Intravital microscopy was performed 12 d after inoculation for hepatocellular carcinoma and 6 wk after inoculation for pancreatic cancer when tumors reached a diameter of 8-10 mm. All animals were re-anaesthetized as described above. A teflon catheter (I.D. 0.5 mm, B.Braun AG, Melsungen, FRG) was inserted into the right internal jugular vein for venous access. Another catheter was placed into the left carotid artery for blood sampling and monitoring of cardiovascular parameters. The abdomen was opened by midline incision. The animal was placed on a special stage automatically maintained at 37 °C. The tumor was macroscopically identified. The tumor bearing pancreatic head was immobilized in a temperature-controlled (37 °C) immersion chamber containing Ringer's solution. For the intravital microscopy of hepatocellular carcinoma, the tumor bearing liver lobe was placed on a rubber stage and superfused with Ringer's solution (37 °C).

For intravital microscopy, the entire preparation was placed under a fluorescence microscope (Leica GmbH, Wetzlar, FRG). The fluorescence filter with excitation 450-490 nm and emission 520 nm was used. After the preparation was completed, all animals received an intravenous injection of 50 mg/kg of FITC-labeled albumin (Sigma Chemicals Co., St. Louis, MO, USA) dissolved in 1 mL saline. This fluorescent plasma marker ensured the maximal contrast of blood vessels and was utilized for the measurement of vessel diameter and vessel density. The microcirculatory images were transmitted by a video camera (CF 8/1, Kappa GmbH, Gleichen, FRG) to a monitor (PVM-1440 M, Sony, Tokyo, Japan) and recorded on a videorecorder (sVHS, AG-7 350-E, Panasonic, Osaka, Japan) for subsequent off-line analysis. After the experiment, the tumors and a fragment of normal tissue were harvested and frozen immediately in liquid nitrogen. The evaluation of vessel diameter and density in tumor microcirculation and in normal tissue was performed using special software (Capimage®, Zeintl GmbH, Heidelberg, FRG). The number of blood vessels was calculated on 3-4 randomly chosen fields and expressed as per 1 mm² of tumor surface.

Immunohistochemistry

After intravital microscopy, the tumors were removed for further histological analysis. The tissue was snap frozen in liquid nitrogen. Five µm thick sections were cut, air-dried and fixed in acetone. Immunohistochemical staining of endothelium was performed using monoclonal antibodies recognising RECA-1 rat endothelial antigen (Clone HIS52, Serotec, Germany) and the LSAB-kit (Dako, Hamburg, Germany). In addition, the slides were counterstained with Mayer's acid hemalum (Fluka, Steinheim, Germany). Quantitative analysis of immunohistochemical staining was performed by computer-assisted image analysis. For this aim, three microscopic fields of 3.18 mm² were randomly chosen by light microscope (Leica DMRB, Leica GmbH, Germany),

digitalized by a colour video camera (CF 20/4DX, Kappa GmbH, Gleichen, Germany) to histological images and saved on a computer. The number of blood vessels was counted and expressed as per 1 mm² of surface.

Statistical analysis

All data were given as mean±SD. Mann-Whitney-U test was used to compare the differences between groups as appropriate. *P*<0.05 was considered statistically significant.

RESULTS

The intravital microscopy after injection of fluorescent plasma marker ensured the excellent contrast of all blood vessels in normal (Figure 1A, E) and in tumoral (Figure 1B, F) tissues. The microvascular system in healthy pancreas showed a capillary network of high density, the single afferent and efferent blood vessels were identified within normal pancreatic tissue (Figure 1A). Healthy liver showed a dense network of hepatic sinusoids which were drained by hepatic venules (Figure 1E). In contrast, the microangioarchitecture of both pancreatic and hepatocellular carcinomas was characterized by lost of normal vascular hierarchy "capillaries-arterioles (sinusoids)-venules", chaotic arrangement of blood vessels, irregular vessel diameters and formation of lacunar blood vessels (Figure 1B, F). In contrast to vascular systems of normal pancreatic and hepatic tissues, there were no specific features discriminating the microangioarchitecture of pancreatic cancer from that of hepatocellular carcinoma (Figure 1).

The measurement of vessel density either by intravital microscopy or by immunohistochemistry demonstrated different results (Tables 2, 3). The vessel density of all tissues measured by intravital microscopy was significantly higher than that measured by immunohistochemistry (*P*<0.05, Tables 2, 3). The vessel density in healthy pancreas was significantly higher compared to pancreatic cancer (*P*<0.001, Table 2). Healthy liver showed also a significantly higher vessel density compared to liver carcinoma (*P*<0.01, Table 3). The low vessel density of both pancreatic and hepatocellular carcinomas was accompanied with the development of tumor necrosis, which appeared frequently in the central area of the tumors and represented a characteristic feature of the tumors showing a cross-sectional diameter of more than 10 mm as opposed to smaller tumors.

Table 2 Vessel density in normal and malignant tissue

Vessel density (n/mm ²)	Healthy pancreas	Pancreatic cancer	<i>P</i>
Intravital microscopy	565±89	116±36	<0.001
Immunohistochemistry	91±22	35±10	<0.001

Table 3 Vessel density in normal and malignant liver tissue

Vessel density (n/mm ²)	Healthy liver	Liver carcinoma	<i>P</i>
Intravital microscopy	689±36	286±32	<0.01
Immunohistochemistry	196±30	49±13	<0.01

The frequency analysis of vessel diameters showed that the most frequent diameters in normal pancreas and liver were considerably smaller compared to the most frequent diameters in pancreatic and hepatocellular carcinomas (Figures 2, 3). Ninety-four percent of blood vessels in normal pancreas, 41% of blood vessels in pancreatic carcinoma and less than 9% of blood vessels in non-malignant and malignant hepatocellular tissues showed a diameter less than 10 µm. The most frequent diameter was between 10 and 20 µm (59%) in pancreatic carcinoma and more than 20 µm in hepatocellular carcinoma (59%).

Figure 1 Microangiarchitecture investigated by intravital microscopy and immunohistochemical staining of endothelium of normal pancreas (A,B), liver (E,F), pancreatic (C,D) and hepatocellular (G,H) carcinoma: The microvascular system in healthy pancreas showed a dense network mainly consisting of capillaries in normal pancreas (A) and sinusoids in the liver (E). Both pancreatic (B) and hepatocellular (F) carcinomas showed a chaotic angioarchitecture with irregular diameter of blood vessels. Either intravital microscopy or immunohistochemical staining of endothelium turn up lower density and higher diameters of microvessels in both tumor types than in corresponding normal tissue (bar 50 μm).

Figure 2 Frequency of vessel diameter in normal pancreas and experimental duct-like pancreatic carcinoma (DSL6A) ■-normal pancreas, □-pancreatic carcinoma.

Figure 3 Frequency of vessel diameter in normal liver and experimental hepatocellular carcinoma (Morris-hepatoma) ■-normal liver, □-hepatocellular carcinoma.

DISCUSSION

Using intravital microscopy, we investigated the microvascular systems of pancreatic and liver carcinoma and performed a quantitative analysis of vessel density and vessel diameter. The present study demonstrated that the mean vessel density in both types of experimental malignant tumors was lower than that in the corresponding normal tissues. This hypovascularity was regarded as a main cause of hypoxia in tumor tissue which is responsible for the development of necrotic areas within solid tumors^[8,11] as it has been observed in the present models of pancreatic and hepatocellular carcinoma once diameters exceeded 10 mm. However, as it was shown in the present study, tumor angiogenesis could compensate in part for this insufficient vascularisation by other mechanisms than growth of new blood vessels. Although vessel sprouting has been accepted as the main mechanism of angiogenesis, some pathological processes might display an angiogenic phenotype characterized by an extensive vessel dilatation^[18,19]. Previous data demonstrated in a model of multistep tumorigenesis in mouse malignant insulinoma^[14] and in the model of thyroid hyperplasia^[18] that vessel dilatation was the first detectable stage of ongoing angiogenesis which preceded vessel sprouting and extended transformation of the cells. The results of the present study allowed to transfer these findings to solid murine tumors and demonstrated that the “non-sprouting” angiogenesis might accompany vessel sprouting during growth of solid pancreatic and hepatocellular cancer in rats. We suggested that the observed vessel dilatation during tumor development and growth could cause an increase of endothelial surface for the diffusion of oxygen and nutrition, representing a possible adaptive mechanism to compensate for the insufficient vascularisation.

In the present study, both tumor types were induced by an implantation of tumor cells and did not arise spontaneously. It is known that tumor blood vessels in transplantable tumor models develop from surrounding tissues^[20,21], whereas the growth of autochthonous blood vessels forms the vascular system in spontaneous tumors^[22,23]. However, the vessel dilatation as an initial step of the vascular transformation has been reported previously in spontaneous tumor model also and seems to be a feature which is likely to be a common feature in both transplanted and spontaneous tumors.

In a previous study we analysed the percentage of vascular surface of pancreatic cancer DSL6A which was performed on histological sections using intravascular perfusion with a fluorescent-labeled plasma marker^[12]. In the present study, the number of blood vessels per mm² was investigated by intravital microscopy and immunohistochemistry. The values of vessel density obtained by these analyses corresponded well and both showed a significantly lower microvascularity of malignant tumors compared to normal tissues. The vessel density investigated by intravital microscopy was higher than that by immunohistochemistry. Since the optical depth of tissue accessible for the intravital microscopy (30-50 µm) is considerably higher than the thickness of histological sections (5 µm), the difference between the results of intravital microscopy and immunohistochemistry finds its logical explanation.

In summary, we compared the vessel density and vessel diameter of two experimental tumors by intravital microscopy. The present study demonstrates that the vessel dilatation is an integral part of the angiogenic activity which represents a possible mechanism by which the tumors expand their diffusion surface of endothelium to compensate for the inadequate neoangiogenesis.

Abstract

AIM: Transcystic biliary decompression (TCBD) has been proposed as an alternative to T-tube placement after laparoscopic choledochotomy (LCD). This permits safe primary closure of the choledochotomy and eliminates the complications associated with T-tubes. TCBD tube has been secured by Roeder knots and transfixation, and removed later than 3 wk after surgery. We presented a modified TCBD (mTCBD) method after LCD using the ureteral catheter and the Lapro-Clip (David and Geck, Danbury, Connecticut, USA), and compared it with T-tube drainage.

METHODS: Between October 2002 and June 2003, patients with choledocholithiasis undergoing LCD with mTCBD (mTCBD Group, $n = 30$) were retrospectively compared to those undergoing LCD with T-tube drainage (T-tube Group, $n = 52$) at a single institution.

RESULTS: There were no significant differences in operative time and retained stones between the two groups. Patients in mTCBD group had a significantly decreased average output of bile compared with those in T-tube group (306 ± 141 vs 409 ± 243 mL/24 h, $P = 0.000$). Removal of drain tubes in mTCBD group was done significantly earlier than that in T-tube group (median, 5 vs 29 d, $P = 0.000$). No complication related to drain tubes was found in mTCBD group, and morbidity rate with the T-tube was significantly higher (11.5%), and bile leakage following T-tube removal was 5.8%.

CONCLUSION: A modified TCBD after LCD is safe, effective and easy to perform. It may reduce postoperative complications, especially bile leakage.

INTRODUCTION

Laparoscopic choledochotomy (LCD) has been proposed as an efficacious, safe, and cost-effective method for the treatment of choledocholithiasis^[1-6]. However, it is associated with a relatively higher morbidity rate, mainly related to T-tube insertion^[7,8]. To eliminate the complications related to T-tubes, some authors have proposed transcystic biliary decompression (TCBD) after LCD, but the TCBD tube is still removed later

than 3 wk after surgery^[9,10], limiting the value of the procedure. We presented a modified TCBD (mTCBD) method using ureteral catheter and Lapro-Clip, and compared it with T-tube drainage.

MATERIALS AND METHODS

Patients

Eighty-two patients with choledocholithiasis undergoing LC plus laparoscopic choledochotomy were retrospectively reviewed at a single institution, between October 2002 and June 2003. mTCBD was performed for 30 patients (mTCBD group) and T-tube drainage for 52 patients (T-tube group). The clinical and demographic details are shown in Table 1. There were no significant differences between the groups. Preoperative investigations included liver function tests and external ultrasound. Six patients had ERCP or MRCP in the mTCBD group, and three in the T-tube group. The criteria for preoperative suspicion of CBD stones were serum alkaline phosphatase or bilirubin levels twice the upper normal limit, and an ultrasonic diameter of the CBD equal to or larger than 9 mm. Patients with acute cholecystitis underwent an operation within 48 h admission. Those with choledocholithiasis associated with acute pancreatitis were operated on after the acute bout of pancreatitis was subsided. The patients were restricted to the American Society of Anesthesiology class I and class II (ASA I and II). Cases were excluded if preoperative and intraoperative endoscopic sphincterotomy (ES) were performed. Two patients had previous biliary surgery in the mTCBD group, and three in the T-tube group.

Table 1 Clinical and demographic details of the patients

	mTCBD ₁	T-tube
<i>n</i>	30	52
Age range(yr)	28-77	26-82
Male:female	12:18	17:35
Jaundice	12	16
Acute cholecystitis	9	13
Acute pancreatitis	3	5
Known CBD stone (s)	16	37
Suspected CBD stone (s)	11	13
Dilated CBD (≥ 9 mm)	18	35
Biliary surgery	2	3

¹Modified transcystic biliary decompression.

Operative techniques

Laparoscopic cholecystectomy was performed by a standardized technique. One 10 mm port was inserted into the left upper quadrant. Intraoperative cholangiography (IOC) was mandatory. Choledochotomy was performed by a vertical incision. CBD stones were retrieved by instrumental exploration with forceps, flushing of CBD with saline, and use of a Dormia basket with a 5 mm chledochoscopy.

Modified transcystic biliary decompression (mTCBD) After complete clearance of the CBD, which was primarily closed with a running suture (3-0 vicryl). A 5Fr ureteral catheter was advanced into the CBD lumen 2 cm to 4 cm and a saline syringe was attached to the three-way stopcock external fitting of the catheter. If the position of the terminal segment of the ureteral

catheter inside CBD was correct, the catheter was fixed to the cystic duct by a 12 mm absorbable Lapro-Clip (Figure 1). Saline irrigation through the catheter was maintained during application of the Lapro-Clip to prevent overtightening the catheter. A loose loop of the catheter was left. A completion IOC was performed to confirm the correct position of the ureteral catheter, also to ensure the adequate closure of the CBD and free flow of contrast into the duodenal lumen. A postoperative cholangiogram was performed on d 3 to 7 after surgery. Under fluoroscopy, the catheter was removed.

T-tube drainage A latex rubber T-tube of appropriate size (12-16 Fr) was inserted completely into the abdomen. The T limbs were advanced with grasping forceps into the choledochotomy. After proper positioning, the choledochotomy was closed using interrupted sutures (3-0 vicryl). T-tube clamping was carried out 7-10 d postoperatively. A postoperative cholangiogram was performed 3 to 4 wk after surgery. If the examination was normal, the T-tube was removed. If retained stones were shown, the T-tube was left for another 3 to 4 wk. A No. 10 Jackson-Pratt drain was placed in the subhepatic space for all patients. The subhepatic drain tube was removed on the 3rd d for most of patients.

Five surgeons performed the 82 laparoscopic choledochotomies. In the mTCBD group, one senior author performed 25 of 30 procedures, whereas the remaining 5 procedures by one junior staff member. In the T-tube group, three senior staff performed 47 of 52 procedures, whereas 7 procedures by two junior members.

The output of bile was measured only during the hospital stay. The data recorded were insufficient in the case notes to compare the number and size of CBD stones, and postoperative liver function test.

A “drain complication” was defined as an event causing morbidity, requiring medical intervention, or resulting in a prolonged admission or requiring readmission. The complication had to be clearly related to the presence or removal of the drain.

Statistical analysis

Statistical analyses were performed using Student's *t* test, chi square test for likelihood ratio, and Mann-Whitney test for nonparametric data. Significance was set at the 5% level.

Figure 1 A 5 Fr ureteral catheter was placed for biliary decompression and secured with a 12 mm absorbable Lapro-Clip.

RESULTS

Outcome of mTCBD group

The average operative time was 178 ± 34 min (Table 2). There were two conversions to open surgery (6.5%). One patient had large impacted stones, and the other had multiple stones. The modified transcystic biliary decompression (mTCBD) was also used in those patients. The average output of bile via the ureteral catheter was 306 ± 141 mL/24 h. The median postoperative time of drain removal was 5 (range 4 to 5) d. Under fluoroscopy, the catheter could be pulled out easily from the cystic duct without any bile leakage or slippage of the Lapro-Clip (Figure 2). No patients developed complications from ureteral catheter occlusion. The median postoperative hospital stay was 5 (range 4 to 6) d.

Table 2 Comparison of clinical outcome between two groups

	mTCBD	T-tube	<i>t</i> or χ^2 (z)	<i>P</i>
Operative time (min)	178	173	-0.469	0.640 ²
Output of bile (mL/24 h)	306	409	2.118	0.037 ²
Postoperative stay(d)	5.4-6 ¹	4.4-6 ¹	(-2.060)	0.039 ⁴
Drain removal (d)	5.4-5 ¹	29.22-32 ¹	(-7.560)	0.000 ⁴
Complications (%)	0	11.5	5.736	0.017 ³
Retained stones (%)	3.3	13.5	2.574	0.109 ³
Convert to open (%)	6.5	3.8	0.315	0.575 ³

¹Median, 25-75% quartile range; ²*t*-test; ³Chi square test with Likelihood Ratio; ⁴Mann-Whitney test.

One patient (3.3%) had unexpected retained stones, requiring endoscopic sphincterotomy (ES). Two patients had problems. The ureteral catheter was dislocated with the biliary tree not shown in the postoperative cholangiogram, but there was no bile leakage.

Outcome of T-tube group

The average operative time was 173 ± 45 min (Table 2). There were two conversions to open surgery (6.5%). Two patients had large impacted stones. The average output of bile via T-tube was 409 ± 243 mL/24 h. The median drain removal time was 29 (range 22 to 32) d. The median postoperative hospital stay was 4 (range 4 to 6) d.

Seven (13.5%) had retained stones (Table 4). There were intentionally retained stones in 5 patients (9.6%), 2 with intrahepatic duct stones, 1 with multiple common duct stones because of difficulty in removing them laparoscopically, and another 2 patients with temporary unavailability of the choledochoscope. There were unexpected residual stones in 2 patients (3.8%). All of the stones were successfully removed, 5 patients through the T-tube tract, using a choledochoscope, and a stone basket. The T-tube was taken out in two patients prior to planned removal, thereby requiring ES.

Table 3 Complications and problems of biliary drainage

Table 4 Retained stones in T-tube group

	<i>n</i> (%)
Known stones	5 (9.6)
Instrument problems	2
Intrahepatic stones	2
Multiple stones	1
Unexpected stones	2 (3.8)
Total	7 (13.5)

Figure 2 A ureteral catheter was pulled out without bile leakage. The cystic duct was closed with the Lapro-Clip.

Postoperative complications occurred in 6 patients (11.5%) (Table 3). Following T-tube removal, three patients had significant bile leakage (5.8%). Two patients developed severe abdominal pain, sweating and tachycardia and were diagnosed as localized bile collection. They were treated with antibiotics, parental fluids, analgesia, and the drain tube was reinserted through T-tube sinus tract. Recovery was achieved with this management. The third patient developed biliary peritonitis and required open drainage.

One patient had a CBD stricture and T-tube stenting was necessary for 3 mo. In the other patient the T-tube was pulled out on the second day after surgery and the subhepatic suction drain provided biliary drainage for two weeks postoperatively.

Other related morbidity was found in one patient with a bile leak around the T-tube. In addition, the tip of the T-tube in one patient was dislocated from the bile duct, but caused no problem.

Comparison of clinical outcome between two groups

The statistical analyses comparing the mTCBD group with the T-tube group are presented in Table 2. There were no significant differences in operative time and retained stones. Patients in mTCBD group had a significantly decreased average output of bile compared with those in T-tube group ($P = 0.000$). The biliary drainage tube in the mTCBD group was removed significantly earlier than that in the T-tube group ($P = 0.000$). No morbidity was directly related to drain tube in the mTCBD group, and the morbidity rate in the T-tube group was significantly higher (11.5%, $P = 0.017$). However, the postoperative hospital stay in the mTCBD group was significantly longer compared with that in the T-tube group ($P = 0.039$).

There was no postoperative mortality or recurrence of choledocholithiasis in this study. The length of follow-up was 4 to 30 wk.

DISCUSSION

Previous studies have documented a temporary obstruction at the lower end of the CBD due to sludge, fibrin debris, or edema following manipulations to extract duct calculi or retained stones in the first few days after surgery^[9,11-16], thus temporary decompression is advisable in the prevention of postoperative bile leakage. A transcystic biliary decompression (TCBD) tube, like a T-tube, could achieve biliary decompression and has the advantage of avoiding the well-known complications of T-tubes. A TCBD tube was secured to the cystic duct with two Roeder knots or a transfixing suture. The biliary drainage tube must be kept in place for 2-4 wk^[9,10]. This might not be easy to manipulate, and could reduce the benefits of the minimal access approach.

In October 2002, a modified TCBD (mTCBD) was placed followed by primary closure of the CBD. The ureteral catheter was inserted down into the CBD and once in the correct position, the cystic duct was clipped by a 12 mm Lapro-Clip. The Lapro-Clip has a two-part compression closure mechanism, the inner flexible track piece could close around the cystic duct, and rigid

outer body could then slide over the track piece to secure the cystic duct^[17]. The ureteral catheter was pulled out easily with no bile leakage and the cystic duct was closed automatically with the Lapro-Clip even if drain displacement occurred.

In mTCBD group, no bile leakage was related to drain tube removal, and median time for ureteral catheter removal was 5 (range 4 to 5) d. The ureteral catheter in two patients was dislocated, this also caused no bile leakage.

Complications related to T-tubes were reported to occur between 5-15.3%^[7,18,19]. Biliary leakage following removal was the most serious. Incidence of bile leak was 4.12-6.9%^[19,20]. There was no difference when laparoscopic cases were compared to open and converted cases for overall complications (13.8% vs 15.5%) or for bile leakage after planned tube removal (6.9% vs 6.9%)^[19].

In our study, postoperative complications in the T-tube group occurred in 6 patients (11.5%) (Table 3). Following T-tube removal, 3 patients developed bile leakage (5.8%). The T-tube was left in the three patients for three weeks postoperatively. Sinus tract formation of the T-tube might need a longer time because of the less reaction of laparoscopic approach^[21-23]. Bile leakage was inevitable with accidental T-tube dislocation^[7,18-20]. The median time for T-tube removed was 29 (range 22 to 32) d, even if cases of retained stones were excluded. The data suggest that placement of T-tube may require a longer time than 4 wk.

Biliary drainage with a TCBD tube and primary closure of the choledochotomy were indicated only for patients whose stones were completely extracted at the time of surgery. Routine intraoperative cholangiogram and chledochoscopy were used in the laparoscopic approach, and the occurrence of retained stones was decreased to accepted levels^[7,24,25]. Endoscopic sphincterotomy could be a back up procedure for retained stones^[25,26]. In the mTCBD group, one patient (3.3%) had unexpected retained stones retrieved by ES.

If there was any possibility of residual stones, T-tube placement was mandatory for postoperative choledochoscopy. Five patients (9.6%) in the T-tube group had intentionally retained stones (Table 4). T-tube placement may be needed for another 3-4 wk^[21-23], in order to form a mature tract. It was worthwhile without any injury to the sphincter of Oddi, and complete removal could be expected.

Although patients in the mTCBD group had a significantly decreased average output of bile compared with those in the T-tube group (306 ± 141 vs 409 ± 243 mL/24 h, $P = 0.000$), it was shown that enough output of bile led to a decrease in the biliary pressure. Consequently, this finding suggested that the output of bile from mTCBD was sufficient to decompress the biliary tract as T-tube. On the other hand, the T-tube drain mostly was clamped on d 7 to 10, which means that many patients were discharged with an open drain.

The postoperative hospital stay in mTCBD group was significantly longer compared with that in T-tube group (median, 5 vs 4 d, $P = 0.039$). It may relate to the drain removal during hospitalization because of our initial trial for the mTCBD.

A modified TCBD is not suitable for patients with abnormal anatomy of cystic duct, intrahepatic duct stones and stricture of duodenal papillary.

The chief concern of the Lapro-Clip is the occlusion of the catheter. Maintaining saline irrigation through the ureteral catheter prevents occluding. We also feel that the diameter of the ureteral catheter is an important factor for avoiding occlusion or dislocation, so a 5Fr ureteral catheter is most suitable. We used a 5Fr ureteral catheter in all mTCBD cases.

A 12 mm Lapro-Clip holds the cystic duct tightly to a 5Fr ureteral catheter while the spring of the Lapro-Clip closes the cystic duct when the ureteral catheter is removed. In this study, no slippage of the clip occurred. The short period of TCBD could reduce the risk of ureteral catheter occlusion. No patients

in the present study developed catheter occlusion.

Our results were similar to the use of exclusive C-tube and elastic thread described by some authors^[27-30]. Our initial experiences demonstrated that the modified transcystic biliary decompression (mTCBD) after laparoscopic choledochotomy (LCD) was useful for decreasing postoperative complications, especially bile leakage, and easy to perform. The patients were discharged without any drainage tube within a wk. If biliary drainage was used carefully with selected indications, patients with laparoscopic choledochotomy for CBD stones could achieve a better postoperative quality of life. We propose mTCBD as an option for patients with CBD stones.

Abstract

AIM: To determine the association between seroprevalence of *Helicobacter pylori* (*H. pylori*) infection and primary biliary cirrhosis (PBC).

METHODS: In this case-control study, 149 consecutive patients (10 males, 139 females, mean age 58.2±11 years, range 26-82 years) suffering from PBC and 619 consecutive healthy volunteer blood donors (523 males, 96 females, mean age 47±5.3 years, range 18-65 years) attending the Hospital Blood Bank and residing in the same area were recruited. A commercial enzyme linked immunosorbent assay was used to detect anti-*H. pylori* (IgG) antibodies in serum.

RESULTS: Antibodies to *H. pylori* were present in 78 (52.3%) out of 149 PBC-patients and in 291 (47%) out of 619 volunteers ($P = 0.24$, OR 1.24, 95% CI 0.85-1.80). In the subjects less than 60 years old, the prevalence of *H. pylori* infection among PBC-patients (40/79) was slightly higher than in controls (50.6% vs 46.2%) $P = 0.46$, OR = 1.19, 95% CI: 0.72-1.95). In those over 60 years, the prevalence of *H. pylori* infection was similar between PBC-patients and controls (54.2% vs 57.8%, $P = 0.7$, OR 0.86, 95% CI 0.36-2.07).

CONCLUSION: There is no association between seroprevalence of *H. pylori* infection and primary biliary cirrhosis.

INTRODUCTION

Helicobacter pylori (*H. pylori*) infection is a chronic one. In most instances, it is acquired during childhood, and is often associated with low socio-economic class. The presence of

the bacterium has been established as the main cause of several gastroduodenal diseases, including peptic ulcer disease^[1,2], gastric carcinoma^[3], and gastric MALT lymphoma^[4].

Since the latest decade, several studies have reported on the link between chronic *H. pylori* or *Helicobacter species* (*H. species*) infections and a variety of extragastric manifestations. These include ischaemic heart disease (IHD), liver diseases, skin diseases, blood disorders and others^[5]. However, the hypothesis of an etiological role has not yet been fully investigated.

Epidemiological studies have frequently involved control selection bias, population of small sizes, and presence of confounders, like age and socio-economic conditions.

Non randomised, long-period and large studies on the follow-up of *H. pylori* eradication in extragastric diseases are lacking.

Several *H. species*, such as *H. bilis*, are capable of colonising different anatomical regions of the gastrointestinal tract in humans, including choledochus, gallbladder, intrahepatic bile ducts and liver^[6].

Primary biliary cirrhosis (PBC) is a chronic cholestatic liver disease in which intra-hepatic bile ducts are progressively destroyed. The etiology of PBC is unknown, but immunological mechanisms may play a part in the pathogenesis. A causal role of infectious agents has been proposed but the data are inconclusive. Recently, Bogdanos and coworkers have shown that microbial mimics, comprising that of *H. pylori*, are major targets of crossreactivity with human pyruvate dehydrogenase in PBC, strengthening the fact that microbial exposure may be instrumental to the appearance and/or maintenance of anti-mitochondrial antibody responses by a cross-reactive mechanism^[7]. These data indicate that a relationship between *H. species* and the biliary tract of humans might exist, where the bacteria could be potentially involved in inflammatory changes or other pathologic manifestations. However, these findings have not been confirmed in other studies^[8].

The prevalence of peptic ulcer is higher in cirrhotics than in control population and the risk is increased by the presence of *H. pylori* infection^[9]. However, in some groups of patients affected from liver disease, as in the case of PBC, the seroprevalence of *H. pylori* infection is still undetermined.

The present study attempted to highlight on the seroprevalence of antibodies against *H. pylori* in a cohort of patients suffering from PBC in comparison to a group of volunteers attending the Blood Bank of the San Giovanni Battista Hospital (Molinette) in Torino, Italy.

MATERIALS AND METHODS

The presence of anti-*H. pylori* antibodies was evaluated in 149 consecutive subjects (10 males, 139 females, mean age 58.2±11 years, range 26-82 years) suffering from PBC.

Patients were considered to have PBC if they fulfilled at least 2 of the following criteria: positive anti-mitochondrial antibody (AMA) at a titer higher than 1/40, abnormal liver function tests (alkaline phosphatase, gamma glutamyl transpeptidase, bilirubin, transaminase level) or liver histology diagnostic or consistent with PBC^[10].

AMA was evaluated by immunofluorescence using rat

stomach and kidney as substrate^[10].

Other causes of liver disease, such as viral (hepatitis B virus, hepatitis C virus), autoimmune (anti-nuclear, anti-smooth muscle and anti-microsome antibodies) or metabolic (serum iron, percentage of transferrin saturation, ferritin, ceruloplasmin, alpha-1 antitrypsin) hepatitis, were ruled out.

The controls were 619 consecutive volunteer blood donors (523 males, 96 females, mean age 47 ± 5.3 years, range 18-65 years) attending the Hospital Blood Bank and residing in the same area^[11].

A commercial enzyme linked immunosorbent assay (ELISA, Helori-test® Eurospital, Trieste Italy) was used to detect anti-*H pylori* (IgG) antibodies in serum. The assay sensitivity and specificity versus histology were 70.6% and 90.5% respectively, positive predictive value was 87.2% and negative predictive value 77.0%^[12].

Briefly, calibrators, positive controls, negative controls and diluted (1:200) serum samples were added to wells coated with purified *H pylori* group-specific antigens. Plates were incubated for 60 min at 37 °C. The plate was then washed thrice and anti-IgG conjugate was pipetted into each well and the plate was incubated again for 60 min at 37 °C. The washing step was repeated, chromogenic substrate was added to each well, followed by incubation for 30 min at 37 °C. The reaction was then stopped. Reading was performed at 405 nm and the mean optical density was expressed as a percentage of the optical density of the positive control serum assayed on the same plate.

A commercial enzyme immunoassay (Helori®-CTX Eurospital, Trieste, Italy) was used to detect serum IgG antibodies against more virulent strains of the bacterium, expressing cytotoxin-associated gene product A (CagA). The manufacturer's instructions were followed. The assay sensitivity and specificity given by the manufacturer were 94.1% and 97.9% respectively.

The seroprevalence of *H pylori* infection in cases and controls was compared using the chi-square test (χ^2) by means of 2×2 contingency table. Fisher's exact test was used for small sample size. Results were considered statistically significant when $P < 0.05$.

RESULTS

Mean age between patients and controls was not statistically different.

The prevalence of antibodies to *H pylori* was 52.3% (78/149) in the patients with PBC compared to 47% (291/619) in the controls ($P = 0.24$, OR 1.24, 95% CI 0.85-1.80).

When the patients were subdivided into age-groups (<60 and ≥ 60 years), the difference was as follows. In the youngest age group (less than 60 years old), the prevalence of *H pylori* infection among CBP-patients (50.6%, 40/79) was higher than in controls (46.2%, 269/581), but this was not significant ($P = 0.46$, OR 1.19, 95% CI 0.72-1.95). In the group over 60 years, the prevalence of *H pylori* infection was lower in CBP-patients (38/70, 54.2%) than in controls (22/38, 57.8%) ($P = 0.7$, OR 0.86, 95% CI 0.36-2.07) (Table 1).

Table 1 Seroprevalence of anti-*Helicobacter pylori* antibodies among patients with primary biliary cirrhosis [PBC] and controls

Age (yr)	Patients with PBC Hp (+)/tot (%)		Controls Hp (+)/tot (%)		P
<60	(50.6)	40/79	269/581	(46.2)	0.46
≥ 60	(54.2)	38/70	22/38	(57.8)	0.7
Total	(52.3)	78/149	291/619	(47)	0.24

The anti-CagA antibodies were detected in 28.1% of patients with PBC (42/149) and in 44.8% of those with seropositivity for

anti-*H pylori* (35/78). In our population, anti-CagA antibodies were present in 61.8% of a general population admitted to the Emergency Care Unit, as published elsewhere^[13].

Out of the 10 patients with a past history of peptic ulcer, 7 had anti-*H pylori* antibodies in circulation. In 29 cases, the signs of portal hypertension [varices or congestive gastropathy] were shown by upper GI endoscopy while in 111 patients there were no abnormalities.

DISCUSSION

The prevalence of *H pylori* infection in patients with liver disease needed to be studied on the basis of clinical and experimental considerations.

From a clinical point of view, the medical history of cirrhotic patients was punctuated by frequent and recurrent hospitalisations due to high rate of complications. Among the most relevant of them, peptic ulcer and upper GI hemorrhage were of peculiar relevance, being life-threatening for the patient and of high cost for Health Care Services, requiring both emergency care and subsequent long hospital stay^[14]. By a multivariate analysis, Calvet *et al.* found that male sex and *H pylori* seropositivity (OR 1.7, 95% CI 1.02-2.81) were variables independently related to peptic ulcer in cirrhotics with different etiologies^[15]. Moreover, in the case of hemorrhage from peptic ulcer, the presence of cirrhosis was independently associated with increased mortality ($P < 0.001$)^[16]. Little information is available on the prevalence of peptic ulcer in subjects suffering from PBC or primary sclerosing cholangitis (PSC). The prevalence of duodenal ulcer (DU) in male cirrhotics was investigated by Rabinovitz *et al.* in 216 subjects. Occurrence of DU amounted to 7.8% in patients and 2.2 % in controls ($P < 0.005$). When the patients were subdivided according to etiology, DU prevalence was observed in 9.4% of HBV-related chronic hepatitis patients, 12.2% of alcohol-related chronic hepatitis patients, 3.5% of cryptogenic, 6.6% of autoimmune cirrhosis, 9.5% of PSC and none of the patients with PBC. However, in the latter case only 9 patients were included^[17].

Since peptic ulcer is related to the presence of *H pylori* infection in non-cirrhotic patients, it is logical to suppose a similar role for the bacterium also in subjects with cirrhosis.

A high prevalence of anti-*H pylori* antibodies in HCV-infected cirrhotic patients has been reported in several North Italian towns^[18,19]. On the contrary, there was no increased seroprevalence in patients suffering from autoimmune hepatitis^[20]. Fan *et al.* demonstrated a higher seroprevalence of *H pylori* in Chinese patients with HBV-related chronic hepatitis than in controls matched for age and socio-economic status^[21]. In Taiwan, Chen *et al.* found no association between peptic ulcer and *H pylori* infection in cirrhotic patients^[22]. Selection biases and methods of diagnosis were possible sources of the heterogeneity of the studies. Contrasting results might arise from the choice of tests used for the diagnosis of *H pylori* infection. Indeed, when the diagnosis relies solely on histological examination of gastric biopsies, sampling error is the source of severe misdiagnosis. The European *H pylori* Study Group has recommended to search for IgG anti-*H pylori* when performing an epidemiological investigation^[23].

Regarding populations of subjects suffering from PBC, Floreani *et al.* showed that *H pylori* colonization was significantly more frequent in controls than in patients but IgG anti-*H pylori* were detected in the same percentage in the two groups^[24]. Thus, the latter finding is in agreement with those of our study. Dohmen and coworkers in Japan, have found that *H pylori* is a possible pathogenic factor in atrophic corpus gastritis in PBC-patients. Furthermore, a positive correlation between the titers of anti-pyruvate dehydrogenase antibody and anti-*H pylori* was confirmed^[25]. However, in this investigation,

no comparison with a control population has been made.

From an experimental point of view, infection of healthy A/JCr male mice with *H. hepaticus* could result in chronic hepatitis and liver cancer in a short time^[26]. Since this report, several other *H. species* have been subsequently found in the liver and biliary tract of cats and dogs suffering from hepatitis and hepatocellular carcinoma. *H. species* have been demonstrated both in the bile and in the gallbladder mucosa of Chilean patients with chronic gallbladder inflammation, raising the question as to whether the frequent finding of gallbladder cancer in Chile might arise from such an infection^[6]. By polymerase chain reaction, hybridisation and partial DNA sequencing in human liver of patients with PBC or PSC, Nilsson *et al.* found the positivity for *Helicobacter* genus-specific primers in 11 out of 12 samples of PBC-subjects and in 9 out of 12 samples of individuals suffering from PSC^[27].

In conclusion, we found that the seroprevalence of *H. pylori* in subjects suffering from primary biliary cirrhosis was not more frequent than in controls, suggesting that the putative role of *H. pylori* in triggering organ-specific autoimmunity does not hold true for PBC.

On the other hand, although these data do not provide proof for the association between *H. pylori* infection and PBC, a type II statistical error, i.e. the probability of accepting the *null hypothesis* when it is false, cannot be ruled out.

Abstract

AIM: To determine the pathological characteristics of gastric leiomyoblastoma.

METHODS: All tissues were obtained during surgery or gastroscopy. Tissue specimens for examination by light microscope were 1 cm×1 cm×1 cm in size, fixed in 40 g/L neutral buffered formaldehyde, embedded in paraffin, and stained with hematoxylin and eosin. The fresh tissues obtained for electron microscopy were 1 mm×1 mm×1 mm in size, and fixed in phosphate buffered 30 g/L glutaraldehyde, postfixed in 10 g/L osmium tetroxide and dehydrated in graded alcohol, embedded in Epon 812. Ultrathin sections of 50 nm were stained with uranyl acetate and lead citrate and examined under a JEM-2000 EX transmission electron microscope.

RESULTS: The most important histopathological feature of leiomyoblastoma was the predominance of large, rounded or polygonal cells with characteristic perinuclear clear zone in cytoplasm. The tumor cells arranged in patch, cell junction or junctional complex could be found occasionally between cells under electron microscope. Most of the neoplastic cytoplasm were filled with myofilaments, dense bodies, and dense patches. Rough endoplasmic reticulum dilated as lakes, and large quantities of protein secretions of intermediate electron density were found in the dilated cisternae. Intracisternal segregation could also be found. The nuclei were round or oval, and anomalous nuclei were found in part of cells.

CONCLUSION: The diagnosis of gastric leiomyoblastoma can be confirmed by electron microscopy. The clear appearance of tumor cells is due to the dilation of rough endoplasmic reticulum, not fat droplets, glycogens or mucus in cytoplasm.

INTRODUCTION

Gastric neoplasms are common in the world, specially in China^[1-8].

Gastrointestinal stromal tumor (GIST) is the most common mesenchymal tumor of gastrointestinal tract^[9], although GIST may arise from any portion of the foregut to hindgut, two thirds of stromal tumors originate from the stomach^[10]. Leiomyoblastoma, also called bizarre leiomyoma or epithelioid leiomyoma, is a rare smooth muscle tumor characterized by epithelioid cells with clear cytoplasm and an unknown biological behaviour. It is an unusual type of smooth muscle tumor which is biologically benign in most cases, but on rare occasions may behave in a malignant manner and metastasize^[11-15]. It is most frequently seen in the gastric wall but may occasionally be encountered in the uterus^[16,17], tongue^[18], round ligament^[19], omentum^[12], vulva^[20], urethra^[21], intestines, mesentery, retroperitoneum, mediastinum, and deep superficial soft tissues^[22,23]. Gastric leiomyoblastoma is a benign neoplasia, extremely uncommon and potentially malignant, arising from the muscular layer of the stomach^[24-26]. These neoplasms form solitary, well-defined, but not encapsulated, rounded or lobulated masses which, when small, tend to be localized intramurally. Multiple tumors are rare^[27-30]. The growth may take place towards the lumen, resulting in a polypoid mass and is covered by an attenuated mucosa.

MATERIALS AND METHODS

All the cases were obtained from the Chinese PLA 117 Hospital. Information of these cases is shown in Table 1. The patient population consisted of two men and three women. Their mean age was 51.4 years, ranging from 48 to 58 years at the time of diagnosis (Table 1). No relevant information of family history was found.

Table 1 Principal manifestations of gastric leiomyoblastoma

No	Sex	Age (yr)	Manifestations
1	Male	48	Abdominal dull pain, gasterorrhagia, dyspepsia
2	Male	56	Abdominal pain, abdominal mass, hemafecia
3	Female	42	Abdominal pain, nausea, vomiting
4	Female	53	Abdominal pain, vomiting, black stool
5	Female	58	Interrupted hematemesis, cupressus defecation

The cytologic samples were negative in all cases. The patients were explored surgically and neoplasms of stomach resected. All tissue specimens for examination by light microscope were 1 cm×1 cm×1 cm in size, fixed in 40 g/L neutral buffered formaldehyde, embedded in paraffin, and stained with hematoxylin and eosin. The fresh tissues obtained for electron microscopy were 1 mm×1 mm×1 mm in size, and fixed in phosphate buffered 30 g/L glutaraldehyde, postfixed in 10 g/L osmium tetroxide and dehydrated in graded alcohol, embedded in Epon 812. Ultrathin sections of 50 nm were stained with uranyl acetate and lead citrate and examined under a JEM-2000 EX transmission electron microscope.

RESULTS

Gross anatomy and gastroscopy

All resected tumors were well-circumscribed, and three tumors were located at the antro-pyloric region (cases 1, 3 and 4), one

at the body (case 2) and one at the gastric antrum (case 5). The size was measured between 2.5 cm and 13 cm, averaging 6.8 cm. The type of tumor growth was intraluminal (1/5) or extraluminal (2/5) or mixed (2/5). An ulcerated nodular tumor, located in the anterior wall and minor curvature of the gastric antrum (case 1), was found by gastroscopy.

Figure 1 Round tumor cells, with clear cytoplasm, vary greatly in size and shape.

Figure 2 Ultrastructure of gastric leiomyoblastoma. A: Tumor cells with many microfilaments, B: Intracisternal segregation could also be found, C: Rough endoplasmic reticulum dilatated as lakes, and protein secretion of intermediate electron density was found in the dilated cisternae, D: Distorted nuclei were found in tumor cells.

Histopathological appearances

Round tumor cells with clear cytoplasm, varied greatly in size

and shape in different parts of the same tumor (Figure 1). The cellular morphology of the muscle neoplasm was all homogenous and the frequency of mitosis was 2 mitoses in case 1 and 4 in case 5 in 10 HPFs, and some areas of fibrosis and degeneration were found in case 3. The most important feature of leiomyoblastoma was the predominance of large, round or polygonal cells with characteristic perinuclear clear zone in cytoplasm (Figure 1). The nuclei might be pleomorphic with prominent nucleoli.

Ultrastructural characteristics

Ultrastructural studies confirmed that the origin of these tumors was smooth-muscle cells, and they were fusiform and round with many microfilaments. Tumor cells arranged in patch, and the cell junction or junctional complex could be found occasionally between cells. Most of the neoplastic cytoplasm were filled with myofilaments, dense bodies, and dense patches (Figure 2 A, B). Rough endoplasmic reticulum dilatated as lakes, and large quantities of protein secretions of intermediate electron density were found in the dilated cisternae (Figure 2C). Intracisternal segregation could also be found (Figure 2B). The nuclei were round or oval, and distorted nuclei were found in part of cells (Figure 2D).

DISCUSSION

The most important ultrastructural features of leiomyoblastoma were myofilaments, dense bodies and dense patches present in most of the tumor cells. The perinuclear clear zone in cytoplasm was caused by dilation of rough endoplasmic reticulum. These characteristics proved that gastric leiomyoblastoma arised from smooth muscle cells of the gastrointestinal (GI) tract. Leiomyoblastoma was often previously diagnosed as GIST. Although the term GIST was first used in 1983 (by Mazur and Clark), the 1998 discovery by Hirota that GIST tumors could contain mutations in the c-kit gene and marked the beginning of a new understanding and reclassification of sarcomas of the GI tract. Prior to the year 2000, GISTs were classified as one of the types of soft tissue sarcoma (STS), including tumors of smooth-muscle origin (most commonly leiomyosarcoma, and also leiomyoma or leiomyoblastoma) and of neural-crest origin (eg, Schwannoma, or nerve sheath tumour).

Most tumors previously diagnosed as gastrointestinal autonomic nerve tumors (GANTs) are also now classified as GISTs and contain essentially the identical KIT mutations as GIST. What establishes GIST as a separate diagnosis from these other soft tissue sarcomas is not just the description of where the tumor is located, but also the additional factor that it is KIT (CD117) positive. Most GIST patients are also CD34 positive and desmin negative. Well, one of the best ways to identify the cancer cell type (aside from just looking at the cells under a microscope) is to determine the proteins that the cells make. Specialized tests allow the pathologist to do this, usually by determining whether the cells will bind to antibodies against the protein of interest. So, “kit-positive” means that the cells make the protein “kit”, desmin-negative means that the cells do not make the protein “desmin”.

With the development of new effective therapies for GIST, it is vitally important that patients with soft tissue sarcomas of the GI tract have their tumor slides tested for KIT (CD117) by a pathologist experienced with GIST and KIT. Some (perhaps many) patients with pathology reports that were done prior to 2001 may think they have leiomyosarcoma, leiomyoma, leiomyoblastoma, or GANT when in fact their pathology slides were never tested for KIT and they might have GIST. Once more, misdiagnosis can be a disaster. Pathology is critical. Fortunately, the pathology of GIST is now (2003) much better understood than it was in five years ago.

Another question is the origin of GIST. GISTs were previously thought to arise from smooth muscle cells of the GI tract. The discovery that GISTs could express KIT protein helps establish that GISTs do not originate from smooth muscles. The current thinking is that GIST tumors arise either from stem cells that differentiate towards interstitial cells of Cajal or directly from interstitial cells of Cajal (ICCs). The interstitial cells of Cajal are the pacemaker cells of the GI tract (they are named after a great Spanish biologist and microscopist named Cajal), they stimulate the movement (contractions) of the GI tract. These movements ("peristalsis") are the waves of contraction which force the digested food through the gut. GIST often spreads from the original (primary) site to distant locations. If this happens, these tumors are called metastases (or simply, "mets"). If GIST tumors metastasize they usually travel to the liver, or the peritoneum. Metastases to lymph-nodes and lungs are rare, but do occur. Metastasis is usually even worse than the growth of the primary one. Metastases can cripple a vital organ such as the liver. They are usually harder to treat than primary tumors. Metastases are the terrorist network of cancer, stealthily spreading to distant sites, where they can grow and do damage.

The results showed that gastric leiomyoblastoma cells did not differentiate to interstitial cells of Cajal, but differentiated to smooth muscle cells. Therefore, we think if definite smooth myocytes are found in this tumor, it should be diagnosed as leiomyoblastoma but not as GIST.

In summary, gastric leiomyoblastomas have a characteristic ultrastructure, electron microscopy may play a crucial role in diagnosis of gastric leiomyoblastoma.

Abstract

AIM: To investigate the fluid shear stress induced changes of $[Ca^{2+}]_i$ in neutrophils in pancreatic microcirculation of experimental acute pancreatitis (AP).

METHODS: Wistar rats ($n = 36$) were randomized into three groups. A model of AP was established by subcutaneous injection of caerulein. Low-shear 30 viscometer was used to provide steady fluid shear stress on separated neutrophils. The mean fluorescent intensity tested by flow cytometry was used as the indication of $[Ca^{2+}]_i$ quantity.

RESULTS: Under steady shear, cytosolic $[Ca^{2+}]_i$ showed biphasic changes. The shear rate changed from low to high, $[Ca^{2+}]_i$ in different groups decreased slightly and then increased gradually to a high level ($P < 0.05$). A close correlation was observed between the cytosolic $[Ca^{2+}]_i$ level and the alteration of fluid shear stress in regional microcirculation of AP.

CONCLUSION: The increase of $[Ca^{2+}]_i$ is highly related to the activation of neutrophils, which contributes to neutrophil adhesion to endothelium in the early phase of AP. The effect of fluid shear stress on $[Ca^{2+}]_i$ may play a crucial role in pancreatic microcirculatory failure of AP.

INTRODUCTION

Studies have confirmed the hypothesis that microcirculatory derangements play a pivotal role in the pathogenesis of acute pancreatitis (AP), including the process of conversion from edematous to necrotizing injury^[1-3]. Although several

pathophysiological sequences, such as protease activation, free radical generation, and inflammatory mediator release, have been described in acute pancreatitis, the precise mechanism by which acute pancreatitis is initiated is unknown^[4-7]. Cellular calcium, a key physiological signaling element in cell function and also a crucial pathological intracellular messenger in cell injury, appears to be involved in the initiation and development of acute pancreatitis^[8-12]. Previous studies have suggested that AP is frequently associated with sequestration of inflammatory cells, particularly neutrophils, within pancreas, and it is generally believed to be an early and important event in the evolution of pancreatitis^[13,14]. Recently, considerable attention has been directed at identifying the chemoattractant substances responsible for leukocyte sequestration within these tissues and the factors released from these inflammatory cells that contribute to progression of AP^[15-21]. Cytosolic free Ca^{2+} , a well-known second messenger, takes part in many cellular reaction processes and regulates the activity of many enzymes^[8]. Caerulein-induced AP has been shown to cause cytosolic free Ca^{2+} transient increase^[9-12]. Increase in leukocyte cytosolic $[Ca^{2+}]_i$ might be involved in intercellular adhesion by regulating the affinity of surface adhesion molecules or by facilitating transendothelial leukocyte migration, which might lead to increased leukocytic infiltration and tissue damage during AP^[9-12].

Previous studies mainly concentrated on the peripheral blood neutrophils during AP under static state due to limitation of experimental methodology. However, to the authors' knowledge, no reports are available about local pancreatic microcirculatory neutrophils during AP under flow state. Although the number of neutrophils in circulation is much less compared with the total mature neutrophils in the body, these circulating cells move with blood in the whole body, and execute disinfectant functions. The stored neutrophils replenish at a certain rate into the blood to maintain a dynamic balance between circulation pool and bone marrow storage pool^[22,23]. When it is necessary, bone marrow can release more neutrophils to enhance the defense efficacy. So blood flow is an important physiological environment for neutrophils^[22,23]. We first undertook to investigate the change of $[Ca^{2+}]_i$ in local pancreatic microcirculatory neutrophils during AP under fluid shear stress. The results of this study might provide a new insight into the pathogenesis of AP.

MATERIALS AND METHODS

Animals

Adult male Wistar rats weighting 250-350 g were purchased from Center of Experimental Animals, Sichuan University, Chengdu, China. All animals were starved for 24 h prior to experimentation. All animal experiments were conducted according to the guidelines of the Local Animal Use and Care Committees and the National Animal Welfare Law.

Induction of acute pancreatitis

All rats of the experimental groups were injected with 5.5 $\mu\text{g/kg}$ and 7.5 $\mu\text{g/kg}$ of caerulein (Sigma Co., USA) subcutaneously

at 0 and 1 h after the beginning of experiment respectively, while the rats of the control group were subcutaneously injected with normal saline solution.

Experimental protocol

Experimental animals were divided into three groups, with 12 rats each group. Group 1: normal control, group 2 (AP-I): rats at 2 h after the induction of AP, and group 3 (AP-II): rats at 4 h after the induction of AP. Rats in each experimental group were killed to obtain blood by splenic vein puncture at 2 and 4 h after first caerulein injection.

Preparation of neutrophils

Rat polymorphonuclear cells (PMNs) were isolated according to the technique described by Hjorth *et al.*^[24] for human PMNs. Blood was immediately mixed with heparin (50 U/mL) and centrifuged in a discontinuous Percoll gradient to yield a fraction of approximately 97% purity. Cell viability, as assessed by trypan blue exclusion, was above 96% under all experimental conditions.

Shear stress action on neutrophil suspension

Low-shear 30 viscometer (Switzerland) was used to provide low shear rate (5.96/s, 14.98/s, 51.2/s, 94.5/s and 128.5/s), then 37 g/L formaldehyde was added to fix neutrophils after sheared for 1 min.

Measurement of $[Ca^{2+}]_i$

Cells were loaded (5×10^6 /mL) with the Ca^{2+} -sensitive fluorescent dye fluo-3/AM (2 μ mol/L; Molecular probes, Eugene OR) at 37 °C for 30 min in 145 mmol/L NaCl, 5 mmol/L KCl, 1 mmol/L $MgCl_2$, 10 mmol/L glucose, 4 mmol/L probenecid, 10 mmol/L HEPES, pH 7.4. Fluorescence intensity was then measured with flow cytometry. The intensity of fluorescence correlated with the concentration of $[Ca^{2+}]_i$. Therefore, the mean fluorescence intensity (MFI) indicated the level of $[Ca^{2+}]_i$.

Statistical analysis

The results were expressed as mean \pm SD. The mean of MRI between groups was compared by a two-tailed Student's *t* tests. $P \leq 0.05$ was considered statistically significant.

RESULTS

Under steady shear, cytosolic $[Ca^{2+}]_i$ had biphasic changes. When the shear rate was very low, $[Ca^{2+}]_i$ decreased slightly. With the increase of shear rate, $[Ca^{2+}]_i$ increased gradually. When the shear rate was increased higher than 50/s, $[Ca^{2+}]_i$ in the experimental group was higher than that in the control group. With the shear rate changed from low to high, cytosolic $[Ca^{2+}]_i$ gradually increased to a significantly high level compared with the stationary control ($P < 0.05$). After treated with a shear rate of 128.5/s, the cytosolic $[Ca^{2+}]_i$ of AP-II group was significantly induced compared with AP-I group ($P < 0.05$) (Figure 1).

Figure 1 Effects of fluid shear stress on cytosolic $[Ca^{2+}]_i$ in neutrophils in pancreatic microcirculation of rats with AP. $^aP < 0.05$ vs normal; $^cP < 0.05$ vs AP-I.

DISCUSSION

Acute pancreatitis remains a clinical challenge because it is difficult to predict whether the disease is mild or runs a severe course with a possibly fatal outcome in a given patient^[25]. In recent years, researches on the morphology of pancreatic microcirculation have revealed that the blood supply of pancreatic lobules in most cases is provided by a single intralobular arteriole^[26]. This arteriole sends forth the tree-like branches when entering pancreatic lobule, and has no anastomosis with adjacent intralobular arterioles and their branches, and could be considered as an end-artery^[26]. This characteristic suggested pancreatic lobules were susceptible to ischemic injury due to spasm of intralobular arterioles, embolization of arterioles, formation of microthrombi or compression by interstitial edema^[1-3]. However, causative factors of early-stage ischemia and the precise triggering factors of local microcirculatory disturbance remain obscure^[3].

Cellular calcium, a key physiological signaling element in cell function and also a crucial pathological intracellular messenger in cell injury, appears to be involved in the initiation and development of acute pancreatitis^[7-12]. The present study provided several lines of evidence supporting this suggestion. We investigated whether calcium was involved in the priming response encountered during AP. We found that cytosolic $[Ca^{2+}]_i$ showed a biphasic changes when the neutrophil suspension was under a steady shear. When the shear rate changed from low to high, cytosolic $[Ca^{2+}]_i$ decreased slightly under a very low shear rate (5.96/s) and then increased gradually to a high level. From this study we could also infer that cytosolic $[Ca^{2+}]_i$ might be an identifying marker for AP.

Activation of neutrophils is one of the critical roles in pathologic process of AP, and cytosolic $[Ca^{2+}]_i$ has a close relation with neutrophil activation^[27,28]. Our study demonstrated the fluid shear stress induced changes of cytosolic $[Ca^{2+}]_i$ in neutrophils in pancreatic microcirculation of rats with caerulein-induced AP. These lines of evidence indicate that altered intracellular calcium might play an important role in the initiation and development of AP. In conclusion, cellular calcium may be an important factor in the pathogenesis of cerulein-induced acute pancreatitis.

Abstract

AIM: To construct a yeast expression system of human augmenter of liver regeneration (hALR) and to examine its bioactivity *in vitro*.

METHODS: With PCR and gene recombination techniques, cDNA of open reading frame of hALR was obtained from recombinant plasmid pcDNA3.1-hALR and inserted into plasmid pPIC9. The cDNA of hALR from recombinant plasmid pPIC9-hALR demonstrated by sequencing was subcloned into plasmid pPIC9K. The recombinant plasmid pPIC9K-hALR was transformed into GS115 with electroporation. hALR was expressed by GS115 under the induction of 5 mL/L methanol and purified with ultrafiltration after it was analyzed by 15% SDS-PAGE and Western blot. The effects of hALR on *in vitro* proliferation of QGY and HepG₂ cells were evaluated by ³H-TdR methods.

RESULTS: The correctness and integrity of recombinant plasmids pPIC9-hALR and pPIC9K-hALR were identified by restriction digestion, PCR and sequencing methods, respectively. hALR as a secretive protein was successfully expressed by GS115. Its molecular weight was about 15 ku and the target protein was about 60% of the total protein in the supernatant from GS115 with plasmid pPIC9K-hALR. The results of Western blot of hALR showed the specific band. The high qualitative hALR was obtained through ultrafiltration. hALR could stimulate *in vitro* proliferation of QGY and HepG₂ cells in a dose-dependent manner, but there was a difference in reactivity to hALR between QGY and HepG₂.

CONCLUSION: The hALR as a secretive protein can be successfully expressed by GS115. It may stimulate *in vitro* proliferation of QGY and HepG₂ cells at a dose-dependent manner. But QGY and HepG₂ cells have different reactivities to hALR.

INTRODUCTION

Augmenter of liver regeneration (ALR) is an important cytokine

recently discovered and cloned from rat livers^[1,2]. It could stimulate DNA synthesis of liver cancer cells *in vitro* and enhance liver regeneration in rats after partial hepatectomy, but there is a debate whether it could directly stimulate DNA synthesis of hepatocytes *in vitro*^[1,3]. It has also been proved that ALR could partially reverse the liver fibrosis in experimental rats^[4] and enhance the success rate of fetal pancreas transplantation in rats^[5]. It seems to bring a bright future in the treatment of severe liver diseases. Although the recombinant human and rat ALR were successfully expressed in *E.coli* in our laboratory^[6-8], there are some defects that the target protein as an inclusion body expressed in *E.coli* could not often be refolded and modified correctly and that the procedure to purify ALR is very complicated. Because the pichia pastoris expressing system could overcome all these defects, it was selected to express ALR, which could be secreted into supernatants so that it was easy to purify ALR. It is possible for us to carry out further study with purified ALR.

MATERIALS AND METHODS

Reagents, plasmid, bacteria and cell strain

Escherichia coli JM109 and TOP10F⁺, plasmid pcDNA3.1-hALR, hepatocarcinoma HepG2 and QGY strains were preserved and monoclonal antibody against hALR was made in our laboratory^[9]. *Pichia pastoris* GS115, plasmids pPIC9 and pPIC9K were from Invitrogen Corporation, USA. DNA ladder marker, restriction endonuclease, and T4 DNA ligase were from Shanghai Sango, China. Peptone and YNB were from Amresco Co. USA. Yeast power was from Oxoid. 8200 cell filter, 5 kD and 30 kD membranes were from Millipore Co. USA. Gene pulser-II was from Bio-Rad Co. Ltd., USA.

Preparation of hALR gene

According to the maps of plasmids pcDNA3.1-hALR, pPIC9 and pPIC9K, the sequences of primers were designed as follows: forward: P₁ 5'-CACTCGAGAAAAGACGGACCCAGCAGAAG C-3', reverse: P₂ 5'-CTGCGGCCGCTTAGTCACAGGAGCCGTC CTTC-3'. *Xho*I and *Not*I restriction sites were introduced and defined by the underline. Primers were synthesized by BoYa Co. Ltd. hALR sequence was amplified by polymerase chain reaction (PCR) for 30 cycles from pcDNA3.1-hALR containing the full-length open reading frame of hALR gene. Each cycle consisted of denaturation for 45 s at 94 °C, annealing for 45 s at 62 °C, and extension for 1 min at 72 °C. The PCR products were analyzed on 1.5% agarose gel electrophoresis as specific band examination.

pPIC9-hALR and pPIC9K-hALR construction and identification

The PCR products of hALR from the gel extraction and pPIC9 were digested with *Xho*I and *Not*I and then purified, respectively. pPIC9 and hALR fragments were mixed with 3:1 mol/L and ligated by T4 DNA ligase overnight at 16 °C, then transformed into JM109 with CaCl₂ method. The positive clones were selected in LB plates with ampicillin and identified by PCR, restriction enzyme digestion and sequencing, respectively. After the correction and integrity of recombinant pPIC9-hALR were

proved, pPIC9-hALR and pPIC9K were digested with *SaII* and *SacI*. A 3.4 kb fragment containing hALR was obtained from pPIC9-hALR and 6.3 kb fragment from pPIC9K. Both fragments were mixed with 2:1 mol/L, ligated by T4 DNA ligase and transformed into TOP10F' with CaCl_2 method. The positive clones were selected in LB plates with ampicillin and karamycin and the plasmids from them were identified by PCR and restriction enzyme digestion on the next day.

