2-D3 lymphadenectomy. The average number of lymph nodes dissected was 16 in each case. The distribution of the single positive node is shown in Table 1 according to the location of the primary tumor. In total, the single nodal metastasis was found in 65.1% of cases in the nearest perigastric node area, in 19.8% of cases in a fairly remote perigastric area, and in 15.1% of cases in the N2 or N3 area without N1 involvement.

Table 1 Distribution of solitary lymph node metastasis

Location of positive node	Location of primary tumor		
	Upper	Middle	Lower
Right cardinal (No1)	2(N1)	1(N1)	1(N2)
Lesser curvature (No3)	7(N1)	7(N1)	20(N1)
Greater curvature (No4d)		2(N1)	14(N1)
Greater curvature (No4s)	2(N1)		1(N3)
Surpyloric (No5)		2(N1)	5(N1)
Infrapyloric (No6)	2(N1)	3(N1)	6(N1)
Left gastric artery (No7)	2(N2)	2(N2)	3(N2)
Common hepatic artery (No8a)	1(N2)	1(N2)	
Splenic artery (No11p)			1(N2)
Proper hepatic artery (No12)		1(N3)	

No4d and 4 s represent nodes on right and left half of greater curvature respectively; No8a represents nodes on the anterior or upper of CHA; No11p represents nodes on proximal splenic artery.

DISCUSSION

Gastric cancer is generally thought to spread to N1 nodes first,

followed by involvement of distant nodes (N2-N3) just as other carcinomas. However, more recent studies have reported that lymph node involvement was noted not only in N1 but also in N2-N3 and that the rate of N2 lymph node metastases in patients with advanced gastric cancers was higher than expected^[4,5]. Lymphatic drainage route must be patient-specific and lesion-specific in gastric cancer due to complicated lymphatic streams from the stomach. Our results suggested that although most of the single nodal metastasis was found in the nearest perigastric node area, approximately one quarter of the patients had the first metastasis in a fairly remote perigastric area and up to 15% of patients demonstrated skip metastasis without N1 involvement. To date, to the authors knowledge, there are only 5 retrospective studies on gastric cancer patients with only one lymph node metastasis^[6-10]. In these studies, the single nodal metastases were distributed beyond the perigastric area in 12.6-29% of gastric cancer patients, which suggested that the conventional lymphatic routes in stomach that have long been generally accepted should be clarified further. Our present data confirm these results. Among 13 cases with skip metastasis in the current study, most (10/13) of the solitary node metastases were found in No.7, 8, or 12. This result seems to be comparable with other reports, where No.7, 8, 9 and 12 nodes were most commonly involved in patients with skip metastasis^[6-10], and suggests that No.7, 8, and 12 to be the most important stations as well as N1^[4,5]. In our study, 3 out of 19 mol/L tumors had transverse metastases, which indicates that gastric lymph channels are multidirectional and form complex networks. The survival and depth of invasion in gastric cancer patients with skip metastases presented in this report suggest that if the preoperative examination diagnosed submucosal invasion, then a ELND should be conducted.

Results from these retrospective studies not only demonstrated the feasibility of SLN concept to gastric cancer but also provided useful information for intraoperative sentinel node mapping. That the perigastric nodal area close to the primary tumor is the first site of metastasis in 65.1% of gastric cancers in the present study indicates that the so-called shine-through effect should be considered in sentinel node mapping by radioisotope (RI) method^[11]. The high incidence of skip metastasis to N2-N3 nodes suggests that blind examination of the nodal area close to the primary tumor can not be a reliable method to detect the first metastasis^[6]. Visualization of dye is useful for real-time observation of lymphatic vessels, but it is difficult to detect multiple sentinel nodes and SLNs in the second or third compartments because vital dye tends to diffuse rapidly from nodal tissue. A probe-guided approach is essential to cover the widespread distribution of SLNs in gastric cancer and is very useful to detect residual SLNs in unexpected areas^[12]. Therefore, a combination of the dye and radioguided methods for systemic lymphatic mapping of gastric cancers may be recommended to improve the detection rate and diagnostic accuracy^[13,14].

It remains unclear why jumping metastases occurred in these cases. The following reasons could all play some role: (1) N1 involved nodes and occult metastases to N1 nodes may have been missed during the dissection and the routine histopathologic examination, which result in a false skip metastasis. The possible sentinel nodes detected by conventional means might not always be primary portions of any metastasis and true skip metastasis in gastric cancer may be rare^[10]; (2) There may have been some aberrant lymphatic drainage patterns in patients with gastric cancer, through which metastasis bypasses lymphatic vessels^[7,8,15]; (3) Direct lymphatic flows to distant affected nodes from primary gastric lesions have been found in SLN mapping intraoperatively^[16]; (4) Lymphatic flows to the N1 nodes may have been blocked with cancer tissue; (5) The microenvironment in the N1 nodes is sometimes unfit for the

development of metastasis^[17]. Free cancer cells may diffuse through regional nodes to distant nodes. In addition, the risk factors associated with skip nodal metastasis may include the stage, depth of invasion, macroscopic classification and pathological type of gastric cancer.

Most surgeons are skeptical about the application of the SLN concept for gastric cancer because of the high incidence of skip metastases and the random process occurring in nodal metastases. However, Kitagawa *et al.*^[18,19] have pointed out that the sentinel node for gastrointestinal cancer is not the node necessarily located anatomically closest to the primary lesion and is not necessarily the only one. In those cases with a jumping metastasis to N2-N3 nodes, sentinel nodes in the second or third compartment are considered to be functionally first compartments. Bilchik *et al.*^[20] proposed the potential for universal application of sentinel node mapping in solid tumors. Cases with one or two lymph node metastasis examined in these retrospective studies only occupy a little part of patients with gastric carcinoma in which one or more SLNs can be detected in every case theoretically. Then the results from these studies can not represent the real characteristic as to the occurrence of SLN in all gastric cancers. Actual data from sentinel node mapping for gastric cancers, rather than a retrospective analysis of metastatic patterns, are needed to explore the feasibility and validity of sentinel node biopsy in gastric cancer.

Abstract

AIM: To investigate the association between Chinese patients with autoimmune hepatitis (AIH), primary biliary cirrhosis (PBC) and the polymorphisms of cytotoxic T lymphocyte-associated antigen-4 (CTLA-4) gene promoter (-318) and exon 1 (+49).

METHODS: CTLA-4 promoter (-318 T/C) and exon1 (+49A/G) polymorphisms were genotyped via restriction fragment length polymorphism methods in 62 Chinese AIH patients, 77 Chinese PBC patients and 160 healthy controls.

RESULTS: We found a significant association in CTLA-4 gene exon1 49 A/G polymorphism between PBC patients and controls ($P = 0.006$) and the frequency of G alleles was significantly increased in comparison with controls ($P = 0.0046$, OR = 1.8). We also found the frequency of C alleles in promoter -318 was significantly increased in AIH patients compared with controls ($P = 0.02$, OR = 0.41). Although the genotype distribution of the CTLA-4 exon 1-promoter gene was not significantly different between AIH and PBC patients and controls, the occurrence of GG-CC was increased in two groups of patients (AIH: 32.3%, PBC: 37.7%, control: 22.5%).

CONCLUSION: Polymorphisms of CTLA-4 gene probably confer susceptibility to AIH and PBC in Chinese population.

INTRODUCTION

Autoimmune hepatitis (AIH) is an immune-mediated chronic inflammation of liver tissue. It is characterized by elevated serum transaminase levels, hypergammaglobulinemia, serum autoantibodies, and a good response to immunosuppressive

therapy^[1,2]. Although its etiology is unknown, genetic factors have been implicated to be involved in its pathogenesis. In previous studies human HLA DRB1*0301, DRB*0401 (in Caucasian) and DRB1*0405 (in Chinese) have been identified as independent determinants of susceptibility to AIH^[3,4]. In addition, tumor necrosis factor α (TNF- α) and complement C4 alleles have been associated with AIH^[5].

Primary biliary cirrhosis (PBC) is also an immune-mediated chronic disease in which progressive destruction of the bile ducts leads to fibrosis and cirrhosis. It exhibits specific autoantibodies and disorder of liver function. Twin and family studies suggest that there is a genetic component in PBC^[6,7]. The genetic typing of HLA class II and III alleles revealed a highly significant increase of HLA DRw8 and C4A-Q0 alleles in patients with PBC compared with controls, and the HLA DRB1*0801-DQA1*0401-DQB1*0402 haplotype was considered to represent a marker of disease progression^[8]. Polymorphism of the interleukin 1 (IL-1) and vitamin D receptor genes have been reported to be associated with PBC^[8,9]. These genes, however, are neither necessary nor sufficient to cause AIH or PBC.

Cytotoxic T lymphocyte antigen-4 (CTLA-4) is involved in the regulation of T cells and is a member of the same family of cell surface molecules as CD28^[10]. CTLA-4 antigen is only expressed on activated T cells, which binds to B7 molecules on antigen-presenting cells. CTLA-4-B7 binding delivers negative signals to T cells affecting T cell proliferation, cytokine production, and immune responses. Breakdown in the B7-CD28/CTLA-4 pathway could alter T-cell response and lead to autoimmune diseases^[11]. Many studies have shown that specific CTLA-4 gene polymorphisms confer susceptibility to several autoimmune diseases, such as Graves' disease, insulin-dependent diabetes mellitus^[12,13]. However, studies on the polymorphisms within CTLA-4 exon 1 (+49) and promoter (-318) gene in rheumatoid arthritis, multiple sclerosis and AIH have shown conflicting results in different ethnicities^[14-20].

In this study, we investigated whether the polymorphisms of CTLA-4 exon 1 (+49) and promoter (-318) genes were associated with susceptibility to AIH and PBC in the Chinese population.

MATERIALS AND METHODS

Patients and controls

Blood samples were obtained from 62 patients with autoimmune hepatitis (40 females; mean age: 50 years with range 16-76 years) and 77 patients with PBC (68 females; mean age: 51.34 years, range 32-79 years). AIH cases included 44 patients with antinuclear antibodies (titer >1:100), 15 patients with antismooth muscle antibodies, 4 patients with antibodies against soluble liver antigen/liver pancreas antigen, and 2 patients with anti-liver/kidney microsomal antibodies. The diagnosis of AIH was based on the revised criteria defined by the International Autoimmune Hepatitis Group. Patients with PBC were positive for antimitochondrial antibody (titer >1:1000) and type M2 antimitochondrial antibody, and had abnormal liver function test, in which 10 patients had liver biopsy. Control group consisted of 160 healthy blood donors (100 females).

DNA preparation

Blood samples from all subjects were obtained for DNA extraction. Blood was collected in EDTA tubes and DNA was extracted using the method of proteinase K treatment and phenol/chloroform extraction.

Figure 1 Gel electrophoresis of the products of BbvI restriction analysis.

Figure 2 Gel electrophoresis of the products of Tru9 I restriction analysis.

Polymorphism typing of CTLA-4 exon 1 (+49) and promoter (-318)

CTLA-4 exon 1 +49 polymorphism was defined using a polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) with BbvI restriction enzyme. PCR was carried out using a forward primer 5'-CCACGGCTTCCTTTCTCGTA-3' and a reverse primer 5'-AGTCTCACTCACCTTTGCAG-3'. Using a MJ PTC-200 Peltier thermal cycler samples were subjected to initial denaturation for 2 min at 95 °C, 40 cycles at 94 °C for 30 s, for denaturing, 45 s at 50 °C for annealing and 30 s at 72 °C for extension. A 327 bp fragment containing +49 A/G polymorphism in exon 1 of CTLA-4 was amplified. The substitution created a Bbv I restriction site in G allele. Amplified products were incubated at 65 °C for 2 h using 2 U of Bbv I per reaction. Digested products were electrophoresed on a 2.0% agarose

gel. Digested G allele yielded fragments of 244 bp and 84 bp, and an allele yielded a 327 bp fragment (Figure 1).

The CTLA-4 promoter polymorphism at position -318 was defined using PCR-RFLP and Tru9 I restriction enzyme. To amplify the target DNA in CTLA-4 promoter, PCR was performed with the forward primer 5'-AAATGAATTGGACTGGATGGT-3' and reverse primer 5'-TTACGAGAAAGGAAGCCGTG-3'. A247 bp fragment was amplified. The following conditions were applied: initial denaturation for 2 min at 95 °C, followed by 40 cycles (at 94 °C for 40 s, at 60 °C for 45 s, 60 °C, at 72 °C for 30 s), and a final extension for 2 min at 72 °C. PCR fragments with thymine at position -318 were cut into three fragments (21, 96 and 130 bp), whereas fragments with cytosine at the same position only had the restriction site at 21 bp (Figure 2).

Statistical analysis

Hardy-Weinberg equilibrium was tested by calculating the χ^2 for goodness of fit. Frequencies of the genotypes, alleles and phenotypes were analyzed by using chi-square test. Statistical significance was defined as $P < 0.05$. The odds ratio (OR) was calculated to measure the strength of the association observed. Calculation was made by using the Internet programs from www.myatt.demon.co.uk/epicalc.htm.

RESULTS

Samples from 62 cases of AIH, 77 cases of PBC and 160 control subjects were successfully genotyped for CTLA-4 exon 1 +49 and promoter -318 polymorphisms. Allelic variation at the +49 site of CTLA-4 exon 1 was significantly associated with PBC ($P = 0.006$). Compared with controls, the frequency of G alleles was increased in patients with PBC (PBC, 70.1%, controls, 56.6%, $P = 0.0046$, OR = 1.8). Although G allele was more frequent in AIH patients (62.9%), the distribution of alleles and phenotype at the +49 site were not associated with AIH (Table 1).

In CTLA-4 promoter (-318) polymorphisms between AIH, PBC patients and controls, CC genotypes occurred more frequently than TT genotypes was less frequently in patients than in controls, but the distribution of genotypes was not significantly different between AIH, PBC patients and controls ($P > 0.05$). Compared with controls, the frequency of C alleles was significantly increased (PBC, 93.6%, controls, 85.6%, $P = 0.02$, OR = 0.41) in patients with AIH (Table 2). The genotype distribution of CTLA-4 exon 1-promoter gene had no significant difference between PBC patients and controls ($\chi^2 = 13.02$, $P = 0.07$), but the frequency of GG-CC was increased in patients with PBC (PBC, 37.7%, controls, 22.5%). The frequency of GG-CC was also higher in AIH patients (32.3%), but the genotype distribution of CTLA-4 exon 1-promoter gene did not reach statistical

DISCUSSION

CTLA-4 is essentially a costimulatory receptor that controls activation of T cells. In contrast to CD28, CTLA-4 delivers negative signals to T cells. CTLA-4 gene is located on chromosome 2q33 and three CTLA-4 gene polymorphisms in exon 1 (adenine or guanine at position) and in promoter -318, and a microsatellite (AT) n marker at position 642 of the 3'-untranslated region of exon 3^[21,22]. The polymorphism, A/G variation at position +49 (+49*A/G) in the first exon of the gene leads to the change of threonine to alanine in the leader peptide. Recently, several independent studies reported a reduced inhibitory function of CTLA-4 in individuals with certain CTLA-4 genotypes^[12,23]. Kouki studied the CTLA-4 expression and T cell proliferative responses in patients with Graves' disease and healthy controls genotyped for +49*A/G. They found a correlation of +49*G/G genotype with reduced inhibitory function of CTLA-4, and suggested that this particular polymorphism was the actual disease-associated allele^[24]. Maurer also got the same result^[25]. A similar effect on CTLA-4 function has been suggested for the second polymorphism^[26]. Wang showed that -318T allele was associated with a higher promoter activity than -318C alleles. The presence of -318T alleles may thus contribute to up regulation of the expression of CTLA-4, and consequently represents one mechanism to inhibit exaggerated immune activity.

Studies on the CTLA-4 polymorphisms in autoimmune liver diseases have shown conflicting results on the relations between the polymorphisms of CTLA-4 exon 1 +49 and AIH^[18,20,27].

Agarwal indicated that CTLA-4 G allele at exon 1 +49 was more common in European Caucoid patients with type 1 AIH and represented a second susceptibility allele, and there might be synergy between HLA-DRB1*0301 and GG genotype in terms of disease risk. Djilali-Saiah found that the presence of +49GG predisposed to AIH type 1 in Canada children. However, Bittencourt found no associations between AIH (type 1 and type 2) and exon 1 CTLA-4 gene polymorphisms at position 49 in the Brazilian population.

In our study, we found that the frequency of -318C alleles was significantly increased in AIH patients compared with the control subjects, and GG-CC genotype occurred more frequently in CTLA-4 exon 1-promoter gene. It is therefore possible that the -318C allele and GG-CC genotype of CTLA-4 may contribute to susceptibility to Chinese patients with AIH. To our knowledge, this is the first report concerning an association of CTLA-4 promoter -318 polymorphism with AIH. In addition, we found a strong association between CTLA-4 exon 1 (+49) polymorphism and PBC, the GG genotype confers susceptibility to PBC in Chinese population. This result was coincident with Agarwal and colleague's conclusion^[19]. Likewise, the GG-CC genotype occurred more frequently compared with control subjects.

AIH and PBC are two autoimmune diseases of unknown pathogenesis. There is a general agreement that induction involves CD4⁺ T cells in the pathogenesis of AIH, but it is still not clear whether the liver damage was due to direct T cell cytotoxicity or involved autoantibodies, either through complement-mediated or antibody-dependent (ADCC) cytotoxic reactions^[28]. T cell responses would certainly participate in the pathogenesis of PBC, as judged by histochemical staining of tissue samples, and by analyzing T cell lines that proliferate in the presence of putative mitochondrial autoantigens^[29]. So we speculate that the single nucleotide polymorphism (SNP) of CTLA-4 (exon 1 +49 and promoter -318), and the interaction between these two SNPs may alter the inhibitory effect of CTLA-4 on T cells, and it may be an important factor in the pathogenesis of autoimmune hepatitis and primary biliary cirrhosis.

Besides CTLA-4 exon 1 (+49) and promoter (-318) polymorphisms, the CTLA-4 (AT) n microsatellite within the 3'-untranslated region of exon 3 was also a good candidate gene of autoimmune disease^[21]. Previous studies demonstrated that AT-rich tracks might contribute to mRNA instability^[30,31]. If the size of CTLA-4 AT tract limited the accumulation of CTLA-4 mRNA, down-regulation of CTLA-4 expression might account for the increase in the risk of an autoimmune disease. Several studies found that CTLA-4 (AT) n polymorphism was associated with Graves' disease and rheumatoid arthritis^[32,33]. Since it may be involved in mRNA stability, further studies are needed to determine the relations between CTLA-4 (AT) n polymorphism and autoimmune liver diseases.

In summary, this study showed a strong association between CTLA-4 exon 1 polymorphism (G-carrying genotypes) and PBC, and a significant association between CTLA-4 promoter -318C allele and AIH. In addition, we found that GG-CC genotype of CTLA-4 exon 1-promoter seemed to be susceptible to Chinese patients with AIH and PBC.

Abstract

AIM: To analyze the diagnostic and therapeutic features of extrahepatic bile duct carcinoma (EBDC) without jaundice.

METHODS: Between 1985 and 1999, 101 patients underwent surgery for EBDC in Xiangya Hospital. These patients were divided into two groups: 84 jaundiced patients and 17 non-jaundiced patients according to preoperative serum total bilirubin levels. The clinical manifestations, laboratory findings, location, pathology and surgical resectability of the tumors were compared between the two groups.

RESULTS: The laboratory parameters such as hemoglobin, serum albumin ALB, AKP, γ -GT, and sonography appearance were similar between the two groups, and there was no significant difference in tumor location, pathological type and resectability. However, the number of non-jaundiced patients associated with cholelithiasis was significantly greater than that of jaundiced patients ($P = 0.008$).

CONCLUSION: The presence of jaundice is not a reliable criterion for the prediction of the resectability and the extent of tumor progression in extrahepatic bile duct carcinoma. Decreased levels of blood hemoglobin and serum albumin, elevated levels of AKP and γ -GT, and /or abnormal sonography may be suggestive. Biopsy of a stenotic or thickened bile duct is strongly recommended for a correct diagnosis before the appearance of jaundice.

INTRODUCTION

Primary carcinoma of the extrahepatic bile duct is an uncommon malignant tumor, with reported incidence rate of about 0.01-0.46%. About 2% of patients who died of cancer were autopsied to have this disease^[1-4]. Jaundice is generally thought to be the most important factor in the diagnosis of this disease, but there are still few cases seeking doctors' consultation before jaundice appears^[5-9]. Those patients could be underdiagnosed or misdiagnosed because of atypical clinical symptoms. In this study, the diagnostic and therapeutic features of bile duct carcinoma without jaundice were compared with those with jaundice.

MATERIALS AND METHODS

From January 1984 to December 1999, two hundred and thirty-nine patients who were diagnosed as extrahepatic bile duct carcinoma were admitted to Xiangya Hospital. One hundred and one were operated and the diagnosis was confirmed by pathology. Patients with carcinomas of gallbladder, intrahepatic bile duct and ampulla of Vater were excluded from the study. The patients under studies consisted of 58 males and 43 females, aged 27 to 76 years (an average age of 61.7 years).

According to the level of serum total bilirubin (STB), the patients were divided into non-jaundiced group (17 patients, $STB \leq 2.0$ mg/dL at the time of diagnosis) and jaundiced group (84 patients, $STB > 2.0$ mg/dL). Clinical data included symptoms, laboratory results, imaging findings, pathological results, treatments and resectabilities.

Statistical analysis

The difference between the two groups was compared using chi-square analysis and Student's *t* test. $P < 0.05$ was considered statistically significant.

RESULTS

Symptoms and signs

Fifteen (88.2%) patients in the non-jaundiced group had anorexia or/and vomiting, abdominal pain compared with 63 (75.0%) in the jaundiced group. Eight (47.1%) patients in the non-jaundiced group and fifty-seven (67.9%) patients in the jaundiced group were found to show positive signs in liver, spleen or gallbladder enlargement. (Table 1).

Laboratory examination

The patients showed no difference in the levels of abnormal serum albumin, alkaline phosphates (AKP), γ -glutamyltranspeptidase (γ -GT), except STB level (Table 2).

Image examination

All patients in the non-jaundiced group underwent sonography. The results showed segmental stenosis of extrahepatic bile duct, thickening of the bile duct wall, and dilatation of intra- or extra-hepatic bile duct proximal to the stenosis. Sixty-seven out of 78 patients showed stenosis or neoplastic space-occupying lesions within the extrahepatic bile duct.

Operation findings

During the operation, 59 patients had neoplasms located in the upper extrahepatic bile duct while 8 in the middle and 34 in the lower. There was no difference with regard to localization of the tumor between the two groups.

Pathological features

All patients were proved to have adenocarcinoma. The patients were categorized into three different grades by the degree of differentiation. The results showed that there was no difference between the patients with or without jaundice.

Treatment

Radical resection, biliary bypass, external drainage or biopsy

were performed according to the surgical findings. There was no difference in tumor resectability between the two groups ($P>0.05$, Table 3).

Table 1 Symptoms and signs

Symptom	Non-jaundiced		Jaundiced		P value
	No.	%	No.	%	
Abdominal discomfort	15	88.2	63	75.0	>0.05
Liver or gallbladder palpable	8	47.1	57	67.9	>0.05
Cholelithiasis	11	64.7	26	31.0	<0.05 ^a

No significant difference was found between the two groups in the clinical symptoms and signs. In the non-jaundice group, the rate of combined cholelithiasis was obviously higher than in the jaundice group.

Table 2 Laboratory data

	Non-jaundiced		Jaundiced		P value
	No.	%	No.	%	
Descending of HB	8	47.1	45	53.6	>0.05
Ascending of AKP	8	72.7	56	86.2	>0.05
Ascending of γ -GT	4	66.7	28	93.3	>0.05
Descending of ALB	4	23.5	39	47.0	>0.05

No significant difference was found between the two groups in laboratory data.

Table 3 Tumor location, pathological type, treatment

	Non-jaundiced		Jaundiced		P value
	No.	%	No.	%	
Location					
Upper	11	64.7	48	57.1	>0.05
middle	0	0.0	8	9.6	
Lower	6	35.3	28	33.3	
Differential					
Good	6	35.3	48	57.1	>0.05
mild	8	47.1	27	32.1	
Poor	3	17.7	9	10.8	
Treatment					
Biopsy	3	17.7	8	9.5	>0.05
drainage	9	52.9	43	51.2	
By pass	0	0.0	1	1.2	
Radical	5	29.4	32	38.1	

No significant difference was found between the two groups in tumor locations, pathological types and treatment methods.

DISCUSSION

Jaundice is the early and main manifestation of extrahepatic bile duct carcinoma. It has been reported to be the initial sign in 83-97% of patients^[5-9]. However, there are few patients coming to hospital before the appearance of jaundice. In the present study 16.8% of the patients with EBDC were diagnosed before the presence of jaundice. These patients were likely to be neglected during busy outpatient service. We found that, there were still some clues to the diagnosis of bile duct carcinoma for these patients without jaundice. Some laboratory parameters, such as hemoglobin, serum albumin, AKP and γ -GT may be suggestive.

Sonography is almost the first tool for the diagnosis of extrahepatic bile duct carcinoma because it is non-invasive and less expensive. Ninety-five of the patients underwent sonography in our study, of whom 84 (88.4%) had positive findings, such as duct stenosis, thickness of the bile duct wall or space-occupying lesions within the duct. The results were in accordance with those documented in the literature^[10-12].

The relationship between choledocholithiasis and bile duct carcinoma is still unclear. As reported, 6-37% of extrahepatic bile duct carcinomas were associated with bile duct stones^[13]. In the present study the number of patients who suffered from choledocholithiasis in the non-jaundiced group was significantly higher than that in the jaundiced group ($P<0.05$). Two factors may contribute to this finding. First, for patients with bile duct stones, the clinical manifestations were so typical that the doctor would pay more attention to the biliary system. Second, during the operation for choledocholithiasis, we usually took the whole layer of bile duct wall for biopsy whenever there was stenosis, sclerosis or nodular change in the bile duct. Eight patients were diagnosed by this means and radical resection was performed.

It was reported that extrahepatic bile duct carcinoma without jaundice occurred in the early stage of the disease. The tumor was well differentiated and the resection rate was usually high^[8]. However, there was no difference between the two groups in our study. The radical resection rate was 29.4% in the non-jaundiced group and 38.1% in the jaundiced group ($P>0.05$). Liver and/or intrabdominal lymph node metastases were found in 12 patients without jaundice. We suggest that the presence of jaundice cannot be taken as the major criterion to predict the tumor resectability or the extent of tumor progression.

ACKNOWLEDGEMENT

We are grateful to Professor Zhong-Shu Yan for his assistance in preparing this manuscript.

Abstract

AIM: To evaluate the diagnosis, management principles and long-term results of congenital choledochal cysts in pregnancy.

METHODS: Three adult patients were diagnosed as choledochal cysts in pregnancy from 1986 to 1989 and their long-term results were evaluated.

RESULTS: The first patient had a Roux-en-Y cysto-jejunostomy with T-tube external drainage and died of septic shock and multi-organ failure 25 d after operation. In the second patient, 4 wk after percutaneous trans-choledochal cyst was drained externally with a catheter under US guidance, four weeks later the patient delivered vaginally, and had a cysto-jejunostomy 3 mo after delivery, and lived well without any complications for 15 years after operation. The third patient received Roux-en-Y cysto-jejunostomy after a vertex delivery by induced labor at 28 wk gestation, and demonstrated repetitively intermittent retrograde cholangitis within 10 years, and then died of well-differentiated congenital cholangioadenocarcinoma one month after re-operation with exploratory biopsy at the age of 36.

CONCLUSION: More conservative approaches such as external drainage of choledochal cyst should be considered for pregnant patients with high risk, complete excision of choledochal cyst during hepaticojejunostomy or modified hepaticojejunostomy is highly recommended at the optimal time.

INTRODUCTION

Choledochal cysts in pregnant women represent a diagnostic and therapeutic challenge to a broad spectrum of the medical profession. Not only the rare association, but also the clinical signs and symptoms are obscured by physiological changes that occur during pregnancy. As a result, diagnosis is often delayed until patients present with life-threatening complications. We

reported our experiences in managing three cases of choledochal cyst in pregnant patients.

MATERIALS AND METHODS

Three adult patients were diagnosed as choledochal cyst in pregnancy from 1986 to 1989 and their long-term results were studied retrospectively (Tables 1, 2).

RESULTS

A 27-year-old primigravida (patient No.1) at 20-wk gestation presented with jaundice, dark urine, nausea, anorexia, vomiting, intermittent upper abdominal pain, fever and weight loss during the past three months and was admitted to our hospital in February, 1986. Physical examination demonstrated a palpable 12 cm×10 cm mass in the upper right quadrant of the abdomen, a tender protuberant abdomen due to her pregnant state, and fullness in the right upper quadrant. Laboratory evaluation data are shown in Table 2. Ultrasound examination showed a cystic lesion, 12 cm×9 cm×10 cm at the right upper quadrant with a connection to tubular structure, and dilated intrahepatic ducts in both lobes of liver. Impressive diagnosis was gestation with a type IV choledochal cyst. Perioperative fluid therapy and transfusion were administered. A Roux-en-Y cysto-jejunostomy was performed for the choledochal cyst with T-tube external drainage in the proximal part of the cyst. Five hundred milliliter bile was drained from T-tube post-surgery and documented everyday. The patient was afebrile with normal vital signs, flatus was released on d 3 and 10 postoperation. Progressive nausea, vomiting, anorexia, occurred with aggravated jaundice, hypokalemia (2.8 mEq/L), serum electrolyte disturbance and hypoalbuminemia, and then developed to retrograde bile duct infection. The primigravida lost, her consciousness on day 19 postoperation. She was diagnosed as incipient (threatened) abortion, and died of septic shock and multi-organ failure on the 25th d postoperation.

Patient No.2 was a 23-year-old primigravida at 36-wk G1P1 gestation with choledochal cyst. She had intermittent upper abdominal pain, progressive nausea, anorexia, vomiting and abdominal tenderness in the upper right quadrant and epigastric burning during the past several weeks. She was admitted to our hospital in February 1987. Physical examination demonstrated a nontender protuberant abdomen due to her pregnant state, and fullness in the right upper quadrant. Her skin and sclera were slightly jaundiced. Sonographic evaluation of the right upper quadrant demonstrated an oval-shaped, 15 cm×16 cm×3 cm cystic mass arising from the portal hepatic separated from the gallbladder, and diffuse dilatation of intrahepatic left ductal system. Clinical diagnosis was a type IV choledochal cyst with gestation (G1P1). Laboratory evaluation data are shown in Table 2. Percutaneous trans-choledochal cyst operation was performed on the patient with a catheter placed for external drainage under the abdominal ultrasonography guidance. About 3000 mL sap green bile was excreted from the cyst, and then about 600 mL sap green bile was excreted daily. Gradually, her clinical conditions were improved and remained stable and her pregnancy progressed without problems. She delivered vaginally 4 wk later without

Table 1 Information in 3 patients diagnosed as choledochal cysts in pregnancy

Patients No.	Age(yr)	Type	Size (cm)	Chief Complaints	Treatment		Complication		Survival time (postoperation)	Prognosis (postoperation)
					Initial operation	Final operation	Early	Late		
1	27	IV	12×9×10	Abdominal pain Jaundice Abdominal mass	Roux-en-Y cystojejunostomy with T-tube external drainage		Septic shock and multi-organ failure		25 d	died
2	23	IV	15×16×3	Abdominal pain Jaundice	Plasement and fixation of a catheterization	Roux-en-Y cystojejunostomy			15 yr	survived
3	26	I	20×20×20	Jaundice Abdominal mass	Roux-en-Y cystojejunostomy	Exploratory biopsy	Retrograde cholangitis	Intermittent recurrence of Retrograde cholangitis Cholangioadenocarcinoma	10 yr	died

Table 2 Analysis of pre-operation laboratory values for 3 patients

Parameters	Normal range	Patient No. 1	Patient No. 2	Patient No. 3
Total bilirubin (μmol/L)	1.6-20.6	59	57	26
Direct bilirubin (μmol/L)	0-6.4	8.0	8.7	8.1

Platelet (10 ⁹ /L)	100-300	92	177	128

complications. As choledochal cyst was extensively attached to the surrounding tissues, it was dissected using cystojejunostomy 3 mo after delivery. Choledochal cyst was histologically confirmed. The patient was discharged from hospital 40 d postoperation and was well without any complications for 15 years.

Patient No.3, a 26-year-old multiparous woman at 28-wk gestation with choledochal cyst was admitted to our hospital in July 1989. Her chief complaint was jaundice and she had a palpable mass in the upper right quadrant of the abdomen during the past 20 d. On examination, the patient was afebrile with normal vital signs with skin and her sclera slightly jaundiced. She had a soft palpable 8 cm×10 cm mass in the upper right quadrant of the abdomen without tenderness. Laboratory evaluation data are shown in Table 2. Ultrasound examination showed a large cyst of 20 cm×20 cm×20 cm at the right upper quadrant connected to tubular structure. The patient gave a vertex delivery by induced labor at 28-wk gestation on the second day of admission. Following treatment with prophylactic antibiotics, the patient received Roux-en-Y cystojejunostomy on d 8 after delivery. The patient had 4 or 5 times of recurrence of intermittent retrograde cholangitis annually for 10 years, lasting for about 20 d each time, and relieved after a few days of conservative antibiotics. However, the patient was not re-operated due to the extensive adherence with surrounding tissues, and died of well differentiated congenital mucinous cholangioadenocarcinoma proved at the age of 36 years.

Figure 1 High-columnar or flat carcinoma cells with darkly stained nuclei and variation in size and shape arranged in irregular glandular pattern with intra- and extra-glandular mucin (hematoxylin and eosin, 40×10).

DISCUSSION

Choledochal cyst is a focal dilatation of the biliary tract. Although rare in adulthood, it is diagnosed more frequently with the advances in biliary imaging techniques^[1]. Of the numerous descriptions and classifications of choledochal cyst, the most practical is the classification proposed by Alonso-Lej 1 and modified by Todani^[1] in 1977 (Table 3). The major point of this classification is that the gallbladder is not usually distended and arises from a small cystic duct, not at the upper end of the cyst^[2].

Table 3 Todani modification of the Alonso-Lej, classification system of choledochal cyst

Type I	Fusiform dilation of the extrahepatic bile duct
Type II	Single saccular dilation or diverticulum of the extrahepatic bile duct
Type III	Dilation of the intraduodenal portion of the bile duct
Type IVa	Combined intra- and extrahepatic dilation of the bile duct
Type IVb	Multiple dilations of the extrahepatic bile duct
Type V	Isolated or diffuse intrahepatic biliary dilation (Caroli's disease when associated with hepatic fibrosis)

Since the first pathological description of a choledochal cyst by Vater in 1723 and the first clinical report by Douglas in 1852, the aetiology of this abnormality has been controversial^[3]. It is unclear whether choledochal cyst is congenital, or acquired. In 1936 Yotsuyanagi^[3] suggested that choledochal cysts arose from inequality in the vacuolization of the biliary tract in early embryonic life. The common channel theory proposed by Babbitt^[3] in 1969 is most widely accepted, which was based on an abnormality of the pancreaticobiliary junction and the formation of an abnormally long common channel (greater than 15 mm) outside the control of the sphincters of Boyden. This configuration permits pancreatic enzymes to reflux into the common bile duct. The pancreatic enzymes then lead to persistent inflammation, epithelial denudation, thinning of the bile duct wall and distal obstruction, then eventually cyst formation. The incidence of choledochal cysts was reported as 1 in 13 000 to 1 in 2 million patients^[3,4]. It affects females 4 times as often as males, and more common in Asians and presents mainly in infancy and childhood (60%)^[1]. It is necessary to classify the type of cysts and to recognize the presence of an abnormal pancreaticobiliary duct junction, visualization of both the biliary tree and pancreatic duct. Thus, direct cholangiography, especially ERCP, is beneficial. But intraoperative cholangiography is not sensitive enough to detect the presence of an abnormal pancreaticobiliary duct junction. Radiographic visualization of both the biliary tree and pancreatic duct prior to surgery is helpful for surgical manipulation and complete excision of the cyst^[5-8]. Other pathologic features of choledochal cysts include acute and chronic mucosal inflammation, mucosal dysplasia, and absence of smooth or elastic fibers. A true mucosal lining may be hard to find, or it is usually cuboidal or columnar and frequently ulcerated if it is present. The cyst wall varies from 1 to 10 mm in thickness. Mucus-producing glands are rarely seen. There is usually a large amount of fibrosis, some of which may be involved in luminal stenoses. The bile is often very thick, and sometimes less pigmented than normal. Biliary calculi are uncommon. Pathologic complications include biliary obstruction, cholangitis, hepatic abscess, rupture, or development of cancer. Cholelithiasis due to choledochal cysts is unusual^[2,9].

Clinical manifestations are nonspecific and variable. The most common symptoms are abdominal pain and jaundice. If untreated, the condition may be fatal due to ascending cholangitis, biliary cirrhosis or diffuse peritonitis following

rupture of the cyst. Malignancy might also develop in the cyst and occur in pregnant women^[10]. Choledochal cyst in pregnancy is rare but poses a threat to both the mother and fetus. The maternal complications include cholangitis, pancreatitis, peritonitis and even malignancy. The fetal complications include fetal loss and preterm labor. Most reported cases were diagnosed when women presented with symptoms. It has been suggested that pregnancy may exacerbate the symptoms due to hormonal effect, compression by the gravid uterus and increase in intraabdominal pressure during pregnancy and postpartum. The cyst might be asymptomatic during the first pregnancy^[11,12], as demonstrated in our third patient. Asymptomatic cysts discovered on routine US could be observed with serial US examinations^[11].

Diagnosis of choledochal cysts during pregnancy is difficult. Radiologic imaging, ultrasound, computed tomography, cholangiography and biliary scintigraphy, could clinch the diagnosis^[1,12-15]. Although ultrasonography is a common useful investigation, difficulty may arise during pregnancy due to distortion of the normal abdominal anatomy and gravid uterus. Furthermore, ultrasound examination cannot demonstrate anatomic details of the biliary tree. Due to exposure of the fetus to ionizing radiation, contrast and ionizing imagings, such as CT or ERCP, should be avoided in pregnancy^[11,12,16]. Magnetic resonance imaging (MRI) could provide clear visualization of the relations between the choledochal cyst and biliary tree and of the extent and size of the choledochal cyst. Therefore, MRI is the investigation of choice in doubtful cases^[12,17]. To improve the management of this potentially serious condition in pregnancy, both clinicians and radiologists should be aware of this possibility in women with a right upper quadrant mass.

Concerning the optimal time of treatment, conservative management is commonly adopted during pregnancy. Once the diagnosis has been established, surgery is the only option for treatment^[11,12]. Surgical time is critical during pregnancy and the operative risk to the fetus and mother has to be balanced against the likelihood of cyst-related complications^[11,12]. Any patient who presents with a symptomatic or rapidly enlarging choledochal cyst or with cyst-related complications during pregnancy should undergo urgent treatment. Unfortunately, surgery during pregnancy has been associated with high fetal and maternal morbidity and mortality rate^[1,11,12,15]. Therefore, other more conservative approaches might have to be adopted until surgery could be performed under optimal conditions. Percutaneous cyst decompression might be done to relieve symptoms of pain and jaundice^[1,11,12,15,16]. In addition, antibiotics should be administered for treatment of cholangitis or for long-term prophylaxis, and the need for subsequent definitive cyst surgery should not be obviated^[11,12]. An operation should ideally be performed in the second trimester when the risk of surgery and anesthesia is lowest. When symptoms occur in the first trimester, surgery should be postponed unless the life of the mother is in danger, while in the third trimester, early cesarean section should be performed when amniocentesis indicates that the fetus is sufficiently mature. At the same time, a temporizing or definitive cyst operation could be undertaken as necessary^[1,11,12]. Definitive surgery depends on the cyst type and associated hepatobiliary pathology. Definitive surgical excision of the cyst can avoid postpartum complication and non-cyst excision may induce long-term complications.

Early reports suggested that internal or external drainage of a choledochal cyst by choledochocystojejunostomy or T-tube choledochocystostomy was a satisfactory treatment, but with a longer follow-up it has become clear that complications such as suppurative cholangitis, lithiasis, pancreatitis, secondary biliary cirrhosis, portal hypertension and intrahepatic abscess occurred in up to 40 percent of cases^[3,4,9,15]. This is similar as our results. The increased risk of bile duct carcinoma in

choledochal cysts has been well characterized^[3,4,9,10,14,15]. The reported incidence of biliary tract carcinoma in choledochal cysts varied from 2.5% to 17.5%, significantly higher than that found in the general population, which was from 0.01% to 0.05%^[3,4,9,10,14,15]. The incidence of cancer in patients with a choledochal cyst and in those undergone enteric drainage without cyst excision was much higher than that of carcinoma of the bile ducts in the general population. The age-related incidence of cyst-associated cancer has been shown to increase from 0.7 % in the first decade of life to 14.3 % after 20 years of age. It means the favorable outcome in congenital choledochal cyst patients was due to earlier diagnosis^[3,4,9,10,14,15].

Kasai *et al.*^[3] reported firstly the increased incidence of carcinoma in choledochal cysts and advocated primary cyst excision. The advances in diagnostic and therapeutic procedures and increased operative experience have lowered the mortality rate to 0-7%^[3,4,9,10,14,15]. Roux-en-Y choledochojunostomy has replaced choledochoduodenostomy as the preferred operative procedure because of the high morbidity rate of cholangitis and the frequent need for reoperation later^[3,4,9,15].

Excision of types I, II and IV choledochal cysts is now widely accepted because of the lower incidence of postoperative complications. In contrast to cyst enterostomy, cyst excision with hepaticojunostomy had satisfactory results. Although the occurrence of intrahepatic cholangiocarcinoma after the excision of a type I cyst has been reported^[18,19], but cyst excision is the primary choice of treatment for type I cysts. Type III cysts require adequate drainage and generally can be managed by endoscopic sphincterotomy and cannot be undertaken, operative sphincteroplasty with transduodenal cyst excision might be attempted^[5]. Sphincteroplasty either endoscopically or surgically has been found to be satisfactory^[20]. Treatment for type IV cysts is still controversial. Either excision of the extrahepatic cyst alone^[5] or total cyst excision including hepatectomy^[21] has been recommended. Concerning type V cysts, some authors recommended hepatic resection for unilobar Caroli's disease^[1].

Complete excision of the extrahepatic bile duct from the hepatic hilum to the pancreaticobiliary duct junction has become the choice of treatment for types I and IV cysts^[3-5,9,11,19,21-23]. However, it should be mentioned that since complete excision seems to be difficult in some patients, pancreaticoduodenectomy or hepatic resection should then be considered. In such cases, the distal choledochus is resected just above the pancreaticobiliary duct junction with the aid of preoperative ERCP and intraoperative US to avoid injuring the pancreatic duct. In the hepatic hilum, the hepatic duct must be resected at the hilum, and hepaticojunostomy with a wide opening by plastic of both the hepatic ducts is necessary.

The reason why the three patients turned out quite different was their different clinical conditions. Our first Patient's situation was not quite good in peri-operation, she had a progressive nausea, vomiting, anorexia, fever, weight loss, and anemia with skin and her sclera slightly jaundiced, hypoalbuminemia, as well as disturbed blood electrolytes. Although the patient received fluid therapy and transfusion in peri-operation, the volume of blood was not enough to improve her clinical conditions within a short period of time, such as anemia, hypoalbuminemia. Gentamicin sulfate 240 000 iu one time per day could not prevent occurrence of retrograde bile duct infection, and the patient died of septic shock and multi-organ failure on day 25 postoperation.

Choledochal cyst in our No. 2 patient was drained externally with a catheter under the abdominal ultrasonography guidance, and she delivered safely. As the choledochal cyst was extensively infused with surrounding tissues, a cysto-jejunostomy was performed 3 mo after delivery. The patient's general condition was good. In our study, the No.3 patient developed a malignant tumor, because she did not receive re-operation for complete cyst excision, hepatojejunostomy or modified hepatojejunostomy

for treatment of repeated occurrence of intermittent retrograde cholangitis, which could be treated or avoided by early diagnosis and early complete cyst excision^[3,4,9,10,14,15], which are very important for the treatment of congenital choledochal cyst patients. Although cyst excision did not completely eliminate the risk of intrahepatic cholangiocarcinoma after the excision of a type I cyst^[3-5,9-11,14,15,18-22], but it significantly decreased the incidence of bile duct carcinoma. Thus, laparotomy during pregnancy should be avoided if possible and non-cyst excision cases should be explored to remove the cyst completely in the optimal surgical time.

Although choledochal cysts rarely occur in pregnancy, clinicians need to be aware of the condition. Inappropriate therapy may be catastrophic for both mother and child. This is why we recommend that patients should be admitted to a specialized hospital once the diagnosis is established. Complete excision of choledochal cyst with Roux-en-Y hepaticojunostomy or modified Roux-en-Y hepaticojunostomy is the choice of treatment for types I, II and IV choledochal cysts in non-pregnant adult patients; whereas in pregnancy, a more conservative approach should be adopted until the time when the surgical risk is lowest. Percutaneous external drainage of choledochal cyst under the abdominal ultrasonography guidance is indicated, if a complication of cystic rupture occurs. Complete excision of choledochal cyst with hepaticojunostomy or modified hepaticojunostomy is helpful in avoiding late complications such as retrograde cholangitis, biliary tract carcinoma, and is the most ideal choice of treatment for types I, II, IV choledochal cysts in pregnant adult patients, and is therefore highly recommended.

Abstract

AIM: Preoperative intra-arterial infusion chemotherapy could increase the radical resection rate of advanced gastric cancer, but its effect on the long-term survival has not been assessed. This study was designed to evaluate the clinical significance of preoperative intra-arterial infusion chemotherapy for advanced gastric cancer.

METHODS: Clinicopathological data of 91 patients who underwent curative resection for advanced gastric cancer were collected. Among them, 37 patients undertaken preoperative intra-arterial infusion chemotherapy were used as the interventional chemotherapy group, and the remaining 54 patients as the control group. Eleven factors including clinicopathological variables, treatment procedures and molecular biological makers that might contribute to the long-term survival rate were analyzed using Cox multivariate regression analysis.

RESULTS: The 5-year survival rate was 52.5% and 39.8%, respectively, for the interventional group and the control group ($P < 0.05$). Cox multivariate regression analysis revealed that the TNM stage ($P < 0.001$), preoperative intra-arterial infusion chemotherapy ($P = 0.029$) and growth pattern ($P = 0.042$) were the independent factors for the long-term survival of patients with advanced gastric cancer.

CONCLUSION: Preoperative intra-arterial infusion chemotherapy plays an important role in improving the prognosis of advanced gastric cancer.

INTRODUCTION

Gastric cancer is one of the most common cancers in China. Despite recent advances in experimental researches, early diagnosis and surgical techniques, the outcome of patients with gastric carcinoma is still far from satisfaction. Surgery remains the mainstay of potentially curative treatment, but the survival rates of patients with advanced gastric cancer are poor. A number of studies have investigated whether intravenous chemotherapy after a resection could improve the survival rate,

but the results were different and disputable^[1,2]. Preoperative regional intra-arterial infusion chemotherapy could increase the radical resection rate of advanced gastric cancer. However, there are few reports about the influence of preoperative intra-arterial chemotherapy on the long-term survival of patients with advanced gastric carcinomas after curative resections. In the current study, we analyzed retrospectively the clinicopathologic data of 91 patients with advanced gastric cancers undergone curative surgeries during recent years. To investigate the effect of preoperative intra-arterial chemotherapy on the prognosis of advanced gastric cancer, the Cox model of proportional hazards was utilized to identify the independent variables affecting the long-term survival of patients with gastric carcinomas.

MATERIALS AND METHODS

Clinicopathologic materials

The study comprised 91 patients who underwent curative resection for advanced gastric cancer from June 1984 to June 1992 at our hospital. All patients received follow-ups for 3 to 220 mo (mean time 57.1 ± 23.8 mo) and their clinicopathologic data were well-provided. There were 69 males and 22 females, their ages ranged from 25 to 73 years with a mean age of 54.9 ± 12.9 years. The tumor staging for each gastric cancer was evaluated according to the new TNM classification system of UICC^[3], and there were 27 patients with stage II, 49 with stage III and 15 with stage IV. Of the 91 cases, 2 had well-differentiated adenocarcinomas, 48 had moderately differentiated adenocarcinomas and 41 had poorly differentiated adenocarcinomas. Thirty-one were negative for lymphatic vessel invasions and 60 were positive for lymphatic vessel invasions. For venous vessel invasion of tumor, 78 cases were negative and 13 were positive. The tumor growth pattern was defined according to Ming classification. There were 40 patients with expansive types and 51 with infiltrative types. Expressions of CD44 splice variants v6(CD44V6) and E-cadherin(E-CD) and proliferating cell nuclear antigen(PCNA) in all the 91 resected gastric carcinomatous tissue specimens were detected by streptavidin-peroxidase immunohistochemistry. Of the patients, 37 patients undergone preoperative regional intra-arterial infusion chemotherapy were used as the interventional chemotherapy group and the remaining 54 patients as the control group. All the patients received systemic chemotherapy after surgeries. The clinicopathologic parameters of the two groups were analyzed and compared.

Preoperative intra-arterial infusion chemotherapy

Preoperative intra-arterial infusion chemotherapy was performed via transfemoral artery route using the Seldinger's approach before surgery. Celiac axis angiogram was initially carried out to document the visceral arterial anatomy and the arterial supply of tumor, and the digital subtraction technique was utilized in the study. According to the results of angiogram, the main blood supplying arteries of gastric cancer were detected and superselective catheterization of these arteries was performed. Then, chemotherapy drugs were administered via the placed catheter. Protocols of chemotherapy were FAP (5-FU 1.0 g+ADM 30-50 mg+DDP 40-60 mg) or FMP (5-FU 1.0 g+MMC 8-10 mg+DDP 40-60 mg). Preoperative interventional

chemotherapy was performed one or two times for each patient, and the interval time ranged from 10 to 14 d. Surgery was carried out two weeks after interventional chemotherapy. Of the 37 patients who underwent interventional chemotherapy, 31 received chemotherapy one time and 6 received two times.

Statistical analysis

The eleven variables observed including gender, age, preoperative intra-arterial infusion chemotherapy, TNM stage classification, differentiation grade, growth pattern, lymphatic vessel and venous vessel invasion, expressions of CD44V6 and E-CD, PCNA labeling index (PCNA LI), were stored in a computer, and analyses were performed using the SPSS 9.0 for Windows. Survival rates were calculated using life table method and the differences among the groups of patients were measured by Log rank test. Univariate analysis was performed first, and the variables found by univariate analysis significantly associated with survival rates were subjected to multivariate analyses using the Cox model of proportional hazards. $P < 0.05$ was considered statistically significant.

RESULTS

Comparison of pathological parameters between two groups

The differences of pathological parameters were not significant between two groups ($P > 0.05$, Table 1).

Comparison of immunohistochemistry results between two groups

The expressions of CD44V6 and E-CD and PCNA were not significantly different between two groups ($P > 0.05$, Table 2).

Comparison of postoperative complications and survival rates between two groups

No death occurred due to surgery in this study. One wound infection and 1 pneumonic infection were found in the interventional chemotherapy group, whereas 2 pneumonic infections and 1 abdominal cavity infection occurred in the control group after surgery. The incidence of postoperative complications was not significantly different between two groups ($P > 0.05$). The 5-year survival rate of the interventional chemotherapy group and the control group was 52.5% and 39.8%, respectively, and the difference between the two groups was significant ($P < 0.05$).

Univariate and multivariate analyses of prognostic factors

The results of univariate analysis demonstrated that the factors including gender, age and tumor cellular differentiation grade

were not associated with postoperative survival rate ($P > 0.05$). The variables significantly correlated with survival rates were TNM stage, growth pattern of tumor, lymphatic vessel and venous vessel invasion, intra-arterial infusion chemotherapy, expressions of CD44V6 and E-CD, PCNA LI ($P < 0.05$). These factors were subjected to multivariate analyses using the Cox model of proportional hazards. These analyses identified three independent prognostic variables which were TNM stage, preoperative interventional chemotherapy and growth pattern of tumor, according to influence strength (Table 3). The survival predicting equation ($\chi^2 = 37.63$, $P < 0.001$) was obtained, it suggested the foundation of the equation be reasonable.