Transformation and expression

Recombinant plasmids pPIC9K-hALR (8 μL) and pPIC9K (8 μL) were linearized, respectively, by digestion with *SaII*. Competent *pitch pastoris* GS115 was prepared according to the manual of Invitrogen Corporation. The linear plasmids pPIC9K (5–10 μg) and pPIC9K-hALR (5–10 μg) were mixed with competent GS115 (80 μL), respectively. Under the conditions of 1500V, 25 μF and 200 Ω , the competent GS115 was transformed by different mixtures using the Bio-Rad gene pulser, then planted and cultured in plates of minimal dextrose medium without histidine at 30 °C for 2 d for screening positive clones. The positive clones with pPIC9K-hALRp or PIC9K were respectively cultured in 3 mL buffered glycerol-complex medium (BMGY) overnight after identified by PCR. Then 15 μL of GS115 was planted into 5 mL BMGY medium and cultured at 28 °C until the optical density at 600 nm (A_{600}) reached four. The GS115 with pPIC9K-hALRp and PIC9K were collected by centrifugation, resuspended by buffered methanol-complex medium to A_{600} reaching one and cultured continuously at 28 °C for 3 d. The 5 mL/L methanol in the medium was kept by methanol compensation at every 24 h. The expressed products at the different time points were analysed by 160 g/L SDS-PAGE and the expressed level was evaluated by computer scan.

Western blot analysis

Supernatants from GS115 with pPIC9K and pPIC9K-hALR were respectively loaded on 150 g/L SDS-PAGE for protein separation and transferred to polyvinylidene difluoride membrane by electrotransfer. After blocked with 50 mL/L milk in PBS, the membrane was incubated with monoclonal antibody (diluted 1:2 000) against hALR for 1 h at room temperature, washed three times with phosphate buffered saline, then mixed with goat anti-mouse IgG antibody coupled with horseradish peroxidase for 45 min, the bands were visualized by 3-3'-diaminobenzidine (DAB).

Purification and quantification

The ultrafiltration purification was selected according to the SDS-PAGE analysis of the supernatant from GS115 with pPIC9K-hALR there were no other bands except target one under 50 kD. The supernatant from GS115 induced by pPIC9K-hALR was centrifuged at 3 000 r/min for 10 min, and passed through 30 kD and 5 kD membranes and the filtrate between 30 kD and 5 kD was collected. As a control the supernatant from GS115 with pPIC9K was treated with same procedure as described above. The purified products were analyzed by 160 g/L SDS-PAGE and qualified by Lowary methods.

hALR bioactivity

Human hepatoma cell lines HepG₂ and QGY were planted at a concentration of 1×10^4 cell/well in 96-well plates supplemented with 80 mL/L fetal bovine serum, 5×10^{-5} mol/L penicillin, 80 $\mu\text{g}/\text{mL}$ streptomycin, and stimulated with different doses of hALR expressed by yeast and *E.coli* at 37 °C, 50 mL/L CO₂ for 8–9 h. The supernatant from GS115 with pPIC9k as negative control was also added. Three parallel wells were stimulated by the same concentration of hALR. The cells were harvested after 12 h of culture by adding 1 $\mu\text{Ci}/\text{well}$ ³H-TdR. The count per minute (cpm) value of cells from each well was measured by liquid

scintillation counter.

Statistical analysis

The data were expressed as mean \pm SD. Comparison was carried out using analysis of variance. *P* value less than 0.05 was considered statistically significant.

RESULTS

PCR result and identification of recombinant plasmid

The specific 400 bp fragment of hALR amplified by PCR from plasmid pcDNA3.1-hALR was analysed by 15 g/L agarose gel electrophoresis. The correctness and integrity of hALR fragments in recombinant plasmid pPIC9-hALR were proved by *XhoI*+*NotI* digestion and sequencing. The 3.4 kb fragment containing hALR was released from pPIC9K-hALR by digestion with *saII* and *sacI*. The 400 bp fragment was also obtained from pPIC9K-hALR by PCR (Figure 1).

Figure 1 Identifications of recombination plasmid. Lane 1: amplified from pPIC9K; Lane 2: amplified from pPIC9K-hALR; Lane 3: pPIC9-hALR digested by *XhoI*+*NotI*; Lane M: 1 kb DNA ladder; Lane 4: pPIC9K-hALR digested by *SacI*+*SaII* (6.3 kb+3.4 kb); Lane 5: 3.4 kb fragment with hALR.

Expression and purification of hALR

Electrophoresis of supernatants from GS115 induced by pPIC9K-hALR showed that there was a specific band with 1.5×10^4 dalton molecular weight coinciding with the theoretical value and the target protein was about 60% of the total protein in the supernatant. There was no corresponding band in supernatant from GS115 transfected with pPIC9K. A single band of hALR was obtained through ultrafiltration purification (Figure 2).

Figure 2 SDS-PAGE analysis of purified hALR. Lane M: protein marker; Lanes 1, 2, and 3: purified hALR.

Detection of protein expression by Western blot

Western blot result showed that the supernatant from GS115 with pPIC9K-hALR could specially bind to monoclonal antibody against hALR in 15 kD site, but the supernatant from GS115 with pPIC9K could not bind (Figure 3).

Table 1 Effect of different dosages of hALR on HepG₂ and QGY proliferation (mean±SD)

Cells	Control	Concentrations of hALR from yeast and <i>E.coli</i>					
			0.1 ng	10 ng	1 μg	8 μg	16 μg

^a*P*<0.05, ^b*P*<0.01 vs control; ^c*P*<0.05 vs hALR from *E.coli*.

**Figure 3** Western blot analysis of supernatants from GS115 treated with different plasmids. Lane 1: supernatant from GS115 with pPIC9K; Lane 2: supernatant from GS115 with pPIC9K-hALR.

Evaluation of hALR bioactivity

Results showed that hALR from GS115 with pPIC9K-hALR could stimulate the proliferation of HepG₂ and QGY on nanogram level in a dose-dependent manner. There was a marked difference in the reactivity to hALR between QGY and HepG₂ although both cells were from human liver cancer. In addition, hALR from yeast had stronger effect on the proliferation of HepG₂ and QGY than that from *E.coli* at same concentration (Table 1).

DISCUSSION

The *Pichia pastoris* system has been widely used in recent years due to its simple procedure, low expenditure and easy scaling up. It is more important that the foreign protein can be correctly refolded and modified, more than 200 proteins have been expressed by this system^[10]. Our results showed that hALR with 1.5×10⁴ dalton molecular weight as a secretive protein was successfully expressed by GS115 and about 60% of total protein was expressed in the supernatant. The ultrafiltration purification for hALR in the supernatant was applied because there were no other bands around the target protein, and a satisfactory purification effect was achieved. Our results demonstrated that not only the purification efficiency was greatly enhanced, but also the purification procedure was obviously simplified. Although it was reported that rat ALR could not directly stimulate liver cancer cells *in vitro*^[1], our data demonstrated that hALR could stimulate QGY and HepG₂ proliferation in a dose-dependent manner. Previously, we and others also obtained the similar results in rat ALR researches^[11,12]. These results suggested that ALR enhanced liver regeneration not only through indirect pathway i.e. immune regulation^[1,13-16], but also through direct one. Our result showed that at the same concentration, hALR expressed in yeast had a stronger effect on the proliferation of HepG₂ and QGY than that expressed in *E.coli*, although it was reported that there was no N-glycosylation site in its amino acid sequence^[1]. Our result suggests that there might exist some unknown modifications such as O-glycosylation site in hALR molecules expressed by yeast, and modification of protein after translation is very important for keeping higher bioactivity of target protein. Hence, the successful expression of ALR in *pichia postoris* and its purification may provide a good tool for further research in this field.

Abstract

AIM: To investigate the photocatalytic killing effect of photoexcited TiO₂ nanoparticles on human colon carcinoma cell line (Ls-174-t) and to study the mechanism underlying the action of photoexcited TiO₂ nanoparticles on malignant cells.

METHODS: Ls-174-t human colon carcinoma cells were cultured in RPMI 1640 medium supplemented with 199 mL/L calf serum in a humidified incubator with an atmosphere of 50 mL/L CO₂ at 37 °C. Viable cells in the samples were measured by using the MTT method. A GGZ-300 W high pressure Hg lamp with a maximum ultraviolet-A (UVA, 320-400 nm) irradiation peak at 365 nm was used as light source in the photocatalytic killing test.

RESULTS: The photocatalytic killing of Ls-174-t cells was carried out *in vitro* with TiO₂ nanoparticles. The killing effect was weak by using UVA irradiation without TiO₂ nanoparticles. In our studies, the photocatalytic killing effect was correlated with the concentration of TiO₂ and illumination time. Once TiO₂ was added, Ls-174-t cells were killed at a much higher rate. In the presence of 1 000 µg/mL TiO₂, 44% of cells were killed after 10 min of UVA irradiation, and 88% of cells were killed after 30 min of UVA irradiation.

CONCLUSION: When the concentration of TiO₂ is below 200 µg/mL, the photocatalytic killing effect on human colon carcinoma cells is almost the same as that of UVA irradiation alone. When the concentration of TiO₂ is above 200 µg/mL, the remarkable killing effect of photoexcited TiO₂ nanoparticles can be found.

INTRODUCTION

The application of TiO₂ photocatalysis has received increasing attention since the first report of microbiocidal effects by Matsunaga *et al.* in 1985^[1]. In recent years, in contrast to many studies using TiO₂ powder for photodecomposition of organic

pollutants^[2-9], few studies have investigated the application of TiO₂ in life science, especially in the field of cancer treatment^[10-12]. The incidence of colon cancer is rising in China. Despite that surgical operation is used currently, people have recognized its limitation. The way to treat cancer usually includes radiation therapy and chemical therapy, which may generate severe side effects in human body. Therefore, this study tried to investigate a new therapy for cancer. Ls-174-t cells were used as experiment objects in this study. The photocatalytic killing effect of TiO₂ nanoparticles on malignant cells and its killing mechanism were investigated.

MATERIALS AND METHODS

Reagent preparation

TiO₂ colloid solutions were prepared^[13,14] by hydrolysis of titanium isopropoxide, Ti [OCH(CH₃)₂]₄ (97%, Aldrich Chemical Co). In brief, 12.5 mL of Ti [OCH(CH₃)₂]₄ was added to 2 mL isopropanol, then the mixture was added to 150 mL of distilled deionized water containing 2 mL of 700 mL/L nitric acid and vigorously stirred for 6 h at 75 °C. Approximately 150 mL of TiO₂ colloid solution being stable for several months at 4 °C was obtained after the organic layer was removed. The average diameter determined by Zetasizer 3000HS_A (USA) was 21.2 nm.

The pH value of TiO₂ colloid solutions used in the subsequent experiment had to be adjusted from 1.8 to 5.5-6.5 in order not to damage the normal growth of cells. Therefore, 1 mol/L NaOH aqueous solution and 1.5 mL/L polyvinyl alcohol were added to the colloid solutions before the pH adjustment to prevent the TiO₂ from precipitation. The final TiO₂ colloid solutions were sterilized by autoclaving and then diluted to the required concentration. Other chemical reagents used were all of analytical purity from commercial sources.

Cell culture and treatment

Human colon carcinoma cell lines Ls-174-t were purchased from Shanghai Institute of Cell Biology, Chinese Academy of Sciences, Shanghai, China. The cell lines were cultured in RPMI 1640 (Gibco) medium supplemented with calf serum 100 mL/L, penicillin (100×10³ µ/L) and streptomycin (100 mg/L). pH was maintained at 7.2-7.4 by equilibration with 50 mL/L CO₂. Temperature was maintained at 37 °C. Cells were sub-cultured with a mixture of ethylenedinitrile tetraacetic acid (EDTA) and trypsin. All experiments were performed using cells during the exponential growth phase. Cell concentration was determined by using a hemocytometer and the cell density was adjusted to the required final concentration.

Ls-174-t cells were treated with TiO₂ diluted in RPMI 1640 medium for 2 h at 37 °C. Then the solutions were irradiated with a GGZ-300W high pressure Hg lamp (E_{max} = 365 nm) at room temperature. A UV pass filter was used to obtain a light wavelength between 300-400 nm. The light intensity at the liquid surface was measured by a VLX-3W radiometer-photometer (USA). The incident light intensity was 3.7 mW/cm². In our study, three groups of tests were carried out. One group was treated in the absence of TiO₂. Another group was treated in the absence of UVA. The third group was treated with different TiO₂ concentrations and irradiated by UVA.

Measurement of the viability of Ls-174-t cells

Viable cells in the samples were measured by using the MTT staining method^[15]. MTT [3- (4, 5-dimethylthiazol-2-yl) -2, 5-diphenyl tetrazolium bromide] was dissolved in phosphate-buffered saline (PBS, pH 7.4) at 5 mg/mL and filtered to be sterilized. Twenty microliters of stock MTT solution were added to all wells for an assay, and plates were incubated at 37 °C for 4 h. One hundred and fifty microliters of DMSO were added to all wells and mixed thoroughly to dissolve the blue-violet crystals. After a few minutes at room temperature to ensure that all crystals were dissolved, the plates were read on a Bio-Rad Novapath[™] microplate reader (Japan), using a test wavelength of 595 nm, taking the solution without MTT as control. Then optical absorptions [A] were obtained. Plates were normally read within 1 h after DMSO was added. The survival rate could be calculated according to $[A]/[A]_i$, where $[A]_i$ is the optical absorption of untreated cells.

RESULTS

Determination of the average diameter of TiO₂ particles

Zetasizer 3000HSA (USA) was used to determine the average diameter of TiO₂ nanoparticles. The result is shown in Figure 1. The average volume size of TiO₂ nanoparticles was 21.2 nm.

Cytotoxicity of TiO₂ nanoparticles

The cytotoxicity of TiO₂ nanoparticles (without UVA irradiation) was determined by exposing cells to various concentrations of TiO₂ in RPMI 1640 (Gibco) medium for 24 h. The surviving fraction of the cells was greater than 90% when the concentration of TiO₂ was in the range of 1 000 µg/mL, as shown in Figure 2. The result confirmed that nonirradiated TiO₂ nanoparticles were not toxic to the Ls-174-t cells. It was consistent with those in literatures^[16-17].

Effect of photoexcited TiO₂ nanoparticles on Ls-174-t cells

The fact that the surviving fraction was greater than 90% after 30 min as shown in Figure 3 (A) indicated that TiO₂ nanoparticles without UVA irradiation showed little toxicity to living cells. The killing effect of UVA without TiO₂ is shown in (B) with the surviving fraction of Ls-174-t cells given as a function of the UVA light irradiation time. About 20% cells were killed after 30 min exposure, whereas after 20 min exposure, more than 90% of the cells survived. Once TiO₂ was added, the Ls-174-t cells were killed at a much higher rate as shown in (C). For example, in the presence of 1 000 µg/mL of TiO₂, 44% of the cells were killed after 10 min of UVA irradiation, and after 30 min irradiation, 80 % of the cells were killed. Therefore it was concluded that photoexcited TiO₂ nanoparticles had an active killing effect on Ls-174-cells.

Effect of TiO₂ concentration on Ls-174-t cells activity

The effect of the TiO₂ concentration ranging from 200 to 1 000 µg/mL on the rate of cell killing by UVA light is shown in Figure 4. The light intensity was 3.7 mW/cm² and kept constant. The experimental results demonstrated that cell viability decreased monotonically as TiO₂ concentration increased and cell viability decreased with time.

Although a higher concentration of TiO₂ could achieve a higher reaction rate, the difficulties in separation and measurement had to be considered. So the effect of a higher TiO₂ concentration ($C > 1\,029\ \mu\text{g/mL}$) on Ls-174-t cell activity was not investigated. The concentration of TiO₂ was set at $< 1\,029\ \mu\text{g/mL}$ with which the dark cytotoxicity was considered to be negligible. The range of TiO₂ concentrations was close to that used previously^[18].

Morphological changes of Ls-174-t cells

Untreated and TiO₂-treated cells were collected by centrifugation and resuspended in RPMI 1640 medium. The samples were pipetted into a 24-well plate, which was directly observed with

an inverted phase-contrast microscope. When treated by photoexcited TiO₂, the cellular shape was condensed and nuclei were dispersed in fragments.

Figure 1 Volume size distribution of TiO₂.

Figure 2 After Ls-174-t cells were incubated in RPMI 1640 medium for 24 h without irradiation, the survival of Ls-174-t cells was shown.

Figure 3 Effect of light and TiO₂ on viability of Ls-174-t cells. (A) TiO₂ (1 000 µg/mL) in the dark; (B) no TiO₂ in the light; (C) TiO₂ (1 000 µg/mL) in the light. Initial cell concentration: 5×10^5 cell/mL, light intensity: 3.7 mW/cm².

Figure 4 Influence of TiO₂ concentration on Ls-174-t cells activity. (A) 204 µg/mL, (B) 524 µg/mL, (C) 804 µg/mL, (D) 1 029 µg/mL.

DISCUSSION

In this experiment, the TiO₂ nanoparticle system was used, displaying its superiority. TiO₂ nanoparticles were easy to attach

to the cellular membranes and accumulate. They were also easy to enter into the cytoplasm via phagocytosis^[19]. It could lead to accumulation of ROS on the surface of cell membranes and in the cytoplasm. Hence under light irradiation, TiO₂ nanoparticles had more significant cell killing effect *in vitro*.

Human colon carcinoma cells treated with photoexcited TiO₂ nanoparticles (C>200 µg/mL) were effectively damaged, with cells contracted and a lot of cell fragments simultaneously observed by an inverted phase-contrast microscope^[18]. According to these characteristics, we assumed that the mechanism of photoexcited TiO₂ in killing human colon carcinoma cells might be through a series of oxidized chain reactions and in inducing cell death by reactive oxygen species^[20-25]. Human colon carcinoma cell damages occurred in two stages. The initial oxidative damage took place on the cell membranes, where the TiO₂ photocatalytic surface had its first contact with intact cells, the membranes became somewhat permeable. At this stage the cells did not lose their viability. Photocatalytic action made the cell membranes permeable, intracellular components began to leak from the cells and free TiO₂ nanoparticles might also diffuse into the damaged cells and directly attack intracellular components, eventually leading to cell death. It is different from the bactericidal effect of TiO₂ photocatalytic reaction. Bacteria are simple prokaryotic cells that do not contain the nucleus characteristics of eukaryotic cells. Whereas human colon carcinoma cells are eukaryotic cells and their structure is complex. Based on their structural differences, we assumed that killing cancer cells might be more difficult than killing bacteria by the photocatalytic reaction of TiO₂ nanoparticles.

In the present study, cultured human colon carcinoma cells were effectively killed by photoexcited TiO₂ nanoparticles *in vitro*. The concentration of TiO₂ affected the photocatalytic killing effect. When the concentration of TiO₂ was below 200 µg/mL, there was only a slight decrease in survival ratio after UVA irradiation for more than 30 min. It was almost the same as that of UVA irradiation alone. It indicated that minor cell membrane leakage might occur and the cell viability was not lost. When the concentration of TiO₂ was above 200 µg/mL, the survival ratio decreased rapidly with increasing TiO₂ concentration. It indicated that major rupture of cell membranes and decomposition of essential intracellular components might take place, thus accelerating cell death. It verified the mechanism of TiO₂ nanoparticles in killing human colon carcinoma cells.

The photocatalytic killing effect of TiO₂ nanoparticles on human colon carcinoma cells suggested the idea of cancer treatment using TiO₂ nanoparticles and light irradiation. Under these conditions, it could be adapted to an anticancer modality by the local or regional treatment of the tumor with TiO₂ nanoparticles, followed by light irradiation focusing on the tumor. Although UVA light (320-400 nm) cannot penetrate the human body deeply, it may be possible that the modality will be applied to several human tumors in the future.

Abstract

AIM: To study the difference of gene expression profile changes in Barrett's esophagus (BE) and cardia intestinal metaplasia (CIM) and to screen the novel genes in the early stage by cDNA microarray.

METHODS: cDNA retrotranscribed from an equal amount of mRNA from BE and CIM epithelial tissues was labeled with Cy3 and Cy5 fluorescence as probes. The mixed probe was hybridized with three pieces of BiostarH-40 s double dot human whole gene chip. The chips were scanned with a ScanArray 4000. The acquired images were analyzed using GenePix Pro 3.0 software.

RESULTS: A total of 141 genes were screened out that exhibited different expression in all three chips. There were 74 upregulated and 67 downregulated genes in gene expression profiles of BE which were two times of that in CIM.

CONCLUSION: There is a difference in gene expression level between BE and CIM epithelia. These 141 genes probably relate to the occurrence and development of BE and the progression to adenocarcinoma.

INTRODUCTION

The incidence of adenocarcinoma in the esophagus and gastroesophageal junction (GEJ) has been increasing over the last two decades in North America and Europe^[1]. Barrett's esophagus (BE) is thought to be a premalignant condition for esophageal adenocarcinoma and most of adenocarcinomas at GEJ^[2]. Recently the presence of cardia intestinal metaplasia (CIM) in some normal GEJ has been described^[3]. The relation of this condition to BE has not yet been investigated.

Recently, cDNA microarray methods are applied to the study of gene expression. The differentially expressed genes in

different specimens may be detected with parallel analysis by gene chips which has greatly improved the traditional experiments in that only a single or several gene expression can be observed for each test, thereby speeding up the identification of differentially expressed genes and the construction of differential expression profiles.

This study was conducted on three 4096-chips, to analyse the gene expression profiles between BE and CIM epithelia, and to screen novel genes by cDNA microarray, which is helpful to understand the molecular mechanism of cell transformation and provides molecular markers and target genes for clinical diagnosis, prevention and treatment of BE and esophageal adenocarcinoma and adenocarcinoma at GEJ.

MATERIALS AND METHODS

Tissue specimens

Tissue specimens in this study were provided by the Second Hospital of Xi'an Jiaotong University, with the approval of hospital and personnel authorities. BE and CIM tissues from 13 operated or biopsy specimens (7 BE and 6 CIM) were proved pathologically. For each sample, one part was cut and frozen in liquid nitrogen immediately after resection, and the other part was used for histopathological examination. Standardized endoscopy was performed by experienced endoscopists. The appearance of sternoclavicular joint (SCJ) was carefully studied from both prograde and retrograde views. BE was defined as any columnar-lined mucosa above the GEJ, which was further confirmed by Alcian blue staining. CIM was defined by the presence of barrel-shaped goblet cells in normal GEJ.

Chip preparation

4 086 of target cDNA clones used in cDNA chips were provided by United Gene Ltd. and cooperative fellows. These genes were amplified with PCR using universal primers and then purified with standard method. The quality of PCR was monitored by agarose gel electrophoresis. The obtained genes were dissolved in 3×SSC spotting solution and then spotted on silylated slides (Telechem, Inc) by Cartesian 7 500 Spotting Robot (Cartesian, Inc). Each target gene was dotted twice. After spotting, the slides were hydrated for 2 h and dried for 0.5 h at room temperature. The samples were cross-linked with UV light and treated with 2 g/L SDS, H₂O and 2 g/L NaBH₄ for 10 min respectively. Then the slides were dried in cold condition and ready for use.

Probe preparation

Total sample RNA was extracted by single step method. Briefly, after taken out from liquid nitrogen, specimens were ground into tiny powder while liquid nitrogen was added in ceramic mortar and then homogenized in D solution plus 10 mL/L mercaptoethanol. After centrifugation, the supernatant was extracted with phenol: chloroform (1:1), NaAc and acidic phenol: chloroform (5:1) respectively. The aqueous phase was precipitated by an equal volume of isopropanol and centrifuged. The precipitates were dissolved with purified H₂O. After further purification by LiCl precipitating method, the obtained RNA sample was analyzed.

mRNAs were isolated and purified with Oligotex mRNA Midi Kit (Quagen, Inc.). The fluorescence-labeled cDNA probe was prepared through retrotranscription, referring to the method of Schena. The probes from CIM tissue were labeled with Cy3-dUTP, while those from BE tissue with Cy5-dUTP respectively. The probes were mixed and precipitated by ethanol, and then resolved in 20 mL hybridization solution (5×SSC + 2 g/L SDS).

Hybridization and washing

Probes and chips were denatured respectively in 95 °C bath for 5 min, then the probes were added on the chip. They were hybridized in a sealed chamber at 60 °C for 15-17 h and washed in turn with solutions of 2×SSC + 2 g/L SDS, 0.1×SSC + 2 g/L SDS and 0.1% SSC for 10 min each, then dried at room temperature.

Fluorescent scanning and result analysis

The chips were read by Scan Array 4000 Scanner (General Scanning Inc). The overall intensities of Cy3 and Cy5 were normalized and corrected by a coefficient according to the ratios of the 40 located housekeeping genes. The acquired image was further analyzed by GenePix Pro 3.0 software with a digital computer to obtain the intensities of fluorescent signals and the Cy3/Cy5 ratio. The data were taken on an average of the two repeated spots. The differentially expressed genes were defined as follows: The absolute value of the Cy5/Cy3 natural logarithm was more than 0.69 (the variation of gene expression was more than 2-fold). Either Cy3 or Cy5 signal value was required for more than 800. The PCR results were satisfactory.

RESULTS

Scatter plot of hybridization signals on gene chip

The scatter plots that were plotted with Cy3 and Cy5 fluorescent signal values displayed a quite disperses pattern in distribution. Most of the spots gathered around a 45° line, in which red spots represented the area where the signal intensities varied between 0.5 to 2-fold compared with those of the control. Some yellow spots distributed beyond or far from 45° line indicated the existence of abnormal gene expressions in BE and CIM epithelia. Their signal intensities were 2 times more than that of the control (Figure 1).

Table 1 Gene function classification between BE and CIM epithelia

Gene function	n	Ratio>2.0	Ratio<0.5
Proto-oncogene and tumor suppression genes	9	6	3
Cell signals and transducing proteins	5	2	3
Cell cycle proteins	8	6	2
Extra-pressure reaction proteins	1	1	0
Cell regulatory proteins	4	4	0
Cell apoptosis related proteins	3	2	1
DNA synthesis, repair and recombinant proteins	3	2	1
DNA binding, transcription and its factor	4	3	1
Cell receptors	1	0	1
Cell surface antigen and adhesion proteins	10	4	6
Ion-channel and transporters	11	6	5
Metabolism-related proteins	16	7	9
Protein synthesis-related genes	11	6	5
Development-related genes	0	0	0
Other genes	38	17	21
New genes	17	8	9
Total	141	74	67

Results and gene expression pattern

As shown in Figure 2, 141 genes were screened out that exhibited different expressions in all three chips, there were 74 up-regulated and 67 down-regulated genes in the gene expression profiles of BE which was 2 times of that in CIM. These genes might be divided into 16 groups (Table 1) according to their functions.

DISCUSSION

Over the last two decades, the incidence of adenocarcinoma of the esophagus and gastric cardia has been increasing rapidly. Barrett's metaplasia is recognized as a precancerous lesion of esophageal adenocarcinoma and most of the adenocarcinomas were found at the GEJ. Progression from metaplasia, dysplasia to adenocarcinoma has been well understood^[4]. Traditionally Barrett's esophagus (BE) is defined as a circumferential segment of columnar lined epithelium of 2 or 3 cm in length in the lower esophagus. Recently this macroscopic definition has been questioned, as it excludes shorter segments and "tongues" of columnar lined epithelium, which are frequently found in the distal esophagus, and endoscopic measurements may be imprecise. It has therefore been proposed that the diagnosis of BE be reserved for patients with intestinal metaplasia detected in biopsy specimens from the distal esophagus. Recently the presence of cardia intestinal metaplasia (CIM) in some normal GEJ has been described^[5-7]. Detection of intestinal metaplasia in the distal esophagus as well as within the gastric cardia was reported with increasing frequency^[8]. The prevalence of BE was reported to vary from 2% to 12% and that of CIM from 5% to 23% in patients undergoing routine upper endoscopy^[9]. The detection of intestinal metaplasia in the BE potentially committed patients to regular surveillance with biopsy. The incidence of adenocarcinoma in patients with BE was estimated to be 30-50 times that of the general population^[10,11]. However, the exact incidence of cancer in patients with BE is unknown, and the role of CIM as a premalignant lesion is still unclear. The relation of this condition to BE has not yet been investigated. It is, however, not clear whether intestinal metaplasia of the

cardia and esophageal mucosa origins has a common pathogenesis and identical risk factors. Despite the frequent occurrence of cardia intestinal metaplasia and its association with *H pylori* gastritis and multifocal gastric intestinal metaplasia, there is still no evidence that this finding could indicate an increased risk of malignancy in the cardia. The well known association of traditional BE with symptoms and endoscopic features of gastroesophageal reflux disease (GERD) has, however, not been confirmed in CIM^[12]. Future studies should differentiate BE from CIM in order to enhance our understanding of the pathophysiology and the malignant potential of each clinical entity. It is therefore necessary to explore new and efficacious diagnostic methods to discriminate BE from CIM.

cDNA microarray methods have been applied in the study of gene expression, DNA sequence, novel genes and gene mutants, DNA polymorphism, and in screening drugs, diagnosing diseases and mapping gene library^[13]. The differentially expressed genes in different specimens may be detected with parallel analysis by gene chips which has greatly improved the traditional experiments in that only a single or several gene expression can be observed for each test, thereby speeding up the identification of differentially expressed genes and the construction of different expression profiles. Profiling of differentially expressed genes of BE to each of the normal upper gastrointestinal (GI) mucosae, including gastric, duodenal, and squamous epithelia of the esophagus by cDNA expression array was also reported^[14]. It has been shown that there was a clear distinction among the expression profiles of gastric, duodenal, and squamous epithelia whereas the BE profiles showed a considerable overlap with normal tissues. Furthermore, the clusters of genes that are specific to each of the tissues from BE, and a cluster of genes distinct from squamous and non-squamous epithelia, were identified. However, no investigation on the difference in gene expression profiles between BE and CIM epithelia by gene chip has been reported yet.

In the present study, we performed an analysis on three 4096 chips in order to acquire the difference in gene expression profiles between BE and CIM epithelia. The results showed that a total of 141 genes were screened out that exhibited different expressions in all three chips. In the gene expression profiles of BE there were 74 upregulated and 67 downregulated genes which were two times of those of CIM. A comparison between these two gene profiles showed that the gene expression levels were different between BE and CIM epithelia. These 141 genes probably relate to the occurrence and development of BE and the promotion or progression in adenocarcinoma, which might be helpful to understand the molecular mechanism of cell transformation and provides molecular markers and target genes for clinical diagnosis, prevention, treatment of BE and esophageal adenocarcinoma and most of adenocarcinomas at GEJ. The gene expression difference between BE and CIM detected by gene chip might provide a new direction for diagnosis, therapy

and prevention of BE.

Abstract

AIM: To construct a DNA vaccine encoding human alpha-fetoprotein (hAFP)/heat shock protein 70 (HSP70), and to study its ability to induce specific CTL response and its protective effect against AFP-expressing tumor.

METHODS: A DNA vaccine was constructed by combining hAFP gene with HSP70 gene. SP2/0 cells were stably transfected with pBBS212-hAFP and pBBS212-hAFP/HSP70 eukaryotic expression vectors. Mice were primed and boosted with DNA vaccine hAFP/HSP70 by intramuscular injection, whereas plasmid with hAFP or HSP70 was used as controls. ELISPOT and ELISA were used to detect IFN- γ -producing splenocytes and the level of serum anti-AFP antibody from immunized mice respectively. *In vivo tumor challenge* was measured to assess the immune effect of the DNA vaccine.

RESULTS: By DNA vaccine immunization, the results of ELISPOT and ELISA showed that the number of IFN- γ -producing splenocytes and the level of serum anti-AFP antibody were significantly higher in rhAFP/HSP70 group than in hAFP and empty plasmid groups (95.50 ± 10.90 IFN- γ spots/ 10^6 cells *vs* 23.60 ± 11.80 IFN- γ spots/ 10^6 cells, 7.17 ± 4.24 IFN- γ spots/ 10^6 cells, $P < 0.01$; 126.50 ± 8.22 $\mu\text{g/mL}$ *vs* 51.72 ± 3.40 $\mu\text{g/mL}$, 5.83 ± 3.79 $\mu\text{g/mL}$, $P < 0.01$). The tumor volume in rhAFP/HSP70 group was significantly smaller than that in pBBS212-hAFP and empty plasmid groups (37.41 ± 7.34 mm^3 *vs* 381.13 ± 15.48 mm^3 , 817.51 ± 16.25 mm^3 , $P < 0.01$).

CONCLUSION: Sequential immunization with a recombinant DNA vaccine encoding AFP and heat shock protein 70 could generate effective AFP-specific T cell responses and induce definite antitumor effects on AFP-producing tumors, which may be suitable for some clinical testing as a vaccine for HCC.

INTRODUCTION

The incidence of hepatocellular carcinoma (HCC) is increasing

worldwide and accounts for as many as 1.2 million deaths annually. It is also rising rapidly in China because of hepatitis B and C infections^[1,2]. Although surgery and liver transplantation are the effective therapy, most patients lost chance due to diagnosis at a late stage or underlying liver insufficiency in the setting of cirrhosis^[3]. Novel therapies for HCC should be developed. A combined therapy is likely to prolong patients' life and living quality.

Much attention has been paid to the induction of host immunity to tumor cells. 80% of HCCs have a high expression of alpha-fetoprotein (AFP), which could serve as a target for immunotherapy^[4-8]. AFP is an oncofetal protein during HCC development, which could generate weaker and less reproducible antitumor protection. A DNA-based vaccine may be a good method for enhancing host immunity^[9-12]. A number of groups have shown that high levels of T-cell immunity could be generated using a heterogeneous prime-boost protocol, in which animals were primed and boosted with a plasmid vector encoding the stimulating molecules and targeted peptides^[8-10]. In many of these vaccine models^[11-15], heat shock protein 70 could combine with certain antigen prime enhanced immunogenicity, presumably through processing and presenting the antigen to host APCs. In the present study, we investigated whether the immunogenicity of AFP could be improved by presenting to APCs through HSP70 molecules. We constructed a eukaryotic expression vector containing the molecular chaperon-HSP70 and AFP fragments. Then priming mice with the genetic vaccine, we elicited robust strong protective immunity.

MATERIALS AND METHODS

Mice and cell line

Balb/c mice were provided by Department of Experimental Animal Center at Capital University of Medical Sciences. SP2/0 mice myeloma cells were maintained in RPMI 1640 (Life Technologies, Inc.) supplemented with 100 mL/L fetal bovine serum (Hyclone Technologies, Inc.). The cells were transduced with pBBS212-hAFP or pBBS212-hAFP/HSP70 through calcium phosphate precipitation (Promega Technologies, Inc.). Positive cell clones were screened by conditioned medium and supernatants were detected by AFP radioimmunoassay (Institute of Nuclear Sciences, Beijing) following the manufacturer's instructions.

Construction of recombinant expression vector

RT-PCR primers were designed to contain the partial hAFP coding region, including the signal sequence. The upper primers were 5'-CCGCTCGAGATGAAGTGGGTGGAATCAA-3', while the downprimers were 5'-CGCGGATCCTTATGGAGTGGGCTTTTGTGTG-3'. RT-PCR template total RNA was isolated from HepG2 hepatocarcinoma cells by TRIzol (Life Technologies, Inc.) reagent. Then the 400-bp hAFP cDNA PCR products were cloned into the pBBS212 empty vector and pBBS212-HSP70 eukaryotic expression vector (provided by Dr. Ye L of Zhongshan Medical University, Guangzhou, China). pBBS212-hAFP/HSP70 and pBBS212-hAFP were constructed using the pBBS212 herpes simplex virus expressing vector, in which the backbone

contained the hygromycin resistance gene, being suitable for screening cell clones. The recombinant vectors were identified by restriction enzyme analysis and sequencing. Different plasmid and recombinant expressing vectors were stored at -80°C for intramuscular immunization^[16].

Mice immunized with recombinant expression vector

Forty female Balb/c mice were divided into rhAFP/HSP70 group, rhAFP group, HSP70 group and empty vector group, PBS group. Each group had 8 mice. Before injection, plasmid and recombinant expressing vectors were diluted in saline to 1 g/L. Various plasmids were injected into the left anterior tibialis muscle of mice. Priming and boosting with plasmid were performed with 100 μg rhAFP or rhAFP/HSP70 vector, whereas pBBS212-HSP70 and empty vectors were used as controls. A 25-gauge, 0.5-inch insulin syringe was used for intramuscular injection. Mice were intramuscularly boosted with above plasmids twice at intervals of two weeks after the first priming.

ELISPOT and ELISA assay

IFN- γ ELISPOT assay was used to measure the frequency of cells producing cytokine IFN- γ in splenocytes harvested from immunized mice. Two weeks after the last immunization, splenocytes were harvested and restimulated directly in anti-IFN- γ monoclonal antibody (PharMingen) coated ELISPOT plate wells *in vitro* with 5 $\mu\text{g}/\text{mL}$ of AFP containing 100 mL/L fetal bovine serum, 10 U/mL of human interleukin-2. The plates were incubated at 37°C for 24 h, then washed and incubated with a biotin-conjugated secondary antibody and developed. The color spots, representing cytokine producing cells, were counted under a dissecting microscope. To detect the level of anti-AFP antibody in mice, we examined the serum of mice tail vein after the last immunization by ELISA using AFP ELISA kits (Biotinge Biomedicine Co, LTD. Beijing) following the manufacturer's instructions.

In vivo tumor load

Another 40 female Balb/c mice were grouped and immunized as above. Tumor challenge was performed 2 wk after the last immunization with 1×10^5 AFP-transfected SP2/0 cells. SP2/0 AFP-transduced tumor cells for challenge were washed after enzymatic digestion and resuspended in 0.2 mL PBS per animal to be injected *s.c.* into the left flank, while empty plasmid and PBS were used as controls. The sizes of tumors were assessed 3 times a week using calipers. Tumor volume was approximated by the following calculation: $4/3 \pi r^3$ (r = radius).

Statistical analysis

Results were expressed as mean \pm SD. The frequency of IFN- γ -producing splenic cells were valued using χ^2 test. The Student's *t* test was performed to analyze the significance of differences between the final tumor volumes of different groups. $P < 0.05$ was considered statistically significant.

RESULTS

Prime-boost vaccines induced T-cell responses and anti-AFP antibody in Balb/c mice

Immunization of Balb/c mice with recombinant hAFP/HSP70 vector elicited much more strong T-cell responses than rhAFP group (95.50 ± 10.90 IFN- γ spots/ 10^6 cells *vs* 23.60 ± 11.80 IFN- γ spots/ 10^6 cells, $P < 0.01$), whereas an intramuscular vaccination with plasmid-HSP70 and empty plasmid produced a weak response (95.50 ± 10.90 IFN- γ spots/ 10^6 cells *vs* 9.25 ± 5.44 IFN- γ spots/ 10^6 cells, 7.17 ± 4.24 IFN- γ spots/ 10^6 cells, $P < 0.01$). Recombinant hAFP/HSP70 immunized mice also produced a higher level of anti-AFP antibody than rhAFP group (126.50 ± 8.22 $\mu\text{g}/\text{mL}$ *vs* 51.72 ± 3.40 $\mu\text{g}/\text{mL}$, $P < 0.01$), while plasmid-HSP70 and empty plasmid produced a lower level (126.50 ± 8.22 $\mu\text{g}/\text{mL}$ *vs* 6.26 ± 4.27 $\mu\text{g}/\text{mL}$, 5.83 ± 3.79 $\mu\text{g}/\text{mL}$, $P < 0.01$) (Table 1).

Boost immunization protected mice from in vivo tumor challenge

Balb/c mice were primed and boosted with rhAFP/HSP70, rhAFP, HSP70 and empty plasmid. The mice were challenged with SP2/0 cells, which were transduced with hAFP. Tumor sizes were significantly smaller in rhAFP/HSP70-immunized mice than in HSP70 and empty plasmid immunized mice (37.41 ± 7.34 mm^3 *vs* 785.83 ± 13.87 mm^3 , 817.51 ± 16.25 mm^3 , $P < 0.01$). Although rhAFP immunized group produced an obvious tumor, it was still significantly bigger than rhAFP/HSP70 group (37.41 ± 7.34 mm^3 *vs* 381.13 ± 15.48 mm^3 , $P < 0.01$) (Table 2).

DISCUSSION

Recent studies on the immunodominant epitopes of AFP have provided a solution to the obstacle of HCC immunotherapy. AFP is produced at low serum levels after birth throughout life^[2-5]. The majority of human HCCs could overexpress the oncofetal antigen AFP, M_r 70 000 glycoprotein^[4,5]. Despite being exposed to high plasma levels of this oncofetal protein during embryonic development, the body has a low immunity to it^[3]. Butterfield *et al.*^[17-19] recently found that four peptides of human AFP processed and presented in the context of HLA-A0201, could

be recognized by human T cell repertoire, and could be used to generate AFP-specific CTL in human T cell cultures. It was also found that murine immune system could generate T-cell responses to this oncofetal antigen^[8]. Therefore, it may be a better target for immunotherapy. But AFP immunization alone still resulted in lower levels of specific response and poorly reproducible protective immunity^[3-7].

How to enhance host's active immunity to AFP may be an interesting strategy for HCC therapy. Previous studies on AFP specific immunotherapy for HCC included AFP plasmid immunization, AFP-transduced DCs immunization and AFP plasmid prime-AFP adenovirus boost immunization^[20-22]. AFP plasmid immunization produced detectable but low levels of AFP specific T cell responses and poorly reproducible protective immunity^[7,20]. DCs engineered to express murine AFP demonstrated a powerful ability to generate tumor-specific immune responses^[21]. However, the need for costly cell culture procedures limited their wide availability for clinical use, and the unstable culture technique might yield tolerating vaccines^[8,21]. AFP plasmid prime-AFP adenovirus boost immunization could engender significant AFP specific T-cell responses and protective immunity in mice^[22]. But the miscellaneous procedures precluded their use. In the present study, we tested a novel strategy to induce antitumor immunity by a DNA vaccine encoding both AFP and HSP70 in mice. We found that the vaccine could elicit strong AFP-specific T-cell responses and produce a distinctively protective effect on AFP-expressing tumors compared with other immunized groups. We should point out that the DNA vaccine hAFP also produced a definite antitumor immunity, but the effect was not sufficient and satisfactory in comparison with that of recombinant vaccine AFP/HSP70. It is of interest to note that recombinant DNA vaccines provoked not only the considerable stability of immunoprotection, but also a detectable level of anti-AFP antibody, although humoral immunity alone had a minor effect on antitumor activity^[23,24].

In the study, we attributed the successful AFP specific T-cell responses in mice to the HSP70 molecules by mediating APCs to efficiently uptake and process of AFP. A number of investigations have shown that HSP70 itself has no antigenicity and its immunogenicity can be attributed to the peptide chaperones carried by itself^[25-29]. It has been verified that HSP70 is a better molecular chaperone and adjuvant, which could process and present weak tumor antigens to MHC-I of host APCs, eliciting specific T-cell responses and CTL reactions^[26-28]. Suzue *et al.*^[29] using a recombinant heat shock fusion protein containing a large fragment of ovalbumin linked to HSP70 injected without adjuvants into Balb/c mice, CTLs were produced that recognized an ovalbumin-derived peptide and the mice were also protected against challenge with ovalbumin-expressing melanoma tumor cells. Several studies have shown that HSP70-associated peptides could anchor antigens on the cell membrane and directly present them to nature killer cells or $\gamma\delta$ T cells as superantigens without dependence on the stimulation of MHC-I molecules^[30-32]. In this experiment, tumor rejection assay demonstrated that recombinant vaccine AFP/HSP70 elicited strong specific antitumor immunity against AFP-producing SP2/0 cells than AFP DNA vaccine. The results indicated that AFP immunogenicity was greatly improved by HSP70 molecules and vaccination with DNA encoding HSP70 could increase both humoral and T-cell proliferation responses to AFP.

In summary, sequential immunization with a recombinant DNA vaccine encoding AFP and heat shock protein70 could generate effective AFP-specific T cell responses and induce definite antitumor effects on AFP-producing tumors, which may be suitable for some clinical testing as a vaccine for HCC.

Abstract

AIM: To study the pathway of apoptosis in chronic liver disease and the role of mitochondria in programmed cell death.

METHODS: Liver biopsy specimens from 72 cases of chronic hepatitis and 29 cases of post hepatitis cirrhosis were studied. The pro-apoptotic protein Fas, FasL, Bax and the anti-apoptotic protein Bcl-2, Bcl-x_L, Bcl-2 α were studied immunohistochemically by SP method. Specimens from 15 cases of chronic hepatitis and post hepatitis cirrhosis were examined for their ultramicrostructures with special attention to their mitochondrial changes. Specimens from 3 normal adults (demised in traffic accidents) were used as control.

RESULTS: The expression of proapoptotic proteins (Fas, FasL, Bax) in hepatocytes was significantly higher in the chronic hepatitis group than in the cirrhosis group ($P < 0.001$). In the study of ultramicrostructure 364 hepatocytes were examined, from 12 cases of chronic hepatitis (including 10 mild cases, 1 moderate case and 1 severe case). Out of 364 hepatocytes 40 (11.0%) hepatocytes were found with various kinds of destruction in their mitochondria. Rupture of the outer membrane of mitochondria and the leakage of matrix from the intermembrane space were definitely demonstrated. The ultramicrostructural changes of mitochondria in the chronic hepatitis group were statistically higher than that in normal adults control group ($\chi^2 = 4.32$, $P < 0.05$).

CONCLUSION: The result of the study was in support of the current view that the apoptotic process in chronic hepatitis patients were largely along the intrinsic pathway (mitochondrial pathway), given that the intrinsic and extrinsic pathways could interlinked (converged) at some point on their progression, also it is impossible at present to exclude the possibility that the two pathways could be chosen by hepatocytes in parallel simultaneously.

INTRODUCTION

Fas receptor induced hepatocellular apoptosis has long been implicated in the pathogenesis of viral hepatitis and potentially other liver diseases. The apoptosis is initiated by binding of the Fas ligand expressed on the surface of lymphocytes to the Fas receptor on the hepatocytes^[1-3]. After initiation the apoptotic process, the cascade reaction of caspases and eventually to the DNA fragmentation and cell death continued^[4,5]. In addition to the above extrinsic pathway it was recognized recently that apoptosis can occur independent of cell surface receptors. Apoptosis can occur through the activation of p53 by DNA damage. Activation of p53 leads to translocation of proapoptotic protein Bax to the mitochondria and form pores at the outer mitochondrial membranes. The formation of pores induces the release of cytochrome c and other proteins from the intermembrane space. The released cytochrome c and other protein then activated other caspases and eventually lead to apoptosis (intrinsic pathway)^[6-8]. In this study we tried to find out the apoptosis pathway in chronic hepatitis. We studied it by immunohistochemical method and ultramicrostructural examination of mitochondrial changes.

MATERIALS AND METHODS

Liver biopsy specimens from 72 cases of chronic hepatitis of more than one year and 29 cases of post-hepatitis cirrhosis were studied immunohistochemically, out of them 12 cases of chronic hepatitis, 3 cases post-hepatitis cirrhosis and 3 normal adults, were examined by electronmicroscopy for the ultramicrostructures of apoptotic hepatocytes. Criteria of clinical and histological diagnoses were carried out in accordance with the consensus protocols published by the 10th Congress of Viral Hepatitis of China. The histological activity of hepatitis was assessed by the histological activity index (HAI) of Knodell *et al.*^[9] The intensity of expression in immunohistochemical assay was divided into (-), (+), (++) and (+++) in this study^[10,11].

Serum markers of HBV infection and anti-HCV antibody were detected by ELISA. Liver biopsy specimens were examined after hematoxylin and eosin staining. The immunohistochemical examination was carried out by streptavidin peroxidase conjugation. Mouse anti-human Bcl-2, Bcl-X_L monoclonal antibody and rabbit anti-human Fas and rabbit anti-human FasL polyclonal antibodies were obtained from Santo Cruz (USA). Mouse anti-Bcl-2 α monoclonal antibody was obtained from Maixin Bio company. Ultramicrostructure of mitochondria was studied by EM of Hitachi H-600 (Japan). The ultramicrostructure changes of mitochondria in specimens from 15 cases of chronic hepatitis and post hepatitis cirrhosis were examined with special attention to their mitochondrial changes. Specimens from 3 normal adults (demised in traffic accidents) were used as control. At least 15 hepatocytes in each section were observed.

The statistics was carried out by χ^2 with MINITAB software.

RESULTS

Immunohistochemical findings

Both the expressions of proapoptotic proteins (Fas, FasL, Bax) and antiapoptotic proteins (Bcl-2, Bcl-2 α , Bcl-X_L) were found mainly in cytoplasm and membranes of hepatocytes. Some expressions could also be found in cytoplasm of epithelial cells of the biliary canaliculus. In 101 cases of chronic liver disease the proapoptotic protein expression was significant higher than the antiapoptotic protein expression. The proapoptotic proteins Fas, FasL, Bax were 87.5%, 94.4% and 91.7% respectively. the antiapoptotic proteins Bcl-2, Bcl-X_L, Bcl-2 α were 56.9%, 61.1% and 38.9% ($P<0.001$) respectively in the chronic hepatitis group (Figures 1, 2, Tables 1-3).

Figure 5 Herniation of matrix from ruptured membranes of apoptotic mitochondria (Trans-EM, original magnification: $\times 20\ 000$).

Untramicrostructure findings

The ultramicrostructures of mitochondria in 12 cases of chronic hepatitis (including 10 mild cases, 1 moderate case and 1 severe

case) were studied. Among the 364 hepatocytes examined, 40 hepatocytes (11.0%) were found with distinct abnormality in their mitochondria (Table 4). Changes of the mitochondria include disappearance of cristae, rupture of the outer membranes (Figures 3, 4), leakage of mitochondrial matrix, “herniation” of matrix from the ruptured membranes (Figures 5, 6).

Figure 6 Degeneration and concentration of apoptotic mitochondria (Trans-EM, original magnification: $\times 15\ 000$).

DISCUSSION

This study demonstrated that the proapoptotic proteins in chronic hepatitis were significantly higher than the antiapoptotic proteins. This was in strong contrast to many tumor cells whose antiapoptotic proteins were higher than proapoptotic proteins. It was also noted that in the 12 cases of chronic hepatitis patients of more than one year the outer mitochondrial membrane damages or ruptures were also in strong contrast to the normal adults control. Recent investigations inclined to support the view that the apoptosis of hepatocytes may be taken the intrinsic pathway (or mitochondrial pathway)^[12-15]. In view of the prominent mitochondrial changes seen in this study the author was highly in favor of the current view that the apoptosis of hepatocytes in chronic hepatitis may begin from the injured DNA which activates the p53 protein to translocate the proapoptotic protein Bax to the mitochondrial and form pores at the outer mitochondrial membrane to release the cytochrome c to the cytosol. This beginning lead to the complete death of the hepatocytes^[16].

The result was considered consistent with the current view that the apoptosis in chronic hepatitis was a comparatively long persistent phenomenon which took place mainly along the intrinsic pathway (mitochondria pathway), although it was impossible at present to exclude the possibility that the intrinsic and extrinsic could take place in parallel simultaneously. Further study of the apoptotic pathway of chronic hepatitis would be helpful in finding out the effective methods of interrupting the progressive course of the disease.

ACKNOWLEDGEMENTS

We would like to express thanks to Professor Yao- Xuan Huang for directions.

Abstract

AIM: To construct a recombinant *E. coli* strain that would highly express the proinflammatory outer membrane protein of human *Helicobacter pylori* (*H. pylori*).

METHODS: The oipA DNA was amplified by PCR, inserted into pET-32a, and transformed into Top10 *E. coli* strain. This recombinant plasmid of Top10 was sent out for nucleotide sequence analysis. Finally this sequence AF479754 was compared with HP0638 and JHP0581.

RESULTS: The sequence of the aim gene was obtained. It had 924 base pairs. The identity was 95.32% against HP0638, 95.02% against JHP0581, which was higher than the identity between HP0638 and JHP0581.

CONCLUSION: Although the aim gene was obtained, but it was different from the published sequence of GenBank. It is not clear what makes this difference. Maybe it is because different strain was used or because there were some variations. So more researches are required to prove it.

INTRODUCTION

In order to find a good vaccine to end the coexistence of human and *Helicobacter pylori* (*H. pylori*), some scientists have focused on exploring some outer membrane proteins in these 10 years. Yamaoka *et al.* found six bands of the outer membrane proteins in *H. pylori* on gels by immunoblot assay kits, 116 ku (CagA), 89 ku (VacA), 35 ku, 30 ku, 26.5 ku and 19.5 ku (Lpp20)^[1-5]. In which 35 ku band is broader than others. It always appears at 33-35 ku. Now a few scientists are studying the 35 ku protein including Yamaoka. They found that 33-35 ku protein was positive in 97.5% patients with peptic ulcer, 70% patients with chronic gastritis. The results showed that it was related to the presence of peptic ulcer. Yamaoka deduced that Hpo638 encoding outer membrane protein oipA had the most possibility, because it had great antigen characteristics, also could increase the

serum level of IL-8. Later studies have shown that oipA is the only index that can differ duodenum ulcer from gastritis, respond to high location of *H. pylori*, serious mucosal infiltration with neutrophils cells, and high level of IL-8.

As so far, there is no study on the oipA in our country. We used PCR technology to amplify oipA gene, to construct the recombinant plasmid, and analyse the DNA sequence. We found that the target sequence AF479754 had some difference with HP0638 and JHP0581.

MATERIALS AND METHODS

Material

H. pylori was afforded by the Department of Microbiology, Chongqing University of Medical Sciences. Top10 *E. coli* strain and pET32a(+) plasmid were presented by the Institute of Viral Hepatitis of Chongqing University of Medical Sciences. Endonucleases, T4 ligase and Pfu -Taq DNA polymerase were purchased from Promega. PCR marker was purchased from Shanghai Sangon. The kits for purification of plasmids and PCR products were obtained from Omega. Primers were synthesized in Shanghai Sangon.

Isolation and identification of *H. pylori*

Each gastric biopsy specimen was inoculated on *H. pylori* medium plates. The plates were incubated at 37 °C under microaerobic conditions (50 mL/L O₂, 100 mL/L CO₂ and 850 mL/L N₂) for 3 to 5 d. A bacterial isolate was identified as *H. pylori* according to typical Gram staining morphology, biochemical tests positive for urease and oxidase, and agglutination with commercial rabbit antibody against whole cell of the microbe. All *H. pylori* isolates were stored at -70 °C.

Preparation of DNA template

Genomic DNA of *H. pylori* were extracted by the conventional phenol-chloroform method and DNase-free RNase treatment. The obtained DNA was dissolved in TE buffer, and its concentration and purity were determined by ultraviolet spectrophotometry.

Polymerase chain reaction

Oligonucleotide primers were designed to amplify the whole sequence of oipA gene from *H. pylori* strain 26 695 based on the published corresponding genomic sequences. The sequence of oipA sense primer with an endonuclease site of *Bam*H I was 5'-CCGGATCCATGAAAAAGCTCTCTTACT-3'. The sequence of oipA antisense primer with an endonuclease site of *Xho*I was 5'-CGCGGCTCGAGTTAATGTTTGTTTTAAAGTT-3'. The total volume per PCR was 100 L containing 2.5 mol/L each dNTP, 500 nmol/L each of the two primers, 15 mol/L MgCl₂, 3.0 U Pfu-Taq polymerase, 100 ng DNA template and 1×PCR buffer (pH8.8). The parameters for PCR were at 94 °C for 4 min, ×1; at 94 °C for 60 s, at 52 °C for 50 s, at 72 °C for 60 s, ×30; then at 72 °C for 7 min, ×1. The results of PCR were observed under UV light after electrophoresis in 10 g. l-1 agarose pre-stained with ethidium bromide.

Construction of *H pylori oipA* recombinant plasmid

PCR products were digested by endonucleases *Bam*H I and *Xho*I, meanwhile pET32a(+) plasmid was cut by *Bam*H I and *Xho*I. After purification by the kits for purification of PCR products, these two fragments were ligated with cohesive ends. Then the recombinant plasmid was transformed into *E. coli* line Top10. The *E. coli* Top10 containing the recombinant plasmid was amplified in LB medium containing AMP. Clones were picked out randomly through blue/white screening. Finally the plasmids were extracted with a plasmid extraction kit according to the manufacturer's instructions and identified by PCR and digestion endonucleases of *Bam*H I and *Xho*I.

Sequence analysis

Top10 *E. coli* strains containing recombinant plasmid were sent to Shanghai GeneCore Biotechnologies Co. for DNA sequence analysis.

RESULTS

PCR amplification of *oipA* encoding sequence

Target fragments of *oipA* genes with expected sizes amplified from DNA template of *H pylori* stains are shown in Figure 1.

Figure 1 Amplification of human *H pylori oipA* gene by PCR. Lane 1: DNA markers (10 000, 8 000, 6 000, 5 000, 4 000, 3 500, 3 000, 2 500, 2 000, 1 500, 1 000, 750, 500, 250 bp from top to bottom); Lane 2: *oipA* gene fragment (924 bp).

Figure 2 Construction technologic route of recombinant plasmids.

Construction and identification of recombinant plasmids

To construct the recombinant plasmid of *H pylori oipA*, purified PCR products were ligated with endonuclease-digested pET32a (+), and the recombinant was transformed into *E. coli* line Top10. White clones were picked out and confirmed by PCR and dual endonuclease digestion with *Bam*H I/*Xho*I. The technologic route is shown in Figure 2. Electrophoresis showed that a fragment of about 924 bp was released (Figure 3).

Figure 3 Dual endonuclease digestion identifications of recombinant plasmids. Lane 1: DNA markers (10 000, 8 000, 6 000, 5 000, 4 000, 3 500, 3 000, 2 500, 2 000, 1 500, 1 000, 750, 500, 250 bp from top to bottom). Lane 2: Digestion fragments of recombinant plasmids.

Sequence analysis

Samples were analyzed with an automatic sequence analyzer. Sequencing results are published in the GenBank. The accession number is AF479754. The identity was 95.32% against HP0638 and 95.02% against JHP0581, which was higher than the identity between HP0638 and JHP0581. HP0638 only was 918 bp while JHP0581 was 924 bp (6 bp TCTCTC at 37th site) and AF479754 also was 924 bp (6 bp CGAACA at 190th site).

DISCUSSION

How to prevent and eradicate *H pylori* infection is the core of the clinical therapy. The native immunity has little effect on it. Some experiments concluded that vaccine could decrease the infection, especial the incidence rate of peptic ulcer and gastric cancer. So an optimal vaccine can end the coexistence of human and *H pylori*. In recent 10 years, studies have gone deep in this wind of proteins, such as CagA, VacA, UreA, UreB, HSP, PldA, Nap.

Yamaoka deduced that Hp0638 encoding outer membrane protein *oipA* was the best candidate, because it had great antigen characteristics, and could increase the serum level of IL-8 also. Later studies showed that *oipA* was the only index that could differ duodenum ulcer from gastritis, respond to high location of *H pylori*, serious mucosal infiltration with neutrophil cells, and high level of IL-8. So far, there is no study on the *oipA* in our country. So we chose this subject. Our results showed that the identity was 95.32% against HP0638 and 95.02% against JHP0581, which was higher than the identity between HP0638 and JHP0581. The difference could be explained in two ways. One is that the strain we used was different from 26695 and J99. Different strains have different gene fragments, just as the difference between HP0638 and JHP0581. The other is that variation of the same strain induced the difference. Compared with JHP0581, AF479754 had the same base pairs. Only the insert site of 6 bp was different. It maybe one subtype of the same strain as 26695 or J99.

The value of the difference lay in three points. First, it contributes to the finding of new strains. Some surveys should be done in the whole country, to show the region characteristics of *H pylori*, and to confirm the main strains in our country. Second, it contributes to the analysis of the changes in pathogenicity and antigen activity, which are very important in elucidating the immune pathogeny. Third, it contributes to the development of new vaccines. The immunity study can provide some help to design the vaccine and optimal immune route. But a variety of strains would bring some difficulties to develop vaccines. So more work should be done to certify the pathogeny of *H pylori*, to develop effective vaccines for the eradication of *H pylori*.

ACKNOWLEDGEMENT

H pylori oipA sequence described in this paper was accepted by GenBank, GenBank accession number for it is AF479754.

Abstract

AIM: To explore the influence of hepatic glucose production on acute insulin resistance induced by a lipid infusion in awake rats.

METHODS: A hyperinsulinaemic-euglycaemic clamp was established in awake chronically catheterized rats. Two groups of rats were studied either with a 4-h intraarterial infusion of lipid/heparin or saline. Insulin-mediated peripheral and hepatic glucose metabolism was assessed by hyperinsulinaemic-euglycaemic clamp combined with [$3\text{-}^3\text{H}$]-glucose infusion.

RESULTS: During hyperinsulinaemic-euglycaemic clamp, there was a significant increase in plasma free fatty acid (FFA, from 741.9 ± 50.6 to $2346.4 \pm 238.5 \mu\text{mol/L}$, $P < 0.01$) in lipid-infused group. The glucose infusion rates (GIR) in the lipid infusion rats, compared to control rats, were significantly reduced (200-240 min average: lipid infusion; 12.6 ± 1.5 vs control; $34.0 \pm 1.6 \text{ mg/kg}\cdot\text{min}$, $P < 0.01$), declining to - 35% of the corresponding control values during the last time of the clamp (240 min: lipid infusion; 12.0 ± 1.9 vs control; $34.7 \pm 1.7 \text{ mg/kg}\cdot\text{min}$, $P < 0.0001$). At the end of clamp study, the hepatic glucose production (HGP) in control rats was significantly suppressed (88%) from 19.0 ± 4.5 (basal) to $2.3 \pm 0.9 \text{ mg/kg}\cdot\text{min}$ ($P < 0.01$). The suppressive effect of insulin on HGP was significantly blunted in the lipid-infused rats (200-240 min: from 18.7 ± 3.0 to $23.2 \pm 3.1 \text{ mg/kg}\cdot\text{min}$ ($P < 0.05$). The rate of glucose disappearance (GRd) was a slight decrease in the lipid-infused rats compared with controls during the clamp.

CONCLUSION: These data suggest that lipid infusion could induces suppression of hepatic glucose production, impairs the abilities of insulin to suppress lipolysis and mediate glucose utilization in peripheral tissue. Therefore, we conclude that lipid-infusion induces an acute insulin resistance *in vivo*.

INTRODUCTION

Insulin resistance plays a primary role in the development of type 2 diabetes and is a feature of other disorders including obesity, dyslipidemias, hypertension, and cardiovascular disease^[1]. The mechanism underlying the occurrence of insulin resistance is unknown but may be related to alterations in lipid metabolism^[2]. More than 30 years ago, Randle and colleagues demonstrated that free fatty acids (FFA) competed with glucose for substrate oxidation in isolated rat heart and diaphragm muscle preparations and speculated that increased fat oxidation might cause insulin resistance associated with diabetes and obesity^[3,4]. Subsequently, some studies have emphasized that, while an increase in circulating FFA during insulin clamp studies could promptly decrease the rate of carbohydrate oxidation, defective glucose uptake which could be detected 3-4 h after lipid infusion in humans^[5,6]. Roden and Dresner have revealed that lipid/heparin infusions could increase plasma FFA levels, inhibit whole-body glucose disposal during hyper- and euglycemic-hyperinsulinemia and insulin-dependent glucose uptake by human forearm tissues *in vivo*, and also found that acute elevations in plasma fatty acids in humans resulted in decreased glucose transport activity, as reflected by decreased concentrations of intracellular glucose 6-phosphate and glucose^[7,8]. Thus, it is possible that chronic elevation of endogenous FFAs contributes to insulin resistance in many pathophysiologic conditions in humans. Acute elevations in plasma FFA levels during a triglyceride emulsion infusion have also been shown to impair insulin-mediated glucose uptake and to inhibit hepatic glucose production (HGP) in rats^[9].

In the current study, we used a triglyceride and cholesterol ester emulsion infusion in combination with hyperinsulinemic-euglycemic clamps to assess the impact of elevated FFA levels on HPG and overall insulin action.

MATERIALS AND METHODS

Preparation of animals

A total of 24 Male Sprague-Dawley rats weighing 250-300 g were housed in individual cages and subjected to an environmentally controlled room with a 12-h light/dark cycle, where they had free access to standard rat chow and water. Five to 7 d before the *in vivo* study, rats were anesthetized with an intraperitoneal injection of pentobarbital (50 mg/kg body mass). A silastic catheter (I.D. = 0.02 in) was inserted into the right internal jugular vein and extended to the level of the right atrium. The catheter for carotid artery was constructed with a short (25 mm) segment of polyethylene tubing (PE-10), connected to a 10-cm length of PE-50 by heating in a flame. The smaller end was advanced through the left carotid artery until its tip reached the aortic arch. The free ends of the catheters were attached to the long segments of steel tubing and tunneled subcutaneously around the side to the back of the neck where they were exteriorized through a skin incision and then securely anchored to the skin by a standard wounded clip. At the end of the procedure, catheters were flushed with 300 μL isotonic saline containing heparin (20 U/mL) and ampicillin (5 mg/mL) and then filled with a viscous solution of heparin (300 U) and 800 g/L polyvinylpyrrolidone (PVP-10, Fisher, NJ) to prevent

refluxing of blood into the catheter lumen.

In vivo clamp studies

Animals were allowed at least five days to recover from the effects of surgery. All studies were conducted in the morning following a 12 to 14-h overnight fast. Throughout the study, the rats were allowed to move freely within the confines of a cage. One hour before clamping the venous and arterial lines were filled with a 9 g/L NaCl solution containing 10 IU/mL heparin. Three double lumen swivels, allowing separate fluid infusions, were connected to three peristaltic pumps. One arterial line was used for the infusion of a 250 g/L glucose solution at a variable rate and the other line was used for infusion of a mixture of (3-³H)-glucose (Amersham Inc, USA), insulin and 150 mL/L lipid emulsion/heparin (20 U/mL). The venous blood sampling tube allowed frequent sampling and repletion of blood loss by means of fresh whole blood obtained from littermates.

At the start of euglycaemic clamp, continuous infusions of isotonic saline (control group, $n = 12$) and lipid emulsion with heparin (lipid group, $n = 12$) were maintained for 4 h at a rate 1.5 mL/h during prolonged euglycaemic-hyperinsulinemic clamp studies. At $t = 60$ min, a bolus (6 μ Ci) and continuous infusion (0.2 μ Ci/min) of (3-³H) glucose were initiated and continued throughout 3 h study. At $t = 120$ min, continuous infusions of insulin (4.8 mU/kg·min) and 250 g/L glucose were maintained for 2 h, 250 g/L glucose was adjusted every 5–10 min, maintaining basal plasma glucose concentrations (~ 5 mmol/L) during the insulin clamp studies. At $t = 0, 120, 200, 220, 230$ and 240 min, blood samples were collected for determination of plasma glucose, insulin, free fatty acid (FFA) and specific activity of tritiated glucose.

A separate set of 240 min lasting control clamp experiments without lipid infusion were performed to investigate the self-amplifying effect of long-term clamping on insulin-mediated glucose metabolism, since glucose metabolism was not constant during a 240 min study^[10]. The experimental procedure was identical to the lipid infusion clamps.

Analytical procedures

Plasma insulin was measured by radioimmunoassay (RIA) using rat insulin as standard (Linco Research, Inc. MO). Inter- and intra-assay variations of the insulin assay were 5.8% and 6.5%, respectively. Enzymatic colorimetric kits were used to determine plasma concentration of FFA (Wako Chemicals, Inc. VA). The inter- and intra-assay variations were 3.6% and 4.2%, respectively, during measurement of plasma FFA. Plasma for [3-³H]-glucose radioactivity (150 μ L) was deproteinized by barium hydroxide-zinc sulphate, the supernatant was evaporated to dryness at 60 °C to eliminate tritiated water and counted for 10 min in a beta scintillation counter.

Calculations

The rate of exogenous infused glucose to maintain euglycaemia during the steady-state period (from $t = 180$ –240 min) was used for the assessment of insulin action. All calculations were carried out in this period when the total amount of glucose taken up by all tissues of the body was equal to the input of glucose into the body. During this steady-state, when the rate of glucose appearance (GRa) was equal to the rate of glucose disappearance (GRd), the glucose turnover rate, which equaled to GRa and GRd in mg/min, was calculated by dividing the [3-³H]-glucose infusion rate (dpm/mg) by the steady-state value of glucose specific activity (dpm/mg). Under these conditions, the glucose turnover rate was equal to the sum of the rates of exogenous infused glucose and of hepatic glucose production (HGP). From this equation the rate of HGP was calculated. Since urinary glucose loss was not present, peripheral glucose uptake (PGU) was taken as glucose turnover rate which equaled to exogenous

glucose infusion rate plus rate of HGP.

Statistical analysis

Data were presented with mean \pm SD. Comparisons between groups were made by the two-tailed Student's *t* test. All statistical analyses were performed using SPSS.

RESULTS

General characteristics of animals

There were no differences in the mean body mass between control and lipid-infusion rats. Basic plasma concentrations of glucose, insulin, and free fatty acids (FFA) were similar in the two groups (Table 1).

Table 1 General characteristics of control and lipid-infusion rats ($n = 12$, mean \pm SE)

Group	Control	Lipid-infusion
Body mass (g)	279 \pm 19	286 \pm 17
Fasting blood glucose (mmol/L)	5.2 \pm 0.1	5.1 \pm 0.2
Fasting plasma insulin (mU/L)	30.3 \pm 2.4	27.9 \pm 2.2
Fasting free fatty acids (μ mol/L)	672.5 \pm 92.2	741.9 \pm 50.6

Effects of surgery

As expected, following surgery catheterized animals lost significant weight during the initial 24-h period, averaged 18 \pm 3 g. Following this catabolic stage they appeared well and normally active. Food intake was qualitatively normal, and average daily weight gain (~ 5 g) closely resembled that of normal littermates that did not undergo surgery.

Figure 1 Time course of glucose infusion rate during hyperinsulinemic euglycemic clamping.

Figure 2 Steady-state hepatic glucose production, glucose disappearance rate, glucose infusion rate during hyperinsulinaemic-euglycaemic clamp studies in control and lipid-infused rats. ^b $P < 0.01$, vs control.

Insulin clamp studies

A lipid infusion of 4 h at a rate of 1 mL/h was used to examine the effect on plasma insulin, FFA, peripheral glucose uptake

FFA: free fatty acids. GIR: glucose infusion rate. GRd: glucose disappearance rate. HGP: hepatic glucose production. ^a*P*<0.05; ^b*P*<0.01 vs control; ^c*P*<0.05; ^d*P*<0.01 vs Basal. The basal values of HGP were determined at 120 min.

and hepatic glucose production. During the euglycemic-hyperinsulinemic clamps blood glucose concentrations remained constant compared to the basal levels and were not different between control and lipid infusion studies. Plasma insulin concentrations increased similarly to ~100 mU/L in both studies (Table 2). The coefficients of variation in plasma glucose and insulin levels were 4.8 and 7.6 %, respectively, in all studies. In the control study the plasma concentration of FFAs dropped by ~65% once the euglycemic clamp was started, but it increased approximately fourfold (from 741.9±50.6 to 2346.4±238.5 μmol/L, *P*<0.01) within 120 min of hyperinsulinemic clamp in the lipid-infused group (Table 2). The time course of the glucose infusion rate (GIR) during insulin clamp is shown in Figure 1. The GIR in lipid infusion rats, compared to control rats, was significantly reduced (200-240 min average; lipid infusion; 12.6±1.5 vs control; 34.0±1.6 mg/kg·min, *P*<0.01, Table 2 and Figure 2), declining to ~35% of the corresponding control values during the last time of the clamp (240 min: lipid infusion; 12.0±1.9 vs control; 34.7±1.7 mg/kg·min, *P*<0.0001, Figure 1). After a 14-h fast there was no significant difference in HGP between the two groups (19.0±4.5 vs 18.7±3.0 mg/kg·min in control and lipid-infused rats, respectively). At the end of hyperinsulinemic-euglycemic clamp study, the HGP in control rats was significantly suppressed (88%) from 19.0±4.5 (basal) to 2.3±0.9 mg/kg·min (*P*<0.01, Table 2). The suppressive effect of insulin on HGP was significantly blunted in lipid-infused rats (180-240 min: lipid infusion; from 18.7±3.0 to 23.2±3.1 mg/kg·min *P*<0.05, Table 2). The time courses of HGP for controls and lipid-infused rats are shown in Table 2. During the clamp, the GRd was significant increased compared with basal values. Although the GRd had no significant difference between the two groups, there was a slight decrease in lipid-infused rats compared with controls (Table 2). Figure 2 shows the average values of HGP, GRd and GIR during the clamp in control and lipid-infused rats.

DISCUSSION

Obesity is associated with insulin resistance and hyperinsulinemia, two important cardiovascular risk factors^[11]. What remains

uncertain is how obesity produces insulin resistance and hyperinsulinemia. It has recently become clear, however, that FFA plays a pivotal role in this process. Although there are a number of studies on this subject, the precise mechanisms of FFA effect on insulin action are not completely understood. In the present study we examined the effect of a 4-h lipid infusion on *in vivo* insulin action in conscious rats, by the hyperinsulinaemic-euglycaemic clamp technique, in combination with a continuous infusion of [3-³H]-glucose. This method is considered to be the most suitable for the measurement of *in vivo* insulin. In our hyperinsulinemic clamping, insulin infusion increased plasma insulin levels to an approximate three-fold over basal insulin level, whereas blood glucose was clamped at approximately 5.3 mmol/L in the control and lipid infusion groups. Plasma FFA concentrations were suppressed by approximately ~65% during clamps in the control group. But in lipid infusion rats, the FFA levels had a rapid increase more than 3.8-fold over basal levels and the increase was maintained to the end of hyperinsulinemic clamp, suggesting that lipid infusion impaired the antilipolytic action of insulin and promoted the release of fatty acids from adipocytes or infused lipid. It is widely known that elevated FFA levels could exert a deleterious effect on insulin's overall actions, and this has been demonstrated in both animals and humans^[12]. The mechanisms underlying FFA-induced insulin resistance are not very clear, but elevated plasma levels of FFA produced at least two distinct biochemical defects: inhibition of insulin stimulated glucose transport and/or phosphorylation, and inhibition of muscle glycogen synthase activity^[13].

In the attempt to better our understanding of the pathophysiology of lipid-induced insulin resistance, we examined the effect of lipid infusions on HGP. We found that HGP was suppressed by ~88% in the controls during hyperinsulinaemic-euglycaemic clamp, suggesting the impact of insulin on the suppression of endogenous glucose production. However, HGP was not significantly suppressed in lipid-infused rats. Thus, lipid infusion elevated the levels of circulating FFA and elevated FFA levels interfered with insulin's ability to inhibit hepatic glucose production. The increased hepatic glucose production in response to lipid infusion suggested that an experimental

elevation of circulating FFA levels could lead to hepatic insulin resistance. On the other hand, during insulin clamp glucose infusion rates (GIR), compared to control rats, were significantly reduced to ~35% of the corresponding control values during the last time of the clamp. At clamping steady state, peripheral glucose uptake was equal to the sum of the rates of exogenous infused glucose (GIR) and hepatic glucose production (HGP). If HGP was completely suppressed, peripheral glucose uptake would equal to GIR (in controls). But, HGP was not significantly suppressed in lipid-infused rats, so peripheral glucose uptake was equal to GIR, which equaled to HGP plus GIR. Total glucose uptake is the sum of glucose removal by insulin-dependent as well as insulin-independent tissues. In the present study we found there was a slight decrease in GIR in lipid infusion groups, although the data did not reach statistical significance. Nonetheless, the trend is obvious since the brain and splanchnic tissues use glucose in an insulin-independent manner, roughly 750 g/L of total glucose utilization is considered to be insulin-independent in fasting condition. Thus, this might indicate that 4 h of lipid infusion induced a partial defect in insulin-stimulated peripheral glucose uptake, consistent with previous *in vivo* studies by Kim *et al.*^[14]. Considering the absence of HGP-suppressing effect of insulin under lipid infusion condition, we concluded that an experimental elevation of circulating FFA levels by lipid/heparin infusions could lead to peripheral and hepatic insulin resistance. The mechanism of lipid-induced insulin resistance remains poorly understood and may involve different IRS-1-associated PI3-kinase activation^[15], and the activity of I κ B kinase- β (I κ B- β , a known serine kinase)^[14,16].

In summary, the current studies showed that infusion of lipid emulsions with heparin to acutely raise plasma fatty acid concentrations could impair the ability of insulin to stimulate overall body glucose disposal and also interfered with insulin's ability to inhibit hepatic glucose production. Thus, we propose that a sustained increase in circulating FFA causes a hepatic insulin resistance, and may lead to a partial defect in insulin-stimulated peripheral glucose uptake, which can be attributed to lipotoxic effect on insulin action.

Abstract

AIM: To establish an experimental animal model of chronic gastritis in a short term and to investigate the effects of several potential inflammation-inducing factors on rat gastric mucosa.

METHODS: Twenty-four healthy, male SD rats were treated with intragastric administration of 600 mL/L alcohol, 20 mmol/L sodium deoxycholate and 0.5 g/L ammonia (factor A), forage containing low levels of vitamins (factor B), and/or indomethacin (factor C), according to an $L_8(2^7)$ orthogonal design. After 12 wk, gastric antral and body mucosae were pathologically examined.

RESULTS: Chronic gastritis model was successfully induced in rats treated with factor A for 12 wk. After the treatment of animals, the gastric mucosal inflammation was significantly different from that in controls, and the number of pyloric glands at antrum and parietal cells at body were obviously reduced ($P < 0.01$). Indomethacin induced gastritis but without atrophy, and short-term vitamin deficiency failed to induce chronic gastritis and gastric atrophy. In addition, indomethacin and vitamin deficiency had no synergistic effect in inducing gastritis with the factor A. No atypical hyperplasia and intestinal metaplasia in the gastric antrum and body were observed in all rats studied.

CONCLUSION: Combined intragastric administration of 600 mL/L alcohol, 20 mmol/L sodium deoxycholate and 0.5 g/L ammonia induces chronic gastritis and gastric atrophy in rats. Indomethacin induces chronic gastritis only. The long-term roles of these factors in gastric inflammation and carcinogenesis need to be further elucidated.

INTRODUCTION

Chronic gastritis including chronic atrophic gastritis (CAG) is common and CAG is a precancer lesion. It is very important to study the etiology of chronic gastritis, especially CAG. We established an experimental animal model of chronic gastritis and investigated the effects of inducing factors on gastric mucosa of rats.

MATERIALS AND METHODS

Animals

Twenty-four healthy, male SD rats weighing 270-290 g were involved in this study. Animals were housed in a controlled environment with a 12/12 h light /dark cycle. The care and handling of the animals were in accordance with the National Institutes of Health Guidelines for the Care and Use of Laboratory Animals.

Chemicals and experimental design

Pure ammonia (Wujin Chemicals Factory, Jiangsu, China) was used to be diluted to a 0.5 g/L solution. Pure alcohol (Yixing Nanxin Chemicals Factory, Jiangsu, China) was diluted to a 60% solution and sodium deoxycholate (DOC-Na) (SERVA Company) was dissolved into sterilized water to make a 20 mmol/L solution. A mixture of carboxymethyl cellulose containing 0.5 mg/mL indomethacin was dispensed.

In this study, an $L_8(2^7)$ orthogonal test was used and comprised 8 testing members, 3 treatment factors (A, B and C) and 2 levels (with or without treatment). Triple tests were conducted and 24 rats were used. Factor A: 0.5 g/L ammonia solution was used as drinking water everyday, intragastric administration of 2 mL of 600 mL/L alcohol was given twice in fasting per week and intragastric administration of 2 mL of 20 mmol/L DOC-Na without fasting everyday but intragastric administration twice in fasting per week was also given. Factor B: forage containing less vitamin was given. Factor C: intragastric administration with 1 mg indomethacin was given everyday. All above doses were used for each rat, the testing period was 12 wk. The control rats had free access to normal rat chow and water.

Histology study

All rats were sacrificed with luxation of cervical vertebra and their stomachs were removed after 12 wk. Gastric mucosa for histological examinations was cut along the lesser curvature from the lower esophagus to the upper duodenum. Samples were immersed in buffered 40 g/L formaldehyde and embedded in paraffin. Paraffin sections were sliced, mounted on glass slides and stained with hematoxylin and eosin (H&E) for histological study. Inflammation grades of gastric antrum and body were based on semi-quantity. Four inflammation grades were classified in accordance with pathological diagnosis of chronic gastritis set up on Huston symposium in 1994^[1]. Four typical signs of inflammation grades were described: 0: no inflammation, the presence of few leukocytes infiltration in gastric mucosa; 1: mild inflammation, a few leukocytes infiltration in upper mucosa or at bottom of gastric glands; 2: moderate inflammation, a large number of leukocytes infiltration in total mucosa; 3: severe inflammation, leukocytes infiltration in heaps in total mucosa. Each inflammation grading result was based on an average of grades of 10 fields under microscope. Thickness of lamina propria mucosa of the stomach was measured at given points which was 150 ± 10 μ m away from the boundary of forestomach in body while 150 ± 10 μ m away from pyloric ring in antrum. Percentage ratio of pyloric gland area to total lamina propria area at gastric antrum was 100 μ m to 200 μ m away from pyloric ring. Also 10 intact oxyntic glands were observed at the above points in gastric body, parietal cell number in each gland and the median number were calculated.

Statistical analysis

All data were analyzed by using variance analysis of an $L_8(2^7)$ orthogonal test. $P < 0.05$ was considered statistically significant.

RESULTS

Effect of inflammation grades on gastric mucosa

At antrum, inflammation grade of gastric mucosa induced by a single factor A was 1.50, 1.67 and 1.75 respectively on three repeated tests. It was significantly higher than that of the control. The grade induced by factor C also was higher than that of the control ($P < 0.01$, Table 1, Figure 1). However, combined treatment of factors A+B+C, A+B, A+C had no effects on enhancing inflammation grades induced by a single factor A. In addition, a single factor B had no effect on inducing gastritis and inflammation grades induced by combined treatment of factors B+C had no difference from that induced by a single factor C (Table 1). The results were similar at gastric body (Table 1, Figure 2).

Figure 1 Severe infiltration of inflammatory cells, decreased thickness of lamina propria and lessened pyloric glands in gastric antrum of rats with gastritis induced by factor A. The results induced by factors A+B+C, A+C, A+B were similar. HE stain $\times 100$. Factor A: Combined intragastric treatments of 600 mL/L alcohol, 20 mmol/L sodium deoxycholate and 0.5 g/L ammonia; Factor B: Treatment of forage containing low levels of vitamins; Factor C: Treatment of indomethacin.

Figure 2 Severe infiltration of inflammatory cells, decreased parietal cells in oxyntic glands in gastric body of rats with gastritis induced by factor A with no changes in thickness of lamina propria. The results induced by factors A+B+C, A+C, A+B were similar. HE stain $\times 100$. Factor A: Combined intragastric treatments of 600 mL/L alcohol, 20 mmol/L sodium deoxycholate and 0.5 g/L ammonia; Factor B: Treatment of forage containing low levels of vitamins; Factor C: Treatment of indomethacin.

Effect of glandular atrophy on gastric mucosa

At antrum, the lamina propria mucosa of rats induced by single factor A was much thinner than that of the control ($P < 0.01$, Table 2) while the lamina propria of rats induced by single factor B or C had no difference from that of the control and there was no statistical difference between that of rats induced by factors A+B+C, A+B, A+C and that of rats induced by single factor A (Table 2). By calculating the percentage ratio of

pyloric gland area to total lamina propria area at antrum, we found the results were similar (Table 3, Figure 1). In addition, we found that although factors A, B or C had no effect on inducing the changes of lamina propria in gastric body, factor A induced a decrease of parietal cells in oxyntic glands. However, combined treatment of A+B+C, A+B, A+C had no synergistic effect with single factor A (Tables 2, 3 and Figure 2). Also no atypical hyperplasia and intestinal metaplasia in mucosa of gastric body and antrum in rats were observed in this study.

DISCUSSION

CAG has been considered a precancerous disease^[2], it is essential to establish a stable, economic and effective experimental animal model of chronic gastritis including CAG for further study on gastritis. Previous studies showed that three methods were practicable to establish experimental models. (1) Biologically induced animal models. Animals such as rats, cats were infected with *Helicobacter pylori* (*H. pylori*) and an experimental model was induced. However, just some of these animals could be induced and models were unstable and it was time-consuming. (2) Animal models induced by physiochemical injury. Models of chronic gastritis were induced by single factors such as alcohol or sodium deoxycholate or ammonia or X-ray irradiation, but the models were unstable and atypical. (3) Immunologically induced animal models. Models of CAG were induced by hypodermic injection with homogeneous, xenogenic or isogenic stomach antigens, but the procedure was complicated and expensive, the effects were unstable^[3-14].

The shortcomings of the above methods have limited further studies on etiology of CAG. However, according to previous studies, we concluded that factors such as infection of *H. pylori*, excessive drinking, reflux of duodenal juice, long-term intake of nonsteroid drugs, malnutrition that could induce continuous gastritis, were considered to be the etiology of CAG^[15-25]. In our study we tried to administer 600 mL/L alcohol to injure gastric mucosa, 20 mmol/L sodium deoxycholate (DOC-Na) as a simulator to reflux of duodenal juice, 0.5 g/L indomethacin to interfere with synthesis of prostaglandin (PG) that was proved to be effective for preventing gastric mucosa from injury and 0.5 g/L ammonia as a simulator to *H. pylori* to induce continuous gastritis in rats. Finally we found that combined administration of 600 mL/L alcohol, 20 mmol/L DOC-Na and 0.5 g/L ammonia for 12 wk could induce an animal model of chronic gastritis with some features of early CAG especially in antrum. Furthermore, our study showed that atrophy of gastric mucosa in rats also developed from gastric antrum to body. It proved once again that excessive drinking, reflux of bile and infection of *H. pylori* played a vital role in inducing chronic gastric mucosal inflammation. It also suggests that the above factors may probably induce CAG. However, we found that indomethacin induced only chronic gastritis but not atrophy of glands in mucosa and had no effect on enhancing glandular atrophy induced by alcohol, ammonia and DOC-Na. In addition, single treatment of forage containing few vitamins in our study could not induce chronic gastritis and glandular atrophy, it is perhaps because the testing duration was too short. The long-term roles of these factors in gastric inflammation and atrophy need to be further elucidated.

In conclusion, an animal model of chronic gastritis can be established by combined intragastric administration with 60% alcohol, 20 mmol/L sodium deoxycholate and 0.5 g/L ammonia. These factors play a vital role in etiology of chronic atrophic gastritis.

Abstract

AIM: To evaluate the efficacy of hepatitis B immunoglobulin (HBIG) in interrupting hepatitis B virus (HBV) intrauterine infection during late pregnancy.

METHODS: We allocated 112 HBsAg positive pregnant women into 2 groups randomly. Fifty seven cases in the HBIG group received 200 IU (unit) HBIG intramuscularly every 4 wk from the 28 wk of gestation to the time of delivery, while 55 cases in the control group received no special treatment. HBsAg, HBeAg, HBcAb, HBeAb, HBsAb and HBV DNA levels were tested in the peripheral blood specimens from all of the mothers at 28 wk of gestation, just before delivery, and in blood from their newborns within 24 h before administration of immune prophylaxis.

RESULTS: The intrauterine infection rate in HBIG group and control group were 10.5% and 27.3%, respectively, with significant difference ($P < 0.05$). It showed ascendant trend as HBV DNA levels in the peripheral blood increased before delivery.

CONCLUSION: HBIG is potent to cut down HBV intrauterine infection rate significantly when administered to pregnant women regularly during late pregnancy. The possibility of HBV intrauterine infection increases if maternal blood HBV DNA $\geq 10^8$ copies/mL.

INTRODUCTION

China is a high incidence area of hepatitis B virus (HBV) infection, with a mean HBsAg positive rate of about 10%. Forty to fifty percent of chronic HBV carriers are caused by vertical transmission, which ranks it among the important modes of HBV infection and an important reason of so many HBV carriers in the crowd. Also, it has close correlations with chronic hepatitis, liver

cirrhosis and liver cancer. Intrauterine transmission is one of the main resources of hepatitis B virus (HBV) vertical infection, but there is no definite prophylaxis up to now^[1-6]. Through HBV DNA quantitation by fluorogenic quantitative polymerase chain reaction (FQ-PCR), we evaluated the efficacy of HBIG in interrupting HBV intrauterine infection during late pregnancy and analyzed the relation between maternal HBV DNA level and the rate of intrauterine transmission.

MATERIALS AND METHODS

Patients

The subjects were drawn from pregnant women who had undergone regular prenatal check-up, and had been admitted for labor and followed up at the Obstetric Department of the Third Affiliated Hospital of Sun Yat-Sen University from December 1999 to October 2001.

The following eligible criteria should all be met: (1) single pregnancy; (2) gestational age ≤ 28 wk; (3) HBsAg positive in serum; (4) normal liver and kidney functions; (5) serial tests were negative for HAV, HCV, HDV and HEV; (6) exclusion of fetal anomalies by B-ultrasonography; (7) no receipt of other agents that were under research, anti-virus, immunomodulating, cytotoxic or steroid hormones during pregnancy; (8) their husbands were not HBV carriers or hepatitis B patients; and (9) ability to give written informed consent.

Methods

A total of 112 pregnant women according to the criteria set above and their newborns of 112 cases were chosen. The pregnant women were randomly divided into a HBIG group (57 cases) and a control group (55 cases). Each case in the HBIG group received 200 IU of HBIG (produced by Sichuan Shuyang Pharmaceutical Ltd.) intramuscularly (im) every four weeks from 28 wk of gestation till delivery, while patients in the control group were given no special treatment. Blood specimens were tested for HBsAg, HBeAg, HBsAb, HBeAb, and HBcAb by enzyme linked immunosorbent assay (ELISA, assay kits produced by Zhongshan Biological Products Ltd.), and HBV DNA quantitation by FQ-PCR (assay kits produced by Da'an Genetic Diagnosis Center of Sun Yat-Sen University) in all the subjects at 28 wk and on the day of delivery, and their newborns (blood from femoral vein) 24 h after birth before the administration of immune prophylaxis. All the subjects followed-up regularly during pregnancy.

HBV intrauterine infection was defined as follows: HBsAg and/or HBV DNA positive in peripheral blood of newborns in 24 h after birth before the administration of active or passive immune prophylaxis.

Statistics

The quantity of HBV DNA was transformed to the form of \log_{10} and then expressed as $\text{mean} \pm \text{SD}$. All data were analyzed as χ^2 (chi-square) test for positive difference and t test for comparisons of means between the 2 groups using SPSS 10.0 for windows. For all comparisons, $P < 0.05$ was considered statistically significant.

RESULTS

Clinical characteristics of pregnant women

There were no significant differences between the two groups as for age, nation, gravidity, abortive parity, gestational weeks, way of delivery, or pregnant complications ($P>0.1$, Table 1).

Table 1 Clinical characteristics of pregnant women of each group

Characteristics	HBIG group (<i>n</i> = 57)	Control group (<i>n</i> = 55)
Age (yr)	26.9±1.8	27.8±2.8
Nationality of Han	57	55
Gravidity	1.5±0.9	1.9±1.2
Abortive parity	0.6±0.7	0.7±1.0
Gestational weeks	39.5±1.9	39±1.3
Rate of cesarean section	27 (47.4%)	25 (45.5%)
Threatened abortion	7	5
Threatened premature labour	2	2
Premature rupture of membrane	0	0
Pregnancy induced hypertension syndrome	1	1
Premature delivery	0	1
Postmature labour	0	0
Elderly primipara	0	0
Medical and surgical associated diseases	2	2
HBeAg positive rate	36 (63.2%)	28 (50.9%)
HBV DNA level (log ₁₀)	5.75±2.98	5.54±3.09

Intrauterine transmission of HBV

There were 6 cases of intrauterine infection in HBIG group. The counterpart in control group was 15. HBV intrauterine infection rate in HBIG group and control group were 10.5% and 27.3%, respectively, with significant difference ($P<0.05$, Table 2).

Intrauterine transmission and the level of HBV DNA in maternal serum

The levels of HBV DNA were divided into 7 grades according to the fluorescent signals set by the operation manual, with grade 0 ($<10^5$ copies/mL), grade 1 ($<10^6$ copies/mL), grade 2 ($<10^7$ copies/mL), grade 3 ($<10^8$ copies/mL), grade 4 ($<10^9$ copies/mL), grade 5 ($<10^{10}$ copies/mL), and grade 6 ($<10^{11}$ copies/mL). The intrauterine infection rate increased with the increase in HBV DNA level in maternal blood, with odds ratio (OR) increasing. The results of rank correlation and *chi*-square test indicated that although it showed an ascendant trend, there were no significant differences in intrauterine infection rate between grade 2 and grade 1, grade 3 and grade 2, grade 5 and grade 4. But there was significant difference between grade 3 and grade 4 ($P<0.05$, Table 3).

Table 2 Characters of neonatal HBV intrauterine infection

	Neonates <i>n</i>	HBsAg	HBeAg	HBcAb	HBeAb	HBsAb	HBV DNA	<i>n</i>	Intrauterine infection <i>n</i> (%)

Table 3 HBV DNA levels in blood of mothers at delivery and HBV intrauterine infection

HBV DNA grade	Mothers (<i>n</i>)	Intrauterine infection		Value of OR
		<i>n</i>	Percentage (%)	
Grade 0 ($<10^5$ copies/mL)	26	0	0	...
Grade 1 ($<10^6$ copies/mL)	22	0	0	...
Grade 2 ($<10^7$ copies/mL)	15	2	13.33	1.00
Grade 3 ($<10^8$ copies/mL)	13	2	15.38	5.55
Grade 4 ($<10^9$ copies/mL)	32	15	46.88	26.91
Grade 5 ($<10^{10}$ copies/mL)	4	2	50.00	30.50

Safety

No adverse events such as fever, rigor, skin rash, inflammation and scleroma at local injected area, or impairment of renal function as well as other discomforts were found during the medication of HBIG. As to Apgar score and development reference such as weight and height of the newborns at delivery, there were no significant difference between the 2 groups ($P>0.1$, Table 4).

Table 4 Development indices of neonates and Apgar score (mean±SD)

	Weight (kg)	Height (cm)	1-minute Apgar score
HBIG group	3.05±0.25	48.0±1.4	10±0.0
Control group	3.04±0.45	48.1±1.5	9.9±0.3

DISCUSSION

Several studies have proved that maternal infectivity is the most important factor in intrauterine transmission of HBV^[7], in which HBV DNA shows directly the condition of replication and infectivity of the virus *in vivo*. The latter can be exactly reflected through HBV DNA quantitation by FQ-PCR test clinically^[8,9]. With the prominent sensitivity and specificity of the FQ-PCR test, our study indicated that the intrauterine infection rate had significant correlation with the level of HBV DNA in the maternal serum before delivery, which showed an ascendant trend; the intrauterine infection rate significantly increased at the level of HBV DNA $\geq 10^8$ copies/mL, which was consistent with the findings by Ngui *et al.*^[10]. Those findings suggest that the threshold of HBV DNA $\geq 10^8$ copies/mL is a potent index of HBV intrauterine infection. To those pregnant women whose serum levels of HBV DNA are high and have high infectivity, we propose to apply highly effective and safe anti-viral medicines to compress the replication of HBV and, therefore, rapidly and dramatically decrease HBV DNA level to interrupt intrauterine infection^[11].

In this study, the intrauterine infection rate in the HBIG group and control group were 10.5% and 27.3%, respectively,

which suggested that the intramuscular administration of HBIG regularly before delivery could effectively interrupt HBV intrauterine infection^[12]. HBIG is a kind of passive antibody. One of its components, HBsAb, can combine with HBsAg, activate the complements, clear HBV, lower the level of virus in maternal blood, and thereby prevent and decrease the infection of normal cells. It was reported that the interruptive effect of HBV intrauterine infection by HBIG might correlate with the acquisition of neonatal passive immune, because placenta could transmit the antibody of IgG actively from mother to fetus during late pregnancy^[13]. However, HBsAb was detected in none of the newborns in our study. The potential reason might be that the HBV level in maternal blood was so high (higher than the quantity that can be neutralized by the passive antibody) that the HBIG administered to mother might not be enough to enter fetal body through placenta. So, we consider to increase the quantity of HBIG in our further studies of HBV intrauterine interruption.

We found that some newborns were HBsAg and HBV DNA negative but HBeAg positive in their blood drawn from femoral vein within 24 h after birth. Whether HBeAg can pass placenta is still under hot debate. It has been suggested that HBeAg can be more easily transmitted via placenta than HBsAg in that it is smaller than the latter and is free from agglutination^[14]. HBeAg or the compound of HBeAg and α -HBeIgG can pass the barrier of placenta by means of active-transfer in human body^[15]. One study also showed that some babies of HBV infected mothers were HBeAg positive and HBsAg negative in femoral blood at birth, and HBsAg titres of the mothers were significantly higher than HBeAg titres (200 times or more). So the positive HBeAg in neonatal serum could not be interpreted as contamination or leakage from the placenta, but can only be explained by that HBeAg can indeed cross placenta^[16]. In our study, babies who were only HBeAg positive were born by mothers who were both HBsAg and HBeAg positive. Moreover, the sensitive and specific HBV-infection marker of HBV DNA quantitation were negative in neonatal peripheral blood, and HBeAg disappeared by 9-12 mo of age. So HBeAg in the neonatal peripheral blood is less likely to be an index of intrauterine infection, but transmitted passively from maternity.

Abstract

AIM: To investigate the expression of tumor suppressor gene *p27* and spindle checkpoint gene *Mad2* and to demonstrate their expression difference in colorectal cancer and normal mucosa and to evaluate its clinical significance.

METHODS: Immunohistochemical staining was used for detection of expression of *Mad2* and *p27* in colorectal cancer and its corresponding normal mucosa.

RESULTS: *Mad2* was significantly overexpressed in colorectal cancer compared with corresponding normal mucosa ($P < 0.01$, $\chi^2 = 7.5$), and it was related to the differentiation of adenocarcinoma, lymph node metastasis and survival period after excision ($P < 0.05$, $\chi^2 = 7.72$, $\chi^2 = 4.302$, $\chi^2 = 6.234$). The rate of *p27* positive expression in adenocarcinomas and normal mucosa was 40% and 80% respectively. There was a significant difference in *p27* expression between adenocarcinomas and normal mucosa ($P < 0.001$, $\chi^2 = 13.333$), which was related to the differentiation degree of adenocarcinoma and lymph node metastasis ($P < 0.05$, $\chi^2 = 8.901$, $\chi^2 = 4$). The positive expression of *p27* was not correlated with survival period after excision.

CONCLUSION: Defect of spindle checkpoint gene *Mad2* and mutation of *p27* gene are involved mainly in colorectal carcinogenesis and associated with prognosis of colorectal cancer.

INTRODUCTION

Genomic instability is a hallmark of malignant cells and occurs either in the form of microsatellite instability or in the form of chromosomal instability (CIN)^[1]. Microsatellite instability is reflected by alteration in polymorphic, short, tandem repeats sequences and is associated with a small fraction of colorectal carcinomas with germ-line or somatic mutations of DNA mismatch repair genes^[2]. On the other hand, CIN, characterized by an alteration in chromosome number and commonly detected as aneuploidy, is likely to occur in most human malignancies. The fact suggests that CIN may contribute to tumorigenesis^[3-5]. In yeast, loss of mitotic checkpoint frequently leads to abnormal

chromosome number, resulting in aneuploidy or polyploidy^[6]. Two major groups of mitotic checkpoint genes, budding uninhibited by benomyl (BUB) 1-3 and mitotic arrest defect (MAD) 1-3, have been identified in budding yeast^[7]. Mammalian homologues of the yeast mitotic checkpoint protein have also been characterized^[8-10]. To date, little information is available in literature about the expression of *Mad2* in carcinoma tissue. In this study, we used immunohistochemical technique to examine the expression of *Mad2* and *p27* in colorectal cancer to elucidate the relation of *Mad2* and *p27* to carcinogenesis and clinical pathological factors.

MATERIALS AND METHODS

Specimens

Cancer tissues and corresponding normal tissues were obtained from Chinese PLA 455 Hospital from January 2001 to May 2003. No patient was treated with anti-neoplasm therapy before tumor removal. Forty patients (22 males, 18 females, aged 25 to 79 years, median age 52.5 years) were as follows: 21 cases of well differentiated adenocarcinoma, 11 cases of moderately differentiated adenocarcinoma, 8 cases of poorly differentiated adenocarcinoma. Twelve cases survived less than 18 mo, 28 cases survived more than 18 mo after excision. All the tissues were fixed in 40 g/L formaldehyde, embedded in paraffin, and cut into 4 μ m thick serial sections.

Reagents

Mad2 polyclonal rabbit antibodies directed against humans were provided by China Science and Technology University. *P27* and immunohistochemical kit were purchased from Beijing Zhongshan Biological Technology Ltd.

Immunohistochemistry

Immunohistochemical staining was performed following the manufacturer's instructions. Anti-*Mad2* antibody was diluted to 1:120. Anti-*p27* was ready to use reagent. For the negative control, the primary antibody was substituted by animal serum. *Mad2* positive expression was stained as brown-yellow mainly in cell plasma. *P27* positive expression was also stained in cell plasma. A semi-quantitative evaluation was used to determine positively expressed cells by viewing 10 vision fields at $\times 400$ magnification as follows^[11]: negative (-), <10% cells were stained; mild positive (+), 11-25% cells were stained; moderately positive (++), 26-50% cells were stained; strong positive (+++), >50% cells were stained. The last three grades were all regarded as positive.

Statistical analysis

The data were analyzed by SPSS version 10.0. χ^2 test was used for statistical analysis. $P < 0.05$ was considered statistically significant.

RESULTS

Expression of Mad2 protein

The positive signals of *Mad2* protein were stained brown-yellow mainly in cell plasma and strength of color was directly proportional to positive percentage (Figure 1A). Positive

expression of *Mad2* protein was detected in 30 of 40 (75%) colorectal cancers, and 18 of 40 (45%) normal tissues. There was a significant difference in *Mad2* expression between colorectal cancer and normal tissue ($P < 0.01$). Moreover, there were significant differences in *Mad2* expression among well, moderately, and poorly differentiated adenocarcinomas (Table 1). The expression of *Mad2* in colorectal cancer was related with lymph node metastasis and survival period after excision.

WD: well differentiated adenocarcinoma; MD: moderately differentiated adenocarcinoma; PD: poorly differentiated adenocarcinoma.

p27 protein expression in colorectal cancer and normal tissue

The positive signals of *p27* protein were stained brown-yellow mainly in cell plasma, weak nuclear staining was also observed. Immunoreactivity for *p27* was found in both normal and neoplastic tissues (Figure 1B). High expression of *p27* was observed in 32 normal tissues, and low expression was observed in remaining 8 normal tissues. Of 40 colorectal cancer samples, 16 (40%) had low expression of *p27*, and 24 (60%) had high expression. There was a significant difference in *p27* expression between colorectal cancer and normal tissue ($P < 0.01$). Moreover, there were significant differences in *p27* expression among well, moderately, and poorly differentiated adenocarcinomas (Table 2). The expression of *p27* in colorectal cancer was related with lymph node metastasis. No relation of *p27* protein was found with survival period after excision.

Correlation between *Mad2* protein and *p27*

We analyzed the correlation between *Mad2* and *p27* protein expressions by χ^2 test. There was no significantly positive correlation between the expressions of *Mad2* and *p27*.

Figure 1 Strongly positive expression of *Mad2* and *p27* in poor differentiated and tubular adenocarcinomas. A: Strongly positive expression of *Mad2* in poor differentiated adenocarcinoma. B: Strongly positive expression of *p27* in tubular adenocarcinoma.

DISCUSSION

Mitotic checkpoints monitor the proper assembly of mitotic spindle and block the onset of anaphase unless all of the chromosomes are stably attached to a specialized region known as kinetochore^[12]. It has been proposed that the mitotic checkpoint proteins, especially *Mad2*, may be crucial for generating the “wait” signal to prevent the onset of anaphase after microtubule disruption^[13-15]. In the present study, the expressions of *Mad2* and *p27* proteins were examined in colorectal cancer and the corresponding normal tissue. *Mad2* expression in colorectal cancer was higher than that in the corresponding normal tissue. The expression of *Mad2* in colorectal cancer was related with histological differentiation, lymph node metastasis and survival period after excision. Our results regarding the expression of *Mad2* are not consistent with the finding that the reduced expression of *Mad2* in breast cancer cells reported by Li and Benezra^[7], but it was similar to the study by Tanaka *et al.*^[15]. The different expression might result from the surrounding in which cells lived. In an organ, cells could be influenced by nerves and endocrine hormones. Michel *et al.* showed that subtle differences in *Mad2* protein level markedly altered checkpoint function^[16]. Therefore, inactivation of *Mad2* would be sufficient to lead to a haplo-insufficient effect and loss of mitotic checkpoint control. The most convincing evidence of the role of mitotic checkpoint defect in CIN in mammalian cells came from two recent studies in *Mad2*^{-/-} mice, and in *Mad2*^{-/-} human and mouse cells, showing that disruption of *Mad2* expression resulted in CIN^[16,17]. It has been reported that CIN cells become aneuploidy, a hallmark of cancer that is associated with an aggressive tumor behavior and a poor prognosis^[18]. Recent studies reported that the *Mad2* protein interacted with estrogen receptor β or the cytoplasmic domain of insulin receptors, which are thought to be regulators

of cellular growth^[19-21]. Our study showed that *Mad2* protein overexpressed in cancer tissue was exclusively present in the cytoplasm of cancer cells. We speculate that cytoplasmic *Mad2* protein may enhance the positive regulatory action of estrogen receptor β and insulin receptor on cell proliferation.

p27 is a member of the Cip1/Kip1 family of cyclin-dependent kinase (CDK) inhibitors and a potential tumor suppressor gene^[22]. Recent studies have demonstrated that targeted inactivation of *p27* could lead to development of multiple organ hyperplasia and malignancy *in vivo*^[23,24]. In this study, we examined the expression of CDK inhibitor *p27* in colorectal adenocarcinomas and corresponding normal tissues. Low expression of *p27* was detected in cancer tissue compared with normal tissues. It was also related to histological differentiation and lymph node metastasis, but not related to survival period after excision. This evidence is similar to that previously reported in other tumors such as tumors of breast, stomach, prostate, lung, liver^[25-32].

Orr-Weaver *et al.* thought that aneuploidy might increase the rate at which tumor suppressors are lost through the loss of heterozygosity. Our study showed that there was no significantly positive correlation between the expressions of *Mad2* and *p27*.

In conclusion, expressions of *Mad2* and *p27* are related to histological differentiation and lymph node metastasis of colorectal cancer. *Mad2* and *p27* proteins might be good markers for predicting histological differentiation and prognosis of colorectal cancer.

Abstract

AIM: To study how intestinal lymph after trauma-induced shock (TIS) interferes with expression of neutrophil adhesion factors (CD11b and CD18) and causes lung injury.

METHODS: Thirty-two adult healthy Sprague-Dawley rats were randomly divided into four experimental groups. Groups 1 and 2 included rats with TIS caused by hitting the mid-upper part of both side femoral bones with a 2 500 kg raw-iron, and with or without ligation of mesenteric lymph duct. Groups 3 and 4 included rats with sham-TIS and with or without ligation of mesenteric lymph duct. Expression of neutrophil CD18 and CD11b in at 1 and 3 h after a 90-min TIS/sham-TIS was evaluated. These rats were killed at 3 h after TIS/sham-TIS, and lungs were taken immediately. The main lung injury indexes (the MPO activity and lung injury score) were measured.

RESULTS: The expressions of CD18 and CD11b at 1 and 3 h after a 90-min TIS and the main lung injury indexes were significantly increased compared with those in the sham-TIS groups ($P < 0.05$). Moreover, at 1 and 3 h after TIS, the expressions of CD18 (32.12 ± 1.25 and 33.46 ± 0.98) and CD11b (29.56 ± 1.35 and 30.56 ± 1.85) were significantly decreased in rats with ligation of mesenteric lymph duct, compared with those (52.3 ± 1.12 and 50.21 ± 1.25 , and 42.24 ± 1.24 and 42.81 ± 1.12 , respectively) in those without the ligation (all $P < 0.05$). The main lung injury indexes in rats with TIS with ligation of mesenteric lymph duct (0.96 ± 0.12 and 6.54 ± 0.35) were also significantly decreased, compared with those (1.56 ± 0.21 and 9.56 ± 0.23) in rats with TIS without the ligation (both $P < 0.05$). However, there was no significant difference in expressions of CD18 and CD11b and the main lung injury indexes between the two sham-TIS groups.

CONCLUSION: Previous ligation of mesenteric lymph ducts prevents or alleviates the up-regulated expression of PMN CD18 and CD11b and the lung injury induced by TIS. Our findings also indicate that neutrophil adhesion molecule activation and lung injury during TIS appear to be caused by some factors that are released or produced by post-ischemic intestine through the mesenteric lymph pathway.

INTRODUCTION

Trauma-induced-shock (TIS) could lead to splanchnic ischemia-reperfusion and gut barrier failure^[1]. These events could get the gut into an inflammatory cytokine-secreting organ, which contributes to the pathogenesis of shock-induced lung injury^[2,3]. Lung injury generally occurs when mediators released by systemic inflammatory processes up-regulate polymorphonuclear neutrophil (PMN) interactions with endothelial cells (ECs), thus favoring PMN sequestration and attack on the lung. Shock and trauma-induced neutrophil activation has been implicated in the pathogenesis of adult respiratory distress syndrome (ARDS) and also as a contributory factor in the development of multiple organ dysfunction syndrome (MODS)^[4,5]. Furthermore, enhanced endothelial-neutrophil interactions resulting in tissue injury appear to be the common pathways by which diverse initiating factors, such as bacterial infection, endotoxin, cytokines, shock, and ischemia can lead to organ injury and MODS^[6]. These events have been implicated in the pathogenesis of pulmonary microvascular injury after intestinal ischemia-reperfusion injuries^[7,8].

However, the exact mechanisms by which intestinal ischemia reperfusion subsequent to trauma and hemorrhage primes neutrophils remain uncertain. There are many discussions about this topic. Since Gonzalez *et al.* demonstrated that port vein blood did not contain such inflammatory mediators in patients with traumatic shock, such as endotoxin or bacteria, more and more people have attached importance to lymph pathway^[9]. Some study in a rat model of trauma-hemorrhagic shock (T/HS) has shown that ligation of the main mesenteric lymph draining the intestine could prevent lung injury^[10], and furthermore, it has been testified that mesenteric lymph from rats subjected to T/HS can prime neutrophils for an oxidative burst^[11]. TIS mesenteric lymph can activate PMNs and increase their ability to injure ECs, and on the other hand, PMN exposure to mesenteric lymph is both necessary and sufficient for the activation of rat PMN respiratory burst by TIS. From a mechanical point of view, respiratory burst activation in response to G-protein-coupled agonists is characterized by enhanced cell calcium $[Ca^{2+}]_i$ flux response to GPC agonists tested^[12,13]. In contrast, portal plasma from TIS rats lacks the potential to activate PMNs.

All these studies lead to the conclusion that lymph from the ischemic gut may be a crucial source of neutrophil priming factors after major hemorrhagic insults, such as lung injury, systemic inflammatory response syndrome (SIRS), MODS, and multiple system organ failure (MSOF). Therefore it has come to be accepted by more and more people that gut-induced lung injury is secondary to a shock-induced gut "inflammatory state", where gut-induced inflammatory factors enter the systemic circulation via mesenteric lymphatics rather than via portal bloodstream. To testify and further extend this concept that neutrophil priming activation was caused by release of factors

from gut into the mesenteric lymphatics, we performed this experiment to study whether TIS could up-regulate neutrophil adhesion molecule expression and cause lung injury, and whether such pathological changes could be prevented or alleviated by ligating mesenteric lymph ducts previously.

MATERIALS AND METHODS

Animals

Adult Sprague-Dawley rats (SD rats) weighing 300-350 g were used after a minimum acclimatization period of 7 d. The animals and their diet were provided by The Laboratory Animal Center, Zhejiang University, College of Medicine, China. The animals were had free access to food and water and were maintained in accordance with the guideline of the National Guide for the Care and Use of Laboratory Animals, and the experiment was approved by the Zhejiang University, College of Medicine.

Experimental design

The aim of this experiment was to assess how the lymph after TIS affected the expression of neutrophil adhesion molecules and caused lung injury in rats. Four groups were included. They were groups of rats subjected to TIS with or without mesenteric lymph duct ligation, and groups of rats subjected to sham TIS with or without mesenteric lymph duct ligation. Femoral artery blood samples were collected 1 and 3 h after a 90-min shock period for further evaluating the expression of PMN. Then these rats were killed immediately, lungs were removed for assessment of the severity of injuries, mainly by measuring myeloperoxidase (MPO) content and lung injury score.

TIS model

As previously described^[14], rats were anesthetized intraperitoneally using sodium pentobarbital (50 mg/kg), and a femoral artery catheter was placed for measuring the artery pressure and an other side femoral artery catheter for taking blood. Then a midline laparotomy was performed to expose the mesenteric lymph duct, which was either ligated with 2-0 silk or just left intact according to the experimental need. The incision was closed. A 2 500 kg raw-iron was used to hit the rat's mid-upper part of both side femoral bones from 30 cm height to cause TIS, then the rat artery pressure was maintained at about 30 mmHg for 90 min, by blood withdrawal or normal saline infusion through one side of the femoral artery catheter, the other side of femoral artery catheter was used to measure the artery pressure. The rats were subjected to TIS for 90 min and then their traumatic legs were tied up closely. The animal body temperature during the experiment was maintained at about 37 °C by using a heating pad.

Sham-TIS model

Except trauma treatment and being subjected to shock state, the sham-TIS model accepted the nearly same treatment as TIS model.

Assay of blood CD11b and CD18

Blood sample (1 mL) collected at 1 and 3 h after 90 min of TIS/sham-TIS state was collected and treated with anti-

coagulant EDTANa2. A 100 µL blood sample was put into a 12 mm×75 mm tube and then 10 µL anti-rat CD11b or CD18 fluorescent labeled monoclonal antibody (BD Pharmingen) was added into the tube. The samples were gently vortexed for 10 min and then placed into a dark room for 40 min. Red blood cells of the sample were lysed and fixed with Coahem Q-PREP equipment (Couletr Company, USA) for 15 min on ice. After centrifuged and washed 3 times, PMN cells were analyzed for adhesion molecule expression using flow cytometer (ESPLL-XL, BECKMAN, USA) according to the recommendation of the manufacturer. The number of these neutrophils labelled with monoclonal antibody in 10 000 neutrophils was counted and the percentage was evaluated.

Assay of myeloperoxidase

Three hours later, rats were killed and the right lung was immediately taken and frozen. The frozen lung tissue was homogenized and processed for measuring myeloperoxidase (MPO) with the reagent kit (Jiancheng Bio-Technology Company, Nanjing, China) according to the manufacturer's instructions. One unit of MPO activity represented the amount of enzyme that reduced 1 µmol/L of peroxidase per minute.

Assay of lung injury score

The lung tissue was fixed in 40 g/L formaldehyde, cut into 4 µm sections and stained with HE. The lung injury score (LIS)^[15] was evaluated with OLMPUS optical microscope (Olympus, Japan). The severity of leukocyte sequestration in the lung tissue was classified as: 0=0%, 1=0-25%, 2=25-50%, 3=50-75%, 4=75-100%. The severity of leukocyte sequestration in lung alveoli was classified as: 0 = none, 1 = few, 2 = a lot, 3 = almost all, 4 = all. The severity of exudation (such as fibrin, transparent membrane and edema liquor) in lung alveoli was classified as: 0 = none, 1 = few, 2 = a lot, 3 = almost full, and 4 = absolute full.

Statistical analysis

Results were expressed as mean±SD. The data were analyzed with SPSS.11.0. The comparison among multiple groups was made with *t* test. Probabilities less than 0.05 were considered statistically significant.

RESULTS

The expressions of CD18 and CD11b in PMN were significantly increased after TIS with or without ligation of mesenteric lymph ducts compared with sham shock groups (*P*<0.05, Table 1). Both CD18 and CD11b expressions were up-regulated by the TIS pathological process. The expressions of CD18 and CD11b in sham shock with or without ligation of mesenteric lymph duct had no significant difference (*P*>0.05). It showed that ligation of mesenteric lymph duct itself had no effect on the expression of CD18 or CD11b. The results also showed that the expressions of CD18 and CD11b after TIS with ligation of mesenteric lymph duct were significantly decreased as compared with TIS without ligation of lymph duct (*P*<0.05). It was suggested that previous ligation of mesenteric lymph duct during TIS could down-regulate the expressions of CD18 and CD11b.

Table 1 Comparison of expressions of CD18 and CD11b in rats of all groups at 1 and 3 h after 90 min of TIS/sham-TIS state(%)

Group	CD18		CD11b	
	1st h	3rd h	1st h	3rd h
TIS with ligation of mesenteric lymph duct (8)	32.12±1.25	33.46±0.98	29.56±1.35	30.56±1.85
TIS without ligation of mesenteric lymph duct (8)	52.3±1.12	50.21±1.25	42.24±1.24	42.81±1.12
Sham TIS with ligation of mesenteric lymph duct (8)	17.02±0.95	15.68±0.98	14.02±1.23	13.63±1.23
Sham TIS without ligation of mesenteric lymph duct (8)	16.23±1.20	16.25±0.53	13.61±1.25	13.51±1.65

The main lung injury indexes (MPO activity and lung injury score) of TIS group were significantly increased compared with sham shock group ($P < 0.05$, Table 2). The results showed that the main lung injury indexes of sham shock groups with or without ligation of mesenteric lymph duct had no significant difference ($P > 0.05$). It seemed that ligation of mesenteric lymph duct itself could not cause lung injury. The results also showed that the MPO activity and lung injury score of TIS with previous ligation of mesenteric lymph duct were significantly decreased as compared with TIS without ligation of lymph duct ($P < 0.05$). It appeared that previous ligation of mesenteric lymph duct could alleviate lung injury effectively during TIS.

Table 2 Comparison of MPO activity and lung injury score in rats of all groups

Group ($n = 8$)	MPO activity (Ug^{-1} lung tissue)	LTS
TIS witht ligation of mesenteric lymph duct	0.96 ± 0.12	6.54 ± 0.35
TIS without ligation of mesenteric lymph duct	1.56 ± 0.21	9.56 ± 0.23
Sham TIS witht ligation of Mesenteric lymph duct	0.45 ± 0.05	2.35 ± 0.56
Sham TIS without ligation of Mesenteric lymph duct	0.50 ± 0.08	2.53 ± 0.41

DISCUSSION

It has been found that the phenomena of neutrophil activation is often companied by TIS, and that activated neutrophils may play a key role in the pathogenesis of lung injury or MODS, MSOF in TIS^[16]. But the mechanism of neutrophil activation, lung injury or MODS is still uncertain. Therefore, the soluble factors in neutrophil activation subjected to TIS and the cellular mechanisms for neutrophil activation are the hot topics. A lot of evidence showed that ischemia-reperfusion gut was an important source of factors that might cause neutrophil activation, lung injury or MODS after TIS^[17-19]. Post-ischemia gut has been shown to be a cytokine-generating organ, and the vascular bed of post-ischemia has been proven to be a priming bed for neutrophils by both clinical and experimental studies^[20]. It is usually believed that the loss of gut barrier function in shock states leads to bacterial translocation. Then such a bacterial translocation might cause sepsis and organ dysfunction in TIS patients. However, studies about TIS showed that neither bacteria nor endotoxin was found in portal blood of severely injured trauma patients. These findings have made people to doubt the theory of bacterial translocation during TIS.

It has been shown that the TIS induced increase in pulmonary capillary permeability could be prevented by ligation of mesenteric lymph ducts^[21], and mesenteric lymph from rats subjected to TIS, but not sham TIS could injure endothelial cells and increase their permeability^[22]. Shock-induced up-regulation of pulmonary endothelial P-selection expression could also be alleviated by mesenteric lymph duct ligation.

Based on these clinical and experimental findings, people come to hypothesize that lymphatics might be the primary route by which intestinal factors leave the gut and cause subsequent injury of lung or other organs instead of portal route. Neutrophil-endothelial interaction is involved in endothelial cell injury and endothelial cell adhesion molecule up-regulation. In order to investigate this hypothesis, we designed these experiments. To explore how TIS lymph affected PMN activation and lung injury, we compared TIS rats with or without ligation of the mesenteric lymph ducts. CD18 and CD11b were chosen as the indicators of PMN activation, and MPO and lung injury score

were chosen as the indicators of lung injury^[23,24].

The results of our study showed that the expressions of PMN CD18 and CD11b and the main lung injury indexes (the MPO activity and lung injury score) of TIS at 1 and 3 h after 90 min of TIS state were significantly increased compared with those of sham shock group, but had no significant difference between two sham shock groups with or without ligation of mesenteric lymph ducts. The results also showed that previous ligation of mesenteric lymph ducts could down-regulate the expressions of CD18 and CD11b and alleviate lung injury in rats subjected to TIS. These results are consistent with the studies of Harkin *et al.*^[25], who showed that mesenteric ligation prevented shock-induced CD11b up-regulation using a less severe shock model. The theory that the gut is a primary source of neutrophil-activating factors is consistent with our study and Adams *et al.*^[26], who found that the ability of plasma from rats subjected to TIS to prime neutrophils for an augment respiratory burst was lost after lymph duct ligation.

Generally, it seems that factors contained in TIS intestinal lymph are both necessary and sufficient to account for neutrophil activation and priming after TIS. The intestine could produce a wide rage of inflammatory mediators, including cytokines, eicosanods, oxidants, platelet-activating factors, complement fragments, and endotoxin^[27,28]. Many of these mediators can prime or activate neutrophils and endothelial cells directly or indirectly. It has been proven that primed and activated neutrophils are involved in the pathogenesis of posttraumatic inflammatory syndromes such as systemic inflammatory response syndrome (SIRS), adult respiratory distress syndrome (ARDS), MODS, and MSOF. It also has been testified that prevention of tissue neutrophil infiltration can reduce lung and other organ injury in the models of TIS^[29]. The results of our experiment also showed that pathologic neutrophil activation by gut lymph was critical to the pathogenesis of TIS.