Table 3 Independent prognostic variables identified by Cox proportional hazard model

Variables	SE	Wald	df	Sig	R	Exp(B)
TNM stage	0.1220	16.3113	1	0.0001	0.1753	1.6304
Interventional chemotherapy	0.2501	4.7491	1	0.0285	0.0681	1.6981
Growth pattern	0.2607	4.0105	1	0.0417	0.0711	1.6953

DISCUSSION

Preoperative chemotherapy was initiated in the 1980s as an auxiliary therapy for malignant neoplasms^[4]. It has been considered that preoperative chemotherapy could reduce activities of tumor cells, contract volumes of tumors, decrease iatrogenic diffusion of tumor cells during surgery, and improve curative resections for tumors. It was reported that serum concentration of chemotherapy drugs in abdominal organs by local intra-arterial infusion was nearly ten times as high as by systemic chemotherapy^[5]. Kosaka *et al.*^[6] investigated the therapeutic efficacy of intra-arterial infusion chemotherapy for advanced gastric cancer, and found that the response rate of tumors to intra-arterial infusion chemotherapy was significantly higher than that to systemic infusion chemotherapy. Liu^[7] reported that the overall response rate to preoperative interventional chemotherapy was 72.8% for gastric carcinomas, and it was revealed that preoperative intra-arterial infusion chemotherapy exerted its effect by introducing apoptosis of cancer cells, restraining tumor cell proliferation and promoting pathological necrosis of tumors^[8]. Tao *et al.* also demonstrated that preoperative regional artery chemotherapy showed inhibitory actions on growth of gastric cancer cells mainly through inhibiting proliferation and inducing the apoptosis of tumor cells^[9]. Our previous study also showed that preoperative intra-arterial infusion chemotherapy could dramatically improve the rate of radical resection for gastric cancer. However, the

Table 1 Comparison of pathological parameters between two groups

Groups	TNM stage			Differentiation grade			Growth pattern		Lymphatic vessel invasion		Venous vessel invasion	
	II	III	IV	Well	Moderately	Poorly	Expensiv	Infiltrative	Negative	Positive	Negative	Positive
Intervetional	11	12	6	1	19	17	15	22	14	23	32	5
Control	16	29	9	1	29	24	25	29	17	37	46	8
	$P > 0.05$			$P > 0.05$			$P > 0.05$		$P > 0.05$		$P > 0.05$	

Table 2 Comparison of immunohistochemistry results between two groups

Groups	Expression of CD44V6				Expression of E-CD				PCNA LI (%)
	-	+	++	+++	-	+	++	+++	
Interventional	8	14	5	10	11	13	9	4	63.8±17.6
Control	16	12	8	18	17	18	13	6	64.7±18.0
	$P > 0.05$				$P > 0.05$				$P > 0.05$

influence of preoperative intra-arterial infusion chemotherapy on the prognosis of patients with gastric cancer has been controversial. Masuyama *et al.*^[10] concluded that preoperative intra-arterial infusion chemotherapy might prevent local and lymph node metastases, but it could not improve the survival of gastric cancer patients. Whereas Shchepotin *et al.*^[11] reported superselective intra-arterial chemotherapy conferred a highly significant survival advantage compared to control or systemic intravenous chemotherapy for advanced nonresectable gastric cancer. This study demonstrated that the 5-year survival rate of preoperative interventional chemotherapy group was significantly higher than that of the control group, and there was no statistical difference between the incidences of postoperative complications of the two groups. It is suggested that preoperative intra-arterial infusion chemotherapy is both effective and safe for patients with advanced gastric cancer.

Among the prognostic factors of gastric cancer, the influence of clinical modalities on the prognosis of patients has been the focus of studies on gastric cancer. It has been proved that the most important prognostic variable for gastric cancer is curative resection of tumor^[12]. In the current study, all patients underwent curative resections of tumors. Furthermore, the clinicopathologic parameters of the two groups were not significantly different. This makes it possible to evaluate the effect of other therapeutic modalities on the prognosis of patients with advanced gastric cancers. As is shown in this article, among the seven variables significantly associated with the survival of patients with gastric cancer by univariate analysis, TNM stage was the most important independent prognostic factor by multivariate analyses using the Cox model of proportional hazards. It was consistent with previous reports^[13]. The results of our study also revealed that preoperative intra-arterial infusion chemotherapy and growth pattern of tumors were the independent prognostic variables affecting long-term survival of gastric cancer patients, suggesting that preoperative intra-arterial infusion chemotherapy is of great importance in improving the prognosis of patients with advanced gastric cancers after undergoing curative resections.

In summary, the results of the present study revealed that preoperative intra-arterial infusion chemotherapy was one of the independent prognostic variables of patients with advanced gastric cancer. Therefore, preoperative intra-arterial infusion chemotherapy in combination with curative resection would have important clinical values in improving the prognosis of patients with advanced gastric carcinoma.

Abstract

AIM: To study the plasma des- γ -carboxy protein C activity, antigen and prothrombin levels in patients with liver diseases and their clinical significance.

METHODS: Plasma protein C activity (PC:C) was detected by chromogenic assay and antigen (PC:Ag) and des- γ -carboxy protein C (DCPC) were detected by ELISA. Total prothrombin and unabsorbed prothrombin in plasma were detected by ecarin chromogenic assay.

RESULTS: Compared with the control, the levels of PC:C and PC:Ag in patients with hepatocellular carcinoma (HCC) and liver cirrhosis (LC) were lower (PC:C: $104.65 \pm 23.0\%$, $62.50 \pm 24.89\%$, $56.75 \pm 20.14\%$, PC:Ag: $5.31 \pm 1.63 \mu\text{g/mL}$, $2.28 \pm 1.15 \mu\text{g/mL}$, $2.43 \pm 0.79 \mu\text{g/mL}$, $P < 0.05$). The levels of PC:Ag in patients with acute viral hepatitis (AVH) also was lower ($2.98 \pm 0.91 \mu\text{g/mL}$, $P < 0.01$), but PC:C was close to the control ($93.76 \pm 30.49\%$, $P > 0.05$). The levels of DCPC in patients with HCC were remarkably higher ($0.69 \pm 0.29 \mu\text{g/mL}$, $1.18 \pm 0.63 \mu\text{g/mL}$, $0.45 \pm 0.21 \mu\text{g/mL}$, $P < 0.05$) and its average was up to 50% of total PC:Ag. But those of DCPC in patients with AVH were not significantly different from the control. The levels of total prothrombin were lower in patients with LC, but higher in patients with HCC. The levels of unabsorbed prothrombin were predominantly higher than those of other groups.

CONCLUSION: PC:C and PC:Ag in patients with liver diseases (except PC:C in AVH) were lower. The total prothrombin was lower in patients with LC. The higher level of unabsorbed prothrombin may be used as a scanning marker for HCC. DCPC may be used as a complementary marker in the diagnosis of HCC.

INTRODUCTION

Protein C is a plasma glycoprotein of M_r 62 000 and is synthesized and degraded in the liver. There is 2-6 mg/L PC of plasma in healthy person, with about 72-139% biological activity. No difference in the content of protein C between males and females was found, but protein C shows an increased trend towards increasing age (with an average increase of 4% every 10 years). Thrombin formed during coagulation is responsible for conversion of protein C to activated protein C (APC). This activation takes place on the surface of endothelial cells and monocytes by compound thrombin with thrombomodulin^[1]. Because protein C is a vitamin K-dependent plasma protein, it is highly homologous in structure to factors X, IX, VII and prothrombin. Many studies have demonstrated that there are changes of factors X, IX, VII and prothrombin in patients with liver diseases, and des- γ -carboxy (abnormal) prothrombin is a useful tumor marker in the diagnosis of hepatocellular carcinoma^[2-4]. But up to now, few reports are available about the association between PC and liver diseases. Therefore, in the present study we not only reported the changes of PC and prothrombin in liver diseases, but also explored the relationship between des- γ -carboxy protein C (DCPC) and HCC.

MATERIALS AND METHODS

Clinical data

Fifty-three patients (33 males and 20 females, aged 20-81 years) were included in this study. Of them, 18 patients with hepatocellular carcinoma (HCC), 20 with liver cirrhosis (LC), 15 with acute viral hepatitis (AVH). They were from The Second Affiliated Hospital of Guangzhou Medical College and the Xiangya Hospital of Central South University. HCC and LC were diagnosed by clinical, pathological and ultrasonic examinations. AVH was diagnosed by clinical and immunological/RT-PCR examinations. Twenty healthy volunteers (10 males and 10 females, aged 25-65 years) were enrolled as the control group.

Materials

Blood sampling and preparation of plasma (for PC:C, PC:Ag assay) were as follows. Blood was drawn into 0.13 mol/L sodium citrate (9/1, v/v), plasma (for DCPC, prothrombin assay) was obtained by drawing blood (9vol) into 0.1 mol/L sodium oxalate (9/1, 1v/v), and centrifugation at 4 000 r/min for 10 min. All were snap frozen and stored at -40°C .

PC activity (PC:C) and PC antigen (PC:Ag) kits were purchased from Shanghai Sun Biotech Company. Vials containing 50 U of ecarin were provided by Sigma Company. Chromogenic substance S2238 was obtained from American Diagnostica Inc. (ADI). BaCl₂, Tris, and others were of analytical grade and purchased from Shanghai Reagent Factory. ELX800 enzyme-linked immunosorbent detector was from America BIO-Tek Instruments Inc.

Methods

PC:C assay PC:C was detected by chromogenic assay (SH Sun Bio CO kits). Excessive activator was put into the diluted human plasma, PC was activate and convert it into activated protein C

(APC). Then chromozym APC was hydrolyzed, and PNA was released. PNA levels are determined by measuring the sample solution absorbances at 405 nm and comparing against those of standard curves generated using a PC:C. The assay procedures performed according to the instructions of the manufacturer.

PC:Ag assay PC:Ag was determined by ELISA (SH Sun Bio CO. kits). Murine PC antibody was used as capture antibody and an enzyme-linked antibody fragment that specifically recognizes bound hPC as detection antibody. After plasma PC bound to capture antibody and detection antibody, the substrate was hydrolyzed by enzyme and chromagenic reaction occurred. The sample absorbance at 492 nm was proportional to the concentrations of plasma PC. The assay procedures were performed according to the manufacturer's instructions.

DCPC assay A total of 40 μ L of 1 mol/L BaCl₂ was added into 500 μ L of normal reference plasma or pending measured plasma. The mixture was surged for 30 min at 4 °C. After centrifuged for 5 min, collect the supernatant was collected. Then the supernatant was absorbed by barium salt again and collected. The level of PC:Ag in the supernatant was measured by ELISA.

Prothrombin assay Ecarin could activate γ -carboxylated and des- γ -carboxylated prothrombin into thrombin and then thrombin amidolyse chromozym P. The absorbance at 405 nm was proportional to the concentration of γ -carboxylated and des- γ -carboxylated Prothrombin. Levels of prothrombin in plasma reflected the total prothrombin and those in plasma absorbed by BaCl₂ reflect the unabsorbed prothrombin.

Statistical analysis

Results were expressed as mean \pm SD. One way analysis of variance and Newman-keuls test were used for comparisons of the mean value in various groups. *P* values less than 0.05 was considered statistically significant.

RESULTS

PC:C and PC:Ag in liver diseases

Compared with the control, the levels of PC:C and PC:Ag in patients with hepatocellular carcinoma (HCC) and liver cirrhosis were lower (*P*<0.05). PC:Ag in acute viral hepatitis (AVH) also was lower, but PC:C was close to the control (*P*>0.05) (Table 1).

Table 1 The levels of PC:C and PC:Ag in patients with liver diseases (mean \pm SD)

	<i>n</i>	PC:C (%)	PC:Ag (μ g/mL)
Control	20	104.65 \pm 23.0	5.31 \pm 1.63
Hepatocellular carcinoma	18	62.50 \pm 24.89 ^a	2.28 \pm 1.15 ^b
Liver cirrhosis	20	56.75 \pm 20.14 ^a	2.43 \pm 0.79 ^b
Acute viral hepatitis	15	93.76 \pm 30.49	2.98 \pm 0.91 ^b

^a*P*<0.05, ^b*P*<0.01 vs control group.

DCPC in liver diseases

As shown in Table 2, the difference of DCPC between acute viral hepatitis group and control group was not statistically significant (*P*<0.01). But DCPC in patients with HCC was remarkably higher than those in patients with acute viral hepatitis and the control (*P*<0.01).

Prothrombin in liver diseases

In contrast to the control, the levels of total prothrombin was lower in patients with liver cirrhosis (*P*<0.05). There was no significant difference in plasma prothrombin between acute viral hepatitis and control groups (*P*>0.10). But the level of total prothrombin in patients with HCC was markedly higher than that in other groups (*P*<0.01). The levels of unabsorbed

prothrombin in patients with HCC were predominantly higher than those in the other groups (*P*<0.01).

Table 2 The levels of DCPC in patients with liver diseases (mean \pm SD)

	<i>n</i>	Total PC:Ag (μ g/mL)	DCPC:Ag (μ g/mL)	DCPC:Ag Total PC:Ag
Control	15	5.23 \pm 1.95	0.69 \pm 0.29	13.19%
Hepatocellular carcinoma	15	2.33 \pm 1.21	1.18 \pm 0.63 ^b	50.64% ^b
Acute viral hepatitis	15	2.98 \pm 0.91	0.45 \pm 0.21	15.10%

^b*P*<0.01 vs control and acute viral hepatitis groups.

Table 3 The levels of prothrombin in patients with liver diseases (mean \pm SD)

	<i>n</i>	Total prothrombin (%)	Unabsorbed prothrombin (%)
Control	20	101.99 \pm 12.29	0.30 \pm 0.18
Hepatocellular carcinoma	18	220.61 \pm 67.95 ^b	2.87 \pm 0.89 ^b
Liver cirrhosis	10	85.33 \pm 6.99 ^a	0.95 \pm 0.45 ^a
Acute viral hepatitis	15	99.05 \pm 14.97	1.09 \pm 0.36 ^a

^a*P*<0.05, ^b*P*<0.01 vs control groups.

DISCUSSION

Vitamin K-dependent zymogens, prothrombin, factor VII, IX, protein C and protein S are synthesized in the liver. It is understandable that the liver diseases are associated with thrombosis and/or hemorrhage. In the present investigation, we observed that the levels of total prothrombin decreased in patients with liver cirrhosis and increased in patients with HCC. The results are consistent with previous reports^[5].

Prior to secretion into plasma, all the vitamin K-dependent proteins undergo post-translational modifications by a vitamin K-dependent carboxylase that converts several specific glutamic acid residues to γ -carboxyglutamic acid (Gla). Gla residues are located in N-terminal of the mature proteins and contribute to the ability of these proteins to bind to Ca²⁺ and offer metal ions such as Ba²⁺, etc. Ca²⁺ binding induces conformational changes leading to expression of membrane-binding phospholipid, which is a key step to bring about biological activities. Therefore, des- γ -carboxylated proteins can not bind to divalent ions and lose their procoagulant or anticoagulant activities. Our data showed that after plasma was absorbed by barium salt, the levels of unabsorbed prothrombin from plasma of patients with HCC was very high and lower in patients with acute viral hepatitis and liver cirrhosis, and less in healthy volunteers. This fact further suggested that high levels of unabsorbed prothrombin in plasma could be used a scanning marker of HCC. It is due to unabsorbed prothrombin essentially reflecting des- γ -carboxy prothrombin(DCP). Recent studies demonstrated that DCP could not only differentiate HCC from nonmalignant chronic liver diseases, but also indicate prognosis for HCC^[3,4]. Because the assay of unabsorbed prothrombin is more economical and simpler than the determination of DCP, it maybe spread in clinic, especially in the developing countries.

The activation of protein C is catalyzed by a compound of α -thrombin and the endothelial cell surface protein thrombomodulin. In contrast to other vitamin K-dependent coagulation factors, activated protein C (APC) functions as an anticoagulant by proteolytic inactivation of factor Va and VIIIa. APC also promotes

fibrinolytic response by forming compounds with plasminogen activator inhibitor-1 and by diminishing the activation of thrombin-activatable fibrinolysis inhibitor via inhibition of thrombin generation. Thus the deficiency of protein C is associated with thrombosis^[6,7]. Previous reports demonstrated that the levels of protein C from plasma in patients with liver diseases were lower^[8,9]. Our data showed that PC:C in patients with hepatocellular carcinoma and liver cirrhosis was lower than control group, and the descendant degree was proportional to the damaged degree (unpublished data). Thus, the results provided further evidence for the association of protein C and liver diseases. However, PC:Ag in acute viral hepatitis (AVH) was also lower, but PC:C was close to the control, the reason is unknown. Protein C inhibitors synthesized in liver can specifically inactivate APC. Perhaps the decrease of protein C inhibitors in liver disease is one of the causes. In addition, the decrease of coagulation factors and some drugs may be partly responsible for it.

Because protein C is one of the vitamin K-dependent proteins synthesized in the liver, its biological functions are also dependent on complete Gla domain. Yashikawa *et al.* reported that the impaired vitamin K-dependent γ -carboxylation in patients with HCC involved not only prothrombin, but also protein C^[10]. Our data showed that the levels of DCPC in patients with HCC were surprisingly high, almost up to 50% of total protein C. This fact shows that the high level of DCPC from plasma can be used as a complementary tumor marker of HCC. As surgical removal or reduction in tumor was with chemotherapy is associated with reduction or elimination of the abnormal prothrombin (des- γ -carboxy prothrombin, DCP), the tumor itself is responsible for the production of DCP. We believe that DCPC may have the same production process like DCP. Up to date, it is still unknown why tumor cells of HCC make so many DCP and DCPC as well as des- γ -carboxy proteins. Because vitamin therapy can not reduce the concentration of DCP and DCPC, the production of des- γ -carboxy protein is not due to vitamin K deficiency. Its specific mechanisms remain unclear.

It is becoming increasingly clear that there is an interaction network between coagulation and inflammation and natural anticoagulants have strong anti-inflammatory effects^[11,12]. Animal experiments indicated that protein C and activated protein C inhibits could inhibit DIC and improve survival rate^[11-13]. Clinical trials could demonstrated that recombinant human activated protein C (rhAPC) could attenuate systemic inflammatory response syndrome and reduces mortality in patients with severe sepsis^[14-16]. Therefore, it may be beneficial when an appropriate dose of protein C or rhAPC is given to the patients with liver diseases especially HCC to prevent and treat sepsis and DIC.

Abstract

Fasciola hepatica, an endemic parasite in Turkey, is still a very rare cause of cholestasis worldwide. Through ingestion of contaminated water plants like watercress, humans can become the definitive host of this parasite. Cholestatic symptoms may be sudden but in some cases they may be preceded by a long period of fever, eosinophilia and vague gastrointestinal symptoms. We report a woman with cholangitis symptoms of sudden onset which was proved to be due to *Fasciola hepatica* infestation by an endoscopic retrograde cholangiography.

CASE REPORT

A 40-year old woman with no prior complaints was admitted to our emergency unit due to fever, chills, nausea, vomiting and persistent right-upper quadrant pain for one week. She was born at the East of Turkey and in her medical history she had a cesarean section five years ago and was operated for inguinal hernia one year ago. She was a non-smoker and had no prior medication.

On her physical examination, she was pale but not jaundiced and had a body temperature of 36.8 °C. She was normotensive with a regular pulse of 92 per minute. She had a mild mid-systolic murmur on the aortic valve, but no additional pathologic heart sounds or murmurs on major arteries were noted. All peripheric pulses were palpable. Auscultation of the lungs revealed no pathology. She had a cesarean section incision and another right lower quadrant incision due to hernia repair. Her bowel sounds were hyperactive on auscultation of the abdomen and she had a prominent right subcostal tenderness, but no liver or spleen enlargements were noted on palpation.

Her complete blood count was: hematocrit 30%, mean corpuscular volume 75 fl (normal, 80-95 fl), white blood cells 8 700/mm³ (normal, 4 000-10 000) with 15% eosinophils on peripheral smear, platelets 169 000/mm³ (normal, 100 000-450 000). The erythrocyte sedimentation rate was 45 mm/h, C reactive protein (CRP) level was 75 mg/L (normal, 0-5). Her complete blood chemistry was normal but alanine aminotransferase (ALT) level was 74 U/L (normal, 5-37), aspartate aminotransferase (AST) level was 93 U/L (normal, 5-37), alkaline phosphatase

level (ALP) was 266 U/L (normal, 32-155), gamma glutamyl transferase (GGT) level was 319 U/L (normal, 7-49). Total bilirubin level and urinalysis were normal.

A chest x-ray and plain abdominal radiograph revealed no pathology. In suspicion of gallstone disease, an ultrasonographic examination was performed and it showed a normal liver parenchyma but two hyperechogen solid lesions measuring 9 mm×9 mm and 7 mm×8 mm in the 7th segment of the right lobe. The gallbladder wall was normal but besides sludge multiple, milimetric, intraluminal echogenic particles were noted. Intrahepatic bile ducts were normal but there was a slight enlargement of the common bile duct (11 mm).

Still in suspicion of cholangitis due to gallstone, ceftriaxone 2 g/d i.v. was empirically started and the patient was referred to our endoscopy unit for endoscopic retrograde cholangiopancreatography (ERCP). After its selective cannulation, the common bile duct was filled with contrast agent and a slight enlargement and multiple, mobile, oval shaped filling defects were noted. Intrahepatic bile ducts were proved to be normal (Figure 1). After sphincterotomy, balloon extraction was performed and five *Fasciola hepatica* worms were noted. All of them were captured and taken out via a dormia basket (Figure 2, 3). After this interesting finding the patient's stool examination disclosed the parasites' ova (Figure 4) and an indirect hemagglutination test proved to be positive in 1/1 320 titer.

Figure 1 Multiple oval shaped filling defects on cholangiogram.

Figure 2 *Fasciola hepatica* next to papilla of Vater after sphincterotomy and balloon extraction.

After extraction of the worms the patient's symptoms

rapidly regressed and her liver enzymes returned to normal levels, then she was put on bithionol treatment 30 mg/kg every other day for 15 doses.

Figure 3 Adult flukes measuring 2.5 cm×1.5 cm in diameter.

Figure 4 Ova of *Fasciola hepatica* (×40).

DISCUSSION

A variety of liver flukes, including *Fasciola hepatica* may colonize the biliary tree where they lay their eggs, which can give rise to the formation of gallstones by serving as nidus for them. Living or dead worms may occlude the bile ducts causing obstruction and sometimes cholangitis.

Fascioliasis is primarily a common disease of livestock animals as cattle and sheep with humans serving only occasionally as accidental hosts. This zoonotic disease is common in Africa, Western Europe and Latin America^[1]. In a recent study from the East of Turkey, its seroprevalance was reported to be 2.78% independent of age, educational and socioeconomic status^[2].

Two stages have been described in human *fascioliasis*, namely an acute phase which coincides with hepatic invasion and a chronic phase due to the presence of flukes in the bile ducts^[3]. The metasercae for this parasite encyst on freshwater plants such as wild watercress and human consumption of aquatic plants harvested from contaminated areas lead to infection. Then developing larvae penetrate the gut wall and enter the peritoneal cavity. After a period of migration for 6 to 9 wk, the young flukes penetrate the capsule of the liver and they mature in the biliary tree and begin to pass their eggs. In the acute phase, the patient may have prolonged fevers, right upper quadrant pain, liver enlargement and eosinophilia which can be easily misdiagnosed. These symptoms abate with the

chronic phase. Once the flukes enter the bile ducts, they may cause symptoms due to cholestasis and cholangitis^[4].

Although the definitive diagnosis for *fascioliasis* can be made by detecting the parasite eggs in stool or duodenal aspirates, egg detection rate is not so high because of the low egg production rate of the parasite. Immunoserological tests become the cornerstone for the diagnosis of *fascioliasis* especially in early stage or ectopic infections^[5] but an ELISA test provides more rapid and reliable results^[6].

Although some parts of our country are endemic areas for human *fascioliasis*, this diagnosis was not suspected prior to give its full term (ERCP) as it is still a very rare cause of biliary obstruction. As usual^[7], sphincterotomy and balloon extraction rapidly alleviated symptoms in our patient.

Unlike other liver flukes, therapeutic failure was common in patients with *Fasciola hepatica* treated with piraziquantel so bithionol or triclabendazole has been the treatment of choice for this parasitic infection^[8]. The use of bithionol with the recommended dose of 30-50 mg/kg every other day for 10-15 doses or repeated doses has resulted in cure of acute and prolonged *fascioliasis*^[9]. Triclabendazole, another effective and safe drug for *fascioliasis*, has been found to be able to eradicate the parasite with a single oral dose of 10 mg/kg^[10]. Our patient was put on bithionol treatment 30 mg/kg every other day for 15 doses and no major side effects were noted.

We report this patient to draw attention to the latter that *fascioliasis* should be kept in mind in patients with cholestasis and preceding vague gastrointestinal symptoms especially in endemic areas of the world.

Abstract

One 63-year-old woman, who presented with cholestatic jaundice due to common bile duct compression produced by primary retroperitoneal fibrosis, is studied. The patient was operated six years ago because of hydronephrosis, when the disease was first diagnosed. Magnetic resonance cholangiopancreatography (MRCP) revealed the presence of extrahepatic bile duct obstruction, which once was considered to be pathognomonic of pancreatic cancer. CT-scan demonstrated the change of retroperitoneal fibrosis around left kidney, atrophy of right kidney, and obstruction of extrahepatic bile duct (pancreatic head). An explorative laparotomy was performed, and the retroperitoneum and pancreas were grayish-white and hard, the fibrotic pancreatic head compressed the common bile duct. Bile duct stricture was managed by Roux-Y hepatocholeangio-jejunostomy. To the best of our knowledge, few similar cases of retroperitoneal fibrosis have been reported.

Zhao MF, Tian Y, Guo KJ, Ma ZG, Liao HH. Common bile duct obstruction due to fibrous pseudotumor of pancreas associated with retroperitoneal fibrosis: A case report. *World J Gastroenterol* 2004; 10(20): 3078-3079
<http://www.wjgnet.com/1007-9327/10/3078.asp>

INTRODUCTION

Retroperitoneum is one of the most complex regions of human anatomy as it contains a variety of organs and structures from different systems, in particular those belonging to the urinary and digestive tracts and the vascular systems. Primary retroperitoneal fibrosis (Ormond's disease) is a rare disorder typically with an insidious clinical course, characterized by the presence of dense, grayish-white plaques centered around the abdominal aorta in this space. The peak incidence of this uncommon disease is between the ages of 40 and 60 years and mostly in men^[1]. Most commonly, it causes fibrous encasement of the ureters and subsequent obstructive hydronephrosis. Atypical sites of involvement include the duodenum, colon, urinary bladder, mesentery, small intestine and epidural space. Typically, mass effect from the enlarging fibrosis plaque leads to compromise of surrounding structures. For example, extrinsic vena compression can lead to small and large bowel obstruction, vena cava stasis, and arterial insufficiency in lower extremities.

In this report, we describe an unusual case of this rare disorder, which presented with obstructive jaundice caused by the compression of common bile duct due to the involved

diffusive pancreatic fibrosis. To the best of our knowledge, few similar cases of Ormond's disease have been reported.

CASE REPORT

One 63-year-old woman was sent to our hospital because of jaundice, slight loss of weight and anorexia in October 2003. The patient was operated six years ago because of hydronephrosis, when the Ormond's disease was first diagnosed. After operation, no corticosteroid was administrated and no reopening of the ureter was observed up to the admission to our hospital. Her antihypertensive medications included *Fufangluobuma* (TCM compound) and metoprolol.

The patient had been jaundiced for 9 d before sent to our hospital, and had no stigmata of chronic liver disease. Physical examination revealed a slight cachectic state. Abdominal examination was unremarkable without signs of ascites, and the liver edge was not palpable below the right costal margin. Patient had no fever and alcohol or drug abuse. Laboratory tests revealed a normal red and white blood cell counts. Erythrocyte sedimentation rate (ESR) was 120 mm/h in the first hour (normal 0-32), C-reactive protein (CRP) 0.4 mg/dL (normal <1 mg/dL). Blood urea nitrogen, creatinine level and amylase were normal. Total bilirubin was 278.3 $\mu\text{mol/L}$ (normal 2-20 $\mu\text{mol/L}$), direct bilirubin 237.1 $\mu\text{mol/L}$ (normal 0-3.4 $\mu\text{mol/L}$), alkaline phosphatase 326 U/L (normal 15-128 U/L), aspartate aminotransferase (AST) 27 U/L (normal 1-38 U/L), and alanine aminotransferase (ALT) 40 U/L (normal 1-41 U/L). Hepatitis and human immunodeficiency viruses were negative. Abdominal ultrasonography showed an enlarged pancreatic head and dilated intra- and extra- hepatic ducts. Additionally, cholecystolithiasis was detected. CT-scan demonstrated the change of retroperitoneal fibrosis around the left kidney, atrophy of right kidney, and obstruction of extra-hepatic bile duct (pancreatic head). The pancreatic head was slightly enlarged, but the enhanced scan showed that the density of the whole pancreas was homogeneous. Also gallbladder stones were found (Figure 1). Subsequent MRCP revealed the interruption of extrahepatic bile duct (Figure 2).

Figure 1 CT-scan demonstrated the change of retroperitoneal fibrosis around left kidney, atrophy of right kidney. The density of the whole pancreas was homogeneous.

A presumptive diagnosis of pancreatic cancer or cholangiocarcinoma was made and an explorative laparotomy was performed. We found that the retroperitoneum and pancreas

were grayish-white, and the consistency of them was hard (Figure 3). The fibrotic pancreatic head compressed the common bile duct. Then the gallbladder was resected and a Roux-Y hepatocholeangio-jejunostomy was constructed. Adjacent lymph nodes were not enlarged or malignant. The patient recovered fully after surgery.

Figure 2 MRCP revealed the interruption of extrahepatic bile duct.

Figure 3 Retroperitoneum and pancreas were grayish-white and hard.

DISCUSSION

Ormond's disease is a rare disorder characterized by transformation of normal fat tissue into a retractile fibrosis mass. Although the etiology of this chronic process is still unclear, the proposed mechanism is thought to be an autoimmune disorder secondary to the development of antibodies produced against ceroid, a polymer of oxidized lipid and protein^[2,3]. This hypothesis is based upon the finding of association between atherosclerotic plaques of the aorta and retroperitoneal fibrosis^[4,5]. It is thought that inflammatory antigens like ceroid pass through the adventitia into the periaortic fatty tissue and produce a periaortic and periarterial fibrosis^[6-8]. In addition, several pharmacological substances have been cited as possible causative agents of retroperitoneal fibrosis^[3]. Methysergide is the only drug that has been proved to cause retroperitoneal fibrosis^[2]. Other suspected causative drugs include β -adrenergic blockers, antihypertensives, analgesics^[3]. The medications of this patient included metoprolol, which is a kind of β -adrenergic blocker, but we were not able to identify the exact etiologic agent of this disease.

The presentation of retroperitoneal fibrosis in this patient was unique for two reasons. Ormond's disease often manifests clinically by constriction and compression of ureters, blood vessels and nerves. This patient had had an initial manifestation of Ormond's disease affecting left ureter before this admission. Uncommonly, upon this admission she presented with clinical manifestation of obstructive jaundice, which was due to the compression of portions of the common bile duct. There have

been only 9 reports of retroperitoneal fibrosis with cholestatic jaundice due to compression of the distal part of the common bile duct by fibrotic pancreatic head^[9-15]. A second distinctive feature of this Ormond's disease case was the direct involvement of the pancreas, which has not previously been highlighted and led to diagnostic difficulty. Obstructive jaundice due to the retroperitoneal fibrosis of pancreas head is easy to mimicking the carcinoma of pancreas. In some authors' opinion, sclerosing pancreatitis due to retroperitoneal fibrosis as this patient has been classified into the new clinical entity-"autoimmune related pancreatitis" or "autoimmune pancreatitis".

Management of retroperitoneal fibrosis includes surgical relief of extrinsically compressed or encased structures, deep tissue biopsies to confirm the diagnosis and to exclude the malignant variant, and the use of corticosteroids (and other immunosuppressants) to prevent further progression of the disease^[2]. There is no definitive duration or dosage of corticosteroids recommended for the therapy of this disease. This patient did not take corticosteroids.

In conclusion, this atypical retroperitoneal fibrosis illustrates that this disease involves the pancreas, and diffusive pancreatic fibrosis (sclerosing pancreatitis) can affect the common bile duct to manifest the initial symptom of cholestatic jaundice. Additionally, surgeons should pay attention to this condition mimicking pancreatic carcinoma or cholangiocarcinoma.

Abstract

The molecular mechanism of how hepatocytes maintain cholesterol homeostasis has become much more transparent with the discovery of sterol regulatory element binding proteins (SREBPs) in recent years. These membrane proteins are members of the basic helix-loop-helix-leucine zipper (bHLH-Zip) family of transcription factors. They activate the expression of at least 30 genes involved in the synthesis of cholesterol and lipids. SREBPs are synthesized as precursor proteins in the endoplasmic reticulum (ER), where they form a complex with another protein, SREBP cleavage activating protein (SCAP). The SCAP molecule contains a sterol sensory domain. In the presence of high cellular sterol concentrations SCAP confines SREBP to the ER. With low cellular concentrations, SCAP escorts SREBP to activation in the Golgi. There, SREBP undergoes two proteolytic cleavage steps to release the mature, biologically active transcription factor, nuclear SREBP (nSREBP). nSREBP translocates to the nucleus and binds to sterol response elements (SRE) in the promoter/enhancer regions of target genes. Additional transcription factors are required to activate transcription of these genes. Three different SREBPs are known, SREBPs-1a, -1c and -2. SREBP-1a and -1c are isoforms produced from a single gene by alternate splicing. SREBP-2 is encoded by a different gene and does not display any isoforms. It appears that SREBPs alone, in the sequence described above, can exert complete control over cholesterol synthesis, whereas many additional factors (hormones, cytokines, etc.) are required for complete control of lipid metabolism. Medicinal manipulation of the SREBP/SCAP system is expected to prove highly beneficial in the management of cholesterol-related disease.

INTRODUCTION

The view of cholesterol as a nasty substance which clogs arteries and causes heart disease is wide-spread, but it does not do the molecule justice. Not only is it a vital component of cell membranes without which the cell cannot function, but it is also the precursor to all steroid hormones, bile acids, and oxysterols, which by themselves are important regulatory molecules in many metabolic pathways.

Cholesterol and fatty acids as building blocks of cell membranes are synthesized via regulated pathways. All cells must control these pathways in order to maintain levels within physiological boundaries. Excessive amounts of cholesterol in cells can destroy membrane function, precipitate as crystals which will kill the cell or result in atherosclerotic damage if spread to blood^[1]. However, the original view of random distribution of cholesterol and lipids in the cell membrane no longer holds: not only differs the lipid composition of the outer leaflet of the plasma membrane from the inner one, but the distribution of lipids and cholesterol in the outer leaflet is organized into domains, with so-called rafts^[2] and caveolae^[3] being rich in cholesterol and sphingomyelin. These structures play intricate roles in cholesterol trafficking to maintain cellular homeostasis, and they are also components of the cellular signalling system. The membranes of endoplasmic reticulum (ER) and Golgi, on the other hand, contain comparatively little cholesterol, a factor important in its own homeostasis, and one objective of this overview.

The understanding of cholesterol regulation has come a long way from the initial recognition of cholesterol feedback inhibition of its rate-limiting synthetic enzyme, 3-hydroxy-3-methylglutaryl coenzyme A (HMGCoA) reductase, through the role of lipoproteins in maintaining plasma cholesterol levels, to the recent discoveries of regulation of cholesterol synthesis via sterol-sensitive response elements (SREs), and degradation via liver X receptor (LXR) - or bile acid receptor (BAR) -regulated pathways.

Lipid homeostasis via SREs in animal cells is achieved by a family of transcription factors called SRE-binding proteins (SREBPs). SREBPs activate directly the expression of some 30-plus genes participating in the metabolism mostly of lipids, but also glucose. Activation of these originally membrane-bound transcription factors involves a proteolytic cascade through which the SREBP molecule is released from the membrane and obtains its mature form as a transcription factor. The active SREBP enters the nucleus and binds to those special DNA sequences, the SREs, in the promoter regions of many different genes.

In the health arena, SREBPs stand at a crucial point: they regulate expression of the LDL receptor, the molecule which enables the hepatocytes to remove cholesterol contained in LDL particles from the bloodstream. High (dietary) cholesterol prevents maturation of SREBPs and not only cuts off cholesterol synthesis, but also LDL receptor synthesis, resulting in high blood cholesterol and the imminent danger of atherosclerotic plaque formation. At this point in time the so-called statins, drugs which block HMGCoA reductase, another target of SREBP-mediated gene expression, are the most effective way to interrupt this vicious circle^[4].

This brief overview is concerned with the SREBP-mediated control of cholesterol and lipid synthesis. Lipid synthesis is subject to many other regulatory influences which cannot be addressed here, nor can the degradation of cholesterol via hormone or bile acid synthesis be covered, which again commands its own set of regulatory substances. The focus of this minireview is to present the latest data on the SREBP-induced mechanism. Recent in-depth reviews have been available^[5-9].

Figure 1 Feedforward and feedback effects of oxysterols FXR = farnesoid×receptor; LRH-1 = liver receptor homologue-1; LXR = liver×receptor; SF-1 = steroidogenic factor-1; SREBP = sterol responsive element binding protein.

OXYSTEROLS AS NEGATIVE AND POSITIVE REGULATORY MOLECULES

Cholesterol is not the only sterol inside the cell to act as a regulatory substance, many of its hydroxylated derivatives, the oxysterols, share these important functions. Oxysterols exert a feed-back effect and down-regulate cholesterol synthesis, to be detailed in the following sections of this overview, but they also up-regulate their own metabolism and elimination via a feed-forward effect which will be briefly described in this section.

Cholesterol directly affects two enzymes which are vital in its own removal. It activates acyl-CoA: cholesterol acyl transferase (ACAT), the enzyme required to synthesize cholesteryl esters, its major storage form, and it also activates cholesterol 7 α -hydroxylase (CYP7A1), the initial and rate-limiting enzyme of bile acid synthesis, the leading pathway of cholesterol elimination^[10].

The side chain-hydroxylated 27-hydroxycholesterol is presumed to function in cholesterol homeostasis by sustaining HDL-mediated reverse cholesterol transport, the process by which cholesterol is brought back to the liver from peripheral tissues^[11]. The most important action of oxysterols, however, is to serve as ligands for nuclear orphan receptors. This family of proteins has been recognized as nuclear hormone receptors based on their molecular properties, but since ligands were initially not known, they were named orphan receptors. Most important among these is liver X receptor (LXR), which controls expression of CYP7A1^[12] as the rate-limiting step of bile acid synthesis^[13,14], reverse cholesterol transport^[15], trafficking of cholesteryl esters, and aids in lipid metabolism^[16] and the intestinal absorption of cholesterol. This receptor displays specific requirements for the position of additional hydroxy group (s) on the cholesterol molecule, the most potent ligands being 20 (S)-OH-, 22 (R)-OH-, 20, 22-di-OH-, and 24-OH-cholesterol^[17,18]. An overview of oxysterol actions is shown in Figure 1.

Furthermore, oxysterols are ligands for steroidogenic factor-1 (SF-1) and liver receptor-homologue 1 (LRH-1), in which they regulate steroid hormone synthesis and sexual differentiation during prenatal development. SF-1 is limited to steroidogenic tissues, whereas LRH-1 occurs in liver and other tissues derived from the gut endoderm^[7]. Oxysterols also play a role in meiosis^[19]. Finally, these bile acids activate the farnesol X receptor (FXR)/retinoid X receptor (RXR)/receptor-interacting protein 14 (Rip14) system, FXR is also known as bile acid receptor (BAR). Binding of bile acids to FXR inhibits bile acids synthesis.

SREBPS, MEMBRANE-DERIVED TRANSCRIPTION FACTORS

SREBPs belong to the large family of basic helix-loop-helix-leucine zipper (bHLH-Zip) transcription factors. Three members of the SREBP family, SREBPs-1a, -1c, and -2, have been identified^[20,21]. They are synthesized as inactive precursors. Isoforms -1a and -1c are produced from a single gene on human chromosome 17p11.2 by use of alternate promoters and splicing,

resulting in different forms of exon-1^[21-23]. SREBP-2 is encoded by a separate gene on human chromosome 22q13^[20,24]. It has about 50% sequence identity with SREBP-1. Adipocyte determination differentiation factor (ADD)-1, a transcription factor which binds to E-boxes and promotes adipocyte differentiation in rats^[25] is the homologue of human SREBP-1c^[23].

Each nascent SREBP protein has a molecular size of about 125 ku and consists of about 1 150 amino acids (aa) in 3 functional domains. The first, NH₂-terminal domain of SREBP contains the bHLH-Zip and an acidic domain, located at the very NH₂ terminus. The acidic domain has to bind a transcription coactivator for function, it is shorter in SREBP-1c than in SREBP-1a, making SREBP-1c a weaker transcription activator^[26]. The acidic domain is essential for function. When removed, the bHLH-Zip portion of SREBP still binds to DNA, but no longer activates transcription, thus acting as an inhibitor^[27].

A adjacent to the acidic DNA-binding domain is a variable area rich in serine, proline, glutamine, and glycine. Next follows the bHLH-Zip sequence, whose basic region mediates DNA binding. The rest of the bHLH-Zip motif imparts the ability to dimerize. Other bHLH-Zips tend to homo-dimerize, whereas SREBP needs other transcription factors such as SP-1 or NF-Y for full function. The remainder of the SREBP molecule has no analogy with other bHLH-Zip transcription factors^[5].

SREBPs are embedded in membranes of the endoplasmic reticulum (ER) and the nuclear envelope, forming what has been called a hairpin shape^[28,29]. The NH₂-terminal portion of the SREBP molecule through the bHLH-Zip region protrudes into the cytosol. The following central portion of SREBP, the membrane anchoring region, is about 90 aa in length. It consists of two hydrophobic, membrane-spanning segments separated by a hydrophilic loop which extends into the lumen of the ER. The COOH terminal segment of about 590 aa again extends into the cytosol and serves as the regulatory domain for transformation into the mature, a transcriptionally active form also known as nuclear SREBP (nSREBP). Neither the membrane-spanning, nor the regulatory regions, are found in other bHLH-Zip transcription factors.

The NH₂-terminal domain of SREBP binds to a sterol binding element (SRE) which must contain a direct, or tandem, repeat of the recognition sequence^[30]. This is another evident difference to bHLH-Zip transcription factors, which will bind only to palindromic (i.e., tail-to-tail connected) repeats. SREBPs display no *in vivo* activity with palindromic sequences^[5,19].

SREBP CLEAVAGE ACTIVATION PROTEIN (SCAP), AN ESCORT AND STEROL SENSOR PROTEIN

SREBPs attain biological activity only after being transferred to the membrane of the Golgi complex, where they are cleaved at the luminal loop and the NH₂-end is released from the membrane. They are confined to the membranes of the ER unless they are

paired up with another protein which serves two functions: to sense the levels of sterols in the cell, and in response to low sterol levels, to escort SREBP to its place of activation. This is achieved by SREBP cleavage activating protein (SCAP), a protein originally cloned from a mutant cell line of Chinese hamster ovary cells which will not suppress SREBP cleavage even with very high sterol levels^[31]. The mutation affects one specific codon, 443, where a C (ytosine) to G (uanine) transition on the DNA side replaces an aspartic acid by an asparagine in the amino acid sequence, rendering SCAP unresponsive to sterols^[32].

SCAP has 1 276 amino acids^[31] in two domains^[33]: a membrane-spanning NH₂ terminal domain of 730 aa, and a COOH terminal domain of 546 aa, which extends into the cytosol. The NH₂-terminus contains eight hydrophobic sequences separated by short hydrophilic loops^[31], the hydrophobic sequences are thought to span the membrane with the hydrophilic loops protruding at either side. SCAP shares this feature with HMGCoA reductase^[34,35]. The membrane-spanning stretches comprise the sterol-sensing area, whereas the COOH-terminus contains all of the remaining biological activity^[31]. The COOH-terminus is organized in five repeat sequences characteristic of the WD family. Wherever this sequence occurs, it mediates protein-protein interactions^[36].

Newly synthesized SREBP forms a tight complex with the WD repeat domains of SCAP^[37], but in the presence of oxysterols this complex is confined to the ER, establishing a feedback loop to control cholesterol synthesis. With oxysterol depletion, the SCAP/SREBP complex appears in vesicles budding from ER membranes^[38] and translocates to another subcellular compartment, the Golgi^[39-43]. Transfer of SREBP and proteolytic cleavage to release nSREBP cannot occur unless this complex has formed^[42]. Oxysterols induce a change of the conformation of SCAP, and an additional protein has been postulated to retain SCAP in the ER once in its sterol-induced conformation^[44]. Not only cholesterol, but also several other oxysterols display

full activity in suppressing SCAP translocation into vesicles, but it has been suggested that cholesterol alone exerts the effect, while high levels of oxysterols simply force translocation of cholesterol from the plasma membrane to the ER^[44]. Complete understanding could be of immense benefit in the management of hyperlipidemias.

SREBP ACTIVATION VIA TWO-STEP PROTEOLYTIC CLEAVAGE

The SREBP/SCAP-containing vesicles from the ER also contain a membrane-anchored serine protease of the subtilisin family, Site-1 protease (S1P), in an inactive form which becomes activated only during its transport to the Golgi^[45]. The SREBP/SCAP complex and S1P now incorporate into the Golgi membrane. As the next step, the activated S1P attaches to the SCAP/SREBP complex and cuts the SREBP molecule right in the middle of its luminal hydrophilic loop^[29]. When active S1P is inserted into the ER, it will cleave SREBP without a need for SCAP^[43].

To release active SREBP, another enzyme is required, Site-2 protease (S2P, a trans-membrane zinc metalloprotease). The cellular location of this enzyme is as yet unclear, but likely resides in the Golgi. S2P cuts the still membrane-anchored SREBP in a rather unusual place, viz., three amino acids into the membrane-spanning portion on the cytoplasmic side^[46,47]. This process is known to regulate intra-membrane proteolysis (Rip)^[48], and typically produces proteins which are transcriptionally active and participate in the control of various cellular processes^[6]. S2P action is not directly affected by cellular oxysterol levels, since this enzyme cannot act unless S1P has separated the bHLH-Zip portion of SREBP from the regulatory COOH terminus^[49]. S2P action results in the release of a mature, 68 kDa nSREBP, consisting of the bHLH-zipper domain with the first three membrane-spanning amino acids attached, which now can migrate to the nucleus and bind to a sterol-responsive element (SRE). SCAP is recycled back to the ER to chaperone another 125 kDa SREBP molecule to the Golgi^[50], whereas the 68 kDa SREBP is degraded. Interestingly, the nuclear

Figure 2 Maturation of SREBPs -NH₂ = amino-terminal ends of SREBP or SCAP. S1P = Site-1 protease (crossed-out = inactive); S2P = Site-2 protease. SRE = sterol-responsive element; nSREBP = nuclear SREBP. Arrangement of the additional transcription factors NF-Y, Sp1, CREB, ARC, CBP, TBP, and DRIC (see text) is tentative as their requirements are not exactly known.

action of nSREBP induces new SREBP mRNA synthesis by way of SREs located in the promoter regions of their own genes^[51]. A synopsis is shown in Figure 2.

The process of SREBP cleavage and activation thus comprises 4 components which, upon mutation, can result in loss of oxysterol-sensitive regulation of cholesterol homeostasis. As a matter of fact, much of the knowledge of the SREBP regulatory system stems from experimentally mutated cell lines and subsequent selection for oxysterol resistance or cholesterol auxotrophy^[8]. Oxysterol resistance has aided in cloning the genes for SREBP and SCAP, respectively. One type, class 1 mutation, produces an NH₂-terminal bHLH-Zip portion of SREBP which is truncated even before the S2P cleavage site^[52,53]. This molecule is therefore not membrane bound and can access the nucleus immediately after its synthesis, turning on the complete SREBP gene battery regardless of cellular oxysterol levels. Class 2 mutants contain a mutated SCAP molecule^[54] which holds the SREBP/SCAP/S1P complex in a permanently active configuration, no matter how high the oxysterol level in the cell, resulting in permanent release of nSREBP with concomitant overproduction of cholesterol^[31].

Cholesterol auxotrophy has been used as a selection criterion to clone the genes for S1P and S2P. With S1P^[55], S2P^[41,46,56] or SCAP^[57] rendered non-functional, cells become dependent on exogenous cholesterol because they cannot produce the enzymes necessary for its biosynthesis.

It is interesting to know that the proteolytic activation of SREBP-1 and SREBP-2, respectively, can be regulated individually. In rodents, treatment with cholesterol suppressing drugs (statins) or with cholesterol-sequestering agents results in up-regulation and increased activation of SREBP-2 while reducing activation of SREBP-1^[58]. Another interesting feature is that polyunsaturated fatty acids inhibit the proteolytic activation of SREBP-1, but contrary to the action of oxysterols, they have no effect on SREBP-2 maturation^[59]. In addition, glucose metabolites such as glucose-6-phosphate may serve to accelerate maturation of SREBP-1c only^[60], but mechanistic details have not been elucidated.

GENE ACTIVATION BY SREBPs, TARGET GENES

Immediately after the second cleavage of the SREBPs the now mature protein enters the nucleus where it binds to SREs in the promoters of the target genes and activates transcription. The SRE nucleotide sequence displays considerable variation among the promoters of the many genes activated by an SRE, a commonly found sequence is represented by 5'-nTCACnCCA Cn-3' (cf.^[6]). However, SREBP alone cannot activate transcription, but must act co-ordinately with additional transcription factors to obtain full activation of target genes.

Transcription factors known to activate SREs in conjunction with SREBP are Sp1, nuclear factor (NF)-Y, and cAMP response element binding protein (CREB)^[10,61-64]. NF-Y interacts directly with SREBP^[62], and Sp1 can stabilize the complex^[61]. It appears that the promoters of different SRE-activated genes respond to different combinations of these transcription factors. Once a stable complex has formed in a promoter region, additional factors such as CREB binding protein (CBP)^[65,66], activated recruited cofactor (ARC)^[67], vitamin D receptor interacting protein (DRIC)^[67], or TATA box-binding protein (TBP)-associated factors may be recruited to initiate transcription. Histone acetylation is also required for full transcriptional activity^[68]. Such complexes have been shown to exist with SREBP-1a and -2, but not with SREBP-1c. This may explain its rather weak potency to activate the SRE gene battery.

SREBP-activated genes predominantly belong to lipid metabolism pathways, viz, cholesterolgenesis, fatty acid synthesis, lipogenesis, triglyceride and phospholipid synthesis, but also glucose metabolism. Yet, the three SREBPs do not activate identical gene batteries. Using transgenic mice over-expressing just one

type of nSREBP it has been discovered that SREBPs-1a and -1c actions favour fatty acid synthesis, whereas SREBP-2 action favours cholesterol synthesis^[5,69-71], but *in vitro* both SREBPs-1a and -2 can trigger expression of the complete set of enzymes required for cholesterol synthesis with similar potency^[72]. While SREBPs-1a and -2 predominate in cultured cells, intact liver and most other tissues primarily express SREBP-1c and -2^[9]. An overview of SREBP pathways is given in Figure 3.