Since no bacteria or endotoxin was found in mesenteric lymph subjected to TIS, further work is needed to study on the characterization and identification the nertrophil-activating factors in the TIS lymph. It has ever been thought that the lipid fraction of lymph was responsible for neutropil activation^[30]. However, Daysl *et al.*^[31] pointed out that the respiratory burst of rat neutrophils was stimulated by the aqueous but not lipid fraction of the lymph samples. The exact explanation for these conflicting results is not known, but it may suggest that TIS lymph contains several factors which are capable of activating neutrophils. So, further study may still be needed to define the factors in TIS gut lymph which could activate neutrophils and cause injury of lung or other important organs.

In conclusion, mesenteric lymph after TIS contains multiple biologically active agents. These agents have the potential to modify both PMN and EC behaviors, which are probably involved in the pathogenesis of lung injury after TIS. The results showed that up-regulated expressions of PMN CD18 and CD11b and the lung injury induced by TIS could be prevented or alleviated by previous ligation of mesenteric lymph ducts. These findings may indicate that lung injury during TIS is caused by PMN adhesion molecule activation induced by some factors released or produced by postischemic intestine through mesenteric lymph pathway rather than traditionally believed portal vein.

Abstract

AIM: To investigate the expression of PTEN/MMAC₁/TEP₁ and vascular endothelial growth factor (VEGF), their roles in biologic behavior and angiogenesis and their association in gastric cancer.

METHODS: Immunohistochemical staining was used to evaluate the expression of PTEN, VEGF and microvascular density (MVD) on paraffin-embedded sections in 70 patients with primary gastric cancer and 24 patients with chronic superficial gastritis (CSG). Expression of PTEN, VEGF and MVD were compared with clinicopathological features of gastric cancer. The relationship between expression of PTEN, VEGF and MVD as well as the relationship between PTEN and VEGF expression in cancer cells were investigated.

RESULTS: PTEN expression significantly decreased ($t = 3.98$, $P < 0.01$) whereas both VEGF expression and MVD significantly increased ($t = 4.29$ and 4.41 , respectively, both $P < 0.01$) in gastric cancer group compared with CSG group. PTEN expression was significantly down-regulated ($t = 1.95$, $P < 0.05$) whereas VEGF expression ($t = 2.37$, $P < 0.05$) and MVD ($t = 3.28$, $P < 0.01$) was significantly up-regulated in advanced gastric cancer compared with early-stage gastric cancer. PTEN expression in gastric cancer showed a negative association with lymph node metastasis ($t = 3.91$, $P < 0.01$), invasion depth ($t = 1.95$, $P < 0.05$) and age ($t = 4.69$, $P < 0.01$). MVD in PTEN-negative gastric cancer was significantly higher than that in PTEN-positive gastric cancer ($t = 3.69$, $P < 0.01$), and there was a negative correlation between PTEN expression and MVD ($\gamma = -0.363$, $P < 0.05$). VEGF expression was positively associated with invasion depth (especially with serosa invasion, $t = 4.69$, $P < 0.01$), lymph node metastasis ($t = 2.31$, $P < 0.05$) and TNM stage ($t = 3.04$, $P < 0.01$). MVD in VEGF-positive gastric cancer was significantly higher than that in VEGF-negative gastric cancer ($t = 4.62$, $P < 0.01$), and there was a positive correlation between VEGF expression and MVD ($\gamma = 0.512$, $P < 0.05$). VEGF expression in PTEN-negative gastric cancer was significantly stronger than that in PTEN-positive gastric cancer ($t = 2.61$, $P < 0.05$), and there was a significantly negative correlation between the expression of VEGF and PTEN ($\gamma = -0.403$, $P < 0.05$).

CONCLUSION: Our results imply that inactivation of PTEN gene and over-expression of VEGF contribute to the neovascularization and progression of gastric cancer. PTEN-related angiogenesis might be attributed to its up-regulation of VEGF expression. PTEN and VEGF could be used as the markers reflecting the biologic behaviors of tumor and viable targets in therapeutic approaches to inhibit angiogenesis of gastric cancers.

INTRODUCTION

Gastric cancer is one of the tumors with a relatively high incidence and mortality in the digestive system. Although many advanced measures have been taken to improve the outcome of patients suffering from gastric cancer, up to now, there has been no radical progress in reducing its incidence and mortality. This could be due to the fact that the underlying mechanism in tumorigenesis and progression of gastric cancer is still poorly understood. Many studies have demonstrated that tumor suppressor genes, such as *p53*, play an important role in oncogenesis and progression of various malignancies. Recently, many investigators have been interested in the role of PTEN/MMAC₁/TEP₁, a novel tumor suppressor gene, located on chromosome band 10q 23.3. Accumulated evidence has suggested that inactivation of PTEN/MMAC₁/TEP₁ gene was implicated in the carcinogenesis and progression of various tumors^[1-10]. Loss of PTEN expression was dominantly attributed to the inactive alteration of PTEN gene, including mutations, deletions, loss of heterozygosity (LOH) and promoter methylation in various malignancies^[11,12], meaning that the expressive intensity of PTEN could almost embody the status of *PTEN* gene.

Several studies have strongly implied that PTEN was associated with tumor-induced angiogenesis^[13-16]. However, less information regarding the role of PTEN in gastric cancer, to our knowledge, was available. The present study was designed to investigate the role of PTEN in tumorigenesis and progression of gastric cancer and its association with angiogenesis and VEGF expression.

MATERIALS AND METHODS

Subjects

Surgical specimens of 70 patients with histologically confirmed primary gastric adenocarcinoma and 24 patients with chronic superficial gastritis and duodenal ulcer were obtained from Department of General Surgery, Affiliated Hospital, Luzhou Medical College and Department of General Surgery, West China Hospital, Sichuan University in 1996-2000. There were 56 male and 14 female patients in gastric cancer group with age range from 31 to 66 (mean 45) years while there were 21 male and three female patients in chronic superficial gastritis group with age

range from 28 to 43 (mean 35) years. All patients with gastric cancer had received radical resection or palliative surgical treatments, but no one had ever accepted chemotherapy and radiotherapy as well as biotherapy before operation.

Evaluation of clinicopathological features

In gastric cancer group, 18 tumors were categorized histologically as well-differentiation and 52 poor-differentiations. Eight tumors were categorized as early-stage gastric cancer and 62 advanced gastric cancer. Thrifty two patients had serosa invasion, and 46 had lymph node metastasis. According to the criteria set out by the Union of International Cancer Commission (new TNM stage, UICC for gastric cancer, 1985), 20 tumors were categorized as stage I, 16 stage II, 30 stage III and four stage IV.

Antibodies and reagents

Rabbit anti-PTEN polyclonal antibody, rabbit anti-VEGF polyclonal antibody, mouse anti-CD34 monoclonal antibody and streptavidin-biotin-peroxidase (KIT-9710, UltraSensitive S-P for mouse or rabbit) as well as DAB reagents were all purchased from Maixin Corporation (Fuzhou, Fujian province, China).

Immunohistochemical staining

Five-micron paraffin-embedded sections were dewaxed in xylene, dehydrated in ethanol. Endogenous peroxidase activity was blocked by incubation of samples in a 3% solution of hydrogen peroxide in methanol and heated in pressure-cooker for 50 s to retrieve antigens. After washing with PBS, the samples were incubated for 60 min with primary antibody against CD34, PTEN or VEGF at 37 °C, for 60 min with the biotin-conjugated second antibody and for 10 min with the third antibody streptavidin-peroxidase at room temperature, and then the immunoreactive products were stained with DAB and counter-stained with methyl green subsequently. PBS was used instead of the primary antibodies for negative controls.

Evaluation of PTEN and VEGF immunostaining

PTEN and VEGF protein expression in benign and malignant gastric epithelium cells was assessed according to the score graded as the percentage of positive immunoreactive cells and the score graded as positive immunoreactive intensity, and the sum of both was used to reflect the level of PTEN and VEGF protein expression. The score graded as percentage of positive immunoreactive cells was defined as follows: <10% as 0, 10-25% as 1, 25-50% as 2, and $\geq 50\%$ as 3. The score graded as positive immunoreactive intensity was defined as follows: negative stain (equal to background) as 0, weak positive stain (weak yellow) as 1, positive stain (yellow) as 2, and strong positive stain (brown) as 3. The sum of scores less than or equal to 2 (≤ 2) was defined as negative PTEN (PTEN⁻) or VEGF (VEGF⁻) protein expression, and more than or equal to 3 (≥ 3) as positive PTEN (PTEN⁺) or VEGF (VEGF⁺) expression.

Microvascular density counting

Microvascular density (MVD) was determined according to the criterion introduced by Weidner^[17]: any separated single vascular endothelium cell or cluster of endothelium cells and microvascular tube with diameter less than 8 erythrocytes were counted. Briefly, the stained sections were screened at $\times 100$ magnifications under a light microscope (Olympus) to identify four regions with the highest number of microvessels, which were then counted at $\times 200$ magnifications, and the average was used to reflect MVD.

Statistical analysis

All results were expressed as mean \pm SD. Statistic software SPSS 11.5 for Windows was used to analyze the results using Student

t test and Pearson correlation analysis. The accepted level of significance was $P < 0.05$ (Two-tailed).

RESULTS

Characteristics and comparison of PTEN and VEGF expression and MVD in gastric cancer with those in chronic superficial gastritis

PTEN and VEGF expression were demonstrated to localize in cytoplasm of gastric glandular epithelium and tumor cells (Figures 1, 2). In gastric cancer, the positive immunoreactive signal in invasive front region was weaker for PTEN, but stronger for VEGF and microvessels (Figure 3) than that in the fundic region of tumor. There was a significant down-regulation of PTEN expression and a significant up-regulation of both VEGF and MVD in gastric cancer in comparison with those in chronic superficial gastritis (Table 1).

Table 1 Comparison in PTEN and VEGF expression and MVD between chronic superficial gastritis (CSG) group and gastric cancer (GC) group (mean \pm SD)

Groups	<i>n</i>	PTEN	VEGF	MVD
CSG	24	3.13 \pm 2.3	1.25 \pm 1.16	29.6 \pm 9.9
GC	70	1.34 \pm 1.75 ^b	2.94 \pm 1.80 ^b	48.3 \pm 19.9 ^b

^b $P < 0.01$ vs CSG group.

Association of PTEN and VEGF expression and MVD with clinicopathological profiles in gastric cancer

As showed in Table 2, The down-regulation of PTEN expression was closely associated with the older patients (>35 years), invasion depth and lymphatic metastasis of tumor, and a downtrend of PTEN expression was observed with the increase of invasion depth of tumor, especially in advanced stage of gastric cancer ($\geq T_2$) (Table 2). The up-regulation of both VEGF expression and MVD were significantly associated with the invasion depth, lymphatic metastasis and TNM stage, but none of them was associated with the histological differentiation of gastric cancer (Table 2).

Table 2 Association of PTEN and VEGF expression and MVD with clinicopathologic profiles in gastric cancer (mean \pm SD)

Variables	<i>n</i>	PTEN	VEGF	MVD
Age (yr)

^a $P < 0.05$, ^b $P < 0.01$ vs different variables.

Figure 1 Expression of PTEN. A: Strongly positive expression in benign gastric glandular epithelium cells (Immunohistochemical staining, S-P×400). B: Positive expression in moderately differentiated cancer cells (Immunohistochemical staining, S-P×100). C: Weakly positive expression in poorly differentiated cancer cells. (Immunohistochemical staining, S-P×400).

Figure 2 Expression of VEGF. A: Weakly positive expression in benign gastric glandular epithelium cells. B: Strongly positive expression in poorly differentiated cancer cells. (Immunohistochemical staining, S-P×400).

Figure 3 MVD in benign/malignant gastric tissues. A: Less and weakly stained microvessel labeled by CD34 was regularly distributed among the benign gastric epithelium gland (Immunohistochemical staining, S-P×400). B: Increased and strongly stained microvessel labeled by CD34 was irregularly infiltrated in poorly differentiated adenocarcinoma (Immunohistochemical staining, S-P×200).

Correlation of PTEN and VEGF expression with MVD in gastric cancer

MVD was significantly higher in PTEN negative ($n = 54$) than in PTEN positive gastric cancer ($n = 16$) (52.7 ± 19.6 vs 33.4 ± 13.2 , $t = 3.69$, $P < 0.01$), and significantly higher in VEGF positive ($n = 52$) than in VEGF negative gastric cancer ($n = 18$) (52.71 ± 19.59 vs 29.78 ± 12.9 , $t = 4.62$, $P < 0.001$). There was a significantly negative correlation between MVD and the intensity of PTEN expression ($\gamma = -0.363$, $P < 0.05$) and a positive correlation between MVD and the intensity of VEGF expression ($\gamma = 0.512$, $P < 0.01$).

Correlation between VEGF and PTEN expression

The intensity of VEGF expression was significantly higher in PTEN negative than in PTEN positive gastric cancer (3.18 ± 1.53 vs 2.15 ± 2.19 , $t = 2.61$, $P < 0.05$). Furthermore, There was a significantly negative correlation between VEGF and PTEN expression ($\gamma = -0.403$, $P < 0.05$).

DISCUSSION

PTEN/MMAC₁/TEP₁-encoding product, a dual-specificity protein-phospholipid phosphatase, which was involved in regulation of a variety of signal transduction pathways through dephosphorylation, including down-regulation of the activity of the focal adhesion kinase (FAK) to inhibit cell adhesion, invasion and metastasis^[18-20], disabling of phosphatidylinositol 3-kinase (PI3'k)/Akt signal pathway to accelerate cell apoptosis and inhibit cell proliferation and inhibition of MAPK signal pathway to restrain cell differentiation^[21-23]. Some studies^[18-20,24-27] have demonstrated that anti-sense or deletion of PTEN gene significantly up-regulates the ability of cell proliferation, adhesion and migration, accompanied by increased activity of FAK and PI3'k/Akt, whereas over-expression of PTEN protein in wild-type PTEN transfected cells is detected, with a resultant cell cycle arrest, increased cell apoptosis, decreased potential in cell mitosis, proliferation, adhesion and migration, and the

concomitant decrease of FAK and PI3'k/Akt activities, suggesting that PTEN regulates negatively the growth, invasion and metastasis of tumors, and then the inactivation of PTEN greatly contributes to the tumorigenesis and progression of tumors.

So far, little information on the expression and role of *PTEN* gene in gastric cancer is available. Recently, Byun *et al.*^[28] showed an abnormally low expression with only in 36% (20/55) gastric cancer tissues and 33% (5/15) cell lines while none of 71 cases with non-cancer tissues showed a decreased expression. The LOH of *PTEN* gene reached at 47% (14/30) and was closely linked to low expression of *PTEN* mRNA in gastric cancer. Furthermore, the rate of LOH was significantly higher in advanced gastric cancers (63%) than that in early-stage tumors (18%), and in poorly differentiated tumors (69%) than in well- or moderately differentiated tumors (29%). Fei *et al.*^[29] compared PTEN expression in 26 gastric cancer, 21 first-degree relatives of gastric cancer patients and 12 healthy individuals by RT-PCR and immunohistochemistry, and found that PTEN expression was significantly decreased in gastric cancer group and the first-degree relatives group compared with those in matched non-malignant gastric tissues and healthy control group. Kang *et al.*^[30] screened 310 cases with gastric carcinoma, and found that 62 cases lost PTEN expression, and the loss of PTEN expression was linked to the promoter methylation of *PTEN* gene, which was significantly associated with tumor depth and size, lymphatic invasion, advanced stage, pTNM stage, and patients' survival, implying that loss of PTEN expression is involved in the pathogenesis of gastric cancer. Nevertheless, there are some discrepant and conflict findings. One study from Japan did not find any mutation and promoter methylation of *PTEN* gene as well as the alteration of mRNA in gastric cancer cell lines and primary tumor tissues^[31]. Another study showed that the mutation rate of *PTEN* gene was not significantly increased in human advanced gastric cancer^[32], suggesting that PTEN does not participate in gastric carcinogenesis and progression as a tumor suppressor gene. In current study, PTEN expression was only slightly decreased in early gastric cancer cells but significantly decreased in advanced gastric cancer cells, compared with that in benign gastric epithelial cells. PTEN expression decreased as the invasion density increased, and lower PTEN expression was observed in gastric cancer with lymph node invasion and in TNM III/IV stage. Our results were very similar to those reported by Kang *et al.*^[30], suggesting that loss of PTEN expression is a relatively later molecule event in the pathogenesis of gastric cancer, and thus plays more important role in the progression than in oncogenesis of gastric cancer. The malignant gastric epithelial cells with loss of PTEN expression may hold the characteristics with a high aggressive and metastatic potential, and thus PTEN can be considered as an objective and reliable marker reflecting the pathobiological behaviors of gastric cancer. Moreover, Lee *et al.*^[33] showed that loss of PTEN expression was significantly associated with poor gastric carcinoma prognosis. In addition, we also observed a significantly decreased expression of PTEN protein in the older patients (>35 years) with gastric cancer compared with the younger patients, implying that PTEN may be more implicated in the gastric carcinogenesis in the elder. In other words, there might hold dissimilar tumorigenetic mechanisms between the older and younger patients with gastric cancer.

Angiogenesis is prerequisite for progressing tumor growth, invasion and metastasis. MVD in tumor tissue is unanimously considered as a better parameter to reflect the level of the neovascularization of tumor. VEGF, one of the most powerful pro-angiogenic factors, is dominantly involved in all the process including vascular endothelial cell mitosis, proliferation, adhesion and migration. VEGF expression is induced in a hypoxia-inducible factor alpha (HIF-1alpha)-dependent way through activation of the PI3 kinase signaling pathway^[34]. VEGF and MVD are all

involved in prognosis in various carcinomas^[35-38]. Our results revealed a significantly increase in MVD and VEGF expression in gastric cancer cells, and both the VEGF expression and MVD were significantly associated with the invasion depth, lymphatic metastasis and pTNM stage. Furthermore, MVD was significantly correlated with the intensity of VEGF expression. These results suggest VEGF is dominantly involved in the neovascularization of gastric cancer, and thus facilitates the tumor's growth, invasion and metastasis.

Several studies^[13-16] have suggested that PTEN is implicated in the regulation of tumor's angiogenesis, and loss of PTEN expression is closely associated with the increased neovascularization in various malignancies *in vitro* and *in vivo*. However, information on the relationship between PTEN protein expression and neovascularization in gastric cancer is scarce. Zheng *et al.* recently showed MVD was negatively related to PTEN expression in gastric cancer. In the present study, we also observed that MVD in PTEN negative gastric cancer was markedly higher than that in PTEN positive gastric cancer, and there was a significantly negative correlation between MVD and PTEN expression in gastric cancer tissue, implying that loss of PTEN expression is highly implicated in the neovascularization of tumor in gastric cancer.

The mechanism of PTEN-related angiogenesis is not well known. Recent *in vitro* studies^[39-41] have suggested that loss of PTEN expression significantly up-regulates VEGF expression via modulation of HIF-1alpha expression and VEGF-mediated pro-angiogenic signaling through PI3'K/Akt-dependent signaling transduction pathway to enhance the anti-apoptotic, proliferative, and chemotactic activity of endothelial cells and the ability of tube formation. Jiang *et al.* screened the expression of *PTEN* and *HIF-1alpha* mRNA and VEGF protein in human colorectal tumor tissues, and observed a negative correlation of *PTEN* expression with *HIF-1alpha* ($\gamma = -0.36$, $P < 0.05$) and VEGF ($\gamma = -0.48$, $P < 0.05$) and a positive correlation between VEGF and *HIF-1alpha* ($\gamma = 0.71$, $P < 0.01$). In this study, we also found a significantly increase in VEGF expression in PTEN negative gastric cancer compared with PTEN positive gastric cancer, and that the intensity of VEGF expression was negatively associated with PTEN expression. Taking all these findings together, we postulate that VEGF is a key downstream molecule for PTEN function in carcinogenesis and progression in a wide range of human carcinomas including gastric cancer. Therefore, inactivation of *PTEN* gene could contribute to gastric tumor progression by directly functioning on tumor cells to enhance the ability of growth, anti-apoptotic, invasion and metastasis through up-regulation of PI3'K/Akt signaling transduction pathway, by up-regulating VEGF expression in tumor cells, which enhances the activity of tumor-derived angiogenesis and functions on vascular endothelial cells to increase angiogenesis in tumor tissues. Based on these data, it is concluded that PTEN and VEGF are reliable targets in the therapeutic approach for the inhibition of angiogenesis in gastric cancer.

Abstract

AIM: To determine and compare the effect of vagus nerve on gallbladder motility in patients with hepatic cirrhosis before and after portal azygous disconnection (PAD).

METHODS: PAD operation (or Hassab's operation) was performed on 18 patients with portal hypertension, and anterior and posterior vagal trunks were cut. On d 3 before operation and d 10 after operation, ^{99m}Tc -EHIDA 185 MBq was administered intravenously to the patients, and scintigraphy was performed at 0.25 min/frame. A standard fat meal was administered 30 min after scintigraphy, and dynamic imaging was performed 60 min after the fat meal. Following appearance of the region of interest (ROI) in gallbladder, the time-activity curve of ROI was established. The following seven parameters were used: radioactivity at 30 min after injection of ^{99m}Tc -EHIDA (RC 30min), bile emptying fraction (EF), bile emptying period (EP), emptying rate (ER), latent period (LP), latent period radiocounting increment (LI), and latent period radiocounting increment rate (LR).

RESULTS: The RC 30 min decreased significantly after operation, compared with that before operation ($2\,693.6 \pm 2\,406.9$ vs $5\,606.8 \pm 2\,625.4$, $P < 0.05$). The radiocounting of gallbladder increased gradually during LP. LP after operation was significantly longer than that before operation (13.36 ± 5.92 vs 2.24 ± 1.48 , $P < 0.01$). LI and LR after operation were significantly higher than those before operation ($2\,861.62 \pm 208.3$ vs 331.21 ± 421.02 , and 113.42 ± 49.52 vs 7.57 ± 10.75 , respectively, both $P < 0.01$). EP after operation was significantly shorter than that before operation (18.5 ± 6.3 vs 24.1 ± 6.4 , $P < 0.05$). EF and ER after operation were significantly lower than those before operation (13.1 ± 5.4 vs 32.3 ± 16.3 , and 0.7 ± 0.3 vs 1.4 ± 0.8 , respectively, both $P < 0.01$).

CONCLUSION: PAD operation is a good clinical model in studying the effect of vagus on gallbladder motility. The gallbladder tension after PAD operation decreases significantly

during the interdigestive phase. The latent period of gallbladder contraction prolongs and the motility weakens apparently after a standard fat meal. Human vagus influences the gallbladder motility, and cutting of the nerve inhibits the gallbladder motility.

INTRODUCTION

Cholecystolithiasis results from multi-factors^[1-5], of which gallbladder motor dysfunction is an important factor^[5,6]. Gallbladder motility is regulated by nerve system and body fluid^[7], especially the vagus^[8-10]. Because of the complicated interfering factor and its difficulty in control, there were few clinical studies on the gallbladder motility. In this study, vagus nerve effect on gallbladder motility was studied in patients with liver cirrhosis.

MATERIALS AND METHODS

Eighteen patients with portal hypertension (10 males and 8 females) with an average age of 50 years were included in this study. They had hypersplenotrophy and certain degree of hypersplenism. The esophagogastric varication was confirmed with gastroscop. No biliary abnormalities were found with ultrasonography. Hepatic function was classified as Child A level. Splenectomy (Hassab's operation) was performed, anterior and posterior trunks of vagus were cut off after inferior segment of esophagus was liberated. Aerofluxus was observed 48-96 h after operation. Hepatic function was recovered to Child A level 10 d postoperation.

With empty stomach on d 3 preoperation and d 10 postoperation, respectively, ^{99m}Tc -labeled diethyl acetyl acid anilide iminodiacetic acid scintigraphy (^{99m}Tc -EHIDA) 185 MBq was administered intravenously. American SPECT of GE Company was adopted to perform scintigraphy, 0.25 min/frame. Standard fat meals (ENSURE 250 mL standard solution containing caloric 1046.0 KJ, protein 14%, fattiness 31.5%, carbohydrate 54.5%) was provided for patients after 30 min of continuous displaying. The region of interest (ROI) in gallbladder and the time-activity curve of ROI were established (Figures 3A, B). Then, 7 parameters were used to analyze. the radiocounting of ^{99m}Tc -EHIDA injected 30 min later (RC 30 min), emptying fraction (EF, %), emptying period (EP min), emptying rate (ER, %/min): EF/EP, latent period (LP, min): the time from having fat meal to the initiation of contraction of gallbladder, latent period radiocounting increment (LI), latent period radiocounting increment rate (LR, %): the increased amount of radioactivity during LP/the initial radioactivity of LP \times 100. The results were expressed as mean \pm SD. SPSS11.0 software was used for analysis.

RESULTS

Each of the paired pre- and post-operative parameters was proved in normal distribution by normality test (Table 1).

Table 1 Comparison of gallbladder contractive function (mean±SD)

Parameters	Pre-surgery	Post-surgery
RC30 min	5 606.8±2 625.4	2 693.6±2 406.9 ^a
LP (min)	2.24±1.48	13.36±5.92 ^b
LI	331.21±421.02	2 861.6±2 028.3 ^b
LR (%)	7.57±10.75	113.42±49.52 ^b
EP (min)	24.1±6.4	18.5±6.3 ^a
EF (%)	32.3±16.3	13.1±5.4 ^b
ER (%/min)	1.4±0.8	0.7±0.3 ^b

^a $P<0.05$, ^b $P<0.01$, vs pre-operation.

Serum ^{99m}Tc-EHIDA in blood was rapidly taken by liver, egested to biliary system, stored and concentrated in gallbladder. Thirty min after injecting ^{99m}Tc-EHIDA, the radioactivity in gallbladder could reflect the bile quantity entered to gallbladder during interdigestive phase. The RC 30 min postoperation decreased obviously than that preoperation (2693.6±2406.9 vs

5606.8±2625.4, $P<0.05$) (Figure 1).

Figure 1 RC 30 min of gallbladder in pre-PAD and post-PAD.

LP in cirrhotic patients was very short preoperation, and LP prolonged significantly postoperation (13.36±5.92 vs 2.24±1.48, $P<0.01$). The radioactivity in gallbladder in LP increased gradually. LI and LR increased significantly postoperation (2861.6±2028.3 vs 331.21±421.02, 113.42±49.52 vs 7.57±10.75, $P<0.01$) (Figures 2A, B, C). EP in cirrhotic patients was shorter postoperation than that preoperation, EF and ER decreased significantly (13.1±5.4 vs 32.3±16.3, 0.7±0.3 vs 1.4±0.8, $P<0.01$) (Figures 2D, E, F).

Figure 2 After administration of fat meal, changes in some parameters of gallbladder contraction. A: LP, B: LI, C: LR, D: EP, E: EF and F: ER.

Figure 3 Time-activity curves of gallbladder in cirrhotic patients before (A) and after portal azygous disconnection (B) as well as their comparison (C).

DISCUSSION

The Portal azygous disconnection (PAD) is a clinical research model to study the function of human vagus. Most studies on vagus function in gallbladder motility were limited to animal experiments^[9-13]. Some scholars studied the gallbladder motility after gastrectomy and speculated that human vagus had an

important effect on gallbladder motility^[14-16]. In PAD anterior and posterior trunks of vagus were cut, while the integrality of alimentary canal was maintained. Therefore, PAD could eliminate many disturbing factors. Although the basic liver function of patients could disturb the research, we reduced the disturbance to the lowest degree by adjusting liver function of every patient to Child A level, and auto-control method was used on same patient pre- and post-operation.

Radioactive nuclide ^{99m}Tc-EHIDA can be specifically taken by liver cells, then egested with bile and discharged through biliary system to intestinal tract. Dynamic flowing of bile can be displayed accurately by SPECT scintigraphy with a clear picture and a high resolution. It has little radiation damage to the patients, and is a good way to study the motility of gallbladder and biliary system^[17-19].

Gallbladder motility is regulated by nerve system and body fluid factors. Gallbladder emptying after ingestion is affected by multiple factors. Vagus cholinergic fibers could cause gallbladder empty after ingestion, sham feeding could result in gallbladder emptying to 25-56%, and this function could be inhibited by cutting vagus or injection of atropine^[8-11,20,21]. Acetylcholine and other parasympathomimetic drugs could enhance the gallbladder tension and motility. Stimulating the vagus of dogs with electric current caused contraction of gallbladder, and gallbladder contracted slowly after both sides of the vagus were completely cut^[10]. In our study, vagus in patients with liver cirrhosis was cut off in PAD to study its effect on gallbladder motility. ^{99m}Tc-EHIDA scintigraphy was used. Gallbladder motility was compared between pre- and post-PAD. We found that EP was shortened post- PAD ($P<0.05$), EF and ER were significantly reduced, and the motility of gallbladder was obviously weak after meal. Our study showed that human vagus had an important regulatory effect on gallbladder motility after meal.

Vagus is an important factor for maintaining gallbladder tension during interdigestive phase^[11,13,22], the gallbladder volume could increase two times if both sides of vagus were completely cut^[10]. Gallbladder was a weak in situation during interdigestive phase, and appeared rhythmic contraction and relaxation^[11]. Tenuity bile was continuously excreted by liver exchanges with condensed bile stored in gallbladder^[23-25]. Our study showed that RC 30 min post-operation was significantly decreased when fasting. The reason might be that cutting the vagus reduced the gallbladder tension during interdigestive phase, and then affected the exchange of bile.

Cholecystolithiasis patients did not contract at once after meal, but had a long latent period^[26]. In this study, LP post-operation after fat meal was prolonged ($P<0.01$). The gallbladder lost the contractive stimulation in cephalic phase after vagus was cut. The result in our study was similar to that previously described^[27] (LI2861.6±2028.3, LR 113.42±49.52%). We conclude that bile containing nuclides entering into gallbladder more rapidly results from the heightened pressure of biliary tract. The motility of Oddi's sphincter is adjusted by vagus^[11], and the bile excreted by liver is mainly adjusted by body fluid^[28-31]. Fat meal may increase the bile excreted by liver through humoral regulation, and amputation of the vagus can weaken the contraction of Oddi's sphincter cephalic phase, so the pressure of biliary tract increases. Further study is required for clarifying the mechanism in detail.

Abstract

AIM: To investigate the expression of E-cadherin, α -catenin, β -catenin, γ -catenin and cyclin D₁ in patients with esophageal squamous cell carcinoma (ESCC), and analyze their interrelationship with clinicopathological variables and their effects on prognosis.

METHODS: Expression of E-cadherin, α -catenin, β -catenin, γ -catenin and cyclin D₁ was determined by EnVision or SABC immunohistochemical technique in patients with ESCC consecutively, their correlation with clinical characteristics was evaluated and analyzed by univariate analysis.

RESULTS: The reduced expression rate of E-cadherin, α -catenin, β -catenin and γ -catenin was 88.7%, 69.4%, 35.5% and 53.2%, respectively. Cyclin D₁ positive expression rate was 56.5%. Expression of γ -catenin was inversely correlated with the degree of tumor differentiation and lymph node metastasis ($\chi^2 = 4.183$ and $\chi^2 = 5.035$, respectively, $P < 0.05$), whereas the expression of E-cadherin was correlated only with the degree of differentiation ($\chi^2 = 5.769$, $P < 0.05$). Reduced expression of E-cadherin and γ -catenin was associated with poor differentiation of tumor, reduced expression of γ -catenin was also associated with lymph node metastasis. There obviously existed an inverse correlation between level of E-cadherin and γ -catenin protein and survival. The 3-year survival rates were 100% and 56% in E-cadherin preserved expression group and in reduced expression one and were 78% and 48% in γ -catenin preserved expression group and in reduced expression one, respectively. The differences were both statistically significant. Correlation analysis showed the expression level of α -catenin correlated with that of E-cadherin and β -catenin ($P < 0.05$).

CONCLUSION: The reduced expression of E-cadherin and γ -catenin, but not α -catenin, β -catenin and cyclin D₁, implies more aggressive malignant behaviors of esophageal carcinoma cells and predicts the poor prognosis of patients.

INTRODUCTION

Esophageal squamous cell carcinoma (ESCC) is one of the most common malignant tumors in China^[1]. In recent years, the postoperative survival of patients with esophageal carcinoma has been improved. However, the overall prognosis for esophageal cancer patients remains poor, the 5-year survival rate of post operative advanced esophageal carcinoma patients was 20-35%. Although surgical techniques and preoperative management have progressed, early diagnosis and treatment are still important^[2-5]. The prognostic clinical characterization of esophageal carcinoma remains inadequate using conventional histological grading and staging systems. Recently, various attempts have been made to investigate the relationship between certain molecular markers and the clinical course of squamous cell carcinoma of esophagus. In fact, the biological factors that determine a different individual outcome (recurrent, survival) at an analogous stage of disease are obscure^[3-6].

E-cadherin and catenin are important adhesion molecules in normal epithelial tissue. Catenins, including α -catenin, β -catenin, γ -catenin, play an important role in the E-cadherin mediated intercellular signal transduction and cell adhesion. Loss of normal cellular adhesion plays a critical role in many aspects of tumor biology. For instance, alterations in cell-cell adhesion in cancer cells are reflected at the microscopic level in degree of cohesiveness and pattern of tumor growth. Detachment of cancer cells is an initial step in invasion of surrounding tissues and in spread to distant organs, and altered tumor cell adhesion is important in these processes. Several studies examined the role of the E-cadherin/catenin complex in growth mediation and maintenance of cell-cell adhesion in various tumors^[7-19]. The expression of adhesion molecules may reflect biological behaviors and characteristics of tumors and are conducive to predict and evaluate the risk of relapse and metastasis in patients with postoperative esophageal carcinoma, thus having practical significance in guiding individualized treatment^[3,18,20-23].

Cyclin D₁ encodes a cell-regulatory protein that is expressed at high level during the G₁ phase of the cell cycle. Cyclin D₁ binds to cyclin-dependent kinases and proliferating cell nuclear antigens. The formation of these complexes has been implicated in the control of cell proliferation^[24]. Cyclin D₁ is the target gene of beta-catenin, overexpression of the latter in the cytoplasm may promote malignant transformation by triggering cyclin D₁ expression in a number of cancers. It was regarded by several reports that cyclin D₁ could predict the prognosis in some cancers, including esophageal cancer^[25-28].

In this study, the expression of E-cadherin, α -catenin, β -catenin, γ -catenin and cyclin D₁ in 62 ESCC patients was

analyzed, concerning the histopathological and survival data, effects on progression of cancer and their prognostic value in ESCC. The results may provide some suggestions for clinical treatments.

MATERIALS AND METHODS

Materials

Specimens of cancer tissues were taken from 62 consecutive patients with squamous cell carcinoma of the thoracic esophagus who had undergone esophagectomy with regional lymph node dissected from January to December of 1996 at the Department of Thoracic Surgery, Cancer Hospital of Shantou University Medical College. None of them received irradiation or chemotherapy preoperatively. The patients included 49 men and 13 women with a mean age of 54 (range 35-79) years. Three tumors were located in the upper thorax, 36 in the middle thorax and 23 in the lower thorax (Table 1). The removed specimens were examined histological with hematoxylin and eosin staining, and then the clinicopathologic stage was determined according to TNM classification. Survival time was calculated from the date of operation to death or the date of last follow-up. Follow-up time ranged from 6 to 54 mo with an average of 36 mo.

Table 1 Background data of patients

Negative	27 (43.5)

Immunohistochemical staining

Immunohistochemical analysis was done retrospectively. Resected esophageal specimens, including both tumor and normal mucosae, were fixed in a 40 g/L formaldehyde solution and embedded in paraffin. The following antibodies were used in this study: mouse monoclonal anti-human cyclin D1 antibody (M-0024C, Antibody Company USA, diluted 1:50 in PBS), rabbit polyclonal anti-human E-cadherin antibody (BA0475, Antibody Company USA, diluted 1:100 in PBS), rabbit polyclonal anti-human α -catenin antibody (C-2081, Sigma Bioscience Company, USA, diluted 1:1 000 in PBS), rabbit polyclonal anti-human β -catenin antibody (C-2206, Sigma Chemical Company, USA, diluted 1:2 000 in PBS), goat polyclonal anti-human γ -catenin antibody (C-20 Santa Cruz Biot Co, USA, diluted 1:200 in PBS).

Four μ m thick sections of formalin-fixed paraffin-embedded tissue blocks of esophageal tumors were cut. The sections were deparaffinized, dehydrated and blocked to remove endogenous peroxidase activated by 3 mL/L H_2O_2 in methanol for 30 min. The sections were treated with microwave in 0.1 mol/L citrate buffer pH 6.0 at 750 W for 12 min. After incubation with 100 mL/L normal goat serum to block non-specific binding, they were then incubated with the primary antibodies overnight at 4 °C. After antibody was washed with PBS, the sections were incubated with the secondary antibody and immunostained by SABC method (γ -catenin, Boster Company, China) and EnVision method (E-cadherin, α -catenin, β -catenin and cyclin D1; EnVision, Cat. No. D-3001, 3002, Antibody Diagnostic Inc) according to the manufacturer's instructions, and finally DAB was visualized. Tissues were counterstained with hematoxylin. Negative control was designed by using PBS instead of primary antibody. Adjacent normal squamous epithelium served as an internal positive control of E-cadherin and catenin protein expression. Known immunostained-positive sections were used as positive control of cyclinD1 protein expression.

Positive criterion of immunohistochemical staining

Tumor sections were scored by light microscopy by 2 independent observers without knowledge of the stage and patient profiles. The percentage of positively stained cells was calculated after 100 cells were counted at more than 5 high-power (40 \times) fields. The following definitions were made: Cyclin D1: more than 10% positive staining in nuclei was defined as positive staining; E-cadherin and catenin: more than 10% positive staining in cell membrane was defined as positive staining; less than 50% positive staining in cell membrane was defined as reduced expression, more than 50% positive staining in cell membrane was defined as preserved expression.

Statistical analysis

χ^2 test or Fisher's exact probability test and Spearman rank correlation coefficient analysis were used to assess the association between immunohistochemical features and clinicopathological characteristics. The cumulative survival rate was calculated by the Kaplan-Meier method, and statistical significance was analyzed by the log-rank test. A *P* value less than 0.05 was considered statistically significant. All the statistical analyses were performed using the SPSS 10.0 V for Windows.

RESULTS

Expression of E-cadherin, α -catenin, β -catenin, γ -catenin and cyclin D1 in esophageal squamous cell carcinoma

The positive expression rate of E-cadherin, α -catenin, β -catenin, γ -catenin and cyclin D1 in 62 esophageal cancer patients was 62.9% (39/62), 79% (49/62), 95.2% (59/62), 75.8% (47/62) and 56.5% (35/62), respectively. The reduced expression rate of E-cadherin, α -catenin, β -catenin and γ -catenin was 88.7%, 69.4%, 35.5%, 53.2%, respectively. Cyclin D1 positive expression showed brown stained signals in the nuclei (Figure 1), only a small number of expressions in cytoplasm or membrane of cells. E-cadherin, α -catenin, β -catenin and γ -catenin positive expression showed brown stained signals in membrane of cells and the intercellular junctions (Figure 2A-C).

Relationship between expressions of E-cadherin, α -catenin, β -catenin, γ -catenin and cyclin D1 in esophageal squamous cell carcinoma

Significant positive correlation was found between the intensity of α -catenin and β -catenin ($r = 0.274$, $P < 0.05$), E-cadherin and α -catenin ($r = 0.279$, $P < 0.05$). No significant differences were seen in other protein expressions.

Relationship between E-cadherin, α -catenin, β -catenin, γ -catenin and cyclin D1 expression and clinicopathologic variables in esophageal squamous cell carcinoma

Expression of E-cadherin correlated significantly only with histological grade. Poor differentiation was associated with reduced or loss of E-cadherin expression ($P<0.05$). Significant inverse correlation existed between the intensity of γ -catenin expression and histological grade, and lymph node metastasis ($P<0.05$). No significant correlation was found between abnormal expression of other proteins and histological grade, lymph node metastasis and depth of invasion (Table 2).

Relationship between E-cadherin, α -catenin, β -catenin, γ -catenin, and cyclin D1 expression and survival

Analysis of the 3-year survival after operation showed that the overall survival rate was 62% in 62 cases of esophageal cancer. Univariate analysis showed that the survival time was associated

with the histological grade, depth of invasion, lymph node metastasis, expression of E-cadherin and γ -catenin. Reduced E-cadherin or γ -catenin expression was correlated with poor prognosis. The mean survival time of grades I, II, III was 41, 45 and 12 mo ($P<0.05$), respectively. The 3-year survival rate was 67.1% and 49.4% in T₃ and T₄ patients ($P<0.05$), respectively, and was 47.8% and 80.3% in patients with positive and negative lymph node metastases ($P<0.05$), respectively. The median survival time was 54 mo and 37 mo in patients with preserved and reduced or loss of E-cadherin expression, the 3-year survival rate was 100% and 56% ($P<0.05$), respectively. The median survival time was 42 and 33 mo in patients with preserved and reduced or lost expression of γ -catenin, the 3-year survival rate was 78% and 48% ($P<0.05$), respectively. No difference in survival curves was seen between reduced expression of α - and β -catenins compared with preserved expression. Similar results were found in the positive and negative expressions of cyclin D1. The median survival time was 39 and 38 mo in the patients with preserved and reduced or lost expression of α -catenin, the 3-year survival rate was 65%. The median survival time was 36 and 39 mo in the patients with preserved and reduced or loss expression of β -catenin, the 3-year survival rate was 65%. The median survival time was 40 and 34 mo in the patients with positive and negative expressions of cyclin D1, the 3-year survival rate was 68% and 58% ($P>0.05$), respectively.

DISCUSSION

The main causes of treatment failure are recurrence and metastasis in resectable esophageal cancer. Modern molecular biology studies have demonstrated that invasion and metastasis of tumors as a continuous process, include three steps: a reduced cell-cell adhesion, alterations in the interaction of tumor cells with extracellular matrix, and invasion into surrounding

**Figure 2** Positive expression of E-cadherin and γ -catenin proteins in membrane of esophageal squamous cell carcinoma. tissues including blood vessels and lymph duct. Thus the first and critical step is that the tumor cells could detach from primary foci and re-adhere to metastatic position^[12,29,30]. E-cadherin is a calcium-dependent cell-cell adhesion transmembrane glycoprotein, maintaining normal epithelial polarity, and intercellular adhesion, which are present in almost all normal epithelial cell surfaces. It is anchored to the cytoskeleton via cytoplasm proteins, including alpha and beta catenin^[13,14,31]. E-cadherin, therefore, is one of the most important adhesion molecules expressed by epithelial cells and is regarded as an invasion suppressor molecule^[13,14]. In this study, overall survival was inversely corrected with E-cadherin expression. Patients with preserved E-cadherin expressing tumor had a better prognosis than those with reduced expression of E-cadherin. This was in agreement with previous studies on a variety of cancers, such as cancer of head and neck^[15,16], breast^[17,18], stomach^[19,32,33], bladder^[27]. In all these studies, reduction or loss of E-cadherin expression was significantly associated with dedifferentiation, increased invasiveness, and high incidence of lymph node metastasis, hematogenous recurrence and poor prognosis in a number of human carcinomas, including esophageal cancer. But some other studies did not acquire the same results^[3]. There were different results of reduced E-cadherin protein expression in specimens from patients with ESCC in various researches^[21,23,32-35]. While in our investigation 88.7% of ESCC showed reduced expression of E-cadherin. It was postulated that selection of the patients entering into the study, immunohistochemical method, antibody origination, tumor heterogeneity and differences in staining evaluation might individually or in combination hold responsibility. As a marker associated with squamous cell differentiation^[36], the level of E-cadherin expression had an inverse correlation with histological grade. Reduced or loss of E-cadherin expression was correlated with poor differentiation, but not with lymphatic metastases and depth of tumor invasion, suggesting that the reduction of E-cadherin expression is associated with loss of the ability of adhesion and facilitate to blood vessel metastases, as previously reported^[21].

Catenins are a family of proteins including α -(102 ku), β -(88 ku), γ -(82 ku) catenins. The cytoplasmic domain of E-cadherin could bind directly to either β -catenin or γ -catenin, whereas α -catenin could link E-cadherin- (β , γ)-catenin complex to acting cytoskeleton. The integrity of the adhesion function of E-cadherin also depended on an intact catenin system^[15]. β -catenin could also play a role in intracellular signaling and function as an oncogene when it bound to T-cell factor 4 (Tcf4)-binding site in the promotor region of cyclin D1 and transactivated genes after translocation to the nuclei^[37-39]. Catenins had different clinicopathological roles in various cancers. In many epithelial carcinomas including carcinoma of the esophagus^[3,6,20,22,23,33], head and neck^[16], breast^[17-19,25], stomach^[19], colon^[24] and bladder^[27], catenins had a prognostic significance in survival. Some investigators reported that abnormal expression of α -catenin was associated with the prognosis of esophageal cancer. It also had predicative values for lymph node metastasis in esophageal carcinoma. Several reports suggested that abnormal expression of β -catenin could indicate poor prognosis in a number of tumors, including esophageal cancer^[17,20,25,33]. γ -catenin was found to be more important in nodal metastasis in tongue cancer. It was also predictive of the presence of subclinical nodal metastasis in clinically node-negative neck^[16]. The expression of α -catenin but not β - or γ -catenin was found to be correlated with the expression of E-cadherin in this study. The reduction or loss of γ -catenin expression was associated with more lymph node metastases than the preserved expression ($P < 0.05$). There was a correlation between poor differentiation of tumor and reduction or loss of γ -catenin expression. The reduction or loss of γ -catenin expression was in association

with shorter median survival time and lower 3-year survival rate. All these suggested that γ -catenin might be one of the prognostic factors in esophageal cancer. However, the expression of α -catenin and β -catenin was not related to the histological grade, depth of invasion, lymph node metastases and survival time.

The clinical significance of cyclin D1 expression was different in various tumors. It has shown that cyclin D1 gene amplification or enhanced expression was correlated with higher histological grade of tumor, lymphatic or hematogenous metastasis and poor prognosis^[40-43]. A controversial report, however, existed^[6]. Some investigators thought cyclin D1 was the target gene of β -catenin. Although a positive correlation between β -catenin activation and cyclin D1 expression was reported, our study did not show such a result. Furthermore, cyclin D1 expression was not associated with the extent of tumor infiltration, grade of differentiation, lymphatic metastases and survival time. These inconsistencies with other authors may be associated with location of tumor, pathologic classification, biologic behaviors, examination methods and evaluating criteria.

Our study showed that the main prognostic factors of postoperative survival time were histological grade, depth of tumor invasion and lymph node metastasis. The reduced expression of E-cadherin or γ -catenin was associated with poor differentiation of tumor cells. Reduced or loss of γ -catenin expression also had predictive values for nodal metastasis. The reduction or loss of E-cadherin and γ -catenin expression could predict the shorter survival time. Therefore we suggest that adjuvant radiation or chemotherapy should be considered in esophageal carcinoma patients with reduced expression of E-cadherin and γ -catenin in T4 stage, poor-differentiation in histopathology, and lymph node metastases in order to improve the survival rate.

Abstract

AIM: To study the relevance of spindle assembly checkpoint protein MAD2 to cellular mitotic status, aneuploidy and other clinicopathological characteristics in gastric cancer.

METHODS: Western blot analyses were performed to analyze the protein levels of MAD2 and cyclin B1 in the tumorous and adjacent nontumorous tissues of 34 gastric cancer patients. Cell cycle distribution and DNA ploidy of cancer tissues were also determined by flow cytometry. Conventional statistical methods were adopted to determine the relevance of abnormal MAD2 level to mitotic status, aneuploidy and clinicopathological parameters.

RESULTS: Out of 34 gastric cancer patients 25 (74%) exhibited elevated MAD2 levels in their tumorous tissues compared with the corresponding nontumorous tissues. Elevation of MAD2 levels significantly correlated with the increased levels of cyclin B1 expression and G₂/M-phase distribution ($P = 0.038$ and $P = 0.033$, respectively), but was not relevant to aneuploidy. The gastric cancer patients with elevated MAD2 levels showed a tendency toward better disease-free and overall survival ($P > 0.05$). However, no association was found between elevated MAD2 levels and patients' clinicopathological characteristics.

CONCLUSION: Elevation of MAD2 level is present in 74% of gastric cancer patients, and correlates with increased mitotic checkpoint activity. However, elevation of MAD2 level is not associated with patients' aneuploidy and any of the clinicopathological characteristics.

Wu CW, Chi CW, Huang TS. Elevated level of spindle checkpoint protein MAD2 correlates with cellular mitotic arrest, but not with aneuploidy and clinicopathological characteristics in gastric cancer. *World J Gastroenterol* 2004; 10(22): 3240-3244

of chromosomes are under the surveillance of one group of proteins, called spindle assembly checkpoint proteins^[1-3]. Mitotic arrest-deficient proteins (MADs) and budding uninhibited by benzimidazole proteins (BUBs) are the major members of spindle assembly checkpoint proteins^[4-6]. Among them, MAD2 is a key component of MAD/BUB complex that can censor mis-segregation of chromosomes by monitoring the microtubule attachment and tension^[4,7,8]. MAD2 is usually expressed at a high steady-state level and distributed at unattached kinetochores^[9,10]. Re-localization of MAD2 along microtubules to the spindle poles is achieved by minus-end-directed dynein-dynactin complex only when all kinetochores properly attach to microtubules^[10]. Once misaligned chromosomes or even a single unattached kinetochore is present, sufficient MAD2 molecules are kept in kinetochores to inhibit the onset of anaphase until all chromosomes exhibit proper bipolar attachment to the spindle. The kinetochore MAD2 can associate with and thus prevent the activation of anaphase-promoting complex (APC)^[7,11-14]. APC is a kinetochore-localizing, CDC27-based ubiquitin ligase responsible for cyclin B1 degradation and in turn down-regulation of cyclin B1-associated CDC2 kinase activity, which is required for metaphase-anaphase transition and for exit from mitosis^[7,11-14]. On the other hand, the microtubule-interfering agents, such as paclitaxel and nocodazole, can also elicit the spindle assembly checkpoint activity of MAD2^[4,15,16]. In paclitaxel-treated cells, MAD2 mediates inhibition of APC's ability to ubiquitinate cyclin B1, which avoids the degradation of cyclin B1 and thus leads the cyclin B1/CDC2 activity to sustain longer^[15]. This persistence of MAD2 and cyclin B1/CDC2 activation renders cells unable to exit from the metaphase and ultimately leads cells to apoptosis^[15].

As described above, the role of MAD2 in spindle checkpoint machinery has been evidenced in many cell line studies. Clinically, it was reported that MAD2 was rarely the target for genetic alterations in digestive tract cancers^[17,18]. Whatever from clinical investigation or animal models, the evidence demonstrating the relevance of MAD2 to cellular mitotic status or other histopathological characteristics is yet lacking. In this study, we investigated the level of MAD2 in 34 gastric cancer patients. The MAD2-related mitotic checkpoint activity was measured by cyclin B1 expression level and cell cycle G₂/M-phase fraction. Our data indicated that 25 out of 34 (74%) gastric cancer patients exhibited elevated MAD2 levels in their tumorous tissues rather than nontumorous tissues. Elevation of MAD2 level correlated with increased mitotic checkpoint activity but was not relevant to aneuploidy (chromosomal numerical alteration). Although the gastric cancer patients with elevated MAD2 levels exhibited a tendency toward better disease-free and overall survival, no correlation was found between abnormal MAD2 level and patients' clinicopathological characteristics.

MATERIALS AND METHODS

Patients and tumor specimens

Thirty-four primary gastric cancer tissues and their corresponding

INTRODUCTION

During the cell division cycle, the localization and segregation

normal mucosa were obtained from patients at Taipei Veterans General Hospital. The patients consisted of 25 men and 9 women (aged 43–80 years; mean: 63.8 years). Informed consent was obtained from each patient. All specimens were snap-frozen immediately after resection and stored at -80°C until use. Parts of the specimens were taken for protein extraction and DNA content determination, and the remaining tissues were fixed in 40 g/L buffered formaldehyde for histologic examination. Hematoxylin and eosin staining of tissue sections was adopted to categorize the tumors according to the classification of Lauren^[19].

Tissue lysate preparation and Western blot analysis

Tissue lysates were prepared by the method described previously^[20]. Briefly, tumor and non-tumor specimens were ground down into powder in the presence of liquid nitrogen. Around 0.5 g of tissue powder was resuspended in 1.5 mL of 10 mmol/L Tris-Cl, pH 7.8, 140 mmol/L NaCl, 5 g/L deoxycholate, 10 mL/L NP-40, 1 mmol/L phenylmethylsulfonyl fluoride, 10 $\mu\text{g/mL}$ aprotinin, 10 $\mu\text{g/mL}$ pepstatin A, and 10 $\mu\text{g/mL}$ leupeptin. The suspension was subjected to homogenization and further sonication on ice, and finally was ultracentrifuged at 100 000 g for 1 h at 4°C . The supernatant was saved and assayed for protein concentration (Bradford method). Aliquots (30 μg protein) of tissue lysates were separated on 100 g/L SDS-polyacrylamide gels, and electrotransferred onto polyvinylidene difluoride membranes. After blocked with PBST (phosphate-buffered saline plus 1 mL/L Tween-20) plus 50 g/L fat-free milk, the membranes were incubated with anti-MAD2, cyclin B1, and β -tubulin antibodies (Santa Cruz Biotechnology, Santa Cruz, CA, USA), respectively, in PBST plus 50 g/L milk at 4°C for 12 h. The membranes were then washed three times with PBST buffer, and incubated with horseradish peroxidase-conjugated secondary antibodies for 1 h at room temperature. After washed three times with PBST buffer, the protein bands were detected by enhanced chemiluminescence (Amersham Biosciences, Piscataway, NJ, USA).

Flow cytometric analysis of DNA content

The DNA ploidy and cell-cycle phase distribution of tissue specimens were measured by flow cytometric analysis^[21]. Frozen specimens were first minced into 2 to 5 mm³ pieces and further digested into single cell suspensions^[22]. Cell suspensions were fixed with 800 mL/L ethanol at -20°C at least for 30 min before subsequent Triton X-100 permeabilization and propidium iodide staining^[16]. The cellular DNA content was analyzed using a FACStar flow cytometer with an argon laser tuned to the 488-nm line for excitation (BD Biosciences, San Jose, CA, USA).

Statistical analyses

Data were analyzed by χ^2 or t test. Survival rate was calculated by the Kaplan-Meier method. Statistical comparisons were made with Logrank test. The difference was considered to be significant when P value was less than 0.05.

RESULTS

Elevated MAD2 level occurs in human gastric cancer

Western blot analysis was performed to analyze the MAD2 expression level of the tumorous and adjacent nontumorous tissues of 34 gastric cancer patients. As shown in Figure 1, the MAD2 protein was detected in both tumorous and nontumorous tissue lysates. In most patients, MAD2 seemed labile in the nontumorous tissues rather than the tumorous tissues. The differential MAD2 level was confirmed by comparison with the

levels of β -tubulin in the same-paired tissue lysates. A patient with elevated MAD2 level was defined as one whose MAD2 level in the tumorous tissue was higher than that in the adjacent nontumorous tissue, and elevated MAD2 level could be found in 25 of 34 (74%) cases of human gastric cancer.

Elevated MAD2 level correlates with increased mitotic arrest but not aneuploidy

The MAD2-related mitotic arrest was measured by cyclin B1 level and cell cycle G₂/M-phase fraction. We found that 18 of 34 (53%) gastric cancer patients had elevated cyclin B1 expression level in their tumorous rather than nontumorous tissues (three examples shown in Figure 1). There was a statistically significant correlation between elevated MAD2 level and elevated cyclin B1 level ($P = 0.038$), as 16 of 25 (64%) gastric cancer patients who had elevated MAD2 levels also manifested higher levels of cyclin B1 in their tumorous tissues (Table 1). Moreover, the DNA contents of tumor specimens of 29 patients were successfully determined by flow cytometric analysis. The data presented by mean \pm SD (%) of phase fractions are shown in Table 2. We observed that the ratio of G₂/M-phase fraction in the tumor specimens exhibiting elevated MAD2 levels was statistically higher than that in the tumorous tissues with a normal MAD2 level ($10.6 \pm 4.9\%$ vs $6.4 \pm 4.0\%$, $P = 0.033$). No significant difference in the ratios of G₀/G₁ and S-phase fractions was found between the tumors with or without elevated MAD2 levels (Table 2). In addition, DNA ploidy was also determined from the tumor specimens of 32 patients. Although 18 of 32 (56%) patients were found to have aneuploid tumor cells, no correlation was observed between the occurrence of aneuploidy and elevated MAD2 level in cancer tissues ($P = 1.000$, Table 3).

Figure 1 Examples of elevation of MAD2 and cyclin B1 levels in human gastric cancer. Western blot analyses were performed to analyze the protein levels of MAD2 and cyclin B1 in the lysates from non-tumorous tissues (N) and tumorous tissues (T) of gastric cancer patients, #195, #198, #249, #269, #214, and #274. The levels of β -tubulin in the same-paired tissue lysates were analyzed as internal control.

Table 1 Cyclin B1 expression status of 34 gastric cancer tissues with or without MAD2 overexpression

	Cyclin B1 level	
	T > N	T = N

Elevated MAD2 level does not correlate with clinicopathological characteristics

The relationship of elevated MAD2 level with clinicopathological characteristics was also investigated and summarized (Table 4). The evaluated parameters included age at diagnosis, tumor site and size, cell differentiation grade, stromal reaction, invasive and metastatic status, *etc.* For the 34 studied patients, age and gender did not associate with higher levels of MAD2 in cancer tissues ($P>0.05$). There was no association between elevated MAD2 levels and different tumor sites (upper, middle, lower or whole stomach), tumor sizes, and other histopathological characteristics including grade of cell differentiation, Borrmann type, stromal reaction (medullary, intermediate or schirrhous type), infiltration type (α , β or γ), Lauren histological classification (intestinal or diffuse type), and TNM staging (I-IV), either. In addition, elevation of MAD2 level in cancer tissues was not correlated with the invasion parameters, including the lymphatic duct or vessel invasion and depth of cancer invasion (mucosa, submucosa, propria muscle, subserosa, serosa, serosa exposed), and metastatic status such as peritoneal dissemination and lymph node or liver metastasis (Table 4). Finally, the patients with elevated MAD2 levels in tumor tissues exhibited higher five-year overall and disease-free survival rates in comparison with those without elevated MAD2 levels (48.0% vs 20.8% and 46.3% vs 11.1%, respectively), but the difference did not reach a significant level ($P = 0.478$ and 0.229 , respectively; Table 4).

DISCUSSION

Spindle assembly checkpoint is one of the mechanisms to guard the fidelity of cell division cycle^[1-3]. MAD2 is a key component of spindle assembly checkpoint complex MAD/BUB that is responsible for monitoring the localization and segregation of chromosomes^[4,7,8]. MAD2 could induce mitotic arrest by associating with and thus inhibiting APC when microtubule-interfering agents were present in cancer cell cultures^[4,15]. However, the evidence demonstrating the clinical relevance of MAD2 to cancer cell mitotic status is yet lacking. In this study, we provided the clinical data to support the mitotic checkpoint role of MAD2 in cancer tissues. We found that 74% of our gastric cancer patients had elevated levels of MAD2 in their tumorous tissues. These patients also exhibited more cyclin B1 expression and G₂/M-phase distribution in their cancer cells. Because MAD2 can interfere with APC and APC is an ubiquitin ligase responsible for cyclin B1 degradation, elevation of both cyclin B1 expression and cellular G₂/M-phase ratio may be resulted from a higher mitotic checkpoint activity that is expected of elevated MAD2 level. Noteworthy, these patients had a tendency toward longer disease-free and overall survival. We speculate that the checkpoint activity of MAD2 exerted in these patients monitors the interaction of chromosomes with spindle fibers, which is finally linked with better disease-free and overall survival. Elevated level of MAD2 seems to be a possible target

for potential development of novel therapeutic or prognostic modalities in the future.

Our data indicate that elevated MAD2 levels did not prevent the occurrence of aneuploidy in gastric cancer. Aneuploidy is one of the hallmarks of cancer cells^[23-25]. Considering spindle assembly checkpoint proteins function as a monitor for the fidelity of chromosomal segregation, impairment of spindle assembly checkpoint is expected to associate with the development of cancer cell aneuploidy. However thus far, many aneuploid cancer cell lines did undergo mitotic arrest in response to spindle damage, indicating that not all cancer cells with aneuploidy had an impaired spindle checkpoint^[26-28]. Moreover, accumulating studies have demonstrated that the BUBs (BUB1, BUBR1 and BUB3) and MADs (MAD1 and MAD2) were rarely the targets for genetic alterations in a variety of human cancer types including head-and-neck squamous cell carcinoma^[29], non-small cell lung cancer^[29,30], thyroid follicular neoplasms^[28], hepatocellular carcinoma^[27], and digestive tract cancers^[17,18,30]. These data suggest that cancer cell aneuploidy may arise from the alternative defects yet to be discovered. Despite of the low frequency of gene mutation, a research of 43 gastric cancer patients concluded that overexpression of BUB1, BUBR1 or/and BUB3 was observed in >60% of cases^[31]. There was no statistically positive correlation between overexpression of BUBs and cancer aneuploidy. Instead, the overexpression was significantly correlated with Ki-67 expression of tumor cells, suggesting that BUBs are proliferation-associated proteins other than spindle checkpoint proteins in gastric cancer^[31].