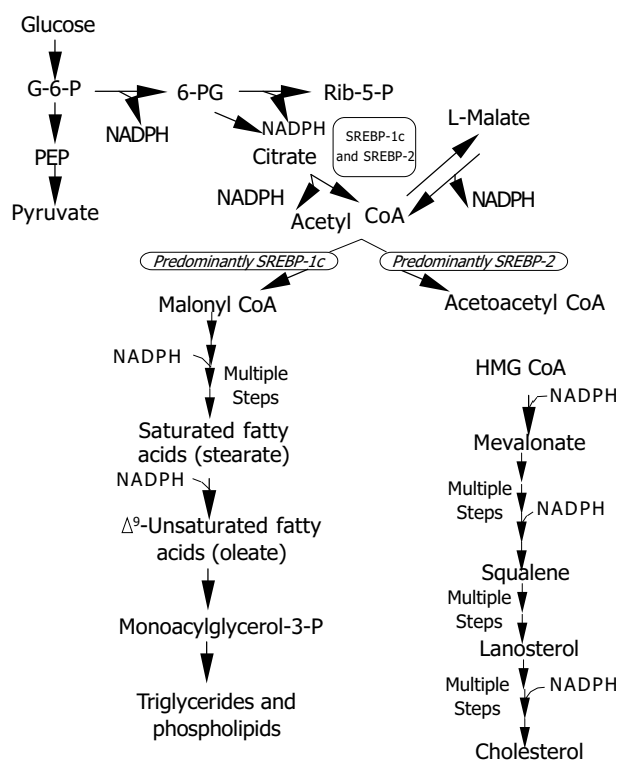

Figure 3 Metabolic pathways regulated by SREBPs G-6-P = glucose-6-phosphate; 6-PG = 6-phosphogluconate; Rib-5-P = ribulose-5-phosphate; PEP = phosphoenol pyruvate; CoA = coenzyme A; HMGCoA = 3-hydroxy-3-methylglutaryl coenzyme A. SREBP-1c and SREBP-2 activate genes for the generation of NADPH (ATP citrate lyase, malic enzyme, G-6-P dehydrogenase, 6-PG dehydrogenase) required in various steps of lipid synthesis.

SREBP-2 over-expression induces all 12 enzymes of the cholesterol biosynthetic pathway^[72], most notably the mRNA for HMGCoA reductase, which may increase as many as 75-fold^[73]. Overall cholesterol synthesis in such animals is up 28-fold, whereas fatty acid synthesis is increased only 4-fold. In contrast, expression of enzymes does not involve cholesterol synthesis but is related to cholesterol metabolism. Cholesterol 7 α -hydroxylase (rate-limiting enzyme for bile acid synthesis) and acyl-CoA:cholesterol acyltransferase (ACAT, catalyses cholesterol ester formation), are not activated^[72].

SREBP-1a appears to be constitutively expressed in most tissues, with as yet no known factor to stimulate its low expression^[26]. Over-expression in adult rats also resulted in over-stimulation of lipid synthesis, but in this case fatty acid synthesis was increased 26-fold, and cholesterol synthesis 5-fold. Since SREBP-1a and -1c (see below) also induce enzymes for fatty acid elongation and desaturation^[73,74], SREBP-1a over-expression resulted in elevated hepatic levels of oleate^[75].

SREBP-1c is predominantly involved in the regulation of adipogenesis and also in the regulation of insulin-responsive genes which control lipogenesis and glucose metabolism^[76,77], but *in vitro* it does not stimulate cholesterol synthesis^[75]. SREBP-1c mRNA synthesis responds to nutritional changes in

parallel to insulin levels^[78]. Insulin heightens the expression of SREBP-1c and its battery of genes involved in the synthesis of saturated and unsaturated fatty acids^[75,79] as well as glucose metabolism genes^[77,78]. The effect is opposed by glucagon and cyclic AMP. In short, available experimental data indicate that SREBP-1c mediates all effects of insulin on lipogenesis. In response to nutritional stimuli SREBP-1c also triggers expression of genes of enzymes required for fatty acid elongation^[74], and of glycerol 3-phosphate acyltransferase required for triglyceride and phospholipid synthesis^[6]. Last but not least SREBPs activate 3 genes necessary for the generation of NADPH, which is needed in fatty acid and cholesterol synthesis.

The promoter of the SREBP-1c gene contains response elements for insulin, glucagon, as well as liver X-activated receptors (LXR) α and LXR β , the latter is activated by sterols^[17,43]. This regulatory pathway, among others, results in increased synthesis of oleate^[75], the major fatty acid used for cholesterol esterification, to ensure its removal from the liver.

KNOCK-OUT ANIMALS AND HEALTH IMPLICATIONS OF SREBPS

Knock-out mice which lack all SREBPs, or S1P to activate them, die at an early stage of embryonic development^[80,81]. Specific knock-out of SREBP-2 also results in embryonic lethality. Deletion of SREBP-1a allows some fetuses to survive, whereas lack of SREBP-1c appears to be of no consequence. The survivors are found to compensate by higher SREBP-2 levels, and consequently, these animals have elevated hepatic cholesterol, but lower fatty acid levels^[9].

In order to study SREBP knock-outs in adulthood, a gene manipulation was used in Brown and Goldstein's laboratory which allows to turn specific genes off at will by stimulating interferon production. Disruption of the SCAP or S1P gene, respectively, almost abolished nSREBPs-1 and -2 in liver and diminished expression of all target genes of cholesterol and fatty acid synthesis. The result was a reduction in cholesterol and fatty acid levels in livers by 70-80%^[9].

The SREBP-related links between fatty acid and glucose metabolism draw immediate attention to the wide-spread disease, diabetes. It would appear that the fatty liver frequently observed in insulin-resistant diabetics is a result of high SREBP-1c levels caused by high insulin levels. Leptin, the organism's response to fat accumulation in adipocytes, opposes SREBP-1c action^[82], and consequently can heal the derailment of fat metabolism in diabetic animals^[83].

One of the genes activated by nSREBP-1c is that for the hepatic LDL receptor, an effect clearly targeting at maintaining plasma lipid homeostasis. At first sight this would appear beneficial for arteriosclerosis since it should reduce elevated LDL-cholesterol levels in blood. However, since nSREBP-1c also induces lipogenesis, its effect is ambiguous, and other factors will decide whether the net result fights arteriosclerosis, or rather exacerbates it^[7]. It is at this point where the HMGCoA reductase inhibitors or statins work, but they are effective only in one third of cases^[84].

It must be understood that fatty acid synthesis is not only subject to SREBP regulation, but a host of other factors, whereas cholesterol synthesis appears to be exclusively controlled by SREBPs. Additional unknowns are the exact regulation of system by which HDL via the scavenger receptor B-1 mediates efflux of cholesterol from the liver, and the ATP-binding cassette-1 (ABC-1) system which mediates transfer of cholesterol to HDL^[84]. Profound knowledge of these pathways will open a perspective beyond the statin drugs to specifically lower cholesterol levels in disease conditions.

Abstract

This paper provides a bird's-eye view both in preclinical and clinical aspects of E-cadherin germline gene (CDH1) in gastric cancer patients and their families. E-cadherin, a product of CDH1 gene, belonging to the functionally related trans-membrane glycoprotein family, is responsible for the Ca^{2+} -dependent cell-cell adhesion mechanism and contributes to dissociation followed by acquisition of cell motility, which usually occurs in the first step of cancer invasion and metastasis. CDH1 gene germline mutation is common in many types of carcinoma, and occurs very frequent in hereditary gastric carcinoma (HGC) patients and their families. Recently, more and more researches support that E-cadherin plays an important role in the differentiation, growth and invasion of HGC. So it is of great value to clarify its mechanisms both for understanding HGC pathogenesis and for clinical therapy, especially in China, where there are a high risk population of gastric cancer and a high HGC incidence rate. In this paper, recent researches on CDH1 gene mutation, especially its role in tumor genesis and progress of HGC, are reviewed, and advances in evaluation of its mutation status for HGC diagnosis, therapy and prognosis, are also discussed briefly.

INTRODUCTION

CDH1 mutation in HGC

Gastric carcinoma is one of the leading causes of cancer mortality in many countries, especially in most Asian countries. It is also one of the leading malignant diseases in China. According to data, approximately one Chinese person died of gastric cancer every 2 to 3 min. In the past decades, the incidence tended to increase gradually. Some population based surveys revealed that about 10% gastric cancer patients demonstrated familial clustering. The identification of genes predisposing to HGC is an essential step towards understanding the molecular events underlying tumorigenesis and critical for the clinical

management. In 1998, a germline mutation in the CDH1 gene, which located on chromosome locus 16q22.1, was first recognized in Maori kindred from New Zealand with diffuse gastric carcinoma. The product of CDH1 gene, E-cadherin protein, a 120 ku transmembranous glycoprotein, is involved in Ca^{2+} -dependent intercellular adhesion. More and more researches confirm that impaired expression of E-cadherin contributes to histogenesis, tumor growth, metastasis and poor survival of gastric cancer patients, especially HGC patients. So further analyses are needed to clarify the mechanism of gastric cancer and provide better strategies for treatment of HGC patients and prophylaxis of their families.

E-CADHERIN: STRUCTURE AND FUNCTION

The newly mutated gene discovered in HGC, CDH1, is composed of 16 exons and 15 introns encoding the E-cadherin protein. E-cadherin, also called epithelial cadherin or uvomorulin, is a member of the subclass of cadherins, which are Ca^{2+} -dependent cell-cell adhesion receptors identified in vertebrates. The 120 ku E-cadherin molecule is made up of a 27 amino acid signal peptide (exons 1-2), a 154 amino acid precursor peptide (exons 2-4), and a 728 amino acid mature peptide. The mature protein consists of three major domains, five extracellular repeats (CAD repeats) (exons 4-13), a single membrane-spanning region (exons 13-14) and a cytoplasmic region (exons 14-16). The N-terminal CAD1 repeat is essential for the homophilic binding specificity that directs "like" E-cadherins with each other. The cytoplasmic domain is bound to the actin cytoskeleton via intracellular attachment proteins, the catenins, forming the E-cadherin/catenin complex (Figure 1).

Figure 1 Formation of E-cadherin/catenin complex. Step1. E-cadherin stand dimers on the two adjacent cells' surface combine together and transfer the signals to catenin complex which is composed of β + α + γ subunits. Step2. The complex promotes actins to contract and enhance the intra-cellular adhesion.

Linkage between transmembranous cadherins and actin filament of the cytoskeleton is localized at the cell-cell adherent junction(AJ) and mediated by many associated undercoat proteins of the junction including catenins, vinculins, and actin^[1]. Catenins are a series of cadherin-associated cytoplasmic proteins that are co-immunoprecipitated with cadherin by nonionic detergent, and classified by their molecular mass as α -(102 ku), β -(88 ku), γ -(80 ku)^[2]. Furthermore, catenins connect cadherin to other integral membrane proteins, such as Na^+ - K^+ -ATPase, or to cytoplasmic structures, such as fodrin or ankyrin^[3]. All these form a transcellular network, mediating structural integrity, cellular polarity and epithelial morphogenesis^[4,5].

The CAD1 domain conformation of E-cadherin contains seven β strands (β A - β G) and two short α helices (α A, α B). The homophilic binding specificity appears to be governed by CAD1 domains through a surface including a HAV motif, which is found in or following β F. CAD1 also possesses the PEN (10-13), LDRE (66-69), DXND (100-104) motifs, while CAD2 possesses a DAD motif. These four Ca^{2+} -binding motifs can form a shared Ca^{2+} -binding pocket. The ligation of Ca^{2+} between tandem CAD domains explains the vulnerability of cadherins to proteolytic degradation when Ca^{2+} is depleted. Removal of Ca^{2+} would alter the junction between tandem CAD domains and likely expose the linkers to proteases. The binding of Ca^{2+} could provide the rigidity suggested by Ca^{2+} -induced changes of the entire extracellular region of E-cadherin from a globular to a rod-like structure observed by electronic microscopy^[2,6].

Full length E-cadherin has a cleavage site near the transmembrane domain and soluble E-cadherin (s-E-cadherin), a soluble 80-84 ku amino-terminal fragment, can be produced artificially in the culture medium digested by trypsin, so E-cadherin is also named as cell CAM120/80^[7]. s-E-cadherin can be detected in the protein extract of tissues, and in serum of peripheral blood or urine by means of immunoenzymometric assay (IEMA) and the volume did not depend on either age or sex^[8]. Research also found it could be released from some human carcinoma cell lines (for instance MCF-7) into the culture medium^[9].

E-CADHERIN ABNORMAL EXPRESSION IN CARCINOMA

E-cadherin is a crucial adhesion molecule which hampers tumor invasion and metastasis. Down-regulation of expression or impaired function would lead cells to poor intercellular adhesion through inhibiting homophilic binding. To normal epithelial tissues, it means poor differentiation, while to tumor, it means invasive growth pattern and easy to spread from the primary place. Disturbance of epithelial cell adhesion has been shown to be due to several mechanisms as shown in Figure1. The first is inefficiency of E-cadherin homophilic binding, the second is abnormality or deletion of catenins, the last is biochemical modification of catenins, such as tyrosine phosphorylation of β -catenin^[10,11]. Among the factors that lead to inefficient homophilic binding of E-cadherin, the most important and widely recognized is E-cadherin down regulation or dysfunction due to CDH1 mutations.

Down-regulation of E-cadherin expression or CDH1 mutations could cause a change towards a less epithelial morphology and also interfered with initial adhesion of cells. Moreover, changed E-cadherins could sharply increase cell motility and change the organization of actin cytoskeleton. Nagafuchi *et al.*^[12] showed that the enhanced expression of E-cadherin cDNA in fibroblastic cells could generate epithelial structures in their recent research. McNeill *et al.*^[13] found that E-cadherin could cause polarized distribution of Na^+ - K^+ -ATPase, an important factor in the establishment of cell polarities. Mutations have been also found at very early non-invasive stages, thus associating E-cadherin mutations with loss of growth control and defining CDH1 as a real tumor suppressor^[14,15]. All of these may contribute to the significant correlation between abnormal E-cadherin expression and degree of differentiation ($P = 0.0001$) or local tumor size ($P = 0.002$)^[16].

Immunohistochemical studies have shown that expression of E-cadherin is reduced or lost in more than 15 different human carcinomas^[17]. The frequency of reduced E-cadherin expression is higher in tumors with infiltrative growth than in those with expansive growth. These observations are supported by *in vitro* studies, which evaluated the influence of E-cadherin on cell behavior. Behrens *et al.*^[18] found MDCK cells could invade into collagen gels when their E-cadherins were inactivated with antibodies. Frixen *et al.*^[19] also observed the similar phenomenon

that the invasiveness of several human carcinoma lines was suppressed by mouse E-cadherin cDNA transfection. Down regulation of E-cadherin or its functional defects could change the construction of actin cytoskeleton, which can weaken intracellular adhesion, increase the activity of epithelial cells and lead to more invasions.

Extensive immunohistopathologic studies, including those of squamous cell carcinomas of the head, neck and prostate also support the possibility that loss of E-cadherin expression may promote tumor metastasis to lymph nodes. Reduced E-cadherin expression of breast cancer was also found to have a higher frequency of blood-borne distant metastasis (*e.g.* bone or lung) than preserved E-cadherin expression of other tumors. There was a significant correlation between the degree of E-cadherin expression and the degree of tumor differentiation, as well as histological type according to the Lauren or the WHO classifications. Similarly, the correlation between E-cadherin expression and prognostic parameters (depth of invasion, lymph node involvement and vascular invasion) could be demonstrated according to some researches. These findings are consistent with the previous hypothesis that inhibition of E-cadherin function could enhance the release of cancer cells from their primary sites.

CDH1 MUTATION IN HGC PATIENTS AND FAMILIES

Lauren's classification of gastric cancer includes the intestinal (glandular) and diffuse type, as well as the mixed type. It has been reported that two histologic types have differences in epidemiology, clinicopathologic profile and molecular genetics, while both originate from *Helicobacter pylori* positive gastritis. The intestinal (glandular) type is especially predominant in high-risk population and elderly patients, and related with environmental factors, and their incident rates are decreasing in developed countries, suggesting that the pathogenesis of intestinal-type gastric carcinoma has an environmental component. Diffuse gastric cancer is determined significantly by heredity and the criteria for familial gastric cancer worked out by some investigators^[20,21] are as follows. There should be at least 3 relatives with gastric cancer. One should be a first-degree relative of the other 2. At least 2 successive generations should be affected. At least 1 should be diagnosed before age 50. Other familial tumors should be excluded.

Several investigations outlined the role of lost or mutated junctional molecules (E-cadherin, catenins, integrins, *etc.*) in the pathogenesis of diffuse gastric cancer (DGC). In particular, more than 50% of advanced diffuse gastric cancer patients showed mutations of CDH1 gene^[22-25]. Germline mutations of the CDH1 gene have been recently reported in gastric cancer families with diffuse-type tumors but not in those with intestinal-type tumors^[26]. These families are characterized by a highly penetrant susceptibility to DGC with an autosomal dominant pattern of inheritance, predominantly in young persons. Familial aggregation of GC occurs in about 1% of gastric cancer patients. Although the genetic factors resulting in this aggregation have been unclear, the study indicates that germline mutations of CDH1 genes, do contribute to such a clustering. Mutations of the CDH1 gene has a high penetrance and confers a lifetime risk of gastric cancer of 75-80% for carriers^[27-30].

The International Gastric Cancer Linkage Consortium (IGCLC) predicted that up to 25% of families fulfilling the criteria for hereditary DGC would harbour CDH1 germline mutations^[29]. CDH1 is well known as a strong invasion suppressor in experimental tumor cell systems. Inactivated mutations have been identified for the CDH1 gene in HGC. To date, 69 somatic mutations have been reported comprising, in addition to few missense mutations, mainly splice site mutations and truncation mutations caused by insertions, deletions and nonsense mutations. Up to now,

27 germline mutations previously reported are distributed along with CDH1 gene in Table 1. While in sporadic gastric cancers, truncation mutations are uncommon and sequence changes usually result in either missense mutations (most commonly in exons 8 and 9) or exon skipping, especially in exons 6-9^[30]. From the 27 CDH1 mutations described to date, 24 are inactivated ones (splice-site, frame shift and nonsense) and the remaining 4 are missense^[31-37].

¹Missence mutation; -No information obtained from the published paper.

Mutant E-cadherins are not localized in the lateral regions of cell-to-cell contact sites of adherin junctions (AJs) and show apical and perinuclear localization. It is explained by an inability of the cells to complete polarization^[38]. These may result in disassembly of AJs and consequently conversion to a spindled and more scattered cell morphology^[39]. Impaired processing of mutant E-cadherin, loss of the putative calcium binding sites or essential amino acid motives, may cause a transition from a rigid to a more globular molecular structure of the extracellular domain. In response to extracellular signals, cells react by dissolving their cell-to-cell contacts and by changing their shape and the strength of their attachment to the substrate, thus resulting in significant reduction or loss of its ability to bind in a homophilic fashion to neighboring cells^[40,41]. Cell motility is thought to be the result of the concerted action of all these individual events.

Mutant E-cadherin lacking the cytoplasmic domain or the β -catenin-binding site may tie up essential catenins, which influences its function to suppress cell motility. Actin filaments are drastically reduced^[42]. The actin belt characteristics of epithelial cells are lost^[43]. Because proper anchorage to the cytoskeleton is necessary for E-cadherin function, suppression of E-cadherin expression or of its functional activity, or a defect in any of the molecules involved in this system, may account for the ability of cancer cells to detach from the primary tumor and invade locally. Cells with initial calcium-dependent cell aggregation exhibits decreased aggregation and remarkably increase cell motility when E-cadherin is not expressed (Figure 2).

We can conclude that these E-cadherin mutations may not only affect cell adhesion but also play an important role in a trans-dominant-active manner, thus leading to increased cell motility. They are the cause of multiple morphological and functional disorders and could induce scattered morphology and invasive behavior of diffuse gastric cancer.

Tissue specific gene expression has been explained by the interaction of promoter sequences with their specific transcription factors. *In vivo*, foot printing analysis revealed that positive regulatory elements of the E-cadherin promoter were specifically bound to transcription factors in E-cadherin-expressing cells. Mapping of DNase type I hypersensitive sites showed that the chromatin structure in the promoter region was loosened in expressing cells but condensed in non-expressing cells. Furthermore, endogenous E-cadherin promoter was methylated at CpG island sites in undifferentiated cells. All these suggested that silencing of the promoter during epithelial mesenchymal transition and tumor progression was due to a loss of factor-binding *in vivo* and chromatin rearrangement in

Figure 2 Schematic of CDH1 germline mutations in HGC. Truncating mutations are shown above the gene and missense mutations below. the regulatory region^[10,44]. Comijn *et al.*^[11] reported that multi-zinc finger protein, SIP1 (ZEB-2) and snail showing specific DNA binding activity could bind to partly overlapping promotor sequences and had similar silencing effects.

CDH1 MUTATION FOR HGC DIAGNOSIS AND THERAPY

Indicator for prophylactic total gastrectomy

HGC was associated with E-cadherin. Penetrance of the gene ranged from 70% to 80%, and the average age of gastric cancer patients was 37 years^[20,45,46]. These characteristics have led to the consideration of prophylactic total gastrectomy (PTG) in family members with CDH1 mutations. Lewis *et al.*^[45] performed this operation on 6 asymptomatic members in 2 families based on family pedigree and genetic analysis. The gastric specimens appeared normal and the results of routine pathologic examination were negative for cancer, but all the patients had microscopic foci of cancer, often at multiple sites, with overlying normal gastric mucosa. These results indicate that CDH1 gene mutations in association with familial gastric cancer are a new disease for PTG. Huntsman *et al.*^[28] also recommended genetic counseling and prophylactic gastrectomy in young people. The morbidity of this operation was much higher than that of other genetic diseases. The morbidity of prophylactic gastrectomy in the young, healthy population has been estimated as following: 1-2% mortality, 10-20% major acute morbidity, principally related to esophageal anastomotic procedure, and 100% long term morbidity related to weight loss, rapid intestinal transit, dumping syndrome, and diarrhoea. The high surgical risk of the procedure should be minimised by operations at centers with experience rich in gastric surgery. The decision to perform prophylactic gastrectomy should be balanced with age based risk and based on age specific penetrance data. Other factors, for example, the decision to operate on children, may affect the decision regarding the timing of prophylactic gastrectomy, and it is essential that patients carrying the gene have the opportunity extensive counseling and discussion with clinicians, geneticists, and counsellors before making the decision. The risk of other cancers (breast, colon) should also be targets of screening, as they may also be increased in this population, and patients should be counselled regarding these. However, germline mutations of E-cadherin could be used to identify individuals with a high risk^[47].

Target for radioimmunotherapy

Radiolabeled mAb used in radioimmunotherapy is limited because of lack of tumor specific antigens. In most cases reported thus far, tumor antigens serving as targets are not tumor-specific, being overexpressed in tumor cells and also at a lower level in normal cells. Only one tumor-specific mAb that recognizes a mutant form of the epidermal growth factor receptor (EGFRv III) has been found in different tumor types^[48]. Inframe deletions of exons 8 or 9 in the mRNA coding for E-cadherin are characteristic of DGC. So a rat mAb (d9mAb) was generated that specifically reacts with this mutation, and d9mAb was found to react with 13% of E-cadherin-expressing DGCs^[49]. Senekowits-Schmidtke *et al.*^[50] conjugated d9mAb with the α -emitting radionuclide ²¹³Bi, and tested for its binding specificity in sc and ip tumors expressing mutant E-cadherin. Seventy-eight percent of the total activity in ascites fluid was bound to free tumor cells, whereas in control cells expressing wild-type E-cadherin, the binding was only 18%. The selective binding of the ²¹³Bi-labeled, mutation-specific monoclonal antibody d9mAb raised its significant potential for the local radio-immunotherapy of disseminated, diffuse-type gastric carcinoma.

Markers for prognosis and evaluation

Gastric cancer remains a major cause of cancer mortality globally

but no good prognostic tumor markers are available. The most frequently used tumor markers in gastric cancer are carcinoembryonic antigen (CEA) and CA19-9^[51]. Gastric cancer antigen MG-7 may be a good marker for GC^[52], or even the detection of circulating DNA in serum reported recently^[53], but only a modest proportion of patients had elevated levels of these markers. Under-expression of E-cadherin molecules has been found in various malignancies and has a potential value as a prognostic marker^[54]. Serum soluble E-cadherin was found in the circulation of normal individuals but was particularly elevated in patients with malignancies. s-E-cadherin might derive from cancer tissues, though the expression of E-cadherin was decreased. With increased protease, the degradation products of tissue E-cadherin could accumulate and release into peripheral blood. However, its value in gastric cancer is controversial. Velikova *et al.*^[55] were unable to show a significant difference in serum soluble E-cadherin between patients with gastric cancer and normal subjects, while Gofuku *et al.*^[8] showed that concentrations were significantly elevated in 67% patients. Chan *et al.*^[56] confirmed its potential value as a prognostic marker. A high concentration could predict palliative/conservative treatment and T4 invasion. Gabbert *et al.*^[57] studied 413 gastric cancer patients, including all histological tumor types and stages. As shown by univariate and multivariate Cox regression analyses, patients with E-cadherin-positive tumors had significantly better 3 and 5 year survival rates than patients with E-cadherin-negative tumors. This prognostic effect remained present in a multivariate Cox regression analysis, including the prognostic parameters pT category, pN category and vascular invasion, suggesting that it is an independent prognostic marker.

In short, hereditary gastric cancer is still a challenge, especially its diagnosis and treatment^[58], although some progress has been achieved in recent years with the development of molecular biology and new methods.

ACKNOWLEDGEMENTS

We greatly thank Professor Bo-Rong Pan of the Fourth Military Medical University for his valuable comments on our study and Dr. Ying Lin, Department of Otolaryngology, Xijing Hospital, the Fourth Military Medical University for her helpful assistance on the manuscript.

Abstract

AIM: Survivin, a recently identified member of the inhibitor of apoptosis protein family, is expressed during development and in various human cancers. However, its expression in normal tissues and clinical relevance in cancers are still debated. In the present study, we analyzed the expression of the survivin gene in human primary and metastatic gastric cancer cells as well as in paired epithelial cells from normal gastric mucosa by means of a novel laser capture microdissection (LCM) technique coupled with reverse transcription - polymerase chain reaction (RT-PCR).

METHODS: Thirty patients who had undergone gastrectomy with lymph node dissection for gastric cancer without preoperative treatments were included. Neoplastic tissue, metastatic lymph nodes, and apparently uninvolved normal tissue were collected from each patient. LCM-captured "pure" cell groups were respectively subjected to RT-PCR analysis with primers specific for the survivin gene.

RESULTS: Of the paired samples from 30 gastric cancer patients studied, 24 (80%) primary gastric cancer cell groups and 7 (23%) adjacent morphologically "normal" gastric epithelial cell groups were shown to have a detectable survivin expression. There was a statistically significant difference in survivin expression between these two groups ($P < 0.01$). Meanwhile, 95% (19/20) of the metastatic gastric cancer cell groups from lymph nodes had a clear expression of the survivin gene. However, no significant correlation between survivin expression and clinicopathological features of gastric cancer was observed in the present study.

CONCLUSION: Survivin expression is present in the majority of gastric cancer cell groups obtained by LCM techniques. The high expression rate in metastatic lesions suggests a possible role of survivin in cancer invasiveness and metastasis. It may contribute to the detection of gastric

cancer micrometastasis as a potential molecular marker. In addition, the high expression percentage renders survivin a potential target in the therapy for gastric cancer.

INTRODUCTION

Alteration of the balance between apoptosis and cell proliferation could result in a disturbance of tissue homeostasis, and dysregulation of apoptosis is associated with various cancers^[1]. Considerable interest has focused on the identification of regulators of apoptosis, which may potentially contribute to the development of cancer. Recently, a novel member of the inhibitor of apoptosis (IAP) protein family, designated as survivin, has been identified. The survivin gene is located on chromosome 17 and spans 14.7 kb, encoding a protein of 142 amino acids. Unlike other IAP proteins, survivin contains a single baculovirus IAP repeat and lacks a C-terminal RING finger^[2]. Another significant feature of survivin is its unique expression pattern as one of the most tumor-specific human gene products^[3]. While embryonic and fetal organs contain abundant survivin mRNA and protein, most terminally differentiated normal tissues do not. By contrast, dramatically strong expression of survivin is detected in the vast majority of tumors^[4]. Moreover, the overexpression of survivin has been shown to be correlated with aggressive and histologically unfavorable neuroblastoma^[5], and associated with the poor prognostic outcome in colorectal cancer^[6], non-small-cell lung cancer^[7], breast cancer^[8], soft tissue sarcoma^[9] and B-cell lymphoma^[10].

However, since its identification five years ago, there have been some contradictory reports about the clinical relevance of survivin expression in cancer. Gianani *et al.*^[11] found the expression of survivin was not a specific marker of adenocarcinoma of the colon but showed characteristic patterns of expression in normal colonic mucosa. In gastric carcinoma which is the second most frequent cause of cancer death according to a worldwide estimation, Lu *et al.*^[12] showed that survivin could promote aberrantly tumor cell viability, whereas Okada *et al.*^[13] indicated that survivin expression in nuclei of tumor cells was predictive of favorable prognosis in patients. In the present study, we used laser capture microdissection (LCM), a novel technique that allows rapid, reliable and accurate procurement of cells from specific regions of tissue sections under direct visualization, to obtain the primary and metastatic gastric cancer cells as well as the matched normal epithelial cells from the same patient and analyzed mRNA expression of the survivin gene.

MATERIALS AND METHODS

Patients

Thirty patients (25 males and 5 females) underwent gastrectomy

with lymph node dissection for gastric carcinoma at China Medical University between March and September of 2 000 were included in the study. None of the patients received preoperative chemotherapy. The patients ranged in age from 33 to 78 years (median, 57 years). Routinely, the resected specimens were histologically examined by H&E staining according to the general rules of the classification of gastric carcinoma suggested by the Japanese Research Society of Gastric Cancer^[14]. Details of the Borrmann gross type, the Lauren histological classification, the Ming classification of growth patterns, grade of differentiation, and levels of lymph node metastasis were obtained from the operative records and the pathology reports. The pT classification representing the depth of wall invasion and the pN classification representing the extent of regional lymph node metastasis were performed using standard criteria of the 5th TNM staging system^[15]. The total lymph node number collected from the tissue was 15 or more for a reliable pN classification.

Tissue samples

Tumor tissues, lymph nodes, and apparently uninvolved normal tissues were collected from each patient immediately after surgical removal and snap-frozen in liquid nitrogen and kept at -80 °C until use. The tissues were then embedded in OCT for subsequent LCM harvest. Sections were cut at 8 µm with a cryostat and mounted on uncoated glass slides. The slides could be immediately stored at -80 °C for a few weeks. In order to exclude the areas of necrosis, tumor tissues from all patients were selected from the most viable areas of tumors. The lymph nodes were obtained according to the standard protocol. The number of removed and positive lymph nodes for various stations was documented by the pathologists. For the selection of matched uninvolved gastric mucosa, specimens were obtained from tissues at a distance of more than 10 cm from the tumor edge and confirmed histologically.

LCM

OCT embedded blocks of frozen tissue were serially cut. For each case, the first section was stained with H&E routinely for histological analysis and digitalized. The following serial sections stained with H&E according to the standard protocol recommended by NIH^[16] were subjected to LCM using a LM200 system (Olympus, Japan/Arcturus Engineering Inc, US). Areas of interest were selected under microscopic guidance, and covered with ethylene vinyl thermoplastic (EVA) film mounted on optically transparent cap. The infrared laser was activated by the push of a button, which melts the film directly above the target cells. This melt caused a binding to form between the cells and the transfer film that was stronger than the binding between the cells and the slide^[17]. The parameters used for LCM included a laser diameter of 7.5 µm, laser power of 50-60 mW. Five thousand laser pulse discharges per specimen were used to "capture" approximately 10 000 morphologically normal gastric epithelial cells, malignant primary gastric cancer cells and malignant metastatic (to a perigastric lymph node) gastric cancer cells from each case. Each population was estimated to be >95% "homogeneous" as determined by microscopic visualization of the captured cells. The caps with captured cells were then fitted onto 0.5 mL microcentrifuge tubes containing 200 µL TRIZOL Reagent. Caps briefly placed onto the section without laser activation were used as negative control.

RNA extraction from LCM-captured cells

Total RNA from each population of laser-captured cells was independently extracted using TRIZOL Reagent (Life Technologies, Inc) by means of a modification of the RNA microisolation protocol recommended by the manufacturer. Briefly, tubes containing collected cells and TRIZOL Reagent

were inverted and allowed to sit at room temperature for 30 min, then 0.5 µL glycogen (20 µg/µL) carrier and 40 µL chloroform were added to each tube. The tubes were vigorously shaken by hand for 15 s and incubated at room temperature for 2 min. The samples were centrifuged at 11 000 g for 15 min at 4 °C. The aqueous layer was transferred to a fresh 0.5 mL tube, 100 µL isopropanol was added and precipitated at -70 °C for 1 h. After centrifuged at 11 000 g for 10 min at 4 °C, the pellet was then washed in 200 µL of 750 mL/L ethanol and resuspended in 7 µL diethylpyrocarbonate-treated RNase free water.

Reverse transcription-polymerase chain reaction (RT-PCR)

For RT-PCR analysis of the LCM-captured cells, first strand cDNA was prepared from total RNA by using a first-strand synthesis kit (Life Technologies, Inc). Seven microliters of total RNA isolated from approximate 10 000 cells was mixed with 1 µL of oligo-(dT)₁₂₋₁₈ primer, 1 µL of random hexamers primer (N₆) and 1 µL of 10 mmol/L dNTPs in a total volume of 10 µL. They were heat denaturated at 65 °C for 5 min, then chilled in ice. Four microliters of 5×first-strand reaction buffer, 2 µL of 0.1 mol/L DTT, 2 µL of 25 mmol/L MgCl₂, 1 µL of RNasin (40 U/µL) (Promega, Madison, WI, USA), and 1 µL of SUPERScript II RTase (200 U/µL) (Life Technologies, Inc) were added and incubated at 25 °C for 10 min, followed by incubation at 42 °C for 50 min for first-strand synthesis. The reverse transcriptase was inactivated at 70 °C for 15 min. PCR amplification with specific primers was performed in a final reaction volume of 50 µL containing 1×PCR buffer, 200 µmol/L each dNTP, 0.5 µmol/L each primer, 1.25 unit of Taq polymerase (TaKaRa Biotech, Dalian, China) and 2 µL of RT product. Programmable temperature cycling (UNO II, Biometra, Germany) was performed using the following profiles: an initial hot start at 95 °C for 2 min, followed by 38 cycles at 95 °C for 30 s, at 58 °C for 20 s and at 72 °C for 30 s. After the last cycle, an elongation step was extended at 72 °C for 5 min. For each set of PCR, parallel reactions with human genomic DNA from peripheral blood were performed to test for genomic DNA contamination, and double distilled water instead of cDNA template was also included as negative control to assure the quality of PCR. An 8 µL aliquot of the PCR product underwent electrophoresis on 15 g/L agarose gel stained with ethidium bromide and was visualized under UV trans-illuminator. The following primers were used: (A) survivin gene, forward primer 5'-CCCTGCCTGGCAGCCCTTTC-3', and reverse primer 5'-CTGGCTCCCAGCCTTCCA-3' (PCR product, 188 bp); (B) glyceraldehyde-3-phosphate dehydrogenase (G3PDH), forward primer 5'-AGGGGTCTACATGGCAACTG-3', and reverse primer 5'-CGACCACTTTGTCAAGCTCA-3' (PCR product, 227 bp).

Statistical analysis

Statistical comparisons for significance between nominal variables were evaluated by the chi-square test and the Fisher's exact probability test. All the statistical analyses were performed using SPSS10.0 computer software and *P* of 0.05 was used as significance criterion.

RESULTS

Survivin expression in microdissected gastric epithelial and cancer cells

As shown in Figure 1, LCM allowed us to precisely sample the targeted cells. In this manner, gastric normal epithelial or cancer cells were homogenously obtained and bonded to the transfer film. When the cap together with the film was lifted from the tissue section, surrounding tissues remained attached to the glass slide. As a result, the morphology of the captured cells was well preserved and could be readily visualized under a microscope. To detect survivin gene mRNA expression by RT-PCR, a pair of specific primers located at 2 flanking exons was

designed and synthesized. The expected specific transcript of survivin gene represented by an 188 bp fragment was amplified (Figure 2). Of the paired samples from 30 gastric cancer patients studied, 24 (80%) primary gastric cancer cell groups and 7 (23%) adjacent morphologically "normal" gastric epithelial cell groups were shown to have a detectable survivin expression. There was a statistically significant difference in survivin expression between these two groups ($P < 0.01$). Furthermore, survivin mRNA was never detected in morphologically non-tumorous gastric epithelial cell groups when the paired cancer cell group was negative for survivin mRNA.

Strikingly, 95% (19/20) of the metastatic gastric cancer cell groups from lymph nodes had a clear expression of the survivin gene. Three cases showed positive results for the surviving-

specific RT-PCR assay in metastatic cancer cells while none of their paired primary cancer cells had a detectable expression of the survivin mRNA.

Relationship between survivin expression and clinicopathological characteristics in gastric cancer patients

We examined the relationship between survivin expression in microdissected primary cancer tissues and the clinicopathological features of gastric cancer (Table 1). There was no significant correlation between survivin expression and Borrmann gross type, depth of wall invasion, Lauren histological classification, Ming's classification of growth patterns, grade of differentiation, the presence and extent of lymph node metastasis.

We also analyzed the survivin gene expression pattern in

Figure 1 Laser capture microdissection of cells from gastric carcinoma. A: Morphology map view for pathological diagnosis ($\times 100$). B: Group of gastric carcinoma cells were selected for LCM ($\times 200$). C: The same section revealed where carcinoma cells were lifted from the section ($\times 200$). D: The carcinoma cells were removed on the plastic film to provide a template for PCR.

Table 1 Relationship between survivin expression and different histopathological features

Variant	Survivin expression in primary cancer		¹ P	Survivin expression pattern in cancer and normal tissues			P
	Positive	Negative		N(-)T(-)	N(-)T(+)	N(+)T(+)	
Gross type							
Borrmann I + II	7	1	² NS	1	4	3	NS

both paired normal and primary cancer cells and its relationship with clinicopathological features. Thirty patients were divided into N (-) T (-), N (-) T (+) and N (+) T (+) groups. Still, no significant correlation between survivin expression pattern and the factors mentioned above was observed.

Figure 2 Representative RT-PCR results of survivin expression in normal (N), tumor (T) and metastatic carcinoma (M) cells obtained by LCM from 3 patients suffering gastric cancer. Case 1 was a patient without lymphatic metastasis, cases 2 and 3 were patients with lymphatic metastasis. G: Genomic DNA from human peripheral blood. W: Water as negative control.

DISCUSSION

Apoptosis plays an important role in organ homeostasis, by eliminating senescent or damaged cells. The suppression of apoptosis has been considered to contribute to carcinogenesis and cancer progression by aberrantly prolonging cell viability with accumulation of mutations^[18,19]. Survivin is a newly identified bifunctional protein that suppresses apoptosis and regulates cell division. Based on the previously published studies, its mRNA is abundantly expressed in fetal tissues, but not in normal adult tissues except placenta and thymus. Meanwhile, reactivation of survivin expression has been demonstrated in tumors of lung^[7], stomach^[20], breast^[8], colon^[21], esophagus^[22], liver^[23], pancreas^[24], bladder^[25], uterus^[26], ovary^[27], *etc.* This specific distribution pattern has aroused great interest in making the survivin gene as a potential cancer therapeutic target. However, the expression of the survivin gene in normal tissues is currently debated. Several recent studies have shown survivin expression in normal tissues including skin^[28], endometrium^[29], endothelial cells^[30], colonic mucosa^[11] and muscle^[9]. In the present studies, we sought to investigate whether survivin expression could be a specific marker during the development of gastric cancer.

It has been generally accepted that molecular analysis of neoplastic tissues *in vivo* is challenged by the heterogeneity of samples. Genetic alternations can be masked by contaminating bystander cells. Survivin mRNA was detected in normal tissue adjacent to soft tissue sarcoma cells^[9]. Therefore, it is necessary to obtain a pure population of cells to evaluate the possible role of the survivin gene in tumor progression. The recent development in LCM, a highly sophisticated technique for the transfer of isolated pure cells from the histological slide into a reaction tube, could afford the opportunity to overcome this obstacle^[31]. A few published studies and our previous data (unpublished data) have shown that LCM coupled with RT-PCR technique is a reliable method for the molecular analysis of gene profiles in specific tissues. We combined RT-PCR with LCM to determine the survivin expression in primary cancer cells, metastatic cancer cells, and paired normal epithelial cells.

Our results demonstrated that 23% of morphologically normal epithelial cells had a detectable survivin mRNA expression. By contrast, Lu *et al.*^[12] reported that no survivin expression was found in normal gastric mucosa neighboring the cancer cells in an immunohistochemical analysis. Meanwhile,

the rate of survivin expression was relatively lower in normal tissue we examined than in previous studies reporting 47.1% in normal esophageal epithelial tissues^[22] and 29.1% or 100% in normal colorectal tissues^[6,11]. One possible explanation for these results could be the different sensitivity of methods and the varied criteria for positivity determination. Further studies may be required to check out whether the expression of the survivin gene in normal tissues is caused by a high proportion of mitotically active cells.

In accordance with the recently published reports showing 88% positive survivin expression in gastric cancer tissues, we found a detectable expression of the survivin gene in 24 of 30 primary gastric cancer cell groups. The percentage was significantly higher than that in normal gastric epithelial cells. These results suggested that survivin expression in gastric cancer was a quite common event and might play an important role in the carcinogenesis of stomach. Several studies have consistently shown that survivin expression could inhibit cell death induced by various apoptotic stimuli^[4]. A role for survivin in blocking apoptosis has also been found *in vivo*^[32]. Like other proteins in the IAP family, survivin might bind specifically to caspase-3 or caspase-9, which are the effectors of apoptosis^[33]. On the other hand, survivin was expressed in the G2-M phase of the cell cycle and its overexpression might contribute to overcoming the G2-M phase checkpoint to enforce progression of cells through mitosis^[34]. Therefore, not surprisingly, survivin was shown to be present in the majority of gastric cancer cells.

Even though no significant correlation was observed between survivin expression in primary cancer or its distribution pattern in normal and cancer tissues and tumor invasiveness or the presence of lymph node metastasis, it is still striking to find that 95% of the metastatic cancer cells from lymph nodes had a clear expression of the survivin mRNA. In three cases, survivin expression was detected in metastatic lesions, but not in primary cancer cell groups. One possible explanation might be that survivin expression was upregulated in some metastatic cancer cells. By sensitive quantitative RT-PCR assay, significantly increased survivin expression levels were found in soft tissue sarcomas with more aggressive biological behavior^[9]. Alternatively, more survivin expressions detected in metastatic lesions could result from the presence of a higher proportion of survivin-expressing cells compared with that in primary sites. Immunohistochemical analysis revealed that the percentage of survivin-positive cells in primary gastric cancer was quite variable, ranging from 20-100%^[12]. It has been shown that failures in normal apoptosis pathways could contribute to cancer progression by supporting anchorage-independent survival during metastasis. Considering the anti-apoptotic function of survivin, it seems reasonable to deduce that survivin expression might facilitate the survival of cancer cells at distant sites^[35]. Also, survivin played a crucial role in angiogenesis^[30,36], which is considered as one of the critical steps for cancer cell spread and metastasis. Moreover, when analyzed retrospectively, cancer patients expressing survivin exhibited a shorter survival, correlated with unfavorable prognosis and accelerated rates of recurrences^[5-10]. These results together with ours suggested a possible role of survivin in cancer invasiveness and metastasis. Further analysis is necessary to assess the expression levels in metastatic lesions by accurately quantitative methods.

Furthermore, the extremely high survivin expression rate in metastatic lesions indicated a possible approach using survivin as a molecular diagnostic marker for micrometastasis in gastric cancer. Our parallel studies have shown that the detection of survivin expression in peritoneal lavaged fluid is a specific and sensitive assay for prediction of peritoneal micrometastasis in gastric cancer. Also, survivin was detected in the urine of all patients tested with new or recurrent bladder cancer, whereas normal volunteers and patients with non-neoplastic diseases were tested negative for urine survivin^[4]. However, a large scale

and long follow-up should be carried out to validate these results.

Recently, expression of a phosphorylation-defective survivin mutant (Thr34→Ala), which acted as a dominant-negative antagonist of survivin pathway and prevented phosphorylation of endogenous protein, has been reported to trigger apoptosis in several human melanoma cell lines *in vitro* and to prevent tumor formation or suppress the growth of existing tumors by 60-70% *in vivo*^[37]. Therefore, the role of survivin in cancer progression has made it an attractive therapeutic target against cancer development.

In summary, our data indicate survivin expression is present in the majority of gastric cancer cell groups obtained by LCM techniques. The high expression rate in metastatic lesions suggests a possible role of survivin in cancer invasiveness and metastasis. It might contribute to the detection of micrometastasis in gastric cancer as a potential molecular marker. In addition, the high expression percentage renders survivin a candidate target in the therapy for gastric cancer.

Abstract

AIM: To determine the role of interferon (IFN) with or without ribavirin in preventing or delaying hepatocellular carcinoma (HCC) development in patients with hepatitis C virus (HCV) related cirrhosis. Data on the preventive effect of IFN plus ribavirin treatment are lacking.

METHODS: A total of 101 patients (62 males and 39 females, mean age 55.1 ± 1.4 years) with histologically proven HCV related liver cirrhosis plus compatible biochemistry and ultrasonography were enrolled in the study. Biochemistry and ultrasonography were performed every 6 mo. Ultrasound guided liver biopsy was performed on all detected focal lesions. Follow-up lasted for 5 years. Cellular proliferation, evaluated by measuring Ag-NOR proteins in hepatocytes nuclei, was expressed as AgNOR-Proliferative index (AgNOR-PI) (cut-off = 2.5). Forty-one patients (27 males, 14 females) were only followed up after the end of an yearly treatment with IFN-alpha2b (old treatment control group = OTCG). Sixty naive patients were stratified according to sex and AgNOR-PI and then randomized in two groups: 30 were treated with IFN-alpha2b + ribavirin (treatment group = TG), the remaining were not treated (control group = CG). Nonresponders (NR) or relapsers in the TG received further IFN/ribavirin treatments after a 6 mo of withdrawal.

RESULTS: AgNOR-PI was significantly lowered by IFN ($P < 0.001$). HCC incidence was higher in patients with AgNOR-PI > 2.5 (26% vs 3%, $P < 0.01$). Two NR in the OTCG, none in the TG and 9 patients in the CG developed HCC during follow-up. The Kaplan-Mayer survival curves showed statistically significant differences both between OTCG and CG ($P < 0.004$) and between TG and CG ($P < 0.003$).

CONCLUSION: IFN/ribavirin treatment associated with re-treatment courses of NR seems to produce the best results in terms of HCC prevention. AgNOR-PI is a useful marker of possible HCC development.

INTRODUCTION

A number of studies have reported that treatment of HCV related cirrhosis might have a preventive effect on hepatocellular carcinoma development^[1-15]. This has been recently confirmed by a meta-analysis concluding that "Interferon (IFN) prevents or delays the development of hepatocellular carcinoma (HCC) in patients with HCV-related cirrhosis, the magnitude of the overall effect is low and the benefit may be partly due to spurious associations. The preventive effect seems more evident among sustained responders to IFN^[16]". However, with old interferon schedules, sustained responders did not exceed 10-15% of treated patients^[1-15].

The response rate to IFN has changed since the introduction of ribavirin^[17], the induction protocols^[18] and, finally, the pegylated interferons^[19]. Data on the preventive effect on HCC of more powerful therapeutic schemes are lacking.

Our study was started in 1997 with the purpose of assessing the efficacy of interferon (given with an induction protocol) plus ribavirin (the gold standard treatment at that time) in the prevention of HCC development.

MATERIALS AND METHODS

Patients

A total of one hundred and one consecutive patients (62 males and 39 females, mean age 55.1 ± 1.4 years) with HCV related liver cirrhosis diagnosed by liver biopsy plus compatible biochemical parameters and ultrasonographic signs of portal hypertension were enrolled in the study. The baseline histologic activity of all patients was moderate to severe.

Study design (Figure 1)

Forty one subjects (27 males and 14 females, mean age 55.0 ± 1.1 years), who were ending a 12-mo IFN course were followed-up without any other treatment (old treatment control group = OTCG). All patients of OTCG underwent liver biopsy at the end of treatment, while still on IFN.

The other 60 untreated patients (35 males and 25 females, mean age 55.7 ± 1.7 years) were randomized in two groups of 30 subjects stratified according to sex and silver stained nucleolar organizer region - proliferative index (AgNOR-PI). Thirty were treated with IFN+ribavirin (treatment group = TG) and the remaining received no drugs (control group = CG). Nonresponders or relapsers to IFN/ribavirin received further courses of treatment after a 6 mo withdrawal. All patients were followed up for five years.

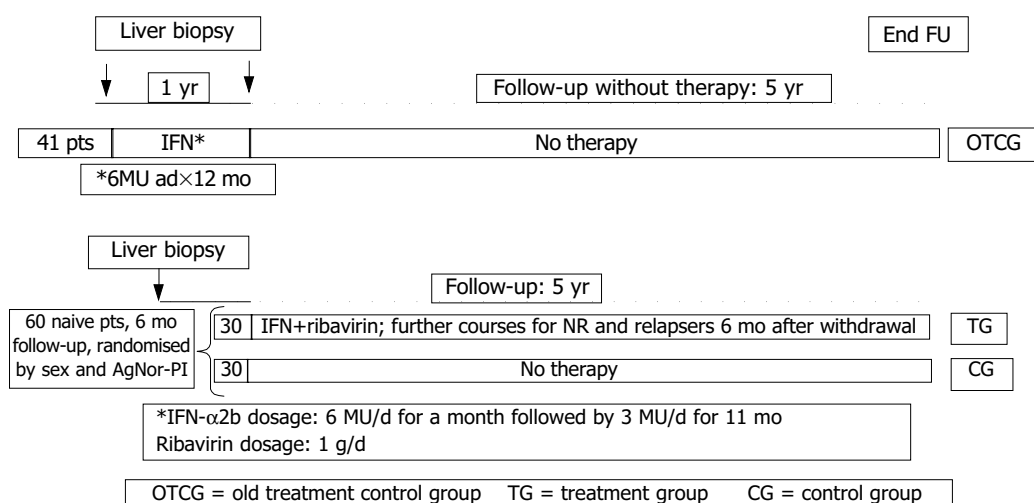

Figure 1 Study design.

The study was carried out according to the Helsinki protocol and all patients gave their written informed consent.

Ultrasonographies, blood cell count, α 1-fetoprotein, γ GT, transaminases, PT, total protein and their fractions were performed every 3 mo in all patients. Additional tests were performed in patients under active treatment: blood cell count every 10 d for two months and then monthly; transaminases, urea, creatinine and uric acid were tested monthly. When focal lesions were detected by ultrasound (US), US-guided liver biopsy was performed.

Protocol treatments

The 41 patients in OTCG were treated with IFN α -2b 6 MU/d for a month followed by 3 MU/d for 11 mo. The 30 patients in TG received the following α -2b schedule: 6 MU/d for a mo then 3 MU/d for 11 mo plus ribavirin 1 g/d for 12 mo. IFN and ribavirin dose reductions were made according to the biochemistry and tolerance of each patient. However, a total dose equal to or greater than 540 MU and 400 mg of ribavirin per day were considered suitable. Nonresponders and/or relapsers received further IFN treatment courses after a 6-mo withdrawal.

Liver histology and AgNOR-PI determination

Ultrasound guided liver biopsies were fixed in 40 g/L formaldehyde solution for 6 h and embedded in paraffin wax. Four 4 μ m thick sections were cut from routinely processed paraffin blocks. Hematoxylin-eosin, silver impregnation, Pearl's staining were performed to define the severity of parenchymal, portal and periportal inflammation and the stage of disease by evaluating fibrosis and the presence of stainable iron into the liver. Histology was evaluated by two blinded independent observers according to Scheuer score.