The gastric cancer patients with different molecular alterations were shown to have distinct histopathological features. For example, simultaneous overexpression of hepatocyte growth factor receptor (c-Met), autocrine motility factor receptor (AMFR) and urokinase-type plasminogen activator receptor (uPAR) was correlated with positive lymphatic vessel invasion and infiltration^[32]. Estrogen receptor (ER) was more expressed in diffuse-type patients with regional lymph node metastasis^[33]. Additionally, positive expression of nm23 was detected in as high as 74% of gastric cancer patients and was related to patients' age, tumor size, Borrmann type, Lauren classification, and TNM stage^[34]. COX-2 overexpression significantly correlated with TNM staging; while abnormal expression of E-cadherin/ β -catenin complex occurred more significantly in Borrmann types III/IV than in types I/II. In our present study, no histopathological parameter was found to be associated with elevated MAD2 level in gastric cancer patients. It was reported consistently that MAD2 was significantly overexpressed in colorectal adenocarcinoma, but was not related to differentiation or other clinical parameters.

In conclusion, an elevation of spindle checkpoint protein MAD2 level was observed in 74% of our gastric cancer patients, and was significantly correlated with the increased levels of cyclin B1 expression and G₂/M-phase distribution in cancer tissues. However, an elevated MAD2 level was not associated with aneuploidy and other clinical factors, including demographic features and histopathological characteristics.

Abstract

AIM: *Survivin* is a novel antiapoptotic gene in which three splicing variants have been recently cloned and characterized. Survivin has been found to be abundantly expressed in a wide variety of human malignancies, whereas it is undetectable in normal adult tissues. We aimed to study the expression of three survivin splicing variants in gastric cancer, and to evaluate the prognostic significance of the expression of survivin variants in gastric cancer.

METHODS: Real time quantitative RT-PCR was performed to analyze the expression of survivin variants in 79 paired tumors and normal gastric mucosa samples at the mRNA level. Proliferative and apoptotic activity was measured using Ki-67 immunohistochemical analysis and the TUNEL method, respectively.

RESULTS: All the cases tested expressed wild-type survivin mRNA, which was not only the dominant transcript, but also a poor prognostic biomarker ($P = 0.003$). Non-antiapoptotic survivin-2B mRNA was correlated with tumor stage ($P = 0.001$), histological type ($P = 0.004$), and depth of tumor invasion ($P = 0.041$), while survivin- Δ Ex3 mRNA showed a significant association with apoptosis ($P = 0.02$).

CONCLUSION: Wild-type survivin mRNA expression levels are of important prognostic value and significant participation of survivin-2B and survivin- Δ Ex3 is suggested in gastric cancer development.

INTRODUCTION

Apoptosis, also called programmed cell death, plays an important

role in the development and homeostasis of tissues. Deregulation of apoptosis is involved in carcinogenesis by abnormally prolonged cell survival, facilitating the accumulation of transforming mutations and promoting resistance to immunosurveillance^[1]. Several studies have consistently shown that survivin could mediate suppression of apoptosis. Surprisingly, in a single copy of *survivin* gene, three alternatively splicing transcripts have been identified. In addition to wild-type survivin, two novel survivin variants (survivin-2B, survivin- Δ Ex3), which have different antiapoptotic properties, have been generated. Survivin-2B has lost its anti-apoptotic potential, whereas its anti-apoptotic potential is preserved in survivin- Δ Ex3^[2,3]. Their different functions in carcinogenesis are largely unknown.

Gastric carcinoma is one of the most frequent human malignancies^[4]. As shown by our group^[5], 34.5% of gastric cancers expressed survivin protein and a positive correlation between accumulated p53 and survivin expression in neoplasia was found. In this study, we investigated the distribution of survivin variants in paired tumors and normal gastric mucosa samples at the mRNA level and assessed the potential relationship between the expression of survivin variants and proliferative activity, apoptosis or prognostic significance.

MATERIALS AND METHODS

Patients and specimens

Matched pairs of tumors and normal gastric mucosa samples were obtained from 76 patients with gastric cancer and 1 patient with malignant lymphoma at the Department of General and Gastroenterological Surgery, Osaka Medical College Hospital during 2000-2002. The specimens resected at surgery were immediately frozen in liquid nitrogen and stored at -80°C until total RNA extraction. Clinicopathological parameters were assigned according to the principles outlined by Japanese Classification of Gastric Carcinoma^[6]. Samples included stage I cases ($n = 22$), stage II cases ($n = 11$), stages III cases ($n = 20$), stage IV cases ($n = 26$). There were 62 (78.5%) males and 17 (22.5%) females, and the mean age of the patients was 65.2 years (SD, 9.6 years; range, 40-87 years). No Patients received chemotherapy or radiation therapy either before or after surgery. The mean follow-up period was 19.7 mo (SD, 14.9 mo; range, 1.5-87 mo). Formalin-fixed paraffin-embedded blocks of primary tumors were taken from pathological archives. Two to four μm thick serial sections of 2-4 thickened were prepared from the cut surface of the blocks at the maximum cross-section of the tumors.

Total RNA extraction

Total RNA was extracted by an acid guanidinium-phenol-chloroform method using ISOGEN (Nippon Gene, Toyama, Japan) according to the manufacturer's instructions. Afterwards the total RNA was purified using DNase I (GIBCO-BRL, Gaithersburg, MD, USA). Extracted total RNA pellets were dissolved with RNase free diethyl pyrocarbonate (DEPC)-treated water.

Reverse transcription

Complementary DNA (cDNA) was synthesized with 5 μg of total RNA and 20 pmol oligo (dT)₁₈ primer using an Advantage

RNA-for-PCR kit (CLONTECH, Inc., Palo Alto, USA), with the exception of 200 U SurperScript™ II RNase H⁻ reverse transcriptase (Invitrogen, Inc., Carlsbad, USA) in a final 20 μ L reaction volume. RT reactions were performed at 50 °C for 120 min. Finally, cDNA solution was diluted to a total volume 100 μ L.

Quantitative real time RT-PCR

Quantitative real time RT-PCR was performed with a LightCycler (Roche Diagnostics, Mannheim, Germany). As an internal control, housekeeping gene G6PDH mRNA expression was measured at the same time. DEPC-treated H₂O was used as a negative control and MKN-74 was used as a positive control. Then, 1 μ L of cDNA mixture was subjected to amplification in 10 μ L reaction mixture. The PCR conditions were initial denaturation at 95 °C for 10 min, followed by 40 cycles of denaturation at 95 °C for 10 s, annealing at 62 °C for 10 s for survivin, survivin-2B and survivin- Δ Ex3 (or at 63 °C for G6PDH), extension at 72 °C for 10 s, respectively. A standard curve using fluorescent data was generated from serial tenfold dilution of specific plasmids from 10⁷ to 10² copies, respectively. The number of gene copies was calculated by the LightCycler Software Version 3.5.3 according to the Fit Points Above Threshold method. Primer pairs and hybridization probes for survivin, survivin-2B, survivin- Δ Ex3 and G6PDH mRNA were as follows. The sequence of the common forward primer for survivin variants was 5'-CCACCGCATCTC TACATTCA-3'. To distinguish the 3 splice variants of survivin, the sequences of reverse primers for survivin variants were designed to correspond to exon/exon borders of the complementary strand (5'-TATGTTCTCTATGGGGTCG-3' for survivin, 5'-AGTGCTGGTATTACAGGCGT-3' for survivin-2B, 5'-TTTCCT TTGCATGGGGTC-3' for survivin- Δ Ex3). The sequences of common hybridization probes for survivin variants were 5'-CAAGTCTGGCTCGTTCTCAGTGGG-3'-FITC and LCRed640-5'-CAGTGGATGAAGCCAGCCTCG-3'. The sequence of the forward primer for G6PDH was 5'-TGGACCTGACCTACGGCA ACAGATA-3'. The sequence of the reverse primer for G6PDH was 5'-GCCCTCATACTGGAAACCC-3'. The sequences of hybridization probes for G6PDH were 5'-TTTTCACCCCACTGC TGCACC-3'-FITC and LCRed640-5'-GATTGAGCTGGAGAAG CCCAAGC-3'.

PCR products were additionally checked by electrophoresis on 30 g/L agarose gels (BIO-RAD, Inc., Hercules, USA) containing ethidium bromide and visualized under UV transillumination.

Sequence analysis

To confirm the identity of the PCR products, their bands were excised from agarose gels and isolated by a QIAquick gel extraction kit (Qiagen, Tokyo, Japan), ligated into a pGEM-T-cloning vector (Promega), and cloned according to standard protocols. Plasmid DNA was recovered using a Plasmid Mini kit (Qiagen, Tokyo, Japan). Cycle was sequenced and analyzed in an ABI-PRISM310 (Applied Biosystems) using T7 or SP6-site specific primers. The sequences of the PCR products were compared with those in GenBank, which were found to be identical (Data not shown).

Ki-67 immunohistochemical staining and assessment of proliferative index

Immunohistochemical staining was performed by the standard avidin-biotin-peroxidase complex technique using L.V. Dako LSAB kit (DAKO, Copenhagen, Denmark) as described previously^[5,7,8]. The antibodies used were monoclonal mouse antibody Ki-67 (MIB-1, diluted 1:50; Immunotech, Marseilles, France). The labeling index (LI) of Ki-67 was determined in those tumor areas with positive stained nuclei. Five random areas within a section were chosen and counted under 200-fold magnification using a point counting technique. The average percentage of positivity was recorded as the Ki-67 LI for each case^[7].

Histochemical detection of apoptosis and determination of AI

Apoptotic cells in tissue sections were detected by terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick end labeling (TUNEL), using an Apop Tag *in situ* detection kit (Oncor, Gaithersburg, MD). The staining procedures were based on a method described previously^[5,6,8]. The apoptotic index (AI) was expressed as the ratio of positively stained tumor cells and bodies to all tumor cells according to the criteria described elsewhere^[5,7]. Five areas were randomly selected for counting under 400-fold magnification.

Statistical methods

All statistical analyses were performed by the SPSS11.0 software package for Windows (SPSS Inc., Chicago, IL). Differences in the numerical data between the two groups were evaluated using the Mann-Whitney U test. The χ^2 test was further used to compare the distribution of individual variables and any correlation between AI or Ki-67 index and expression of survivin variants. The correlation between AI and expression of survivin variants for each case was also analyzed by Spearman's rank correlation test. Survival curves were calculated using the Kaplan-Meier method and analyzed by the log rank test. A two-tailed *P* value less than 0.05 was considered statistically significant.

RESULTS

Expression of survivin variants in clinical materials and cell lines

Among the 79 tumor samples, survivin expression was detected in all tumor samples (79/79), survivin-2B expression was demonstrated in 78.5% (62/79) of the samples and survivin- Δ Ex3 expression was detected in 64.6% (51/79) of the samples (Figure 1). In contrast, survivin expression was detectable in 46 (58.2%) of the normal mucosa samples, while survivin-2B expression and survivin- Δ Ex3 were detected in 23 (29.1%) and 12 (15.2%) of the mucosa samples respectively.

Figure 1 Amplification, separation and visualization of survivin (185 bp), survivin-2B (214 bp) survivin- Δ Ex3 (184 bp), and G6PDH (256 bp) mRNA (40 cycles) in a typical case.

The relative amounts of survivin variant mRNA were determined by dividing the amount of survivin variant mRNA by that of G6PDH mRNA for each sample. In tumor samples, the relative levels of survivin-2B and survivin- Δ Ex3 was further normalized by matched survivin. Because three alternatively spliced variants are derived from a common hnRNA precursor pool, these ratios seemed to be independent of any possible bias imposed by variations in housekeeping gene expression levels^[9,10]. Although there was a significant difference in G6PDH expression between normal tissues and cancer samples at the same amount of total RNA used ($P < 0.0001$, Mann-Whitney U test, Figure 2A), the survivin variant/G6PDH ratio in our cancer tissues were significantly higher than that in non-neoplastic tissues ($P < 0.0001$, Mann-Whitney U test, Figure 2B).

Table 1 Relationship among expression levels of survivin variants and clinicopathologic parameters, proliferative activity or apoptosis

Parameters	No. of patients (%)	Sur/G6PDH	Sur-2B/G6PDH	Sur- Δ Ex3/G6PDH	Sur-2B/sur	Sur- Δ Ex3/sur

Two-tailed P values were calculated by the Mann-Whitney U test. Differentiated type: Papillary type, Tubular type. Undifferentiated type: Poorly differentiated type, Signet ring cell type, Mucinous type. Not invasion: No invasion of the serosa. Invasion: invasion of the serosa.

Figure 2 A: RT-PCR amplification of G6PDH in paired samples of normal gastric mucosa and gastric carcinoma. B: Relative (G6PDH-normalised) mRNA levels of survivin variants in paired samples of normal gastric mucosa and gastric carcinoma. Two-tailed P values were calculated by the Mann-Whitney U test.

Relationship between expression levels of survivin variants and clinicopathological parameters

The expression level of survivin-2B was significantly ($P = 0.001$, Table 1, $P < 0.0001$, χ^2 test, Figure 3A) decreased in advanced (III+IV) stage compared with early (I+II) tumor stage. Furthermore, the level of survivin-2B was inversely correlated with the grade of tumor differentiation ($P = 0.004$, Table 1, $P = 0.023$, χ^2 test, Figure 3B) and depth of tumor invasion ($P = 0.042$, Table 1, $P = 0.021$,

χ^2 test). A stage-dependent decrease of survivin-2B was also confirmed by the ratio of survivin-2B/survivin ($P = 0.018$, Table 1, $P = 0.022$, χ^2 test, Figure 3C).

None of the investigated clinicopathological parameters showed a statistically significant correlation with the expression of other types of survivin variants besides survivin-2B.

Correlation between expression levels of survivin variants and AI

Apoptotic cells and bodies were detected in all cases of gastric carcinoma tested (Table 1, Figure 4A). The mean AI was 1.07% (SD, 0.41%; range, 0.38-2.38%) with a median of 0.95%. The mean AI in survivin- Δ Ex3-low expression samples was significantly higher than that in survivin- Δ Ex3-high expression samples ($P = 0.02$, Table 1, $P = 0.028$, χ^2 test, Table 1). There was no correlation between apoptotic index and clinicopathological parameters described. Spearman's rank correlation test demonstrated a significant negative correlation between apoptotic index and expression level of survivin- Δ Ex3 ($\Gamma = -0.257$, $P = 0.022$).

Association of expression levels of survivin variants with PI

Proliferative cells were detected by intense nuclear immunoreactivity to the Ki-67 antigen, as illustrated in Figure 4B. The mean proliferative index (PI) in gastric tumors tested was 48.46% (SD, 9.54%; range, 28.49-82.98%) with a median of 46.87%. No significant relationship was identified between PI of tumor cells and clinicopathological parameters, as demonstrated in Table 1. In addition, no significant association was found between PI and any type of survivin variants.

Prognostic value of survivin mRNA expression

Postoperative survival of the 79 gastric cancer patients was analyzed according to the expression level of survivin variants. Results are shown in Figure 5. Each survivin variant value was divided by the median value. The survival curve of patients with high-survivin expression was significantly lower than that of those with low-survivin expression ($P = 0.003$, log-rank test). No prognostic significance for either survivin-2B or survivin- Δ Ex3, however, was found in the current study.

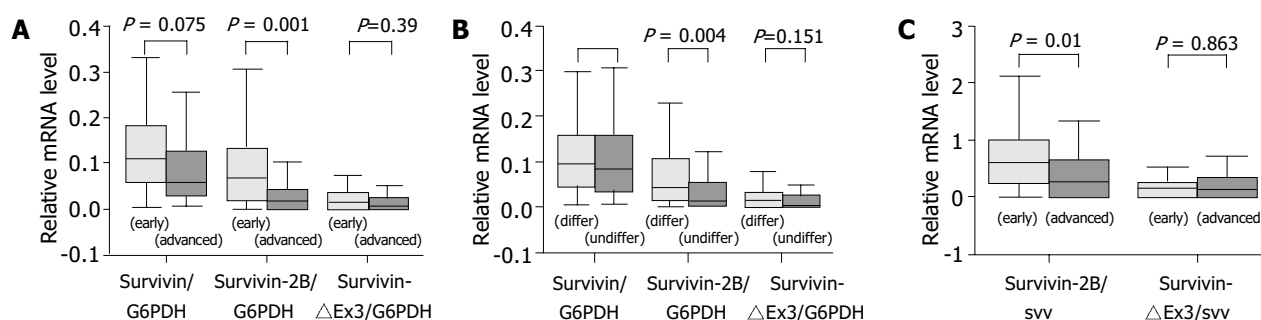

Figure 3 Relative mRNA levels of survivin variants. A: Significant decrease of relative (G6PDH-normalised) mRNA levels of survivin-2B in advanced stages ($P = 0.001$, Mann-Whitney U test). B: Significant decrease of relative (G6PDH-normalised) mRNA levels of survivin-2B in undifferentiated type ($P = 0.004$, Mann-Whitney U test). C: Significantly lower ratio of survivin-2B/survivin in advanced stages than that in early stages ($P = 0.018$, Mann-Whitney U test).

B: Ki-67 nuclear immunohistochemical staining revealing proliferating tumor cells in adenocarcinoma (magnification $\times 400$).

Figure 5 postoperative survivals of 79 gastric carcinoma patients. A: Shorter survival time of patients with high expression of wild-type survivin mRNA compared to patients with low expression of wild-type survivin expression ($P = 0.003$, log-rank test). B: No significance in expression of survivin-2B mRNA ($P = 0.166$, log-rank test). C: No significance in expression of survivin- Δ Ex3 mRNA ($P = 0.441$, log-rank test).

DISCUSSION

In this study, the prognostic significance of the expression of three survivin splicing variants in gastric carcinoma was examined for the first time. Interestingly, only increased wild-type survivin mRNA expression was prominently correlated with reduced survival time, whereas neither survivin-2B nor survivin- Δ Ex3 showed an association with prognosis. In accordance with recent studies, we did not find a correlation between mRNA expression levels of anti-apoptotic variants (survivin or survivin- Δ Ex3) and the investigated clinicopathological parameters^[9,10]. There is no doubt, however, survivin plays a role in enhancing the malignant behavior of tumors. In cell culture systems, over-

expression of survivin was consistently associated with inhibition of cell death^[2]. Strong survivin mRNA expression showed chemoradio resistance^[11-13] and a correlation with recurrence in patients^[14]. In retrospective trials, increased survivin mRNA or protein expression was reported to be a prognostic indicator of tumor progression in different types of human cancer^[15-19]. Our observations further confirmed that survivin mRNA was a poor prognostic biomarker. This suggests that a relatively straightforward detection of survivin protein or mRNA in clinical patients may provide an initial marker of aggressive diseases, potentially requiring in-depth follow-up protocols or alternative treatment regimens in the future.

The notion that survivin inhibits apoptosis has been established, but the mechanism (s) by which this occurs has not been conclusively determined. The actual molecular interaction partners of survivin variants, however, have remained elusive^[2]. Although there is a good agreement that deregulation of cell death/survival pathways contributes to malignant transformation, the potential predictive/prognostic impact of apoptosis regulatory molecules and AI has remained controversial^[8]. This study failed to show the relationship between apoptotic index and survivin expression in gastric carcinoma although it was shown in previous^[5,20] studies showed in gastric cancer that survivin expression was inversely correlated with apoptosis. These controversial findings were attributed in part to the dual function by which survivin regulates cell death and cell division. In recent studies, frameshift carboxyl terminus of survivin- Δ Ex3 was found to contain a bipartite localization signal, which mediates its strong nuclear accumulation and might interfere with degradation of survivin- Δ Ex3 protein by ubiquitin tagging. Survivin- Δ Ex3, therefore, could evade cell cycle-specific degradation by the ubiquitin-proteasome pathway, known for survivin. In contrast, cytoplasm has been found to be the most probable location of both survivin and survivin-2B^[21,22]. Other unique features in survivin- Δ Ex3 were also identified, including a mitochondrial localization signal and a BH2 domain, which might inhibit apoptosis by association with bcl-2, and suppress Caspase-3 activity by BIR-dependent pathway^[23]. Consequently, survivin- Δ Ex3 may play a more crucial role in the regulation of apoptosis.

Although mRNA levels of survivin-2B and survivin- Δ Ex3 have been found in different tumors^[3,10,24,25], little is known about the protein levels of endogenous survivin-2B and survivin- Δ Ex3, due to the lack of survivin variant-specific antibodies. Our results showed that a low mRNA expression level of survivin-2B was inversely correlated to the advanced (III+IV) stage, undifferentiated tumor histology and deep tumor invasion. There are at least two reasonable explanations for this finding. After losing its antiapoptotic potential, survivin-2B was hypothesized to be a naturally occurring antagonist of survivin from competitive binding to heterologous interaction partners, or from the formation of inactive survivin: survivin-2B heterodimers with respect to recently observed dimer formation of survivin^[21]. Downregulation of survivin-2B might weaken its functional antagonism, and moreover, could permit the generation of more survivin or survivin- Δ Ex3 because three survivin variants come from the same pool of a hnRNA precursor. Thus, the decrease in survivin-2B may result in the development, invasion and anaplasia of carcinomas.

In addition, our data showed that all gastric carcinoma samples expressed wild-type survivin at a significant level compared to the matched normal gastric mucosa samples. Similarly, the expression of survivin-2B or survivin- Δ Ex3 was significantly elevated in carcinoma tissue. Among three survivin variants, survivin was the dominant transcript. In this regard, our results were consistent with those of two recent TR-PCR studies^[10,26] on gastric cancer in which a few gastric mucosa samples (17-23%) of the first-degree relatives also expressed survivin mRNA, but the normal control subjects did not. All these findings may help explain why survivin variants played important roles in the early stage of carcinogenesis of gastric cancer.

In summary, survivin mRNA is a poor prognostic biomarker and that non-antiapoptotic survivin-2B was correlated to tumor stage, histological type and depth of tumor invasion. Even more striking is the observation for the first time that neither survivin nor survivin-2B show a close association with the apoptosis index, as observed in survivin- Δ Ex3, although further experimental work is necessary to elucidate

the functional properties of different splicing variants in more detail.

ACKNOWLEDGEMENTS

We thank Ms. Akiko Miyamoto and Drs. Takaharu Suga and Yoshiaki Tatsumi, Department of General and Gastroenterological Surgery, or Dr. Noda Naohiro, First Department of Pathology, Osaka Medical College for their excellent assistance throughout this investigation.

Abstract

AIM: To investigate the relationship between bcl-2 gene and its related protein bax and intrahepatic cholangiocellular carcinoma (CCC).

METHODS: Semi-nested *in situ* PCR (SNISPCR) and immunohistochemistry were performed to detect bcl-2/JH fusion gene and bcl-2, bax protein expression in 29 cases of CCC.

RESULTS: No bcl-2/JH fusion gene was found in all cases of CCC, 72.4% of 29 cases expressed bcl-2 protein. Bcl-2 protein expression was related to histopathological grades ($P < 0.05$). There was no corresponding relationship between bcl-2/JH fusion gene formation and bcl-2 protein expression in CCC ($P < 0.05$). Bax was expressed in 10.3% of 29 cases. The ratio of bcl-2 to bax in normal liver tissues (3.5 to 1) was different from that in tumor tissues (7.0 to 1).

CONCLUSION: It is suggested that bcl-2/JH fusion gene formation is not a frequent event and may not play an important role in the pathogenesis of CCC. However, aberrant ratio of bcl-2 to bax protein expression may be involved in the course of tumorigenesis of CCC. Abnormal bcl-2 protein expression may not be solely resulted from bcl-2/JH fusion gene.

INTRODUCTION

Bcl-2 gene was first identified in B-cell leukemia and follicular lymphoma which conferred a survival advantage on B-cells by inhibiting apoptosis. Bcl-2 gene at chromosome 18 is juxtaposed with the immunoglobulin heavy chain gene (JH) on chromosome 14^[1]. The t (14; 18) chromosome translocation was present in 70% to 85% of follicular lymphoma and in 20% to 30% of diffuse large-cell lymphomas^[1-4]. While aberrant expression of bcl-2 protein was also found in follicular lymphoma. In the early study, bcl-2 gene was mainly investigated in lymphoid tissues. Recently, bcl-2 gene aberrant expression has been observed in a variety of tumors, such as adenocarcinoma of the prostate, bladder carcinoma, squamous cell carcinoma of the lung, nasopharyngeal carcinoma, breast carcinoma and cholangiocarcinoma^[5-17]. However, bcl-2/JH fusion gene and its relationship with bcl-2 protein expression have not been detected in

cholangiocellular carcinoma (CCC).

Bax, an important homologue of bcl-2, is a promoter of apoptosis. It has been proposed that the sensitivity of cells to apoptosis stimuli be closely related to the ratio of bcl-2/bax and other bcl-2 homology. When bcl-2 is in excess, cells are protected. However, when bax is in excess and bax homodimers dominate, cells are susceptible to apoptosis^[18]. Whether bcl-2/bax expression ratio is involved in the course of tumorigenesis of CCC remains unknown.

In this study, we demonstrated that bcl-2/JH fusion gene, bcl-2 and its related protein bax expression with semi-nested *in situ* PCR (SNISPCR) and immunohistochemistry in 29 cases of CCC to understand the relationship between bcl-2 gene and its related protein bax in CCC.

MATERIALS AND METHODS

Tissue preparation

A total of 29 samples were obtained by surgical resection in our department from 1995-06-01 to 1998-02-28. All samples were independently reviewed by two pathologists and graded as recommended by WHO. The cases of CCC were classified as follows: 6 cases of well differentiated, 14 cases of moderately differentiated and 9 cases of poorly differentiated carcinomas. Undamaged liver tissues from surgical resection specimens of young adults with minor liver injury who underwent partial hepatectomy were used as normal controls. All tissues were fixed in 40 g/L formaldehyde (pH 7.0) for 12-24 h and embedded in paraffin and then 4 μ m thick serial sections were cut and mounted on poly-L-lysine coated slides.

Immunohistochemical staining

The sections were deparaffinized and rehydrated routinely. Antigens were retrieved by heating the sections in a microwave oven at 700 W in 10 mmol/L citrate buffer (pH 6.0) for 10 min. After blocked with 3 mL/L H₂O₂ and swine serum, specimens were then incubated with the primary antibodies, directed against bcl-2 (Maxim Biotech Co., China) and bax (Santa Cruz). The staining was performed by streptavidin peroxidase enzyme conjugate method using a S-P kit (Zymed). Reaction products were visualized by DAB. Brown-yellow granules in cytoplasm were recognized as positive staining.

Semi-nested *in situ* PCR

Pretreatment: Sections were deparaffinized and dehydrated routinely, then washed in 0.1 mol/L HCl and PBS, digested with proteinase K (10 mg/L), and placed on the platform in a DNA thermal cycler at 98 °C for 2 min.

Amplification *in situ*: The final volume of 20 μ L (200 μ mol/L each of dATP, dCTP, dGTP and dTTP, 1.5 U Taq polymerase, 10 \times buffer). Two and half sets of primers specific for the two hot breakpoint regions on bcl-2 gene were synthesized according to the DNA sequences published by Gribben^[19]. The following oligonucleotides were used as primer pairs: A, 5'-CAGCCTTGA AACATTGATGG-3' for the mbr (in major breakpoint region); B, 5'-CGTGCTGGTACCACTCTG-3' for the mcr (in minor breakpoint region); C, 5'-TATGGTGGTTTGACCTTTAG-3' for the mbr (in major breakpoint region); D, 5'-GGACCTTCCTTGG

TGTGTTG-3' for mcr (in minor breakpoint region); Immunoglobulin heavy chain (JH), 5'-ACCTGAGGAGACGGTGACC-3'. At first, mbr-JH fusion gene was amplified by primer A and JH, and mcr-JH fusion gene was amplified by primer B and JH. The slides were covered after adding reaction mixture. The samples were subjected to 25 amplification cycles, each cycle consisting of denaturation at 94 °C for 1 min, annealing at 55 °C for 1 min and extension at 72 °C for 1 min. The final extension period was extended to 10 min. Reamplification was performed for 30 cycles using primer C, JH for mbr-JH fusion gene and D, JH for mcr-JH fusion gene. The conditions were the same as stated above.

In situ hybridization

The covers were removed and dehydrated routinely. The slides were incubated in 40 g/L poly formaldehyde for 10 min. Forty µL hybridization solution (probe concentration 50 pmol/L) was added on slides overnight at 37 °C in a wet box. The oligonucleotide probe was labeled with biotin. Sequences of the probes were 5'-CCCTCCTGCCCTCCTCCG-3' for mbr and 5'-GGACCTTCCTTGGTGTGTTG-3' for mcr.

Non-specific antigen was blocked with 20 mL/L bovine serum and 3 g/L Triton X-100, followed by incubation with anti-biotin antibody alkaline phosphates mixture for 1 h. Slides were then visualized with BCIP/NBT. Purple-blue granules in nuclei were regarded as positive.

Controls

Follicular lymphoma was used as positive control. Negative controls included blank control with no primers, dNTP or Taq polymerase omission in PCR reaction solution, and probe omission in hybridization solution. To exclude false positive or negative results, each sample was analyzed at least twice. Non-corresponding tissues such as normal skin tissue were also treated to exclude the false positive possibility.

Statistical analysis

Statistical significance was calculated by χ^2 test, which was used to analyze the relation between bcl-2 and bax protein staining and positive bcl-2/JH fusion gene and histopathological grades. $P < 0.05$ was considered as statistically significant.

RESULTS

Expression of bcl-2 protein in CCC

Twenty-one of 29 cases expressed bcl-2 protein, including 5 well differentiated, 13 moderately differentiated and 3 poorly differentiated carcinomas. There was a statistically significant difference between moderately differentiated and poorly differentiated carcinomas in Bcl-2 expression ($P < 0.05$, $\chi^2 = 5.58$). Bcl-2 was also expressed in 87.5% (14/16) in normal liver tissues of small bile ducts (Figures 1, 3).

Detection of bcl-2/JH fusion gene in CCC

Bcl-2/JH fusion gene was not detected in any case of CCC and normal liver tissues.

Relationship between bcl-2 protein expression and bcl-2/JH fusion gene

No bcl-2/JH fusion gene was detected in bcl-2 protein positive and negative groups. There was no correlation between bcl-2 protein expression and bcl-2/JH fusion gene.

Expression of bax protein in CCC

Bax was expressed in 3 (10.3%) of 29 cases, in which 1/6 was well differentiated carcinoma, 2/14 were moderately differentiated carcinomas and none was poorly differentiated carcinoma. There was no statistically significant difference between bax expression

and histological grades. Four (25%) of 16 normal liver tissue samples expressed bax protein (Figures 2, 4).

Figure 4 Normal liver. Brown-yellow staining in cytoplasm of small bile duct epithelial cells for bax protein (arrowhead) Immunohistochemistry staining $\times 200$.

Ratio of bcl-2 to bax in normal liver and CCC

In normal liver tissues, the expression rates of bcl-2 and bax

were 87.5% and 25%, while positive rates of bcl-2 and bax were 72.4% and 10.3% in CCC respectively. The ratio of bcl-2 to bax was 3.5 to 1 in normal liver tissues and 7.0 to 1 in CCC (Figure 5).

Figure 5 Non-Hodgkin's lymphoma. Purple-blue deposition in nuclear of lymphoma cells (positive for mbr, arrowhead). In situ PCR $\times 400$.

DISCUSSION

Varying results of bcl-2 protein expression in CCC were reported. Bcl-2 protein expression in normal and pathological human liver has been reported by Charlotte *et al.*^[11]. In the report, Charlotte *et al.* described that bcl-2 protein was expressed by small bile duct epithelia in normal liver, but not by hepatocytes or large bile duct epithelia. Eight of 11 CCCs were stained positively for bcl-2, whereas all 15 hepatocellular carcinomas were bcl-2 negative. So the authors suggested that bcl-2 protein appeared to be a diagnostic marker in distinguishing CCC from hepatocellular carcinoma^[11]. Skopelitou *et al.* found all ten samples of CCC were positive for bcl-2 protein staining^[12]. Ito *et al.* reported 31.7% (13/41) of CCCs were positive for bcl-2 protein^[13]. However, Terada *et al.* showed low or negative expression of bcl-2 protein in bile duct epithelia and CCC^[14-17]. In our report, 21 of 29 CCCs expressed bcl-2 protein (72.4%), which was similar to that reported by Charlotte *et al.* Significant differences of bcl-2 expression in CCC have not been known yet, probably because of the different methods used, and the difference of intrahepatic cholangiocarcinoma specimens from the liver^[13,16].

To clarify the role of bcl-2/JH in the pathogenesis of CCC, mbr-JH and mcr-JH which have been shown to be the important molecular event in the genesis of follicular lymphoma, were also studied in 29 cases of CCC. This is the first study to examine bcl-2/JH fusion gene in CCC by *in situ* PCR. Mbr-JH or mcr-JH was negative in all cases of CCC. It is suggested that bcl-2/JH fusion gene formation was not a common event and might not play an important role in the pathogenesis of CCC.

In the present study, bcl-2 protein expression did not correlate with bcl-2/JH in CCC. Similar results were also found in mucosa-associated lymphoma, large cell lymphoma, Hodgkin's disease and nasopharyngeal carcinoma^[20-25]. These findings suggested that abnormal bcl-2 protein expression might not be solely resulted from bcl-2/JH fusion sequences. Whether other types of bcl-2 gene aberrance such as mutation or methylation corresponding to bcl-2 protein expression are existed in CCC requires further investigation.

Compared to a high expression rate of bcl-2 in CCC (72.4%), only 10.3% (3/29) samples expressed bax. To understand the significance of the ratio of bcl-2 to bax in the regulation of apoptosis, Oltvai *et al.*^[18] found that over-expressed bcl-2 in two cell lines with high levels of bax and in cells with the lowest bcl-2 to bax ratio (0.55) was 73% viable at 24 h, but lost viability by d 7. When cells with high bcl-2 to bax ratios (2.04 and 1.65), they possessed viable cells over 2 wk following IL-3 deprivation. These data suggested a model in which the ratio of bcl-2 to bax could determine survival or death following an apoptotic stimulus. Similar results were also found by Lilling *et al.* and others^[26-29].

The alteration of Bcl-2 and Bax might be an important mechanism in the pathogenesis and progression of some tumors^[30-32]. Yue *et al.*^[30] showed that Bcl-2/Bax in acute myelogenous leukemia was significantly higher than that in normal control ($P < 0.001$). Madewell *et al.*^[31] found that the bax:bcl-2 ratio was lower in skin tumors than that in normal skin. But a lowered bcl-2/bax ratio and increased apoptosis were observed in oral squamous cell carcinomas, compared with normal oral epithelium^[32]. In this study, the ratio of bcl-2 to bax (7.0 to 1) in CCC was different from that in normal small bile ducts (3.5 to 1). We suppose that the changes of the ratio between bcl-2 and bax protein may influence the susceptibility of bile duct cells to apoptosis and would be involved in the tumorigenesis of CCC. Further evidence would be obtained from further investigations.

Abstract

AIM: Activation of transcription factor nuclear factor- κ B (NF- κ B) has been shown to play a role in cell proliferation, apoptosis, cytokine production, and oncogenesis. The purpose of this study was to determine whether NF- κ B was constitutively activated in human colorectal tumor tissues and, if so, to determine the role of NF- κ B in colorectal tumorigenesis, and furthermore, to determine the association of RelA expression with tumor cell apoptosis and the expression of Bcl-2 and Bcl-x_L.

METHODS: Paraffin sections of normal epithelial, adenomatous and adenocarcinoma tissues were analysed immunohistochemically for expression of RelA, Bcl-2 and Bcl-x_L proteins. Electrophoretic mobility shift assay (EMSA) was used to confirm the increased nuclear translocation of RelA in colorectal tumor tissues. The mRNA expressions of Bcl-2 and Bcl-x_L were determined by reverse transcription polymerase chain reaction (RT-PCR) analysis. Apoptotic cells were detected by terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate fluorescence nick end labeling (TUNEL) method.

RESULTS: The activity of NF- κ B was significantly higher in adenocarcinoma tissue in comparison with that in adenomatous and normal epithelial tissues. The apoptotic index (AI) significantly decreased in the transition from adenoma to adenocarcinoma. Meanwhile, the expressions of Bcl-2 and Bcl-x_L protein and their mRNAs were significantly higher in adenocarcinoma tissues than that in adenomatous and normal epithelial tissues.

CONCLUSION: NF- κ B may inhibit apoptosis via enhancing the expression of the apoptosis genes Bcl-2 and Bcl-x_L. And the increased expression of RelA/nuclear factor- κ B plays an important role in the pathogenesis of colorectal carcinoma.

INTRODUCTION

Rel/NF- κ B is a family of dimeric transcription factors that control the expression of numerous genes involved in cell growth, differentiation, regulation of apoptosis, cytokine production, and neoplastic transformation^[1,2]. The Rel/NF- κ B family comprises NF- κ B1 (p50), NF- κ B2 (p52), and the Rel proteins, RelA (p65), RelB, and c-Rel, which have a high level of sequence homology within their NH₂-terminal 300 amino acids, the Rel homology domain^[3]. The p50 and p52 can interact with the RelA proteins to form all possible homo- and heterodimer combinations. The most common dimer is the RelA (p65)/NF- κ B1 (p50) heterodimer, i.e., NF- κ B. In most unstimulated cells, Rel/NF- κ B proteins are sequestered in the cytoplasm and are complexed with specific inhibitor proteins called I κ B that render the Rel/NF- κ B proteins inactive^[3]. Stimulation of cells leads to phosphorylation and degradation of I κ B and allows translocation of Rel/NF- κ B to the nucleus, resulting in expression of target genes^[4]. A surprising variety of inducers have been found to activate Rel/NF- κ B^[3]. These pathways are involved in innate immune responses that involve cytokines such as tumor necrosis factor (TNF) - α and IL-1, responses to physical stresses such as UV light and ionizing radiation (χ and γ), and responses to oxidative stresses such as hydrogen peroxide and butyl peroxide^[5].

Several investigators have reported constitutive activation of NF- κ B in various types of human tumor cell lines, including those of lymphoid origin such as Hodgkin/Reed Sternberg cells^[6], T-cell lymphoma Hut 78 cells^[7], and multiple myeloma cells^[8]. In addition, nonlymphoid cell lines including ovarian cancer cells^[9], lung carcinoma cells^[10], breast cancer cells^[11], thyroid carcinoma cells^[12], melanomas^[13], and bladder cancer cells^[14] exhibited enhanced NF- κ B activity.

Recent studies also indicated that NF- κ B was constitutively activated in tumors such as pancreatic cancer and breast cancer^[15,16]. However, little information is available concerning NF- κ B activation in colorectal carcinoma, which is one of the most aggressive forms of cancer. The major objective of this study was to determine whether NF- κ B was constitutively activated in colorectal carcinoma tissues, to examine whether the expression of Bcl-2 and Bcl-x_L was regulated by NF- κ B activation, and to evaluate the correlation between NF- κ B activity and apoptosis in colorectal carcinoma.

MATERIALS AND METHODS

Materials

Ten normal colorectal mucosa, thirty colorectal adenoma (average age of the patients: 56.8 years), and thirty colorectal carcinoma (average age of the patients: 58 years) patients who gave informed consent before surgical treatment were entered into the present study. Specimens were obtained from the Department of Pathology, Renmin Hospital, Wuhan University (Wuhan, China). The patients had received neither chemotherapy nor radiation therapy before tumor resection. To justify comparisons, we excluded lesions from patients with familial colon carcinoma syndrome and suspected de novo cancers. Tissues were fixed with 40 g/L formaldehyde and embedded in paraffin for H & E staining and

immunohistochemistry. Tissue specimens were snap-frozen immediately in liquid N₂ and stored at -80 °C for EMSA assays and RT-PCR analysis. The study was approved by the Institutional Board of the Ethics Committee of Wuhan University under full consideration of the declaration on human rights of Helsinki.

Immunohistochemistry

Formalin-fixed, paraffin-embedded tissue blocks were cut into 5 µm thick and mounted onto glass slides. After that, they were kept in an oven at 4 °C overnight. Immunostaining was performed as previously described with a slight modification^[17]. Sections were deparaffinized in xylene and rehydrated. Endogenous peroxidase activity was blocked with 1% hydrogen peroxide for 20 min. To improve the quality of staining, microwave oven-based antigen retrieval was performed. Slides were probed with either anti-RelA (1:50, mouse monoclonal, Santa Cruz Biotechnology), anti-Bcl-2 (1:100, mouse monoclonal, Santa Cruz Biotechnology) or anti-Bcl-x_L (1:100, mouse monoclonal, Santa Cruz Biotechnology). Sections were washed three times with PBS for 10 min each and incubated with biotin-labeled anti-mouse IgG for 1 h at room temperature. After three washes with PBS for 10 min each, sections were stained with a streptavidin-peroxidase detection system. Incubation with PBS instead of the primary antibody served as a negative control. In specimens containing positive cells, the positive cells were counted in ten randomly selected fields under high power microscope (200-fold or 400-fold magnification) for each sample, and the average was expressed as the density of positive cells.

Determination of apoptosis

The TUNEL assay, originally described by Gavrieli *et al.*^[18], was used with minor modifications. Briefly, tissue sections of 5 µm were mounted onto glass slides, deparaffinized, hydrated, and treated for 15-30 min at 37 °C with proteinase-K (Roche Co.; 20 µg/mL in 10 mmol/L Tris-HCl buffer, pH 7.4). Slides were rinsed twice with PBS. Then, 50 µL of TUNEL reaction mixture (450 µL nucleotide mixture containing fluoresceinated dUTP in reaction buffer plus 50 µL enzyme TdT from calf thymus, Roche Co.) were added to the samples. To ensure homogeneous distribution of the TUNEL reaction mixture on tissue sections and to avoid evaporative loss, slides were covered with coverslips during incubation. Slides were incubated in a humidified chamber for 60 min at 37 °C. After rinsed, slides were incubated with anti-fluorescein antibody, with Fab fragment from sheep, conjugated with horse-radish peroxidase for 30 min at 37 °C. Slides were rinsed twice with PBS. Then, 50-100 µL of DAB substrate was added and incubated for 10 min at room temperature. Samples can be counterstained prior to analysis by light microscope. Positive signals were defined as presence of a distinct brown color nuclear staining of the neoplastic cells or morphologically defined apoptotic bodies. The apoptotic index (AI) was determined by counting a total of at least 1 000 neoplastic nuclei in 10 randomly chosen fields at 400-fold magnification. Apoptotic cells were identified using a TUNEL assay in conjunction with characteristic morphological changes such as cell shrinkage, membrane blebbing, and chromatin condensation, to distinguish apoptotic cells and apoptotic bodies from necrotic cells.

EMSA

Nuclear extracts were harvested according to protocols described previously.^[19] In brief, fresh samples were minced and homogenized in 400 µL of hypotonic lysis buffer A (10 mmol/L HEPES pH 7.9, 10 mmol/L KCl, 0.1 mmol/L EDTA, 0.1 mmol/L EGTA, 1 mmol/L DTT, and 1 mmol/L PMSF). Homogenized tissues were incubated on ice for 5 min, NP-40 was added to a

final concentration of 5 g/L, and samples were vigorously mixed and centrifuged. The cytoplasmic proteins were removed and the pellet nuclei were resuspended in 50 µL buffer C (20 mmol/L HEPES pH 7.9, 0.4 mol/L NaCl, 1 mmol/L EDTA, 1 mmol/L EGTA, 1 mmol/L DTT, and 1 mmol/L PMSF). After 30 min agitation at 4 °C, the samples were centrifuged and supernatants, containing nuclear proteins, were transferred to a fresh vial. The protein concentrations of nuclear extracts were determined by Bio-Rad protein assay. The nuclear extracts were stored at -80 °C until use. Nuclear protein extracts of carcinomas, adenomas, and normal tissues were analyzed by EMSA for NF-κB nuclear translocation as previously described^[20-22]. EMSA binding reaction mixture contained 8 µg protein of nuclear extracts, 2 µg of poly (deoxyinosinic- deoxycytidylic acid) (Sigma Co.), and [³²P]-labeled double-stranded oligonucleotide containing the binding motif of NF-κB probe (4 000 cpm) in binding buffer (10 mmol/L HEPES pH 7.9, 50 mmol/L NaCl, 1 mmol/L EDTA, 1 mmol/L DTT, 100 mL/L glycerol, and 0.2 g/L albumin). The sequence of the double-stranded oligomer used for EMSA was 5'-AGTTGAGGGGACTTTCCCAGGC-3'. The reaction was incubated for 30 min at room temperature before separation on a 50 g/L acrylamide gel, followed by autoradiography. For supershift experiments, 2 µg of mouse monoclonal antibodies against the p65 subunit (Santa Cruz Biotechnology) of NF-κB was incubated with the nuclear extracts 10 min before the addition of the [³²P]-labeled probe and then analyzed as described.

RT-PCR

The mRNA expressions of Bcl-2 and Bcl-x_L were assessed using RT-PCR standardized by coamplifying housekeeping gene β-actin, which served as an internal control. Total RNA was isolated from the normal epithelial, adenomatous and adenocarcinoma tissues by the single-step method^[23]. Total RNA was reversely transcribed into cDNA and used for PCR with human specific primers for Bcl-2, Bcl-x_L and β-actin. Sequences of Bcl-2 primers were 5'-CAGTGCACCTGACGCCCTT-3' (forward primer) and 5'-GCCTCCGTTATCCTGGATCC-3' (reverse primer), generating a 199 bp PCR product; for Bcl-x_L, the forward primer was 5'-AAGGATACAGCTGGAGTCAG-3' and the reverse primer was 5'-ATCAATGGCAACCCATCCTG-3', generating a 316 bp PCR product; for β-actin, the forward primer was 5'-AGCGGGAATCGTGCGTGAC-3' and the reverse primer was 5'-ACTCTGCTTGCTGATCCACATC-3', producing a 471 bp PCR product^[24,25]. Briefly, the PCR was amplified by 32 repeat denaturation cycles at 95 °C for 30 s, annealing at 60 °C for 30 s, and extension at 72 °C for 30 s. During the first cycle, the denaturation was extended to 2 min, and in the final cycle the extension step was extended to 5 min. PCR products were separated on 15 g/L agarose gels containing 0.5 g/L of ethidium bromide and visualized by UV transillumination.

Statistical analysis

All statistical analyses were performed with SPSS10.0 statistical package for Microsoft Windows. Student's *t* test and one-way analysis of variance (ANOVA) were used to compare continuous variables among groups. Correlation coefficients between continuous variables were calculated by the method of Pearson's correlation coefficient. The χ² test was used to compare binomial proportions. A *P* value of <0.05 was considered significant.

RESULTS

RelA/NF-κB expression in colorectal carcinoma tissues

To investigate whether RelA/NF-κB-DNA binding activities were altered in human colorectal carcinoma tissues, we first carried out immunohistochemical analyses. The monoclonal antibodies used in this study detected only activated RelA

Figure 1 Immunohistochemical staining of RelA in tissue sections of colorectal adenoma (A) and adenocarcinoma (B, C). RelA protein is mainly expressed in the cytoplasm of tumor cells and nuclear accumulation of RelA is also detected. $\times 200$.

proteins^[17]. RelA staining was shown as brown color and detected in normal colorectal mucosa, colorectal adenoma and colorectal adenocarcinoma specimens. In colorectal adenoma and adenocarcinoma, positive staining of RelA was mainly observed in the cytoplasm, and nuclear staining for RelA was also detected (Figure 1). Tissues of colorectal adenocarcinoma showed more cells with nuclear staining for RelA than those in colorectal adenoma tissues. No nuclear staining for RelA was found in normal colorectal mucosa. As shown in Table 1, the density of RelA-positive cells was significantly increased ($P < 0.01$) in the transition from normal mucosa to adenoma and adenocarcinoma.

EMSA

To confirm the finding that RelA/NF- κ B-DNA binding activities were activated in human colorectal carcinoma tissues, we carried out EMSA analyses. Figure 2 shows increased NF- κ B DNA binding activity in adenocarcinoma tissues compared with that in adenoma and normal tissues. HPIAS-1000 SOFTWARE ANALYSIS took the image of electrophoresis. The absorbance of EMSA bands showed that the RelA/NF- κ B complexes were not presented in normal colorectal epithelium, 0.6587 ± 0.0021 in adenocarcinoma, and 0.2153 ± 0.0013 in adenoma. The RelA expressions were significantly increased ($P < 0.05$) in the transition from normal colorectal epithelium to colon tumor tissues. To confirm the specificity of NF- κ B DNA binding, we performed supershift analysis with antibodies specific for RelA (p65) and a competitive study with a 50-fold excess of unlabeled oligonucleotide. An antibody specific for RelA which recognizes RelA/NF- κ B heterodimer, unlabeled oligonucleotide diminished the intensity of RelA/NF- κ B complexes, indicating that complex was the NF- κ B binding-specific band. Our results showed that RelA was frequently activated in human colorectal tumor tissues but not in normal colon tissue.

Figure 2 Electrophoretic mobility shift assay demonstrating increased nuclear translocation and DNA binding of NF- κ B. A: lane 1, positive control (using Hela nuclear extract); lane 2, normal; lanes 3-6, adenocarcinoma; lanes 7-10, adenoma. B: lane 1, positive control (using Hela nuclear extract); lanes 2-3, specific competitor (using excess of unlabeled oligonucleotide);

lanes 4-5, adenoma; lanes 6-7, adenocarcinoma; lane 4 and 6, supershift (addition of p65 antibodies to the nuclear extracts).

Bcl-2 and Bcl-x_L protein expression in colorectal carcinoma tissues

In the present study, the expressions of Bcl-2 and Bcl-x_L were also investigated using immunohistochemistry. Immunostaining specific for Bcl-2 and Bcl-x_L was cytoplasmic and shown as brown color (Figures 3, 4). The expressions of Bcl-2 and Bcl-x_L were significantly increased ($P < 0.01$) from normal mucosa to tumor tissue (Table 1). Expressions of Bcl-2 and Bcl-x_L were both significantly associated ($r = 0.95, 0.88$; $P < 0.05$) with RelA expression in adenoma and adenocarcinoma.

Table 1 Changes in expression of RelA, Bcl-2, Bcl-x_L and AI in transition from normal mucosa to tumor tissues

Group	n	RelA	Bcl-2	Bcl-x _L	AI
Normal	10	9.31 ± 0.56	15.62 ± 0.75	11.35 ± 0.71	13.09 ± 0.78
Adenoma	30	54.01 ± 4.53	55.64 ± 6.51	56.43 ± 6.14	105.91 ± 6.11
Adenocarcinoma	30	70.92 ± 7.23	78.23 ± 8.33	77.32 ± 6.51	31.53 ± 3.71

Bcl-2 and Bcl- x_L mRNA expression in colorectal carcinoma tissues

RT-PCR analysis of mRNA expressions of Bcl-2 and Bcl- x_L was standardized by co-amplifying these genes with the housekeeping gene β -actin. HPIAS-1000 SOFTWARE ANALYSIS took the image of electrophoresis with β -actin as internal standard. The relative absorbance of mRNA expression for Bcl-2: $2.43 \pm 0.27\%$ in normal tissues, $17.96 \pm 1.51\%$ in adenoma, and $36.71 \pm 2.17\%$ in adenocarcinoma; for Bcl- x_L : $3.54 \pm 0.33\%$ in normal tissues, $23.02 \pm 2.11\%$ in adenoma, and $39.71 \pm 2.49\%$ in adenocarcinoma (Figure 5). Our results showed that colon tumor tissue constitutively expressed Bcl-2 and Bcl- x_L . The mRNA expressions of Bcl-2 and Bcl- x_L were significantly increased ($P < 0.05$) in the transition from normal colorectal epithelium to colon tumor tissue.

Cell apoptosis

In this study, TUNEL staining was restricted to the nucleus of apoptotic cells. TUNEL-positive staining cells were detected in normal colorectal mucosa, adenoma, and adenocarcinoma. The AI was significantly increased ($P < 0.01$) in the transition

from normal colorectal mucosa to adenoma, but decreased from adenoma to adenocarcinoma (Figure 6). There was no association between the AI and the histological classification of adenoma and adenocarcinoma. The density of RelA-positive cells inversely correlated with the AI in the transition from adenoma to adenocarcinoma ($r = -0.89$; $P < 0.001$).

DISCUSSION

We have demonstrated that RelA-DNA binding activity was constitutively activated in the majority of human colorectal carcinomas. Whereas the role for RelA/NF- κ B in tumorigenesis has not firmly established, recent work has suggested that it may play a role in this process. RelA/NF- κ B activation has been shown to be necessary for tumor formation in Hodgkin lymphoma cells^[26,27]. More recently, the inhibition of RelA/NF- κ B activity through the use of specific NF- κ B inhibitors (gliotoxin and MG132) resulted in spontaneous caspase-independent apoptosis in Hodgkin and Reed-Sternberg cells^[28]. Also, an increase in RelA/NF- κ B levels was identified in breast cancer

cell lines, primary human breast cancer, hepatocellular carcinoma, pancreatic adenocarcinoma, and gastric carcinoma when compared with nontransformed controls or normal tissues^[29-32]. In addition, NF- κ B transcriptional activity was required for oncogenic Ras-induced cellular transformation^[33], which likely occurred through the inhibition of transformation-associated apoptosis^[34]. However, the role of NF- κ B in colorectal tumorigenesis is unknown and currently under investigation.

We primarily used immunohistochemistry to detect NF- κ B activation in human colorectal carcinoma tissues. Its expression was significantly increased in the transition from normal colorectal mucosa to adenoma and adenocarcinoma. In our immunohistochemical analyses, we used monoclonal antibodies to detect RelA/NF- κ B-DNA binding activities, and their sensitivity and specificity have been characterized previously. They were useful in differentiating between activated and inactivated forms of RelA and facilitated the detection of the activated RelA proteins. In the current investigation, only 10-20% of RelA/NF- κ B protein was detectable in the nucleus, which was consistent with previous reports^[32]. And 80-90% of RelA still remained in the cytoplasm when RelA proteins were activated. It is unclear why the majority of RelA/NF- κ B proteins that were freed from I κ B remained in the cytoplasm. Possible explanations for this^[32] are: (1) I κ B was mutated and therefore could not bind to RelA and masked the nuclear translocation signal in RelA; (2) mutations in RelA prohibited I κ B binding to RelA, and (3) the RelA upstream signal transduction cascades were constitutively activated.

The Bcl-2 proto-oncogene is an apoptosis inhibitor originally described in association with the t(14; 18)(q32; q21) translocation in follicular B cell lymphoma, which places the Bcl-2 gene under the stimulatory control of the IgH promoter-enhancer at 14q32, resulting in increased Bcl-2 mRNA and protein^[35] and inhibition of apoptosis. The Bcl-x_L proto-oncogene, a member of Bcl-2 family, is a homologue of Bcl-2 and is an apoptosis inhibitor. The Bcl-2 and Bcl-x_L oncoproteins have been described in normal colonic mucosa^[35], where these were restricted to the epithelial regenerative compartment and the intestinal crypt bases. In our study, the expression of Bcl-2 and Bcl-x_L was increased in the transition from normal mucosa to adenoma and adenocarcinoma. These results also show that the increased RelA/NF- κ B expression occurred concomitantly with an increased expression of Bcl-2 and Bcl-x_L. To date, a number of gene products that inhibit apoptosis have been identified. These include Bcl-2 and Bcl-x_L genes. Indeed, Bcl-2 and Bcl-x_L have been identified as NF- κ B target genes^[36], but the exact role NF- κ B plays in its regulation remains controversial.

In recent years, increasing evidence indicates that activation of NF- κ B plays an important role in coordinating the control of apoptotic cell death. NF- κ B has been shown to prevent Fas-induced death in B cells through the upregulation of Bcl-2 and Bcl-x_L expression^[36], but has also been demonstrated to promote apoptosis in thymocytes by downregulating Bcl-2 and Bcl-x_L gene expression^[37]. However, the exact mechanism of NF- κ B in the regulation of apoptosis is not entirely clear. There are at least two distinct mechanisms by which NF- κ B blocks apoptosis^[38]: (1) induction of antiapoptosis factors including IEX-IL, TRAF1, TRAF2, c-IAP-1, c-IAP-2 *etc*; (2) interference of apoptotic pathway by protein-protein interaction. However, these two distinct mechanisms are not mutually exclusive since either mechanism alone cannot fully explain the antiapoptotic action of NF- κ B. In our study, apoptosis was significantly decreased in the transition from adenoma to adenocarcinoma, which was in contrast to the expressions of RelA, Bcl-2, and Bcl-x_L. We also observed an inverse relation between AI and the expression of RelA in the transition from adenoma to adenocarcinoma, implying that increased RelA protein expression to a certain level might be anti-apoptotic and thus promote tumorigenic

cell behavior. The anti-apoptotic role of NF- κ B has been well characterized and various down-stream targets of NF- κ B, including Bcl-2 and Bcl-x_L have been identified. In the present study, the statistical correlation between the increased expression of RelA, elevated Bcl-2 and Bcl-x_L expression implies that in colorectal tissue, activation of RelA might exhibit anti-apoptotic effects at least in part through upregulation of Bcl-2 and Bcl-x_L expression. This has been shown to decrease mitochondrial permeability changes and cytochrome C release and thus to block apoptosis^[39].

To date, NF- κ B has been believed to play an important role in coordinating the control of apoptotic cell death. However, the mechanism by which NF- κ B blocks apoptosis is still controversial. Some laboratories have reported that activation of NF- κ B is able to either promote or prevent apoptosis, depending on different stimuli and different cell types^[40-42]. For example, Grimm *et al.*^[43] reported that serum starvation activated NF- κ B and induced human embryonic kidney cells into apoptosis. Qin *et al.*^[44] found that NF- κ B activation contributed to the excitotoxin-induced death of striatal neurons. However, somewhat inconsistent results have also been presented by Beg and Baltimore^[45] that NF- κ B activation generally inhibited apoptosis in embryonic fibroblasts. A question arises: who is right on earth? We think the answer is expected by further studies.

In conclusion, our results demonstrate that the RelA/NF- κ B pathway is activated constitutively in colorectal carcinoma tissues, suggesting that activation of RelA/NF- κ B might play an important role in colorectal tumorigenesis. Further studies are required to elucidate the mechanisms of NF- κ B activation and to determine whether NF- κ B might serve as a therapeutic target in the anti-neoplastic treatment of colorectal cancer.

Abstract

AIM: To investigate the expression of vascular endothelial growth factor-C (VEGF-C) and the relationship between VEGF-C and lymphangiogenesis, lymph node metastasis in colorectal cancer.

METHODS: Fifty six cases of colorectal cancer were selected randomly. Expression of VEGF-C was detected by immunohistochemistry, and lymphatic vessels were stained by enzyme histochemical method.

RESULTS: VEGF-C expression was found in 66.7% (37/56) patients. In VEGF-C positive and negative patients, the lymphatic vessel density was 25.16 ± 7.52 and 17.14 ± 7.22 , respectively ($P < 0.05$). The rate of lymph node metastasis in VEGF-C positive patients (81.1%) was significantly higher than that in the negative group (42.1%).

CONCLUSION: VEGF-C expression may induce lymphangiogenesis in colorectal cancer, as a result, tumor cells can entry the lymphatic vessels easily. VEGF-C may serve as a useful prognostic factor in colorectal carcinoma.

INTRODUCTION

Colorectal cancer is a common cause of death throughout the world including China. The lymphatic system is the primary pathway of metastasis for gastrointestinal tract malignancies, and the extent of lymph node involvement is a key prognostic factor for the outcome of patients. However, the mechanism of lymphatic metastasis remains unclear.

Lymphangiogenesis, the development of new lymph vessels, is a relatively new area of clinical investigations. Recently, vascular endothelial growth factor C (VEGF-C) has been identified as a new member of the VEGF family^[1,2], and is believed

to be the only lymphangiogenic factor in the VEGF family. It activates both vascular endothelial growth factor receptor 2 (VEGFR-2) and VEGFR-3^[3,4]. VEGF-C induces the proliferation of lymphatic vessels in the stroma of gastric carcinoma by activating VEGFR-3 in lymphatic endothelial cells^[5]. But the precise role of VEGF-C in colorectal cancer has not been clearly understood. Therefore, in the current study, we used an enzyme-histochemical method for 5'-nucleotidase (5'-Nase) to distinguish lymph vessels in colorectal carcinoma, and immunohistochemistry to examine the correlation between the expression of VEGF-C, lymphangiogenesis and the clinicopathologic features.

MATERIALS AND METHODS

Patients

Fifty-six Chinese colorectal carcinoma patients were surgically treated in the Department of Surgery, the Forth Hospital of Hebei Medical University, China from 2001 to 2002. The patients included 34 males and 22 females, and ranged in age from 33 to 75 years (average age 58.5 years). The lesions included 13 colon cancers and 43 rectal cancers, two patients with stage I, 17 patients with stage II, 34 patients with stage III and three patients with stage IV.