The AgNOR staining was performed on routine sections of liver tissue on poly-lysine pretreated slides after immersion in xylene and ethanol. After progressive re-hydration sections were covered with plastic resistant to high temperature, put in a sodium citrate (100 g/L, pH 6.0) solution and boiled in pressured ovens (120 $^{\circ}$ C for 20 min). Then, sections were stained by silver impregnation in a gelatine solution (formic acid 10 mL/L and silver nitrate 500 g/L, 100:2 v/v) according to Ploton^[20], for 10 min, at 37 $^{\circ}$ C. Quantitative analysis of Ag-NOR proteins was made by measuring silver-stained areas (μ m²) within nuclei present in 50 consecutive microscopic fields (40 \times magnification) using a specific computer-assisted imaging software on biopsy specimen sections (VIDAS, Kontron Elektronik, Germany). The percentage of hepatocytes with an AgNOR area >7 μ m² (indicative of a proliferative state) was expressed as proliferative

index (AgNOR-PI) (cut-off = 2.5%).

Statistical analysis

Results were expressed as mean \pm SE. The statistical analysis was carried out according to the intention to treat analysis. Wilcoxon test was used when appropriate and the Kaplan-Mayer model was applied to the evaluation of survival probability.

RESULTS

Biochemistry

Demographic and biochemical characteristics of the patients at enrollment are shown in Table 1. The three groups were comparable for age, sex, biochemical parameters, genotype distribution and AgNOR-PI.

Table 1 Baseline patient characteristics

	OTCG	TG	CG	P<
M:F ratio	27:14	17:13	18:12	NS
Age (yr)	55.3 \pm 1.8	54.6 \pm 2.1	57.2 \pm 2.0	NS
AST (U/L)	67.1 \pm 6.6	61.9 \pm 7.2	79.4 \pm 8.4	NS
ALT (U/L)	92.5 \pm 10.8	79.8 \pm 8.7	91.8 \pm 9.1	NS
γ GT (U/L)	56.5 \pm 7.2	52.1 \pm 7.3	65.2 \pm 9.4	NS
Albumin (g/dL)	4.2 \pm 0.07	4.2 \pm 0.07	4.1 \pm 0.06	NS
α 1feto (ng/mL)	6.8 \pm 1.25	8.4 \pm 2.36	6.3 \pm 1.0	NS
HCV1b	63%	67%	65%	NS
AgNOR-PI (%)	20.1 \pm 2.35	19.6 \pm 2.84	18.2 \pm 2.6	NS

OTCG = old treatment control group; TG = treatment group, CG = control group.

AgNOR PI

A significant reduction in AgNOR-PI was observed after IFN-treatment (Figure 2).

A significant difference in HCC development was observed according to AgNOR-PI: 9 out of 35 (26%) with basal AgNOR-PI >2.5% vs 2 out of 66 (3%) with basal AgNOR-PI <2.5% (P <0.01) (Figure 3).

Virological response

Six months after IFN withdrawal 8 out of 19 responders (24.5%) achieved sustained response (6 with genotype 2 or 3 and 2 with genotype 1) in the OTCG. Twenty one out of 30 patients in TG (70%) achieved a virological response that was sustained in 13 (43%) (9 genotype 2 and 4 genotype 1). None of the re-treated patients showed a sustained response.

Figure 2 AgNOR-PI in OTCG before and after 1 year of IFN treatment.

Figure 3 Incidence of HCC according to AgNOR-PI.

Figure 4 Percentage of HCC according to response to IFN.

Figure 5 Survival probability evaluated by Kaplan-Meier model.

HCC appearance

Two nonresponders in OTCG developed HCC during 5 years of follow-up after about 50 mo from interferon withdrawal. No subject in TG while 9 (30%) patients in CG developed HCC (Figure 4). The Kaplan-Meier survival model showed statistically significant differences both between OTCG and CG ($P<0.004$) and between TG and CG ($P<0.003$) (Figure 5). The HCC annual

rate of incidence in the CG was 5%.

DISCUSSION

The present data add new evidence on the clinical efficacy of IFN re-treatment of cirrhotic patients and show the usefulness of AgNOR-PI. The ability of IFN to prevent HCC development is evident both alone and in combination with ribavirin.

Previous observations in patients with chronic hepatitis C^[21-24], with or without cirrhosis, reported that re-treatment with IFN was more effective than single courses in preventing HCC appearance. However, in these studies^[21-24], the vast majority of patients had chronic hepatitis and no conclusions could be drawn on cirrhotic patients. We extended those observations to patients with HCV related cirrhosis. In accordance with a previous study^[1], a single course of IFN did not seem to be protective toward HCC appearance in a long term follow-up. In fact, in the two nonresponder patients of OTCG, HCC developed after about 50 mo, suggesting that the protective effect of IFN may vanish over time. This hypothesis is strengthened by the observation that re-treatment of nonresponders in the TG prevented HCC development during the 5 years of follow-up.

It is interesting to note that no statistically significant difference was observed in survival between TG and OTCG. This may suggest that the addition of ribavirin to IFN did not add any significant benefit in cirrhotics. However, the number of patients was probably not sufficient to appreciate any possible difference coming from the higher rate of sustained response obtained with the combination treatment. However, it remains that the key to HCC prevention is treatment with interferon that might be helpful even after a curative resection of HCC^[25].

Our study also showed that AgNOR-PI was a useful marker of hepatocyte regeneration which is able to predict a possible evolution to HCC. Furthermore, the two patients who developed HCC in the OTCG were those with the highest AgNOR-PI without improvement after treatment. This underlines the relevance of the index in the clinical setting, particularly in nonresponders to IFN. In fact, it may restrict the need of a strict surveillance only to those patients with a higher risk of developing HCC.

Previous observations with different techniques^[26-29] have shown that high hepatocyte proliferation is associated with HCC development. A recent paper evaluating nucleolar hypertrophy in patients with HBV and HCV related cirrhosis reported the index was significantly predictive of HCC development only in patients with HBV related cirrhosis^[30]. In patients with HCV related cirrhosis the index was not significantly related with HCC development, although a trend could be appreciated. A much larger and more homogeneous population of patients with HCV related cirrhosis (only Child A) in our study could account for the different results between the two studies.

In conclusion, the preventive effect of IFN on HCC development in HCV related cirrhosis is confirmed. Furthermore, a more efficacious treatment associated with re-treatment courses of nonresponders seems to produce the best results in term of HCC prevention. AgNOR-PI is a useful marker of hepatocyte proliferation that identifies patients at higher risk of developing HCC.

Abstract

AIM: To study the cell cycle alterations of human hepatoma cell line HepG₂ *in vitro* after ⁶⁰Co γ-irradiation and further to examine the mechanisms underlying the enhancement of radiosensitivity to γ-irradiation in HepG₂ transiently transfected with wild type p27^{kip1}.

METHODS: The proliferation of HepG₂ cells was evaluated with MTT assay, and the cell cycle profile and apoptosis were assessed by cell morphology, DNA fragmentation analysis and flow cytometry. HepG₂ cells were transfected with p27^{kip1} wild type by using Lipofectamine (LF2000), and the expression and subcellular localization of p27^{kip1} in HepG₂ were detected by immunocytochemistry.

RESULTS: ⁶⁰Co γ-irradiation inhibited the growth of HepG₂ cells in a dose-dependent manner. Apoptosis of HepG₂ cells was induced 48 h after γ ray exposure. Furthermore research was carried out to induce exogenous expression of p27^{kip1} in HepG₂. The expression of p27^{kip1} induced G₀/G₁ phase arrest in HepG₂ cells. The overexpression of p27^{kip1} enhanced ⁶⁰Co γ-irradiation-induced radiosensitivity in HepG₂ cells.

CONCLUSION: Overexpression of p27^{kip1} is a rational approach to improve conventional radiotherapy outcomes, which may be a possible strategy for human hepatoma therapy.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a relatively common malignancy, ranking fifth in frequency on a worldwide basis and causing more than one million deaths annually^[1,2] and there has been a progressive increase in the number of hepatoma cases over the past two decades^[3]. Unfortunately, most of the

cases of hepatoma are not curable because extensive resection is not possible. Though many approaches, such as transarterial chemoembolization (TACE), percutaneous ethanol injection (PEI), radiofrequency ablation (RFA), radiotherapy and liver transplantation have been developed to treat it, and the effective and survival rates are increased, a large number of patients would die from recurrence and metastasis^[4-8]. It is well known that improving the overall therapeutic effects of liver cancer depends on the combined therapies. The purpose of combined interventional therapies for HCC is to increase their therapeutic efficiencies and to reduce the side effects and complications.

Radiotherapy presents another interesting option for the treatment of HCC amidst the wide array of non-surgical modalities available^[11] and experimental and clinical studies have been reported that gene therapy is one of the more promising approaches for patients with advanced liver tumours^[9-12].

It is unknown about the combination of radiotherapy and gene therapy, especially the relationship between p27^{kip1} and radiosensitivity, although p27^{kip1} is a target for cancer therapeutics^[13]. p27^{kip1} is a key molecule in cell cycle control because of their specific and periodic expression during cell cycle progression. Knowledge of the function of cell cycle checkpoints in tumour cells may be important to develop treatment strategies for human cancers. Recent studies indicate that mutations in the p27^{kip1} gene have not been seen in many tumors including human hepatoma^[14]. Down-regulation and mislocalization expression of p27^{kip1} have recently been found to be associated with a poor prognosis in patients with hepatoma^[15]. However, the role of p27^{kip1} expression and gamma irradiation-induced apoptosis in human hepatoma cells has not been examined previously.

The purpose of this study was to investigate the function of p27^{kip1} and ⁶⁰Co γ-irradiation in the HepG₂ cell cycle progress and apoptosis, and then to examine the molecular mechanisms of radiosensitivity induced by p27^{kip1} and gamma irradiation in human hepatoma cells, focusing on the possibility that it might act, at least in part, by increasing the expression of p27^{kip1} in human hepatoma cells. This study may help us to understand radiosensitivity and develop a new treatment strategy.

MATERIALS AND METHODS

Reagents

RPMI-1640 medium and Lipofectamine (LF2000) were purchased from GIBCO. Anti-Flag (M2) was purchased from Sigma. FITC conjugated-IgG was purchased from Santa Cruz Biotechnology. The plasmid containing p27^{kip1} was kindly provided by Dr. Keiichi Nakayama at Kyushu University, Japan.

Cells and treatment with gamma-irradiation radiation treatment

Human hepatoma cell line, HepG₂, was routinely maintained in RPMI-1640 medium supplemented with 100 mL/L heat-inactivated fetal bovine serum at the 100 mL/L concentration and incubated in 100 U/mL penicillin-streptomycin in 50 mL/L CO₂ in air at 37 °C with 50 mL/L CO₂. Hepatoma cells were plated into 6-well culture plates (5×10⁴ cells/well) and exposed to 0, 1.0, 2.0, 3.0, 4.0, 5.0 and 6.0 Gy of γ-irradiation from a telecobalt therapy source at a dose rate of 5.0 cGy/minute.

Transient transfection of p27^{Kip1}

Transfection of the cells with wild type p27^{Kip1} cDNA constructs was performed using Lipofectamine (LF2000) reagent according to the manufacturer's instructions. Briefly, cells were plated in a 6-well plate at a density of 5×10^4 /well and incubated overnight in RPMI-1640 supplemented with 100 mL/L FCS. The cDNA constructs encoding p27^{Kip1} were diluted in RPMI-1640 (100 μ L) and then mixed with the transfection solution for 15 min. After washed twice with phosphate-buffered saline (PBS) to remove serum, the cells were incubated with the transfection mixture at 37 °C for 4 h and then refreshed with RPMI-1640 medium.

Proliferation assays

Cell proliferation was measured by MTT assay. After HepG₂ cells were treated with different dose gamma-irradiation for indicated time and dose, then 10 μ L MTT (5 mg/mL) was added to each well and incubated for an additional 4 h, and then the liquid in the wells was evaporated. To dissolve the formazan, 200 μ L of DMSO was added. Control wells were treated with 1 g/L DMSO alone. The absorbance was detected in the microplate reader 550 model at 570 nm wavelength. Growth inhibition was equal to $(1 - \text{absorbance of the treated wells}) / (\text{absorbance of the control wells}) \times 100\%$.

Immunohistochemistry

Immunohistochemical staining was performed to determine the expression of Flag-P27^{Kip1} fusion protein. HepG₂ cells transiently expressing p27^{Kip1} were grown on a glass coverslip in a 6-well plate for 24 h after transfection. The cells on the coverslips were fixed in 20 g/L paraformaldehyde at room temperature for 5 min on the next day of transfection, and sequentially incubated for 60 min with anti-mouse Flag (M2) and then FITC-conjugated second antibody. The slides were lightly counterstained with Hoechst 33258, washed with water and then mounted. Finally coverslips were mounted with other glass slides, the cells were examined by immunofluorescence microscopy at the excitation/emission wavelengths of 488 nm and 520 nm alternatively.

Flow cytometry analysis

HepG₂ cells were plated onto a 6-well plate (5×10^4 cells/well) in RPMI-1640 containing 100 mL/L FBS and grown overnight to allow cell attachment. They were then treated with irradiation, harvested, fixed with 700 mL/L ethanol, centrifuged, resuspended in 400 μ L of PBS, and 2 mg/mL RNase was added to avoid double-stranded RNA staining, then stained with 400 μ L of 0.1 mg/mL propidium iodide (PI). The cell suspension was filtered through a 60- μ m Spectra/Mesh nylon filter. Samples of 20 000 cells were then analyzed for DNA histograms and cell cycle phase distributions by flow cytometer using a FACSCalibur instrument (Becton Dickinson), and the data were analyzed by a CELLQuest computer program.

DNA fragmentation assay

The integrity of DNA was assessed by agarose gel electrophoresis. Cells (1×10^6) were centrifuged for 5 min at 3 000 r/min, washed once with PBS, and cell pellets were resuspended in 100 μ L of lysis buffer (50 mmol/L Tris-HCl, pH 8.0, 10 mmol/L tetraacetic acid, 4 g/L SDS, 0.5 g/L proteinase K) and incubated for 8 h at 50 °C, then 10 μ L of 0.5 g/L RNase A was added. The samples were incubated for 1 h at 50 °C and heated to 70 °C for 5 min, then 100 μ L of phenol: chloroform:isopropanol (25:24:1) was added. After centrifugation, the supernatants were transferred to new tubes, and twice volume ethanol (ice cold) was added. After centrifugation, the pellets were solubilized in TE buffer and loaded on 18 g/L agarose gel for electrophoresis. The gel was stained with ethidium bromide, and photographed with UV illumination.

Hoechst 33258-propidium iodide counterstaining

Apoptosis and death cells were identified by Hoechst 33258-PI counterstaining^[16]. Briefly, cell pellets (1×10^9) were suspended by 100 μ L PBS containing Hoechst33258 at the concentration of 1 μ L/mL. The cells were incubated at 37 °C for 7 min, and then centrifuged. The cell pellets were resuspended in 100 μ L staining solution containing PI at the concentration of 5 μ g/mL. The stained cells were analyzed using a fluorescence microscope. Samples of 200 cells were then analysed.

Statistical analysis

Data were represented as mean \pm SD. Differences were evaluated by SPSS10.0 software. $P \leq 0.05$ was considered statistically significant.

RESULTS

Growth inhibition of HepG₂ cells by ⁶⁰Co γ -irradiation

The irradiation of HepG₂ cells caused a dose-dependent cell growth inhibition, and a maximum inhibitory effect was observed at 6 Gy. MTT assay showed that irradiation had anti-proliferative effects on HepG₂ cells in a dose-dependant manner. At the dose of 0, 1.0, 2.0, 3.0, 4.0, 5.0 and 6.0 Gy, the inhibitory rate was $2.62 \pm 0.18\%$, $26.85 \pm 0.21\%$, $54.11 \pm 0.47\%$, $57.19 \pm 0.54\%$, $60.26 \pm 0.53\%$ and $67.12 \pm 0.65\%$ respectively (Figure 1). The cell growth inhibitory effect was due to apoptosis or necrosis induced by excessively high dose irradiation. The counterstaining of PI and Hoechst 33258 proved to be an excellent probe to distinguish apoptotic cells from necrotic cells. Live and apoptotic cells were only probed by Hoechst 33258 (blue in color) and exclusion of propidium iodide due to plasma membrane integrity. The morphological features of apoptotic cells were cell shrinkage, nuclear condensation and genomic fragmentation down to the size of individual nucleosome units. On the contrary, necrotic cells were probed by PI (red in colors) (Figure 2). The apoptotic rate reached the top at the dose of 4.0 Gy, when irradiated by 6.0 Gy, most of HepG₂ cells were in necrotic state (Figure 3).

Figure 1 Effect of irradiation on proliferation of HepG₂ cells.

p27^{Kip1} expression enhanced radiosensitivity induced by ⁶⁰Co γ -irradiation in HepG₂ cells

Overexpression of p27^{Kip1} protein was observed in transfected cells (Figure 4). As a result, the proliferation of HepG₂ cells was greatly inhibited and cell cycle was arrested in G₁ phase after exogenous p27^{Kip1} expression (Figure 5). Further results showed that overexpression of p27^{Kip1} enhanced radiosensitivity in HepG₂ cells induced by ⁶⁰Co γ -irradiation, and 2.0 Gy irradiation induced maximum apoptotic rate by 40.6% in HepG₂ cells transfected with p27^{Kip1}, whereas HepG₂ cells transfected empty vector, only 4.0 Gy reached the maximum apoptotic rate of 35.3% (Figure 6). Apoptosis of HepG₂ cells indicated by flow cytometry and Hoechst33258 staining was then confirmed by DNA fragmentation, which was visualized as the characteristic oligonucleosome-sized fragmentation in ethidium bromide after DNA agarose gel electrophoresis (date not shown).

Figure 2 Counterstaining of Hoechst 33258 and propidium iodide to distinguish apoptotic from necrotic cells.

Figure 3 Comparison of apoptosis and necrosis rate of HepG₂ treated by ⁶⁰Co γ -irradiation. ^a $P < 0.05$, ^b $P < 0.01$ vs necrosis.

DISCUSSION

HCC remains one of the most difficult tumors to treat. Primary HCC is the second most common cancer and the leading cause of cancer deaths behind gastric cancer in China. Surgical resection has been accepted as the only curative therapy for primary liver cancer. Unfortunately, most patients are surgically unresectable, and are sometimes recommended to receive non-surgical therapies, including radiotherapy, radiofrequency hyperthermia, genetherapy or combination of the above methods. Radiation therapy has been commonly used in the treatment of unamenable human hepatoma. Unfortunately, the cause of this radiosensitization has not met expectations fully. New approaches that may reduce side-effects and provide good quality of life are required. Thus, it is imperative to develop new and effective treatments, such as gene therapy, in order to treat this disease.

Gene therapy is one of the more promising approaches for patients with advanced liver tumour. Experimental and clinical studies have reported that gene therapy and molecular prevention are becoming a part of patient management and

Figure 5 Flow cytometry analysis of cell cycle of nontransfected and transiently transfected HepG₂ cells. A: nontransfected HepG₂ cells. B: p27^{Kip1} transiently transfected HepG₂ cells.

Figure 6 Apoptotic rates induced by γ -irradiation in nontransfected and transfected HepG₂ cells. ^b $P < 0.01$ vs control.

would eventually complement or in part replace the existing therapeutic and preventive strategies^[17]. Recent researches have indicated that p27^{Kip1} is a new target for gene therapy and p27^{Kip1} is a new suitable candidate for gene therapy^[9,18]. The protein p27^{Kip1} is an important factor that regulates cell cycle progression and apoptosis. Mutations in p27^{Kip1} gene have not been seen in many tumors including human hepatoma. Down-regulation and mislocalized expression have recently been found to be associated with poor prognosis in patients with hepatoma. Therefore, regulation of p27^{Kip1} activity is a new strategy for hepatoma therapy.

Pretreatment of hepatocellular carcinoma cells with overexpression of p27^{Kip1} protein before irradiation enhanced the cell-killing effect of irradiation. Interaction with moderate doses of radiation caused a substantial increase in tumor cell killing. The beneficial effect of this interaction was further evidenced by the significant increase in the number of apoptic cells. The HepG₂ cells treated with p27^{Kip1} and exposed to 6.0 Gy showed a maximum apoptosis percentage when compared to the other irradiation doses or p27^{Kip1} transfection. Our results showed that overexpression of p27^{Kip1} could enhance the radiosensitivity in HepG₂ cells. Overexpression of p27^{Kip1} in HepG₂ cells could sensitize cells to ionizing radiation. Recent advances have been made in the understanding of molecular

events following cell exposure to ionizing radiation. Our results suggest that p27^{kip1} protein could be used to modulate radio-induced cellular responses.

However, the molecular mechanism of p27^{kip1} in radiosensitivity induced by ⁶⁰Co γ-irradiation is still unclear, and further studies are needed to identify the molecular mechanisms for the radiosensitizing activity, with emphasis on the study of p27^{kip1} in cell cycle progress and radiosensitivity.

Our results here provide some experimental evidences that overexpression of p27^{kip1} increases the radiosensitivity of gamma irradiation. It may help us understand radiosensitivity and develop strategies for liver cancer.

Abstract

AIM: To establish a nude mice model of human hepatocellular carcinoma (HCC) via orthotopic implantation of histologically intact tissue, in order to study biologic features of HCC *in vivo* and to direct clinical treatment respectively.

METHODS: Histologically intact fresh specimens of HCC were orthotopically implanted in nude mice (BALB/c, nu/nu). Survival rate and growth curve were investigated with B-ultrasound. Morphological characteristics of pathology and spontaneous metastatic rates were detected with microscopy. Expression of multidrug resistance genes studied with immunohistochemical method and RT-PCR, and other biologic features of implanted tumor were observed and compared with human HCC specimens.

RESULTS: Out of the specimens from two patients with HCC, only one specimen survived in nude mice. The orthotopic implantation tumor survival rate, spontaneous intrahepatic metastatic rate, pulmonary metastatic rate and bone metastases rate were 100%, 75.0%, 37.5% and 37.5% respectively in the first passage. AFP was kept on secreting and increasing with the size of the tumor. The morphological characteristics and biologic features were similar to the donor's, the protein and mRNA of MDR1 and LRP were expressed in tumors of the model and the donor, and there was no significant difference between them ($P > 0.05$).

CONCLUSION: The model of nude mice with orthotopic implantation of histologically intact HCC tissue is an ideal model to study biologic features of HCC *in vivo* and to direct clinical treatment.

INTRODUCTION

Liver cancer is one of the most common carcinomas, the highest

age-standardised mortality rate in China, and accounts for 53% of all liver cancer deaths worldwide^[1,2]. Surgical resection has been accepted as the best treatment for hepatocellular carcinoma (HCC). However, recurrence and metastases and non-sensitivity to chemotherapy remain the major obstacles for further prolonging survival after resection^[3]. Study of HCC, therefore, has become an important issue. But the experiments can not be done on patients with HCC. So human HCC model in nude mice is needed for the study of HCC and its mechanism, chemotherapy, multidrug resistance (MDR), *etc.*

Shimosato *et al.*^[4,5] established a series of human tumors in nude mice including the human HCC nude mice model for study of alpha-fetoprotein (AFP) in relation to tumor growth in 1976. Liu *et al.*^[6] established a nude mice xenograft model from human HCC in 1995. Leveille-Webster *et al.*^[7] established an intrahepatic xenograft of human HCC in severe combined immunodeficiency mice for the study of multidrug resistance in 1996. Sun *et al.*^[8,9] reported a metastatic human HCC model in nude mice with 100% of spontaneous metastases to lung, lymph node and liver. Peng *et al.*^[10] established a human HCC model in nude mice using orthotopic implantation and observed malignant behavior. Tao *et al.*^[11] established a human HCC in nude mice model using SMMC-LTNM tumor transplanted into abdominal cavity and liver, the lung metastatic rate was 59%. Genda *et al.*^[12] reported the construction of metastatic models using orthotopic implantation of human HCC cell lines into livers of SCID mice, two of the 5 cell lines injected showed vascular tumor thrombi and intrahepatic metastases. Zheng *et al.*^[13] established an orthotopic implantation tumor model from the subcutaneous model of human HCC in nude mice, the spontaneous metastatic rate was 57.8%. Shi *et al.*^[14] established a human HCC model in nude mice with a high metastatic rate in lymph node.

Metastatic models constructed in nude mice by orthotopic implantation of histologically intact patient specimens have been used in Hoffman's group, and several such models including cancers of the lung, pancreas and ovary, have been reported^[15-17]. However, patient-like human HCC model in nude mice with metastatic behaviors was not found. After the study on HCC cell lines and subcutaneous HCC model in nude mice, we established a patient-like human HCC model with spontaneous metastases in liver, lung and bones.

MATERIALS AND METHODS

Mice

There to four weeks BALB/c, nu/nu, nude mice (Experimental Animal Center, Tongji Medical College, Huazhong University of Science and Technology, Wuhan), weighting 10.1-16.0 g, were used in this study.

Surgical specimens of human HCC

Fresh surgical specimens were obtained from 2 patients with HCC who underwent surgery at the Hepatic Surgery Center, Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology. The specimens were rinsed and preserved in saline at 4-8 °C and sent to the Experimental Animal Center as soon as possible. After necrotic tissue and non-

cancerous tissue of the specimens were removed, the remaining cancerous tissues were cut into small pieces of about 1 mm³ in size.

Implantation procedure

Tumor pieces were implanted into the livers of nude mice. A left subcostal incision was made under anaesthesia with 200 g/L urethane. The left lobe of the liver was exposed and the liver capsule was mechanically injured with needle. Then one or two pieces of tumor tissue were filled into the liver tissue with forceps which could be seen as a white spot and abdominal wall was finally closed. Mice were kept in laminar-flow cabinets under specific-pathogen-free conditions.

Evaluation of growth and metastases

Nude mice were weighted and the size of tumors was weekly measured with B-ultrasound from 2 to 9 wk after orthotopic implantation. Tumor size (mm³) was evaluated by measurement of two diameters with B-ultrasound and using the formula $1/2 LW^2$, where L is the longest diameter and W is the shortest diameter. Bone metastases was detected with SPECT 8 wk after implantation and then other organ metastases was detected with autopsy and microscopy when the mice were killed. The liver, lymph node, lungs, and bone suspected of metastases were collected and processed for routine gross and microscopic examination. Metastases was diagnosed if at least one microscopic metastatic lesion was found in any resected organ.

Serum detection

AFP in serum from tail vein was detected every two weeks, and hepatitis virus-B surface antigen (HBsAg), antibody to hepatitis virus-B surface (HBsAb), hepatitis virus-B e antigen (HBeAg), antibody to hepatitis virus-B e (HBeAb) and antibody to hepatitis virus-B core (HBcAb) of serum from heart blood were detected after mice were killed (ELISA assay).

Immunohistochemical studies

Expression of MDR1 and LRP was studied by using mouse anti-human MDR1 C219 and LRP monoclonal antibodies (neomarkers) respectively. Tumor tissues from patients with HCC and mice carrying human HCC were fixed in formalin and embedded in paraffin. Sections of 5 µm were assayed for MDR1 and LRP expression by immunoperoxidase staining with the SP method (SP kit, Zhongshan Biocompany, China).

Table 1 Primers for MDR1 and LRP

Gene	Size (bp)	Quantification method	Sequence (5'-3')
B-actin	530	Forward primer	GTGCGTGACATTAAGGAG
		Reverse primer	CTAAGTCATAGTCCGCCT
MDR1	174	Forward primer	CATTGGTGTGGTGAGTCAGG
		Reverse primer	CTCTCTCTCCAACCAGGGTG
LRP	237	Forward primer	TAAGGGCTTCCAGCACCAAC
		Reverse primer	GGAGTTCTCGTTCTCGTCC

Detection of MDR1 and LRP expression by RT-PCR

Total RNA was extracted from tumors of nude mice and patients using Trizol (Promega) according to the manufacturer's instructions. Reverse transcription (RT) was performed with random primers using a complementary DNA (cDNA) synthesis kit (promega). Following RT-reaction reagents were added: 2 µL MgCl₂ (50 mmol/L), 2 µL RT buffer (Tris-HCL pH 8.3), 2 µL deoxynucleotide mixture (100 mmol/L), 0.5 µL RNase (20 units), 1 µL M-MLV reverse transcriptase, 1 µL of random primers (500 µg/mL) and 5 µg substrate RNA. The final volume of RT-reaction (25 µL) was completed with RNase free water. First strand cDNA synthesis was carried out at 37 °C for 60 min in a

DNA thermal cycler. Afterwards, the tubes were incubated at 95 °C for 5 min to terminate the reaction. Then each tube was kept at -20 °C until PCR was performed. Primers of the target gene MDR1, LRP and endogenous reference GAPDH were designed using the Primer Express software (Applied Biosystems) (Table 1). The final volume of PCR reaction (50 µL) was completed including an initial phase at 94 °C for 4 min, and followed by 30 cycles at 94 °C for 1 min, and at 56 °C for 45 s, at 72 °C for 45 s, and finally at 72 °C for 10 min.

Statistical analysis

Data were presented as mean±SD and analyzed with SPSS11.0. $P < 0.05$ was considered statistically significant.

RESULTS

Establishment of patient-like metastatic HCC model

Human HCC model of orthotopic implantation was successfully established in nude mice with histologically intact tissues. Out of the 2 specimens from 2 patients with HCC, only one specimen from a 39-year-old man with HCC was at Edmonson grade II-III, whose serum AFP (1 746 ng/mL), HBsAg, HBeAg, HBcAb were all positive, and he had extensive intrahepatic metastases but no hilus hepatis lymph node metastases during operation. Bone metastases were found in the patient one month after operation. Two weeks after implantation, all the livers of 8 nude mice gave rise to tumors and the size of tumors was observed every week with B-ultrasound or by autopsy after they were killed. (Figures 1-3).

Figure 3 Relation between volume of implanted tumor and time after implantation.

Figure 4 Implanted tumor in nude mice liver metastases to lungs. The first passage just formed a few metastatic lesions A; The 4th passage formed multiple metastatic lesions B; and metastatic lesions in lungs were found under microscope C.

Figure 5 Implanted tumor in nude mice liver spontaneously metastasized to bone. The first passage metastasized to vertebra thoracica just as the donor A, and the 4th passage showed multiple bone metastases B, C. Metastatic lesions were shown in bones under microscope D.

Figure 6 Relation between density of AFP in serum and time of tumor after implantation.

Figure 7 Edmonson grade II-III HCC specimen from patients A and in tumor tissue from nude mice model B.

Figure 8 MDR1 and LRP expressed in tumors of the donor (2) and the nude mice model (3), and the expression had no significant difference between both. A: MDR1 expressed in tumors. B: LRP expressed in tumors.

The tumor behavior of this model was the same as the tumor in the patient who donated the specimen. Nine weeks after

implantation, the 8 nude mice with normal weight were killed by drawing blood from heart. According to autopsy and microscopic examination, implanted tumor survived in all nude mice (8/8), intrahepatic invasion was seen in all nude mice (8/8), intrahepatic metastases was seen 75% (6/8) (Figure 2), lung metastases was seen in 3 nude mice (35.5%) (Figure 4), the wound seeding was seen in all mice (8/8), and bone metastases occurred in 35.5% (3/8) (Figure 5), but lymph node metastases was not found.

Findings in serum

Serum AFP was detected from tail blood of nude mice (Figure 6), but all markers of hepatitis were negative.

Histological findings

Histological characteristics of the model tumor were similar to those of the donor's tumor (Figure 7).

Immunohistochemistry and RT-PCR results (Figure 8, Table 2)

DISCUSSION

Subcutaneous tumor implantation has been used as a standard method to establish animal models of human cancer^[18,19]. Although such models help to understand the nature of human cancers and their therapeutic approaches, but many problems still remain unsolved. One major problem is that the tumor which was derived from a patient and implanted subcutaneous into an immunodeficient animal no longer behaves as it did in the patient. Although the tumor could sometimes grow subcutaneously, it was encapsulated and usually failed to metastasize either regionally or at distant site^[19].

Recently, a new strategy of "orthotopic implantation" has been used to develop rodent models of metastatic human cancer^[19,20]. In the first generation of these models, cell lines or disaggregated cells were injected into the organ of mice that corresponded to the organ from which human tumor was derived. This method allowed metastases to occur at least in certain cases^[19,21-23]. The cell line and disaggregated cells used for orthotopic implantation were obtained by disrupting the original structure of human tumor tissue, which might lead to a change in nature and biological behavior and could be the basis of the greatly reduced metastases rate^[24]. Holfman^[25] developed an orthotopic implantation model utilizing intact tissues obtained directly from surgery. This approach has yielded a high survive rate and frequent metastases in cancers of the colon^[26], bladder^[24], lung^[27], pancreas^[28], prostate^[29] and stomach^[30]. These models of human cancer in nude mice could show various manifestations similar to tumor behavior in patients.

However, it remains difficult to obtain satisfactory models for human cancers in nude mice, particularly with regard to spontaneous metastases and reduction of the latent period when cell suspension or histologically intact tissues were used for orthotopic implantation, which could not really reflect the nature of HCC of patients and preclude *in vivo* effective study of important events including spontaneous metastases and multidrug resistance. Therefore, our approach includes the selection of highly invasive and intrahepatic metastases of human HCC samples and orthotopic transplantation of histologically intact tissues into 3-4 wk old nude mice. In the first generation, the result demonstrated that the specimen from the 39-year-old patient with HCC gave rise to growth of tumor at the implantation site in all the 8 nude mice 2 wk after implantation. In the course of the study, lung and bone metastases were found in the patient donating specimens 1 mo after operation. So we began to pay attention to nude mice in terms of metastases. Fortunately, metastases occurred in all the mice 7-8 wk after implantation, 3 (3/8) had lung metastases, and 3 (3/8) had spontaneous bone metastases, and all had wound seeding and intrahepatic invasion. Lymph node metastases, however, was not found. Spontaneous metastases of human cancer xenografts in nude mice was rare^[9,11]. We believe the reasons of cancer growth and metastases in nude mice were that the specimen selected was highly metastatic and that the nude mice were younger (3-4 wk) than those used in other studies^[13,31]. But metastases was not found in all the mice. We believe the reasons might be that the time after implantation was not so

long that the metastases could not occur in each one, and that it was related to the methods detecting the metastases. So in the 2-4 passages, the nude mice carrying implantation tumor were not killed until they developed signs of distress so as to give full time to metastases and to observe the nature of the tumor. As a result, intrahepatic, lung and bone metastases and wound seeding and multiple metastatic sites in those organs were surprisingly observed in all nude mice over a period ranging 5-16 wk after implantation. Besides selection of the highly invasive and metastatic samples and age of the nude mice, we think there were two key factors, one was that we selected and isolated more higher metastatic subpopulation from the parent tumor, and the other was that a long time could give chance to implanted tumor to metastasize.

As shown in the results, the expression of AFP, MDR1, and LRP was well maintained in locally growing tumor tissues as well as in metastases. These results indicated that this nude mice model represented the majority of biological natures including local invasion, spontaneous lung, bone and intrahepatic metastases, MDR and secreted AFP, suggesting that our model indeed has some features resembling the natural biological behaviors of human HCC.

Although spontaneous metastases models of HCC have been established in nude mice, but bone metastases and MDR studies are not available. Our model well maintained the native structure of HCC and exhibited spontaneous lung metastases, especially spontaneous bone metastases and expression of MDR just as the patient donating the specimen. Thus, this model represents the features of patients with HCC, and could be an interesting tool for studying human HCC.

Abstract

AIM: To detect the relationship between absolute ethanol injection quantity, the interval and formation of fibreboard, the curative effect in treatment of hepatocarcinoma and to evaluate the clinical application of percutaneous hepatic quantified ethanol injection (PHQEI) in treatment of hepatic carcinoma (HCC).

METHODS: (1) Experimental study: Twenty-four human hepatic carcinoma SMMC-7721 xenografted nude mice were randomly divided into three groups: group A injected with quantified ethanol at short intervals (QESI), group B with quantified ethanol at long intervals (QELI) and group C with a small quantity of ethanol at long intervals (SQLI). The tumor tissues were sent for patho-histology and electron microscopic examinations. The diameters of tumors were measured with high frequency ultrasound before and after therapies and tumor growth index (TGI) was calculated. (2) Clinical study: Tumors of 122 cases of pathologically proved HCC were injected with quantified ethanol guided by ultrasound every 3-5 d 4-10 times per period of treatment. The quantity of ethanol was calculated according to the regressive equations where $Y = 2.885X$ when the mass was ≤ 5 cm in diameter and $Y = 1.805X$ when the mass was > 5 cm in diameter (X is the maximal diameter of the mass with the unit cm, Y is the ethanol quantity with the unit mL). The survival rates of 1, 2, 3 and 4 years and recurrent rates *in situ* as well as dystopia in the liver were calculated.

RESULTS: (1) Experimental study: TGI of QESI group (0.072 ± 0.018) and QELI group (0.094 ± 0.028) was apparently lower than that of SQLI group (1.982 ± 0.482) ($P < 0.01$). TGI of QESI group seemed to be lower than that of QELI group, but it was not markedly different ($P > 0.05$) between two groups. Severe degeneration and necrosis could be seen in QESI group by patho-histology examination. Coagulative necrosis could be seen in most tumors of QESI group and there were no residual cancer cells under electronic microscope, while the residual cancer and inflammatory cells and fibre tissues could be seen around the tumors of QELI group. Infiltration of inflammatory cells could be seen and fibre tissues were formed. (2) Clinical study: B mode ultrasound showed that 62.5% of tumors shrank after PHQEI. The survival rates of 1, 2, 3 and 4 years of the group with tumors ≤ 3 cm in diameter

were higher than those of the group with tumors > 3 cm in diameter. The recurrent rates of tumors *in situ* of the former group were apparently lower than those of the latter group. The recurrent rates of tumors in dystopia in the liver of the former group were markedly lower than those of the latter group. The 122 cases underwent a total of 1221 PEI. There were no complications such as hemorrhage and severe heart, liver and kidney functional injuries except for 1 case of melena and 4 cases of jaundice who recovered after 1-2 wk under common therapies.

CONCLUSION: The experimental study shows quantified ethanol at intervals of 3-5 d could improve the curative effect of hepatocarcinoma. The clinical study shows PHQEI is an effective therapeutic method for HCC with few side-effects, and a low-cost. The treatment efficacy is more remarkable for tumors ≤ 3 cm in diameter.

INTRODUCTION

Because ultrasound-guided percutaneous ethanol injection (PEI) has the advantages of easy operation, definite curative effect, little damage and few side-effects, it has been widely used in clinical practice in recent years since the report by Japanese scholars in 1983^[1-10]. Though more ultrasound-guided methods have been applied since then^[11-20], PEI is still one of the most widely used non-operative methods in the treatment of hepatic carcinoma. Because there is no common standard for ethanol injection quantity and interval, the efficacy is affected apparently. In order to improve the efficacy, according to the pathological biological characteristics of HCC that there are capsula and tiny satellitic foci of cancer cells in the periphery of HCC, we once conducted the study of percutaneous hepatic quantified ethanol injection (PHQEI) in treatment of HCC (Ethanol was injected until the diffusing area was 1-2 cm more than the maximal diameter of tumor ≤ 5 cm in diameter. According to the endurance of patients the ethanol was injected from several directions and diffused throughout the nodules > 5 cm in diameter as fully as possible.) and we put forward the regressive equations^[21]: $Y = 2.885X$ ($X \leq 5$ cm), $Y = 1.805X$ ($X > 5$ cm) (X is the maximal diameter of the tumor with the unit cm, Y is the ethanol quantity with the unit mL). Recently, some scholars have reported that it could cause cancer cells to remain as the fibreboard in tumors affected the wide infiltration of ethanol^[22]. So we carried out experimental studies to prove the relationship between absolute ethanol injection quantity and the formation of fibreboard. We have followed up 122 cases of hepatocarcinoma treated by PHQEI for 1-4 years to assess its clinical application.

MATERIALS AND METHODS

Experimental studies

Experimental animals For the experiment, we used 24 BALB/CA nude mice, which were 5-8 wk old, provided by the Medical Experiment Animal Unit of Anti-cancer Center of Xiamen University, China. The average weight was 18 ± 2.1 grams. They were raised in the layer drift shelves under aseptic conditions. The cages, cushion, drinking water and standard forage provided by Shanghai Bikai Company were changed periodically.

Experimental methods Twenty-four nude mice with human HCC-transplanted hypodermically were randomly divided into three groups: group A injected with quantified ethanol (the ethanol diffused throughout the tumor) at short intervals (5 d) (QESI), group B with quantified ethanol at long intervals (10 d) (QELI) and group C with a small quantity of ethanol (half quantity of ethanol as used in QESI) at long intervals (SQLI). Each group contained 8 nude mice.

Three dimensional diameters of the tumors were measured by high frequency ultrasound (Aloka-5500 with 10 MHz probe) after 10 d of transplantation of HCC and the volume was calculated. Then ethanol was injected into the center of the tumor with No.5 needles. All the mice were injected twice. The three dimensional diameters of the tumors were measured again 5 d after the last injection and then the mice were killed. The center and peripheral tissues of tumors were sent for pathologic histology and electron microscopic examination. The experiment was carried out with double blind method.

Observation indexes Tumor growth index (TGI) was calculated by the formula: volume of the tumor (after treatment-before treatment)/volume of the tumor (before treatment). The degree of degeneration and necrosis, inflammatory response of tissues and fibre tissue were observed by pathologic histology examination. The microstructure of tumor tissues, inflammatory cells and fibre cells, fibreboard were observed under electron microscope.

Statistical methods

The data of each group were expressed as mean \pm SD. Necrosis area of each group was calculated and analyzed with ANOVA. $P < 0.05$ was considered statistically significant. All statistical analyses were performed using SPSS for windows version 8.0 software package.

Clinical studies

Patients One hundred and twenty-two cases of HCC, including 96 cases recurring after operation, consisted of 105 males and 17 females were enrolled in the study. The mean age was 54.8 years (range, 28-81). The diagnosis was established by pathocytology and/or histology. One hundred and twenty-two cases had 168 nodules including 62 cases with single nodules. The mean diameter of tumor was 3.8 cm (1.2-7.2 cm) and 122 cases comprised 64 cases with tumors < 3 cm in diameter and 58 cases with tumors > 3 cm in diameter (27 cases with tumor > 5 cm in diameter). Seventy-eight cases had AFP > 20 ng/mL.

Instruments Real-time ultrasonography (Aloka-650, 1700, Japan) was performed with a 3.5 MHz probe. The puncture needles were 22G PTC fine-needles and 15-20 cm in length. The platelet count of the patients was $> 50 \times 10^9/L$.

Injection methods The point of puncture was determined by ultrasonography. Under local anesthesia, the fine needle punctured from the point into the posterior of the axis of nodules. Then ethanol was injected into the nodule gradually and the needle was withdrawn slowly. The injection quantity was calculated according to the regressive equations: $Y = 2.885X$ ($X < 5$ cm), $Y = 1.805X$ ($X > 5$ cm) (X is the maximal diameter of the tumor with the unit cm, Y is the ethanol quantity with the unit mL).

All the cases were injected every 3-5 d 4-10 times per period of treatment. The tumor > 5 cm in diameter could also be injected 10-20 times per period of treatment.

Follow-up time The follow-up period lasted for 12-48 mo (mean period 34 mo). The survival rates of 1, 2, 3 and 4 years and recurrent rates *in situ* as well as dystopia in the liver of each group were calculated and compared using ANOVA. The 14 nodules of 9 cases were resected after quantified ethanol injection 2-4 times and sent for pathologic examination.

RESULTS

Experimental studies

Tumor growth index Table 1 shows that TGI of QESI and QELI groups was apparently smaller than that of SQLI group ($P < 0.01$). TGI of QESI group seemed to be smaller than that of QELI group, but not different markedly ($P > 0.05$).

Table 1 Comparison of TGI between groups (mean \pm SD)

Groups	Cases (n)	TGI	P
A: QESI	8	0.072 ± 0.018	$> 0.05^1$
B: QELI	8	0.094 ± 0.028	$< 0.01^b$
C: SELI	8	1.982 ± 0.482	$< 0.01^d$

¹ $P > 0.05$ vs group B, ^b $P < 0.01$ vs group C, ^d $P < 0.01$ vs group A.

Table 2 Comparison of the percentage of tumor necrosis between groups

Necrosis area	QESI (A)	QELI (B)	SELI (C)	P
80%-	87.5 (7/8)	50 (4/8)	0	$< 0.01^b$ $< 0.01^d$
30%-	12.6 (1/8)	50 (4/8)	100 (8/8)	$< 0.01^f$

^b $P < 0.01$ between groups A and C, ^d $P < 0.01$ between groups A and B, ^f $P < 0.01$ between groups B and C.

Figure 1 Coagulation necrosis in the center to periphery of the tumors of QESI after injection. (A, HE $\times 10$). The center of the tumor of SELI appeared coagulation necrosis, but in the periphery cancer cells grew luxuriantly after injection (B, HE $\times 10$).

Figure 2 Inflammation cell infiltration (A) and faciculus (B) in the periphery of tumors of SELI group. electron microscope examination.

Figure 3 Degeneration cancer cells (A) and fasciculus (B) in the periphery of the tumors of QELI. Shown in electron microscope examination after injection.

Figure 4 Necrosis changes such as karyolysis, karyorrhexis and cell membrane disappearance in the tumors of QESI after injection under election microscope.

Patho-histology examination Table 2 shows the percentage of tumor necrosis of each group. Necrosis of QESI group was most severe. Coagulative necrosis could be seen from center to periphery of the tumor of QESI group. Eighty-seven point five percent of QESI group showed necrosis area $>80\%$, markedly higher than those of QELI and SELI groups. None of SELI group showed necrosis area $>80\%$. The center of the tumor of SELI group showed necrosis but in the periphery cancer cells grew actively (Figure 1).

Electron microscopic observation (1) SELI group: Cancer cells showed coagulation necrosis in the center only and most cancer cells grew luxuriantly, especially in the periphery. Most cancer cells only showed orbicular karyotheca, nuclei in different size, abundant euchromatin, orbicular cytomembrane, many inflammatory cells, fibrocytes and fasciculus (Figure 2).

(2) QELI group: Coagulation necrosis was comparably severe, but in the periphery orbicular cancer cells, some degenerative cancer cells, inflammatory cells and fasciculus could be seen (Figure 3).

Figure 5 Reduction of the average diameter of HCC nodules from 3.6 cm (before injection, A) to 2.6 cm (two years after injection, B) and hyperechogenic rings in the periphery with haloes surrounding them after injection.

(3) QESI group: Necrotic changes, such as karyolysis, karyorrhexis and cell membrane disappearance could be seen in most cancer cells (6/8) (Figure 4). There were severe degenerative cancer cells in which heterochromatin agglutinated under the nuclear membrane. No fasciculus formed.

Clinical studies

Ultrasonography, CT or MRI showed that 168 nodules in 122 cases of HCC shrank 2-8 wk after the last PHQEI. The average diameter reduced from 3.8 cm to 2.9 cm. Ultrasound showed the echoes of tumor nodules enhanced after PEI therapy. Hyperechogenic rings could be seen in the periphery of 25% (42/168) cases of haloes surrounding them (Figure 5). The diameters of 62.5% (105/168) tumors shrank and the internal echo enhanced and facula or light dot formed (Figure 6). Tumor nodules disappeared in 12.5% cases. CT showed that the nodules showed homogeneous hypodensity or/and non-enhanced changes in 62 cases after PHQEI. MRI showed that 38 nodules of 26 cases showed low T1 and T2 signals. fine-needle or/and

thick-needle biopsies were taken 1-3 times in all the cases and no cancer cells appeared in 88.5% (108/122) cases and degenerative cancer cells appeared in 11.5% (14/122) cases with nodules >5 cm in diameter. After therapy AFP reduced in 78 cases with high AFP before therapy and 82.1% (64/78) cases turned negative.

Figure 6 A: Average diameter of HCC nodule was 4.4 cm. B: It was 4.8 cm after 10 injections of absolute ethanol and the echogenic enhanced. C: After 42 mo of therapy the tumor shrank to 2.9 cm in diameter and formed facula.

Table 3 Efficacy of PEI reported in literature

Scholar	Time	Cases	Diameters of nodules (cm)	Survival rate (%)				
				1 yr	2 yr	3 yr	4 yr	5 yr
Ebara	1992	112	≤3	94	84	63	49	39
Castells	1992	162	<5	90	80	63		
Li Po	1996	188	4.6	85	44	19		
This article	2002	58	>3	84	64	58	52	
This article	2002	64	≤3	94	85	72	63	

Table 3 shows the survival rates of 1, 2, 3 and 4 years of each group with tumors <3 cm (64 cases) and >3 cm in diameter (58 cases) and the treatment efficacy reported by different scholars.

Table 4 shows that the recurrent rate of tumors *in situ* and dystopia of the group with tumor ≤3 cm in diameter was apparently lower than that of the group with tumor >3 cm in diameter.

None of 9 cases with 14 nodules but 1 case showed cancer cells in pathologic examination of the resected specimens after 2-4 PHQEI.

The 122 cases underwent a total of 1 221 PHQEIs. There were no complications such as hemorrhage and severe heart, liver and kidney functional injuries except that 1 case of melona after the injection of 8 mL ethanol and 4 cases of jaundice after 2-3 PHQEIs recovered after 1-2 wk under common therapies. Different degrees of pains occurred in 33.6% (41/122) cases after 1-2 PHQEIs and disappeared in 30 min without any therapy. Low-fever appeared in 56.6% (69/122) cases and disappeared after 2-4 d. GPT increased in 16.4% (20/122) cases and reduced

to normal in 1 mo. There were no apparent changes of kidney function and ECG examination in all cases before and after therapy.

DISCUSSION

HCC is one of the most common cancers throughout the world. In order to surmount the obstinate disease scholars at home and abroad have conducted a great number of studies from many aspects, such as causa moli, pathology, diagnosis and therapy, and have acquired some accomplishments, especially in therapy^[23-35]. Operation is the most common method in early stage, while HCC has the biologic characteristics of early invasion to blood vessels and multiple origins, which cause low resection rate and high recurrent rate (90%) of 5 years. With the advantages of definite efficacy, low complication and easy operation, PEI is still one of the most appropriate non-operative methods for small HCC which is unsuitable for resection and recurrent hepatic carcinoma. The mechanism of PEI is to make cancer cells incur dehydration and coagulative necrosis by injecting ethanol into tumors. But there is not a unified standard for total injection quantity, quantity per time and injection interval. At present, some scholars have adopted the formula^[36]: $V = 4/3 \pi (r+0.5)^3$ (V is the total quantity, r is the radius of focus.) and others used the calculation^[37]: Injection quantity (mL) = diameter (cm) or quantity (mL) = diameter (cm) + 1 (tumor ≤5 cm in diameter) and quantity (mL) = diameter (cm) + 2 (tumor >5 cm in diameter). Liu *et al.*^[38] reported that 238 cases of HCC were given PEI with 1-20 mL ethanol per injection and 1-2 times per week. The injection area involved the center as well as periphery of tumor and the part adhering closely to the capsule. Excessive ethanol increases side-effects and unnecessary liver injury, while too little ethanol could not kill cancer thoroughly and cause tumors to recur and metastasize. We once conducted the study of percutaneous hepatic quantified ethanol injection in treatment of HCC and put forward the regressive equation based on tumor diameter and injection quantity of ethanol^[21]. The initial clinical application and following observation showed PHQEI had apparent efficacy. This experimental study was to further probe the pathologic basis of ethanol injection quantity, interval and the formation of fibreboard and to assess the clinical application value of PHQEI by follow-up observations.

Experimental study showed that tumor growth of QESI group (The ethanol diffused throughout the tumor and was injected every 5 d) was markedly inhibited after 2 injections. Extensive coagulative necrosis could be seen from the center to periphery of tumors and the necrosis area of 87.5% (7/8) cases reached more than 80% by pathologic histology. Electron microscopy showed the majority had coagulative necrosis and some had severe degenerative tumor cells. Though the growth of tumor of QELI group (The injection quantity was the same as that of QESI, but the interval was prolonged twice.) was also inhibited, the necrosis area of only 50% (4/8) cases was >80%. There were more residual cancer cells in the periphery of tumors and fibre tissue and inflammatory cells could be seen under electron microscope. Because ethanol injection was only half of that of QESI group and the injection interval was prolonged twice, growth inhibition and necrosis degree of tumors of SQLI group

Table 4 Comparison of the recurrent rates between groups

Group	Total Cases	Recurrent rate <i>in situ</i> (%)				Recurrent rate in dystopia (%)			
		1 yr	2 yr	3 yr	4 yr	1 yr	2 yr	3 yr	4 yr
>3 cm (A)	58	6.9 (4/58)	7.1 (3/42)	24.2 (8/33)	28.6 (6/21)	15.5 (9/58)	21.4 (9/42)	36.4 (12/33)	52.4 (11/21)
≤3 cm (B)	64	0 (0/64) ^a	2.1 (1/48)	5.1 (2/39) ^a	4.2 (1/24) ^a	9.0 (6/64)	10.4 (5/48)	12.8 (5/39) ^a	20.8 (5/24) ^a

^a $P < 0.05$ vs group A.

were apparently slighter than those of the former two groups. Except for necrosis in the center, cancer cells grew luxuriantly, inflammatory response appeared and fasciculus formed in the periphery of the tumor.