Immunohistochemistry

Immunohistochemical staining for VEGF-C was performed using the streptavidin-peroxidase technique. Formalin fixed and paraffin embedded tissues were cut into 4 μ m thick sections and placed on saline coated slides. After deparaffinization in xylene and rehydration, endogenous peroxidase activity was blocked after incubated with 30 mL/L hydrogen peroxidase for 20 min. Tissue sections were then autoclaved at 121 °C in 10 mmol/L citrate buffer (pH 6.0) for 10 min for antigen retrieval and cooled at room temperature for 30 min, then incubated for 3 h with a 1:40 dilution of anti-VEGF-C rabbit polyclonal antibody (Santa Cruz Biotech, USA). Bound peroxidase was visualized using a solution of diaminobezidine as chromogen, and nuclei were counterstained with hematoxylin. Scoring was carried out by two independent observers who were blinded to the patient's status. Positive staining was defined as the presence of VEGF-C immunoreactivity in at least 10% of tumor cells.

Enzyme-histochemistry

Cryosections (7 μ m thick) of tissue were processed for 5'-nucleotide-alkaline phosphatase (5'-Nase-ALPase) double staining according to Ji *et al.*'s report^[6]. After rinsed in 0.1 mol/L cacodylate buffer (pH 7.2), specimens were incubated in the reaction medium for 5'-Nase for 50 min at 37 °C with 5'-adenosine monophosphate (AMP) (Sigma chemical, St. Louis, MO, USA) as a substrate, lead nitrate (Sigma, USA) as a capture agent, and 2 mmol/L L-tetramisole (Sigma, USA) as an inhibitor of nonspecific alkaline phosphatase. After washed with distilled water, the tissues were treated with 10 mg/L ammonium sulfide solution for 1 min at room temperature. Then, the sections were incubated in the reaction medium for ALPase for 30 min at 4 °C with fast blue BB, N,N-

dimethylformamide, naphthol AS-MX phosphate (Sigma, USA).

Lymphatic vessel density (LVD) counting

The stained sections were screened at $\times 40$ magnification to identify the regions of the highest vascular density within the tumor. Lymphatic vessels were counted in 3 regions of the highest vascular density at $\times 100$ magnification. The number of lymphatic vessels was the mean of vessels in these areas.

Statistical analysis

The data were analysed by *t* test and χ^2 test. All reported *P* values were two-sided, and $P < 0.05$ was considered statistically significant.

RESULTS

Immunohistochemistry

In specimens of normal colorectal mucosa, no VEGF-C protein was stained. Among the 56 examined tumors, 37 (66.7%) showed VEGF-C protein expression in the cytoplasm (Figure 1).

Figure 1 VEGF-C in cytoplasm of colorectal adenocarcinoma (SP $\times 200$).

Enzyme-histochemistry

Lymphatic vessels were 5'-Nase positive (brown) and blood vessels were ALPase positive (blue). The most lymphatic vessels were enlarged and dilated especially in peritumor areas. The walls of lymphatic vessels were thinner than that of blood vessels, and their profiles of lumens were more irregular. While the intratumoral lymphatic vessels were strip-like (Figure 2). The LVD of VEGF-C positive tumors (25.16 ± 7.52) was significantly higher than that of VEGF-C negative tumors (17.14 ± 7.22) ($P = 0.04$). No significant lymphangiogenesis was observed in normal and adenoma tissues.

Figure 2 Positive 5'-Nase (brown) and ALPase (blue) in lymphatic and blood vessels ($\times 100$).

Correlation between VEGF-C and clinicopathologic factors

VEGF-C expression was observed frequently in patients with colorectal carcinoma. A positive association between VEGF-C expression and lymphatic metastasis was observed ($P < 0.05$, Table 1). However, no significant correlations with gender,

histologic differentiation, invasive depth, TNM stage were observed.

Table 1 Relationship between expression of VEGF-C and clinicopathologic features in colorectal carcinoma

Characteristic	<i>n</i>	VEGF-C		<i>P</i>
		(+)	(-)	
Gender				
Male	34	25	9	0.143
Female	22	12	10	
Lymph node metastasis

Adventitia	39	27	12	
Stage				
I-II	19	13	6	0.790
III-IV	37	24	13	

DISCUSSION

Clinical and pathological data pointed to the metastasis of solid tumors via the lymphatics as an important early event in metastatic diseases^[7]. However, little has been achieved in lymphangiogenesis and the role of lymphangiogenesis in promoting the metastasis of tumor cells via the lymphatic vessels. This might, in part, be due to difficulty in studying lymphatic vessels because of their morphology and lack of lymphatic-specific markers^[6,7]. Approximately 10 years ago, Kato *et al.*^[8] developed an enzyme-histochemical method for 5'-Nase-ALPase to distinguish lymphatic vessels from blood vessels. Many other markers such as LYVE1 and podoplanin were found later^[9,10]. Now, lymphangiogenesis or new lymphatic vessel growth has become an exciting area of research in cancer biology^[11]. So far, the occurrence and involvement of lymphangiogenesis have been demonstrated in some experimental mouse tumors, human head and neck cancers, oral squamous cell cancer by using these markers^[12-16]. Similarly, in our study, lymphangiogenesis was observed in primary colorectal carcinomas, and the vicinity of tumor was the dominant region. Most of lymphatic vessels were dilated, as a result, tumor cells could invade the lymphatics easily. On the other hand, most of the intratumor lymphatic capillaries were strip-like. It is believed that tumor cells could utilize peritumoral lymphatics to spread, while intratumoral lymphatics should be regarded as an additional pathway rather than a necessity for metastasis^[17].

Vascular endothelial growth factor-C (VEGF-C) is the first lymphangiogenic factor identified. Moreover, there is ample evidence for the expression of VEGF-C in human tumors. But the precise role of VEGF-C in colorectal cancer is less well understood. With respect to VEGF-C expression, several authors have demonstrated associations between this growth factor expression and poor clinicopathological outcome^[18-25]. Immunohistochemical detection of VEGF-C expression at the deepest invasive site of colorectal carcinoma was found in about 50% advanced tumors. Furudoi *et al.*^[26] suggested that the expression of VEGF-C was correlated with lymphatic and venous invasion, lymph node status, Dukes stage, liver metastasis, depth of invasion, poorer histological grade and microvessel density.

It is widely known that VEGF-C can bind to both VEGFR-2

and VEGFR-3. Activation of VEGFR-2 results in the mitogenesis of vascular endothelial cells. In contrast, VEGFR-3 activation by VEGF-C is considered to induce proliferation of lymphatic endothelial cells. Thus, angiogenic versus lymphangiogenic responses to VEGF-C have been found to depend on the expression of its receptors in blood versus lymphatic endothelial cells of the target tissue^[27]. In addition, the activation of lymphatics by VEGF-C is considered to induce secretion of chemokines and similar factors by the lymphatic endothelium, thus attracting tumor cells and facilitating their entry into lymphatics^[28]. Besides VEGF-C, another new member of VEGF family, VEGF-D, could also stimulate lymphangiogenesis by activating VEGFR-3 in human tumors^[29-32]. But the relationship between VEGF-C and VEGF-D expressions, as well as the role of VEGF-D in human tumors is still unclear.

In summary, our findings demonstrate a causal role of lymphangiogenesis in tumor metastasis, suggesting VEGF-C expression is related to the high incidence of metastasis in colorectal carcinoma. However, the mechanism of lymphangiogenesis is extremely complex, which is a subject of ongoing investigation.

Abstract

AIM: To determine the genotypes and phylogeny of hepatitis B viruses (HBVs) in asymptomatic HBV carriers, and the prevalence of occult HBV infection in Long An County, Guangxi Zhuang Autonomous Region, an area with a high incidence of hepatocellular carcinoma.

METHODS: A nested polymerase chain reaction (nPCR) was used for detection of HBV DNA in serum samples from 36 blood donors with asymptomatic HBV infection, and in serum samples from 52 HBsAg negative family members of the children who did not receive hepatitis B vaccination in Long An County. PCR products were sequenced, and the genotype of each HBV sequence was determined by comparison with sequences of known genotypes in the GenBank and EMBL nucleotide databases using the BLAST programme. Phylogenetic trees were constructed by the quartet maximum likelihood analysis using the TreePuzzle software.

RESULTS: Twenty (55.56%) of 36 HBV asymptomatic carriers were positive for HBV DNA. They were all genotype C by comparison with sequences of known genotypes in the GenBank and EMBL nucleotide databases. The full-length HBV DNA sequence isolated from the sample No. 624 contained 3 215 bases. No interesting mutations were found in this isolate. The homology analysis showed that this strain was closer to the Vietnamese HBV genotype C strain, with a homology of 97%, compared its relation to the same genotype of HBV isolated in Shanghai. Six (11.5%) of the 52 HBsAg negative family members were positive for HBV DNA. A point mutation was found in the sample No. 37, resulting in the substitution of amino acid glycine to arginine in the "a" determinant. Other samples with positive HBV DNA did not have any unusual amino acid substitutions in or around the "a" determinant, and were attributed to the wild-type HBV.

CONCLUSION: The HBVs isolated from asymptomatic

carriers of Long An County were all identified as genotype C, and the prevalence of occult HBV infection in the population of the county is as high as 11.5%. It is suggested that genotype C and persistent occult HBV infection may play an important role in the development of HCC in the county.

INTRODUCTION

Infection with hepatitis B virus (HBV) may lead to a wide spectrum of liver diseases ranging from mild, self-limited to fulminant hepatitis in acute infection, and from an asymptomatic carrier state to severe chronic hepatitis, cirrhosis, and hepatocellular carcinoma (HCC) in chronic infection. Human HBV, a prototype member of the family hepadnaviridae, is a circular, partially double-stranded DNA virus of approximately 3200 nt^[1]. Traditionally, HBV was classified into 4 subtypes or serotypes (adr, adw, ayr, and ayw) based on antigenic determinants of hepatitis B surface antigen (HBsAg)^[2]. Epidemiological studies found that the prevalence of these serotypes varied in different parts of the world. In addition, antibody to the common determinant "a" confers protection against all serotypes. Advances in molecular biology techniques revealed significant diversities in sequences of HBV isolates, accounting for allelic differences among the 4 major HBV serotypes. Based on an intergroup divergence of 8% or more in the complete nucleotide sequence, HBV has been classified into eight genotypes, designated as A to H^[3-5]. Recent reports suggested that infections with HBV genotype C were associated with more severe liver diseases, including HCC, than infections with genotype B^[6-8]. However, HBV genotype B was suggested to be associated with the development of HCC in Taiwanese below the age of 50 years^[9].

Occult HBV infection is characterized by the presence of HBV infection with undetectable HBsAg. Undoubtedly, carriers of occult HBV may transmit the virus through blood transfusion or organ transplantation. Epidemiological and molecular studies performed since the 1980s indicate that persistent HBV infection might play a critical role in the development of HCC and in HBsAg-negative patients^[10,11].

The incidence rate of HCC in Long An County, southern Guangxi, China, is about 49.9/100 000, the highest in the world, and over 90% of HCC cases in the county are individuals with positive HBsAg in serum^[12,13]. In this study, HBV preC and basic core promoter from 36 HBV asymptomatic carriers in Long An County were amplified and sequenced. The whole genome of a strain from one of the carriers, and genotypes and phylogeny of all the isolates were also analyzed to clarify the difference among HBV strains from different areas. In addition, 52 serum samples from family members of children without hepatitis B vaccination, with negative HBsAg, from the county were

detected for HBV DNA to determine the prevalence of occult HBV infection in the population.

MATERIALS AND METHODS

Serum samples

A total of 36 sera were obtained from asymptomatic blood donors who were infected persistently with HBV in Long An County, southern Guangxi, China. Another 52 serum samples were collected from family members of children failed to have hepatitis B vaccination from the county. Sera were tested for HBsAg, anti-HBc, anti-HBs, HBeAg, and anti-HBe using HBV Marker ELISA kits (produced by Xiamen Xinchuang Scientific Technology Company, Limited, Fujian, China) (Tables 1, 2).

PCR amplification and sequence analysis

DNA was extracted from 85 µL serum by phenol/chloroform extraction following digestion by pronase. For preC and basic core promoter amplification: the first round of PCR 35 cycles was carried out using primers B935 (nt 1240-1260, 5'-GCGCTGCAGAAGGTTTGTGGCTCCTCTG-3') and MDC1 (nt 2304-2324, 5'-TTGATAAGA TAGGGGCATTG-3'). For each cycle, the samples was amplified at 94 °C for 30 s, at 50 °C for 30 s, and at 72 °C for 90 s in a 50 µL reaction. The second

round of 30 PCR cycles was carried out on 5 µL of the first round product using primers CPRF1 (nt 1 678-1 695, 5'-CAATGTCAACGACCG ACC-3') and CPRR1 (nt 1 928-1 948, 5'-GAGTAACTCCACAG TAGCTCC-3') and the same reaction conditions of the first round.

For the surface gene amplification: the first round of 35 cycles PCR was carried out using primers MD14(5'-GCGCTGCAGCTATGCCTCATCTTC-3', nt 418-433) and HCO2 (5'-GCGAAGCTTGCTGTACAGACTTGG-3', nt 761-776). For each cycle, the samples was amplified at 94 °C for s, at 45 °C for 45 s, and at 72 °C for 2 min in a 50 µL reaction. The second round of 30 PCR cycles was carried out on 5 µL of the first round product using primers ME15 (5'-GCGCTGCAGCAAGGTATGTTG CCG-3', nt 455-470) and HDO3 (5'-GCGAAGCTTCATCAT CCATATAGC-3', nt 734-748) and the same reaction conditions of the first round. PCR products from the second round were confirmed by 15 g/L agarose gels electrophoresis and then purified using the Wizard (PCR Preps DNA purification system (Promega, Madison, WI) according to the manufacturer's instructions. Cycle sequencing was carried out directly on 2 mL purified DNA using primers CPRF1 and 33P-dATP by the thermo sequenase radiolabeled terminator cycle sequencing kit (USB Corporation, Cleveland, OH) according to the manufacturer's instructions.

Sample NO. 624 was selected for whole genome sequencing. Its DNA was extracted from 170 µL serum by phenol/chloroform extraction following digestion by pronase. The whole HBV genome was amplified in three fragments. Primers for fragment 1 for the first and second round PCR were LSOB1, BPOLEO1 and LSB11, and POLSEQ2. Primers for fragment 2 for the first and second round PCR were MDN5, BPOLEO1, BPOLBO2 and PSISEQ2. Primers for fragment 3 for the first and second round PCR were POLSEQ1, MDD2, POLSEQ6 and MDC1. The conditions of 30 PCR cycles were at 94 °C for 30 s, at 50 °C for 30 s, and at 72 °C for 90 s in a 50 µL reaction. PCR products from the second round PCR for each fragment were cloned into the vector pCR2.1 (Invitrogen, Leek, The Netherlands) and mini preparations of DNA made from 1.5 mL of 15 mL cultures of individual colonies by phenol extraction and ethanol precipitation of the cell pellet. Plasmids with inserts were identified by digestion with *EcoRI* and remainder of the cultures used for extraction of DNA using a QIAprep spin kit (Qiagen, Crawley, UK). The purified DNA was sequenced as above. Sequencing primers for fragment 1 were LSB1, PSISEQ2, ds 2, ds, ADELN, MD14, ADELN, POLSEQ8, POLSEQ9, POLSEQ6, POLSEQ2. Primers for fragment 2 were BPOLBO2, POLSEQ4, LSOB1, POLSEQ5 and PSISEQ2. Primers for fragment 3 were POLSEQ6, B935, BPOLEO1, MDN5, B936 and MDC1 (Tables 3, 4).

Database sequences

The following complete genomes (represented by their accession number) were used in phylogenetic tree analyses: genotype A: AJ344115; genotype B: AF282917, D00331; genotype C: AY040627, AF461357, M38454, AY057948, AF241410, AF241411, AF330110, AB048705, AB026812, D00329, AB014398, X75665, X14193, X52939, X59795; genotype D: AF280817, AJ344116; genotype E: X75664; genotype F: AB036908; genotype G: AF405706.

Genotype and phylogeny analysis

The genotype of each HBV sequence was determined by comparison with sequences of known genotypes in the GenBank and EMBL nucleotide databases using the programme BLAST^[14]. Phylogenetic trees were constructed by maximum likelihood analysis by quartet puzzling^[15]. TreePuzzle is available at <http://www.tree-puzzle.de>.

RESULTS**HBV genotypes**

Compared with sequences of known genotypes in the GenBank and EMBL nucleotide databases using the programme BLAST, all genotypes of each HBV sequence from the 20 asymptomatic HBV carriers in Long An County were found to be genotype C viruses.

Characterization of HBV genome structure

The full-length HBV-DNA sequence of HBV isolated from sample No. 624 was determined by direct sequencing. This strain contained 3 215 bases. Its serotype is adw. There were 40 point mutations in polymerase gene resulting in changes of 11 amino acids. There were 11, 2, 3 point mutations in PreS1, PreS2 and S genes, leading to 3, 1, 1 amino acids changed in the respective regions. The amino acid mutation in PreS1 was TPP→PHQ at codes 68-70. Six point mutations including the double mutations were found in X gene causing changes of 4 amino acids. There were also 13 point mutations in C gene, leading to 2 amino acids changed. No mutation was found in “a” determinant and Pre C.

Phylogeny analysis

The homology with 23 HBV strains in GenBank was determined

by using the programme TreePuzzle. The HBV strain isolated from sample No. 624 in Long An County was closer to the Vietnamese HBV of genotype C, with 97% homology between them, as compared to the isolates of the same genotype from Shanghai, Beijing and Tibet in evolution (Figure 1).

Figure 1 Phylogenetic trees based on comparison of the whole genome. The trees were created by maximum likelihood analysis using the TreePuzzle software with AF241411 as outgroup.

Prevalence of occult HBV infection

After nested PCR amplification, six samples of 52 family members of children without immunization of HBV vaccine were positive for HBV DNA, counting for 11.5% (6/52) (Table 2). The region of surface ORF of the samples with positive HBV DNA positive, including the “a” determinant of HBsAg, was sequenced. A point mutation from guanosine to adenosine at nucleotide position 587 resulted in an amino acid substitution from glycine to arginine in the highly antigenic “a” determinant of HBsAg, which was found in sample No. 37 only and was negative for both HBsAg and anti-HBs. The other samples with positive HBV DNA did not have unusual amino acid substitutions in or around the “a” determinant, and were attributed to the wild-type HBV of genotype C.

DISCUSSION

In 1988, Okamoto *et al.*^[3] established a method to classify HBV, and analyzed the complete HBV nucleotide sequences and classified them into four different HBV genotypes designated from A to D, according to an intergroup divergence of >8%, and an intragroup divergence of <5.6%. Today, HBV has been classified into eight different genotypes designated from A to H^[4,5,16,17] and HBV genotypes have a pattern of geographical distribution^[18,19]. Genotype A is prevalent in Northern and Central Europe, but is also common in North America and sub-Saharan Africa. Genotypes B and C are confined to Asia, genotype D is widespread but is the predominant genotype in

the Mediterranean region, while genotype E is found mainly in West Africa. Genotype F shows the highest divergence among the genotypes and is indigenous to aboriginal populations of the Americas^[20]. Genotype G was found in USA and France^[4], genotype H in the Central America^[5], and genotypes A, B, C and D in China. The predominant genotype in China is genotypes B and C^[21,22].

The incidence of HCC in Long An County is about 49.9/100 000 and the prevalence of HBsAg in the county is 16%^[13,23] and more than 90% of hepatocellular carcinoma (HCC) cases are individuals positive for HBsAg in serum^[12]. In Japan, HBV genotype C was found to be closely associated with severe liver diseases and the development of HCC^[7,24], although young HCC patients were found to be HBV genotype C in Taiwan^[25].

HBV infection is usually diagnosed when the circulating HBsAg is detected. However, advances in molecular biology techniques revealed that a low level of HBV DNA could be detected in serum and liver tissue in some individuals who were negative for HBsAg^[26,27]. Although there are some studies on occult HBV infection, the precise prevalence of this clinical entity is still unknown. Luo *et al.*^[28] found that the prevalence rate of occult HBV infection in Guangdong and Hainan Provinces was 2.0% (6/294) and 3.4% (68/1 995), respectively in the general population. Bower *et al.*^[29] reported that the prevalence was 4.3% (11/258) in subjects without liver disease in USA. In this study, we found that the prevalence of occult HBV infection in Long An County was higher (11.5%, 6/52). The mechanisms that HBV carriers have a low, but stable level of viral replication remain to be defined. HBV strains might have mutations in S region resulting in occult HBV infection^[30,31]. This kind of mutations was found in one of our samples. In addition, this type of carriers should be added to the typical HBsAg-positive carriers constituting about 16% of the general population, to estimate more precisely the proportion of asymptomatic HBV carriers in Long An County. It is clear that the prevalence of HBV infection in Long An County is in correspondence with its high incidence of HCC.

To extend the knowledge of molecular features of natural HBV isolates, sample No. 624 in this study was selected for whole genome sequencing. This strain contained 3 215 bases. HBsAg region sequence showed that it belonged to serotype adw. No special mutation which could change the expression function of viral proteins was found in the sequence of this isolate. By homology analysis with 23 HBV strains in GenBank, this isolate was found to be closer to the Vietnamese HBV genotype C strain^[32] than to the genotype C isolates from Shanghai in evolution^[33], with 97% homology with the Vietnamese isolate. At present, the only explanation about this is that Long An County is geographically close to Vietnam.

In summary, HBV infections in Long An County are attributable to HBV genotypes C. The prevalence of occult HBV infection in Long An County is higher.

ACKNOWLEDGMENTS

We are very grateful to the Beijing Municipal Committee of Science and Technology for the financial support in part and the Center for Disease Prevention and Control of Long An County for their help in collecting samples.

Abstract

AIM: To evaluate the efficacy and safety of oxymatrine capsule in treatment of hepatic fibrosis in patients with chronic viral hepatitis.

METHODS: It was a randomized, double blind, placebo-controlled, multicenter clinical study. One hundred and forty-four patients were divided into oxymatrine capsule group (group A) and placebo group (group B). The course was 52 wk. Patients were visited once every 12 wk and the last visit was at 12 wk after cessation of the treatment. All patients had liver biopsy before treatment. part of them had a second biopsy at the end of therapy. Clinical symptoms, liver function test, serum markers of hepatic fibrosis were tested. Ultrasound evaluation was performed before, during and at the end of therapy.

RESULTS: One hundred and forty-four patients enrolled in the study. Of them 132 patients completed the study according to the protocol, 49 patients had liver biopsy twice (25 patients in group A and 24 in group B). At the end of therapy, significant improvements in hepatic fibrosis and inflammatory activity based on Semi-quantitative scoring system (SSS) were achieved in group A. The total effective rate of the treatment was 48.00%, much higher than that of 4.17% in group B ($P < 0.05$). Significant improvement in serum markers of hepatic fibrosis such as hyaluronic acid (HA) and type III procollagenic

peptide (P III P) in group A was seen ($P < 0.05$). The total effective rate of serum markers at the end of therapy in group A was 68.19%, much higher than that of 34.85% in group B ($P < 0.05$). The total effective rate of noninvasive markers at the end of therapy in group A was 66.67%, much higher than that of 30.30% in group B ($P < 0.05$). The rate of adverse events was similar in two groups.

CONCLUSION: Oxymatrine capsule is effective and safe in treatment of hepatic fibrosis due to chronic viral hepatitis.

INTRODUCTION

Hepatic fibrosis is a kind of compensating and healing response in the liver to liver injury induced by a variety of causes and also a common pathological process of many chronic liver diseases characterized by hyperplasia and deposition of fibro-connective tissues. It is essential to block the genesis and progress of hepatic fibrosis^[1-5,30,31]. Oxymatrine is a kind of alkaloid extracted from a Chinese herb *Sophora alopecuroides* L. which has been proved to have antihepatic fibrosis effect^[6,7,18-20]. In this paper, we reported the clinical study data of oxymatrine capsule in treatment of hepatic fibrosis in patients with chronic viral hepatitis.

MATERIALS AND METHODS

Research design

This study was a clinical trial characterized by multicentre, randomization, double blinding, and placebo-control. Enrolled patients were randomly assigned into oxymatrine capsule group (group A) or vacant placebo control group (group B), with 72 cases in each group and a treatment course of 52 wk. This study was conformed to the Good Clinical Practice (GCP) of China. The research protocol was discussed and approved by the Ethic Committee of National Clinical Research Base of Drugs in the Institute of Digestive Disease of Renji Hospital. Informed consent was obtained from each patient.

Selection of subjects

Enrolled criteria were age: 18-65 years regardless of sex; positive serum markers of hepatitis B virus (HBV) and hepatitis C virus (HCV) for at least 6 mo before enrollment; abnormal serum value of alanine transaminase (ALT) twice or more within 6 mo before enrollment; liver biopsy examination during 1 mo before enrollment indicating the stage of hepatic fibrosis from 1 to 4 according to National Criteria of Grading and Staging for chronic

viral hepatitis amended in 1995 and the scores of stage equal or more than 1 assessed by the semi-quantitative scoring system (SSS) of hepatic fibrosis; total serum bilirubin level less than or equal to 85.5 $\mu\text{mol/L}$; no history of administering following drugs: antiviral drugs, immunoregulating drugs and other antifibrotic agents; promising not to receive other systemic antiviral agents, cytotoxic agents, immunoregulators, drugs capable of reducing serum enzyme activity and bilirubin level, and Chinese traditional medicines, *etc.* Following situations should be excluded: patients with positive laboratory test of HIV; uncompensable liver diseases; suggestive of autoimmune diseases with antinuclear antibody (ANA) titer greater than a 1:160 dilution; bone marrow inhibition; abnormality of serum creatinine with a value 1.5 times greater than normal; concurrence of other associated diseases which might affect the present treatment such as unstable diabetes, renal insufficiency, unstable angina pectoris, alcoholic liver disease, epilepsy, obvious manifestations of neurosis, drug abuser, psychosis, pancreatitis, disability of absorption and malignant disease, and so on; Having taken other drugs in clinical trial within 30 d before the first medication; hypersensitive to oxymatrine capsule; pregnancy and during breast-feeding period; female conceptive patients not adopting any contraceptives.

Treatment procedures and drugs

After completion of selection and assessment, qualified subjects were allocated into group A or B randomly. The patients in group A took 300 mg oxymatrine capsules orally 3 times a day, and 2 tablets of complex vitamins B and C at the same time for 52 wk. The patients in group B took 3 tablets of vacant capsules instead of oxymatrine capsules and complex vitamins B and C at the same frequency as described above for 52 wk. All patients received follow-up once every 12 wk during treatment and were followed up at out-patient department 12 wk after treatment. Oxymatrine capsule, vacant placebo capsule, complex vitamins B and C tablets were manufactured and provided by Ningxia Pharmaceutic Institute and Shanghai Green Valley Ecological Engineering Co.LTD.

Observation of indexes and assessment

Clinical manifestations Clinical symptoms and signs were divided into grades from 0 to 3 according to the symptomatic grading criteria, evaluated at each follow-up visit, and examined 24 and 52 wk after treatment and 12 wk after drug withdrawal.

Analysis of blood and urine routines and related liver function indexes These indexes were evaluated at each follow-up visit and examined 52 wk after treatment and 12 wk after drug withdrawal.

Analysis of serum markers of hepatic fibrosis Tests of serum hyaluronic acid (HA), laminin (LN), type III procollagenic peptide (p III p), type IV collagen-7S (IV-7S) were fulfilled by Military Clinical Immunologic Research Centre of Changzheng Hospital, Second Military Medical University. The above markers were evaluated before treatment, 24 and 52 wk after treatment, 12 wk after drug withdrawal respectively, and examined 24 and 52 wk after treatment, 12 wk after drug withdrawal, respectively.

Imaging examination (type B ultrasound) The detection included 5 indexes: maximal oblique radius of right liver lobe, main trunk diameter of portal vein and its blood flow parameters per minute; width of spleen at the hilus and the diameter of splenic vein. Ultrasound examination was performed on fixed machines and by fixed operators and the data were recorded and input in computers which were read by experts. All the indexes were evaluated before treatment and 52 wk after therapy, examined 52 wk after drug withdrawal.

Histopathological detection Histopathological specimens were independently observed and assessed based on National Criteria of Grading and Staging for chronic viral hepatitis amended in

1995 and SSS by 3 pathologists from Department of Pathology, Medical College, Fudan University. The observed results were checked by another 3 pathologists who did not anticipate in the study by Kappa test. The reciprocal consistence among the above pathologists was satisfactory. The observed results in all patients were evaluated before therapy and part of them were evaluated 52 wk after therapy. All data were examined 52 wk after therapy.

During treatment and after therapy was terminated, the following events were recorded: combined medication, adverse reactions and the compliance of patients.

Assessment of therapeutic effects

Indexes of histopathology The curative effect was evaluated based on SSS. Distinctly effective: the scores of hepatic fibrosis based on SSS from liver biopsy decreased at least 6 scores compared with that before treatment. Effective: the above scores decreased at least 2 scores. Ineffective: the effect did not meet the effective criteria.

Assessment of indexes of noninvasive tests These indexes were evaluated comprehensively in terms of clinical manifestations, serum liver fibrotic markers and ultrasound detection data. Distinctly effective: any two values among serum liver fibrotic indexes decreased by at least 80% compared with that before treatment, at least the main trunk diameter of portal vein and splenic width returned to normal after treatment, clinical symptoms and signs disappeared or their total scores decreased by at least 75% compared with that before treatment. Effective: any two values among serum liver fibrotic indexes decreased by at least 40% compared with that before treatment, the main trunk diameter of portal vein and splenic width reduced after treatment, clinical symptoms and signs disappeared basically or their total scores decreased by at least 25% compared with that before treatment. Ineffective: the effect did not meet the effective criteria.

Assessment of safety

Any abnormal clinical manifestations and laboratory tests occurred during treatment were recorded and divided into 4 grades according to the criteria published by WHO and the Ministry of Public Health of China in 1994.

Statistical analysis

Statistical analyses were performed by professor Su BH and He QB from Department of Statistics, Shanghai Second Medical University, and SAS 6.12 software kit was used.

RESULTS

Selected patients

A total of 144 patients satisfied the selection criteria. Of them, 12 cases withdrew or were excluded during treatment, 132 cases fulfilled the treatment course according to the required protocol (66 cases in group A and 66 cases in group B). Before treatment, the following general data between two groups were similar ($P>0.05$, respectively): sex, age, drinking history, duration of hepatitis, duration of abnormality of liver function and a more than 2-fold normal elevation of serum ALT, *etc.* Each qualified patient received liver biopsy before treatment. A total of 49 cases had a second liver biopsy (25 cases in group A and 24 cases in group B).

Analysis of observed indexes

Clinical symptoms and signs Clinical manifestations in group A were obviously improved 52 wk after therapy ($P<0.05$), except for epistaxis ($P = 1.0000$). Hepatomegaly was also improved significantly after therapy ($P=0.0313$), symptoms of gum bleeding

and epistaxis were not improved obviously in group B ($P>0.05$). Signs of hepatomegaly, splenomegaly and liver palm were significantly improved in group B ($P<0.05$), improvement of anorexia in group A was greater than that in group B ($P=0.0263$).

Liver function Indexes of liver function in group A were significantly improved 52 wk after treatment ($P<0.05$) except for serum gamma glutamino transpeptidase (GGT) and TB ($P>0.05$). In group B, indexes such as serum ALT, AST, TB and alkaline phosphatase (ALP) had no obvious difference before and after therapy ($P>0.05$). Compared with group B, the improvement of ALT and AST in group A was much greater ($P=0.0007$ and 0.0025). Fifty-two wk after therapy, the normalization rate of ALT in group A was 70.77%, much higher than 39.68% in group B ($P=0.0003$). In groups A and B, 14 out of 46 cases (30.43%) and 12 out of 25 cases (48.00%) had their serum ALT levels returned to normal 52 wk after treatment, and their serum ALT levels became abnormal again after drug withdrawal.

Liver histologic examination Evaluation of hepatic fibrosis based on SSS: In group A, the scores of hepatic fibrosis after therapy were 4.72 ± 5.63 , much smaller than 6.76 ± 6.67 before therapy ($P=0.0001$), while the scores in group B after therapy increased significantly ($P=0.0009$). There was an obvious difference between two groups ($P=0$) (Table 1). Evaluation of histologic inflammatory activity based on SSS: In group A, the scores of histologic activity decreased from 46.08 ± 3.84 before treatment to 4.00 ± 2.97 after therapy ($P=0.0002$), while the scores in group B after therapy did not decrease obviously ($P=0.2344$). There was an obvious difference between two groups ($P=0.0008$) (Table 2).

Evaluation of serum markers of hepatic fibrosis In group A, serum levels of HA, LN, p III p and IV-7S decreased significantly 24 and 52 wk after treatment ($P<0.05$). In group B, serum levels of LN, p III p and IV-7S also decreased obviously after treatment ($P<0.05$). However, degrees of improvement in HA and p III p

between two groups were distinctly different ($P<0.05$). In group A, except for LN ($P=0.1493$), the other 3 liver fibrotic markers increased significantly 12 wk after drug withdrawal compared with that 52 wk after treatment ($P<0.05$). In group B, except for HA ($P=0.4212$), the other markers also increased obviously 12 wk after drug withdrawal compared with that 52 wk after treatment ($P<0.05$). The increase of HA in group A was more than that in group B ($P=0.0002$) and the increase of IV-7S in group B was more than that in group A ($P=0.0048$).

Imaging examination After treatment, the average values of main trunk diameters of portal vein and splenic width in group A obviously decreased ($P<0.05$). However, in group B, the above two parameters and the parameters of blood flow volume per minute of portal vein and diameters of splenic vein all increased significantly compared with those before therapy ($P<0.05$). The changes in main trunk diameters of portal vein and splenic width between two groups were statistically significant ($P<0.05$).

Analysis of therapeutic effect

Assessment of histopathology based on SSS After treatment, the rates of distinct effectiveness and effectiveness in group A were both 24.00%, and the total effective rate was 48.00%. In group B, none achieved distinct effectiveness and the effective rate was only 4.17%; Comparison of the rates of distinct effectiveness and effectiveness between two groups had a significant difference ($P=0.004$) (Table 3).

Assessment of serum markers of hepatic fibrosis The total effective rate of group A 24 and 52 wk after therapy was 57.43% and 68.19%, more than 24.24% and 34.85% of group B ($P=0.0002$ and 0.0004 , respectively). Twelve weeks after treatment, the total effective rate of group A was 50.00%, more than 15.16% of group B ($P=0.00$).

Assessment of noninvasive indexes of hepatic fibrosis After treatment, the rates of distinct effectiveness and effectiveness

in group A were respectively 3.03% and 63.64%, and the total effective rate was 66.67%. In group B, the rates of distinct effectiveness and effectiveness were respectively 0% and 30.30%, and the total effective rate was 30.30%. The comparison of the above statistics between two groups had a significant difference ($P = 0.0001$) (Table 4).

Adverse effects

In group A, there were 5 patients who suffered from adverse drug reactions and the incidence was 6.94%. The adverse drug reactions mainly included nausea, rash, chest discomfort, fever, epigastric comfort, diarrhea and poor taste, and most of them were mild or moderate. None of the patients withdrew because of adverse drug reactions. In group B, adverse effects occurred in 7 patients and the incidence was 9.72%. The manifestations were similar to those in group A and 1 patient withdrew because of weakness, anorexia, epigastric discomfort after taking drugs.

DISCUSSION

Hepatic fibrosis, a precursor of cirrhosis, is a consequence of sever liver damage that occurred in many patients with chronic liver disease, and involves the abnormal accumulation of extracellular matrix^[3,4,11,12]. Liver fibrosis represents a major worldwide healthcare burden. Current therapy is limited to removing the causal agent. This approach has been successful in some diseases, particularly in haemochromatosis and chronic viral hepatitis^[9,10,17,28]. However, for many patients treatment was not possible, while other patients presenting to medical attention were at an advanced stage of fibrosis^[8,9]. There is therefore a great need for novel therapies for liver fibrosis. Tremendous insights into the understanding of hepatic fibrosis have taken place over the past ten years. Foremost among these is the recognition that hepatic stellate cells (formerly known as lipocytes, Ito cells, or fat-storing cells) play a central role based on their ability to undergo activation following liver injury of any cause^[11,15,16,29]. Hepatic stellate cells have been recognised to be responsible for most of the excess extracellular matrix observed in chronic liver fibrosis. The detailed understanding of hepatic stellate cell biology has allowed the rational design of novel antifibrotic therapies^[29]. Effective therapy for hepatic fibrogenesis would probably also be multifactorial, based on the basic mechanisms underlying the fibrogenic process^[13,14,21-23].

At present, it is considered that treatment of hepatic fibrosis and antihepatic fibrosis are two different concepts and antifibrotic drugs should act on various parts of the genesis and development of hepatic fibrosis. Firstly, as for etiological treatment, oxymatrine could effectively treat chronic viral hepatitis and promote the serum markers of hepatitis B virus (HBV) and hepatitis C virus (HCV) in chronic hepatitis B and C to convert to negative and reduce serum level of ALT^[6,7]. Secondly, oxymatrine could inhibit the proliferation of hepatic stellate cells (HSC) at the concentrations of 0.5-16 $\mu\text{g/mL}$ *in vitro*. In addition, oxygen stress and lipid peroxidation are important mechanisms responsible for hepatic injury and hepatic stellate cell activation. Therefore, inhibition of lipid peroxidation is an essential strategy of antihepatic fibrosis^[12-16]. By establishing D-galactosamine-induced rat liver

fibrosis model, we observed the effect of oxymatrine on serum and tissue biochemical indexes, content of liver hydroxyline, expression of TGF β 1 mRNA and changes of tissue pathology, the results showed oxymatrine had prophylactic and therapeutic effects on D-galactosamine induced rat liver fibrosis. This was partly by protecting hepatocytes and suppressing fibrosis accumulation through anti-lipoperoxidation^[10]. In present study, We found that the scores of hepatic fibrosis after therapy in group A were 4.72 ± 5.63 , much smaller than 6.76 ± 6.67 before therapy, and the scores in group B after therapy increased significantly. There was an obvious difference between two groups. The scores of histological inflammatory activity in group A decreased from 46.08 ± 3.84 before treatment to 4.00 ± 2.97 after therapy, and the scores in group B after therapy did not decrease obviously. There was an obvious difference between two groups both in improvement of histopathology and in improvement of noninvasive indexes such as clinical manifestations, serum markers of hepatic fibrosis^[24-27]. Associated indexes of liver function and imaging detection indicated that oxymatrine was an ideal drug of antihepatic fibrosis. It is valuable to pay more attentions to the basic and clinical research of oxymatrine in order to explore the accurate mechanisms of its effect on antihepatic fibrosis.

Abstract

AIM: Studies on *Helicobacter pylori* (*H pylori*) and gastroduodenal diseases have focused mainly on the distal sites of the stomach, but relationship with the gastric cardia is lacking. The aim of this study is to determine if the gastric topology and genotypic distribution of *H pylori* were associated with different upper gastrointestinal pathologies in a multi-ethnic Asian population.

METHODS: Gastric biopsies from the cardia, body/corpus and antrum were endoscoped from a total of 155 patients with dyspepsia and/or reflux symptoms, with informed consent. *H pylori* isolates obtained were tested for the presence of *26kDa*, *ureC*, *cagA*, *vacA*, *iceA1*, *iceA2* and *babA2* genes using PCR while DNA fingerprints were generated using random amplification polymorphic DNA (RAPD).

RESULTS: *H pylori* was present in 51/155 (33%) of patients studied. Of these, 16, 15 and 20 were isolated from patients with peptic ulcer diseases, gastroesophageal reflux diseases and non-ulcer dyspepsia, respectively. Of the *H pylori* positive patients, 75% (38/51) had *H pylori* in all three gastric sites. The prevalence of various genes in the *H pylori* isolates was shown to be similar irrespective of their colonization sites as well as among the same site of different patients. The RAPD profiles of *H pylori* isolates from different gastric sites were highly similar among intra-patients but varied greatly between different patients.

CONCLUSION: Topographic colonization of *H pylori* and the virulence genes harboured by these isolates have no direct bearing to the clinical state of the patients. In multi-ethnic Singapore, the stomach of each patient is colonized by a predominant strain of *H pylori*, irrespective of the clinical diagnosis.

INTRODUCTION

Helicobacter pylori (*H pylori*) is a common gastric pathogen that has infected more than 50% of the world's population^[1]. It is the major aetiological agent of chronic active gastritis and is generally accepted as being the primary cause of peptic ulcer disease and a carcinogenic factor for gastric cancer (GC)^[2]. However, only a minority of *H pylori* infected subjects develops these diseases. This has led to the suggestion that clinical sequelae that develop may be dependent upon differentially expressed bacterial determinants, e.g., bacterial virulence genes: *cagA*, *vacA*, *iceA1*, *iceA2*, *babA2*^[3-5]. In many parts of Asia, the prevalence of *cagA* and *vacA* strains is high regardless of the presence or absence of disease states^[6]. This limits the usefulness of using these genes as markers to predict clinical outcome. Instead, other factors like host susceptibility as well as specific interactions between a particular strain and its host that occur during decades of coexistence might have contributed to an increased risk of developing certain clinical manifestations^[7].

Our current knowledge on the epidemiology of the organism is predominantly based on data obtained from serologic studies. It has also been reported that a single strain of *H pylori* predominates the gastric antrum and corpus of infected patients in Singapore^[8]. However, there is a need to study whether the topographic distribution of *H pylori* genotypes in various gastric sites in patients of different ethnic origins affects the disease state. Being an Asian country with a multi-ethnic population, Singapore is suitable for this investigation.

MATERIALS AND METHODS

Patients

Consecutive patients with dyspepsia and/or reflux symptoms presenting for upper gastrointestinal endoscopic examination to one of the authors (KYH) and who have not been exposed to antibiotics, proton pump inhibitors (PPI) or bismuth compounds within the past four weeks were invited to participate in the study. Patients who previously had been treated for *H pylori* infection, patients who refused gastric biopsies, patients who were unable to give consent because of age or mental illness and patients in whom gastric and oesophageal biopsies were contraindicated (e.g., coagulopathy, oesophageal varices and severe co-morbidity), subjects who were pregnant and those who were <18 years old, were excluded. Informed consent was obtained from each patient.

A total of 155 patients were included in the study. The patient population comprised 122 (79%) Chinese, 17 (11%) Indians, 8 (5%) Malays and 8 (5%) subjects of other ethnicities. Of these, 95 (61%) were males and 60 (39%) females. The mean age was 48.4±15.5 (range, 24-88) years. Based on clinical history and endoscopic examination, patients were classified into the following groups: gastroesophageal reflux disease (GERD) (*n* = 50), peptic ulcer disease (PUD) (*n* = 36) and non-ulcer dyspepsia (NUD) (*n* = 69). GERD was defined as the presence of predominant symptoms of reflux, e.g., heartburn, acid regurgitation and/or the presence of any length of mucosal break in the oesophagus due to gastroesophageal reflux. NUD was defined as patients with neither a history of GERD nor endoscopic evidence of organic pathologies. PUD refers to patients who were either

diagnosed upon endoscopy as suffering from gastric ulcers (ulcers at the corpus) or duodenal ulcers (ulcers at the antrum). A total of 465 biopsy specimens were obtained from the 155 patients.

Endoscopy

After an overnight or six hour fast, upper gastrointestinal endoscopy was performed according to standard technique. From each patient, one biopsy specimens was obtained using sterilized standard biopsy forceps from each of the three sites of the stomach: the cardia just below the z-line, the middle gastric corpus and the antrum within 2 cm of the pylorus, in that order. The biopsy forceps were thoroughly cleaned with alcohol swaps between biopsies to avoid contamination between specimens. The biopsies were transported in 0.85% sterile saline to the microbiological laboratory for processing within 6 h.

H pylori culture

Each biopsy specimen was homogenised aseptically in 500 µL of Brain Heart Infusion Broth (BHI, Oxoid Ltd., Basingstoke, UK) enriched with 4 g/L yeast extract (Oxoid Ltd., Basingstoke, UK). Approximately 100 µL homogenised specimens in BHI broth were inoculated onto *H pylori* selective chocolate blood agar plates and non-selective chocolate blood agar plates respectively. The selective blood chocolate agar was supplemented with 3 mg/mL vancomycin, 5 mg/mL trimethoprim, 10 mg/mL nalidixic acid and 2 mg/mL amphotericin B. All the antibiotics were from Sigma-Aldrich Chemie, Steinheim, Germany. The plates were incubated at 37 °C for up to 14 d in an incubator (Forma Scientific, USA) containing 50 mL/L CO₂.

Aliquots of 50 µL of BHI-biopsy suspension were each inoculated into catalase reagent, oxidase reagent and 20 g/L urea solution for their respective testing. An isolate was identified as *H pylori* if minute (~1 mm in diameter) rounded translucent colonies with gram-negative S-shaped motile cells that exhibited positive catalase, oxidase and urease activities. For this study, a patient was considered positive for *H pylori* if the organism was isolated from any of the three gastric sites.

Genotyping of *H pylori*

The DNA of each 3-d old *H pylori* culture was extracted according to the method as described by Hua *et al.*^[8]. A 50 ng working stock of DNA was used to amplify 26kDa^[9], ureC^[10], cagA^[11], vacA^[12], iceA1^[5], iceA2^[5] and babA2^[4] genes according to the protocol as described by Zheng *et al.*^[6] using the specific

forward and reverse primers for each of the corresponding genes (Table 1). The DNA fingerprint of the *H pylori* was obtained by PCR using the universal primer, 5' - AACGCGCAAC-3' and amplified according to protocol as described by Hua *et al.*^[13]. The PCR products obtained were electrophoresed and the ethidium bromide stained gels^[13] were then photographed with filtered UV illumination on Chemi Genius² (SynGene, Cambridge, UK).

Statistical Calculation

The significance of the results obtained was calculated using SPSS v.10 for Windows (SPSS, Chicago IL) to determine the Pearson chi-square whereby a *P* value <0.05 was considered to indicate statistical significance.

RESULTS

H pylori isolates in various clinical groups

Of the 155 patients studied, 51 (33%) were found to harbour *H pylori* in at least one of the 3 gastric biopsy sites. In all, 43, 47 and 44 isolates were obtained from gastric antrum, corpus and cardia respectively, giving a total of 134 isolates. *H pylori* was present in 16/36 (44%) PUD patients as compared with 15/50 (30%) GERD patients (*P* = 0.169) and 20/69 (29%) NUD patients (*P* = 0.113) (Table 2).

Table 2 Relationship between *H pylori* status and disease states

Groups	No. of patients	No. of biopsies	No. of <i>H pylori</i> (+)	<i>P</i>
PUD	36	108	16 (44%)	-
GERD	50	150	15 (30%)	0.169
NUD	69	207	20 (29%)	0.113

PUD, peptic ulcer disease; GERD, gastroesophageal reflux disease; NUD, non-ulcer dyspepsia. All test values were calculated with respect to PUD; *P* < 0.05 indicates statistical significance.

Relationship between topographic distribution of *H pylori* isolates and clinical outcomes

Of the 51 *H pylori* positive patients, 38 (75%) showed the presence of *H pylori* in all the three gastric sites while 1 (1%), 2 (4%) and 4 (8%) had *H pylori* isolated from antrum & corpus, antrum & cardia, and corpus & cardia, respectively. *H pylori*

was isolated from a single site of the stomach in 6 (12%) patients, among which 2 isolates were from the antrum and 4 were from the corpus. This topographical pattern of *H pylori* colonization was observed in all the patients irrespective of the underlying clinical diagnosis.

Relationship between topographic distribution of *H pylori* genes of interest and clinical outcomes

All the *H pylori* isolates possessed the 26kDa gene and the ureC genes. The prevalence of virulence genes of interest were present in equal ratios in all the *H pylori* isolates obtained from all the 3 different gastric biopsy sites: 74-81% for *cagA* and 80-86% for *vacA*; 53-59% for *iceA1* and 36-42% for *babA2* regardless of the underlying clinical diagnosis. However, the *iceA2* gene was present less frequently, at 20-26% of the *H pylori* isolates. It is noted that the difference in gene frequency between the various sites was also not statistically significant (Table 3).

Similar observation was noted with respect to the distribution of virulence genes of *H pylori* isolated from the same site among the different disease groups. The prevalence for each virulence gene within the same site was highly similar. No significant association of the virulence gene was found to be associated with a particular biopsied site, regardless of the disease state, with the exception of *cagA* in isolates from the corpus of the stomach of GERD patients (Table 4).

Table 3 Anatomical location of the 134 *H pylori* isolates and their virulence genes

PUD, peptic ulcer disease; GERD, gastroesophageal reflux disease; NUD, non-ulcer dyspepsia. All test values were calculated with respect to PUD. ¹Indicates statistical significance ($P = 0.031$).

Relationship between topographic distribution of *H pylori* strain based on RAPD fingerprinting and clinical outcomes

For comparison, differences in 2 or more bands of the RAPD profile are considered different while variations in band intensity were not taken into account. On this basis, the RAPD profiles of all the *H pylori* strains isolated showed an overall similarity in profiles within individual patients, with minor differences such as the presence or absence of a single band. However, distinct differences in the DNA profiles were observed between patients (Figure 1). In this study, no comparison could be made in 6 patients since *H pylori* was isolated from only one site of the stomach in these patients.

Figure 1 PCR-based RAPD patterns of *H pylori* isolated from 3 gastric sites of 4 individual patients. Lane1: λ HindIII M marker, Lane 14: 1 kb M marker; Lane 2-4, 5-7, 8-10, 11-13 for patients 1, 2, 3 and 4 respectively. A: antrum; B: body; C: cardia.

DISCUSSION

It is noted that 50% of the world's population are infected with *H pylori* but only a small proportion manifest different gastroduodenal diseases^[14]. One of the factors contributing to this phenomenon could be the patchy distribution of *H pylori* in different gastric sites of the stomach. As most of the earlier studies focused on *H pylori* isolated from the distal sites of the stomach^[8,15], the present study shows that *H pylori* isolates obtained from all the 3 gastric sites, namely cardia, corpus and antrum, in 38/51 (75%) *H pylori* patients were similar genotypically. Care was taken in cleaning and disinfecting the biopsy forceps between biopsies to avoid contamination between specimens. The results imply that *H pylori* colonises the entire stomach instead of a predominant site in three quarters of our *H pylori* positive patients, irrespective of the underlying clinical diagnosis. The finding suggests that the site of *H pylori* colonization or topographic distribution does not contribute significantly to the outcome of the infection.

While studies in Europe suggested that virulence genes, e.g., *cagA* and *vacA* affect the clinical outcome of *H pylori* infection^[3,5], the present study confirms previous studies carried out in Asian countries^[6,15] that showed a high prevalence of *cagA* and *vacA* genes regardless of the clinical outcome. This study comprised Singapore patients of various ethnicities (Chinese, Malays, Indians and other races), also shows that each of the virulence genes, i.e., *cagA*, *vacA*, *iceA1*, *iceA2* and *babA2* were equally distributed in *H pylori* isolates obtained from all the three anatomical sites studied regardless of the disease states. Similarly, comparisons of these genes from the same anatomical site of different patients showed no significant presence, except for *cagA* in the corpus of GERD isolates. However, it is important to point out that the number of isolates obtained from each is relatively low ($n \leq 18$), regardless of the disease state. As such, the significant presence of *cagA* in the corpus of GERD patients needs further analysis with a larger pool of samples to confirm conclusively its contribution to the onset of GERD. The data therefore suggest that virulence genes and their topographic distribution do not contribute to the clinical status, at least in the Singapore population. This study supports the earlier reports^[15-17] that identifying such virulence genes in order to predict clinical outcome may be of limited value in Asian *H pylori* isolates.

The finding that RAPD profiles of the *H pylori* isolates were similar from 3 different anatomical sites (antrum, corpus & cardia) of each patient further strengthens our earlier study^[9] where isolates from 2 sites (antrum & corpus) were identical. This finding is complemented by the similar status of presence of various virulence genes in these isolates obtained from the respective patients. As such, the isolation of a strain from any gastric site in a single patient could be taken as representative of *H pylori* infection present in the *H pylori* infected gastric environment.

This study, which included consecutive patients with dyspepsia and/or reflux symptoms showed a lower frequency of PUD as compared with that of GERD. *H pylori* was found in only 44% of patients with PUD. This seems to run counter to the generally held view that *H pylori* occurs frequently in Asians patients with PUD^[13]. However, this finding is supported by an earlier study from the same unit^[18] showing the frequency of reflux oesophagitis was increasing while that of duodenal ulceration was decreasing in Singapore. The high frequency of patients with GERD in this study also relates to the fact that the endoscopist (KYH) sees most of the GERD patients in the hospital. The decreasing frequency of *H pylori* associated peptic ulcers was reported to be attributed to the increasing proportion of ulcers due to NSAID use^[19].

In summary, the present study shows that in Singapore, the topographic colonization of *H pylori* and their virulence genes within the host stomach do not play a significant role in the clinical manifestations of *H pylori* infection. This study also demonstrates that in Singapore, which has a multiethnic Asian population, the stomach of each patient with dyspeptic and/or reflux symptoms is colonized by a single predominant strain of *H pylori*, irrespective of the site of isolation and the clinical diagnosis of the patient. We suggest that the pathogenesis of *H pylori* induced gastroduodenal diseases is due to a more complex mechanism possibly involving host-pathogen interaction, environmental and dietary factors.

Abstract

AIM: Inducible nitric oxide synthase (iNOS) plays a central role in the pathway of reactive oxygen and nitrogen species metabolism when *Helicobacter pylori* (*H pylori*) infection occurs in humans. iNOS Ser⁶⁰⁸Leu allele, a novel genetic polymorphism (C/T) occurring within exon 16 of the iNOS reductase domain, may have a dramatic effect on the enzymatic activity. The aim of this study was to determine whether iNOS C/T polymorphism was associated with increased susceptibility to gastric cancer.

METHODS: We conducted a population based case-control study in a high gastric cancer incidence area, Yangzhong, China. Questionnaires from 93 patients with intestinal type gastric cancer (IGC), 50 with gastric cardia cancer (GCC) and 246 healthy controls were obtained between 1997 and 1998, and iNOS genotyping was carried out. Odds ratios (ORs), interaction index (γ), and 95% confidence intervals for the combined effects of iNOS genotype and *H pylori* infection, cigarette smoking or alcohol drinking were estimated.

RESULTS: The frequency of (CT+TT) genotypes was higher in cases than in control group (24.48% vs 23.17%), but the difference was not statistically significant. After adjusting for age and gender, past cigarette smokers with (CT+TT) genotypes had a significantly increased risk of IGC (OR = 3.62, 95% CI: 1.23-10.64), while past alcohol drinkers with (CT+TT) genotypes had a significantly increased risk of GCC (OR = 3.33, 95% CI: 1.14-9.67). *H pylori* CagA negative subjects with (CT+TT) genotypes had a significantly increased risk of both IGC and GCC (OR = 2.19 and 3.52, respectively).

CONCLUSION: iNOS Ser⁶⁰⁸Leu allele may be a potential determinant of susceptibility to cigarette -alcohol induced gastric cancer, but larger studies are needed to confirm the observations.

INTRODUCTION

On a global scale, gastric cancer remains the world's second most common malignancy. There is a substantial international variation in gastric cancer incidence with the highest rates reported from China, Japan and other Eastern Asian countries^[1]. The discovery of *Helicobacter pylori* (*H pylori*) in the early 1980 s has been proven to be a turning point in understanding the pathogenesis of this malignancy. A major advance in this field came with the recognition that chronic *H pylori* infection could induce physiologic and morphologic changes within the gastric milieu, which increase the risk of neoplastic transformation^[2]. It has been widely accepted that chronic *H pylori* infection induces hypochlorhydria and gastric atrophy, both of which are precursors of gastric cancer^[2]. Epidemiological studies have also indicated that infection with *H pylori* is considered as a risk factor for gastric cancer^[3,4] and the WHO IARC has classified this bacterium as a definite biological carcinogen^[5]. However, while the majority of infected individuals develop no significant clinical disease, others develop two kinds of divergent clinical outcomes-peptic ulcer disease and gastric cancer^[2]. The reasons for developing these two extreme phenotypes, especially important in gastric cancer, have remained poorly understood, and are not explained by bacterial virulence factors alone^[2]. This highlights the need to explore potential candidate genes of the host in the pathways involved in the natural history of *H pylori* infection and its interactions with other risk factors in the development of gastric cancer in a high-risk population.

The inducible form of nitric oxide (NO) synthase (iNOS) is one of the most important enzymes involved in the pathway of reactive oxygen and nitrogen species metabolism in the presence of *H pylori* infection in humans. iNOS is a major source of NO production that is produced during inflammation by macrophages^[6,7]. Expression of iNOS in response to cytokines is part of the inflammatory response and contributes to tissue damage, suggesting its possible role in the processing of carcinogens^[7]. iNOS contains many sites for prosthetic groups and substrate binding^[8], which are all potentially important for the function of the enzyme. Furthermore, studies have indicated that even single amino acid changes may have dramatic effects on enzymatic activity^[8,9]. The human iNOS gene comprises 27 exons with the transcription start site in exon 2 (E2) and the stop codon in E27^[10]. E1-13 code for the oxygenase domain, and E14-27 encode for the reductase domain of the protein. Both of the domains represent different functional parts of the enzyme^[9]. Increased iNOS activities have been observed in patients with chronic gastritis caused by *H pylori* infection, and gastric cancer^[11,12]. A 13-21 years follow-up study showed that among the *H pylori* positive group, the expression of iNOS and nitro-tyrosine was significantly higher in the group that developed gastric cancer than the one that showed no evidence of gastric cancer, suggesting that *H pylori* positive subjects with high levels of reactive nitrogen species in gastric mucosa may be a high-risk group for gastric cancer^[13]. Furthermore, recent studies have revealed that *H pylori* infection may lead to a sustained production of reactive nitrogen species and the formation of nitro-tyrosine contributes to DNA damage and apoptosis in gastric mucosa^[12]. Infection with *H pylori* strains

possessing cytotoxin-associated gene (Cag) A, a molecular marker of *H pylori* virulence^[14,15], is particularly associated with an increased risk of developing adenocarcinoma of the stomach. It is suggested that iNOS may be a susceptible gene involved in the metabolic pathway of nitrogen and oxygen species of free radicals, and thus may be associated with both gastric cancer risk and *H pylori* infection.

Yangzhong city is one of the areas in China with the highest gastric cancer mortality and incidence rate. The crude mortality rate of gastric cancer was from 96.9 to 110.9/100 000 during 1991 and 1997, and the average adjusted incidence rate in the same period was over 115/100 000 (unadjusted rate was 155.46/100 000), which is over ten times higher than that in the United States^[16]. Based on the understanding of the physiology and pathogenesis of gastric cancer, and the genetic pathway related to *H pylori* infection, we hypothesized that higher frequency of iNOS Ser⁶⁰⁸Leu allele (i.e. C/T polymorphism)^[9,17] was responsible for the higher gastric cancer incidence in this area. We were especially interested in knowing whether the association between the polymorphism and gastric cancer was modified by infection with *H pylori* CagA strains and cigarette smoking reflecting high exposure to nitrogen and oxygen species of free radicals. Therefore, the aim of this study was to determine whether iNOS C/T polymorphism was associated with increased susceptibility to gastric cancer, and the effects of *H pylori* infection.

MATERIALS AND METHODS

Study subjects

All gastric cancer patients and "healthy" controls in this study were Han ethnic Chinese living in Yangzhong city for at least 25 years. Gastric cancer was diagnosed according to the International Classification of Diseases for Oncology IX, code = 151, and the criteria of Laurén^[18]. Because most diagnosed gastric cancer cases in Yangzhong were intestinal type gastric cancer (IGC) and gastric cardia cancer (GCC), we focused on these two kinds of cancers in the present study. A population based case-control design was used, and 165 gastric cancer cases (108 IGC, 57 GCC) and 295 controls were enrolled. The finally analyzed cases and controls were 143 (93 IGC, 50 GCC) and 246 cases, respectively, because of missing genotype data for some subjects. There were no significant differences comparing the finally analyzed subjects and those with missing data by age and sex. All cases were identified by endoscopic and pathological diagnosis in Yangzhong City Municipal Hospital from January 1997 to December 1998. To reduce misclassification of the histological types, two pathologists reviewed and confirmed all diagnosed cases. Controls were selected from cancer-free subjects living in the same community, who were either cases' siblings or their non-blood relatives (spouses and spouses' siblings with the same gender as cases). Both types of controls differed slightly in demographic features^[19]. Their results were combined to increase the sample size and to decrease type I error. This study was approved by the regional ethics committee, and all participants were given an explanation of the nature of the study, and informed consents both written and oral, were obtained. Study subjects completed a questionnaire administered by trained interviewers.

The questionnaire was designed to obtain detailed information on cigarette smoking, alcohol drinking, family history of cancers, and occupational and hazard exposures. Cigarette smokers were defined as subjects who reported ever smoking at least one cigarette per day for 12 mo or more, or whose accumulated cigarette consumption was over 18 packs per year. Past smokers were those who had stopped smoking 1 or more years before the interview. Alcohol drinkers were defined as subjects who reported to have an average of one drink or more per week for one or more years. Past alcohol drinkers were also defined as those

who had stopped drinking for 1 or more years before the interview.

Laboratory analysis

Blood was drawn from each participant by the designated coordinator according to the Guidelines of the National Heart, Lung, and Blood Institute Working Group on Blood Drawing, Processing, and Storage for Genetic Studies. Twenty milliliters of forearm venous blood was collected from each subject via venipuncture into two 10-mL vacutainer tubes containing EDTA. Puragene DNA isolation kits (Gentra Systems, Minneapolis MN) were used to isolate genomic DNA for genotyping. All blood samples were separated, and plasma was collected as soon as possible. The plasma was then stored at -20 °C in six 1.5-mL tubes for the detection of IgG antibody to *H pylori* CagA.

Denaturing high performance liquid chromatography (DHPLC) was used to scan the potential single nucleotide polymorphisms (SNPs) in all exons of iNOS, and then sequencing was performed to confirm the possible mutations. Finally, a new C/T polymorphism, which changes the coding amino acid from serine (TCG) to leucine (TTG), was identified^[17]. PCR-RFLP was carried out to identify the genotype of iNOS according to the features of SNP, which created a restriction enzyme recognition site of *Tsp 509 I*. Genomic DNA was amplified with primers F: 5'-TGTAACCAACTTCCGTGGTG-3' (Tm = 60.82 °C) and R: 5'-GTCTCTGCGGGTCTGAGAAG-3' (Tm = 60.14 °C). PCR was performed in a MJRESEARCH PCR system (PTC-225, USA), and in a 10 µL reaction volume containing 1 µL 10×PCR buffer, 1.6 µL dNTPs (1.25 µmol/L), 0.2 µL MgCl₂ (25 mmol/L), primers (20 µmol/L, Resgen Corp.) at 0.15 µL each, DMSO 0.5 µL, 6.34 µL dH₂O, 50 ng genomic DNA dried on the plate, and Hot Start Taq DNA polymerase 0.06 µL (5 U/µL, Promega Corp.). Touch down PCR procedure was used to amplify the target fragment. After an initial denaturation at 94 °C for 15 min, amplification was carried out for 10 cycles at 94 °C for 30 s, at 61 °C for 45 s, at 72 °C for 45 s and decreasing 0.5 °C per cycle. Then amplification was again carried out for 35 cycles at 94 °C for 30 s, at 56 °C for 45 s, and at 72 °C for 45 s, followed by a final elongation at 72 °C for 7 min. Then, 10 µL PCR products was digested with 0.2 µL *Tsp 509 I* (10 U/µL, NEB Corp.) in a 15 µL volume including 2 µL 10×buffer 1 (NEB Corp.), 0.15 µL BSA (100×) and 2.65 µL dH₂O. Digestion was performed for 15 h at 65 °C. The products were then electrophoresed on a 30 g/L agarose gel to allow unambiguous detection with ethidium bromide staining. Homozygous wide-type individuals (CC) showed 113 bp and 175 bp fragments, heterozygous individuals (CT) showed three bands: 113 bp, 142 bp and 175 bp, and homozygous rare allele individuals (TT) showed two bands: 113 bp and 142 bp^[17].

H pylori CagA IgG antibody in plasma was measured by an enzyme-linked immunosorbent assay (ELISA) kit offered by Jingying Biotech Limited Company, Shanghai, China (batch number 0052). The Absorbency at 450 nm was determined after terminating the enzyme reaction. The cutoff value equaled to the average A of the negative controls provided by the manufacturer plus 0.3 A units. A values of samples equaled to or higher than the cutoff point were considered positive.

Statistical analysis

All data were input double blinded into EPI-6 program by two persons separately. After modifying all errors and non-logical data, the differences in the relative associations between cases and controls were assessed by calculating crude odds ratios (OR) from contingency tables. The corresponding chi-square test on the cancer patients and controls was carried out, and 95% confidence intervals (95% CI) were determined using the Fisher exact test. A *P*-value <0.05 was considered statistically significant. Unconditional logistic regression analysis was performed in both univariate and multivariate models to assess the association between iNOS functional polymorphism and

gastric cancer susceptibility after adjusting for important confounding factors such as age and sex. Test of trend and interaction index (γ) that was determined by coefficient (β) in a multiple logistic regression model were calculated through logistic models based on dummy variables to examine the potential gene-environment interaction^[20]. All analyses were performed with the SAS package Genmod (SAS Institute, Cary, NC).

RESULTS

Table 1 compares the characteristics of study subjects. The mean age of cases was significantly greater than the controls (59.36 vs 51.89, $P < 0.01$). There was no significant difference in the male/female ratio between cases and controls. The proportions of past smokers and alcohol drinkers was significantly greater in the cancer group (36.97% and 30.30%) than in the control group (12.54% and 14.92%). However, there were more current smokers and drinkers in the control (47.12% and 30.85%) than in the case group (26.67% and 10.91%). Compared with controls, cases were significantly less likely to be positive for *H pylori* CagA antibody.

The frequency of iNOS genotypes in gastric cancer and control subjects showed no significant difference, although the

frequency of (CT+TT) genotypes was slightly higher in cases than in controls (24.48% versus 23.17%). A gene dose-response effect was not observed, i.e. the effect of heterozygote (CT) genotypes did not lie at or between the homozygotes (CC and TT).

For (CT+TT) the genotype frequency of iNOS in the past smoking subgroup, there were significant differences between the total cases and the controls and between GCC group and controls with an OR of 3.62 (95% CI: 1.23-10.64) and 4.63 (95% CI: 1.15-18.58), respectively. No significant difference was found between IGC cases and controls (Table 2). Although no gene dose-response effect was observed in heterozygote (CT) and homozygote (TT) individuals because of the small number in each cell, there was still a possible interaction between C/T polymorphism and past cigarette smoking in increasing the risk of GCC. In the past alcohol drinkers, there were significant differences in the C/T polymorphism between total cases and controls and between IGC group and controls with an OR of 3.33 (95% CI: 1.14-9.67) and 3.42 (95% CI: 1.03-11.35), respectively. No significant difference between GCC group and control group was found (Table 3). In *H pylori* CagA negative group, subjects with (CT+TT) genotypes had significantly increased risk of both IGC and GCC, with an OR of 2.19 (95% CI: 1.01-4.76) and 3.52 (95% CI: 1.44-8.61), respectively. *H pylori*

¹Adjusted for age and gender, $\chi^2_{\text{trend}} = 33.40$, df = 1, $P = 0.00$, $\gamma = -0.84/-0.79 = 1.06$ ²Adjusted for age and gender, $\chi^2_{\text{trend}} = 28.53$, df = 1, $P = 0.00$, $\gamma = -1.41/-1.08 = 1.31$ ³Adjusted for age and gender, $\chi^2_{\text{trend}} = 12.42$, df = 1, $P = 0.0004$, $\gamma = -0.15/-0.27 = 0.56$.

CagA positivity showed significant protective effects in IGC group in both on CC and CT+TT iNOS genotypes, with an OR of 0.24 (95% CI: 0.07-0.89) and 0.34 (95% CI: 0.17-0.70), respectively. However, no significant association was observed between iNOS genotypes and GCC (Table 4).

DISCUSSION

H pylori infection could produce a state of chronic immunostimulation in gastric epithelium^[21]. It could lead to changes in many factors that are important in the pathogenesis of gastric cancer, including reactive oxygen and nitrogen oxide species^[22]. NO, a potentially toxic gas with free radical properties is one of the most important bio-regulatory and signaling molecules produced in the process. It has been recently reported that NO, acting as a messenger molecule mediating various physiological functions^[23,24], may also play a role in the process of carcinogenesis.

It has been found that NO is synthesized enzymatically from L-arginine by NO synthase^[23,25]. Chronic infection and immuno-stimulation elevate endogenous synthesis of NO. High concentration of NO generated by macrophages after iNOS induction contributed to their cytotoxic and carcinogenic activity^[26]. There is now increasing evidence that NO produced by activated phagocytes may play a role in multistage carcinogenesis by mediating DNA damage^[27,28]. A to T substitution in the iNOS gene, leads to more activated iNOS expression in the target cells, and finally elevates NO to a high level. Hence, it is reasonable to assume that human iNOS gene may be another important candidate gene for the development of gastric cancer by elevating NO production in target cells when functional polymorphisms occur. Nevertheless its genomic localization at chromosome 17q11.2^[29] was not the same as other gastric cancer susceptible genes related to the inflammatory response pathway, such as interleukin 1 β and interleukin 1RN, located at 2q14^[30]. The key question for gastric cancer agents is how *H pylori* infection could be associated with such totally divergent clinical outcomes as gastric cancer and peptic ulcer disease. A large number of previous studies have focused on the role of the bacterial virulence factors that contribute to the degree of tissue damage in the pathogenesis of these diseases. But these results still could not explain the different outcomes^[2,22,31]. With the development of a key concept about the interaction between

acid secretion and *H pylori*-induced gastritis during 1990 s, El-Omar proposed the idea for the first time that host genetic factors relevant to pro-inflammatory responses might be relevant to the development of gastric cancer. They explored a candidate IL-1 β gene in the context of *H pylori* related disease^[32,33]. Because IL-1 β can also induce the expression of many other genes, including pro-inflammatory mediator iNOS, by either regulating at the transcriptional level or initiating their mRNA^[8,9,34], it is easy to consider that functional polymorphisms occurring in the iNOS gene might also contribute to the increased risk of *H pylori* related gastric cancer.

We have previously reported a newly discovered C/T polymorphism in a Chinese population^[17] that had a high mutated allele frequency (24.4%). A report by Johannesen also showed that C/T polymorphism was one of the most frequent SNPs among 10 polymorphisms of human iNOS gene identified in a Danish population. They suggested that the amino acid change in exon 16 might be of functional interest^[9]. Our results showed no significant difference in the frequency of (CT+TT) genotypes between cases and controls, and no apparent gene dose-response effect was found. However, in past cigarette smokers and past alcohol drinkers, C/T polymorphism significantly increased the risk of gastric cancer despite the histological subtypes differed, i.e. past cigarette smokers with (CT+TT) genotypes had an increased risk of IGC, while past alcohol drinkers with (CT+TT) genotypes had increased risk of GCC. These findings suggest that C/T polymorphism in iNOS gene alone is not sufficient to show the increasing risk of gastric cancer. The importance of the interaction between C/T polymorphism and cigarette smoking or alcohol drinking varied depending on different histological subtypes of gastric cancer. Similar results were found by Machado for IL-1 genetic markers^[35]. Although these findings were not the major hypothesis we proposed, it is biologically plausible that oxidative stress due to carcinogenesis in cigarette might attribute to the increase of gastric cancer risk through interactions with iNOS C/T polymorphism. Larger and independent studies are needed to confirm these findings.

In the *H pylori* CagA positive group, regardless of whether subjects had CC or (CT+TT) genotypes, we always observed a significant protective effect when comparing IGC cases with controls. This suggests that plasma positive for *H pylori* CagA antibody in a highly infected area plays a protective role. This

is in concordance with the finding that *H pylori* density became progressively lower with progression from mild gastritis to severe gastritis, atrophy, intestinal metaplasia and finally gastric cancer^[29]. In *H pylori* CagA negative subjects with (CT+TT) genotypes, a high risk was found for gastric cancer group (OR = 2.53, 95% CI: 1.29-4.98) and both subgroups (IGC and GCC). No interaction was found between iNOS genotype and infection with *H pylori* CagA strains.

iNOS protein is a catalytic enzyme with two domains. In terms of functional importance, the deletion mutants retained maximal NO activity at lower concentrations of free Ca²⁺ compared with the wild-type^[36]. Identified C/T polymorphism in E16 of iNOS was located at the N-terminal of six amino acids from the deletion reported by Daff *et al.*, and the amino acid change in E16 might be of functional interest^[9]. To our knowledge, this study was the first one to examine the significance of iNOS polymorphism in gastric cancer. A research on other type of disease might support our observation^[9]. Gastric cancer patients having allele T polymorphism could have an increased expression of iNOS, resulting in higher levels of NO in gastric mucosa, mediating many pathological changes and finally leading to carcinogenesis in these patients. But specific functional tests of C/T shift need to be performed to substantiate the putative importance of the Ser⁶⁰⁸Leu locus in gastric cancer development.

Potential weaknesses in our study include possible recruitment bias in the selection of controls including cases' siblings. This kind of selection might create overmatching. Siblings were more likely to have the same genotypes as the cases than the non-blood related controls, thereby leading to some loss of statistical efficiency, i.e., larger sample sizes were required to attain the same statistical precision^[37]. Thus, our data may be more likely to underestimate the true effect of iNOS T alleles on the risk of gastric cancer. But others considered that the use of sibling controls could generally improve efficiency for gene-environment interactions^[38,39]. We could not rule out the potential influence of systematic differences between participants and non-participants.

In conclusion, the risk of gastric cancer is increased among past cigarette smoking or alcohol drinking individuals with a C/T polymorphism in E16 of iNOS gene in a Chinese population. But the findings need to be confirmed in other ethnic populations.

ACKNOWLEDGEMENTS

We thank Zhao-Xi Wang for his excellent technical assistance; and Professor Regina M. Santella and Dr. Yu-Jing Zhang for editing the manuscript. We also thank all the doctors for their kind help in collecting the biological samples and epidemiological data. We thank all participants for their co-operation.

Abstract

AIM: To isolate the subtypes of 3' region of *cagA* gene in *Helicobacter pylori* (*H pylori*) strains from Zhejiang Province in China and to investigate their relations to *H pylori*-associated gastroduodenal diseases.

METHODS: One hundred and thirty-seven *H pylori* clinical strains were isolated from the gastric mucosa specimens of 74 patients with chronic gastritis, 61 with peptic ulceration, and 2 with gastric cancer. Bacterial genomic DNA was extracted and 3' region of *cagA* gene was amplified by polymerase chain reaction (PCR). Subtypes of 3' region of *cagA* gene were determined by the size of PCR amplified segments. The sequences of the subtypes were analyzed by PCR-based sequencing.

RESULTS: Of the 137 *H pylori* isolates from Zhejiang Province, 132 (96.4%) yielded PCR products that could be classified into three groups of subtypes, named as subtypes I, II, and III according to their sizes. The sizes of subtypes I, II, and III were 648-650 bp, 705-707 bp, and 815 bp, respectively. Among the 132 *cagA*-positive *H pylori* strains, 123 (93.2%) belonged to the group of subtype I, 6 (4.5%) presented subtype II, 1 (0.8%) was subtype III, and 2 (1.5%) presented subtypes I and III both. The primary structure of subtype I was composed of 3 repeats of R1, 1 repeat of R2 and 1 repeat of R3. Subtype II possessing 4 repeats of R1, 2 repeats of R2 and 1 repeat of R3 was a newly found type of 3' region of *cagA* gene which had not been reported before. The primary structure of subtype III consisted of 4 repeats of R1, 1 repeat of R2 and 2 repeats of R3. Comparison of the sequences of subtype I strains with the corresponding sequences deposited in GenBank, showed a similarity of 95.0% (94.0-96.1%) for nucleotide sequences and 95.9% (94.9-97.4%) for deduced amino acid sequences. Comparison of the sequences of subtype III strains with the corresponding sequences deposited in GenBank, showed a similarity of 93.9% (90.8-96.9%) for nucleotide sequences and 93.2% (90.2-96.2%) for deduced amino acid sequences. Among subtype II strains, the nucleotide and deduced amino acid sequences showed a similarity of 95.2% (94.1-96.5%) and 96.4% (93.8-97.9%), respectively. There were no statistical differences in the

distribution of subtypes of 3' region of *cagA* gene among different *H pylori*-associated gastroduodenal diseases ($\chi^2 = 11.544$, $P > 0.05$).

CONCLUSION: There are three subtypes (I, II, and III) of 3' region of *cagA* gene in *H pylori* strains isolated from Zhejiang Province, and subtype I is predominant. Subtype II is a newly found subtype of 3' region of *cagA* gene. The result of this study does not support the view that the subtypes of 3' region of *cagA* gene in *H pylori* isolated from Zhejiang Province are correlated with the clinical outcomes of *H pylori* infection.

INTRODUCTION

Although *Helicobacter pylori* (*H pylori*) is present in stomachs of at least half of the world's population^[1], only a small proportion of the carriers develop symptomatic diseases^[2]. The clinical spectrum of *H pylori* infection ranges from asymptomatic gastritis to peptic ulcer and gastric cancer^[3]. The causes of different outcomes of *H pylori* infection may include the virulence of infectious strains, the susceptibility of hosts, and environmental cofactors^[4-8]. The cytotoxin-associated gene A (*cagA*) is located at one end of a 40-kilobase DNA segment called *cag* pathogenicity island (*cag* PAI), which contains open reading frames encoding for a putative *H pylori* secretion system that may be associated with export of virulence factors to the extracellular compartment^[9,10]. The presence of *cagA* gene can be considered as a marker for *cag* PAI and is associated with more virulent *H pylori* strains^[11]. The structure of *cagA* gene contains a 5' highly conserved region and a variable 3' region, in which the presence of a variable number of repeat sequences results in a protein (CagA) with a molecular mass of 120 to 140 ku^[12]. Yamaoka *et al.*^[13] from Japan found that the structural organization of 3' region of *cagA* gene in Japanese *H pylori* isolates could be divided into four types (types A to D), and type C was associated with gastric atrophy and carcinoma. However, the genetic structure of 3' region of *cagA* gene in Chinese *H pylori* strains has been little exploited. In this study, we attempted to investigate the subtypes of 3' region of *cagA* gene in *H pylori* strains isolated from Zhejiang Province in China and their relations to *H pylori*-associated gastroduodenal diseases.

MATERIALS AND METHODS

H pylori isolates

A total of 137 *H pylori* isolates were obtained from *H pylori*-infected patients at the Second Affiliated Hospital of Zhejiang University and the Renmin Hospital of Daishan County in Zhejiang Province. The patients, consisting of 95 men and 42

women with a mean age of 42.6 years (ranging from 16 to 71 years), were classified into 3 groups including chronic gastritis ($n = 74$), peptic ulcer ($n = 61$), and gastric cancer ($n = 2$), according to the results of endoscopic and histological examination.

H pylori culture

Bacteria isolated from biopsy specimens were cultured on ECY selective solid medium^[14] at 37 °C for 5 d, under 100% humidity and microaerophilic conditions (50 mL/L O₂, 100 mL/L CO₂, and 850 mL/L N₂). *H pylori* strains were identified by the following criteria: Gram staining, colony morphology, rapid urease test, and catalase test. The cultured bacteria were defined to be *H pylori* if they formed typical colonies on the medium, were negative Gram stain with curved or spiral shape, and positive for urease and catalase production^[15].

Preparation of *H pylori* genomic DNA

The bacteria were harvested from the agar plates, then genomic DNA was extracted and purified from each *H pylori* isolate using cetyltrimethyl ammonium bromide (CTAB), phenol-chloroform-isoamyl alcohol, and ethanol precipitation^[16].

Amplification of 3' region of *cagA* gene by PCR

The primers 5'-ACCCTAGTCGGTAATGGGTTA-3' (CAG1) and 5'-GTAATTGTCTAGTTTCGC-3' (CAG2) described by Yamaoka *et al.*^[13] were used to amplify 3' region of *cagA* gene in this study. PCR was performed in a volume of 25 µL containing 2.5 µL of 10×PCR buffer, 2 µL of 25 mmol/L MgCl₂, 2.5 µL of 2 mmol/L dNTPs, 0.5 µL of 20 µmol/L primer sets, 0.2 µL of Taq DNA polymerase, 1 µL of bacterial genomic DNA, and 15.8 µL of H₂O. PCR amplification was performed as following: an initial denaturation at 95 °C for 3 min, followed by 30 cycles, each consisting of denaturation at 94 °C for 30 s, annealing at 56 °C for 30 s, and extension at 72 °C for 45 s. The final cycle included a further extension at 72 °C for 7 min to ensure the full extension of PCR products. PCR products were analyzed by 20 g/L agarose gel electrophoresis with ethidium bromide staining.

Sequences analysis

PCR products were purified with the DNA purification kit (Shanghai Shenyong Biotechnology Co., Ltd.) according to the manufacturer's instructions. Purified PCR products were consigned to Shanghai BioAsia Biotechnology Co., Ltd. for sequencing. Biological software DNAssist (version 1.0) was used to analyze the sequences of 3' region of *cagA* gene and to compare them with the corresponding sequences deposited in GenBank.

Statistical analysis

The categorical data were analyzed using Chi-square (χ^2) test, and $P < 0.05$ was considered statistically significance.

RESULTS

PCR products of 3' region of *cagA* gene

PCR products of 3' region of *cagA* gene were electrophoresed on 20 g/L agarose gel (containing 0.5 µg/mL ethidium bromide). Of the 137 *H pylori* strains isolated from Zhejiang Province, 132 (96.4%) strains yielded PCR products of three different sizes. The three different-size PCR-amplified segments were respectively named as subtype I (648–650 bp), subtype II (705–707 bp), and subtype III (815 bp) (Figure 1). Among the 132 *cagA*-positive strains, 123 (93.2%) presented subtype I, 6 (4.5%) presented subtype II, 1 (0.8%) presented subtype III, and 2 (1.5%) presented both subtypes I and III.

Figure 1 Amplified products of 3' region of *cagA* gene by PCR (20 g/L agarose gel electrophoresis) Lane 1: 100 bp DNA ladder; Lane 2: subtype I (648 bp); Lane 3: subtype II (705 bp); Lane 4: subtype III (815 bp); Lane 5: from a patient with both subtypes I and III.

Sequence analysis of subtypes of 3' region of *cagA* gene

The primary structure of 3' region of *cagA* gene was composed of a variable number of repeat regions, including R1 (15 bp), R2 (42 bp) and R3 (147 bp). The primary structures of the subtypes of 3' region of *cagA* gene in this study are illustrated in Figure 2. The primary structure of subtype I was composed of 3 repeats of R1, 1 repeat of R2 and 1 repeat of R3, so subtype I was equal to type A in Japanese *H pylori* strains reported by Yamaoka *et al.*^[13]. The primary structure of subtype III consisting of 4 repeats of R1, 1 repeat of R2 and 2 repeats of R3 was similar to that of type C reported by Yamaoka *et al.*^[13]. Subtype II possessing 4 repeats of R1, 2 repeats of R2 and 1 repeat of R3 had the primary structure not similar to any types reported by Yamaoka *et al.*^[13] and was regarded as a newly found subtype of 3' region of *cagA* gene in *H pylori*. Comparison of the sequences of 5 *H pylori* strains presented subtype I with the corresponding sequences of a Japanese type A strain JK25 deposited in GenBank (GenBank accession number AF043487), showed a similarity of 95.0% (94.0–96.1%) for nucleotide sequences and 95.9% (94.9–97.4%) for deduced amino acid sequences. Comparison of the sequences of 2 *H pylori* strains presented subtype III (including a strain presented both subtypes I and III) with the corresponding sequences of a Japanese type C strain Jk269 deposited in GenBank (GenBank accession number AF043489), showed a similarity of 93.9% (90.8–96.9%) for nucleotide sequences and 93.2% (90.2–96.2%) for deduced amino acid sequences. Among the 6 *H pylori* strains presented subtype II in this study, the nucleotide and deduced amino acid sequences showed a similarity of 95.2% (94.1–96.5%) and 96.4% (93.8–97.9%), respectively. Alignments of the deduced amino acid sequences of 5 strains presented subtype I and 2 strains presented subtype III with the corresponding sequences deposited in GenBank are illustrated in Figure 3 A, B. Alignments of the deduced amino acid sequences of 6 strains presented subtype II are also illustrated in Figure 3 C.

Figure 2 Primary structures of three subtypes of 3' region of *cagA* gene R1: 15 bp repeat region; R2: 42 bp repeat region; R3: 147 bp repeat region.

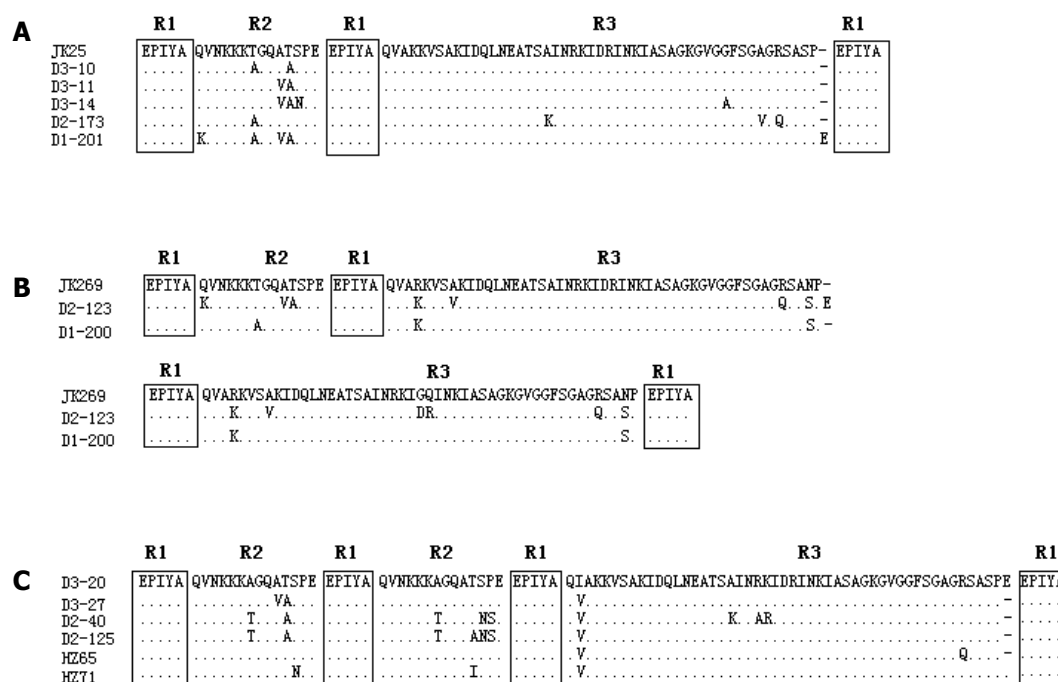

Figure 3 Alignment of amino acid sequences of subtypes of 3' region of *cagA* gene. A: Alignment of the deduced amino acid sequences of subtype I strains with the sequence of the corresponding region of a Japanese type A strain JK25 (GenBank accession number AF043487). Strain D2-173 was from a patient with chronic gastritis, and the remaining four strains were from patients with peptic ulcer. B: Alignment of the deduced amino acid sequences of subtype III strains with the sequence of the corresponding region of a Japanese type C strain JK269 (GenBank accession number AF043489). Strain D1-200 was from a patient with chronic gastritis, and strain D2-123 was from a patient with gastric ulcer. C: Alignment of the deduced amino acid sequences of six subtype II strains. Strain HZ65 and HZ71 were from patients with chronic gastritis, strain D2-40 was from a patient with gastric cancer, and the remaining three strains were from patients with peptic ulcer.

Relationship between subtypes of 3' region of *cagA* gene and gastroduodenal diseases

The distributions of the subtypes of 3' region of *cagA* gene in different groups of gastroduodenal diseases are demonstrated in Table 1. Statistical analysis showed that there were no significant differences among the subtypes of 3' region of *cagA* gene in different groups of gastroduodenal diseases ($\chi^2 = 11.544$).

Table 1 Relationship between subtypes of 3' region of *cagA* gene and different group of gastroduodenal diseases (n, %)

Group of diseases	Subtype I	Subtype II	Subtype III	Subtypes I and III	Total
Chronic gastritis	69 (95.8)	2 (2.8)	0 (0)	1 (1.4)	72
Peptic ulcer	53 (91.4)	3 (5.2)	1 (1.7)	1 (1.7)	58
Gastric cancer	1 (50.0)	1 (50.0)	0 (0)	0 (0)	2
Total	123 (93.2)	6 (4.5)	1 (0.8)	2 (1.5)	132

$\chi^2 = 11.544$, $P = 0.17 > 0.05$.

DISCUSSION

H. pylori, a spiral shaped gastric organism, is the cause of chronic gastritis, and plays an important role in the pathogenesis of peptic ulceration, mucosa associated lymphoid tissue lymphoma, and gastric adenocarcinoma^[17-20]. It has been reported that 50-60% of *H. pylori* strains contain *cagA* gene and consequently produce CagA protein^[21]. The CagA is a highly immunogenic outer membrane protein with a molecular weight of 120 to 140 ku. Variation in size of the protein has been correlated with the presence of a variable number of repeat sequences located in 3' region of the gene^[22,23]. The biological importance of the repeat sequences in 3' region of *cagA* gene remains unknown. Because CagA is strongly immunogenic, these repeat sequences have been supposed to alter immunogenicity

of the protein^[24]. This alteration in the gene and its protein seems to correlate with clinical outcomes *in vivo*. The proportion of *cagA*-positive *H. pylori* isolates varies from one geographic region to another. Studies from Japan, Korea, and China have shown that more than 90% of *H. pylori* strains are *cagA*-positive^[25-28], while in the United States of America, Canada, and Europe, these percentages are lower^[24,29,30]. Therefore, *cagA* gene cannot be used as a marker for the presence of severe gastroduodenal diseases in those regions where the prevalence of *cagA*-positive *H. pylori* strains is uniformly high. Since allelic variation in *cagA* exists and distinct *H. pylori* subtypes may circulate in different regions, differences in *cagA* subtype might provide a marker for differences in virulence among *cagA*-positive *H. pylori* strains^[12].

Yamaoka *et al.*^[13] reported that 3' region of *cagA* gene in *H. pylori* isolated from Japanese patients could be classified into four types (types A, B, C, and D) depending on the types and number of repeat regions including R1 (15 bp), R2 (42 bp) and R3 (147 bp). The PCR products of type A ranged from 642 to 651 bp, and possessed 1 repeat of R2 and 1 repeat of R3. The PCR products of type B and type D were all 756 bp, but type B possessed 3 repeats of R2 and 1 repeat of R3, while type D had 2 repeats of R3 and no repeat of R2. Type C having 1 repeat of R2 and 2 repeats of R3 yielded PCR products of 813-815 bp and was associated with high levels of CagA antibody and severe degrees of atrophy. The same authors have also found that the sequences of the second repeat regions of 3' region of *cagA* gene in *H. pylori* strains from East Asia are completely different from those in strains from non-Asian countries^[31]. Non-Asian strains possess 102 bp second repeat regions, and East Asian strains possess 162 bp second repeat regions^[31,32].

In the present study, we used the same PCR primers as those described by Yamaoka *et al.*^[13] and found 132 (96.4%) of 137 strains yielded amplified products. The high prevalence of *cagA*-positive strains in Zhejiang Province was in accordance

with the result of our previous study^[13] and the findings in other Chinese areas^[11,27]. The PCR products could be classified into three subtypes according to their sizes and were named as subtype I, subtype II, and subtype III, respectively. The PCR products of subtype I ranged from 648 to 650 bp and possessed 1 repeat of R2 and 1 repeat of R3, so subtype I was equal to type A reported by Yamaoka *et al.*^[13]. The predominance of subtype I strains (93.2%) in this study was in agreement with that of type A strains (93.5%) in Japanese patients^[13]. The size and genetic structure of subtype III indicated that subtype III in this study was equal to type C in Japanese strains^[13]. Three (including 2 multiple subtypes strains) of 132 *cagA*-positive strains presented subtype III, and the prevalence of this subtype (2.3%) was close to that of type C (4.5%). In contradiction to the two above-mentioned subtypes, subtype II having the size of PCR product of 705-707 bp and the structure of 2 repeats of R2 and 1 repeat of R3 has not been reported before. Because sequence analysis showed that the structure of subtype II still accorded with the characteristics of 3' region of *cagA* gene in Asian strains, subtype II in this study was regarded as a new subtype of 3' region of *cagA* gene in Asian *H pylori* strains. The fact that we did not find type B and type D reported by Yamaoka *et al.*^[13], but discovered a new subtype revealed the diversity and randomness of the assembling mode of repeat regions located at 3' region of *cagA* gene and the possibility that this assembling mode varied in *H pylori* strains isolated from different areas. In addition, 2 strains presenting more than one subtype were observed in this study and thought to be from the patients with multiple *H pylori* infection. Sequence analysis revealed high similarities between the sequences of 3' region of *cagA* gene in *H pylori* isolated from Zhejiang Province and those in *H pylori* strains from Japanese patients and high similarities among the 6 subtype II strains, so we could draw a conclusion that despite of the genetic diversity of 3' region of *cagA* gene in *H pylori* strains isolated from Zhejiang Province, the sequences of the same subtype were still conservative. There were no significant differences among the subtypes of 3' region of *cagA* gene in different groups of gastroduodenal diseases, so the subtypes of 3' region of *cagA* gene in *H pylori* isolated from Zhejiang Province seemed not to be correlated with the clinical outcomes of *H pylori* infection.

In conclusion, there are three subtypes of 3' region of *cagA* gene in *H pylori* strains isolated from Zhejiang Province. Subtype I is a predominant one and subtype II is a newly found subtype of Asian *H pylori* strains. The result of this study does not support the view that the subtypes of 3' region of *cagA* gene in *H pylori* isolated from Zhejiang Province are correlated with the clinical outcomes of *H pylori* infection.

Abstract

AIM: To clarify the role of cag pathogenicity island (cagPAI) of *Helicobacter pylori* (*H pylori*) in the pathogenicity and immune prophylaxis of *H pylori* infection.

METHODS: Three pairs of *H pylori* including 3 strains of cagPAI positive wildtype bacteria and their cagPAI knockout homogenic mutants were utilized. *H pylori* binding to the gastric epithelial cells was analyzed by flow cytometry assays. Apoptosis of gastric epithelial cells induced by *H pylori* was determined by ELISA assay. Prophylaxis effect of the wildtype and mutant strains was compared by immunization with the sonicate of the bacteria into mice model.

RESULTS: No difference was found in the apoptosis between cagPAI positive and knockout *H pylori* strains in respective of the ability in the binding to gastric epithelial cells as well as the induction of apoptosis. Both types of the bacteria were able to protect the mice from the infection of *H pylori* after immunization, with no difference between them regarding to the protection rate as well as the stimulation of the proliferation of splenocytes of the mice.

CONCLUSION: The role of cagPAI in the pathogenicity and prophylaxis of *H pylori* infection remains to be cleared.

INTRODUCTION

Helicobacter pylori (*H pylori*) infected over half of human adults in the world, especially in Asian-Pacific countries. Only a small portion of patients display clinical symptoms such as peptic ulcer and gastric cancer^[1-14]. The difference between the infection and the outcomes is determined by both bacterial factors and host responses. Among the bacterial factors, cag pathogenicity island (PAI) had been studied widely, while the immune response to the infection is the overwhelming host factor that affects the outcome of infection. In respect of the bacterial factors, cytotoxin associated gene A (cag A) protein is usually considered as a toxic marker of the bacterium. A related gene cluster, PAI encodes several proteins with the similar biological activities. To define the relationship between cagPAI and the pathogenicity of *H pylori*, three pairs of *H pylori* harboured

cagPAI and their isogenic PAI knockout mutants were utilized. Their roles in the binding and apoptosis inducing activities as well as the immune protection were compared *in vivo* and *in vitro*.

MATERIALS AND METHODS

Materials

CT, PKH26, PMA and Ionomycin were obtained from Sigma Co. U.S.A; granulocyte-macrophage-colony-stimulating-faction (GM-CSF) enzyme linked immunosorbent assay (ELISA) kit was bought from Boehringer-Mannheim Co. German; Three pairs of *H pylori* harbouring cagPAI and their isogenic PAI knockout mutants were provided kindly by Professor Peter B Ernst from DyKesas University USA; *H pylori* strains and gastric epithelial cells (Kato-III) were from the Research Institute of Digestive Disease, Nanfang Hospital, First Military Medical University in Guangzhou, China. *H pylori* strains are showed in Table 1.

Table 1 cagA positive wildtype bacteria and their cagA knockout homogenic mutants

<i>H pylori</i>	cagPAI
LC11	+ wildtype
AH244	knockou cagPAI knockout of LC11
84183	+ wildtype
2-1	knockou cagPAI knockout of 84183
26695	+ wildtype
8-1	knockou cagPAI knockout of 26695

Methods

***H pylori* culture and *H pylori* sonicate (SON) preparation were performed by standard procedures** There was no difference between the groups of wildtype and knockout bacteria in the rate of growing (Figure 1).

Figure 1 Equivalent growth of wildtype and knockout strains after 2 d culture.

Flow cytometry was used to detect adhesion of *H pylori* binding to gastric epithelial cells *H pylori* strain (ATCC26695) was marked by 10 mL/L PKH-26 and washed three times. The liquid after the third washing was used in the control groups, then bound to gastric epithelial cells (KatoIII) (bacteria/cells = 300:1), and incubated at 37 °C for 60 min. After washed, the sample was detected by FACs.

ELISA was used to detect apoptosis of gastric epithelial cells induced by *H pylori* The basic mechanism was to detect the release of DNA combined histone. According to the recommended procedures, cracked Kato-III cells with anti-histone monoclonal antibody were incubated and color was developed after adding substrate. Absorbency at the 405 nm level was measured in the enzyme-tagging instrument. Then, the apoptotic index (AI) was calculated in comparison with control group.

Mice were divided into 4 groups, five mice each group, except for the natural death. PBS Group: 200 μ L PBS /one mouse was fed once via mouth as negative control; CT Group: CT (10 μ g) 200 μ L/per mouse was fed once via mouth as adjuvant control Group; CagPAI positive Group: ultrasonic smashed *H pylori* 26695 (100 μ L) and CT (10 μ g) was fed at a time via mouth; CagPAI negative Group: ultrasonic smashed *H pylori* 8-1 (100 μ L) and CT (10 μ g) were fed once via mouth.

Immunity procedures

Before immunization and inoculation of *H pylori*, the mice were prohibited from water and food for over 12 h. Thirty min before inoculation, the mouse was fed with 200 μ L (0.01 mol/L) NaHCO_3 solution to neutralize gastric acid. The experimental group and the control group were inoculated with antigens and adjuvants, immunized on d 0, 7, and 14. They were allowed to drink water 1 h after immunization. Each group was attacked with *H pylori* 10^8 CFU once every other day, 3 wk after the latest immunization. The mice were killed 8 wk after the latest attack.

Evaluation of bacterial implantation

The spleen and stomach were removed immediately after the mouse neck was broke. The spleen was kept in the axenic cell culture media temporarily and dealt with it for 4 h. The stomach was cut along the greater curvature, washed with axenic fluid, then some tissues were sampled for rapid urea enzyme test and histological examination. Histological examination was graded semi-quantitatively according to the standard as follows: 0 point: no *H pylori*; 1 point: 1-2 *H pylori* in some gastric pits; 2 points: 3-10 *H pylori* in majority of gastric pits and 3 points: over 10 *H pylori* in majority of gastric pits.

Spleen cell proliferation text

Spleen tissue was triturated into homogenates at asepsis environment. The spleen cells were counted and implanted in the 96 well plate (2×10^5 cells/well) containing 500 ng/mL PMA and 10 ng/ml ionomycin RPMI1640 (including cow blood serum, mycillin, Hepes *ect*), *H pylori* ultrasonic smashed antigen was added into them in terms of 2.5, 5, 10 mg/mL, cultured for 24 h, then H^3 -thymidine was added, and cultured for 8 h, then the cell were collected and degraded. Each control group was compared with the blank control group in the count, and the proliferation quotiety was calculated. Differential proliferation quotiety equals each group's proliferation quotiety/PBS group's proliferation quotiety $\times 100\%$.

Statistical analysis

Data and their variance were analyzed using EXCEL software. $P < 0.05$ was considered statistically significant.

RESULTS

Adherence of CagPAI and *H pylori*

CagPAI positive culture and mutant strains showed a different bacteria/cell ratio, and were, marked with PKH26, then they were incubated with stomach cell Kato-III, the adherence ability was measured with flow cytometry positive cells and mean fluorescence intensity (MFI) were calculated. No difference was found between wild strain and mutant strain. The result was displayed in Figure 2.

Figure 2 Binding of cag PAI wildtype *H pylori* and their mutant to gastric epithelial cell Kato-III.

Apoptosis-induced ability of cagPAI and *H pylori*

CagPAI and mutant strain were cultured with gastric epithelia cells at the ratio 300:1 for 24 h. The cells were degraded, the cell apoptosis was detected by ELISA. We found that the apoptosis-induced ability of 26 695 was slightly higher than that of 8-1 strain, and no difference was found in other couples. The result is displayed in Figure 3.

Figure 3 Apoptosis of gastric epithelial cells induced by positive cagPAI and knockout *H pylori* strains (determined by ELISA $^aP < 0.05$ vs the control).

Immune prevention to the cagPAI and *H pylori*

The protection rate of groups PBS, CT, 26695 and 8-1 was 0%, 0%, 40%, 60% (Table 2). CagPAI positive strain ATCC26695 and mutant strain 8-1 accompanied with mucous membrane adjuvant cholera toxin prevented *H pylori* from growing in the stomach of mice. There was no difference between the CagPAI positive strain and CagPAI negative strain. We found that full-protect rate of the two *H pylori* immune group was only 20% or so. It was found that immune was apparently decrease in semi-quantitative counting. No obvious difference was found between groups, and CT group had no prevention effect. The result is displayed in Figure 4.

Table 2 Ultrasonic smashed substance's protection against mice *H pylori* (result of urease test)

Immune project	Urease test (+)/number of animals (piece)	Protecting ratio (%)
PBS	5/5	0
CT	5/5	0
26695 SON+CT	3/5	40 ^a
8-1 SON+CT	2/5	60

^a $P < 0.05$, vs control groups.

Figure 4 Semi-quantitative results of bacteria by histological examination. ^a $P < 0.05$ vs PBS control.

cagPAI and cell immune of mice *H pylori*

Comparing with PBS control, the CT control number of spleen cells was slightly increased, but that of two *H pylori* antigen-immune groups was greatly increased. The number of CagPAI mutant strains was more obvious. Compared with the two groups, no difference was found, ($P < 0.05$, Figure 5).

Figure 5 Specific proliferation index of immunized mice (compared to PBS group).

DISCUSSION

CagA is cytotoxin correlative protein, which is one of *H pylori* nosogenetic factors. The PAI is regarded as one of the signs of *H pylori* infection. Early researches found that this positive sign was higher in peptic ulcer and gastric carcinoma than in gastritis. For example, foreign researchers found that anti-CagPAI in serum was positive in 93% of the gastric carcinoma patients^[2], it is different in Asian-Pacific area, the positive ratio of the bacterial strain was much higher. A large number of reports approved that the pathogenicity of CagA (+) was stronger than that of CagA (-), inducing the production of IL-8 and GRO- α , ENA78 could produce and activated related nucleic transcription factors^[3]. Few reports about comparison of wildtype strain isogenic mutant strain *in vitro* were available. We studied three pairs of cagPAI wildtype strain and cagPAI gene-knockout mutant strain constructed by Dr. Bery. No difference was found between the growing speed and activity of the two strains.

There were many gene products concerned with *H pylori* adherence, including NLBH, porins, BabA *etc*^[4-9]. Our study showed that there was no difference in adherence to the epithelia of stomach between cagPAI (+) strain and cagPAI (-) strain.

CagPAI (+) strain could cause apoptosis and proliferation in stomach epithelia^[10]. However, it was proved by ELISA in our research that *in vitro* cagPAI was not concerned with apoptosis-induced ability, which did agree with the result of Le'Negrate. They found that cagE in cagPAI participated in the process of Fas-induced *H pylori* causing stomach epithelial apoptosis due to different the strain. we chose two stains in three pairs of strains, so the result was probably accurate.

In the immune prevention of *H pylori* infection, it was reported that cagA could prevent infection of the cagPAI (+). In our research,

SS1 strain which was used to infect animals was cag (+) strain, but we found that there was no difference in preventive effect between cagPAI (+) strain and mutant strain. Although there was no statistical difference, mutant stain had a higher protective trend. It showed that the immune prevention was not caused by protein coded by cagPAI. We do not support regarding cagPAI gene product is immune antigen of *H pylori* bacterin.

Cellular immunity, especially CD4⁺T cellular immunity is a very important mechanism, which can help B cells produce sIgA. We selected the spleen cell proliferation test as the target in immune. Because B cells could not live *in vitro*, the proliferation cells were mainly T cells. Both cagPAI (+) and cagPAI (-) strain were stimulated to proliferate T cells, indicating that some special T cells clones are existed in spleen cells. The number of cagPAI mutant strains is more than that of cagPAI (+) strains, agreeing with the histology.

The effect of cagPAI on *H pylori* immune and pathogenesis is very complex and needs further study.

Abstract

AIM: To investigate the pathway (s) mediating rat antral circular smooth muscle contractile responses to the cholinomimetic agent, bethanechol and the subtypes of muscarinic receptors mediating the cholinergic contraction.

METHODS: Circular smooth muscle strips from the antrum of Sprague-Dawley rats were mounted in muscle baths in Krebs buffer. Isometric tension was recorded. Cumulative concentration-response curves were obtained for (+)-cis-dioxolane (cD), a nonspecific muscarinic agonist, at 10^{-8} - 10^{-4} mol/L, in the presence of tetrodotoxin (TTX, 10^{-7} mol/L). Results were normalized to cross sectional area. A repeat concentration-response curve was obtained after incubation of the muscle for 90 min with antagonists for M1 (pirenzepine), M2 (methoctramine) and M3 (darifenacin) muscarinic receptor subtypes. The sensitivity to PTX was tested by the ip injection of 100 mg/kg of PTX 5 d before the experiment. The antral circular smooth muscles were removed from PTX-treated and non-treated rats as strips and dispersed smooth muscle cells to identify whether PTX-linked pathway mediated the contractility to bethanechol.

RESULTS: A dose-dependent contractile response observed with bethanechol, was not affected by TTX. The pretreatment of rats with pertussis toxin decreased the contraction induced by bethanechol. Lack of calcium as well as the presence of the L-type calcium channel blocker, nifedipine, also inhibited the cholinergic contraction, with a reduction in response from 2.5 ± 0.4 g/mm² to 1.2 ± 0.4 g/mm² ($P < 0.05$). The dose-response curves were shifted to the right by muscarinic antagonists in the following order of affinity: darifenacin (M₃) > methoctramine (M₂) > pirenzepine (M₁).

CONCLUSION: The muscarinic receptors-dependent contraction of rat antral circular smooth muscles was linked to the signal transduction pathway(s) involving pertussis-toxin sensitive GTP-binding proteins and to extracellular calcium via L-type voltage gated calcium channels. The presence of the residual contractile response after the treatment with nifedipine, suggests that an additional pathway could mediate the cholinergic contraction. The involvement of more than one muscarinic receptor (functionally predominant type 3 over type 2) also suggests more than one pathway mediating the cholinergic contraction in rat antrum.

INTRODUCTION

The mechanisms involved in the regulation of cholinergic contraction of intestinal smooth muscle are complex and not fully understood, despite the important role of the cholinergic system in the physiology of gastric emptying, and pathophysiology of several motility disorders. Cholinergic agonists activate muscarinic receptors which transduce cholinergic signals by activating G proteins^[1,2]. Different signal transduction pathways in different species, as well as different pathways for the circular and longitudinal layers of intestinal smooth muscle have been reported^[3-15].

Specific muscarinic receptors are abundantly present in the smooth muscles of gastrointestinal tract^[16-22]. Muscarinic receptor subtypes have shown a G-protein coupling specificity, however the published data are inconsistent. In some studies M₁, M₃, M₅ receptor subtypes were preferentially coupled to the Gq/11 protein class, the M₂ and M₄ receptors were linked to the PTX-sensitive Gi/Go proteins^[23-25]. Whereas in other studies muscarinic M₂ receptors were insensitive to pertussis toxin^[26].

Relatively few references are published characterizing rat stomach muscarinic receptor subtypes, again with conflicting results. Prevalence of M₃^[13,22,27], or of M₁^[28], or M₂ receptors^[29-33] has been reported. Which muscarinic receptor is more functionally important in the cholinergic contraction of antral circular muscle has not been determined.

The aim of this study was to examine the signal transduction pathway (s) mediating rat antral smooth muscle cholinergic contraction to fill the existing knowledge gaps: (1) what type of calcium channel was involved and was there a dependence on extracellular Ca²⁺ influx; (2) whether PTX-sensitive- or PTX-insensitive-G proteins coupled to muscarinic receptors were involved; and (3) what subtypes of specific muscarinic receptors were functionally involved. Determining the physiology of the pathway (s) mediating cholinergic contraction of the antrum should be helpful in understanding the functional motility changes described in models of disease conditions, such as diabetes^[34-36]. Preliminary accounts of some of these observations have been published in abstract form^[37,38].

MATERIALS AND METHODS

Animals

Young adult male Sprague-Dawley rats (Charles River Breeding Laboratories), weighing 200-450 g were used. Animals were anesthetized by ip injection of sodium pentobarbital (30-65 mg/kg). Anesthesia was given immediately before the tissue removal to avoid the effect of anesthesia on the contractile properties of the tissue. The abdomen was explored through midline incision and the stomach was removed. After the tissue was removed, animals were euthanized by injection of an overdose of pentobarbital. All our studies were approved by the Institutional Animal Care and Use Committee of the PSU College of Medicine.

Smooth muscle strip bath preparation^[39]

The antrum tissue was pinned in a dissecting dish in oxygenated Krebs solution, mucosa was gently removed by scraping, and strips were cut in the circular muscle orientation. The muscle was oxygenated in Krebs physiological buffer containing (in mmol/L) 130 Na, 4.7 K, 2.5 Ca, 1.0 Mg₂, 140.7 Cl, 19 HCO₃, 1.0 PO₄ and 10 glucose at 37 °C. The strips were sutured at one end to a glass rod and at the other end to an inelastic wire. The tissue, the rod and a wire were placed in a 10-mL double walled glass chamber with a constant temperature 37 °C. Glass surfaces were silicone coated with Sigmacote to prevent binding of the peptides. The chambers were filled with 5 mL of Krebs buffer and gassed with 95:5 mixture of O₂/CO₂. The free end of wire was attached to an isometric force transducer (Grass Instrument Co) and recordings were made on a multichannel rectilinear dynograph recorder (Beckman Instruments). The strips were allowed to equilibrate for 1 h. Tissues were stretched to an initial length (L_i) from which any additional stretch resulted in an increase in tension. The isometric tension response to bethanechol (10⁻⁴ mol/L) was noted. The strips were rinsed and the length increased by 1 mm increment until the maximum response to bethanechol (10⁻⁴ mol/L) was recorded. This length was labeled L_o. All subsequent studies were conducted at this length. Drugs were added to the tissue bath and the peak response within 8 min was compared with the maximum tension recorded during 5 min before addition of drugs. Antagonists were added 1 min before the addition of agonist. The peptidase inhibitors bestatin and phosphoramidon (both at 10⁻⁶ mol/L) were added at least 5 min before the agonist addition. The response was calculated as the change in the maximal force of contraction in g of tension normalized to the cross sectional area which was calculated as: cross section (mm²) = weight (g)/specific density × length (mm), where the specific density of muscle tissue = 1.056 (g/mm³).

Dispersed single muscle cell preparation^[40,41]

Smooth muscle cells were isolated from the circular muscle layer of the antrum. The mucosa was removed by dissection and the longitudinal muscle layer (with enteric plexus ganglia) was removed in strips using a Stadie-Riggs tissue slicer (Thomas TM). The circular muscle layer was minced and incubated for 45 min twice in Hepes buffer containing collagenase (CLS type II, Worthington) and 0.1 g/L soybean trypsin inhibitor at 31 °C. Partially digested strips were washed with enzyme-free Hanks' medium. Muscle cells were allowed to disperse spontaneously under the gentle force of bubbling 950 mL/L O₂+50 mL/L CO₂ for 30 min (no agitation), and then filtered through 500 µmol/L Nitinol mesh, to the culture media. Viability was checked by trypan blue exclusion test. Aliquots of cells were added to solutions containing the agonists at room temperature. The reaction was stopped after 30 min, by addition of acrolein to the final concentration of 1%. Aliquots were sealed under coverslips. Computerized image analysis (NIH Image 1.62) was used for quantification. A scale slide was used for reference. The length of single muscle cells was measured (at least 50 cells per concentration).

Contractile response of antrum smooth muscle strips to cholinergic agonist

To determine the effect of bethanechol on antrum circular smooth muscle contraction, muscle strips were exposed to the increasing doses of muscarinic agonist, bethanechol, at the concentrations of 10⁻⁴ to 10⁻⁷ mol/L in an organ bath.

Characteristics of effect of extracellular Ca²⁺ and type of calcium channel involved

To determine whether cholinergic contraction depended on the influx of extracellular Ca²⁺, the response to bethanechol chloride in the physiological Krebs buffer was tested, then the buffer was changed into Ca-free buffer (in mmol/L: NaCl 132.5; KCl 4.

7; MgCl₂ 1.0; NaH₂PO₄ 1.2; NaHCO₃ 20.0; D-glucose 10; EGTA (50 µmol/L), and contraction was subsequently recorded after 5 and 10 min.

To characterize the type of calcium channel involved in the cholinergic contraction, nifedipine (an L-type calcium channel antagonist) was used. Nifedipine was dissolved in ethanol and added to the physiological Krebs buffer at the concentration of 10⁻⁵ mol/L^[42] and contraction was recorded. Statistical significance of the difference between contraction in the presence and absence of nifedipine was calculated by paired *t*-test, the results were considered statistically significant at *P* ≤ 0.05.

Treatment with pertussis toxin (PTX)

In order to determine whether PTX-sensitive pathway was involved in cholinergic contraction, strips and dispersed muscle cells (myocytes) isolated from the antrum of PTX-pretreated and non-pretreated animals were compared.

Rats were injected with 100 mg/kg of PTX (dissolved in saline) intraperitoneally 5 d before the study^[43]. Muscle strips from PTX-treated and control rats in the tissue bath were exposed to cholinergic agonist, bethanechol, at the concentration of 10⁻⁴ to 10⁻⁶ mol/L. Statistical significance of the difference between the contraction of the muscle from PTX-pretreated and non-treated rats was defined by non-paired *t*-test, the results were considered statistically significant at *P* ≤ 0.05.

The changes in the pattern of contraction of muscle cells in dispersed cell suspension were also measured (detailed description in the "dispersed muscle cell preparation" section of Materials & Methods). Two concentrations of bethanechol (10⁻⁷ and 10⁻⁸ mol/L) were added to the cell suspensions in the tubes in the physiological buffer. Their contractions were measured as the percentage of the control cell diastolic length^[44]. The mean lengths of cells from control rats were compared to those of the cells from PTX-treated animals. Results were presented as mean ± SE. Statistical significance of the difference was calculated by the paired *t*-test, the results were considered statistically significant at *P* ≤ 0.05.

Characterization of muscarinic receptor subtypes involved

For the characterization of muscarinic receptor subtypes involved in cholinergic contraction we used a non-selective muscarinic agonist, (+)-cis-Dioxolane^[45,46] and relatively specific receptor subtype antagonists.

The conditions of organ bath were described above in the "Smooth muscle strip bath preparation" section of Materials and Methods. At the start of the experimental protocol, the viability of each tissue was assessed by determining the contractile response to bethanechol (10⁻⁴ mol/L). After washed, tissues were re-equilibrated for 10 min and allowed to regain baseline tension. Cumulative concentration-effect curves of (+)-cis-Dioxolane, (10⁻⁸ to 3 × 10⁻⁵ mol/L) were constructed for each tissue. Tissues were then equilibrated in either the absence (control) or presence of the antagonist for 90 min. Subsequently, a second concentration-effect curve to (+)-cis-Dioxolane was constructed. Smooth muscle strips were incubated with increasing concentrations of antagonists demonstrating a relative specificity for M₁, M₂ or M₃ muscarinic receptor subtypes (pirenzepine, methoctramine and darifenacin, respectively). Each antral smooth muscle strip was exposed to only one concentration of antagonists and incubated for 90 min at 37 °C, with a fresh antagonist added to the medium every 30 min^[47,48].

The EC₅₀ values for muscarinic antagonists were obtained (i.e. antagonist concentration resulting in 50% of inhibition of the contraction induced by cholinergic agonist, (+)-cis-Dioxolane (10⁻⁶ mol/L).

Drugs

Tetrodotoxin (TTX), sigmacote, neurokinin A (NKA), nifedipine,

papain, peptidase inhibitors bestatin and phosphoramidon, soybean trypsin inhibitor, acrolein and pirenzepine (predominantly M_1 muscarinic receptor antagonist), were from Sigma, St. Louis, MO.

(+)-cis-dioxolane (cholinergic agonist) and methocramine (predominantly M_2 muscarinic receptor antagonist) were purchased from RBI Inc., Natick, MA. PTX was purchased from List Biological Labs, Inc., Campbell, CA. Bethanechol chloride was purchased from Merck, West Point, PA and collagenase (CLS type II) from Worthington, PA. Darifenacin (predominantly M_3 muscarinic receptor antagonist) was a generous gift from Pfizer Ltd, Sandwich, Kent, GB.

RESULTS

Dose-response curve to cholinergic agonist

A contractile dose-response was observed, when the antral circular smooth muscle strips were exposed to the increasing doses of muscarinic agonist, bethanechol, at the concentrations of 10^{-4} to 10^{-7} mol/L in an organ bath. A significant increase of the tension over the baseline was observed at the bethanechol concentrations of 10^{-4} to 10^{-6} mol/L (Figure 1, $n = 4$).

Figure 1 Effect of bethanechol on smooth muscle contraction. Antrum circular smooth muscle strips were incubated with increasing concentrations of bethanechol (10^{-4} mol/L to 10^{-7} mol/L). The vertical axis represents the developed tension (in grams per mm^2). Bethanechol significantly increased circular muscle tension ($P < 0.05$; paired t -test). Each data point represents mean \pm SE, $n = 4$.

Effect of tetrodotoxin (TTX)

Antrum circular smooth muscle strips were exposed to bethanechol at the concentration of 10^{-5} mol/L, in a buffer containing tetrodotoxin (10^{-5} mol/L), added prior to bethanechol to the organ bath. The cholinergic contraction was not affected by tetrodotoxin, neuronal toxin, with the contraction at $94.9 \pm 3.2\%$ of control.

The lack of inhibition of the contraction by TTX confirmed that a cholinergic agonist could induce contraction via muscarinic receptors present at the smooth muscle, without participation of neuronal factor.

Effect of calcium depletion on cholinergic contraction and characterization of a calcium channel subtype involved

Calcium-free buffer Incubation in calcium-free buffer diminished the antral contractile response to bethanechol (10^{-4} mol/L), with a reduction in response from 2.5 ± 0.4 g/ mm^2 to 1.2 ± 0.4 g/ mm^2 ($P < 0.05$) after 5 min of incubation in calcium-free buffer. After 10 min of incubation in Ca^{2+} -free buffer contractile activity was almost abolished (Figure 2).

Full recovery of the contraction was seen after return of the Ca^{2+} to the tissue bath medium, indicating that there was no damage to the cell resulting in a decreased contraction. These results showed that cholinergic contraction was dependent on the presence of extracellular calcium, a receptor-operated Ca^{2+} or voltage-sensitive Ca^{2+} channels.

Effect of calcium channel blocker The L-type calcium channel blocker, nifedipine at a concentration of 10^{-5} mol/L inhibited the cholinergic contraction response of antrum to the bethanechol, at the concentration of 10^{-4} mol/L from 4.02 ± 0.9 to 0.49 ± 0.18 g/ mm^2 ($P < 0.05$), indicating that the L-calcium channel could mediate this contraction.

Figure 2 Effect of depletion of Ca^{2+} from medium on the contraction of antral circular smooth muscle strips to bethanechol (10^{-4} mol/L). Ca^{2+} depletion caused a significant decrease in the muscle tension; after 5 min incubation ($P < 0.06$, paired t -test); and after 10 min incubation ($P < 0.005$, paired t -test) compared to the base contraction induced by bethanechol before Ca^{2+} depletion. Each data point represents mean \pm SE, $n = 3$.

Identification of G-protein-linked signal transduction pathway by PTX

The response to bethanechol of antral circular muscle strips and dispersed smooth muscle cells from PTX-pretreated and control rats was compared (see Methods).

Smooth muscle strips The contractile response to bethanechol of the muscle strips from the PTX-pretreated animals was significantly lower than that of the muscle strip from the non-treated control rats at all concentrations, 10^{-6} to 10^{-4} mol/L (Figure 3, $P \leq 0.01$).

Figure 3 Effect of PTX on antrum circular smooth muscle strips contraction to bethanechol (10^{-4} mol/L to 10^{-6} mol/L). PTX significantly inhibited the contractile activity of the smooth muscle ($P \leq 0.01$; paired t -test) compared to control rats. Each point represents mean \pm SE, $n = 7$; dotted bars represent control animals; solid bars-PTX-pretreated animals.

The inhibiting effect of PTX on the contraction implied that cholinergic agonist was activating a PTX-sensitive pathway.

A low level of residual contractile activity was observed in the contraction of PTX-treated muscle strips suggesting either that there was a small PTX-insensitive fraction involved, or that the dose of PTX used was insufficient to completely inhibit PTX-sensitive pathways.

Dispersed antral smooth muscle cells When dispersed myocytes from PTX-treated rats and controls were compared, cells from PTX-pretreated rats showed significantly less contraction to

bethanechol than the cells isolated from the rats non-treated with PTX, at both bethanechol concentrations, 10^{-8} and 10^{-7} mol/L (Figure 4, $P \leq 0.005$). The inhibiting effect of PTX on the dispersed myocytes contraction, confirmed the smooth muscle strip data and suggested that the cholinergic agonist involved an occupation of specific muscarinic receptors coupled to PTX-sensitive mediated pathway.