Tumors in 122 cases of pathologically proved HCC, including 58 cases with tumors >3 cm in diameter and 64 cases with tumors ≤3 cm in diameter, were given PHQEL. We followed up the cases for 12-48 mo and proved that PHQEI had good efficacy, especially for tumors ≤3 cm in diameter. The 1-4 year survival rates of the group with tumors ≤3 cm in diameter were markedly higher than those of the group with tumors >3 cm in diameter and *in situ* tumor as well as dystopia recurrent rates were lower than those of the latter group. The reason might be that the ethanol quantity was not enough to meet the therapy standard for tumors >5 cm in diameter of 27/58 cases for the patients were weak and their liver function was bad. Giorgio *et al.*^[39] reported that 112 cases were given single-session percutaneous large dosage ethanol infection therapy with 16-120 mL ethanol per injection in panplegia. Five patients died after 7-10 h, and the 1, 2 and 3 year survival rates of the remaining 107 cases were 88%, 76% and 76%, respectively. The result showed that large amount ethanol injection could improve the treatment efficacy, while the side-effect also increased. So patients with advanced HCC of large tumors should be closely observed and an appropriate injection quantity should be chosen^[40].

Recently, some scholars have proposed that fibreboard also appeared in HCC of 3 cm in diameter and the infiltration capacity of absolute ethanol was bad. In order to improve the treatment efficacy, ethanol should be injected from different points repeatedly^[22]. Some scholars used drugs with a stronger infiltration capacity, for example, 50% acetic acid injection (PAAI)^[41]. Ohnishi *et al.*^[42] reported that the 1 and 2 year survival rates of PAAI were 100% and 92%, markedly higher than those of PEI which were 63% and 53%, respectively. The recurrent rate was 8%, lower than that of PEI which was 37%. But our study showed that the survival rate of HCC ≤3 cm in diameter was not lower and the recurrent rate was not higher than those of PAAI. The 4 year recurrent rate *in situ* was only 4.2% (1/24). Except for 1 case with a tumor of 5.1 cm in diameter none of the 9 cases with 14 nodules showed cancer cells in pathologic examination of resected specimens after 2-4 PHQEIs. Okuda *et al.* reported that about 90% of small HCCs had different degree of gross fibre pseudo-capsule and tumors <1 cm in diameter seldom had fibre capsule due to the gradually enhanced immune response of the body during the growth of tumor^[22]. Our experimental study showed that SQLI injection could stimulate strong immune response of organisms and cause inflammatory cell infiltration and fibreboard formation even if the tumor was less than 1 cm in diameter.

In conclusion, the experimental study shows that, in order to improve the efficacy of PEI adequate quantity must be adopted to maintain a strong diffusing capacity of ethanol in tumor and the interval must be short (The appropriate interval is 3-5 d) because small dosage and long interval will cause incomplete coagulated necrosis and formation of fibreboard and/or fasciculus which will influence the infiltration of ethanol and cause cancer cells to remain and metastasize.

The clinical study also shows that PHQEI has a high application value. So PEI is still the method with advantages of convenience, few side-effects and effectiveness. To further improve the treatment efficacy, studies on the quantity per injection and injection interval are needed.

Abstract

AIM: To evaluate the value of multi-phasic CT arterial portography (CTAP) and CT hepatic arteriography (CTHA) in differential diagnosis of liver diseases, and to improve the specificity of CTAP and CTHA for liver cancer detection.

METHODS: From January 1999 to December 2002, multi-phasic CTAP and CTHA were performed in 20 patients with suspected liver disease. CT scanning was begun 25 s, 60 s and 120 s for the early-, late- and delayed-phase CTAP examinations, and 6sec, 40 s and 120 s for the early-, late- and delayed-phase CTHA examinations respectively, after a transcatheter arterial injection of non-ionic contrast material. If a lesion was diagnosed as a liver cancer, transcatheter hepatic arterial chemoembolization (TACE) treatment was performed, and the follow-up CT was performed three or four weeks later.

RESULTS: All eighteen HCCs in 12 cases were shown as nodular enhancement on early-phasic CTHA. The density of the whole tumor decreased rapidly on late and delayed phases, and the edge of 12 tumors (12/18) remained relatively hyperdense compared with the surrounding liver tissue, and demonstrated as rim enhancement. All HCCs were shown as perfusion defect nodules on multi-phasic CTAP. Five tumors (5/18) were shown as rim enhancement on delayed-phasic CTAP. Rim enhancement was shown as 1 to 2-mm-wide irregular, uneven and discontinuous circumferential enhancement at late-, and delayed-phase of CTHA or CTAP. Five pseudolesions and 4 hemoangiomas were found in multi-phasic CTAP and CTHA. No pseudolesions and hemoangiomas were shown as rim enhancement on late- or delayed-phasic CTHA and CTAP.

CONCLUSION: Multi-phasic CTAP and CTHA could help to recognize the false-positive findings in CTAP and CTHA images, and improve the accuracy of CTAP and CTHA of liver cancer detection.

INTRODUCTION

CT arterial portography (CTAP) and CT hepatic arteriography (CTHA) are considered as the most sensitive imaging methods of detecting small liver cancers^[1,2]. Micro liver cancer as small as 0.2 cm in diameter could be detected by CTAP and CTHA^[3]. However, the prevalence of tumor-mimicking benign perfusion abnormalities decreases the specificity of these examinations and the accuracy of tumor detection^[4,5]. In order to improve the specificity of CTAP and CTHA for liver cancer detection, multi-phasic helical CT arterial portography (CTAP) and multi-phasic helical CT hepatic arteriography (CTHA) are recommended^[6-8]. From January 1999 to December 2002, multi-phasic CTAP and multi-phasic CTHA examinations were performed for more accurate evaluation in 20 patients with suspected liver malignancy.

MATERIALS AND METHODS

Materials

From January 1999 to December 2002, 20 patients (10 men, 5 women) with suspected liver diseases underwent multi-phasic CTAP and CTHA including 12 cases of hepatocellular carcinomas (HCCs), 3 of cavernous hemangiomas, and 5 of pseudolesions. They aged from 25 to 64 years (mean age, 42.5 years). The serum level of α -fetoprotein (AFP) was elevated in all patients with small HCC, ranged from 410 ng/mL to 2540 ng/mL. Cirrhosis occurred in all 12 cases with HCC. Five patients with HCC were histologically proven by needle biopsy, and 7 were clinically diagnosed when tumors were demonstrated as lipiodol deposit foci on follow-up CT (lipiodol-CT, Lp-CT) images after transcatheter hepatic arterial chemoembolization (TACE), and the elevated AFP level returned to normal in all patients with HCC.

In this work, we decided a lesion was a pseudolesion when it was proved as normal hepatic tissue by needle liver biopsy, and did not change for at least 1 year. The diagnosis of a cavernous hemangioma was basic on typical findings on dynamic enhanced CT and MRI (very long T2) images, and when it did not enlarge for at least 1 year.

Methods

Multi-phasic CTAP examinations were performed with incremental scanning of liver in cranial-to-caudal direction with 2.7-mm to 5-mm collimation on an CT Twin Flash scanner (Philips Corp.). Data acquisition was started 25 s, 60 s and 120 s for the early-, late- and delayed-phase CTAP respectively, after a transcatheter superior mesenteric arterial injection of 40 mL of non-ionic contrast material at 3.0 mL/s, using an automatic power injector (Medrad, Pittsburgh). During the catheterization, contrast material administered before CT scanning was limited to 10 mL injected by hand to visualize aberrant vessels and to facilitate proper catheter placement.

Multi-phasic CTHA examinations were done 20 min after CTAP. Data acquisition was started 6 s, 40 s and 120 s for the early-, late- and delayed-phase CTHA respectively, after the initiation of a transcatheter common hepatic arterial injection of 15 mL of contrast material at 3.0 mL/s.

If serum AFP level exceeded 400 ng/mL, and a lesion was

highly suspected as an HCC on CTAP and CTHA images, TACE treatment was recommended to this patient, and plain CT scanning was performed 3 or 4 wk later (Lipiodol CT, Lp-CT).

RESULTS

The images of multi-phasic CTAP and CTHA in 20 cases were

carefully interpreted by two experienced radiologist. On early-phasic CTHA, all eighteen HCCs were shown as nodular enhancement. The density of the whole tumor decreased rapidly and became hypodense or isodense compared with the surrounding liver tissue on late and delayed phases. However, the edge of tumors (12/18) remained relatively hyperdensity compared with the surrounding liver tissue, and demonstrated as rim enhancement. Rim enhancement was demonstrated as

Figure 1 Images of multi-phasic CTAP and CTHA. A: A nodular perfusion defect of HCC on CTAP image. B: A small round enhancement nodule of HCC on early-phasic CTHA image. C: Rim enhancement of HCC on delayed-phasic CTHA image obtained 2 min later.

Figure 2 HCC on early-phasic CTAP and late-phasic CTHA. A: HCC shown as a well-defined hypodense nodule on early-phasic CTAP image. B: HCC demonstrated as rim enhancement on late-phasic CTHA image. C: HCC demonstrated as irregular enhancement on CTHA image.

Figure 3 Pseudolesions on CTAP and CTHA. A: No lesion demonstrated on CTAP. B: Pseudolesion shown as an irregular enhancement focus on early-phasic CTHA. C: Change in shape and size of pseudolesion on late-phasic CTAP. D: Pseudolesion demonstrated as isodensity to liver tissue on delayed-CTHA.

Figure 4 Hemangiomas on CTAP and CTHA. A: A small hemangioma in segment II of left lobe as a perfusion defect nodule on CTAP. B: Lesion demonstrated as a punctuate, peripheral enhancement focus on early-phasic CTHA. C: Hemangioma demonstrated as hyperdensity to liver tissue on delayed-CTHA.

distinct 1 to 2-mm-wide circumferential enhancement at late-, and delayed-phase of multi-phasic CTHA (Figure 1). The shape of enhancement might be irregular, uneven and discontinuous.

All HCCs were shown as perfusion defect nodules on multi-phasic CTAP. The edge of five HCCs (5/18) became relatively hyperdense compared with the surrounding liver tissue and demonstrated as rim enhancement during delayed CT scanning (Figure 2).

Four of 5 pseudolesions were found in the segment IV of left lobe, and one in the segment VI of right lobe. All pseudolesions were shown as isodense or hypodense compared with the surrounding liver tissue on CTAP images. On CTHA images, pseudolesions were demonstrated as oval, wedge or irregular enhancement. The shape and size of pseudolesions were changed during delayed CT scanning. All pseudolesions gradually became isodense compared with the surrounding liver tissue on delayed phase. No pseudolesions were demonstrated as rim enhancement on late- or delayed-phasic CTHA and CTAP (Figure 3).

Four hemangiomas of 3 cases were shown as well-defined nodular perfusion defects on multi-phasic CTAP images. On early-phasic CTHA, hemangiomas were demonstrated as peripheral enhancement or nodular enhancement foci. On delayed CT scanning, all hemangiomas became isodense compared with the surrounding liver tissue. There was no hemangioma demonstrated as rim enhancement on late- or delayed-phasic CTHA and CTAP images in our study (Figure 4).

DISCUSSION

CTAP and CTHA have a high sensitivity for detection of liver diseases^[3,9]. Especially, the use of helical CT technique has greatly improved the quality of images and accelerated the scanning^[1]. However, the false-positive findings on CTAP and CTHA images have greatly limited its further clinical application^[5,10]. Many methods were performed to improve the specificities of CTAP and CTHA for the detection of liver cancer, and combined CTHA and CTAP was recommended to interpret a malignant lesion^[9]. Inoue *et al.*^[8] and Matsuo *et al.*^[6] performed combined CTAP and biphasic CTHA in the pre-operative detection of liver neoplasms. Their results suggested that late-phasic CTHA was useful in differentiating a malignant hepatic tumor from a pseudolesion. Ueda *et al.* performed single-level dynamic CTHA in differentiating hypervascular pseudolesion from hypervascular HCC. They found that the stain of pseudolesion on CTHA was transient and could be divided into three phases: (1) inflow of contrast material into the portal vein within the lesion, (2) lesion staining, and (3) fading out of the staining. However, the staining of HCC might have four phases: (1) inflow of contrast material into tumor, (2) tumor staining, (3) inflow of contrast material into adjacent liver, and (4) "coronal staining"

of adjacent liver^[7,11].

Rim enhancement was demonstrated as distinct 1 to 2-mm-wide irregular coronal or circumferential enhancement at late-, and delayed-phase of multi-phasic CTHA or CTAP^[12,13]. According to our experience, the indistinct circumferential enhancement was only transiently demonstrated during multi-phasic of CTHA and CTAP. Delayed CT scanning 120 s after a transcatheter arterial injection of material might increase the detection of rim enhancement of liver malignancy.

Inoue *et al.* reported that 84% of hepatocellular carcinomas and 73% of hepatic metastases showed rim enhancement on late-phase CTHA, and all non-tumorous perfusions on CTHA images did not show rim enhancement^[8]. They concluded that biphasic CTHA was useful in differentiating hepatic malignancy from benign perfusion abnormalities. Similar findings were confirmed by Matsuo *et al.*^[6] and Ueda *et al.*^[7].

The reason why the malignant tumors showed delayed rim enhancement and pseudolesions did not at late-, or delayed-phase CTHA or CTAP is unclear^[14,13]. Ueda *et al.*^[7] suggested that rim enhancement in hepatocellular carcinoma was caused by inflow of contrast material from tumor into the adjacent liver. They studied the haemodynamics of hepatocellular carcinoma using single level dynamic CTHA, and demonstrated that arterial blood flowed into the tumor via the hepatic artery, filled the inner part of the tumor, penetrated the capsule, ran through the surrounding hepatic parenchyma and entered the portal branches. The haemodynamics can explain the change of homogeneous enhancement pattern on early-phasic CTHA to rim enhancement on late- or delayed-phasic CTHA. However, the contrast material inside pseudolesions faded out after lesion staining, just like liver tissue.

In our study, rim enhancement usually demonstrated on late-phasic CTHA images could be shown on late- and delayed-phase of CTAP in some cases. The reason of similar findings on CTAP might be that some HCCs could obtain blood supply from portal vein branches surrounding the tumor, especially, in the edge of tumor. This "double" blood supply usually occurred in liver tumors with less vascularity^[15]. The border of tumor could be enhanced as a rim of relatively high density during late- and delayed-phase CTAP.

There is a controversy that rim enhancement originates from the normal hepatic tissue surrounding the tumor or from the border of tumor (such as capsule or pseudo-capsule of tumor). Irie *et al.* had performed an CT-pathologic study of metastatic liver tumors, and suggested that rim enhancement of tumor on delayed-phasic CTAP or CTHA images was perilesional enhancement, and it could mainly be caused by an increased supply of arterial flow, a draining of tumorous blood, or an increased interstitial space in the hepatic parenchyma due to fibrotic and desmoplastic changes^[12]. However, Semelka *et al.* suggested that rim enhancement might be the enhancement of

histological tumor border that was defined as the histologically altered liver parenchyma surrounding the tumor, rather than the outer portion of the tumor^[14].

To our knowledge, it is difficult to distinguish tumor border from perilesional area on CT images. During growth, the tumor infiltrates and compresses surrounding hepatic tissue. The capsule or false-capsule of tumor is formed and contains rich blood flow. It might be difficult to distinguish perilesional enhancement of normal tissue from circumferential enhancement of tumor border on CT and MR images. Rim enhancement demonstrated on late- or delayed-phasic CTHA and CTAP might not be confined to the tumor border because it could extend into the surrounding normal liver tissue.

One of the commonest pseudolesions on CTAP and CTHA images was seen in the liver adjacent to gallbladder or in dorsum of segment IV^[4,16]. In our study, four of 5 pseudolesions were found in the left lobe, and one in segment VI of the right lobe. All five pseudolesions demonstrated as isodense lesions or perfusion defects on CTAP images. The shape of enhancement on early-phasic CTHA images might be oval, wedge or irregular. Pseudolesions were changed in shape and size on multi-phasic CTHA images, and gradually became isodense to normal on delayed phase. No pseudolesions were demonstrated as rim enhancement on late- or delayed-phasic CTHA.

Yamagami *et al.*^[4] investigated the haemodynamics of pseudolesions using a biphasic CTHA examination, and suggested that pseudolesions on segment IV were caused by direct blood inflow from cholecystic vein to the liver parenchyma, and concluded that later phase CTHA could clearly differentiate pseudolesions from tumors.

Multi-phasic CTAP and CTHA were valuable for differentiating benign lesions from malignancy^[10,17]. Hemangiomas were found on multi-phasic CTAP and CTHA images. Four hemangiomas of 3 cases were shown as well-defined perfusion defect nodules on CTAP images, and as nodular enhancement on early-phasic CTHA. On delayed CT scanning, all hemangiomas became isodense to the normal. No hemangioma was demonstrated as rim enhancement on late- or delayed-phasic CTHA images in our study. According to our experience, rim enhancement on multi-phasic CTHA could also be used as a characteristic finding to differentiate malignancy from benign lesions, such as hemangiomas.

In conclusion, multi-phasic CTAP and CTHA could raise the specificity for malignant hepatic tumor detection. Rim enhancement demonstrated on late- and delayed-phasic CTAP and CTHA images might help to differentiate a HCC from benign lesions.

Abstract

AIM: To explore the activation of signal transduction pathways related with the carcinogenesis of sporadic colon cancers.

METHODS: A gene array monitoring the activation of 8 signal transduction pathways (PathwayFinder GEMatrix) was used to screen the differentially expressed genes between colorectal cancer and normal colon tissues. The differentially expressed genes were further analyzed by RT-PCR, using RNA derived from colorectal cancer and normal colon tissue of 35 patients.

RESULTS: The expression of HSF1, HSF27, HSP90 and iNOS was increased in colon cancer tissues compared to normal colon tissue using PathwayFinder GEMatrix. The RT-PCR results showed that the expression of HSF1 was increased in 86% (30/35) patients and the expression of iNOS was increased in 63% (22/35) patients.

CONCLUSION: The induction of HSF1 gene expression is associated with sporadic colon cancer. HSF1 induces heat shock stress signaling pathway, which might play a role in the carcinogenesis of sporadic colorectal cancer.

INTRODUCTION

Colorectal cancer (CRC) is one of the most common cancers in China. The incidence of CRC has increased over the last years and the fourth or fifth most prevalent cancers in China. The incidence of CRC increases 3.7% in Chinese cities annually^[1] while the five-year survival rate has not improved significantly. Early detection and treatment remain a major factor for good survival rate of CRC. Therefore, exploration of early diagnostic markers and the mechanism study on CRC oncogenesis are in imminent need for early diagnostic and better treatments. Recently, mutation of APC tumor suppressor gene has been found to be responsible for initiating neoplastic process of familial adenomatous polyposis (FAP)^[2]. APC is a major regulator in the Wnt signal pathway that is activated due to

APC mutation in FAP. The Wnt signal pathway is the oncogenic pathway for FAP. Although APC mutation was found in 60% sporadic CRC, Wnt signal pathway has not been proved to be an oncogenic pathway for sporadic CRC or any specific type of CRC. The oncogenic pathway for sporadic CRC remains to be determined.

Potter^[3] has once summarized four signal pathways attributing to oncogenesis of hereditary CRC: APC-catenin-TCF-c-myc pathway (Wnt signal pathway) in FAP; microsatellite unstable pathway with mutation in hMLH1, hMSH2, hMSH6, hPMS1 or hPMS2 in HNPCC; p53 signal pathway with p53 mutation for CRC associated with chronic colon inflammation; estrogen receptor hypermethylation pathway for CRC associated with menopause. FAP and HNPCC are two hereditary CRCs. Other hereditary CRC also includes Peutz-Jeghers syndrome and juvenile polyposis whose genetic predisposition is currently under investigation. The hereditary CRCs makes up less than 1/3 of CRCs while more than 2/3 of CRCs are sporadic. Therefore, it is important to identify oncogenic pathways for sporadic CRC. As an open system, colon receives various chemical, physical and biological stimuli constantly. These stimuli vary among individuals according to their occupations, living environments and life styles. Some signal pathways that are activated by certain stimuli associated with particular occupations, environments and life styles may induce sporadic CRC. To explore the association between sporadic CRC and activation of signal pathways, we used PathwayFinder GEMatrix from SuperArray, a gene array capable of monitoring activation of 8 common signal transduction pathways to screen differential gene expression between colorectal cancer tissue and normal colon tissue. We found expressions of HSF1, HSF27, HSP90 and iNOS were increased in CRC tissue in comparison with normal colon tissue. RT-PCR was used for further confirmation. Our results suggest activation of heat shock stress signal pathway may attribute to oncogenesis of sporadic CRC.

MATERIALS AND METHODS

GEMatrix

PathwayFinder GEMatrix kit was obtained from SuperArray Bioscience Corp. (Frederick, MD, USA). It included reagents for probe generation and hybridization, and two identical gene arrays containing 23 marker genes for each array. The marker genes were used to monitor the activation of their associated pathways. The induction of marker genes suggested the activation of their associated pathways. The marker genes were transcriptional target genes of their associated pathways. These 8 signal transduction pathways and their associated marker genes are listed below.

Signal transduction pathways
Mitogenic signaling pathway
Stress signaling pathway

NFκB signaling pathway
NFAT signaling pathway
Anti-proliferation/TGFβ signaling pathway
Wnt signaling pathway
P53 signaling pathway
CREB signaling pathway

Tissue and RNA preparation

Specimens of colorectal cancer and normal colon tissues were obtained from 36 patients (age: 32-89 years) at the Second Affiliated Hospital of Zhejiang University. The membranes of cancer and normal tissues of each patient were separated and placed into liquid nitrogen immediately after the removal of cancer mass from the patients. Total RNA was prepared from each specimen using Trizol kit from GIBCO (San Diego, CA, USA) to derive total RNA from cancer tissue and normal tissue. One pair of specimens from a patient (patient 1) was used to perform gene array analysis and the rest of 35 pairs of specimens were used for RT-PCR analysis.

Probe preparation

Anneal Five μ g total RNA was used to mix with 2 μ L buffer A containing gene specific primers GEAprimers (SuperArray, Frederick, MD, USA) and water to bring up a volume to 20 μ L. The annealing of GEAprimers to RNA was achieved at 72 °C for 2 min at 42 °C for 2 min in water bath.

Reverse transcription for probe labeling A cocktail containing the following components was assembled in a 0.5 mL centrifuge tube containing 16 μ L of 5 \times GEAlabeling buffer, buffer B (SuperArray, Frederick, MD, USA), 10 μ L of [α -³²P]-dCTP (370 GBq/L), 2 μ L of RNase inhibitor, 4 μ L of MMLV reverse transcriptase (50 MU/L), 8 μ L of RNase-free H₂O. The cocktail was placed in 42 °C water bath for 2 min followed by aliquoting 20 μ L of the cocktail into the above primer annealed RNA from cancer tissue and 20 μ L of the cocktail into above primer annealed RNA from normal tissue. After mixed, the mixture was placed in 42 °C water bath for 25 min for reverse transcription and labeling cDNA with α -³²P.

Labeling termination A 5 μ L of 10 \times stop solution, buffer C (SuperArray, Frederick, MD, USA) was added to each reaction mixture to stop reverse transcription.

Probe denaturation: The labeled probe was placed in 94 °C heat block for 5 min, then immediately placed on ice until use.

Hybridization

Two PathwayFinder GEArrays were prehybridized with 10 mL GEHyb solution (SuperArray, Frederick, MD, USA) for 2 h at 68 °C. The denatured probes obtained from cancer and normal tissues of patient 1 were then added separately to two 5 mL GEHyb solution preheated to 68 °C. Each of the probe-containing GEHyb solution was then used to hybridize with one PathwayFinder GEArray at 68 °C overnight. The GEArray was washed twice with 2 \times SSC, 10 g/L SDS for 20 min at 68 °C and twice with 0.1 \times SSC, 5 g/L SDS at 68 °C. X-ray films were placed on GEArrays to capture array images at -70 °C overnight.

Density scan and analysis

The hybridization signals on the X-ray film were scanned by IS1000 system to obtain digital number for its density. The average signal was obtained from duplicates of each gene. The normalized value for each gene was calculated by the ratio of averaged value of each gene divided by the average value of β -actin or GAPDH.

RT-PCR

A 1 μ g of total RNA obtained from each specimen was mixed with oligo (dT)₁₅ for reverse transcription using MMLV (Promega, Madison, WI, USA) to derive the first strand cDNA. A pair of gene specific PCR primers was designed for HSF1, iNOS, MDR1 and β -actin genes. HSF1: CCATCCTGCGGGAGA GTG AA for 5' end of the gene and GGCTCCGAGCCTGTCAG CA for 3' end of the gene. iNOS: CACCATCCTGGTGGAACCTCT for 5' end of the gene and TCTTGGGGCTTCAGGCT GTT for 3' end of the gene. MDR1: GCTCAAGTTAAAGGGGCTATA for 5' end of the gene and GCTCAAGTTAAAGGGGCTATA for

3' end of the gene. β -actin: GGCA TCCTCACCCTGAAGTA for 5' end of the gene and GTCCAGACGCAGGATGGCA for 3' end of the gene. PCR reaction was carried out at 95 °C for 3 min for denaturing followed multiple cycles at 95 °C for 15 s, at 56 °C for 10 s, at 72 °C for 45 s. For HSF1, iNOS and MDR1, the cycle number was 35 and for β -actin, the cycle number was 25. The PCR products were separated by electrophoresis and their quantity was determined by Kodak 1D image analysis software.

RESULTS

Identification of differential gene expression between cancer and normal colorectal tissues

Two identical PathwayFinder gene arrays from SuperArray (Frederick, MD, USA), each of which contained 23 marker genes monitoring the activation of 8 signal transduction pathways, were used to hybridize with labeled probes obtained from total RNA of cancer and normal colorectal tissues of a patient separately. The hybridized signal detected for each gene was normalized to the signal obtained for β -actin or GAPDH on the same gene array to derive gene expression value for each gene. After comparing gene expression value of each gene between two gene arrays, we found increased expressions of HSF1, HSF27, HSF90 genes of stress signaling pathway and iNOS gene of NF κ B pathway in cancer tissue in comparison with normal tissue (Figure 1, Table 1).

Figure 1 Comparison of hybridization results of gene arrays. Genes and their corresponding positions on gene arrays were as follows: ATF-2: 1A and 1B; Bax: 1C and 1D; CD5: 1E and 1F; c-fos: 2A and 2B; c-myc: 2C and 2D; Cyp19: 2E and 2F; egr-1: 3A and 3B; fas ligand: 3C and 3D; gadd45: 3E and 3F; hsp1: 4A and 4B; hsf27: 4C and 4D; hsp90: 4E and 4F; ikBa: 5A and 5B; Il-2 5C and 5D; iNOS: 5E and 5F; mdm2: 6A and 6B; NF κ B: 6C and 6D; p19: 6E and 6F; p21^{waf1}: 7A and 7B; p53: 7C and 7D; p57^{kip2}: 7E and 7F; Pig7: 8A and 8B; Pig8: 8C and 8D; β -actin: 3G and 4G; GAPDH: 5G, 6G, 7G, 8E, 8F and 8G; PUC18: 1G and 2G.

HSF1, HSF27 and HSP90 are marker genes for the stress signaling pathway. The induction of these genes in colorectal cancer tissue compared to its normal tissue indicated the activation of stress signaling pathway in cancer tissue. iNOS is a marker gene for NF κ B signaling pathway and its activation suggested that NF κ B might be activated. Since we did not detect

activation of other NF κ B pathways associated marker genes, the induction of iNOS expression might be due to the activation of other signal pathways other than NF κ B signal pathways.

Table 1 Analysis of scanned density on gene arrays

Gene	Ratio of cancer tissue vs normal tissue (β -actin) ¹	Ratio of cancer tissue vs normal tissue (GAPDH) ²

RT-PCR analysis for association of with sporadic colon cancer

A pair of gene specific PCR primers was designed for HSF1 and iNOS. RT-PCR was used to analyze the gene expression level of HSF1 and iNOS in both colon cancer and normal tissues of 35 patients. We confirmed increased HSF1 expression in 30 out of 35 patients in their cancer tissue in comparison to their normal tissue (Table 2). The average HSF1 expression value was 1.116 ± 0.849 for normal tissue and 1.823 ± 1.337 for cancer tissue. Using pair-wise *t* test analysis, the *t* value was 4.433 and *P* value was <0.001 (<0.05). Thus, it was statistically significant. The induction of HSF1 expression in tumor tissue was confirmed to be strongly associated with sporadic colorectal cancer. We also confirmed increased iNOS expression in 22 out of 35 patients in their cancer tissue in comparison to their normal tissue (Table 2). The average iNOS expression value was 0.867 ± 0.761 for normal tissue and 1.133 ± 0.843 for cancer tissue. Using pair-wise *t* test analysis, the *t* value was 1.803 and *P* value was 0.08 (>0.05). Thus, it was not statistically significant.

HSF1 was found to induce expression of MDR1. To explore whether HSF1 induction could increase expression of MDR1, we performed RT-PCR analysis on the same specimens from 35 patients. To our surprise, we found reduction of MDR1 expression in most (23/35) cancer tissues in comparison to normal tissues. The average MDR1 expression value was 1.099 ± 0.885 for normal tissue and 1.443 ± 1.096 for cancer tissue. Using pair-wise *t* test analysis, the *t* value was -2.329 and *P* value was 0.026 (<0.05). Thus, it was statistically significant.

Among sporadic CRCs from these 35 patients, 5 cases were at stage A, 12 at stage B, 17 at stage C and 1 at stage D. Five cases whose HSF1 expression did not increase in cancer tissue mainly belonged to late-stage patients (3 cases at stage C, 1 at stage D and 1 at stage B). However, statistical analysis could not be performed due to the limited number of cases.

DISCUSSION

Cellular signal transduction regulates almost all biological and physiological functions within cells. It is executed by a complex system where multiple signal transduction pathways interact together and are tightly controlled at different levels. The abnormality in cellular signal transduction can affect various cellular functions such as cell growth and proliferation, differentiation and metabolism and eventually lead to various diseases. Cancer is a typical disease resulting from abnormality in cellular signal transduction. Mutations of multiple genes in somatic cells are involved in the process of neoplastic formation. These mutations result in activation of oncogenes and inactivation of tumor suppressor genes, which lead to uncontrolled cell growth due to the loss of cellular differentiation and/or apoptosis ability. Further mutations in genes controlling cellular adherence and movement lead to tumor metastasis. Therefore, multiple signal transduction pathways in cell growth and proliferation, differentiation, apoptosis, adherence and movement are involved in initiation and progression of cancer.

There are four signal transduction pathways described by Potter^[3,4] to be involved in the oncogenesis of hereditary CRC: APC- β -catenin-TCF-myc (Wnt) pathway^[5], microsatellite unstable pathway^[6], p53 pathway and estrogen receptor hypermethylation pathway. However, the signal transduction pathways involved in sporadic CRC remain unclear. APC mutation responsible for FAP's oncogenesis was also found in 60-70% sporadic CRCs^[7,8]. Similarly, microsatellite instability was found in over 30% sporadic CRCs^[9] and p53 mutation was found in 50% sporadic CRCs^[10]. In addition, non-steroidal anti-inflammatory drugs (NSAIDs) were found to efficiently suppress tumorigenesis of CRC by inhibiting Cox-2 activity^[11-14]. It indicates Cox-2 pathway is involved in CRC oncogenesis as well. These results suggest multiple signal pathways are involved in the oncogenesis of

sporadic CRC. To efficiently identify signal pathways involved in sporadic CRC, we employed PathwayFinder gene arrays that utilize pathway target genes to monitor the activation of 8 important pathways related to cell growth, proliferation, survival, stress, apoptosis and inflammation. Monitoring induction of target genes by PT-PCR was found to be an effective way to identify the activation of Wnt signal pathway in adenomas of FAP compared to matched normal mucosa^[15,16]. The utilization of gene array to identify induction of target genes greatly increased its efficiency.

We found HSF1 gene expression was significantly increased (30/35) in cancer tissue compared to its normal tissue in 35 patients. HSF1 stands for heat shock transcription factor 1 and is a transcription factor with a molecular weight of 82KD. HSF1 could be induced by heat, chemicals and hypoxia^[17-19] and usually exists as a monomer in the cytoplasm. After heat stimulation, it became a trimer and could be translocated into nucleus^[20]. Its transcriptional activity was greatly increased by the phosphorylation of serine induced by stimuli. HSF1 could activate transcription of its target genes by binding to a heat shock element^[7]. The heat shock element was present in the promoter region of many genes such as HSP90, HSP27, HSP70 and drug resistant gene MDR1^[21]. Hoang^[22] recently reported HSF1 expression was increased in a prostate cancer cell line. Our study not only provided the first evidence to demonstrate the association of HSF1 gene expression and CRC, but also suggested that the induction of HSF1 gene expression might be associated with a broad range of cancer. The reduced HSF1 expression in the remaining 5 cancer tissues might be due to different oncogenic mechanisms occurring in these CRCs from HSF1 induction related sporadic CRCs.

In this study, the induction of HSF1 gene expression was accompanied with the induction of HSP27 and HSP90 which were two target genes of HSF1, suggesting that the induction of HSF1 gene expression could activate HSF1 heat shock stress signal pathway in sporadic CRC. Heat shock stress signal pathway is highly involved in carcinogenesis since heat shock proteins (HSP90, HSP70, *etc.*) are responsible for maintaining the conformation, stability and function of key oncogenic client proteins involved in signal transduction pathways leading to proliferation, cell cycle progression and apoptosis, as well as other features of the malignant phenotype such as invasion, angiogenesis and metastasis^[23-26]. HSP90 has currently served as an anti-cancer drug target for various drug development^[27-29]. Also, HSP70 was found to inhibit apoptosis^[30]. Our result suggested heat shock stress pathway contributed to carcinogenesis actively instead of passively as a bystander. Our hypothesis of heat shock stress pathway contributing to carcinogenesis of sporadic CRCs coincides with the fact that colon is an open system where it could retain and receive various kinds of "stress" substances for a long period of time. The "stress" substances might come from meat, alcohol, inflammatory tissue and others^[31]. The prolonged exposure of these "stress" substances could lead to activation of heat shock stress pathway, thus leading to carcinogenesis through enhancing function of oncogenic proteins occurring in cells. The heat shock stress pathway could be further activated by hypoxia occurring in the tumor which was found to increase HSF1 expression as well^[18,19]. Vegetables, nonsteroidal anti-inflammatory drugs (NSAIDs), hormone replacement therapy, and physical activity^[31] could reverse the activation of heat shock stress pathway and therefore suppress carcinogenesis.

Hoang *et al.*^[22] found HSF1 expression was increased in a prostate cancer cell line PC-3 derived PC-3M clone with metastatic ability compared to its parent cell line. By Western-blot and immunohistochemistry analysis of 18 prostate cancer and 4 normal prostate tissues, they confirmed the induction of HSF1 expression in prostate cancer tissues. However, since

Western-blot and immunohisto-chemistry analyses detect protein expression instead of gene expression, it remains to be confirmed that the induction of HSF1 is at gene expression level. Our gene array analysis and RT-PCR directly measured mRNA level. We clearly demonstrated the induction of HSF1 was on the gene expression level and its strong association with sporadic CRCs. Nevertheless, in our study, each cancer tissue was paired with its matched normal tissue from the same patient for comparison of gene expression eliminating differential gene expression caused by individual genetic background.

PathwayFinder gene array from SuperArray provided two spots for each gene. The variation between the two spots was below 5%. According to Table 1, if β -actin expression level was used for normalization, genes whose expression was increased in cancer tissue included HSP27 (1.58 fold), iNOS (1.49 fold), HSF1 (1.43 fold), HSP90 (1.31 fold), i κ B (1.25 fold), egr-1 (1.16 fold). However, if GAPDH expression level was used for normalization, genes whose expression was increased in cancer tissue only include HSP27 (1.28 fold), iNOS (1.22 fold), HSF1 (1.17 fold), HSP90 (1.06 fold). Therefore, it is important to use multiple housekeeping genes for normalization since expression of housekeeping genes such as β -actin and GAPDH may fluctuate sometimes.

Vilaboa^[31] found HSF1 could bind to the promoter region of MDR1 to increase its expression transcriptionally. However, MDR1 was also a target gene for Wnt signal pathway and the expression of MDR1 was increased in precancerous lesion of FAP patients^[32]. We found reduced MDR1 gene expression in most (23/35) cancer tissues. Our result suggested MDR1 gene expression was not regulated under heat shock stress signal pathway in colon tissue, more likely under Wnt signal pathway. The reverse association of MDR1 expression with HSF1 and β -catenin (Wnt pathway) indicated that different signal pathways contributed to the carcinogenesis of FAP and sporadic CRC. The reduced MDR1 gene expression was also found in other cancers such as kidney cancer^[33] and brain cancer^[34].

Recently, a large number of studies have revealed the association of iNOS expression with various cancers^[35-39]. Yagihashi^[40] studied 22 cases of colorectal cancer tissues by immunohistochemistry and RT-PCR and found increased iNOS expression was associated with colorectal cancer. Bing *et al.*^[37] found increased expression of iNOS and production of prostanooids in colorectal cancer paralleled to the increase in COX-2, confirming the importance of this enzyme in colon cancer. Ropponen^[39] found iNOS expression in colorectal cancer might be used as a prognosis marker as well. Our study also confirmed induced iNOS expression in 22 out of 35 cancer tissues, indicating that the biological significance of MDR1 and iNOS expression in CRC needs to be further studied.

Abstract

AIM: To find new potential biomarkers and to establish patterns for early detection of colorectal cancer.

METHODS: One hundred and eighty-two serum samples including 55 from colorectal cancer (CRC) patients, 35 from colorectal adenoma (CRA) patients and 92 from healthy persons (HP) were detected by surface-enhanced laser desorption/ionization mass spectrometry (SELDI-MS). The data of spectra were analyzed by bioinformatics tools like artificial neural network (ANN) and support vector machine (SVM).

RESULTS: The diagnostic pattern combined with 7 potential biomarkers could differentiate CRC patients from CRA patients with a specificity of 83%, sensitivity of 89% and positive predictive value of 89%. The diagnostic pattern combined with 4 potential biomarkers could differentiate CRC patients from HP with a specificity of 92%, sensitivity of 89% and positive predictive value of 86%.

CONCLUSION: The combination of SELDI with bioinformatics tools could help find new biomarkers and establish patterns with high sensitivity and specificity for the detection of CRC.

INTRODUCTION

Colorectal cancer (CRC) is one of the most common malignant tumors that threaten people's health^[1-5]. At present, CRC is one of the three leading causes of worldwide cancer mortality and the second leading cause of cancer-related deaths in the Western world^[6,7]. The prognosis of CRC is strongly related to early diagnosis. CRC patients diagnosed in early stage have a

five-year survival post-operation of over 80%, but in the advanced stage the five-year survival is lower than 40%. So, early diagnosis is very important to improve the prognosis of CRC^[8].

Recently serum tumor markers, such as carcinoembryonic antigen (CEA), are commonly used to detect CRC for the advantages of less pain and accessibility. However all the existing biomarkers have a low diagnostic sensitivity in CRC (sensitivity of 23% with CEA^[9]). New biomarkers with a high sensitivity and specificity to detect CRC in early stage are urgently needed. A novel proteomic approach for the detection of cancer which is called surface enhanced laser desorption/ionization time-of-flight mass spectrometry (SELDI-TOF MS), and ProteinChip technology, have been developed. SELDI-TOF MS coupled with bioinformatics approach has successfully found new biomarkers and achieved high sensitivity and specificity for the diagnosis of cancers of bladder^[10], prostate^[11-14], ovary^[15,16], breast^[17,18], liver^[19], neck^[20], lung^[21,22], pancreas^[23].

The aim of this study was to find the potential biomarkers in CRC and to establish the patterns to diagnose CRC.

MATERIALS AND METHODS

Samples

A total of 182 serum samples were obtained from the serum banks of the Cancer Institute of the Second Affiliated Hospital of Zhejiang University Medical College. The cancer group consisted of 55 serum samples from CRC patients at different clinical stages: Dukes' A ($n = 8$), Dukes' B ($n = 22$), Dukes' C ($n = 13$), Dukes' D ($n = 12$). The median age of CRC patients was 57 years (range, 31-84 years). The two non-cancer control groups included 35 serum samples from patients with colorectal adenoma (CRA) and 92 serum samples from healthy persons (HP). They were age and sex matched with cancer group. Diagnoses were pathologically confirmed, and specimens were obtained before treatment. All samples were stored at -80°C .

Proteinchip array analysis

Serum samples were thawed in ice and centrifuged at 3 000 r/m for 5 min at 4°C , supernatants were retained. We added 90 μL of 5 g/L CHAPS (Sigma) (pH 7.4) in PBS to 10 μL of each serum sample, and vortex-mixed them. The diluted samples were added to 100 μL Cibacron Blue 3GA (Sigma) (previously equilibrated with 5 g/L CHAPS three times) in a 96-well cell culture plate and agitated on a platform shaker at 4°C for 60 min. After centrifuged at 1 000 r/m, 50 μL supernatant was sampled and further diluted by 150 μL 20 mmol/L HEPES (pH 7.4) and applied to each well of a bioprocessor (Ciphergen Biosystems) containing hydrophobic surface (H4) chips previously activated with 20 mmol/L HEPES. The bioprocessor was then sealed and agitated on a platform shaker for 60 min at 4°C . The excess serum mixtures were discarded, and the chips were washed three times with 20 mmol/L HEPES and 2 times with deionized water. The chips were then removed from the bioprocessor, air-dried. Before SELDI analysis, 0.5 μL of a saturated solution of α -cyano-4-hydroxycinnamic acid (CHCA) in 0.5 L/L acetonitrile and 5 mL/L trifluoroacetic acid was applied onto each chip twice, air-dried.

Chips were detected on the protein biological system II

(PBS-II) plus a mass spectrometer reader (Ciphergen Biosystems). Data were collected by averaging 65 laser shots with an intensity of 135, a detector sensitivity of 7, a highest mass of 30 000 Da and an optimized range of 2 000-20 000 Da. Mass accuracy was calibrated to less than 0.1% using the all-in-one peptide molecular mass standard (Ciphergen Biosystems).

Bioinformatics analysis

The spectra intensities of all samples were normalized to the total ion current of m/z between 2 000 and 30 000 Da. The noise of spectra was filtrated and peaks were detected with an automatic peak detection pass using signal-to-noise ratio. Peak clusters were completed to cluster the peaks in different samples that had similar masses (defined by a mass window in 0.3% mass error). All these were performed using ProteinChip Software 3.1 (Ciphergen). The peak intensities were preprocessed by scaling all the data to the range[-1, 1].

The pattern recognition techniques were applied to diverse areas including prediction of cancer^[24], gene microarray^[25] and mass spectrometry^[26]. We utilized a multi-layer perception (MLP) ANN with a scaled conjugate gradient (SCG) optimized back propagation algorithm for discriminating CRC from HP, and a linear support vector machine (SVM) for discriminating CRC from CRA. They were powerful tools for analysis of the complex data^[14] derived from SELDI-MS.

Feature selection

We estimated the power of each peak in discriminating different group samples by integrating approaches such as *t*-test, receive option curve (ROC) and mean square error (MSE) of ANN.

The ANN used to calculate the MSE of each peak had 3 layers, with 1 node in input and output layer, 2 nodes in hidden. For each peak the ANN was trained with all the samples, performed 1 000 epochs to get the MSE respectively. The MSE was calculated as the difference between the target output and the ANN predictive value. The lower MSE value of the peak showed a higher relative importance value for their ability to accurately discriminate the different groups.

Integrated ANN classifier

The ANN established for discriminating different groups had 4 layers. Except output layer and input layer ANN also had 2 hidden layers each with 100 nodes. We randomly selected 1/3 of all the samples to be the blinded test set, and the remaining 2/3 samples for training, the procedure was repeated 10 times.

In the procedure of training ANN we used a cross-validation approach to reduce the risk of "over fit"^[27]. The samples for training were randomly divided into 2 sets: 2/3 samples for training set and 1/3 samples for validation set. The random shuffling was redone 100 times. Thus 100 different ANNs were established to predict the blinded test set samples. The predictive values of the blinded test set samples were the average of all the predicted outputs of 100 ANNs.

SVM classifier

SVM is a new machine learning approach originally proposed and developed by Vladimir Vapnik. SVM applications were actively pursued in various areas recently, from genomics to face recognition^[28,29]. SVM is powerful for small sample data. We used the linear SVM classifier and set the cost of the constrain violation (C) to 1. The 3-fold cross-validation approach was applied to estimate the accuracy of the classifier.

RESULTS

Bioinformatics analysis of CRC and HP data

After noise was filtrated by Ciphergen ProteinChip Software 3.1,

there were 61 peaks detected for discriminating CRC from HP and 235 peaks for discriminating CRC from CRA. The peaks were between 2 k and 30 kDa. Peaks with an m/z <2 kDa were mainly ion noise from the matrix and therefore excluded^[10].

The 61 qualified peaks detected from the two groups were ranked by the MSE values of ANN. We input the 61 peaks respectively. For each peak we trained the ANN with all the 147 healthy and CRC samples to give an MSE value. The top 15 peaks with lower MSE values were selected for further analysis (Figure 1). The *t*-test and ROC method confirmed the results with the same 15 peaks.

Figure 1 MSE values of the top 15 peaks. A: m/z of peaks. B: MSE values of peaks.

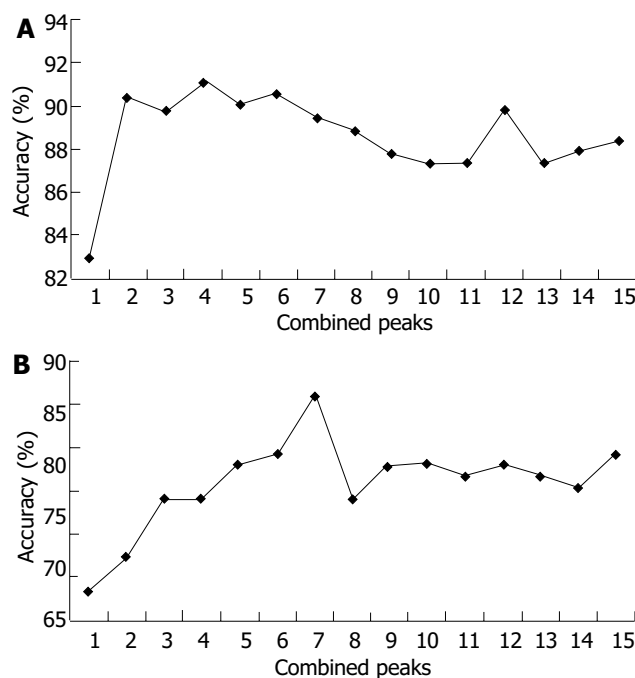

Figure 2 Accuracies of different combinations of peaks. A: Accuracies of different combinations of peaks in the pattern discriminating CRC patients from HP. B: Accuracies of different combinations of peaks in the pattern discriminating CRC patients from CRA patients.

To further select the set of candidate biomarkers, we used a stepwise approach in which many integrated ANNs were trained. The top 1 peak with the highest ability to predict the two groups (had the lowest MSE value) was selected as a single input to build the integrated ANN. We estimated the discriminating ability of this integrated ANN by the accuracy of blind test set. Next, the top 2 peaks were input to integrated ANN and the accuracy was calculated. The following peaks were added as

input stepwise to train integrated ANN and the accuracy was calculated. In this way, the 15 models combining different peaks were built. The peaks input to the model with the highest accuracy were selected as the set of potential biomarkers. The top 4 peaks were finally selected as potential biomarkers, an accuracy of 92% was achieved. The accuracies of these 15 models are plotted in Figure 2 (A).

The *m/z* of the 4 candidate biomarkers were 5 911, 8 922, 8 944, 8 817 Da. These 4 peaks all appeared to highly express in CRC and lowly express in healthy persons, as shown in Figure 3 (A, B). Between the two groups, the *P* value of *t*-test ($<10^{-9}$) and the area under the ROC curve (>8.0) showed statistical significance of all the 4 peaks. Table 1 shows the descriptive statistics of the 4 peaks.

Table 1 Descriptive data for the 4 potential biomarkers in the pattern discriminating CRC patients from HP (mean \pm SD)

M/Z (Da)	AUC	HP	CRC patients
5 911	0.908	0.824 \pm 0.504	2.763 \pm 1.720
8 922	0.872	1.254 \pm 0.724	2.767 \pm 1.445
8 944	0.828	0.999 \pm 0.626	2.651 \pm 1.851
8 817	0.811	0.878 \pm 0.607	1.744 \pm 0.940

AUC: area under the curve.

The 4 peaks were combined and evaluated by integrated ANN. We trained the integrated ANN with 89 samples and tested 49 samples. We randomly selected the test set 10 times, and each time 100 ANNs were built to predict the test set. So 1 000

ANNs were built up. Table 3 shows the results of this classifier. For the integrated ANN classifier, the estimated specificity in the blind test set was 92% with a 95% confidence interval of 89-95%, the estimated sensitivity was 89% (85-93%), the estimated positive predictive value was 86% (82-90%).

Table 2 Descriptive statistics for the 7 potential biomarkers in the pattern discriminating CRC patients from CRA patients (mean \pm SD)

M/Z (Da)	<i>P</i> value ($\times 10^{-5}$)	CRA patients	CRC patients
17 247	0.71	0.211 \pm 0.130	0.113 \pm 0.100
18 420	1.27	0.039 \pm 0.036	0.076 \pm 0.040
5 911	1.71	1.459 \pm 0.977	2.763 \pm 1.720
9 294	2.76	0.617 \pm 0.385	1.105 \pm 0.563
4 654	6.74	0.503 \pm 0.493	1.164 \pm 0.943
21 694	7.48	0.489 \pm 0.145	0.698 \pm 0.267
21 742	12.10	0.536 \pm 0.161	0.744 \pm 0.282

Table 3 Predicted results of classifier for discriminating CRC patients from HP

	Test set (49 \times 10)		Training set (98 \times 10)	
	HP	CRC	HP	CRC
HP (92 \times 10)	287	25	599	9
CRC (55 \times 10)	19	159	29	343
Specificity (%)	92(287/(287+25))		99(599/(599+9))	
Sensitivity (%)	89(159/(159+19))		92(343/(343+29))	
Positive value (%)	86(159/(159+25))		97(343/(343+9))	

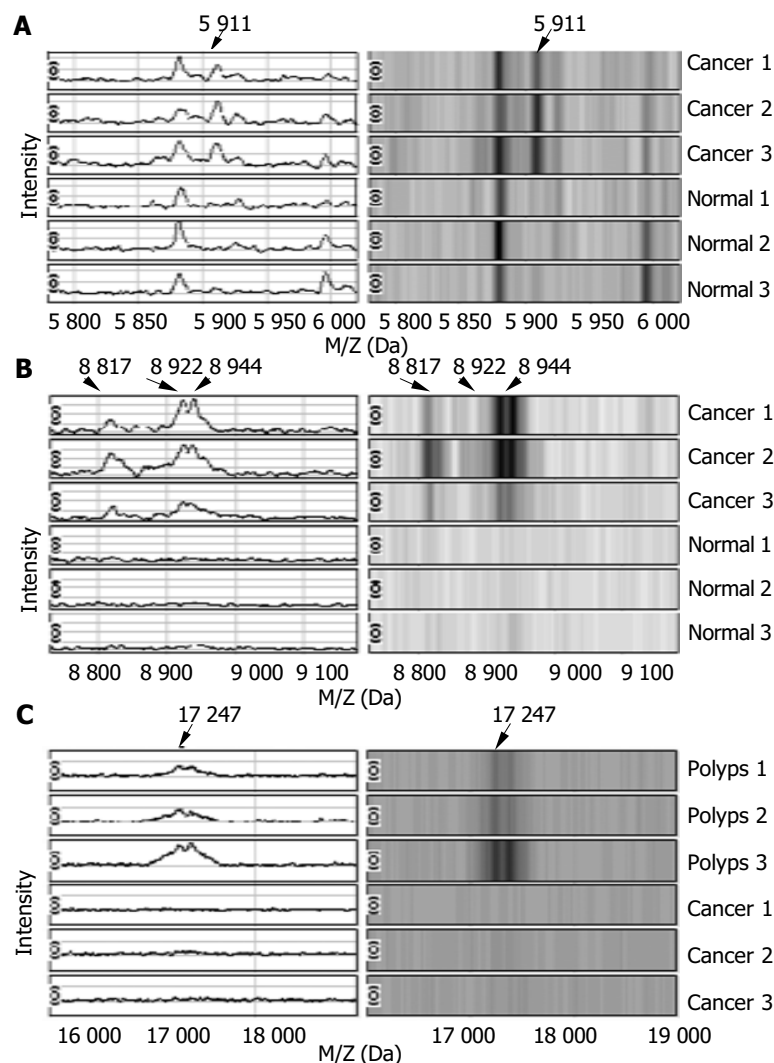

Figure 3 Spectra and gel maps of potential biomarkers. A: Spectra and gel maps of the peak with the *m/z* of 5 911 Da. B: Spectra and gel maps of the peak with the *m/z* of 8 922, 8 944, 8 817 Da. C: Spectra and gel maps of the peak with the *m/z* of 17 247 Da.

Bioinformatics analysis of CRC and CRA data

The 235 qualified peaks detected from the two groups were ranked by the *P* values of *t*-test. The top 15 peaks were selected for further analysis. For these data we utilized the 3-fold cross-validation SVM classifier to select the potential biomarkers to build the model to predict the test sets. This approach randomly selected 1/3 of samples to be the blinded test set, and the remaining 2/3 samples to be the training set and the procedure was repeated 3 times. We still used stepwise method to add the peaks in the rank of *P* value one by one to be the input of 3-cross-validation SVM. The top 7 peaks with the highest accuracy (86.7%) were selected as final potential biomarkers to separate the two groups. Table 2 shows the descriptive data of the 7 peaks. Between the two groups, the *P* values of *t*-test ($<10^{-4}$) and the area under the ROC curve (>7.0) showed the statistical significance of the 7 peaks. In the 7 peaks only the peak of 17 247 Da appeared to lowly express in CRC and highly express in CRA as shown in Figure 3C, others were highly expressed in CRC.

We used 3-fold cross-validation SVM to combine the 7 peaks, and trained it with 60 samples. For the 3-fold cross-validation SVM, the estimated specificity in the blind test set (30 samples) was 83% with a 95% confidence interval of 79-87%, the estimated sensitivity was 89% (86-92%), the estimated positive predictive value was 89% (86-92%). Table 4 shows our results for this classifier.

Table 4 Predicted results of classifier for discriminating CRC patients from CRA

	Test set (30×3)		Training set (60×3)	
	CRA	CRC	CRA	CRC
CRA (35×3)	29	6	56	14
CRC (55×3)	6	49	16	94
Specificity (%)	83(29/(29+6))		80(56/(56+14))	
Sensitivity (%)	89(49/(49+6))		85(94/(94+16))	
Positive value (%)	89(49/(49+6))		87(94/(94+14))	

DISCUSSION

CRC screening includes fecal occult blood test (FOBT), sigmoidoscopy, air-contrast barium enema examination, colonoscopy^[30]. But they have not been commonly accepted due to costs, bowel preparation, sedation and perforation risks. Detection of serum tumor markers (such as CEA) is an inexpensive and facile screening method compared to others. However, all the existing biomarkers in serum lack sufficient sensitivity for screening and diagnosis of CRC^[31-35]. In this study, we detected CEA values (cut-off value of CEA level of 5 ng/mL) of 182 serum samples (including 55 from CRC patients, 35 from CRA and 92 from HP which were also detected by SELDI), and a sensitivity of 47% was achieved in screening for CRC. The results also showed that CEA lacked sufficient sensitivity for screening and diagnosis of CRC.

Because of the multi-factorial nature of CRC, it is very clear that a combination of several markers would be necessary to effectively detect and diagnose CRC. SELDI-MS and the ProteinChip technology could provide the high-throughput proteomic profiling^[36]. Coupled with sophisticated bioinformatics tools for complex data analysis they could find the "fingerprints" of CRC and build the diagnosis model.

One hundred and forty-seven CRC patients and HP were detected by SELDI-TOF-MS and the complex data were analyzed by integrated ANN, we found 4 potential biomarkers and achieved a specificity of 92% (89-95%), sensitivity of 89% (85-93%), positive predictive value of 86% (82-90%). Ninety CRC and CRA patients were detected by SELDI-MS and analyzed by an SVM classifier. We found 7 potential biomarkers and achieved

a specificity of 83% (79-87%), sensitivity of 89% (86-92%), positive predictive value of 89% (86-92%).

Early detection remains one of the most urgent issues in CRC research^[37]. Our two patterns could recognize early Dukes samples as efficiently as other Dukes samples. The biomarkers used in the final selection were not sensitive to different Dukes, stages of cancer patients. In almost all the patients with CRC, preceding lesions were asymptomatic adenomas^[38]. So it is very important to discriminate the noncancer CRA patients from early CRC. We also achieved a high sensitivity and specificity model to recognize CRC and CRA patients.

We developed an integrated approach using bioinformatics and biostatics tools to analyze the large data of spectra. The ROC curve, *t*-test and MSE values were used to rank and select the peaks according to their contribution to the separation of two groups. To accurately estimate the sensitivity and specificity of the classifiers established by potential biomarkers, the test sets were randomly selected many times, independent of training sets each time.

The peak of 4 645 Da was identified as doubly charged forms of 9 294 Da by Ciphergen ProteinChip Software 3.1. The recognition of both the doubly charged and the singly charged forms of these peaks suggested their importance in discriminating the two diagnostic groups. The peak of 5 911 Da was selected as a potential biomarker in both the pattern discriminating CRC patients from HP and the pattern discriminating CRC from CRA patients. The expression of this biomarker increased step by step in HP, CRA and CRC patients as shown in Figure 3A. Therefore the peak of 5 911 Da may play an important role in the formation and progression of CRC.

In conclusion, SELDI-TOF-MS in combination with sophisticated bioinformatics tools could facilitate the discovery of new biomarkers and establish patterns with a high sensitivity and specificity for the detection of CRC.

Abstract

AIM: Traditional hepatitis B virus (HBV) genotyping methods using restriction fragment length polymorphism (RFLP) can reliably identify genotypes A to F. As HBV genotypes G and H have been recently identified, this study was to establish an accurate and simple genotyping method for all eight HBV genotypes (A to H).

METHODS: Two hundred and forty HBV small S sequences obtained from GeneBank were analysed for restriction enzyme sites that would be genotype-specific. Restriction patterns following digestion with restriction enzymes BsrI, StyI, DpnI, HpaII, and EaeI, were determined to identify all eight HBV genotypes. Mixed genotype infections were confirmed by cloning and further RFLP analysis.

RESULTS: The new genotyping method could identify HBV genotypes A to H. Genotypes B and C could be determined by a single step digestion with BsrI and StyI in parallel. This was particularly useful in the Far East where genotypes B and C are predominant. Serum samples from 187 Chinese HBV carriers were analysed with this genotyping system, and the genotype distribution was 1.1% (2), 51.9% (97), 40.6% (76) and 4.8% (9) for genotypes A, B, C, and D, respectively. Mixed genotypes were found in only 3 patients (1.6%). Sequence data analysis confirmed the validity of this new method.

CONCLUSION: This HBV genotyping system can identify all eight HBV genotypes. It is accurate and simple, and can be widely used for studies on HBV genotyping.

INTRODUCTION

Hepatitis B virus (HBV) exhibits genetic variability which gives

rise to the well recognized subtypes and genotypes of the virus. In addition, virus variants arise during replication as a result of nucleotide misincorporations, in the absence of any proof-reading capacity by the viral polymerase. Based on an inter-group divergence of 8% or more in the complete genome nucleotide sequence, HBV has been classified into at least 8 different genotypes^[1-4]. Genotyping could also be accomplished based on partial sequences from the pre-S or S genes of the HBV genome^[5-7].

HBV genotypes have distinct geographical distributions. Genotypes A and D occur frequently in Africa and Europe^[5,8], while genotypes B and C are prevalent in Asia^[1]. Genotype E is almost entirely restricted to Africa, and F is found preferentially in Central and South America^[9]. Genotype G was reported in France and the United States^[3]. Recently, the eighth genotype H has been described in Central America^[4].

An increasing number of studies showed that HBV genotypes might influence HBeAg seroconversion rates^[10], mutation patterns in precore and core promoter regions^[11,12], severity of liver disease^[13-15] and response to antiviral treatment^[11,16]. In order to confirm and extend these observations, further studies are needed to be carried out, using reliable and simple methods for HBV genotyping. Though several HBV genotyping methods have been reported so far^[5-7,17,18], these could identify genotypes A to F, but not G or H.

The aim of this study was therefore to establish a simple and accurate HBV genotyping system using restriction fragment length polymorphism (RFLP) of the small S gene region, which could identify HBV genotypes A to H and would be applicable to large-scale studies.

MATERIALS AND METHODS

HBV sequences and computerized analyses

Two hundred and thirty-two complete and 8 S sequences of HBV were obtained from the DNA database (GenBank), comprising 24 sequences of genotype A, 35 of B, 97 of C, 38 of D, 5 of E, 30 of F, 8 of G and 3 of H. The small S gene regions of all these sequences were aligned and analysed to identify conserved regions and restriction enzyme sites that were genotype-specific. Five restriction enzymes were deemed to be appropriate for this purpose, and restriction patterns were determined by computerized analysis of each of the above mentioned sequences. The DNASIS software package (Hitachi Software Engineering, 1991) was used in this study.

Patient sera and HBV genotypes

Serum samples from 190 Chinese patients with chronic hepatitis B were collected from 2 liver units in mainland of China, and stored at -70 °C. All subjects (male/female = 161/29, mean age = 29.5±9.16 years) were HBsAg-positive by commercially available immunoassays (Abbott Laboratories). Of them, 116 (61%) were HBeAg positive, and the mean alanine transaminase value (ALT) was 248.5±342.8 IU/L. These samples were initially genotyped by RFLP analysis of pre-S amplicons as previously described^[6].

Genotyping PCR and restriction enzyme treatment

The S gene sequences were amplified by nested PCR. Based

on the most conserved regions, we designed PCR primers to amplify the sequence between nt 203 to nt 787, yielding an amplicon of 585 bp. The outer primers were PrsS2 (sense, nt 2820-2837, 5'-GGGACACCATATCTTG) and S1R (antisense, nt 842-821, 5'-TTAGGGTTTAAATGTATACCCA). The inner primers were YS1 (sense, nt 203-221, 5'-GCGGGGTTTTTCTTGT TGA) and YS2 (antisense, nt 787-767, 5'-GGGACTCAAGATG TTGTACAG). DNA was extracted from the serum as previously described^[19]. A 5 µL of the resuspended DNA was added to an amplification mixture containing 5 µL of 10× Taq polymerase buffer, 5 µL of 25 mmol/L deoxyribonucleotide triphosphates, 1 µL (2U) of Taq polymerase (Promega, Beijing, China) and 10 pmol each of primers PrsS2 and S1R (total volume of 50 µL). The PCR profile was an initial 3 min denaturation at 94 °C, followed by 35 cycles of amplification including denaturation for 45 s at 94 °C, annealing for 60 s at 53 °C, and extension for 90 s at 72 °C. Strand synthesis was completed at 72 °C for 6 min. A 1 µL of the first-round PCR products was then used for the second-round PCR under the same conditions but with the primers YS1 and YS2.

A 10 µL of the second-round PCR products was mixed with 0.5 µL (5U) of the chosen restriction enzyme (New England Biolabs, Hong Kong, China), 1.5 µL of 10× buffer and 3.0 µL of water. After incubation at 37 °C for 4 h, the samples were electrophoresed on a 30 g/L agarose gel. A 10 µL of undigested second-round PCR products was run in parallel with the enzyme-digested samples. The restriction patterns were read visually under ultraviolet light.

Identification of mixed genotypes

When non-specific, atypical or mixed RFLP patterns were found, and the small S gene region was amplified with primers BS1 (sense, nt 56-76, 5'-CCTGCTGGTGGCGCCAGTTCC) and S1R, yielding an amplicon of 797-bp in length. These PCR products were purified and ligated into the pGEM-T vector using a commercial kit (Promega, Beijing, China). Ten positive clones were selected for further analysis. Extracted plasmid DNA was amplified with primers YS1 and YS2. PCR products were digested with restriction enzymes and analysed by electrophoresis. Samples that did not give clear results were then sequenced directly.

Sequencing and sequence data analysis

Three serum samples each of genotypes B, C and D, and 2

serum samples of genotype A by our method were randomly selected for sequencing. The small S gene region was amplified with primers BS1 and S1R and ligated into the pGEM-T vector as described above. Plasmid DNA was extracted from positive clones and sequenced using an ABI automatic DNA sequencer. Sequences were then edited, aligned and compared with reference sequences using the DNASIS software.

RESULTS

Predicted RFLP patterns

Following alignment of S gene sequences, five restriction enzymes, StyI, BsrI, DpnI, HpaII and EaeI were deemed to be suitable for yielding restriction patterns that would identify all eight HBV genotypes.

Genotype C had a StyI site at nt position 455, cutting the S gene into two fragments of 253- and 332-bp in length. This restriction pattern was found in 95 of 97 genotype C sequences examined. This restriction site was absent in all other genotypes. All genotype B sequences could be distinguished by the fact that the S gene had a unique BsrI site at nt position 328, which gave two characteristic bands of 126- and 459-bp in length. A BsrI site at nt position 502 was observed in 22 of 24 genotype A and all genotype E and G sequences. Moreover, genotype E PCR products could be digested at position 706 by HpaII, while genotype G had no EaeI site, which was present in all other genotypes. The BsrI site at nt position 502 was also found in 1 of 38 genotype D sequences, which could be mistaken as genotype A. Thus the sequences which still left unresolved were those of genotypes D, F and H. For genotype F, a DpnI site was found at nt positions 491 and 747, while genotypes D and H were cut at nt position 491 but not at 747. Finally, a HpaII site at nt position 292 in genotype H could be differentiated from genotype D. The sequences recognized by these enzymes are shown in Figure 1. The patterns created by these enzymes from the small S gene region are shown in Table 1.

Strategy for HBV genotyping using the new method

The optimal strategy, using the new method, which could be applied to a particular geographical region according to the most prevalent HBV genotype in that region, is summarized in Figure 2. For example, genotypes B and C were the most prevalent in the Far East. After parallel digestion by BsrI and

StyI, more than 90% of the serum samples from Chinese patients could be genotyped.

Comparison with genotyping by RFLP of PreS1 regions

Of the 190 serum samples, 3 were HBV DNA negative by nested PCR. Thus, 187 serum samples were analysed in this study, and compared to the results obtained by RFLP analysis of the

pre-S1 region. One hundred and eight-one of the 187 serum samples were classified as genotypes A (2), B (95), C (75) and D (9). These results were in full agreement with those obtained with our new method. Because of nonspecific amplification and atypical restriction patterns, 6 samples could not be classified by RFLP analysis of pre-S1 amplicons. However, these were resolved into either genotypes B (2), C (1) or mixed B+C (3) by

Figure 1 Genotype-specific sites recognized by restriction enzymes. GeneBank accession numbers and consensus sequences from HBV genotypes A to H are listed. The shaded letters indicate the sequences recognized by the relevant enzyme. StyI recognizes sequence C | C (A/T) (A/T) GG; BsrI, C | CAGT; DpnI, GA | TC; HpaII, C | CGG; EaeI, (C/T) | GGCC (A/G). *nt position number is from the unique *EcoRI* site according to the reference sequence x001587 (genotype C).

Figure 2 Diagrammatic representation of the position of PCR primers and RFLP analyses for HBV genotyping. The second round PCR products, which were 585 bp, were digested by (1) BsrI, (2) StyI, (3) DpnI, (4) HpaII and (5) EaeI. Genotypes B and C could be typed in one step using parallel digestion with BsrI and StyI.

Figure 3 RFLP of S amplicon of HBV from 187 nested PCR-positive serum samples from Chinese carriers. Lane M: 100 bp ladder from 100-600 bp fragments, P: undigested PCR product. A: After the first step of parallel digestion with BsrI and StyI, the samples were divided into four groups: genotypes B, C, A/E/G and D/F/H; B: Groups A/E/G and D/F/H could be further resolved by the second parallel digestion. In this study, genotypes E, F, G and H were not observed, while genotypes B and C were the major ones.

our method after cloning and repeat RFLP analysis. These results were verified subsequently by direct sequencing of the S gene. Thus the final genotype distribution of the samples was A, 2 (1.1%); B, 97 (51.9%); C, 76 (40.6%); D, 9 (4.8%) and mixed (genotypes B and C), 3 (1.6%). Examples of RFLP analysis using the new method are shown in Figure 3.

Verification of reliability of the new method

Nucleotide sequences of 11 samples randomly selected were determined and then compared to reference sequences for genotypes A (X02763), B (D00329), C (X01587) and D (X59795). The homologies of the S gene region under investigation were 97.9-98.3%, 99.3-99.9%, 97.5-98.8% and 98.2-98.5%, respectively, which confirmed the validity of the new RFLP technique.

DISCUSSION

Great importance has been attached to the differences between HBV genotypes. In earlier studies^[20,21], a higher frequency of liver dysfunction was observed in patients with subtype adr (most often genotype C) compared to those with subtype adw (mainly genotype B). These findings concurred with those reported by Lindh *et al.*^[13] and Orito *et al.*^[15]. Mayerat *et al.*^[14] found that genotype A was more frequent in chronic hepatitis B patients than genotype D, while the opposite situation was true in acute hepatitis B patients. A study from Taiwan reported that genotype C was associated with more active liver disease compared to genotype B^[22], and this was supported by a more recent study^[23]. A retrospective study of 332 cases^[10] showed that patients with HBV genotype B had a lower prevalence and earlier seroconversion to anti-HBe than those with genotype C, which could explain the less active liver disease seen in patients with genotype B. Another study^[24] suggested that HBV genotype might influence HBV recurrence after liver transplantation as patients with genotype D appeared to have a higher risk for HBV recurrence and mortality. The correlation between HBV genotype and response to interferon therapy has also been reported. HBV genotype C was associated with a higher frequency of core promoter mutation and a lower response rate to interferon alfa therapy^[16]. Hou *et al.*^[11] studied 103 chronic hepatitis B patients from 16 European centers and found that HBV genotype A responded better to standard interferon treatment than other genotypes. This appeared to be related to its molecular characteristics, having a greater tendency to develop core promoter mutations and less variation in the nucleocapsid protein. A study reported that patients carrying the adw subtype were associated with a higher risk of lamivudine resistance than those with ayw subtype^[25], although Chan *et al.* found that HBeAg seroconversion after treatment by lamivudine was not influenced by the HBV genotype^[26]. To

interpret these differences between HBV genotypes, larger-scale investigations are needed. So, development of accurate, simple and inexpensive HBV genotyping methods would be very useful in this respect.

Several methods have been used for HBV genotyping including direct sequencing, RFLP, PCR with genotype-specific primers^[17], line probe assay^[18] and enzyme-linked immunoassay^[27]. Genotyping based on complete genome sequences is an ideal method, but sequencing is costly and cannot be easily carried out in clinical diagnostic laboratories for large-scale studies. Currently, PCR-RFLP is the most widely used method for HBV genotyping because it is simple and inexpensive. Nordor *et al.*^[2] found that HBV genotyping could be accomplished based on the sequence of the S gene. After analyzing 73 HBV sequences from GeneBank, Lindh *et al.*^[5] developed a genotyping method based on RFLP patterns of a S gene amplicon, which first identified HBV genotypes A-F. They also reported another genotyping technique based on RFLP analysis of the pre-S region^[6]. However, pre-S gene was less suitable for genotyping than S gene because it was not so conserved as S gene^[28]. Mizokami *et al.*^[7] compared 68 complete and 106 small S HBV sequences and confirmed that S gene could be used to accurately identify the six HBV genotypes A to F. They also described a RFLP genotyping system using five enzymes, HphI, NciI, AlwI, EarI, and NlaIV. Because genotypes G and H were not discovered then, they could not be assessed by these methods.

Compared with previous methods, our new method has several relative advantages. Firstly, it can identify all eight HBV genotypes. Secondly, it is more accurate because it was based on analysing many of the sequences deposited in GeneBank. Thirdly, a simple and inexpensive strategy can be adopted according to the most prevalent HBV genotypes in a particular geographical region. For example, the strategy shown in Figure 2 was especially suitable for the Far East where genotypes B and C are mostly found (85-98.6%)^[21,29,30]. The RFLP patterns are simple, with one or two bands, and therefore easy to be recognized.

In this study, a new method for HBV genotyping based on RFLP analysis of S gene amplicons was established, and could identify all eight HBV genotypes. This HBV genotyping system is accurate, simple and can be expected to be widely used in studies of HBV genotyping.

Abstract

AIM: To investigate the change of immunological characteristics of HBsAg caused by the mutation at codon 145 of HBsAg using DNA-based immunization.

METHODS: Plasmids expressing mutant and wild type envelope antigens were transfected into human hepatocellular carcinoma cells via electrotransformation. The antigenicity of HBsAg was studied with EIA and immunocytochemical staining. Then plasmids were used to immunize 5 C57BL/6 mice. Sera of mice were detected for anti-HBs and anti-preS2 with ELISA.

RESULTS: The mutant HBsAg could be detected by native antibody in EIA and immunocytochemical study. But the $A_{(450\text{ nm})}$ value of the mutant HBsAg in the supernatant was apparently lower than that of the wild-type. Both mutant and native HBsAg expression plasmid could stimulate a strong humoral immune response to HBsAg and preS2 antigen in mice. Protective antibodies against HBsAg elicited by the native HBsAg occurred earlier than that elicited by the mutant HBsAg about one to two weeks. The occurrence of protective antibodies against preS2 antigen was one to two weeks earlier than that of anti-HBs.

CONCLUSION: The amino acid substitution causes changes of the antigenicity and immunogenicity of HBsAg, but mutant HBsAg can still induce a protective humoral immune response in mice.

INTRODUCTION

Hepatitis B infection is a serious problem worldwide. HBV vaccine is effective in preventing HBV infection. Antibody responses to the common epitope of HBsAg, the "a" determinant,

are considered to confer protection against HBV infection regardless of viral subtypes. HBV infection still occurs in spite of the presence of anti-HBs^[1-3]. Some cases were infected with a variant of HBV. This variant has a point mutation from guanosine to adenosine at nucleotide position 587 of the *s* gene that results in an amino acid substitution of arginine for glycine at codon 145 of HBsAg^[4,5]. This mutation would greatly destroy the antigenicity of HBsAg, which directly impacts on the diagnosis and therapy of HBV^[6]. Also, this variant was found in patients who had liver transplantations for end-stage liver diseases associated with HBV infection and received human monoclonal anti-HBs antibody or HBIG in an attempt to prevent recurrent hepatitis B^[7-9]. This study was undertaken to determine whether the change from glycine to arginine at amino acid 145 of HBsAg could cause a loss of antigenicity and immunogenicity of HBsAg, thus allowing the mutant HBV to evade the humoral immune response.

MATERIALS AND METHODS

Reagents, plasmid, antibodies and animals

Restriction endonucleases and *T4* DNA ligase were obtained from Sangon Co. (Canada). Plasmid P II containing overlenth HBV genomes was endowed by Dr. Jian-Wen He. Plasmid P II had a point mutation from guanosine to adenosine at the nucleotide position 587 of *s* gene and resulted in an amino acid substitution of arginine for glycine at codon 145 of HBsAg. Plasmid pCMV-S2.S was a generous gift of Dr. Heather Davis (Loeb Research Institute, Ottawa, Canada). This vector contained a cytomegalovirus promoter and respiratory syncytial virus enhancer element and encoded HBsAg and MHBs proteins. Plasmid SEAP expressing alkaline phosphatase was a generous gift of Dr. Jian-Wen He. HBsAg and HBsAb ELISA reagents were purchased from Abbott Laboratories and Sino-American Biotechnology Co., respectively. PreS2 antigen and preS2-specific antibodies were measured using ELISA kits from Hepatic Disease Institute of Beijing Medical University. The mouse monoclonal antibody against HBsAg was purchased from DAKO (USA). Sheep anti-mouse IgG-HRP was obtained from CALBIOCHEM (Germany). QIA quick gene gel kit and plasmid extraction kit were purchased from QIA gene. C57BL/6 mouse strain bought from Animal Center of Shanghai Birth Control Research Institute was kept under standard pathogen-free conditions in the animal facility and maintained on a 14:10 light-dark schedule (lights off at 10 pm, on at 8 am). Mice used were aged 6-8 wk.

Construction of DNA expression plasmid

Plasmid P II used as the source of mutant viral gene and plasmid pCMV-S2. S used as the source of the vector were digested with *Dra* III and *Xho* I, respectively. Then the segment of mutant *s* gene from plasmid P II was inserted into the vector from pCMV-S2.S by *T4* DNA ligase. Eukaryotic expression plasmid pCMV-S2.S+145R containing a point mutation from guanosine to adenosine was constructed. Plasmid pCMV-S2.S+145R was confirmed by restriction endonuclease digestion and HBV insert was sequenced by the dideoxy method using a commercial kit. The plasmid was grown in DH5 α and extracted by QIA quick gene kit. DNA was dissolved in double distilled water, adjusted to 1.6 mg/L, and then diluted to a final concentration of 1 mg/L

for *in vivo* studies. Concentration and purity of the DNA were confirmed by measuring the optical density at 260 nm and by agarose gel electrophoresis.

***In vitro* assays for HBV protein expression**

Human hepatocellular carcinoma cell lines (Hep G2) were transfected with the eukaryotic expression vectors pCMV-S2.S+145R, pCMV-S2.S or pcDNA3.0 via electroporation. The change of binding power of mutant antigens to anti-HBs was studied by EIA and immunocytochemical staining. To control transfection efficiency, cells were cotransfected with an alkaline-phosphatase-containing vector SEAP. Cells were lysed by freeze-thawing three times in phosphate-buffered saline (PBS), and the supernatants were collected at various time points after transfection for viral protein studies.

Analysis of viral proteins by ELISA

Concentrations of HBsAg and preS2 envelope proteins derived from culture supernatant or cell lysates of transfected cells were measured by enzyme-linked immunosorbent assay reagents according to the manufacturer's instructions. One hundred μ L of culture supernatant or cell lysates was incubated with 100 μ L of 2 \times SEAP buffer at 37 $^{\circ}$ C for 10 min. Twenty μ L substrate buffer was added to the assay. $A_{(450\text{ nm})}$ value was determined after incubated at 37 $^{\circ}$ C for 30 min. All results were corrected according to the transfection efficiency using the SEAP assays.

Expression of viral proteins

Transfected cells were collected by centrifugation and spread on sterile glass slides, and then fixed with acetone at 4 $^{\circ}$ C for immunochemical staining. Slides were blocked with normal goat serum for 30 min at room temperature, then incubated either with monoclonal mouse anti-HBs at a dilution of 1:200 for detection of HBsAg or with monoclonal mouse anti-preS2 (1:500) for detection of preS2 antigen for 12 h at 4 $^{\circ}$ C. After washed with PBS, a secondary antiserum consisting of biotin-conjugated goat anti-mouse immunoglobulin G was applied at a 1:100 dilution for 30 min at 37 $^{\circ}$ C. The slides coated with antibody were washed with PBS, treated with streptavidin-horseradish peroxidase conjugates at a 1:600 dilution for 30 min at 37 $^{\circ}$ C, stained with nitroblue tetrazolium chloride and 5-bromo-4-chloro-3-indolyl-phosphate (NBT/BCIP, MAXIM Co.), and counter-stained with Mayer's hematoxylin before mounted.

DNA immunization

Mice were injected on a single occasion with 100 μ g of recombinant plasmid DNA pCMV-S2.S, pCMV-S2.S+145R or pcDNA3.0 in 100 μ L of 0.9 g/L NaCl distributed into the anterior tibialis muscle of C57BL/6 mice 5 d after the injection of 100 μ L bupivacaine (0.2-0.4%). Immunization with the empty plasmid pcDNA3.0 vector (mock) was used as a negative control. Mice were anesthetized with pentobarbitone prior to phlebotomy from the retro-orbital plexus 200 microliter using heparinized glass pipettes every week. Serum was isolated by centrifugation. Anti-HBs and anti-preS2 concentrations were analyzed by using ELISA kits according to the manufacturer's instructions.

Detection of serum anti-HBs and anti-preS2 titers

Standard anti-HBs at titres 80, 40, 20, 10 or 0 mIU/L was detected by ELISA at the time when serum samples were detected. The $A_{(450\text{ nm})}$ value was 0.872, 0.442, 0.225, 0.107 and 0.046, respectively. The data were analyzed by linear regression, and the equation between the $A_{(450\text{ nm})}$ value and the antibody titers was $y = 94.442x - 1.959$. According to the manufacturer's instructions, inhibition rate (%) = (A value of negative control - A value of sample) / (A value of negative control - A value of positive control) \times 100%.

Statistical analysis

The data were analyzed by SAS software.

RESULTS

Construction of recombinant eukaryotic expression plasmid pCMV-S2.S+145R

The results of endonuclease digestion and electrophoresis were in accordance to the graphic map of plasmids. The result of sequencing was same as the sequence in the other report^[10], except the point mutation from guanosine to adenosine at the nucleotide position 587 of *s* gene (Figure 1).

Secretion and expression of HBsAg and preS2 antigen

HepG2 cells were transfected with pCMV-S2.S+145R, pCMV-S2.S or pcDNA3.0 and culture supernatant was collected at various intervals of 3, 5, 7 d after transfection. pCMV-S2.S-transfected cells secreted a higher amount of HBsAg compared with the pCMV-S2.S+145R-transfected cells in the culture supernatant and the cell lysates of transfected cells (Figure 2). But preS2 antigen was not detected in the culture supernatant or in the cell lysates of pCMV-S2.S-transfected and pCMV-S2.S+145R-transfected cells. In contrast, immunocytochemical studies clearly showed a substantial cytoplasmic accumulation of HBsAg and preS2 antigen in both of the pCMV-S2.S-transfected and pCMV-S2.S+145R-transfected cells. Furthermore, there was no difference in the expression of HBsAg and preS2 antigen between the two plasmid transfected cells. No staining pattern was observed in mock-transfected cells (data not shown).

Humoral immune response to HBV proteins

Anti-HBs responses to pCMV-S2.S+145R were detectable 4 wk after the immunization in C57BL/6 mice. The titer of anti-HBs increased gradually by the end of observation. The highest titer was 95.60 mIU/L at the twelfth week after immunization. Most importantly, anti-HBs responses to pCMV-S2.S were detectable 2 wk after immunization in C57BL/6 mice. The titer of anti-HBs also increased gradually by the end of observation. The highest titer was 99.57 mIU/L at the twelfth week after immunization. The mice immunized with pCMV-S2.S+145R developed anti-HBs after a delay of approximately 2 wk compared with those injected with pCMV-S2.S (Figure 3). The occurrence of protective antibodies against HBsAg elicited by native HBsAg was one to two weeks earlier than that elicited by mutant HBsAg. Nevertheless, pCMV-S2.S+145R-immunized as well as pCMV-S2.S-immunized mice developed a strong humoral immune response against HBsAg at levels far above the known anti-HBs protection limit for humans (>10 mU/mL). Anti-HBs response was not detected in C57BL/6 mice immunized with pcDNA3.0.

Both pCMV-S2.S+145R-immunized and pCMV-S2.S-immunized mice developed a significant preS2-specific antibody response, whereas antibody responses to the preS2 antigen were detectable two weeks after immunization. There was a slight difference between the two groups with respect to the level of anti-preS2 antigen response (Figure 4A).

Standardization of anti-HBs titer

In order to analyze the difference in immune response induced by pCMV-S2.S+145R and pCMV-S2.S and the validity of immunization and the titer of Anti-HBs were corrected according to the inhibition rate of anti-preS2 which was little affected by the point mutation, because the structures of pCMV-S2.S+145R and pCMV-S2.S were exactly the same except for a point mutation from guanosine to adenosine at the nucleotide position 587 of *s* gene. Therefore, the ratio of HBsAg and preS2 antigen expressed by the two plasmids was similar. Then the difference between the two plasmids due to the mutation could be observed correctly (Figure 4B).

Figure 1 Partial sequences of plasmids pCMV-S.S2 and pCMV-S.S2+145R A: “↓”±stands for the “G” in gene sequences of pCMV-S.S2 B: “↓”±stands for the “A” in gene sequences of pCMV-S.S2+145R, namely mutant point.

Series b: anti-preS2 level in pCMV-S.S2+145R-immunized mice. Series c: negative control. B: Comparison of humoral immune responses to HBsAg. Series a: pCMV-S.S2-immunized mice. Series b: pCMV-S.S2+145R-immunized mice. Series c: negative control.

DISCUSSION

The antibody responses to the common “a” determinant of HBsAg confer protection against infection with HBV of all subtypes. Using monoclonal antibodies, this determinant is composed of a number of epitopes, and its tertiary structure is important for its antigenicity. The amino acid arginine, which is substituted for glycine, is a much larger residue and charged^[11]. As a result the hydrophobicity profiles of this region of the two antigens are quite different and would be expected to affect the secondary and tertiary structures of the antigen. This amino acid substitution lies within the “a” determinant and so potentially alters the epitopes recognized by the protective immune response.

The secondary and tertiary structures of HBsAg expressed by the eukaryotic expression vector were most similar to those of viruses, which could exclude possible alterations of the antigenic properties by purification procedures of the recombinant vaccine. In transfection and *in vitro* expression study, HBsAg secreted by pCMV-S.S2-transfected cells had a higher affinity to the anti-HBs compared with that secreted by pCMV-S.S2+145R-transfected cells in the culture supernatant and the cell lysates of transfected cells, although the transfection efficiency was corrected. The antigenicity of HBsAg was altered by this single amino acid substitution. The mutant antigen could not be totally recognized by anti-HBs induced by naive antigens. The point mutation could influence the affinity, but mutant antigen could still be detected by anti-HBs.

The immunogenicity of HBsAg was also altered by this point mutation. The anti-HBs titer to the native HBsAg induced by mutant HBsAg was significantly lower than that induced by native HBsAg, while there was no significant difference between the titers of anti-preS2 induced by the two antigens. These results support the suggestion that this mutation was the result of immune pressure^[12]. This variant could evade the immune response elicited after natural infection or after vaccination^[13,14].

Both HBsAg and preS2 antigens, expressed by these two plasmids, were able to induce a strong humoral immune response. Indeed, anti-HBs titers induced by both plasmids were far above 10 mIU/L. The level of anti-HBs was sufficient to protect humans against HBV infection after exposure to the virus. This DNA vaccine could also confer the protection against infection with prototype HBV.

The preS2 antigen was not detected in the culture supernatant or cell lysates of transfected cells, but a substantial cytoplasmic accumulation was detected in plasmid transfected cells by immunocytochemical study, and the anti-preS2 was also detected in mice after DNA immunization. It is likely that the preS2 antigen was a nonsecreted protein expressed by this vector in HepG2 cells. It could be a nonsecreted protein *in vivo*, but it was possible that bupivacaine followed by plasmid DNA injections caused early activation of nonspecific inflammatory mediators by recruiting professional APCs^[15,16], B cells, and T cells. In addition,

a specific immune response against muscle cells expressing viral peptides or proteins might subsequently lead to damage of muscle fibers and release of sequestered antigens. Such antigens might eventually reach lymph nodes or alternatively taken up locally by APCs. The occurrence of protective antibodies of anti-HBs2 was one to two weeks earlier than that of anti-HBs in the same group. This result was similar to other reports^[17,18]. There was little difference in occurrence, high titre and duration of anti-preS2 between the mutant and native viral protein expression plasmids. It indicated that this mutation had little impact on the antigenicity and immunogenicity of preS2 antigen. Therefore, the ingredient of preS2 antigen in hepatitis B vaccine would protect humans against this mutant HBV infection after exposure to the virus, and it also could shorten the occurrence of protective antibody and give an early stage protection. This would benefit the infants born by HBeAg positive mothers and persons exposed to HBV.

In conclusion, DNA immunization with the mutant HBsAg expression vector, produces a lower affinity than that elicited by the native HBsAg expression vector. The mutation changes the antigenicity and immunogenicity of HBsAg, and also induces a protective immune response.

Abstract

AIM: To establish the transgenic mouse line harbouring complete hepatitis B virus (HBV) genome with mutant *s* gene (*adr* subtype).

METHODS: Transgenic mice were generated by microinjecting HBV genome into fertilized eggs. Integration, expression, replication of HBV gene and histological changes in transgenic mice were estimated by genomic DNA PCR, serum DNA PCR, Southern blot, ELISA, HE staining, immunohistochemistry and transmission electron microscopy. Transgenic mice with HBsAg positive in serum were bred and analyzed.

RESULTS: A total of 288 eggs survived from microinjections were transplanted into the oviducts of 13 pseudopregnant mice and 49 pups were produced. Twenty-six mice were identified to have the integrated HBV gene. Serum HBsAg and HBeAg were detected in 2 of 43 mice. HBsAg and HBcAg in cytoplasm or nuclei of hepatocytes were detected in 10 mice. Founders with HBsAg in serum were named lineages G145R-15 and G145R-18. Of the 16 F1 offsprings generated by G145R-15 founder, 12 were positive for HBV genome with PCR, 10 were positive for HBsAg and HBcAg with immunohistochemistry and 7 were positive for HBsAg and HBeAg with ELISA. Only 1 of 8 F1 offsprings generated by G145R-18 founder was survived and it was detected positive for HBV genome, HBsAg, HBcAg and HBeAg. Both of the two lineages had some pathological characteristics of mild chronic hepatitis B in the liver, such as swelling of hepatocytes and focal hepatocellular necrosis and parenchymal lymphomononuclear cell infiltrate.

CONCLUSION: Transgenic mice harbouring HBV with mutant *s* gene can be generated. The HBV genes are integrated in the transgenic mice genome and can be expressed, replicated, packaged and excreted. HBV DNA can be stably transmitted in the transgenic mice.

INTRODUCTION

Hepatitis B virus (HBV) is a major pathogen causing human acute and chronic hepatitis B^[1] and has a very close association with cirrhosis and human hepatocellular carcinoma (HCC)^[2-5]. Hepatitis B (HB) vaccine can protect human from infecting HBV. Many children born from HBeAg positive mothers would suffer from HBV after HB vaccination because of the mutation of HBV^[6-7]. Genetic mutation in viruses is usually associated with escape of host immune responses, development of drug resistance, modification of virulence and patterns of epidemiology of diseases. In addition, HBV has a limited host range, which impedes much of the study on its biological characteristics and human hepatitis B. Over the past several years, many transgenic lineages harbouring intact HBV gene^[8] or expressing the HBV envelope, core, precore and X proteins^[9] under the control of HBV or cellular liver-specific promoters have been generated, thereafter, the transgenic mouse system was applied in HBV studies^[10-12]. However, no reports of transgenic mouse harbouring mutant HBV are available.

HBV belongs to hepadnavirus family, containing a small (3.2-kb), circular, double-stranded DNA genome. The minus strand includes at least four open reading frames (ORF), of which, S-ORF is divided into *pres1*, *pres2* and *s* gene. HBsAg encoded by the *s* gene is the major component of hepatitis B vaccine. It is also an important diagnostic evidence of HBV infection. Hepatitis B immunoglobulin could be used to protect the liver from reinfection after liver transplantation, but it depends on the interaction of HBsAg and anti-HBs. Therefore, the change of antigenicity of HBsAg has a direct impact on the diagnosis and therapy of HBV. It is most common to find the mutation at aa145 where glycine is substituted by arginine (G145R). This mutant could result in the failure of HB vaccination^[13] and failing to protect the liver from reinfection after liver transplantation^[14-16]. Recently, several lines of evidence of horizontal transmission have been found^[17-18]. It brings about many new problems to prophylaxis and therapy of HB. It is necessary to study further on the change of biological characteristics related with this point mutation. Transgenic mice harbouring G145R mutant are a good animal model in study of changes of antigenicity and immunogenicity as well as pathogenicity of HBV. Therefore, we generated transgenic mice harboring complete genome of HBV (*adr* subtype) G145R mutant by microinjection method, in which HBsAg and HBeAg could be expressed, and genomic DNA of HBV could be replicated and packed into complete virus particles. This model makes it possible to examine many aspects of HBV and its associated biomedical issues *in vivo*, and is an animal model for drug screen and therapy involved in this mutant.

MATERIALS AND METHODS

Reagents, Plasmid, antibodies and animals

Restriction endonucleases and T4 DNA ligase were obtained from Sangon Co. Canada. Plasmid P II was endowed by Dr. Jian-Wen He and contained overlenth HBV genomes, beginning at the middle of the X gene, terminating at nucleotides 1982, just downstream of the unique polyadenylation signal in the HBV genome at a unique *Bam*HI site. Plasmid P II contained a point mutation at the site of *s* gene nt 587(G→A). HBsAg and HBeAg ELISA reagents were purchased from Abbott Laboratories and Sino-American Biotechnology Co., respectively. Mouse monoclonal antibody against HBsAg and rabbit HBc/eAg primary anti-serum were purchased from DAKO, USA. Sheep anti mouse IgG-HRP was obtained from CALBIOCHEM, Germany. Serum DNA extraction kit was got from Sino-American Biotechnology. QIA quick gene gel kit and plasmid extraction kit were purchased from QIA-gene. C57BL/6 mice were SPF level and maintained on a 14:10 light-dark schedule (lights off at 10 pm, lights on at 8 am every day).

Microinjection and embryo manipulation of founder animals

HBV transgenic mice were produced by microinjection of the *Pvu* II fragment excised from plasmid P II into C57BL/6 embryos by conventional technology. In brief, the *Pvu* II fragment containing 1.2 copy HBV DNA was gel purified and dissolved in TE buffer (10 mmol/L Tris-HCl, 0.2 mmol/L EDTA, pH 7.5) at a final concentration of 1 mg/L (2000 copies/pL). After it was injected into male pronuclei obtained from C57BL/6 females, the eggs were implanted into oviducts of pseudopregnant recipients to enable further development before term. Founder animals were screened by analysis of serum for HBsAg and HBeAg. Animals positive for both antigens were expanded by repetitive backcrossing against the C57BL/6 strain and bred for analysis.

DNA isolation and PCR analysis of integrated transgenes

To isolate the total genomic DNA, approximately one third of the tail of 10-d-old mice was cut and placed into a 1.5 mL microcentrifuge tube containing 500 μ L of TB buffer. The tubes containing the tail fragments were incubated overnight at 55 °C. DNA was extracted once with 500 μ L of 1:1 (v/v) equilibrated phenol-chloroform, and precipitated with 2 volumes of ethanol. After centrifugation, precipitates were resuspended in 500 μ L water.

Total tail genomic DNA (1 mg) was analyzed by PCR using HBV-specific primers (5'-CCCAA CCTCC AATCA CTCAC CAACC-3' [sense, nt 2 139 to 2 153] and 5'-GGCCC CCAAT ACCAC ATCAT CCATA -3' [antisense, nt 2 583 to 2 556]). A 20 μ L of samples of the products from direct PCR amplifications was analyzed by electrophoresis on a 10 g/L agarose gel in the presence of 0.5 μ g of ethidium bromide per mL. DNA bands were visualized by UV fluorescence.

Southern blot analysis

Southern blot analysis was performed on the total genomic DNA by agarose gel electrophoresis of 20 μ g of restricted genomic DNA as previously described. Before electrophoresis, all DNA samples were digested with *Eco*R I at 10 U/ μ g for 4 h at 37 °C. Nylon filters were hybridized with HBV-specific digoxigeninlabeled DNA probes as previously described^[19].

PCR analysis of HBV DNA in serum

Total serum genomic DNA from transgenic mice was extracted according to the manufacturer's instructions, and analyzed by PCR using HBV-specific primers as described above.

Immunohistochemical analysis of the expression of HBV

In selected experiments, liver tissue derived from transgenic mouse lineages was also studied. In some experiments, mice

were anesthetized with pentobarbitone (Harvest Pharmaceutical Co. LTD) prior to phlebotomy from the retro-orbital plexus and before they were sacrificed by cervical dislocation. In the other experiments, mice were anesthetized with pentobarbitone prior to biopsy of the liver at the age of 3, 6, 9, 12, 15, 18 mo. Intracellular distributions of HBcAg and HBsAg were assessed by the labeled-avidin-biotin detection procedure^[20]. Briefly, paraffin-embedded sections in PBS, pH 7.4, were treated for 15 min at 37 °C with 30 mL/L hydrogen peroxide and washed with PBS. After the sections were blocked with normal goat serum for 30 min at room temperature, rabbit anti-HBc/eAg primary antiserum or mouse anti-HBsAg monoclonal antibody was applied at a 1:100 (HBcAg) or 1:500 (HBsAg) dilution for 12 h at 4 °C. After washed with PBS, a secondary antiserum consisting of biotin-conjugated goat anti-rabbit or goat anti-mouse immunoglobulin G was applied at a 1:100 dilution for 30 min at 37 °C. The antibody coated slides were washed with PBS, treated with streptavidin-horseradish peroxidase conjugates at a 1:600 dilution for 30 min at 37 °C, stained with nitroblue tetrazolium chloride and 5-bromo-4-chloro-3-indolyl-phosphate (NBT/BCIP, MAXIN Co.), and counterstained with Mayer's hematoxylin before mounted.

Serological analysis of the expression of HBV

Transgenic mice of lineages G145R-15 and G145R-18 were anesthetized with pentobarbitone prior to phlebotomy from the retro-orbital plexus 200 μ L every week. Serum was isolated by centrifugation. HBsAg and HBeAg concentrations were analyzed every month by using commercially available enzyme-linked immunosorbent assay reagents according to the manufacturer's instructions.

Serum antibody analysis of transgenic mice

Serum from transgenic mice was also assayed for anti-HBsAg, anti-HBeAg and anti-HBcAg every month by using commercially available enzyme-linked immunosorbent assay reagents according to the manufacturer's instructions.

Electron microscopy

Intracellular nucleocapsid particles were analyzed exactly as described elsewhere. Briefly, thin liver sections were fixed overnight at 4 °C in 40 g/L paraformaldehyde-1 g/L glutaraldehyde in PBS. Sections were then postfixed in 10 g/L OsO₄ in cacodylate buffer (pH 7.4) for 1 h at room temperature, dehydrated in gradient ethanol, and embedded in epoxy resin (TAAB 812; Emmer Green, Reading, England). Sections were cut on a LKB Ultratome III, mounted on copper grids, stained in uranyl acetate and lead citrate, and viewed with a Hitachi H-800 electron microscope.

Serum-derived virus particles were analyzed as follows. Five hundred microliters of transgenic-mouse serum was centrifuged (300 000 g) for 12-16 h at 4 °C through 2.4 mL of 100 g/L sucrose into 0.8 mL of 600 g/L sucrose. Fractions (100 μ L) were collected from the bottom, and the first fraction was incubated for 45 min at room temperature on MA18/7-coated (100 μ g/mL) Parlodion-carbon-coated nickel grids that were subsequently drained with a piece of filter paper and washed twice in PBS. The grids were then fixed in 15 g/L glutaraldehyde for 2 to 5 min, washed twice in H₂O, negatively stained with uranyl acetate, and viewed with a Hitachi H-800 electron microscope.

Histological analysis

Tissue samples were fixed in 40 g/L neutral buffered formaldehyde, embedded in paraffin, sectioned (4 μ m), and stained with hematoxylin and eosin as described^[8].

Biochemical evidence of hepatocellular and renal injury

Serum alanine aminotransferase (sALT), serum aspartate

aminotransferase (sAST), blood urea nitrogen (BUN), creatinine (Cr) and γ -glutamyl transpeptidase (γ -GT) were tested with an auto-biochemical analyzer.

RESULTS

Microinjection and production of transgenic mice

Hundreds of molecules of target fragments were microinjected into male pronuclei of fertilized eggs. A total of 288 eggs survived from microinjections were transplanted into the oviducts of 13 pseudopregnant mice and consequently, the mice were pregnant and gave birth to 49 pups. In addition, 43 were survived. HBsAg and HBcAg in cytoplasm or nuclei of hepatocytes were detected in 10 mice. Two of 43 founder animals whose sera were positive for both HBsAg and HBcAg were produced and named lineages G145R-15 and G145R-18. They were expanded by repetitive backcrossing against the C57BL/6 strain and studied in detail. Sixteen F1 offsprings of lineage G145R-15 founder mice were born. Twelve of them were identified as the integration of HBV gene by PCR and Southern blot hybridization analysis of tissues. HBsAg and HBcAg were detected in eight of them by immunohistochemistry. HBsAg and HBcAg were detected in seven of them by using ELISA. Only one of eight F1 offsprings generated by lineage G145R-18 founder was survived. In addition, all above methods detected it positive. F1 offsprings were positive for both HBsAg and HBcAg and expanded by repetitive backcrossing against the nontransgenic C57BL/6.

Analysis of integrated transgenes

Total DNA was isolated from tail tissues of lineages G145R-15 and G145R-18, digested with an enzyme (*Eco*R I) that was not cut within the transgene, and analyzed by Southern blot (Figure 1).

Figure 1 Southern blot analysis of 20 µg of total DNA extracted from transgenic mouse tail tissues of lineages G145R-15 and G145R-18. Lane 0: Positive control; Lane 1: lineage G145R-15; Lane 2: lineage G145R-15; Lane 3: F₁ transgenic mice of lineage G145R-15; Lane 4: F₁ transgenic mice of lineage G145R-18; Lane 5: lineage of transgenic mice harbouring prototype HBV genome; Lane 6: non-transgenic mice as negative control. All DNA samples were RNase treated before gel electrophoresis. The filters were hybridized with a digoxigeninlabeled HBV specific DNA probe.

Expression of viral proteins

At the protein level, HBsAg (a product of the 2.1-kb mRNA)

and HBcAg (a product of the 3.5-kb mRNA) were easily detectable in the serum in both lineages (Table 1). As expected, HBcAg (also a product of the 3.5-kb mRNA) and HBsAg were easily detectable in the liver by immunohistochemical staining (Figures 2A, B).

Table 1 Serum HBV antigen levels

	4 wk	8 wk	12 wk	16 wk	72 wk
Normal mouse					
HBsAg ¹	0.056	0.052	0.056	0.055	0.053
HBe/cAg ²	0.052	0.059	0.053	0.052	0.055

Figure 3 Ultrastructural analysis of HBcAg in the liver.

Distribution of HBcAg and HBsAg in liver

Both lineages displayed the same subcellular and architectural distribution of HBcAg in the liver. Figure 2A and 2B shows that HBcAg and HBsAg were present in the cytoplasm of almost all the hepatocytes distributed widely throughout the hepatic lobules from the centrilobular region around central veins to the periportal region around the portal tracts, but positive hepatocytes surrounding the central veins were much more than those around centrilobule. At the nucleic level, however, only HBcAg was detectable (Figure 2C). Typical 25-30 nm HBcAg particles (core particles and nucleocapsid particles) were detected in the nuclei (Figure 3). All indicated the existence of important host influences on viral gene expression in these animals.

Figure 2 Immunohistochemical analysis of HBsAg and HBcAg in the liver. A: Presence of cytoplasmic HBsAg in almost all of hepatocytes in immunohistochemical analysis of the liver of an 6-week-old male mouse. Magnification, $\times 100$. B: Cytoplasmic HBcAg in centrilobular region hepatocytes surrounding the central veins. Magnification, $\times 200$. C: Nuclear HBcAg scattering widely throughout the hepatic lobule. Magnification, $\times 100$.

Circulating viral particles

To determine whether potentially infectious viral particles were formed and secreted into the blood of these mice, serum was analyzed for the presence of HBV DNA and sedimentable particles displaying the ultrastructural characteristics of complete virions (Dane particles). HBV DNA was detectable in the serum of an HBV transgenic-mouse lineage that replicated the viral genome.

Histopathological findings

Animals from lineages G145R-15 and G145R-18 were monitored histologically for over eighteen months without evidence of pathological changes in the kidney, brain, spleen, lung, testis, ovaries, skin, and muscle except for the liver. In some region of the liver, swollen hepatocytes, hydropic degeneration or ballooning degeneration was observed in hepatic lobules that were distributed in the centrilobular region around central veins (Figure 4A, B). In the other, focal or unicellular necrosis, together with predominantly lymphocyte infiltrate was present (Figure 4D). In the portal or periportal tract, mild or moderate inflammation was also observed, as illustrated in Figure 4C. Interface inflammation could be observed in some cases. However, fibrosis was absent. Acidophilic body was scarce.

Serum antibody in transgenic mice

The ELISA test indicated that there was no significant positive result of HBV antibodies in HBV transgenic mouse serum.

Biochemical evidence of hepatocellular and renal injury

Animals from lineages G145R-15 and G145R-18 were monitored to have biochemical changes for over eighteen months without evidence of hepatocellular and renal injury, although there were histopathological changes in the liver.

DISCUSSION

In the study of vaccinated children whose mothers were positive for HBeAg, about 15% of them became anti-HBc positive. A proportion of these would be HBsAg positive and

become the HBV carriers. About half of those were infected with variants of MHR, the most consistently observed to be G145R. Three population-based studies from Singapore, UK and USA had remarkably similar results. Mathematical modeling indicated it would be the dominant viral strain, although it could take a long time to emerge. Vaccination at birth is an ideal situation for selection of escape variants, being similar to liver transplantation, where high titer anti-HBs preparations are administered to prevent graft infection. Furthermore, naturally occurring G145R strains were reported.

To study the biological properties and pathologic conditions associated with this mutant, HBV transgenic mice whose hepatocytes expressed and replicated the virus and whose genome harbor HBV mutant G145R were produced with a terminally redundant, 1.2 genome length transgene that starts in the middle of the X gene and ends just downstream of the unique HBV polyadenylation site.

Only two of the forty-three founders were serum HBsAg-positive, and the expression level of the others was very low, which might be due to the different integrated sites of HBV DNA. In general, the exogenous gene would be integrated into multi-sites in transgenic mice. This is similar with other reports. Immunohistochemical assays of several tissues from transgenic mice revealed that HBV gene expressions were tissue-dependent, and the genes were only expressed in the liver and kidney, this is similar to HBV-infection in nature. The regulation of expression of a foreign gene in transgenic mice was subjected to different parameters, such as site of integration, influence of the mouse flanking sequences, cellular factors and structure of the integrated sequences. However, the general finding was that transgenes kept their developmental and tissue specific control of expression. Mouse genomic sequences might potentially have an influence on the level of transcription of tissue specificity. The important influence of cellular factors on expression was apparent since many hepatocytes, all the Kupffer cells, endothelial cells and bile duct epithelium in the tissue were antigen negative, although most cells in the liver probably contained integrated HBV DNA. It may be germane

Figure 4 Analysis of pathological changes in the liver of transgenic mice by HE staining. Magnification $\times 100$. A: Mild swollen hepatocytes around the central veins (CV) in the centrilobular region. B: "Ballooning degeneration" around the central veins or between the two central veins in the liver. C: Predominantly lymphocytic cell infiltrates in portal tract area and hepatic lobules. D: Focal necrosis and predominantly lymphocytic cell infiltrates in hepatic lobule. E: Liver of normal mice.

that hepatocyte nuclear factor 1 alpha (HNF 1 α) and retinoic acid are known to be preferentially expressed in hepatocytes. Interestingly, the positive cells were clustered like clones of cells. This was described in infected humans, and it was proposed that the synthesis of viral antigens depended on the metabolic state of cells.

HBcAg was detected both in the nuclei and in the cytoplasm of hepatocytes. The presence of HBcAg in the nuclei of hepatocytes was found in most of HBV-infected humans. Cytoplasmic location of HBcAg was also observed in some cases with active viral replication. Capsid antigens of ground squirrel hepatitis virus, duck hepatitis B virus and woodduck hepatitis virus were found almost exclusively in the cytoplasm. This may be the consequence of the constantly high level of replication of these viruses. Pre-core RNA is only used as a mRNA for the production of HBeAg that is secreted into the serum. This polypeptide can be aggregated into unstable particles but its location is in cytoplasm. Therefore, it is likely that it is responsible for the cytoplasm structure.

HBV transgenic mice showed replication of HBV in hepatocytes and had evidence of pathological lesions in the liver, which are different from other reports. Although there were some pathological characteristics of mild chronic hepatitis B in the transgenic mice, the change was obviously different from that of human chronic hepatitis B. Cellular pathological changes, such as swelling of hepatocytes and focal hepatocellular necrosis and parenchymal lymphomononuclear cell infiltrate were the main lesions. While the histological changes, such as the change or destruction of structure of hepatic lobules caused by hyperplasia of fibers, were not observed in all transgenic mice. Even fibrocytes and fibrous tissue were difficult to be observed in the portal tract, it was likely due to the difference of species. In normal mice, the borderline of hepatic lobules is not clear as that of human being's.

Serum anti-HBs, anti-HBc and anti-HBe detected by ELISA were negative in all of the transgenic mice, suggesting that these mice were tolerant to HBsAg, HBcAg and HBeAg. This result is consistent with that of another report.

What caused the pathological changes of the liver? We supposed the immune response of transgenic mice caused the pathological lesions. Some of transgenic mice were partially immunological tolerant to viral antigens. In our and another study, HBsAb could be induced by injection of HB vaccine into muscles of the HBV transgenic mice. This indicated that the immunological tolerance was not complete. We assume that although the gene of virus was integrated in the genome of mice, the time of expression of exogenous gene in thymus was a little later than the formation of immunological tolerance. Some children whose mothers were HBeAg positive did also have pathological changes in their liver, but without HBsAb in the serum.

In conclusion, HBV genome introduced by microinjection can be integrated into the mouse genome, and HBV genes can be expressed, replicated and packaged. Therefore, these lineage mutant HBV transgenic mice may be used as animal models for the study on mutant HBV and its associated biomedical issues. It can also be applied in the selection of anti-mutant HBV drugs and vaccine.

Abstract

AIM: To assess the possibility of non-invasive screening of atrophic chronic gastritis for preventing further development of gastric cancer.

METHODS: One hundred and seventy-eight consecutive *Helicobacter pylori* (*H pylori*)-positive dyspeptic patients after detection of serum levels of pepsinogen-1 (PG-1) and gastrin-17 (G-17) by enzyme immunoassay were proposed for endoscopy and histology. The serologic and morphologic results were compared with estimating the sensitivity, specificity and prognostic values of the tests.

RESULTS: There was statistically significant reverse dependence between the grade of stomach mucosal antral or corpus atrophy and the proper decreasing of serum G17 or PG1 levels. The serologic method was quite sensitive in the diagnosis of non-atrophic and severe antral and corpus gastritis. Also, it was characterized by the high positive and negative prognostic values.

CONCLUSION: Detection of serum G-17 and PG1 levels can be offered as the screening tool for atrophic gastritis. The positive serologic results require further chromoendoscopy with mucosal biopsy, for revealing probable progressing of atrophic process with development of intestinal metaplasia, dysplasia or gastric cancer.

INTRODUCTION

According to the modern representations about stages of gastric carcinogenesis, it is supposed that chronic *Helicobacter pylori* (*H pylori*) infection is the trigger mechanism in 60-90% of gastric cancer cases^[1,2]. In 1975, Correa proposed the consecutive line of events leading to gastric cancer development: normal mucosa - chronic active gastritis - chronic atrophic gastritis - intestinal metaplasia - dysplasia - carcinoma *in situ*. At present, this cascade of changes associates with a trigger role of *H pylori* and is called "Correa's gastric precancerous cascade"^[2,3]. The early detection of gastric precancerous changes, mainly atrophic

gastritis, may be helpful in prevention of gastric cancer or in diagnosis of cancer at curable stages. So, there is a critical need for valid diagnostic methods of stomach mucosal atrophy, that would be inexpensive and non-invasive, that is, suitable for screening of large groups of people.

Taking into account the known interrelations between the morphological status and functional activity of gastric corpus and antral mucosa and the secretion of, respectively, pepsinogen 1 and gastrin 17^[4,5], we carried out a prospective study with the aim to detect *H pylori*-induced gastric precancerous changes, that were leading to cancer formation, and to evaluate the possibility of non-invasive screening of dyspeptic patients.

MATERIALS AND METHODS

Materials

The study was carried out in a group of dyspeptic *H pylori*-infected patients.

Methods

H pylori antibodies (Hp-Ab), serum levels of pepsinogen I (PGI) and gastrin-17 (G-17) were analyzed by enzyme immunoassay with Biohit GastroPanel® (Biohit Plc, Helsinki, Finland). According to the instructions of its manufacturer, serum levels of PG1 <25 µg/L were estimated as markers of gastric corpus atrophy, serum levels of G17 <5 pmol/L were estimated as markers of gastric antral atrophy, serum levels of G17 <10 pmol/L in a combination with serum levels of PG1 <50 µg/L were estimated as markers of mild gastric corpus atrophy. HPAb IgG titers were estimated as follows: < 32 enzyme immunoassay unit (EIU) - negative result, 32 - 44 EIU - doubtful result, >44 EIU - positive result. The numerical meanings of researched parameters were analyzed by the program GastroSoft® (Biohit Plc, Helsinki, Finland) enclosed to test-system Biohit GastroPanel®. On the basis of inserted data, the program composed the diagnosis in a view of the presence or absence of *H pylori*-infection and mucosal atrophy, with the estimation of gastric cancer or peptic ulcer risk and with recommendations on the treatment according to Maastricht-2 consensus.

After getting the GastroSoft® diagnosis, we randomized 178 patients for the following study. The patients underwent the upper gastrointestinal endoscopy with subsequent biopsy of the antral and corpus mucosa. To increase the accuracy of endoscopic diagnosis, we carried out an additional chromoendoscopy with methylene blue staining allowing the detection of foci of intestinal metaplasia (IM) of gastric mucosa which were unrecognized by routine endoscopy. Biopsy specimens were stained with hematoxylin-eosin and PAS reaction in combination with alcian blue at pH 2.5. The grade of stomach mucosal atrophy was estimated from 0 to 3 according to Houston visual analogous scale.

Statistical analysis was used to calculate the statistical significance of received data (Mann-Whitney criterion). Spearman's correlation coefficient (r_s), positive predictive value (PPV) and negative predictive value (NPV) of diagnosis by Biohit GastroPanel®.

Figure 1 Comparison of serum PG1 (g/L) and G17 (pmol/L) levels and grade of gastric corpus and antral atrophy. A: Comparison of serum PG1 level and grade of gastric corpus atrophy. B: Comparison of serum G17 level and grade of gastric antral atrophy. ^a $P < 0.05$ vs non-atrophic state.

RESULTS

Of the 178 patients, non-atrophic chronic gastritis (no antral atrophy and no corpus atrophy) was detected only in 5 patients. The mean of serum PG-1, G-17 and anti-*H. pylori* IgG in this group was 85.28 ± 35.07 $\mu\text{g/L}$, 14.44 ± 1.90 pmol/L and 85.68 ± 17.81 EIU, respectively. In all these cases there was no IM or dysplasia in stomach mucosal epithelium.

The morphological status of gastric corpus mucosa was compared with serum PG-1 levels (Figure 1A). The non-atrophic corpus mucosa was detected in 99 (55.62%) of 178 patients, mild atrophy of corpus mucosa was detected in 17 (9.55%) patients, moderate atrophy of corpus mucosa was detected in 36 (20.22%) patients, severe atrophy of corpus mucosa was detected in 26 (14.61%) patients.

The statistical analysis revealed that there were marked differences between the levels of PG1 in non-atrophic and atrophic corpus gastritis. The levels of PG1 in mild, moderate and severe corpus atrophy were significantly lower ($P < 0.0001$) than those in non-atrophic state. In turn, the levels of PG1 in mild, moderate and severe corpus atrophy were significantly different from each other ($P < 0.0001$).

The morphological status of gastric antral mucosa was compared with serum G-17 levels (Figure 1B). The non-atrophic antral mucosa was detected in 12 (6.74%) of 178 patients. Mild atrophy of antral mucosa was detected in 31 (17.42%) patients. Moderate antral mucosa atrophy was detected in 69 (38.76%) patients. Severe antral mucosal atrophy was detected in 66 (37.08%) patients.

The statistical analysis revealed that there were marked differences between the levels of G17 in non-atrophic and atrophic antral gastritis. The latter was significantly lower ($P < 0.0001$). Moreover, the levels of G17 in mild, moderate and severe antral atrophy were significantly different from each other ($P < 0.0001$).

Table 1 Comparison of serum anti-*H. pylori* IgG titers (mean \pm SD) and grade of mucosal atrophy

	Anti- <i>H. pylori</i> IgG, EIU
No antral or corpus atrophy	85.68 \pm 17.81
No antral atrophy	62.29 \pm 12.02
Mild antral atrophy	78.25 \pm 5.86
Moderate antral atrophy	74.08 \pm 4.39
Severe antral atrophy	73.38 \pm 5.38
No corpus atrophy	68.76 \pm 8.35
Mild corpus atrophy	77.21 \pm 6.13
Moderate corpus atrophy	76.47 \pm 5.04
Severe corpus atrophy	72.61 \pm 4.72

Both antral and corpus stomach mucosal atrophy were not accompanied with statistically significant changes in anti-*H. pylori* IgG serum titers (Table 1).

We detected intestinal metaplasia in 119 of 178 patients. The comparison of the grade of IM and the serum levels of PG-1 and G-17 showed the absence of invariables and statistically significant dependence between these parameters, except for the cases of moderate IM (Table 2).

Dysplasia of stomach mucosal epithelium was detected in 113 patients. We revealed the statistically significant dependence between the grade of dysplasia and the increased serum levels of PG-1, and the decreased levels of G-17 (Table 3), except the cases of severe dysplasia where the number of patients was not quite sufficient (6 subjects).

Table 2 Comparison of serum PG1 and G17 levels (mean \pm SD) and grade of IM

	No IM	Mild IM	Moderate IM	Severe IM
PG-1, $\mu\text{g/L}$	52.5 \pm 7.74	66.07 \pm 8.36	82.65 \pm 10.72 ^a	53.08 \pm 12.24
G-17, pmol/L	6.79 \pm 0.55	5.48 \pm 0.50	4.73 \pm 0.67 ^a	5.11 \pm 1.02

^a $P < 0.05$ vs non-metaplastic state.

Table 3 Comparison of serum PG1 and G17 levels (mean \pm SD) and the grade of dysplasia

	No dysplasia	Mild dysplasia	Moderate dysplasia	Severe dysplasia
PG-1, $\mu\text{g/L}$	33.6 \pm 5.41	79.98 \pm 7.92 ^a	84.41 \pm 10.98 ^a	71.88 \pm 27.25
G-17, pmol/L	7.37 \pm 0.46	5.28 \pm 0.50 ^a	3.73 \pm 0.66 ^a	4.53 \pm 1.95

^a $P < 0.05$ vs non-dysplastic state.

Among the 178 consecutive patients we detected 6 cases of gastric cancer: 2 early cancers and 4 progressed tumors. The mean of serum PG-1, G-17 and anti-*H. pylori* IgG in these cases was 46.73 ± 22.25 $\mu\text{g/L}$, 4.78 ± 2.086 pmol/L and 89.5 ± 11.7 EIU, respectively.

In general, our results showed that there was a statistically significant dependence between the presence and severity of stomach mucosal atrophy (antral or corpus) and the proper serologic markers (G17 or PG1) in *H. pylori*-associated chronic gastritis. On the other hand, the presence and degree of IM did not correspond to the serum level of G17 or PG1. Thus, the serologic screening by means of Biohit GastroPanel® was useful for the selection of patients with stomach mucosal atrophy by subsequent thorough endoscopic and histological examination for the possible development of precancerous or malignant changes in stomach mucosa.

Table 4 Correlations between results of different methods in diagnosis of gastric mucosal changes

Parameters	r_s
Detection of IM by endoscopy and histology	0.41
Detection of IM by chromoendoscopy and histology	0.92
Detection of antral atrophy by histology and serum levels of G-17	-0.75
Detection of corpus atrophy by histology and serum levels of PG-I	-0.71
Degree of stomach mucosal atrophy and IM	0.21
Degree of stomach mucosal atrophy and dysplasia	0.23
Degree of IM and dysplasia	0.41

Table 5 Sensitivity (Se) and specificity (Sp), PPV and NPV of Biohit GastroPanel® in diagnosis of antral mucosal atrophy

Degree of antral atrophy (by histology)	Se (%)	Sp (%)	PPV (%)	NPV (%)
No	83	95	53	99
Mild	61	84	45	91
Moderate	67	90	81	81
Severe	89	99	98	94

Table 6 Sensitivity (Se) and specificity (Sp), PPV and NPV of Biohit GastroPanel® in diagnosis of corpus mucosal atrophy

Degree of corpus atrophy (by histology)	Se (%)	Sp (%)	PPV (%)	NPV (%)
No	92	97	98	91
Mild	71	92	48	97
Moderate	72	96	81	93
Severe	88	97	82	98

Table 7 Sensitivity (Se) and specificity (Sp), PPV and NPV of routine endoscopy and chromoendoscopy in diagnosis of intestinal metaplasia (IM)

	Routine endoscopy				Chromoendoscopy			
	Se (%)	Sp (%)	PPV (%)	NPV (%)	Se (%)	Sp (%)	PPV (%)	NPV (%)
No	98	6	35	86	94	99	98	97
Mild	4	98	50	68	88	88	79	94
Moderate	no data	no data	no data	no data	71	95	80	92
Severe	6	99	33	89	82	98	82	98

Furthermore, we compared the results of the serology, endoscopy and histology by Spearman's correlation coefficient. As shown in Table 4, the correlation between the results of routine endoscopy and histology was positive, but obviously weaker than the correlation between the results of chromoendoscopy and histology. As it was expected, there was a strong reverse correlation between the presence and degree of stomach mucosal atrophy and the serum levels of proper markers of its functional activity. The correlation between the degree of stomach mucosal atrophy and the subsequent morphological changes of mucosa - IM and dysplasia, was positive but quite weak.

The levels of sensitivity and specificity, PPV and NPV of Biohit GastroPanel® in diagnosis of stomach mucosal atrophy are presented in Tables 5 and 6.

Thus, the investigated non-invasive method was quite sensitive in the diagnosis of non-atrophic and severe antral and corpus gastritis. Also, this method was characterized by the high PPV and NPV (except the cases of mild stomach

mucosal atrophy).

Finally, we carried out the comparison of sensitivity and specificity, PPV and NPV for routine endoscopy and chromoendoscopy in the diagnosis of IM (Table 7).

As a result, we established the obvious advantage of a method of chromoendoscopy in the diagnosis of IM, that had doubtless diagnostic importance in revealing precancerous changes of gastric mucosa.

DISCUSSION

Chronic *H pylori* gastritis eventually could lead in more than half of the affected subjects to a gradual loss of glandular structures with its specialized cells and a collapse of the reticulin skeleton of the mucosa, a condition of atrophic gastritis^[8]. As a result, the glandular layer of the mucosa became thinner, and glands were replaced by fibrosis and intestinal metaplasia. The major clinical importance of this condition was that it could significantly increase the risk for the intestinal type of gastric cancer. This risk might be elevated up to 90- fold in subjects with severe atrophic gastritis throughout the complete stomach^[9]. The annual incidence of gastric cancer among patients with atrophic gastritis varied in cohort studies between 0.3 and 1.0%^[10]. This could explain the interest in the diagnosis of atrophic gastritis. At present, there is a wide circle of questions related to the diagnosis of critical stages of gastric carcinogenesis - gastric epithelial atrophy, intestinal metaplasia and dysplasia. Therefore, it is extremely important to recognize dyspeptic patients who have very high risk of gastric malignant changes and require dynamic surveillance with the purpose of early revealing of the preneoplastic changes in stomach mucosa. Atrophic gastritis is a serious disease, which often does not receive much attention. The relationship between gastritis, atrophic gastritis and other diseases of the stomach is based on the fact that infection and atrophy could alter the physiological functions of the stomach^[11] and influence the growth and growth control of epithelial cells in the stomach. These consequences varied depending on whether the changes of the gastric mucosa caused by gastritis were located in the antrum or the corpus or both.

The most accurate diagnostic method of gastrointestinal tract diseases is endoscopy with subsequent biopsy, which should be made in all patients with the presence of clinical symptoms. However, because of patchy characteristics of atrophic changes in stomach mucosa, some histological researches could give false - negative results. Besides, biopsy was an expensive and labor-consuming method of research^[12], so it could not be carried out for all patients in succession. Contrarily, due to invasiveness of biopsy, it is expedient to make only for monitoring precancerous changes in stomach mucosa. For the selection of patients recommended to biopsy, the presence of a screening method is necessary. Such a method should be capable of reflecting objectively the functional condition of stomach mucosa and its morphological status.

It has been known for over two decades that atrophic gastritis of the corpus and fundus of the stomach can be determined reliably by measuring the serum level of pepsinogen I (PGI) or the PGI/PGII ratio from a blood sample^[13-15]. However, it has not been possible to determine from a blood sample the types of atrophic gastritis in which the atrophic changes are located solely in the antrum. The GastroPanel® serum test also enables the determination of atrophic gastritis of this antrum-limited subtype.

Group I pepsinogens are synthesized solely in the oxyntic glands and mucous neck cells of the gastric corpus. On the other hand, however, pepsinogens of group II are uniformly formed in the glands of the entire stomach and to some extent also in the Brunner glands in the first part of the duodenum.

The majority of pepsinogens are secreted into the lumen of the stomach where they are metabolized into an active pepsin. A small proportion of the pepsinogens leak for one reason or another into the blood circulation. In case of atrophic corpus gastritis, the level of serum pepsinogen I decreases whereas the level of pepsinogen II remains stable or decreases slightly. The level of serum pepsinogen I or the ratio of serum pepsinogen I to pepsinogen II could reflect with high reliability the number of cells and oxyntic glands in the corpus area of the stomach, i.e., they could reflect the degree of atrophy of the corpus mucosa^[14-16]. As the severity of atrophic corpus gastritis corpus increases, the level of serum pepsinogen I or the PGI/PGII ratio decreases.

Gastrin is synthesized in G-cells, which are found in the gastric antrum. The gastrin secreted by the antrum is over 90% of type G-17 whereas the gastrin secreted by the duodenum is primarily type G-34. The fasting serum gastrin is primarily in the form of G-34 but the proportion of type G-17 increases after the dietary stimulus. The secretion of gastrin-17 can be studied with a simple protein stimulation test. First, a blood sample is taken after fasting, after which the patient eats a protein-rich meal. The maximum increase in the level of gastrin-17 can be seen in the serum within 20 min. If the serum gastrin does not increase as a result of protein or other physiological stimulation it is an indication of the loss of gastrin secreting G cells, i.e., an indication of the atrophy of the antrum mucosa. It is possible to make indirect conclusions of the status of the antrum mucosa by simultaneously assaying the serum gastrin and acid output^[17]. In the cases with atrophic antral gastritis and loss of antral G cells, serum gastrin remains low although the stomach is achlorhydric or hypochlorhydric.

Several research groups have renewed the interest in serology for atrophic gastritis by combining gastrin and pepsinogens with *H. pylori* serology. In this issue, Väänänen and colleagues presented a smart algorithm for the differentiation in both antrum and corpus between atrophic and non-atrophic gastritis^[18]. The algorithm was tested in a cross-sectional study correlating gastric mucosal histology with *H. pylori* IgG serum antibodies, serum PGI levels, and fasting and postprandial serum gastrin-17 levels. It appeared that in roughly 80% of the 404 cases tested, histology and serology matched a similar diagnosis. Sixty (15%) of the 404 subjects had atrophic gastritis, 6 (1%) had previously undergone antral resection, and 340 (84%) had a non-atrophic gastric mucosa either with or without inflammation. In this population with a rather low prevalence of atrophic gastritis, the negative predictive value of the serology panel was 93-97% and the positive predictive value was 64-75%. For these calculations, the authors combined all subjects with atrophic gastritis of the antrum, the corpus, or both. The data, however, showed that the serology panel performed much better in diagnosing atrophic gastritis in the corpus than in the antrum. Only 19 (50%) of the 38 patients diagnosed by serology as having antrum atrophic gastritis had this condition confirmed by histology. This revival of interest in the serological testing of the condition of the gastric mucosa is of importance, given the fact that *H. pylori* eradication may cure gastritis and help to prevent further progression of gland loss. It is likely that this might also reduce the risk for gastric cancer^[19], although many more data on this are needed. Screening and treatment of *H. pylori* infection might in theory be cost-effective for the prevention of gastric cancer^[12].

Sipponen *et al.*^[20] have recently shown that simultaneous detection of serum concentrations of PGI and G17 and HPAb titers is an effective method for non-invasive screening and diagnosis of atrophic gastritis using blood samples of the patients.

In our present research, the use of the test - system GastroPanel® allowed to receive statistically significant differences between

the serum concentrations of PGI and G17 depending on a degree of stomach mucosal atrophy. We obtained the very satisfactory means of the PPV and NPV of GastroPanel® test in revealing the atrophic state of stomach mucosa. Moreover, this test was sufficiently sensitive and specific as it was proven by chromoendoscopy and histology.

Thus, our study confirmed the usefulness of the test - system GastroPanel® as a "serologic biopsy" for authentic and non-invasive diagnosis of atrophic changes of stomach mucosa in patients with dyspepsia associated with *H. pylori* - infection. Besides, we managed to show the advantage of a chromoendoscopy method prior to routine endoscopy in the diagnosis of intestinal metaplasia. Now is the time, almost a decade after the conclusion of the World Health Organization (WHO) about *H. pylori* as a class I carcinogen^[21], to use this serology for further studies in selected and general populations. This will allow evaluation of the feasibility of screening and treatment for gastritis and prevention of gastric cancer.

In conclusion, the noninvasive detection of gastric mucosal atrophy by means of enzyme immunoassay with assessment of G-17 and PGI levels can be offered as the screening tool for gastric precancerous conditions. On the other hand, this method does not allow to diagnose intestinal metaplasia and cancer development in stomach mucosa. Therefore, the results of serological screening indicating the stomach mucosal atrophy require carrying out the chromoendoscopy with subsequent mucosal biopsy, for revealing probable progressing of atrophic process with development of intestinal metaplasia, dysplasia or gastric cancer.

Abstract

AIM: To investigate the role of soluble Fas ligand in autoimmune diseases.

METHODS: RT-PCR was performed to amplify sFasL cDNA from the total RNA extracted from activated human peripheral blood lymphocytes. DNA fragments were cloned into PCR vector. After sequenced, sFasL gene fragments were inserted into pQE-31 vector and expressed in *E. Coli* M15 respectively. Proteins were purified through affinity chromatography column with ligand of 6×His tag and identified by SDS-PAGE and Western blot. Mice were immunized with sFasL protein and specific anti-serum was harvested 6 wk after immunization. Monoclonal anti-human FasL antibody was made from the immunized mice. Serum level of sFasL in different patients was detected using anti-FasL antibodies from the immunized mice.

RESULTS: The protein expressed was 24 ku by SDS-PAGE electrophoresis. The protein was specially bound to anti-human FasL antibody by Western blot analysis. The sFasL protein could induce Jurket cell apoptosis *in vitro*. The concentration of serum sFasL in patients with autoimmune diseases was higher than that in normal individuals. sFasL could reduce arthritis in collagen induced arthritis (CIA) mice model by subcutaneous injection.

CONCLUSION: sFasL may be involved in either induction of apoptosis or autoimmune diseases. Furthermore, sFasL may have potential application in treatment of autoimmune diseases.

INTRODUCTION

Autoimmune diseases are a kind of diseases induced by auto-

reactive T or B cells. Most common autoimmune diseases include rheumatoid arthritis (RA), insulin-dependent diabetes mellitus (IDDM), multiple sclerosis (MS) and systemic lupus erythematosus (SLE). Among these diseases, RA, IDDM and MS are believed to be autoimmune diseases induced by Th1 cells which can recognize auto-antigens on special tissues. For example, RA is a common disease characterized by the chronic lesion of polyarthritides. Autoimmunity to cartilage antigens may play a significant role in the pathogenesis of chronic inflammatory polyarthritis. It has been commonly accepted that cell mediated immune responses are involved in chronic inflammation since T and B lymphocytes and antigen presenting cells are observed to be enriched in the synovium fluid of RA patients. *In vivo* studies showed that T cells infiltrating into the synovium could express IL-2 receptors, IL-10, IFN- γ and activated CD4 T cells could be detected in the synovial fluid of RA patients^[1,2]. It is believed that if auto-reactive T cells can be cleaned from circulation or RA can be located, the lesion induced by auto-reactive T cells may relieve. Actually, anti-TNF- α and anti-CD4 monoclonal antibodies have been used in treatment of RA patients.

In this study, we reported that sFasL proteins were expressed in *E. Coli* system. Anti-FasL antibodies were prepared in the mice using expressed FasL. Meanwhile, we set up a special ELISA method to identify sFasL molecules and its content in the serum of patients with RA, IDDM, MS and SLE. We also tried to use sFasL made in our laboratory to treat collagen induced arthritis in this study.

MATERIALS AND METHODS

Blood samples and reagents

Fresh blood samples were supplied by healthy individuals. PHA was purchased from Sigma Com. San Diego, USA) IPTG and plasmid mini-prep Kit were products of Promega (Chicago, USA). DNA purification kit, Histidine resin, sequencing vector PCR2.1 and protein expression vector pQE-31 were purchased from QIAGEN (San Diego, USA). Rabbit anti-human FasL polyclonal antibody was purchased from Santa Cruz (Sweden). Goat anti-rabbit IgG/HRP was purchased from Huamei (Shanghai, China). Nitrofile membrane was purchased from Amersham (London, England). Trizol, dNTP, restricted enzymes were purchased from Gibco BRL (San Diego, USA) and MBI Fermentans (Philadelphia, USA).

Activation of lymphocytes

Peripheral blood monocytes (PBMC) were isolated from blood from healthy individuals with Ficoll. PBMC were re-suspended in 100 mL/L fetal calf serum RPMI 1640 and incubated at 37 °C in humidified atmosphere containing 5 mL/L CO₂ for 24 h. PHA (20 μ g/mL) was added into the culture and incubated for another 8 h.

Identification of sFasL expression

sFasL expression on the cell surface was detected by direct fluoroscense labeling with cytometry. Briefly, activated lymphocytes were collected and washed with PBS. FITC-labeled goat anti-human FasL (Oncogen Company, LA, USA) was added into the cells and incubated on ice for 30 min. The labeled

cells were washed with PBS and expression of FasL on the cell surface was detected by FACS. The percentage of expression of FasL was analyzed using system software II.

Amplification of gene fragments of sFasL

Total RNA was isolated from cells in which sFasL expression was enhanced and reversed into cDNA. sFasL gene fragments were amplified from cDNA template by special primers. sFasL: the sequence of forward primer was: 5'-ACG GAT CCG CAG CAG CCT TCA ATT A CC-3'; reverse primer: 5'-AAG CCG AAT ATA TTC GAG ATT AAG CTT CGC CG-3'. The size of sFasL fragments amplified from cDNA was 540 bp.

sFasL cloning and expression

PCR bands were cut and purified with gel extraction kit (QIAGEN). The purified PCR products were inserted into PCR 2.1 vector and DH 5 α (*E. Coli*) was transfected with TA cloning kit (Invitrogen) according to the manufacturers introductions. White clones were picked up on selected LB plates containing ampicillin and X-gel and expensed in 3 mL of LB medium overnight. Plasmids were prepared from the culture with mini-prep Kit (Promega). The positive clones were identified by *EcoR* I digested and sequenced by Shanghai South Gene Tech Ltd. The identified sFasL fragments were digested by *Bam*HI and *Hind* III and purified by gel extraction kit. The purified sFasL fragments were ligated into the expression vector pQE-31 and M15 (*E. Coli*) was transfected. White clones were picked up on selected LB plates containing Kanamycin and expensed in 3 mL of LB medium overnight and inoculated in 200 mL of selected LB medium containing Kanamycin until A reached to 0.7. A 1 mol/L of IPTG was added to culture and shaken for another 4 h. Bacteria were collected by spinning at 6 000 r/min for 10 min and lyzed in lysis buffer. Protein expressed was purified by His Tag resin.

Identification of expressed sFasL

sFasL expressed was identified by SDS-PAGE electrophoresis and Western blot. sFasL showed a single band with M_r 24 000 respectively after running from SDS-PAGE (120 g/L concentrated gel and 40 g/L separated gel). The sFasL bands were transferred onto membranes and blocked with 50 mL/L of free fat milk for 2 h at room temperature. The membranes were washed 3 times with PBS. The rabbit anti-human sFasL polyclonal antibody was added and incubated for 1 h at room temperature. Goat anti-rabbit IgG-HRP was added and incubated for another 1 h at room temperature after washed with PBS. DAB and H₂O₂ were added and the reaction was stopped by washing the membranes with water when brown color was visible.

Detection of apoptosis

sFasL (25, 50 and 100 μ g/L) was added into 1×10^8 /L of Jurket cell lines respectively and incubated for 8 h at 37 °C in humidified atmosphere containing 5 mL/L CO₂. The cells were collected and fixed by 700 mL/L ethanol for 45 min at 4 °C. Ten μ L of RNase was added to the fixed cells after washed with PBS and incubated for 30 min at 37 °C. Then 10 μ L of PI (50 mg/mL) was added to the cells and detected by cytometry. The percentage of apoptotic cells was calculated by apoptotic peak (A₀) area.

Preparation of mouse anti-human sFasL antibody

Two Balb/C mice were immunized with 80 μ g of expressed sFasL mixed with complete Freund's adjuvant by injection with s.c on back. The mice were injected three times with sFasL, once every two weeks. Then blood was collected and anti-FasL titer was measured with ELISA.

Induction of collagen-induced arthritis in Wistar rats

Wistar rats were bred under pathogen-free conditions. Female

mice were used at 2-3 mo of age and allowed free access to standard laboratory diet and water. Collagen II (CII) emulsion was prepared in an equal volume of IFA. A 100 μ L (containing 300 μ g of CII) of CII/IFA emulsion was intradermally injected, using the loose skin at the base of the tail. Seven days later, the primary immunization was administered, a booster intradermal injection containing 100 μ g of CII in IFA. The rats were observed every day from the 4th wk after primary immunization. Arthritis was evaluated with standard 4 scores.

Administration of arthritis rats with sFasL

When arthritis occurred in rats immunized with CII/IFA, 1 μ g of sFasL expressed in 100 μ L of PBS was injected into one ankylosis side. Meanwhile 100 μ L of PBS was injected into another ankylosis side of same arthritis rats as control. The injection was given three times, once every two days.

Detection of serum sFasL concentration using prepared mouse anti-human FasL antibody

Serum level of soluble FasL in different patients was detected with indirect ELISA. The ELISA plate was coated with 100 μ L of serum and incubated overnight at 4 °C. The coated plate was completely washed with PBS and prepared mouse anti-human FasL antibody was added. Rabbit anti-mouse IgG-HRP was then added and incubated for another 1 h at room temperature after washed with PBS. DAB and H₂O₂ were added and the reaction was stopped by washing the membranes with water when brown color was visible.

RESULTS

Enhanced expression of FasL on PMBC after PHA activation

PBMC was isolated from healthy individuals FasL was expressed on the cell surface after activated with PHA. The expression of FasL in PBMC was significantly higher after activated. The percentage of FasL detected on the non-activated PBMC was very low (2.15 \pm 1.7%), while FasL expressed on the activated PBMC reached 17.98 \pm 1.8% using cytometry detection after cells were labeled with specific fluorescence anti-human FasL antibody (Figure 1).

Figure 1 Peripheral blood mononuclear cells isolated from healthy individuals using Ficoll and co-cultured with PHA for 8 h at 37 °C in humidified atmosphere containing 50 mL/L CO₂. The expression of FasL on PBL before and after PHA stimulation was detected by special antibody using flow cytometer. Open bar indicates the percent of FasL on cells surface before PHA activation. Shadow bar shows the percent of FasL on cell surface after PHA stimulation.

Human sFasL cloning and expression

Human sFasL DNA fragments were amplified from activated PBMC using RT-PCR. The size of PCR product was 540 bp (Figure 2) which matched the size reported in the GenBank. The product was inserted into PCR2.1 vector and DH5 α was

successfully transfected. The insert was confirmed by digestion with *EcoR* I after plasmid was miniprepared. The fragments were separated with a 3.9 kb vector. This result showed that sFasL (Figure 3) fragments were successfully inserted into the vector. The sequences of the inserted fragments were same as reported by GenBank after sequenced with 377 Sequencer. Identified fragments were digested by both *Bam*HI and *Hind* III and ligated into the expression vector pQE-31. The ligated products were put on selected LB plates after M15 was transfected and incubated for 18 h at 37 °C. The expression was induced by IPTG for 4 h. The protein was purified by 6-histidine column. The molecular weight and purification of the protein were identified by SDS-PAGE. The result indicated that there was only one band in sFasL (24 000 dalton). Special mouse anti-human FasL antibody was used to confirm the bands transferred onto membranes with Western blotting. The result showed there was a sFasL positive band. This indicated that the protein expressed in M15 was human sFasL (Figure 4).

Figure 2 Reversion of total RNA isolated from PHA activated peripheral blood mononuclear cells to cDNA.

Figure 3 PCR bands and transfected DH 5a. Band1: inserted fragment of sFasL in pQE-31; Band 2: no inserted fragment.

Figure 4 sFasL expression in SDS-gel (A) and hybridization with special anti-sFasL antibody (B).

Jurkat cell line apoptosis induced by sFasL expressed in M15
Different doses of expressed sFasL were added to log phase growing Jurkat cell line and cultured for another 18 h. The

percentage of apoptosis of tested cell line was determined by cytometry after stained with PI dye. Figure 5 shows the apoptosis of Jurkat cells after co-cultured with expressed sFasL. The percentage of apoptotic Jurkat cells was similar to that of apoptotic cells co-incubated with commercial human sFasL. This result indicated that sFasL was able to induce cell apoptosis (Figure 5).

Figure 5 Cell apoptosis induced by different doses of sFasL (25, 50 and 100 µg/L).

Generation of anti-human sFasL antibody in mice immunized with expressed sFasL

Serum was isolated from two mice immunized with expressed human sFasL. We coated plates with this serum and detected anti-human FasL titer using special commercial standard sFasL protein by ELISA. The result showed that there was a high titer (>1:1 000) of anti-human sFasL special antibody in the serum of immunized mice. This indicated that expressed sFasL could specifically bind to standard human sFasL protein.

Figure 6 Levels of soluble FasL in serum from patients with different diseases. Cont: serum from healthy individuals; IDDM: serum from patients with IDDM; SLE: serum from IDDM; RAa: serum from RA patients with activated stage; Ca-ga: serum from patients with gastric cancer; Leuk: serum from patients with leukemia; Shadow bar: serum level detected by commercial sFasL kit. Open bar: serum level detected by anti-sFasL antibody.

Prepared special anti-humans sFasL antibody could be used to detect concentration of sFasL

We coated ELISA plates with special anti-human sFasL antibody generated from immunized mice to detect the concentration of sFasL in the serum of patients with tumor and autoimmune diseases. Twenty serum samples from healthy individuals, 95 serum samples from patients with different autoimmune diseases and 30 serum samples from patients with leukemia and cancer were detected by this way. As a parallel experiment, the concentration of sFasL in these serum samples was identified in duplicate using commercial Kit at the same time. The data showed that the concentration of sFasL was

significantly higher than that in healthy individuals ($P < 0.05$). The result determined with prepared sFasL antibody in our laboratory was same as that detected by commercial Kit (Figure 6).

Arthritis reduced by sFasL immunized rats

Arthritis occurred as early as 15 d after primary immunization with CII emulsified with IFA. The significant ankylosis was observed in rats. The joints of rats were red and swollen. The arthritis rats lost ability to move and showed difficult to reach food. The percentage of arthritis was 90% (Table 1). The mean score could reach the maximum 24 d after immunization began to decrease from d 30 (Figure 7).

Table 1 Incidence of chicken CII-induced arthritis in Wistar rats

Group	Immunized with	Incidence	Percentage of CIA (%)
Experimental	CII+CFA	18/20	90
Control	CII	0/5	0
	CFA	0/5	0

Wistar rats were intradermally injected with collagen II (CII) emulsion in an equal volume of IFA (100 μ L (containing 300 μ g of CII). Seven days later, a booster containing 100 μ g of CII in IFA intradermally administered. The rats were observed every day from 4 wk and evaluated with standard 4 scores.

Figure 7 Mean arthritis score of rats with CIA.

When arthritis had a score of 7-8, 1 μ g of sFasL in 100 μ L of PBS was injected into one ankylosis side of rats. Meanwhile, 100 μ L of PBS was injected into another ankylosis side of the same arthritis rats as control. After the arthritis rats were injected 3 times with sFasL, the rats showed reducible arthritis (Figure 8A) while control rats which received an equal volume PBS suffered from a more serious ankylosis (Figure 8B).

DISCUSSION

Human Fas ligand (CD95 ligand, FasL) was identified by

Nagata's laboratory in 1993. Human FasL is consisted of 281 amino acids and a member of TNF family. The N terminal of FasL was located in the cytoplasm and C terminal is on cell surface. The region of the molecules in cytoplasm is consisted of 80 amino acids. The region though the cell membrane of FasL is consisted of 22 amino acids. The region of FasL exposed to outside of the cells is consisted of 179 amino acids^[3]. Fas ligand molecules can be cut by matrix metalloproteinases (MMP) from membranes^[15] and become a soluble form which is called soluble FasL (sFasL). FasL could induce apoptosis of cells when it binds to Fas which expresses on cell surface and acts as a special receptor of FasL.

Fas is ubiquitously expressed on a number of different cells including tumor cells. Likewise, as a ligand of Fas, FasL has many important functions. The expression of FasL is not only restricted to activated T cells and NK cells, but also on immune privileged sites such as eyes and testis. FasL can be up-regulated when cells are responsive to UV irradiation or treated by cytotoxic drugs. Over expression of FasL can inhibit some autoimmune diseases by deleting auto-immune memory cells^[4,5]. Moreover, Fas-FasL interaction can protect allografts from immune attack and induce anti-tumor responses. Thus, myoblasts engineered to express FasL have been found to prolong the survival of co-transplanted islet allografts in diabetic mice. FasL expression on allogeneic fibroblasts was found to abolish tumor growth and induce specific protective immunity when mixed with neoplastic cells before implantation *in vivo*. Apoptosis induced by Fas-FasL interaction is believed to involve inflammation, anti-tumor and autoimmune reaction and aging^[6-8]. Apoptosis has been found in almost all processes of the life. For example, activation induced cell death (AICD) may play a very important role in T cell activation and differentiation.

As the out-membrane region of FasL, sFasL involves the deletion of potentially hazardous peripheral memory cells^[5]. Some studies suggested that change of sFasL in serum might be involved in many processes and progress of diseases. The serum level of sFasL was high in patients with large granule lymphocyte leukemia and NK like lymphoma, SLE, RA and EAE^[9-11]. sFasL was upregulated on the tumor surface upon drug incubation in chemosensitive tumor cells. Tumor cells could mediate autocrine or paracrine to release soluble FasL (sFasL) and induce apoptosis of peripheral normal cells, CTL and NK which could express Fas and promote local tumor invasion or metastases^[11-13]. Matsuno *et al.* reported that both sFas and sFasL were higher in the synovium fluid of RA patients compared with other arthritis^[14]. Serve RA showed a higher level of sFasL than mild RA^[13,21]. The concentration of Fas, receptors of FasL and sFasL, were changed in the process of diseases. Some investigators reported that sFas might block apoptosis by binding FasL or sFasL^[5,6]. Membrane-bound FasL induced apoptosis in cultured synovial cells from RA and OA patients, but naturally processed human sFasL did not^[23]. The role of sFasL still remains unclear.

T cells express both Fas and FasL on cell surface after stimulation. FasL exists in two forms: membrane-bound FasL and soluble FasL (sFasL). The out-membrane region of FasL is cleaved by a metalloproteinase (MP) and falls down from membrane to serum or body fluid^[14]. Inhibition of metalloproteinase cleavage could enhance the cytotoxicity of FasL^[15]. Activated T cells would die in a few minutes if no IL-2 was added after stimulation with antigens or mitogens. This process is called activated induced cell death (AICD). Because sFasL shows the same function of FasL but has smaller molecules. We expressed sFasL first in *E. Coli*. For preparing sFasL cDNA and stimulated T cells with PHA in this study. The expression of sFasL reached 20% after stimulation for 24 h compared with 3% expression on naïve T cells. We harvested sFasL expressed

T cells before they died and mRNA of sFasL was extracted. The fresh mRNA of sFasL was reversed into cDNA and successfully amplified. The sFasL was ligated into PCR2.1 vector. After the sFasL insert was confirmed by sequencing analysis, the fragment of sFasL was inserted into pQE-31 vector and expressed in M15 strain.

To identify whether sFasL expressed in this study had biological functions after purification, we chose Juckett cell line as a report cell because Fas molecules were expressed on Juckett cell line surface. When Fas expressed on cell surface bound to sFasL, the cells were activated and went to die after 48 h of binding. The results demonstrated that the expressed sFasL could induce Juckett cell line apoptosis. The percent of apoptosis increased with the increased concentration in the culture. This result indicated that sFasL had the same function membrane FasL.

Recently, some reports demonstrated that FasL and sFasL played a different role in apoptosis. Generally, membrane-bound FasL, or FasL is fully competent in transducing Fas-mediated signals for apoptosis and NF-kappaB nuclear translocation because membrane FasL could possess both Fas-focusing and signal transducing functions. While sFasL is known to be deficient in transducing signals upon engagement with membrane Fas^[4,14]. But in some cases, sFasL was found to be involved in the deletion of potentially hazardous peripheral memory cells^[10]. A more study suggested that change of sFasL in serum was involved in the process and progress of diseases^[9]. The report indicated there was a high serum level of sFasL in patients with large granular lymphocyte leukemia and NK-like lymphoma^[12]. sFasL increased significantly in the serum of patients with activated systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA). In some autoimmune diseases the serum level of sFasL was dramatically decreased after treatment in some patients^[10,13]. We detected the serum level of sFasL in more than 90 samples from autoimmune disease in this study. Among these diseases, the serum levels were detected from 32 patients with IDDM, 31 patients with SLE, 16 RA patients in active stage and 16 RA patients in resting stage. This result indicated that the circulation level of sFasL was higher in these autoimmune diseases. The role of sFasL in the pathogenesis of these autoimmune diseases is still under investigation.

It has been commonly accepted that activated CD4 T cell mediated immune responses are involved in the pathogenesis of RA. Both CD4 and CD8 T cells were observed to be enriched in the synovial fluid of RA patients. It is possible that if autoreactive T cells can be cleaned from circulation or RA can be located, the lesion caused by inflammation induced the autoreactive T cells may relieve. Similar with RA, it is believed that Th1 is involved in the pathogenesis of CIA. Collagen induced arthritis (CIA) has become a common animal model in studying the pathogenesis of rheumatoid arthritis^[2,17]. Many potential factors involved in CIA^[2,18-20], Th1 cells are mainly involved in the CIA. If Th1 cells are deleted from joints, the evolution of joints in CIA may be lighter. Mattsson *et al.*^[20] reported that the T cell marker O×40 was up-regulated in OVA-inhibited non-arthritis animals compared to control CIA animals. They found that the complete inhibition of CIA caused by addition of OVA to the collagen II inoculum was due to the presence of a TH2 environment resulting from an increased production of IL-4 mRNA and a parallel increase in O×40+ T cells^[20]. In this report, we used sFasL to treat CIA mice. The anklylosis was reduced after 3 times of sFasL injection in arthritis rats. This result indicated that sFasL might induce apoptosis of activated autoimmune Th1 cells which infiltrated in joints and synovium so that the inflammation induced by autoimmune T cells decreased, or the above process increased the Th2 switch. But how sFasL induces these changes is still under investigation.

In this study, human sFas ligand was engineered in *E. Coli*. The expressed sFasL could induce apoptosis of Jurkat cell line. Anti-human sFasL antibody could be generated in the mice immunized with expressed sFasL. Anti-human sFasL antibody could be used in detection of sFasL in the serum of patients with autoimmune diseases. The results demonstrated that the level of sFasL in sera of patients with IDDM, SLE and RA was much higher than that in healthy individuals. Meanwhile, the result showed that sFasL antibody revealed the same sensitivity as commercial sFasL antibody. Injection of sFasL with sc in CIA rats could reduce inflammation, which may indicate that sFasL can be used in treatment of autoimmune diseases.

ACKNOWLEDGEMENTS

We thank professors Kang-Yan Zhou and Shan-Qing Tong for their critical review of this paper and Dr. Zuo-Qing Li for his assistance in preparation of this manuscript.

Abstract

AIM: To explore the dynamical changes of histology, histochemistry, energy metabolism, liver microcirculation, liver function and posttransplant survival of liver graft in rats under different warm ischemia times (WIT) and predict the maximum limitation of liver graft to warm ischemia.

METHODS: According to WIT, the rats were randomized into 7 groups, with WIT of 0, 10, 15, 20, 30, 45, 60 min, respectively. The recovery changes of above-mentioned indices were observed or measured after liver transplantation. The graft survival and postoperative complications in each subgroup were analyzed.

RESULTS: Liver graft injury was reversible and gradually resumed normal structure and function after reperfusion when WIT was less than 30 min. In terms of graft survival, there was no significant difference between subgroups within 30 min WIT. When WIT was prolonged to 45 min, the recipients' long-term survival was severely insulted, and both function and histological structure of liver graft developed irreversible damage when WIT was prolonged to 60 min.

CONCLUSION: The present study indicates that rat liver graft can be safely subjected to warm ischemia within 30 min. The levels of ATP, energy charge, activities of glycogen, enzyme-histochemistry of liver graft and its recovery potency after reperfusion may serve as the important criteria to evaluate the quality of liver graft.

INTRODUCTION

Attributed to the widespread applications of effective immunosuppressants and the perfect perioperative management, liver transplantation has achieved a great success during the

past 40 years, but the shortage of liver donors has limited its clinical usage greatly. Quality of liver graft is a key factor for liver transplantation. Organs from NHBD (non-heart-beating donors) seem to be an option to alleviate the problem of liver donor shortage effectively^[1]. However, warm ischemia to the liver related to cardiac arrest remained a main obstacle to the use of livers from NHBD^[2-4]. Moreover, in liver transplantation, the allograft sustains inevitable cold ischemia in addition to rewarming injury during liver reperfusion^[5]. Therefore, warm ischemia-reperfusion injury of liver grafts has become a hot topic with theoretical and clinical significance, and it has drawn more and more attention^[1]. It is a main unfathomed problem of how to evaluate the quality of liver grafts and how to ascertain the safety time limit for warm ischemia of liver grafts. The outcomes of this research were rather different mainly because the previous researches focused on the relationship between warm ischemia time (WIT) and the short-time survival, neglecting the long-term survival and complications. We investigated the dynamical changes of histology, histochemistry, energy metabolism, microcirculation, especially focusing on liver function and posttransplant survival of liver graft, under different WIT to establish the predictive limitation of liver graft to warm ischemia injury, which might be helpful for the further research in similar clinical situation.

MATERIALS AND METHODS

Establishment of animal model

Adult healthy male Sprague-Dawley rats, weighing 250-300 g, supplied from Experimental Animal Center in Sun Yat-Sen University, were used for the models. Breeding conditions were in coincidence with SPF (specific pathogen free animal) standards. Mean weight of recipient rats was a little heavier than that of donor rats.

Animal model of warm ischemia A midline laparotomy was performed in supine position after an ether aspiration anesthesia, 0.2 mL of heparin sodium solution (1 250 U heparin sodium) was injected via dorsum of penis vein to heparinize the donor liver. Thereafter, we sheared diaphragm, clamped the basilar part of the heart and blocked the thoracic aorta. Thus, a donor liver warm ischemia model was established.

Animal model of liver transplantation After the predicted warm ischemia duration in each group, 20 mL of 0-4 °C lactic acid ringer's solution (50 U/mL heparin sodium) was infused into the abdominal aorta via a catheter. The liver graft turned fulvous when filling solution flowed out via the sheared right atria. All of the liver ligaments were dissected, the pyloric vein was ligated proximal to the portal vein after the hepatic proper artery and portal vein were freed, the infra-hepatic inferior vena cava was isolated and the right suprarenal vein and right renal vein were cut. The supra-hepatic inferior vena cava was cut in the position close to the diaphragm anulus, the hepatic artery was ligated and cut, the portal vein was cut in the confluence of portal vein and splenic vein, the infra-hepatic inferior vena cava was cut over the left renal vein. Specimens of donor liver were preserved in the 4 °C lactic acid ringer's solution. Anesthesia, position and incision were all the same in donors and recipients' operations. We modified the angio-anastomotic technique^[6] on the basis of cuff technique suggested by Kamada *et al.*^[7] and Sun *et al.*^[8].

Cold ischemia time (CIT) was 50 ± 3.5 min, anhepatic phase was 20 ± 2.5 min.

Group and observation index

Three hundred and seventy eight SD rats were used in our study. Forty two (6 in each group with WIT of 0, 10, 15, 20, 30, 45 and 60 min) were used for the observation of histology, histochemistry, ultrastructure and metabolism change after only warm ischemia injury; other 336 rats were performed with orthotopic liver transplantation according to the "modified cuff method"^[6]. Among the 336 rats, 168 were used for donors and 168 for receivers. The donor group was randomly divided into 2 subgroups: 84 for prolonged survival observation, including spirit, activity, complications, death diagnosis and mean survival; the other 84 rats for investigation of the dynamical changes of liver function, histology, histochemistry, microcirculation, energy metabolism and ultrastructure (transmission electron microscope and scanning electron microscope). Both groups were divided into 7 subgroups with WIT of 0, 10, 15, 20, 30, 45 and 60 min, each subgroup consisted of 12 rats. Liver transplantation and postoperative follow-up were performed respectively. Careful attention was paid to the fluid replacement after blood withdrawal.

Statistics analysis

Data were expressed as mean \pm SD. Analysis of variance (ANOVA including SNK-*q* test) was used to analyze the data. Enumeration data were analyzed by Chi-square test and Fisher test. The activity and distribution of succinic dehydrogenase (SDH), cytochrome oxidase (CO) and ATPase, were respectively observed under microscope in a semi-quantitative way. Kaplan-Meier analysis was applied for the relationship between WIT and survival, while correspondence analysis was applied for that between WIT and complication. All the statistical procedures were performed with SPSS package and $P < 0.05$ was considered statistically significant.

RESULTS

Survival situation

In groups with WIT of 0, 10, 15, 20, 30, 45 and 60 min, the median survival time was 140.5, 132.5, 76, 109, 58, 13.5 and 3 d, respectively (Figure 1). One week, 1-mo and 3-mo postoperation survivals of each group are shown in Table 1. There was no significant difference between groups with WIT less than 30 min. One week survival in WIT of 0 min and 60 min group was significantly different ($P < 0.05$). The difference was also significant between 45, 60 and 0 min in 1-mo and 3-mo survival ($P < 0.05$)^[9].

Dynamic histological and subcellular structure observation

The histological and subcellular structure change was a dynamic process^[10]. Histological structure changed slightly when WIT was less than 30 min. Cytoplasm loosening, cells edema and focal vacuole degeneration were noted when WIT was over 30 min, especially in the lobule center area, leukocytes infiltration was noted in the portal area, acidophilus was obvious in some hepatocytes. The above pathologic changes aggravated when WIT elongated to 60 min, cell degeneration was diffuse or extended to a focal area, and even lipid degeneration could be seen. The degree of degeneration was depending on the duration of WIT, but necrosis could hardly be observed under light microscope. Six hours and 24 h after reperfusion, injury to liver graft became severer; in WIT 30 min group, hepatic cells presented obvious edema and some ballooning degeneration; in WIT 45 min group, focal like necrosis could be noted, which was presented first in the lobule center area, the change aggravated with the elongation of WIT. Forty

eight hours after reperfusion, hepatic injury resumed gradually in groups with WIT less than 45 min, while in WIT 60 min group, hepatic cells presented plaque or diffuse necrosis and the pathologic change was irreversible^[11].

Electroscopically, swollen mitochondrion was noted and glycogen increased 24 h post liver transplantation in groups with WIT less than 30 min. When WIT was over 45 and 60 min, more swollen mitochondrion, vacuole degeneration, broken rough endoreticular, drop of nucleoprotein and hepatic apoptosis were observed, and cells necrosis could be noted with karyopyknosis, karyorrhexis and karyolysis. Thus, the subcellular structure then underwent irreversible injury. In addition, in WIT 45 min and 60 min groups, hepatic cells and endothelial cells presented apoptosis increasingly, and cells apoptosis and necrosis could be noted simultaneously^[12,13].

Table 1 One week, 1-mo and 3-mo survival rate under different WIT (n,%)

Warm ischemia time (min)	1-wk survival rate	1-mo survival rate	3-mo survival rate
0	91.7 (11/12)	83.3 (10/12)	83.3 (10/12)
10	83.3 (10/12)	66.7 (8/12)	66.7 (8/12)
15	83.3 (10/12)	58.3 (7/12)	50.0 (6/12)
20	75.0 (9/12)	58.3 (7/12)	58.3 (7/12)
30	83.3 (10/12)	58.3 (7/12)	50.0 (6/12)
45	66.7 (8/12)	33.3 (4/12) ^{a,c}	8.3 (1/12) ^{a,c}
60	8.3 (1/12) ^{a,c}	0.0 (0/12) ^a	0.0 (0/12) ^a

^a $P < 0.05$ vs WIT 0 min group (Fisher's exact test); ^c $P < 0.05$ vs groups WIT less than 45 min (Fisher's exact test).

Figure 1 Statistical analysis of survival time.

Dynamic changes of histochemistry

The activities of SDH, CO, ATPase and content of glycogen decreased gradually after different WIT in a time-dependent manner, and especially significant over 30 min. The activities of SDH, CO, ATPase and content of glycogen of liver graft significantly decreased in 45 min and 60 min groups^[14].

Hepatic glycogen and enzyme activities were positively related to warm ischemia time in a time-dependent manner during the reperfusion period. In WIT 15 and 30 min groups, periodic acid-Schiff reaction (PAS reaction) and enzyme histochemical activities showed a recovery potency. While in WIT 45 and 60 min groups, the liver graft underwent an irreversible injury; therefore, no evident recovery potency was found 24 h after implantation.

Microcirculation change patterns of liver graft

The microcirculation changes of liver graft were measured by serum hyaluronic acid (HA) and ultrastructural observation. The microcirculation of liver graft injury could be gradually resumed normal after reperfusion when WIT was less than 30 min. In the WIT 45 min group, part of blood sinusoids were full of the cytoplasmic blebs stemming from the microvilli of

hepatocytes and hemocytes accumulated there; the level of serum HA of each group within 45 min of WIT would almost recover after reperfusion^[15].

Measurement of energy metabolism

ATP, TNA (Total adenine nucleotides) and EC in all groups were decreased dramatically after warm ischemia injury^[16,17]. ATP in WIT 10, 15, 20, 30, 60 min groups was decreased to 58.7%, 34.7%, 30.1%, 20.5%, 15.3%, and 9.3% of that in WIT 0 min group, respectively. Twenty-four hours after transplantation, ATP, TNA and EC showed a tendency of recovery potency. ATP, TNA and EC had no significant difference between groups with WIT less than 30 min and WIT 0 min group. But when WIT was over 45 min the observation showed significant difference, which also could be seen between the WIT 45 min and 60 min groups. Forty-eight hours after transplantation, the above mentioned indexes recovered close to the normal level, there was no difference between groups with WIT less than 45 min and WIT 0 min group, while the indexes in group with WIT 60 min were still different from those in WIT 0 min group and WIT 45 min group^[18].

Liver function

Twenty-four hours after transplantation, AST, ALT and LDH increased sharply with the elongation of WIT, the following recovering change showed a step-like pattern^[19,20]. AST and ALT in groups with WIT less than 30 min decreased close to the normal level 3 d after transplantation, and the recovering course took 5 d in WIT 45 min group. LDH in groups with WIT less than 45 min recovered to the normal level 3 d after transplantation, while enzymes in WIT 60 min group could hardly recovered to the normal^[21].

Figure 2 Survival curve (Kaplan-Meier method).

Figure 3 Relationship between WIT and complications (correspondence analysis). WIT 1, 2, 3, 4, 5, 6 and 7 represent WIT 0 min, 10 min, 15 min, 20 min, 30 min, 45 min and 60 min, respectively. A: Hemorrhage; B: SVC (superior vena cava) thrombosis; C: IVC (inferior vena cava) thrombosis; D: PV (portal vein) thrombosis; E: Liver dysfunction; F: Pulmonary infection; G: Abdominal infection; H: Bile leakage; I: Bile obstruction; J: Adhesive intestinal obstruction; K: Liver abscess; L: Unexplained; M: Natural death.

Relationship between WIT and survival

The survival curves are demonstrated in Figure 2. Survival time in groups with WIT less than 30 min had no statistical difference. Though short-term survival might be possible in WIT 45 min group, warm ischemia injury had insulted the long-term survival of liver graft. And in WIT 60 min group, the liver graft underwent irreversible injury.

Relationship between WIT and complication

The relationship between WIT and complications was illustrated by correspondence analysis (Figure 3). Complications in groups with WIT less than 30 min were similar, the incidence of liver graft dysfunction increased with the elongation of WIT and the incidence of biliary blockage was positively related to the survival time of recipient animals^[22-24].

DISCUSSION

In the past 40 years, liver transplantation has achieved a great success and become the most effective method to treat end-stage hepatic diseases. Nowadays, liver transplantation is developing rapidly as a result of the perfect perioperative treatments and widespread applications of some immunosuppressants. However, there is an obvious problem that recipients are greatly more than donors. The disparity between the increasing demand for liver donors and the limited supply of donor organs has led to a reconsideration of the use of marginal pools, such as NHBD^[25-27]. NHBD programs have been used successfully in kidney transplantation, and were able to increase donor pool of kidneys by 40%. In the field of liver transplantation the use of livers from NHBD shows a less favorable clinical results, because of the limited hepatic tolerance against warm ischemic damage compared with kidneys^[28-30]. Although several clinical and experimental studies have shown that liver can compensate 60 min of WIT during liver resection^[31,32], in transplantation settings, there were few studies about limit of the period of warm ischemia before transplantation. To evaluate the quality of liver grafts and to ascertain the safety time limit for warm ischemia of liver grafts, we should focus on the long-term survival of liver graft and the complications after transplantation^[33].

In present study, we found that the pathologic changes of hepatic cells undergoing only warm ischemia injury was irreversible when WIT was less than 60 min, only part of hepatic cells underwent irreversible injury. But the damage to liver graft would aggravate in the cold preservation, operative ischemia stage and the reperfusion process. Histological and subcellular structure changes were reversible in groups with WIT less than 30 min, especially at 48 h after transplantation. In WIT 45 min and 60 min groups, hepatocellular degeneration became severer, necrotic cells spread from the center lobule area to a sheet or foci-like area involved several hepatic lobules, the liver graft then underwent irreversible injury^[34].

The present study indicates that hepatic injury is reversible within 30 min of warm ischemia injury by cytochemical and histochemical dynamic observation. The glycogen and enzyme-histochemistry activities of liver graft and their recovery potency after reperfusion may serve as criteria to evaluate the quality of liver graft.

ATP, TAN and EC decreased after warm ischemia injury, especially in the first 30 min, the change was reversible within 30 min of warm ischemia injury. WIT and hepatic energy metabolism recovering potency were key factors to the postoperative survival. ATP, EC and their recovering potency of the liver graft may serve as criteria to evaluate the quality of liver graft.

Microcirculation of grafted liver could be gradually resumed normal after reperfusion when WIT was less than 30 min, which indicated that hepatic cells held the recovery potency and could regained normal microcirculatory structure after reperfusion if

the WIT was less than 30 min. After 45 min of warm ischemia, most hepatic sinus was unobstructed, but there were still some sinus filled with cytoplasm blebs, reticular fibrosis and hemocytes. So 45 min may be the deadline of hepatic warm ischemia. When WIT was more than 60 min, microcirculatory structure of liver graft presented irreversible injuries.

Besides the researches on the influence of warm ischemia time on energy metabolism, morphology and function, special attention was paid on the influence of warm ischemia on the postoperative long-term survival and complications. Correspondence analysis showed that complications in groups with WIT less than 30 min were similar; and the incidence of liver dysfunction increased gradually in a time-dependent manner; incidence of biliary obstruction increased with the elongation of survival time of the recipient rats. Kaplan-Meier analysis showed that survival time in groups with WIT less than 30 min had no significant difference. In WIT 45 min group, the animal might still survive early postoperative period, but the long-term survival was severely insulted, when WIT prolonged to 60 min, both function and histological structure of graft would develop irreversible damage and no recipients could survive.

Abstract

AIM: To study the protective effects of tumor necrosis factor α (TNF α) antibody and ulinastatin on liver ischemic reperfusion in rats.

METHODS: One hundred and twenty male SD rats were randomly divided into four groups: normal control group, ischemic group, TNF α antibody group and TNF α antibody + ulinastatin group. The animals were killed at 0, 3, 6, 9, 12 h after ischemia for 60 min and followed by reperfusion. Serum alanine aminotransferase (ALT), malondialdehyde (MDA) and liver histopathology were observed.

RESULTS: After ischemic reperfusion, the serum ALT and MDA were remarkably increased, and the hepatic congestion was obvious. Treatment of TNF α antibody and ulinastatin could significantly decrease serum ALT and MDA levels, and relieve hepatic congestion.

CONCLUSION: Ulinastatin and TNF α antibody can suppress the inflammatory reaction induced by hepatic ischemic reperfusion, and have protective effects on rat hepatic ischemic reperfusion injury.

INTRODUCTION

Liver ischemic reperfusion injury is induced when liver gets the retrieval of its blood perfusion or oxygen supply, and hepatic injury would aggravate due to ischemia and hypoxia injury^[1-4]. Hepatic insufficiency or primary liver graft non-function can be caused by liver ischemic reperfusion injury after portal blockage, hemorrhagic shock or liver transplantation. As liver ischemic reperfusion is hard to be avoided in hepatic surgical practice and the existing prevention and cure methods are not satisfactory, research of the mechanisms and therapy on liver ischemic reperfusion becomes one of the hotspots in hepatic surgery^[5,6].

Cytokines are polypeptides with extensive biological activities, and play important roles in the immunoregulation. They prevent body from diseases and accelerate tissue rehabilitation. But on the other hand, too many cytokines can also lead to or aggravate tissue damages^[7,8]. Recent researches have demonstrated that TNF α plays an important role in ischemic reperfusion injury of liver^[9-12]. At the same time, ulinastatin has been applied in the clinical treatment of pancreatitis, shock and extracorporeal circulation because of its significant inhibitory effect on inflammation^[13-15]. In the present study, we attempted to relieve ischemic reperfusion injury of liver by using TNF α antibody and ulinastatin, so as to provide experimental and theoretic bases for prevention and treatment of liver ischemic reperfusion injury.

MATERIALS AND METHODS

Animals

A total of 120 male Spargue-Dawley (SD) rats weighing 230 \pm 20 g, were obtained from Animal Research Center of Shaanxi Chinese Medical Institute, and fed with standard rat chow.

Drugs

Ulinastatin (Tianpu Co. Ltd., Guangdong, China) was diluted to 50 U/L by saline prior to use. TNF α monoclonal antibody (Jingmei Co. Ltd., Guangdong, China) was diluted 100 times by saline prior to use.

Experimental grouping

The rats were randomly divided into four groups. Group I: the control group, sham operation was performed, hepatic lobes of the rats were exposed without any treatment. Group II: ischemic reperfusion injury group, in which blood stream of the rats' liver lobes were blocked and then recovered after 60 min. Group III: TNF α antibody treatment group, in which TNF α antibody (2.0 mg/kg) was injected into the rats through dorsum veins of penis 5 min prior to reperfusion. Group IV: TNF α antibody and ulinastatin treatment group, in which both TNF α antibody (2.0 mg/kg) and ulinastatin (500 000 U/L, 0.5 mL) were simultaneously injected into the rats through dorsum veins of penis 5 min prior to reperfusion. Blood samples (2 mL) of all animals in each group were taken from hepatic superior and inferior vena cava at 0, 3, 6, 9 and 12 h after reperfusion. Then the rats were killed and liver samples were obtained.

Operation

The animals were intraabdominally anesthetized by pentobarbital sodium (30 mg/kg, 0.1 mL/10 g), and incised through median incision of the abdomen. After the liver pedicle between left and middle lobes of liver was exposed, ligaments between liver and septum transversum and abdominal wall were cut. The scatheless vascular clamp was used to block blood stream of portal veins and hepatic arteries of left and middle lobes of liver. After 60 min, the vascular clamp was released and blood stream recovered. So approximately seventy percent of liver was hypoxia, thus severe congestion of the mesentery vein was prevented.

Table 1 Levels of serum ALT in rats (U/L)

Group	n	Time of after reperfusion (h)

Determination of ALT and MDA in serum

The blood samples in each group were poured into centrifuge tubes and the placement lasted for 20 min without shaking. After centrifugation at 2 000 r/min for 10 min, the sample serum was extracted and stored at -80 °C for determination.

ALT levels of sample serum were determined by an automatic biochemistry analyzer. MDA levels of sample serum were determined by the method introduced by Mourek *et al.*^[16], and the kit was purchased from Juli Biomedical Engineering Institute of Nanjing, China.

Pathological changes of liver

Fresh tissues of liver in each group were sampled. Haematoxylin-Eosin (HE) staining was performed on 100 g/L formaldehyde-fixed tissue sections. The histological patterns of the liver samples were observed under light microscope.

Statistical analysis

All the data were analyzed by Student's *t* test and expressed as mean±SD. $P<0.05$ was considered statistically significant and $P<0.01$ as very statistically significant.

RESULTS

ALT levels of sample serum

ALT levels of sample serum in each group were determined to assess the liver function of rats. The levels of ALT in ischemic reperfusion injury group at different time points were significantly higher than those in control ($P<0.01$). The levels of ALT increased gradually after reperfusion, reached the peak 6 h after reperfusion, and then decreased mildly. The levels of ALT in TNF α antibody treatment group were remarkably lower than those in ischemic reperfusion injury group ($P<0.01$). The levels of ALT in TNF α antibody and ulinastatin treatment group were lower than those in ischemic reperfusion injury group and TNF α antibody treatment group ($P<0.01$).

MDA levels of sample serum

The oxygen-derived free radicals induced lipid peroxidation reaction of polyvalent unsaturated fatty acid at plasmalemma, which developed lipid peroxidation products, such as MDA. So the MDA levels of sample serum showed the degree of lipid peroxidation injury of liver. The levels of MDA in ischemic reperfusion injury group at different time points were significantly

higher than those in control ($P<0.01$). The levels of MDA increased gradually after reperfusion, reached the peak 6 h after reperfusion, and then decreased. The levels of MDA in TNF α antibody treatment group were remarkably lower than those in ischemic reperfusion injury group ($P<0.01$). The levels of MDA in TNF α antibody and ulinastatin treatment group were lower than those in ischemic reperfusion injury group and TNF α antibody treatment group ($P<0.01$).

**Figure 1** Serum ALT level after reperfusion in rats.**Figure 2** Serum MDA level after reperfusion in rats.

Histopathological observation

The blood stream in middle and left lobes of livers of rats was reperused 1 h after blocked for 60 min. In ischemic reperfusion injury group, the middle and left lobes of livers were found to be swollen and faint. HE staining showed disorganized hepatic

lobules and extensive hepatocytic edema with various degrees of vacuolation and lamellar necrosis. The liver tissues in TNF α antibody treatment group and in TNF α antibody + ulinastatin treatment group were found to insignificantly swollen and faint in appearance. HE staining showed a sprinkle of hepatocytic edema without vacuolation and lamellar necrosis.

Figure 3 Disorganized hepatic lobules and extensive hepatocytic edema with various degrees of vacuolation and lamellar necrosis in ischemic reperfusion injury group.

Figure 4 A sprinkle of hepatocytic edema without vacuolation and lamellar necrosis in TNF α antibody + ulinastatin treatment group.

DISCUSSION

Liver ischemic reperfusion injury can be frequently seen in surgical practice, and plays important roles in severe infection, trauma, shock, cardiorespiratory malfunction, organ transplantation, *etc.* Ischemic reperfusion can cause a series of injuries on metabolism, structure, and function in hepatic tissues and cells, and even liver function failure. So it is one of the major factors influencing the prognosis, operative success and survival of patients.

Cytokines, are the soluble polypeptides excreted by immunocytes, and play important roles in immunological activation and inflammatory reaction. The study of cytokine effects on ischemic reperfusion injury in liver has become highlights at present^[17-22]. TNF α is the polypeptide excreted by activated macrophages, endothelial cells, neutrophilic granulocytes and B lymphocytes, and plays an important role in inflammatory reaction. Liver possesses tremendous Kupffer cells (KC) that have the great potency to produce TNF α in human body. At the time of liver ischemia, for the blockage of ATP production, calcium pump of liver is in dysfunction, which causes intracellular calcium overload. Aggravated calcium overload can activate Kupffer cells. On the other hand, Kupffer cells have complement receptors, intracellular protein was released during ischemic reperfusion, thus activating complements, which can also activate Kupffer cells. The activated Kupffer cells excrete TNF α . Liver has plenty of TNF α receptors, and also is the major target organ of TNF α ^[23-26]. Some mechanisms were used to explain

the liver damage caused by TNF α ^[27-30]. Firstly, TNF α could directly injure hepatocytes. Secondly, TNF α could activate neutrophilic granulocytes and mononuclear macrophages to express IL-1 and IL-6, and phosphatidase A2 that can decompose arachidonic acids. Inflammatory media were produced such as platelet active factor, leukotriene, and thromboxane A2. So the inflammatory reaction was aggravated. Thirdly, the toxic effect of TNF α on endothelial cells could induce the circulatory disorder of hepatic sinusoid, and TNF α could activate complement system that aggravates tissue damage by cytotoxicity. Finally, the oxygen-derived free radicals induced by TNF α could facilitate oxidation explosion of neutrophilic granulocytes, which could also result in liver damage. Therefore, the way to block the production of TNF α in liver can be used to prevent liver from injury by TNF α .

Ulinastatin is one kind of glycoproteins containing 143 amino acids with molecular weight of 67 ku. It is the typical urine protease inhibitor isolated and purified from human urine. Ulinastatin has two active function domains which have a wide restrained zymogram with no overlapped region each other. So ulinastatin can inhibit many hydrolytic enzymes in one time, including trypsin, phospholipase A₂, alidase and elastase. Moreover, the components of low molecular mass decomposed from ulinastatin can also inhibit hydrolytic enzymes strongly. On the other hand, ulinastatin could ameliorate the shock situation by blocking the production of myocardial depressant factors and stabilizing the membrane of lysosome^[31-33]. Recent researches found that ulinastatin could block the release of inflammatory factors, prevent cascade reaction of cytokines, inhibit excessive activation of leukocytes and block vicious circles among cytokines, inflammatory factors and leukocytes. So when pancreatitis, shock or other severe infection occurred, the action of multiple hydrolytic enzymes necessitated the use of ulinastatin, which can inhibit many hydrolytic enzymes at the same time and alleviate the vicious effects of multiple proteases on tissues and organs^[34-36].

The present study was to verify the protective effect of TNF α antibody and ulinastatin on ischemic reperfusion injury of liver. The results showed that the levels of ALT and MDA in TNF α antibody and ulinastatin treatment group were remarkably decreased as compared with those in ischemic reperfusion injury group. Pathological changes of liver also demonstrated the significant protective effect of TNF α antibody and ulinastatin on ischemic reperfusion injury of liver. The present results suggest TNF α antibody and ulinastatin can effectively prevent ischemic reperfusion injury of liver. But further work is needed to make clear of their best concentrations, best ratio and their effect on immune system of the body.

Abstract

AIM: To investigate the curative effects of oral and nasal administration of chicken type II collagen (CII) on adjuvant arthritis (AA) in rats with meloxicam-induced intestinal lesions.

METHODS: AA model in Sprague-Dawley (SD) rats with or without intestinal lesions induced by meloxicam was established and those rats were divided randomly into six groups which included AA model, AA model+meloxicam, AA model+oral CII, AA model+nasal CII, AA model+meloxicam+oral CII and AA model+meloxicam+nasal CII ($n = 12$). Rats were treated with meloxicam intragastrically for 7 d from d 14 after immunization with complete Freund's adjuvant (CFA), and then treated with chicken CII intragastrically or nasally for 7 d. Histological changes of right hind knees were examined. Hind paw secondary swelling and intestinal lesions were evaluated. Synovocyte proliferation was measured by 3-(4,5-dimethylthiazol-2-thiazolyl)-2,5-diphenyl-2H tetrazolium bromide (MTT) method. Activities of myeloperoxidase (MPO) and diamine oxidase (DAO) from supernatants of intestinal homogenates were assayed by spectrophotometric analysis.

RESULTS: Intragastrical administration of meloxicam (1.5 mg/kg) induced multiple intestinal lesions in AA rats. There was a significant decrease of intestinal DAO activities in AA+meloxicam group ($P < 0.01$) and AA model group ($P < 0.01$) compared with normal group. DAO activities of intestinal homogenates in AA+meloxicam group were significantly less than those in AA rats ($P < 0.01$). There was a significant increase of intestinal MPO activities in AA+meloxicam group compared with normal control ($P < 0.01$). Oral or nasal administration of CII (20 μ g/kg) could suppress the secondary hind paw swelling ($P < 0.05$ for oral CII; $P < 0.01$ for nasal CII), synovocyte proliferation ($P < 0.01$) and histopathological degradation in AA rats, but they had no significant effects on DAO and MPO changes. However, oral administration of CII (20 μ g/kg) showed the limited efficacy on arthritis in AA+meloxicam model and the curative effects of nasal CII (20 μ g/kg) were shown to be more efficient than that of oral CII (20 μ g/kg) both in AA model and in AA+meloxicam model ($P < 0.05$).

CONCLUSION: Oral administration of CII shows the limited efficacy on arthritis in AA rats with intestinal lesions, and nasal administration of CII is more efficient than oral administration of CII to induce mucosal tolerance in AA rats.

INTRODUCTION

Rheumatoid arthritis (RA) is a chronic autoimmune disease characterized by inflammation of the joints including proliferation of the synovium and progressive erosion of cartilages and bones^[1]. The goals of treatment include reduction of pain and inflammation, maintenance of functional ability, slowing of disease progression, and prevention of adverse effects of drugs^[2]. Administering antigens via a mucosal route has been recognized as a means to induce tolerance. The phenomenon of oral tolerance (OT) was first reported in 1911 by Wells^[3]. Further studies demonstrated that CII could suppress arthritis induced by adjuvant^[4], antigen^[5], pristane^[6] and collagen^[7] in mice and rats. Moreover, several clinical trials based on the results from those experimental animal systems, have been conducted to test the feasibility of using oral tolerance in the treatment of RA^[8,9]. However, it was reported that oral administration of CII in a low dose of 10 μ g for 10 times demonstrated a doubtful effect on murine collagen-induced arthritis (CIA) model^[10]. In clinical trials, oral administration of CII showed no efficacy in human arthritis given along with existing treatment^[11] and moreover, the Peyer's patches (pp) in the gut-associated lymphoid tissue (GALT) were considered to mediate oral tolerance^[12]. As we know, nonsteroidal anti-inflammatory drugs (NSAIDs) including meloxicam, which have been usually considered as the main drugs in the management of RA, could induce digestive lesions^[13,14], and it might be an important reason for the invalidation of oral administration of CII. Therefore, nasal administration of CII should be considered as an alternative.

Adjuvant arthritis (AA) in rats is an experimental model that shares some features with human RA, such as swelling, cartilage degradation and loss of joint function^[15]. In the present study, therefore, AA rats with or without intragastrically administration of meloxicam were used to compare the curative effects of oral and nasal administration of CII in rats with or without intestinal lesions. Based on the results of our report that oral administration of CII suppressed pro-inflammatory mediator production by synovocytes in rats with adjuvant arthritis from 5 to 500 μ g/kg^[12], we chose the single dose of 20 μ g/kg in the present study.

Diamine oxidase (DAO) is an intracellular enzyme with a high activity existing in intestinal villous cells and can catalyze the oxidation of diamines such as histamine, putrescine and cadaverine in both human beings and all other mammals. The activity of DAO in intestinal mucosa decreases when its cells are injured. Thus the determination of the DAO activity of intestinal mucosa can reflect the changes in its cellular integrity^[16]. Myeloperoxidase (MPO) plays a fundamental role in oxidant production by neutrophils and is considered to be a major effector in the tissue damage^[17]. In our studies, MPO and DAO were used as markers of intestinal dysfunction.

The purpose of the present study was to compare the curative effects of oral and nasal administration of CII in AA rats with or without intestinal lesions induced by meloxicam.

MATERIALS AND METHODS

Animals

Male Sprague-Dawley (SD) rats weighting 147 ± 25 g were purchased from Shanghai BK Experimental Animal Center (Grade II, Certificate No D-65). All rats were housed, five per cage and fed a standard laboratory chew and water and kept on a 12 h dark/12 h light cycle at a constant temperature of 20 ± 5 °C. All experimental protocols described in this study were approved by the Ethics Review Committee for Animal Experimentation of Institute of Clinical Pharmacology, Anhui Medical University.

Drugs and materials

Meloxicam (batch number 020401), nasal chicken CII (batch number 00031004) and oral chicken CII (batch number 00031002) were obtained from Shanghai Institute of Herb and Bio-medical Engineering and dissolved in sterile water containing 5 g/L carboxymethylcellulose (CMC-Na) solution. Dimethyl sulfoxide (batch number 000601) was obtained from Shanghai Vitriolic Factory. Bacillus Calmette Guerin (BCG) was obtained from Shanghai Biochemical Factory. Collagenase type II, trypsin, 3-(4,5-dimethylthiazol-2-thiazolyl)-2,5-diphenyl-2H tetrazolium bromide (MTT), RPMI 1640 medium, lipopolysaccharide (LPS), horseradish peroxidase, cadaverine dihydrochloride, diamine oxidase (DAO) and *O*-dianisidine were purchased from Sigma Chemical Co. (St. Louis, MO, USA).

Induction and evaluation of AA

Complete Freund's adjuvant (CFA) was prepared by suspending heat-killed BCG in liquid paraffin at 10 mg/mL. AA was induced by a single intradermal injection of 100 µL of CFA into the left hind paw. On d 0, 14, 16, 20, 24 and 28 after immunization, the right hind paw volume was measured with a water replacement plethysmometer (Mukomachi Kiai CD, Japan). Paw swelling (mL) was calculated by taking away the paw volume on d 0 from the related one on d 14, 16, 20, 24 and 28.

Drug treatment

The rats with AA were divided randomly into six groups which included AA model, AA model+meloxicam, AA model+oral CII, AA model+nasal CII, AA model+meloxicam+oral CII and AA model+meloxicam+nasal CII. From d 14 after immunization, the rats were fasted for 12 h and then treated with meloxicam (1.5 mg/kg body weight) intragastrically for 7 d. The rats in normal group, AA group, AA model+oral CII group and AA+nasal CII group, were treated with an equal amount of vehicle. From d 21 after immunization, the rats were treated with oral or nasal administration of CII (20 µg/kg body mass) for 7 d. The rats in normal group, AA group and AA+meloxicam group, were treated with an equal amount of vehicle.

Evaluation of intestinal lesions

Rats were sacrificed on day 29 after immunization. The small intestines were removed, spread out on filter paper and opened by a longitudinal incision along the antimesenteric side. The length and width of each lesion were observed and the extent of haemorrhage was also observed according to scale scores 0-2: 0, absence; 1, slight haemorrhage; 2, severe haemorrhage.

Synoviocyte proliferation

Synovial tissue from rat knees was excised and dispersed with sequential incubation of 4 g/L collagenase type II and 2.5 g/L trypsin and then synoviocytes were suspended in RPMI-1640

medium with 200 mL/L fetal bovine serum (FBS) at a concentration of 1×10^6 cells/mL. In 96-well plates, 100 µL of synoviocyte suspension (1×10^5 cells/well) was cultured in triplicate with 100 µL of LPS (10 mg/L) in RPMI-1640 medium (pH7.0) containing 200 mL/L heat-inactivated FBS, 100 U/mL penicillin, 100 g/L streptomycin, 2 mmol/L *L*-glutamine, 5×10^{-5} mol/L 2-mercaptoethanol and 25 mmol/L HEPES. After cultured for 48 h at 37 °C in humidified atmosphere containing 50 mL/L CO₂ in air, proliferation of synoviocytes was measured by the MTT colorimetric method^[18]. In brief, 48 h later, MTT was dissolved in phosphate buffered saline (PBS) at a dose of 5 mg/mL and added to all wells (10 µL/well), then the plates were incubated at 37 °C in humidified atmosphere containing 50 mL/L CO₂ for an additional 4 h. After incubation, the cells were centrifuged at 1000 r/min for 10 min and all the supernatants were discarded. Then 200 µL of dimethyl sulfoxide was added to each well, and the plates were read 30 sec later in an ELISA plate reader at a wavelength of 490 nm. The absorbance (*A*) of each well was regarded as the degree of synoviocyte proliferation.

Histological examination

The right legs and hind paws of rats were removed and fixed with 100 g/L paraformaldehyde in PBS, and then decalcified for 10 d with ethylene diamine tetraacetic acid (EDTA) and embedded in paraffin for histologic analysis. The paraffin sections were stained with hematoxylin and eosin. The slides were evaluated histologically by two independent observers, and the gradation of arthritis was scored from 0 to 4 according to the intensity of lining layer hyperplasia, mononuclear cell infiltration, and pannus formation, as described previously^[19]: 0, normal ankle joint; 1, normal synovium with occasional mononuclear cells; 2, definite arthritis, a few layers of flat to rounded synovial lining cells and scattered mononuclear cells and dense infiltration with mononuclear cells; 3, clear hyperplasia of the synovium with three or more layers of loosely arranged lining cells and dense infiltration with mononuclear cells; 4, severe synovitis with pannus and erosions of articular cartilages and subchondral bones.

MPO bioassay

Animals were sacrificed and their small intestines were flushed with 10 mL of sterile saline, followed by separation from bodies. After dried with filter paper, 0.5 g of intestinal specimens was weighed and placed in 5 mL of ice-cold potassium phosphate buffer (pH 6.0) with 5 g/L hexadecyl-trimethylammonium bromide. The specimens were homogenized for 20 s (2×10 s) and sonicated for 30 s (3×10 s) and centrifuged at 12000 g for 15 min at 4 °C. The supernatant was spectrophotometrically assayed for MPO activity by measuring the change in absorbance (at 460 nm) over time. The assay buffer consisted of 50 mmol/L potassium phosphate, pH 6.0 (50 mL), 0.83 mL of H₂O₂ (3 mL/L solution), and 8.34 mg of *O*-dianisidine hydrochloride. The supernatant was mixed at 1:80 (supernatant: assay buffer). MPO units were expressed as $\Delta A/(\text{min} \cdot \text{g})$.

DAO bioassay

Intestinal DAO activity was determined as follows. In brief, to 0.5 mL homogenate of intestinal specimens gained according to the above method or 0.5 mL diluted standard solution, 3 mL of PBS (0.2 mol/L, pH 7.2), 0.1 mL of horseradish peroxidase (4 µg), 0.1 mL of DAO (500 µg), and 0.1 mL of dianisidine were added. After mixed, the mixture was incubated in a water bath at 37 °C for 30 min, then the absorbance value at 436 nm (*A*₄₃₆) was recorded after rested for 5 min in the air. The DAO activities were calculated according to the standard curve. Protein activities of the tissue homogenates were determined with Lowry's method^[20]. DAO units were expressed as A/mg pro.

Statistical analysis

Results were expressed as mean \pm SD, and *t*-test was used to make comparisons between the groups. *P*<0.05 was considered statistically significant.

RESULTS

Intestinal lesions induced by meloxicam

As shown in Figure 1, intragastrical administration of meloxicam (1.5 mg/kg) for 7 d induced multiple intestinal lesions in AA rats. In normal control rats (Figure 1A), AA rats (Figure 1B), AA rats treated with oral CII (Figure 1D) and AA rats treated with nasal CII (Figure 1E), haemorrhage was not observed in antimesenteric side of small intestine (grade 0). In AA rats given meloxicam intragastrically (Figure 1C), AA+meloxicam rats treated with oral CII (Figure 1F) and AA+meloxicam rats treated with nasal CII (Figure 1G), severe haemorrhage was observed in antimesenteric side of small intestine (grade 2). After the animals were treated with oral or nasal administration of CII (20 μ g/kg) for 7 d, development of these lesions was not prevented.

Figure 1 Intestinal lesions induced by meloxicam. A: Normal control rats; B: AA rats; C: AA rats given meloxicam intragastrically; D: AA rats treated with oral CII; E: AA rats treated with nasal CII; F: AA+meloxicam rats treated with oral CII; and G: AA+meloxicam rats treated with nasal CII.

DAO activities in intestinal homogenates

The levels of DAO in intestinal homogenates are shown in Table 1. There was a significant decrease of intestinal DAO activities in AA+meloxicam group (*P*<0.01) and AA model group (*P*<0.01) compared with normal group. DAO activities of intestinal

homogenates in AA+meloxicam group were significantly less than those in AA rats (*P*<0.01). Oral or nasal administration of CII had no significant effects on DAO changes.

MPO activities in intestinal homogenates

The levels of MPO in intestinal homogenates are shown in Table 1. There was a significant increase of intestinal MPO activities in AA+meloxicam group compared with normal control (*P*<0.01). Oral or nasal administration of CII had no significant effects on MPO changes.

Table 1 Effects of oral and nasal administration of CII on activities of intestinal MPO and DAO in AA rats with or without intragastrical administration of meloxicam (*n* = 12, mean \pm SD)

Groups	DAO (A/mg pro)	MPO (Δ A/(min·g))
Normal	0.37 \pm 0.065	99.47 \pm 22.54
AA model	0.26 \pm 0.031 ^b	139.80 \pm 25.14
AA model+meloxicam	0.15 \pm 0.032 ^{ab}	165.42 \pm 21.27 ^b

^a*P*<0.05 vs AA model; ^b*P*<0.01 vs normal control.

Effects of oral or nasal administration of CII on secondary arthritis in AA rats with or without intragastrical administration of meloxicam

As shown in Table 2, secondary arthritis appeared on d 14, and maintained to d 28 after immunization in AA rats (*P*<0.01). In AA+meloxicam rats, hind paw secondary swellings were suppressed on d 20 (*P*<0.05). The hind paw secondary swellings were suppressed on d 20 in AA model+meloxicam +oral CII group and AA model+meloxicam+nasal CII group (*P*<0.05). Oral treatment with CII (20 μ g/kg body mass) significantly suppressed hind paw secondary swelling not only on d 24 and 28 in AA rats (*P*<0.05), but also on d 24 in AA rats with intestinal lesions induced by meloxicam (*P*<0.05). The effects of oral CII were more obvious in AA model than in AA model with intestinal lesions on d 28. While nasal treatment with CII at the same dose significantly suppressed hind paw secondary swelling on d 24 and 28 in both AA rats and AA rats with intestinal lesions (*P*<0.01). The effects of nasal CII in AA model were similar to those in AA+meloxicam model, and the effects of nasal CII were more efficient than those of oral CII both in AA model and in AA+meloxicam model (*P*<0.05).

Effects of oral or nasal administration of CII on synoviocyte proliferation in AA rats with or without intragastrical administration of meloxicam

As shown in Table 3, synoviocyte proliferation in AA rats and AA+meloxicam rats was increased ($P < 0.01$). Oral or nasal administration of CII (20 $\mu\text{g/kg}$) for 7 d significantly suppressed synoviocyte proliferation ($P < 0.01$) in AA rats. In AA rats with intestinal lesions, nasal administration of CII (20 $\mu\text{g/kg}$) could also significantly suppress synoviocyte proliferation ($P < 0.01$), while oral administration of CII at the same dosage suppressed synoviocyte proliferation at a lower degree ($P < 0.05$). There was a significant difference between degrees of synoviocyte proliferation in AA rats with intestinal lesions treated by oral CII and those in the same model treated by nasal CII ($P < 0.05$).

Table 3 Effects of oral and nasal administration of CII on synoviocytes proliferation in AA rats with or without intragastrical administration of meloxicam ($n = 12$, mean \pm SD)

Groups	Dose ($\mu\text{g/kg}$)	Synoviocytes proliferation (A_{490})
Normal	-	0.27 ± 0.024

AA model+meloxicam+nasal CII	20	0.25 ± 0.041^{bc}

^a $P < 0.05$ vs AA model; ^b $P < 0.01$ vs AA model; ^d $P < 0.01$ vs normal control; ^c $P < 0.05$ vs AA model+meloxicam+oral CII.

Effects of oral or nasal administration of CII on knee joint histopathology in AA rats with or without intragastrical administration of meloxicam

In normal rats, synoviocytes were monolayer (Figure 2A). In AA rats, synoviocytes proliferated three to eight layers and

became ovalis types, and articular cartilages were destructed and infiltrated with inflammatory cells. The hyperplastic synovial membranes in AA rats formed a large number of fibroblasts and new blood vessels. Proliferation of collagen fibrils was found under synovial membranes of AA rats (Figure 2B). In AA rats given meloxicam intragastrically, knee joint histopathology was similar to that in AA rats (Figure 2C). In AA rats treated with oral CII, hyperplastic synoviocytes decreased to two or three layers (Figure 2D). In AA rats treated with nasal CII, a few of hyperplastic fiber cells under synovial membranes could be found (Figure 2E). In AA+meloxicam rats treated with oral CII, synovial hyperplasia was observed and articular cartilages were destroyed and infiltrated with inflammatory cells (Figure 2F). In AA+meloxicam rats treated with nasal CII, a few of hyperplastic fiber cells under synovial membranes and partially reversed articular cartilage destruction could be found (Figure 2G).

Oral or nasal administration of CII could ameliorate the pathologic changes in AA rats or AA+meloxicam rats, but oral administration of CII showed limited efficacy on suppressing the histopathological degradation in AA model with intestinal lesions.

DISCUSSION

In this study, it was found that intragastric administration of meloxicam (1.5 mg/kg) could induce multiple intestinal lesions in AA rats. The activities of DAO in intestinal homogenates were decreased and the activities of MPO were increased. Oral or nasal administration of CII at a dose of 20 $\mu\text{g/kg}$ could suppress secondary hind paw swelling, synoviocyte proliferation and histopathological degradation in AA model and AA+meloxicam model. Moreover, oral administration of CII showed the limited efficacy on arthritis in AA+meloxicam model and curative effects of nasal CII were shown to be more efficient in comparison with oral CII both in AA model and AA+meloxicam model.

Just like RA, AA is a chronic disease and the ongoing disease can be blocked using antibodies to T cells. They are associated with major histocompatibility complex (MHC) and the primary inflammatory attack is directed to diarthrodial peripheral joints^[21].

Thus, development of mucosal tolerance methods for treatment of RA is suitable and could be found successfully both in humans^[22,23] and in animal models induced with various heterologous antigens^[4-6,24]. Histopathological study showed that oral administration of CII resulted in reduction of synovial hyperplasia, mononuclear infiltration, pannus formation and cartilage erosions^[6]. Results from the present study also showed that oral CII suppressed secondary paw swelling, synoviocyte proliferation and histopathological changes in AA rats. Furthermore, clinical studies with oral administration of heterologous CII in RA were carried out and had disputable results^[8,22]. Barnett *et al.*^[25] found that very low doses tended to give an overall ameliorative effect, whereas higher doses were negative. In addition, intranasal administration of CII could ameliorate ongoing arthritis in pristane-induced arthritis (PIA), collagen-induced arthritis (CIA) and AA^[26]. The use of nasal instead of oral administration of the autoantigens has been shown to be more efficient and to require lower tolerogen doses, as demonstrated in several models including CIA in mice^[27]. It was also demonstrated that nasal administration of CII in murine CIA model more efficiently inhibited the induction of CIA and CII-specific immune responses than oral administration^[10]. Our present study indicated that nasal CII could suppress secondary paw swelling, synoviocyte proliferation and histopathological changes in AA rats and was superior to oral CII.

Meloxicam is a NSAID belonging to the enolic acid group of the oxicam family^[28]. As a cyclooxygenase -2 inhibitor, meloxicam has been considered with a good gastric tolerance^[29,30]. But it was also reported that meloxicam could induce gastric lesions^[31]. Neutrophils, which secrete MPO, appear to be the main effector cells in meloxicam-induced small intestinal damage^[32]. On the other hand, there are two major mechanisms which have been put forward to explain the oral tolerance: active suppression or the antigen specific induction of regulatory cells and T cell clonal anergy/deletion^[33,34]. Cells from PP in GALT were reported to mediate the induction of active suppression^[35]. PP cell dysfunction induced by NSAIDs might be the main mechanism of the limited therapeutic effects of oral CII in the suppression of RA in clinical trials. So far, there are few reports to determine it.

In our study, we found that meloxicam (1.5 mg/kg) could induce multiple intestinal lesions in AA rats, and in this model, the activities of DAO were decreased and the activities of MPO were increased. We also found that meloxicam had little effect on AA rats from d 24. These results also indicated that there was a functional turbulence in intestinal systems of AA rats. Furthermore, we found that the effects of oral CII were more obvious in AA model than in AA model with intestinal lesion induced by meloxicam. However, the effects of nasal CII were not influenced by meloxicam in AA rats with intestinal lesions. The results suggested that nasal CII was more efficient than oral CII both in AA rats and in AA rats with intestinal lesions.

In conclusion, at the dose of 20 µg/kg, oral administration of CII has a limited efficacy on arthritis in AA+meloxicam model and the effects of nasal administration of CII on AA are more efficient than that of oral administration of CII both in AA rats and in AA rats with intestinal lesions induced by meloxicam.

Abstract

AIM: A low vessel density is a common feature of malignant tumors. We suggested that the expansion of vessel diameter might reconstitute the oxygen and nutrient's supply in this situation. The aim of the present study was to compare the number and diameter of blood vessels in pancreatic and liver carcinoma with normal tissue.

METHODS: Tumor induction of pancreatic (DSL6A) or hepatocellular (Morris-hepatoma) carcinoma was performed in male Lewis (pancreatic cancer) and ACI (hepatoma) rats by an orthotopic inoculation of solid tumor fragments (pancreatic cancer) or tumor cells (hepatoma). Six weeks (pancreatic cancer) or 12 d (hepatoma) after tumor implantation, the tumor microvasculature as well as normal pancreatic or liver blood vessels were investigated by intravital microscopy. The number of perfused blood vessels in tumor and healthy tissue was assessed by computer-assisted image analysis.

RESULTS: The vessel density in healthy pancreas (565 ± 89 n/mm²) was significantly higher compared to pancreatic cancer (116 ± 36 n/mm²) ($P < 0.001$). Healthy liver showed also a significantly higher vessel density (689 ± 36 n/mm²) compared to liver carcinoma (286 ± 32 n/mm²) ($P < 0.01$). The comparison of diameter frequency showed a significant increase of vessel diameter in both malignant tumors compared to normal tissue ($P < 0.05$).

CONCLUSION: The expansion of endothelial cells during tumor angiogenesis is accompanied to a large extent by an increase of vessel diameter rather than by formation of new blood vessels. This may be a possible adaptive mechanism by which experimental pancreatic and hepatocellular cancers expand their endothelial diffusion surface of endothelium to compensate for inadequate neoangiogenesis.

INTRODUCTION

Angiogenesis, defined as proliferation of endothelial cells and

subsequent formation of new blood vessels from pre-existing vessels, is a characteristic feature of numerous pathological processes, including cancer^[1,2]. Tumor growth depends on a continuous blood supply to cover increasing requirements for nutrients and oxygen. During tumor neovascularization, new capillaries are recruited from the existing microvasculature, a process that is controlled by positive and negative regulators of blood vessel growth^[3]. In contrast to the angiogenesis occurring in wound healing, the tumor angiogenesis is characterized by a discordance between pro- and anti-angiogenic factors. This discordant process of tumor angiogenesis leads to the formation of a microvascular system with a typically distorted vessel architecture^[4,5], and consequently irregular flow patterns and heterogeneous oxygen supply^[6,7] resulting in hypoxia^[8,9]. These parameters contribute to a unique tumor microenvironment which in turn modulates the therapeutic responsiveness of solid tumors, e.g., towards chemotherapeutic agents or radiation therapy^[10,11].

Our previous studies reported that the increased vessel diameter was an important feature of tumor microangiarchitecture in pancreatic^[12] and hepatocellular^[13] cancer of the rat. This feature was not only specific for transplantable tumor models and was found in spontaneous pancreatic tumors in transgenic mice^[14]. We showed that the vessel dilation was the first detectable stage of ongoing angiogenesis during multistep tumorigenesis which preceded vessel sprouting^[14]. These observations encouraged us to start a detailed investigation of tumor blood vessels by a combination of different techniques including intravital microscopy and immunohistochemistry. We hypothesized that the vessel dilation indicated a possible adaptive process, which may help the tumor to expand their diffusion surface of endothelium and to compensate for the inadequate supply with oxygen and nutrients. In the present study, we used intravital microscopy and immunohistochemistry to investigate this phenomenon in normal and malignant pancreatic tissues as well as in hepatic tissue of rats. The present study demonstrated that the decrease of vessel density in experimental pancreatic and liver carcinoma was accompanied with an increase of vessel diameter.

MATERIALS AND METHODS

Tumor inoculation

Established cell lines of pancreatic duct-like (DSL6A)^[15] and hepatocellular carcinoma (Morris-hepatoma MH-3924A)^[13] of rats were used. Since the expression profile of tumor cells was strongly dependent on the site of growth, e.g. implantation^[16,17] we decided to inoculate the tumors orthotopically which ensured the appropriate microenvironment for tumor cell growth. Twelve male Lewis rats (160-180 g) were used for the inoculation of pancreatic carcinoma. Hepatocellular carcinomas were inoculated on 12 male ACI rats (220-250 g). Each animal was anesthetized with intramuscular injection of xylazine (10 mg/kg, Rompun®, Bayer, Leverkusen, Germany) and ketamin (40 mg/kg, Ketanest®, Parke Davis, Berlin, FRG).

Tumor implantation was performed as previously described

for pancreatic^[12] and hepatocellular^[13] carcinoma. For the inoculation of pancreatic cancer, two sterile polymethylmethacrylate (PMMA)-plates (Ø 11 mm, Glasflex, Stirling, NJ, USA) were applied in "sandwich-technique" on both sides of the pancreatic head. The tumor of approximately 1 mm³ was harvested from a subcutaneous parent tumor of a syngeneic rat and interposed intrapancreatically between the plates. Hepatocellular carcinomas were induced by a subcapsular injection of tumor cells (Morris hepatoma MH-3924A, 0.01 mL, 0.5×10⁶ cells) into the left upper liver lobe. Major steps of both models are summarized in Table 1.

Table 1 Summary of tumor models used in present study

	Pancreatic cancer	Hepatocellular cancer
Tumor cell line	DSL6A	Morris hepatoma 3924A
Syngeneic strain	Lewis	ACI
Tumor inoculation	Solid tumor fragment	Cell suspension
Time after inoculation	6 wk	12 d

Intravital microscopy