Figure 4 Effect of PTX on dispersed antral circular smooth muscle myocytes from PTX-pretreated rats contraction to bethanechol (10^{-7} mol/L and 10^{-8} mol/L). Myocytes from PTX-treated rats contracted less than myocytes from control rats. Each point represents mean \pm SE; of the percentage of the control cells diastolic length (no bethanechol). At least 50 myocytes per point were calculated, $P < 0.005$; $n = 7$ and 11. Dotted bars represent control animals; solid bars PTX-pretreated animals.

Characterization of the type of muscarinic receptor subtypes involved in contraction to cholinergic agonist To define pharmacologically the muscarinic receptors involved in the cholinergic contraction, specific muscarinic receptor antagonists were used in the presence of tetrodotoxin (10^{-7} mol/L).

For this functional muscarinic receptor study we chose a non-selective cholinergic agonist, (+)-cis-Dioxolane (see Methods), instead of bethanechol, which has been reported to selectively stimulate M_3 receptor^[45,46,49].

Pirenzepine, the M_1 muscarinic receptor antagonist, was used at the concentrations from 3×10^{-5} to 10^{-8} mol/L. Pirenzepine caused a significant inhibition of the of the contractile muscle response to the (+)-cis-dioxolane (Figure 5).

Figure 5 Concentration-response curves for the contractile effect of (+)-cis-Dioxolane alone and in combination with different concentrations of M_1 antagonist, pirenzepine (10^{-8} mol/L to 10^{-5} mol/L) on the rat antral circular smooth muscle strips. Each point represents the mean \pm SE, $n = 6, 6, 7$ and 8 strips. Cumulative concentration-effect curve was constructed for each strip for (+)-cis-Dioxolane, (10^{-8} to 3×10^{-5} mol/L). After washing, strips were equilibrated in either the absence (control) or presence of pirenzepine for 90 min. Subsequently, the second concentration-effect curve for (+)-cis-Dioxolane was constructed for each strip. Pirenzepine caused a significant inhibition of the contractile muscle response to (+)-cis-dioxolane.

Methocramine- M_2 muscarinic receptor antagonist was used at the concentration range between 3×10^{-5} and 10^{-8} mol/L. Methocramine caused a significant inhibition of the of the contractile muscle response to the (+)-cis-dioxolane (Figure 6).

Darifenacin was used at the concentration range from 3×10^{-5} to 10^{-9} mol/L (Figure 7). Darifenacin caused a significant inhibition of the contractile muscle response to the (+)-cis-dioxolane.

Figure 6 Concentration-response curves for the contractile effect of (+)-cis-Dioxolane alone and in combination with different concentrations of M_2 antagonist, methocramine (from 10^{-8} mol/L to 10^{-5} mol/L) on the rat antral circular smooth muscle strips. Each point represents the mean \pm SE; $n = 4, 9, 10$ and 11 strips. First, cumulative concentration-effect curve was constructed for each strip for (+)-cis-Dioxolane, (10^{-8} to 3×10^{-5} mol/L). After washing, tissues were equilibrated in either the absence (control) or presence of methocramine for a 90 min. Subsequently, the second concentration-effect curve for (+)-cis-Dioxolane was constructed for each strip. Methocramine caused a significant inhibition of the contractile muscle response to (+)-cis-Dioxolane.

Figure 7 Concentration-response curves for the contractile effect of (+)-cis-Dioxolane alone and in combination with different concentrations of M_3 antagonist, darifenacin (from 10^{-10} mol/L to 10^{-6} mol/L) on the rat antral circular smooth muscle strips. Each point represents the mean \pm SE; $n = 4, 7, 11, 10$ strips. First, cumulative concentration-effect curve was constructed for each strip for (+)-cis-Dioxolane, (10^{-8} to 3×10^{-5} mol/L). After wash, tissues were equilibrated in either the absence (control) or presence of darifenacin for a 90 min. Subsequently, the second concentration-effect curve for (+)-cis-Dioxolane was constructed for each strip. Darifenacin caused a significant inhibition of the contractile muscle response to (+)-cis-Dioxolane.

Comparison the muscarinic M_1 , M_2 and M_3 receptor antagonists mediating the rat antral circular smooth muscle contraction

All three receptors (M_1 , M_2 and M_3) subtype antagonists inhibited the antral circular muscle contraction to cholinergic agonist (+)-cis-dioxolane. Darifenacin (M_3) was most potent in inhibiting rat antral smooth muscle cholinergic contraction. The dose-response curves were shifted to the right by muscarinic antagonists in the following order of affinity: darifenacin (M_3)

>methocramine (M_2) >pirenzepine (M_1). The EC_{50} for each antagonist was as follows: darifenacin 7.9, methocramine 7.2 and pirenzepine 6.8 (Figure 8).

Figure 8 Comparison of the inhibition of the contractile response to cis-Dioxolane by 3 muscarinic receptor antagonists: M_3 - darifenacin, M_2 - methocramine, and M_1 - pirenzepine. The M_3 antagonist, darifenacin, was the most potent inhibitor of the contraction induced by (+)-cis Dioxolane (10^{-6} mol/L). The EC_{50} values for each were: for darifenacin (M_3) -7.9; for methocramine (M_2) -7.2; and for pirenzepine (M_1) -6.8.

DISCUSSION

It is well established that cholinergic agonists are of major importance for the stimulation of antral smooth muscle contraction and that their effect is mediated by muscarinic receptors. In various smooth muscle cells, the action of cholinergic agonists involved the occupation of specific receptors, activation of receptor-coupled G-proteins and subsequent activation of the second messenger systems, which would lead to the mobilization of Ca^{2+} from intracellular storage pools^[10]. Certain steps of the signaling pathway (s) for the cholinergic contraction of antral circular smooth muscle in rats are still not understood, for example, the second messenger system or the functional characteristics of the muscarinic receptor subtypes involved. In our study the cholinergic rat antral circular muscle contraction *in vitro* was sensitive to the depletion from the extracellular Ca^{2+} that significantly diminished the cholinergic contraction. This finding along with the inhibitory effect of nifedipine indicated a dependence on extracellular Ca^{2+} influx via L-type calcium channels^[50].

It is still not clear whether cholinergic contractile pathways of antral circular smooth muscle are mediated by PTX-sensitive GTP-binding protein through an increased inflow of extracellular calcium, or mediated via PTX-insensitive, inositol triphosphate (IP_3)-dependent pathway. The circular muscle of cat esophagus and the lower esophageal sphincter (LES) were reported to be linked to different pathways. LES circular muscle cholinergic contraction was shown to be linked to the PTX-insensitive pathway, whereas esophageal circular muscle cholinergic contraction has been reported to be linked to the PTX-sensitive pathway^[11-14].

In the present study, pretreatment with PTX significantly inhibited the contractile response to bethanechol of the antral smooth muscle strips in the organ bath and of the dissociated myocytes.

More than one muscarinic receptor may be responsible for cholinergically mediated contractility at a particular area^[6,22,51-56]. A major role for M_3 and a minor role for M_2 receptors in cholinergic-induced smooth muscle contraction have been shown at the tissue of various species and organs^[57-59], but it is still not clear how different receptors may interact to mediate a specific function. For example, M_2 receptor might serve as an inhibitory presynaptic autoreceptor^[60], or M_2 receptor could act by gating cation channels that were subsequently modulated by M_3 receptors^[61].

The functional characteristics of muscarinic receptor subtypes regulating antrum circular muscle cholinergic contraction have not been previously reported. In our functional studies, cholinergic contraction in response to cis-dioxolane in rat antral circular muscles was mediated mostly through M_3 , less by M_2 , and the least by M_1 muscarinic receptor subtypes.

The involvement of PTX-sensitive GTP-binding proteins in mediating the contractile response to muscarinic agonists has been reported to be linked to muscarinic M_2 receptor in many studies, such as in cat esophageal circular muscle^[11,12]. In contrast, our experiments in rat antral circular muscles indicated that the M_3 muscarinic receptor was functionally prevalent, and yet, PTX-sensitive pathways were shown to be activated in the process of antral cholinergic contraction. A few published reports were in agreement with our results^[13,22,26].

Possible explanations of the reported differences include: (1) Different experimental systems were used to compare the homogenous suspension of smooth muscle cells was compared with smooth muscle strips. (2) M_3 and M_2 receptors were expressed together at the shared site of the signaling pathways^[22,54,57,60,62]. (3) The cholinergic agonist (+/- cis-Dioxolane) was used in our studies. Although, it has been reported to be non-selective^[46,48,52], +/- cis-Dioxolane might be more selective for M_3 muscarinic receptor than it was originally described^[63]. (4) It has been suggested that seven transmembrane spanning receptors including muscarinic are promiscuous in that they could form interactions with multiple G-proteins^[64] or activate many different transduction pathways at the same time^[65]. (5) M_2 receptor might be masked by M_3 receptor, thus detectable when M_3 receptor was inhibited. Separating out these possibilities would require more specific antagonists than the currently available.

In conclusion, the rat antral circular smooth muscle contracts to cholinergic agonists (bethanechol chloride and (+)-cis-Dioxolane) in a dose-dependent fashion through activation of muscarinic receptors at the smooth muscle. The contractile responses to cholinergic agonists are dependent on the increase in intracellular calcium induced by the influx of extracellular calcium via L-type voltage gated calcium channels. Bethanechol activates M_3 and M_2 muscarinic receptors coupled to pertussis-toxin sensitive GTP-binding protein (s). The presence of a residual contractile cholinergic response after 5 and 10 min in calcium-free buffer, as well as a residual contractile response after the treatment with nifedipine, suggests a role for an additional pathway (s). M_3 receptor is predominant out of three functionally tested M_1 , M_2 , and M_3 muscarinic receptors regulating cholinergic contraction. The involvement of more than one muscarinic receptor indicates more than one pathway (s) regulating the cholinergic contraction of rat antrum circular smooth muscle.

The results of these studies have important clinical implications for possible treatment of gastric dysfunction with muscarinic subtype-selective agents.

ACKNOWLEDGEMENTS

Authors would like to thank John Ellis, Ph.D, for helpful discussions. An excellent technical assistance of Rohini Polavarapu is acknowledged.

Abstract

AIM: To investigate coxsackievirus B₃ infection and its gene mutation in Keshan disease.

METHODS: The expression of Coxsackievirus B₃ RNA was detected in autopsy specimens of acute (12 cases), sub-acute (27 cases) and chronic (15 cases) Keshan disease by *in situ* hybridization. In sub-acute Keshan disease specimens, 3 cases with positive result by *in situ* hybridization were selected RT-PCR analysis. The DNA segments were then sequenced.

RESULTS: Coxsackievirus B₃ RNA was detected in the cytoplasm of myocardiocyte. The positive rate was 83% in acute, 67% in sub-acute and 80% in chronic Keshan disease. In the conservative region of Coxsackievirus B₃ genome, there was a mutation in 234 (C-T) compared to the non-cardiovirulent strain, CVB_{3/0}.

CONCLUSION: Coxsackievirus B₃ RNA can survive and replicate in heart muscle of Keshan disease, which may play an important role in the occurrence of Keshan disease. The possible mechanism of occurrence of Keshan disease is associated with point a mutation in Coxsackievirus B₃ genome.

INTRODUCTION

Enteroviruses, particularly Coxsackie B viruses (CVB), are the most common cause of human viral myocarditis and are associated with dilated cardiomyopathy (DCM)^[1-3]. In general, neonates and children suffer more severe clinical syndromes due to CVB infection, often severe or life threatening, because of inflammation and necrosis of heart muscle^[4]. Many diseases are considered to have relationship with CVB₃ infect, but the mechanism is still not well understood. Although the immune response of the host undoubtedly plays an important role in the pathogenesis of viral heart disease^[5], direct viral cytotoxicity has been found to be crucial for organ pathology both during acute and persistent heart muscle infection. Coxsackievirus B₃ (CVB₃), one of six CVB serotypes, is a member of the genus *enterovirus* within the family *Picornaviridae* and its structure is well understood^[6,7].

Some studies suggest that the 5'NTR of enteroviruses maybe play an important role in producing or sustaining the myocardial virulence^[8-14].

Keshan disease is endemic exclusively in selenium-deficient rural areas of China, including 14 provinces and autonomous regions^[15]. Its clinical features are low body selenium content and acute or chronic episodes of heart disorder characterized by cardiogenic shock, arrhythmia, ECG changes (for example, right branch block), and/or congestive heart failure, with an enlarged heart. Four types of the disease are seen: acute, subacute, chronic, and latent or compensated. The basic pathological change is multifocal myocardial necrosis and fibrous replacement throughout the myocardium, with various degrees of cellular infiltration and calcification, depending upon the type of disease^[16,17]. Research suggests that not a single but several more factors may have a relationship with the occurrence of Keshan disease. The reasons are often considered as global, biological chemical factors (selenium deficiency), dietary nutritional factors (vitamin E deficiency) and infection (virus, especially enteroviruses). This hypothesis can explain both endemic and seasonal features of Keshan disease. Recent studies have also demonstrated a possible etiological role of enterovirus infection in a particular form of heart muscle disease, selenium deficiency-related endemic cardiomyopathy (Keshan disease), seen in China^[18,19]. Presently, patients of Keshan disease are rare and there is no ideal animal model, research of viral etiology of Keshan disease is relatively few. In this study, we detected all the four types of Keshan disease using *in situ* hybridization and sequenced the 5'NTR of CVB₃ from subacute Keshan disease in order to investigate the relationship between Keshan disease and CVB₃ infection.

MATERIALS AND METHODS

Case selected

All the samples were cardiac tissue isolated at post mortem and fixed in formaldehyde and embedded in paraffin wax and preserved in Institute of Keshan Disease, Jilin University from 1959-1985. The samples included 12 acute patients (7 males, 5 females, average age 16.3 years), 27 subacute patients (12 males, 15 females, average age 4.3 years) and 15 chronic patients (9 males, 6 females, average age 23.8 years). We used three non-Keshan disease patients as controls, including two normal and one perinatal period cardiomyopathy. The cultured human amniotic cell containing a cardiovirulent strain of CVB₃ served as positive control and by RT-PCR.

In situ Hybridization

An oblongonucleotide probe was purchased from Shanghai Sangon Biological Engineering Company. This probe, labeled with biotin, was designed to detect coxsackievirus B₃, whose sequence was 5'-GTC CGC AAT GGC GGG CGG TGG TGG TGT CTC-3'.

All slides were treated by APES solution (1:50 acetone) in order to prevent the section slipping from the slide. The 5 μm thick section was baked 3-4 h at 80 °C and overnight at 60 °C.

The paraffin wax was removed by immersing the slide in xylene. The slides were then rehydrated, treated with 0.1 g/L Triton X-100 for 2 min, digested with proteinase K (0.25 mg/mL) in PBS for 5 min at room temperature, then sealed with histidine (2 mg/mL) for 2 min, and then dehydrated in graded concentrated

ethyl alcohol. The tissue sections were denatured on heating block for 2 min at 80 °C and then cooled on ice immediately. They were pre-hybridized for 3-4 h at 42 °C by covering them with pre-hybridization liquid (6×SSC, 5×Denhardt, 5 g/L SDS, 100 µg/mL herring sperm DNA, 500 g/L deionized formamide) in a wet chamber. After removal of the pre-hybridization liquid, the sections were allowed to hybridize overnight under the same conditions as described above.

Following the hybridization, the slides were rinsed twice with 2×SSC containing 500 g/L deionized formamide, twice with 2×SSC, treated with 1 g/L Triton X-100 for 2 min and washed twice with buffer I (1 mol/L NaCl, 0.1 mol/L Tris, pH 7.5). Buffer II (3 g bovine serum albumin dissolved in buffer I) was added to each section and incubated for 1 h. After pouring off buffer II, the SA-AP (streptavidin-alkaline phosphatase conjugation) was added onto the tissue sections, and allowed to react in this mixture for 20 min, rinsed with buffer I and then with buffer III (0.1 mol/L NaCl, 0.1 mol/L Tris-Cl, 50 mmol/L MgCl₂, pH 9.5). Finally, freshly prepared developer solution (BCIP/NBT) was applied to the slides and incubated for 30 min to 4 h. A brownish blue color reaction was produced. Following routine dehydration, the sections were cleared and mounted.

To assess the specificity of the hybridization signal, the culture cell infected by CVB₃ were alternatively hybridized with the labeled oblongonucleotide probe encoding CVB₃ before and after digestion by Rnase, and hybridization solution without containing the labeled oblongonucleotide probe encoding CVB₃ was also used as negative control.

RT-PCR

Total RNA was extracted from paraffin-embedded heart tissue of patients with Keshan disease according to the following procedures. Several section slices (5-10 µm) were put into a 1.5 mL Eppendorf tube in which approximately 1 mL xylene was added in order to exclude paraffin. The xylene was changed every 2 h and the last time it was kept overnight at room temperature. After being centrifuged at 5 000 r/min for 5 min, the tissue was washed with non-water ethanol and then baked at 55 °C. The total RNA from the dried tissue was then extracted using Trizol reagent (GIBCO). Positive controls were the cultured human amniotic cells containing CVB₃. The RNA precipitate was dissolved in 10 µL of diethyl pyrocarbonate-treated H₂O.

The enterovirus specific primers used for RT-PCR and sequencing of the 5'NTR were purchased from Sigma Genosys Australia Pty. Ltd. The sequence of the primers was 3P: 5'-TCA ATTGTC ACCATA AGCAGCAGCCA-3' and 5P: 5'-CGG TAC CTTTGTGCCCTGTTT-3'.

RT was carried out following the manufacturer's instructions. A 2 µL of specific primer 3P and 1 µL of 10 mmol/L dNTPs were mixed with 8 µL of RNA template. The mixture was immediately put on ice after incubated at 65 °C for 5 min. Then the mixture of 4 µL of 5×first strand buffer, 1 µL of Rnase inhibitor, 1 µL Superscript II Rnase H-free reverse transcriptase and 3 µL of diethyl pyrocarbonate-treated H₂O was added to the reaction tube, followed by incubation at 42 °C for 5 min, and at 70 °C for 15 min in order to inactivate the reverse transcriptase.

PCR was carried out with a 25 µL mixture containing 10 pmol deoxynucleotide triphosphates, 15 pmol forward primer (5P), 15 pmol reverse primer (3P), 1×reaction buffer (Dingguo Biocompany), and 3 µL of the RT reaction product. The PCR reaction mixture was pre-denatured at 95 °C for 2 min, and then amplified through 30 cycles, each cycle consisting of denaturation at 95 °C for 45 s, annealing at 55 °C for 45 s, and extension at 72 °C for 45 s. Finally, an additional extension was carried out at 72 °C for 10 min. A negative control containing 22 µL of the reaction mixture plus 3 µL of autoclaved H₂O and a positive control containing 22 µL of the reaction mixture plus 3 µL of the RT reaction product from cells infected with the virulent laboratory strain

of CVB₃ were included in each set of PCR.

The amplification products of PCR were analyzed on 17 g/L agarose gel by electrophoresis and stained with ethidium bromide. To assess the specificity of RT-PCR, the extracted total RNA were digested by Rnase then used for PCR as template. The distilled water was also used as template in PCR reaction as negative control.

DNA sequencing

The sequencing reaction cycle was carried out using 4 µL of DNA polymerase FS-terminator mix (PE-ABI), 3.2 mmol/L primer, and 5 ng of PCR product per 100 bp length of template DNA with the volume made up to 10 µL with H₂O. Reactions were run for 25 cycles as follows: 96 °C for 30 s, 50 °C for 15 s, and 60 °C for 4 min. DNA was precipitated, dissolved in loading buffer (167 g/L formamide, 733 g/L dextran), and separated on 41 g/L denaturing polyacrylamide gel on an ABI model 377 DNA sequencer. This procedure was performed by Shanghai Sangon Biological Engineering Company.

RESULTS

In situ Hybridization

According to the feature of positive signal of the culture cell, the positive hybridization signals of the Cocksackievirus RNA appeared as deep brownish blue mass or granules (Figure 1). This criterion was applied to the tissue sample. In longitudinal sections, they were seen to adhere to myofibrils in one or several strings of beads (Figure 2A). They varied in size and, in cross section, were usually localized in the sarcoplasm in proximity to myocyte nuclei, but no signals were found in the nuclei themselves. The color of signal was the darkest in the myocardium of papillary muscles, trabeculae carneae and subendocardial muscle. It was lighter and less intense in the cells of the outer layers than those in the middle layers of ventricular walls. The myocardial cells surviving in fresh lesions and surrounding old necrotic foci often showed the hybridization signal. No signal was found in necrotic foci, and there were slight differences in the distribution and manifestation of positive hybrid signals in several types of Keshan disease. In most acute and subacute

Figure 1 Positive signal in cultured cell A: the positive hybridization signals of the Cocksackievirus RNA appeared as deep brownish blue mass or granules (arrow) B: control, only hybridization solution was applied.

Figure 2 Positive signal of *in situ* hybridization in subacute myocardial tissue A: Feature positive signal of *in situ* hybridization with cardiac tissue is seen as deep brownish blue and seems to adhere onto myofibril, linked together in one or several strings of beads, when observed longitudinally ($\times 400$). B: The granules of positive signal were thick and with clear border in varying size and localized in the sarcoplasm.

cases, the signal appeared predominantly in the myocyte surrounding foci and surviving in fresh foci as well as cells beneath the endocardium and of papillary muscles. The hybridization-positive granules were thick, and had clear border. The sarcoplasm appeared dark, and sometimes, homogeneously blue (Figure 2B). In most of the chronic cases, the granules were usually distributed in all parts of the myocardium, and were small and without clear borders, like dirt. The detection rate in subacute specimens was the highest, and the rate in acute specimens was higher than that in chronic specimens, but there were no significant differences among the three types of Keshan disease.

The positive rate of hybridization in the three type of Keshan disease was 83% (10/12) in acute, 67% (18/27) in sub-acute and 80% (12/15) in chronic Keshan disease. No positive signals were found in any negative controls.

Results of 3 myocardial control specimens investigated with *in situ* hybridization were negative.

RT-PCR

RT-PCR revealed that the RNA extracted from the myocardial tissue with positive control of *in situ* hybridization amplified a DNA fragment about 541 bp, while the three negative controls did not amplify (Figure 3). The RNA extracted from cultured cell infected by CVB₃ were also amplified the DNA fragment about 541 bp.

Figure 3 Agarose gel electrophoresis results Lanes 1, 2, 3: negative control; Lanes 4-6: subacute Keshan disease; Lanes 7: positive control; Lane 8: DL-2000 DNA Marker. A 541 bp DNA segment can be seen in lanes 4-7.

Sequence analysis

The DNA segments from RT-PCR were sequenced and compared to the non-cardiovirulent control, CVB_{3/0}, and the cardiovirulent strain, CVB_{3/Nancy} and CVB_{3/20}. We found that the sequence of the amplified segment had one nucleotide different compared to that of CVB_{3/0}. The 234th nucleotide in the genome of CVB_{3/0} was C while ours was T. But the sequence of our segment was similar that of CVB_{3/Nancy}, CVB_{3/20} and the positive control (Figure 4).

DISCUSSION

Keshan disease has been studied for over 60 years in China. One of the key issues is the complex etiology of this endemic disease, with a focus on environmental nutritional factors and infectious agents. Selenium deficiency in the food chain has been recognized as a major but not exclusive environmental-nutritional factor, and increasing evidence supports an etiological role of enteroviruses in Keshan disease. Recently, Peng *et al.*^[20] determined the sequences of the 5'NTR and the 3' end of the VP1 coding region from six enteroviruses isolate from cases of Keshan disease or outbreak myocarditis. From their results, they drew a conclusion that the sequence data confirm that coxsackievirus group B serotypes are predominant in the region where Keshan disease is endemic, and may be the etiological factors in outbreaks of myocarditis, and VP1 genotyping of enteroviruses is accurate and reliable. Animal experiments indicate that isolates may differ in pathogenicity. Virus infection combined with selenium deficiency in environments and vitamin E deficiency in dietary can illustrate both endemic and seasonal features of Keshan disease. The hypothesis of virus infection was accepted once it appeared, but the methods used in virology limited the development of a virus infection hypothesis of Keshan disease. The rapid development in molecular biology brings vitality to virology.

In situ hybridization is a method to detect the nucleic acids in a tissue or cell using a labeled oblongonucleotide chain as probe. This technique has already been widely used in biology and medicine because of its high specificity, sensitivity and location precision. Using a cloned cDNA probe obtained from CVB₄ infected cells and labeled by biotin-11-dUTP, Easton *et al.*^[21] found that 46% (6/13) patients who had been diagnosed coxsackievirus myocarditis can be found enterovirus infection in their myocardial tissue. Archard *et al.*^[22] examined enteroviruses

Figure 4 Sequence of segment of RT-PCR Compared to the nonvirulent strain of CVB_{3/0}, there was one nucleotide different (arrow). The nonvirulent strain of CVB_{3/0} was C while ours was T.

infection in human myocardial tissue using an enterovirus specific probe, and found that the rate of enterovirus infection was 45% (21/47) in myocarditis patients and 43% (35/82) in cured myocarditis and DMC patients. In our research, the specific oblongonucleotide probe of CVB₃ was labeled by biotin on 5' end, and the specimen was paraffin-embedded myocardial tissue from autopsy patients of Keshan disease. The object was to detect the coxsackievirus B₃ RNA by *in situ* hybridization. Among the three types of Keshan disease patients, we found the positive rate was 83%, 67%, and 80% in acute, sub-acute and chronic Keshan disease patients, respectively. Our results provide a new support to the hypothesis that enterovirus, especially CVB₃, might play an important role in pathogenesis of Keshan disease. Moreover, the area, range and the distribution of the positive signal of CVB₃ were associated with the development of Keshan disease. The positive signals in acute and sub-acute Keshan disease were located in the surviving myocardiocyte in or around the necrosis foci while they were dispersed in almost all the myocardiocyte in chronic Keshan disease. The results of *in situ* hybridization suggested that enterovirus could lead to heart muscle lesion when they involved in the myocardial tissue, and they can dispersed to the normal heart muscle with increase of time.

Though there was a high enterovirus infection rate in myocardial tissue of Keshan disease patients^[23,24], it is well known that the enterovirus could also be detected in many patients who had no heart muscle lesion. The change of viral cardiovirulence can undoubtedly play an important role. Some research has demonstrated that under some conditions, such as selenium deficiency, vitamin deficiency, the phenotype of enterovirus can be changed, that is, a non-cardiovirulent strain can change into a cardiovirulent strain, or the cardiovirulence can be increased in these conditions^[25-27]. Beck *et al.*^[28] sequenced the mutated strain, CVB₃₀Se, which was extracted from the heart muscle of selenium deficient mice, and found that there were six mutation points in CVB₃₀Se- and compared to the two-cardiovirulent strains, CVB_{3/20}, CVB_{3/MI}, all mutated points were turned into that of a cardiovirulent strain. Can the same episodes also happen in Keshan disease patients? In our research, we found an about 541 bp DNA segment by RT-PCR. Compared to CVB_{3/0}, a non-cardiovirulent strain, the sequence of our segment had only one nucleotide different, which was 234 T. But the segment had the same sequence as that of CVB_{3/Nancy} and CVB_{3/20}, cardiovirulent strain. This result can give us some indications that the mutation of virus genome might play an important role in the pathogeny of Keshan disease. But this needs to further investigation.

As we know that RNA is degraded easily, so its detection is difficult, especially in paraffin-embedded tissue^[29,30]. But the paraffin-embedded myocardial tissue we select have been kept in our institute for a long time (10-50 years), and are generally thought not to be optimal for RNA research, but our results displayed that results of both *in situ* hybridization and RT-PCR were satisfactory.

Abstract

AIM: To investigate the effect of actin microfilament on potassium current and hyposmotic membrane stretch-induced increase of potassium current in gastric antral circular myocytes of guinea pig.

METHODS: Whole-cell patch clamp technique was used to record potassium current in isolated gastric myocytes.

RESULTS: When the membrane potential was clamped at -60 mV, an actin microfilament disruptor, cytochalasin-B (Cyt-B, 20 μ mol/L in pipette) increased calcium-activated potassium current ($I_{K(Ca)}$) and delayed rectifier potassium current ($I_{K(V)}$) to $138.4 \pm 14.3\%$ and $142.1 \pm 13.1\%$ respectively at +60 mV. In the same condition, an actin microfilament stabilizer phalloidin (20 μ mol/L in pipette) inhibited $I_{K(Ca)}$ and $I_{K(V)}$ to $74.2 \pm 7.1\%$ and $75.4 \pm 9.9\%$ respectively. At the holding potential of -60 mV, hyposmotic membrane stretch increased $I_{K(Ca)}$ and $I_{K(V)}$ by $50.6 \pm 9.7\%$ and $24.9 \pm 3.3\%$ at +60 mV respectively. In the presence of cytochalasin-B and phalloidin (20 μ mol/L, in the pipette) condition, hyposmotic membrane stretch also increased $I_{K(Ca)}$ by $44.5 \pm 7.9\%$ and $55.7 \pm 9.8\%$ at +60 mV respectively. In the same condition, cytochalasin-B and phalloidin also increased $I_{K(V)}$ by $23.0 \pm 5.5\%$ and $30.3 \pm 4.5\%$ respectively. However, Cyt-B and phalloidin did not affect the amplitude of hyposmotic membrane stretch-induced increase of $I_{K(Ca)}$ and $I_{K(V)}$.

CONCLUSION: Actin microfilaments regulate the activities of potassium channels, but they are not involved in the process of hyposmotic membrane stretch-induced increase of potassium currents in gastric antral circular myocytes of guinea pig.

INTRODUCTION

Cytoskeleton is an intracellular superstructure that consists of microfilaments of actin and associated proteins, microtubules,

and intermediate filaments. Actin microfilaments of the cytoskeleton form a complex network, providing the structural basis for simultaneous interactions between multiple cellular structures. It is well established that many ion channels and transporters are anchored in the membrane by either direct or indirect association with the cytoskeleton. In addition, there is growing evidence that altering the integrity of cytoskeletal elements, in particular actin microfilaments, could modulate the activity of a variety of ion channels^[1] and receptors^[2]. Many previous studies have demonstrated that actin microfilament could mediate different types of potassium channels of a variety of cells such as those in rat collecting duct^[3], smooth muscle cell line DDT1 MF-2^[4], cardiac myocytes of guinea pig^[5], human meningioma cells^[6], rat hippocampal CA1 pyramidal neurons^[7], rat ventricular myocytes^[8] and xenopus oocytes^[9]. Wang *et al.*^[10] reported that neither the microfilaments nor the microtubules were involved in the enhancement of $I_{K(V)}$ induced by cell distension in ventricular muscle cells of guinea pig. However, Ribeiro *et al.*^[11] showed that microtubule was involved in the cell volume-induced changes in K⁺ transport across the rat colon epithelial cells. Our previous study demonstrated that main outward current was carried by calcium-activated potassium channel and delayed rectifier potassium channel in gastric antral circular myocytes of guinea pig and hyposmotic cell swelling enhanced the activity of that two kinds of potassium channel^[12,13]. In order to investigate the mechanism of hyposmotic membrane stretch-induced increase of potassium current, in the present study, the effect of actin microfilament on potassium currents was observed and the possibility whether actin microfilament was involved in the process of hyposmotic membrane stretch-induced increase of potassium currents was examined.

MATERIALS AND METHODS

Single cell preparation and electrophysiological recording

Fresh, single smooth muscle cells (SMCs) were isolated enzymatically from the circular layer of guinea pig antrum as previously described^[14]. Isolated SMCs were stored at 4 °C KBS until the time of use. All experiments were performed within 12 h after cell dispersion. The isolated cells were transferred to a small chamber (0.1 mL) on the stage of an inverted microscope (IX-70 Olympus, Japan) for 10-15 min to settle down. Solution was perfused at a speed of 0.9-1.0 mL/min through the chamber by gravity from the 8-channel perfusion system (L/M-sps-8; list electronics, Germany). Glass pipette with a resistance of 3-5 M Ω was used to make a giga seal of 5-10 G Ω the whole-cell currents were recorded with an Axopatch 1-D patch-clamp amplifier (Axon Instrument, USA).

Drugs and solution

Tyrod solution containing (mmol/L) NaCl 147, KCl 4, MgCl₂·6H₂O 1.05, CaCl₂·2H₂O 0.42, Na₂PO₄·2H₂O 1.81, and 5.5 mmol/L glucose was used. Ca²⁺-free PSS containing (mmol/L) NaCl 134.8, KCl 4.5, glucose 5, and N-[2-hydroxyethyl] piperazine- N-[2-ethanesulphonic acid] (HEPES) 10 was adjusted to pH 7.4 with Tris [hydroxymethyl] aminomethane (TRIZMA). Modified K-B solution containing (mmol/L) L-glutamate 50, KCl 50, taurine 20, KH₂PO₄ 20, MgCl₂·6H₂O 3, glucose 10, HEPES 10 and egtazic

acid 0.5 was adjusted to pH 7.40 with KOH. Isosmotic solution (290 mOsm/L) containing (mmol/L) NaCl 80, KCl 4.5, HEPES 10, $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ 1, $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ 2, Glucose 5, Sucrose 110, was adjusted to pH 7.4 with Tris. Hypoosmotic solution (200 mOsm/L) contained (in mmol/L) sucrose 30, and other ingredients was the same as the isosmotic solution. Pipette solution recording $I_{\text{K}(\text{Ca})}$ contained (mmol/L) potassium-aspartic acid 110, Mg-ATP 5, HEPES 5, $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ 1.0, KCl 20, egtazic acid 0.1, di-tris-creatine phosphate 2.5, disodium-creatine phosphate 2.5 and its pH was adjusted to 7.3 with KOH. Pipette solution recording $I_{\text{K}(\text{V})}$ contained (mmol/L) EGTA 10, and other ingredients was the same as the pipette solution recording $I_{\text{K}(\text{Ca})}$. Cytochalasin-B was dissolved in dimethyl sulphoxide (DMSO, 20 mmol/L) and phalloidin was dissolved in alcohol (1 mmol/L). The same amount of DMSO or alcohol as the final experimental solution was added to the pipette solution. All the chemicals in this experiment were purchased from Sigma (USA).

Data analysis

All data were expressed as mean \pm SD. Statistical significance was evaluated by a *t*-test. Differences were considered to be

significant when *P* value was less than 0.05.

RESULTS

Effect of Cyt-B and phalloidin on $I_{\text{K}(\text{Ca})}$

Under the whole cell configuration, the membrane potential was clamped at -60 mV, $I_{\text{K}(\text{Ca})}$ was elicited by step voltage command pulse from -40 mV to +100 mV for 440 ms with a 20 mV increment at 10 s intervals. An actin microfilament disruptor, Cyt-B (20 $\mu\text{mol/L}$ in pipette) markedly increased $I_{\text{K}(\text{Ca})}$ to $138.4 \pm 14.3\%$ at +60 mV ($n = 15$, Figures 1B, C). In the same condition, an actin microfilament stabilizer, phalloidin (20 $\mu\text{mol/L}$ in pipette) inhibited $I_{\text{K}(\text{Ca})}$ to $74.2 \pm 7.1\%$ at +60 mV ($n = 15$, Figures 2B, C).

Effect of Cyt-B and phalloidin on $I_{\text{K}(\text{V})}$

Under the whole cell configuration, the membrane potential was clamped at -60 mV, $I_{\text{K}(\text{V})}$ was elicited by step voltage command pulse from -40 mV to +80 mV for 440 ms with a 20 mV increment at 10 s intervals. Cyt-B (20 $\mu\text{mol/L}$ in pipette) markedly increased $I_{\text{K}(\text{V})}$ to $142.1 \pm 13.1\%$ at +60 mV ($n = 12$, Figures 3B, C). In the same condition, phalloidin (20 $\mu\text{mol/L}$ in pipette) inhibited $I_{\text{K}(\text{V})}$ to $75.4 \pm 9.9\%$ at +60 mV ($n = 12$, Figures 4B, C).

Figure 4 Effect of phalloidin on $I_{K(Ca)}$. A: Representative current trace of $I_{K(Ca)}$. B: I/V relationship of $I_{K(Ca)}$. C: Phalloidin inhibited $I_{K(Ca)}$ in isosmotic condition. ($n = 15$, $^aP < 0.05$, $^bP < 0.01$ vs control).

Figure 5 Effect of hyposmotic membrane stretch on $I_{K(Ca)}$. A: Representative current trace of $I_{K(Ca)}$. B: I/V relationship of $I_{K(Ca)}$. C: Hyposmotic membrane stretch increased $I_{K(Ca)}$. ($n = 15$, $^aP < 0.05$, $^bP < 0.01$ vs control).

Figure 6 Effect of hyposmotic membrane stretch on $I_{K(V)}$. A: Representative current trace of $I_{K(V)}$. B: I/V relationship of $I_{K(V)}$. C: Hyposmotic membrane stretch increased $I_{K(V)}$. ($n = 15$, $^aP < 0.05$, $^bP < 0.01$ vs control).

Figure 7 Effect of Cyt-B and phalloidin on hyposmotic membrane stretch-increase of $I_{K(Ca)}$. A, B and C: I/V relationship of $I_{K(Ca)}$. ($n = 15$, $^aP < 0.05$, $^bP < 0.01$ vs 290 mOsm). D: No effect of Cyt-B and phalloidin on the increased of $I_{K(Ca)}$ induced by hyposmotic membrane stretch ($n = 15$).

Figure 8 Effect of Cyt-B and phalloidin on hypotonic membrane stretch-increase of $I_{K(V)}$. A, B and C: I/V relationship of $I_{K(V)}$. ($n = 12$, $^aP < 0.05$, $^bP < 0.01$ vs 290 mOsm). D: No effect of Cyt-B and phalloidin on the increased of $I_{K(V)}$ induced by hypotonic membrane stretch ($n = 12$).

Effect of hypotonic membrane stretch on $I_{K(Ca)}$ and $I_{K(V)}$

Using the same pulse protocol, the effect of hypotonic membrane stretch on $I_{K(Ca)}$ and $I_{K(V)}$ was observed. When the cells were superfused with hypotonic solution (200 mOsm/L), step command pulse-induced $I_{K(Ca)}$ increased from 0 mV (Figure 5B) and the increasing amplitude was $50.6 \pm 9.7\%$ at +60 mV ($n = 15$, Figure 5C). In the same condition, hypotonic superfusing increased step command pulse-induced $I_{K(V)}$ from +40 mV (Figure 6B) and the increasing amplitude was $24.9 \pm 3.3\%$ at +60 mV ($n = 12$, Figure 6C).

Effect of Cyt-B and phalloidin on hypotonic membrane stretch-induced increase of $I_{K(Ca)}$

To determine the possibility of actin microfilament involved in hypotonic membrane stretch-induced increase of $I_{K(Ca)}$, the effects of Cyt-B and phalloidin on $I_{K(Ca)}$ in which cells were perfused with isosmotic and hypoosmotic solutions were observed respectively. Hypotonic membrane stretch increased $I_{K(Ca)}$ from 0 mV (Figure 7A) and the increasing amplitude was $50.6 \pm 9.7\%$ at 60 mV in the control group ($n = 15$, Figures 7A, 8D). In the presence of Cyt-B and phalloidin (20 $\mu\text{mol/L}$ in pipette) hypotonic membrane stretch also increased $I_{K(Ca)}$ by $44.5 \pm 7.9\%$ ($n = 15$, Figures 7B, D) and $55.7 \pm 9.8\%$ ($n = 15$, Figures 7C, D) at +60 mV respectively. There was no significant difference between control group and Cyt-B group or phalloidin group.

Effect of Cyt-B and phalloidin on hypotonic membrane stretch-induced increase of $I_{K(V)}$

Hypotonic membrane stretch increased $I_{K(V)}$ by $24.9 \pm 3.3\%$ at +60 mV in the control group ($n = 12$, Figures 8A, D). In the presence of Cyt-B and phalloidin (20 $\mu\text{mol/L}$ in pipette) hypotonic membrane stretch also increased $I_{K(V)}$ by $22.9 \pm 5.5\%$ ($n = 12$, Figures 8B, D) and $30.3 \pm 4.5\%$ ($n = 12$, Figures 8C, D) at +60 mV respectively. There was no significant difference between control group and Cyt-B group or phalloidin group.

DISCUSSION

Cytoskeleton is an intracellular superstructure that consists of

microfilaments of actin and associated proteins, microtubules, and intermediate filaments. Actin microfilament, in particular, are involved in structural support and a functional role in cell motility^[15]. Recent evidence indicated, however, actin-based cytoskeleton was involved in the control of ion channel activity across the plasma membranes of different cell types. For example, actin microfilaments were implicated in the regulation of sodium channels in human jejunal circular smooth muscle cells^[16] and ATP-sensitive potassium channel in ventricular myocytes^[5, 17]. Actin microfilaments could also regulate voltage-dependent channels, for example, actin microfilaments could mediate voltage-dependent epithelial sodium channels in neuron cells^[18].

It was proposed that cell surface proteins and extra cellular matrix were linked to the cytoskeleton by transmembrane proteins and modulate ion channels and enzymes by mechanical deformation under physiological conditions. In the present study, we observed that an actin microfilament disruptor, Cyt-B increased $I_{K(Ca)}$ and $I_{K(V)}$ significantly (Figures 1B, C, Figures 3B, C). However, an actin microfilament stabilizer, phalloidin inhibited $I_{K(Ca)}$ and $I_{K(V)}$ markedly (Figures 2B, C, Figures 4B, C) in gastric myocytes. These results suggested that when actin microfilaments were disrupted, $I_{K(Ca)}$ or $I_{K(V)}$ could be activated; while, when actin microfilaments were stabilized, $I_{K(Ca)}$ or $I_{K(V)}$ could be inhibited in gastric myocytes. Many previous studies also supported our experiment. For example, Cyt-D activated calcium-activated potassium channel in human meningioma cells^[6], Cyt-B activated K (ATP) channels in cardiac^[5].

Stretch is a physiological stimulation in gut smooth muscles. There are two kinds of potassium current, calcium-activated potassium current and delayed rectifier potassium current. In the present study, the two kinds of potassium current were activated by hypotonic swelling in gastric antral smooth muscle cells of guinea pigs (Figures 5-6). In order to investigate the mechanism of hypotonic membrane stretch-induced increase of $I_{K(Ca)}$ and $I_{K(V)}$, the relationship between potassium channel activity and actin microfilaments was observed. When actin microfilaments were disrupted by Cyt-B or stabilized by phalloidin, hypotonic membrane stretch-induced increase of

$I_{K(Ca)}$ and $I_{K(V)}$ was not affected (Figures 7-8). These results indicated that actin microfilaments were not involved in the increase of potassium current induced by hyposmotic cell swelling in gastric circular myocytes of guinea pig. Previous studies supported our results. For example, Wang *et al.*^[10] observed that neither the microfilaments nor the microtubules were involved in the enhancement of $I_{K(V)}$ induced by cell distension in ventricular myocytes of guinea pig. We also observed that unsaturated fatty acids, exogenous and endogenous, were involved in the increase of calcium-activated potassium current induced by hyposmotic membrane stretch (data not shown). So that hyposmotic membrane stretch-induced increase of potassium currents may be related to unsaturated fatty acids in cell membranes.

Our previous study demonstrated that actin microfilaments played an important role in the modulation of membrane stretch-induced calcium influx and hyposmotic membrane stretch-induced increase of muscarinic current in guinea-pig gastric myocytes^[19,20]. It is obvious that cytoskeleton plays a different role in different types of cells and different kinds of ion channels. In gastric smooth muscle actin microfilaments may be involved in the process of hyposmotic membrane stretch-induced depolarization of membrane potential. However, actin microfilaments would not be involved in the process of cell swelling-induced hyperpolarization of membrane potential.

In summary, actin microfilaments regulate potassium channel activities in normal condition. However, actin microfilaments are not involved in hyposmotic cell swelling-induced increase of potassium currents.

Abstract

AIM: To explore the feasibility of direct separation, selective proliferation and differentiation of the bone marrow-derived liver stem cells (BDLSC) from bone marrow cells with a culture system containing cholestatic serum *in vitro*.

METHODS: Whole bone marrow cells of rats cultured in routine medium were replaced with conditioning selection media containing 20 mL/L, 50 mL/L, 70 mL/L, and 100 mL/L cholestatic sera, respectively, after they attached to the plates. The optimal concentration of cholestatic serum was determined according to the outcome of the selected cultures. Then the selected BDLSC were induced to proliferate and differentiate with the addition of hepatocyte growth factor (HGF). The morphology and phenotypic markers of BDLSC were characterized using immunohistochemistry, RT-PCR and electron microscopy. The metabolic functions of differentiated cells were also determined by glycogen staining and urea assay.

RESULTS: Bone marrow cells formed fibroblast-like but not hepatocyte-like colonies in the presence of 20 mL/L cholestatic serum. In 70 mL/L cholestatic serum, BDLSC colonies could be selected but could not maintain good growth status. In 100 mL/L cholestatic serum, all of the bone marrow cells were unable to survive. A 50 mL/L cholestatic serum was the optimal concentration for the selection of BDLSC at which BDLSC could survive while the other populations of the bone marrow cells could not. The selected BDLSC proliferated and differentiated after HGF was added. Hepatocyte-like colony-forming units (H-CFU) then were formed. H-CFU expressed markers of embryonic hepatocytes (AFP, albumin and cytokeratin 8/18), biliary cells (cytokeratin 19), hepatocyte functional proteins (transferrin and cytochrome P450-2b1), and hepatocyte nuclear factors (HNF-1 α and HNF-3 β). They

also had glycogen storage and urea synthesis functions, two of the critical features of hepatocytes.

CONCLUSION: The selected medium containing cholestatic serum can select BDLSC from whole bone marrow cells. It will be a new way to provide a readily available alternate source of cells for clinical hepatocyte therapy.

INTRODUCTION

Several recent reports have highlighted the broad developmental potential of bone marrow-derived stem cells and the term “stem cell plasticity” has been coined^[1]. Bone marrow-derived stem cells have been reported to produce not only all of the blood lineages, but also skeletal muscle^[2,3], neurons^[4,5], cardiac muscle^[6,7], pulmonary epithelium^[8], and liver epithelium^[9]. The transdifferentiation of bone marrow-derived cells into hepatic cells was described in rats^[9], mice^[10] and humans^[11,12]. This has brought a new hope for cell therapy using autologous bone marrow cells which have few ethical problems and applied to severe liver disease^[13]. However, bone marrow contains hematopoietic^[14,15], mesenchymal stem cells^[16,17] and multipotent adult progenitor cells^[18]. The characteristic surface markers of these specific bone marrow-derived liver stem cells (BDLSC) are still obscure. It is difficult to identify and sort these particular cells by immunological methods, such as fluorescent activated cell sorting (FACS)^[14] and magnetic activated cell sorting (MACS)^[19]. Although various bone marrow stem cells were found to proliferate injured liver cells, previous attempts at isolation of liver stem cells resulted in a mixture of hematopoietic cells and potential hepatocyte progenitors because they all shared common cell surface receptors and antigens, including hematopoietic stem cell markers CD34, Thy-1, c-Kit, and flt-3^[20-22]. It is necessary to find a new way to isolate and purify BDLSC. According to the principle that cells in culture can survive only when they accommodate to the existing environment, we assumed to develop a culture system that can select BDLSC from whole bone marrow cells directly. Within such a system, only BDLSC can survive while the other bone marrow cells cannot. This particular culture system must contain factors that can activate the proliferation of liver stem cells and ingredients inhibiting the growth of other cells. Studies of the relative mechanisms of liver regeneration and liver stem cells corresponding to liver injury^[23-26] indicated that the pathological serum after severe liver injury might provide the above conditions. We developed the culture system using cholestatic serum obtained after ligation of common bile duct to induce liver lesions, to select and proliferate BDLSC from whole bone marrow cells *in vitro*. We named this medium system as “pathological microenvironment” selecting medium.

MATERIALS AND METHODS

Preparation of conditional selection medium

Preparation of cholestatic serum Sprague-Dawley (SD) rats weighing 200–250 g were performed common bile duct ligation and transection under general (ether) anesthesia to induce cholestasis. After 10 d, whole blood of each rat was collected and serum was separated. The serum was then subjected to liver function test, and inactivated and aseptically for culture use.

Ingredients of conditional selection medium Twenty mL/L, 50 mL/L, 70 mL/L, and 100 mL/L cholestatic serum were added into DMEM (Gibco) containing 20 mmol/L HEPES (Sigma), 10^{-7} mol/L dexamethasone (Sigma), and antibiotics to act as the conditional selection medium.

Selection, proliferation and differentiation of BDLSC

Culture of whole bone marrow cells Rat bone marrow cells were obtained by flushing femurs. The femurs were accessed through laparotomy to avoid contamination and to increase the cell yield. Bone marrow cells were suspended in DMEM and plated at the density of 1×10^9 cells/L onto culture dishes. DMEM enriched with 100 mL/L fetal bovine serum (FBS, Hyclone), 20 mmol/L HEPES, 10^{-7} mol/L dexamethasone, and antibiotics was used. Dishes were placed in a humidified incubator containing 50 mL/L CO₂–950 mL/L O₂ at 37 °C.

Selection, proliferation and differentiation of liver stem cells

Three days after the culture, the medium and suspended cells were discarded and replaced by conditional selection medium with various concentrations of cholestatic serum. Cells cultured in medium containing FBS were used as control. After 4 d, the media were enriched with 25 µg/L hepatocyte growth factor (HGF, Peprotech EC). Medium was replaced every 3 d and the cultures were maintained for about 2 wk.

Morphological and phenotypic markers of differentiated cells

Immunohistochemistry Bone marrow cells were cultured and selected with the conditional selection medium on 6-well dishes with cover glasses. Twelve days after replacement of the conditional selection medium, cover glasses and the above differentiated BDLSC were taken out and fixed with 40 g/L paraformaldehyde (Sigma) for 30 min at room temperature. The primary antibodies were goat anti-rat albumin, alpha-fetoprotein (AFP), and cytokeratin-8/18 (CK8/18) polyclonal antibodies. The slides were incubated with various primary antibodies at room temperature for 2 h in a humidified chamber. Blocking serum and biotinylated

secondary antibody were matched with the primary antibody. Immunoperoxidase was stained and counterstained with DAB and Gill-I hematoxylin.

Electron microscopy Culture dishes were washed with PBS (pH 7.4), and fixed in cold 25 g/L glutaraldehyde in 0.1 mol/L sodium cacodylate buffer (pH 7.4) for 48 h. After fixation, cells were curetted and centrifuged to form aggregates. After postfixed in 10 g/L osmium tetroxide in 0.1 mol/L sodium cacodylate (pH 7.4), cells were dehydrated in graded alcohols and embedded in low viscosity epoxy resin. Ultrathin sections were stained with uranyl acetate and lead citrate and viewed under electron microscope.

Total RNA isolation and reverse transcriptase-polymerase chain reaction (RT-PCR) Total RNA was extracted from 1×10^6 differentiated cells by using Trizol (Promega). cDNA was prepared from 2 µg of total RNA in a buffer containing MMLV reverse transcriptase (Promega) and 0.5 µg random primer (Takara). The RNA was incubated at 70 °C for 5 min, at 37 °C for 1 h, and at 95 °C for 5 min. Samples of cDNA corresponding to the input RNA were amplified in PCR reaction buffers containing primers and LA Taq DNA polymerase (Takara). Primers used for amplification were hepatocyte nuclear factor-1α (HNF-1α), hepatocyte nuclear factor-3β (HNF-3β), CK18, CK19, albumin, AFP, transthyretin (TTR), and cytochrome P450-2b1 (CYP2b1). The sequences are listed in Table 1. After initial denaturation (at 94 °C for 5 min), 30 cycles of PCR were performed (at 94 °C for 30 s, annealing at the optimal temperature for each pair of primers for 30 s, at 72 °C for 30 s), and extension at 72 °C for 7 min. Amplified products were subjected to electrophoresis in 20 g/L agarose gels and stained with ethidium bromide. All the procedures were performed according to the manufacturer's instructions.

Function tests of differentiated cells

Periodic acid-Schiff staining for glycogen Differentiated cells were fixed in 950 mL/L ethanol for 10 min, rinsed in dH₂O. Afterwards, cells were oxidized in 10 g/L periodic acid for 15 min and rinsed three times in dH₂O, then treated with Schiff's reagent for 30 min and rinsed in dH₂O for 10 min, stained with Mayer's hematoxylin for 1 min and rinsed in dH₂O.

Urea assay Urea concentrations were determined by colorimetric assay (640-A, Sigma). Differentiated cells were plated on 6-well dishes. Each well contained 1×10^6 cells. Urea concentrations were detected every day for 4 d according to the manufacturer's instructions. Culture medium and blank tube were used as negative controls.

	A:5'-TCCTTCTCCATGCGCAGA-3'	

RESULTS

Preparation of the conditioning selection medium

Ten days after the ligation of common bile duct, TBIL of the cholestatic rats was $107 \pm 48.2 \mu\text{mol/L}$. The conditional selection media containing 20 mL/L, 50 mL/L, 70 mL/L, and 10 mL/L cholestatic sera had TBIL concentrations of 2.1 $\mu\text{mol/L}$, 5.3 $\mu\text{mol/L}$, 7.4 $\mu\text{mol/L}$ and 10.8 $\mu\text{mol/L}$ accordingly.

Bone marrow cells cultured in different concentrations of cholestatic serum

In routine culture condition, part of the bone marrow cells attached to the plate in about 3 d, and then became elongated and fibroblast-like, conforming to the mesodermal characteristics of their origin. After replaced by the conditional selection medium containing 20 mL/L cholestatic serum, the attached cells still survived while the rapid growth was hindered. Seven days after cultured in the medium, colonies were mainly composed of fibroblast-like cells. Only a few colonies acquired hepatocyte-like morphology, although HGF was added. In the presence of 50 mL/L cholestatic serum, a large number of the attached cells exfoliated within 3 d, while many small colonies appeared (Figure 1). These colonies were composed of small, undifferentiated cells in the center, and epithelioid cells at the periphery. The cells enriched with HGF proliferated rapidly. In 70 mL/L cholestatic serum condition, most of the cells exfoliated, fewer colonies appeared, and HGF could not stimulate their proliferation. When the concentration increased to 100 mL/L, all of the cells exfoliated and became apoptosis.

Figure 1 Cell colonies 3 d after selection. Polygonal surrounding cells could be seen.

Morphological evidence of BDLSC differentiation

During the first 3 d many colonies appeared in conditional selection culture containing 50 mL/L cholestatic serum. After enriched with HGF, the colonies enlarged, and the cells proliferated rapidly. Large hepatocyte-like colony-forming units (H-CFU) came into being in about 12 d. The H-CFU were composed of small, undifferentiated cells in the center, and large cells with regular multilateral contours, low nuclear-to-cytoplasmic ratio, and single round nuclei at the periphery. The differentiated cells formed cords or trabeculae resembling the hepatocyte cords in hepatic lobules (Figure 2). The largest colonies contained 1×10^6 cells and could be observed macroscopically, whereas the small colonies were about 30-50 cells. The central undifferentiated cells could still form H-CFU when they were picked out and cultured in the selection medium containing 50 mL/L cholestatic serum and HGF in about 1 wk.

Ultrastructurally, the differentiated cells were rich in endoplasmic reticulum and ribosomes and contained abundant ellipsoid mitochondria (Figure 3), which were different to the control cells. These ultrastructural features are typical of adult hepatocytes.

Phenotypic markers of differentiated cells

The identification of hepatocyte-like cells in 12-day-old selection

medium cultures prompted us to analyze these cells for biochemical evidence of hepatocytic differentiation. Immunohistochemistry was performed in cells grown on the cover glasses for the existence of albumin (Figure 4), AFP and CK8/18, the characteristic proteins expressed during hepatocyte development. Immunoperoxidase staining for these proteins revealed diffuse cytoplasmic staining of hepatocyte-like cells. In contrast, the fibroblast-like cells grew in the routine cultures did not express these proteins. RT-PCR further convinced the hepatocytic characteristics of differentiated cells as the results showed that there were mRNA transcripts of HNF-1 α , HNF-3 β , albumin, AFP, CK-18, CK-19, TTR, and CYP2b1, all of which were hepatic specific (Figure 5).

Figure 2 Appearance of hepatocyte-like colony forming units (H-CFU) 12 d after selection A: H-CFU, undifferentiated round cells in the center, surrounded by polygonal hepatocyte-like cells B: Regular arrangement of surrounding hepatocyte-like cells similar to the cords of hepatocytes.

Function tests of differentiated cells

We analyzed the levels of glycogen storage by periodic acid-Schiff (PAS) staining. Glycogen storage was seen as accumulation of magenta staining in the cytoplasm of hepatocyte-like differentiated cells (Figure 6). The control cells did not show similar staining. Urea production and secretion by hepatocyte-like cells were measured at various time points after the differentiated morphology appeared. Bone marrow cells and fibroblast-like cells did not produce urea. Urea assay revealed that urea concentration in the medium increased in a time-dependent manner (Figure 7).

DISCUSSION

Since the results of cross-sex and cross-strain bone marrow and whole liver transplantation experiments indicated that the bone marrow might be a source of hepatocyte progenitors, great interests have been aroused in identification and isolation of liver stem cells from bone marrow cells. Until recently, several subsets of bone marrow cells have been found to have the potential to differentiate into hepatocytes, such as KTLS cells (c-kit^{high}Thy^{low}LinSca-1⁺)^[20], β_2 -mThy-1⁺ cells^[27,28], multipotent adult progenitor cells (MAPC, CD44⁺CD45⁻HLA-c-kit⁻)^[18], and C1qR⁺LinCD45⁺CD38⁻CD34⁺ cells^[29]. These stem cells could express different surface markers, and might represent different stages or different branches along the differentiation and developmental processes of bone marrow stem cells. So far, the characteristic surface markers of BDLSC and their pedigrees in the derivation of bone marrow stem cells remain obscure. Any subset sorting methods based on phenotypes would certainly lose other stem cells that have the ability to differentiate into hepatocytes. Furthermore, the sorting manipulations of the above stem cells with complicated surface markers are very difficult.

Studies on liver regeneration showed that liver stem cells could correspond to and repair liver injury only under certain severe pathological circumstances such as extensive liver necrosis due to chemical injury or hepatocytes treated with chemicals that could block their proliferation^[24]. Based on this mechanism, we assumed to imitate the *in vivo* pathological microenvironment of liver injury in culture of whole bone marrow cells, in order to provide specific proliferation signals for BDLSC, and to avoid resource loss of liver stem cells and complicated manipulation due to subset sorting. The key of this method is to develop an optimal "pathological microenvironment". Olynyk *et al.* demonstrated that in the cholestatic model of common bile duct ligation, intrahepatic liver stem cells showed great proliferation^[25]. Avital *et al.* recently reported that β_2 -mThy-1⁺ cells in bone marrow could differentiate into cells with hepatocyte-like phenotypes when co-cultured with adult hepatocytes in a medium containing cholestatic serum^[27], suggesting that there are stimulating factors in cholestatic serum. In our experiments, we used pathologically conditional selection medium containing cholestatic serum to culture whole bone marrow cells. Results showed that in the selection medium, a large number of the bone marrow cells exfoliated, only part of the remaining cells presented colonial growth during the first 3 d. When enriched with HGF on d 4, rapid proliferation and differentiation emerged, and H-CFU with various size appeared in 2 wk. The morphology and phenotypic markers manifested that the cells of H-CFU were similar to embryonic hepatoblasts. They expressed markers of embryonic hepatocytes (AFP, albumin and CK18), biliary cells (CK19), hepatocyte functional proteins (TTR and CYP2b1), and hepatocyte nuclear factors (HNF-1 α and HNF-3 β). HNF-1 α is a transcription factor required for subsequent hepatocyte differentiation, and transcription factor HNF-3 β was known to be important in endoderm specification. These results proved that H-CFU were colonies of liver stem cells.

In the culture system containing cholestatic serum, the concentration of "pathological microenvironment" needs to be considered. We found that 100 mL/L cholestatic serum was fatal to all of the bone marrow cells, 70 mL/L cholestatic serum prevented the colonies from growth and proliferation, 20 mL/L cholestatic serum could not inhibit the growth of other cells, while only 50 mL/L cholestatic serum acquired pure H-CFU. The differences can be explained by the toxic contents of cholestatic serum, which are the metabolic products cumulated under the circumstances of common bile duct obstruction and hepatic insufficiency, including bilirubin, bile acid, endotoxin, and ammonia, *etc.* When cholestatic serum was confined to the optimal concentration, BDLSC, possessing functions of bilirubin conjugation and detoxification^[30], could metabolize these toxic

products and survive, and selectively proliferate responding to the signal of liver injury. On the other hand, non-BDLSC could not adapt to the environment and resulted in apoptosis. To confirm that if the H-CFU had functional characteristics of hepatocytes, we tested the glycogen and urea synthesis functions of the cells and proved that the selected cells possessed hepatocyte-like functions. Therefore, the "pathological microenvironment" selecting medium based on cholestatic serum can select BDLSC in two ways, providing selective proliferation signals for BDLSC and eliminating non-BDLSC, so as to purify BDLSC.

We demonstrated that a "pathological microenvironment" selecting medium could select, proliferate and differentiate BDLSC from whole bone marrow cells *in vitro*. This method can not only provide a new and effective way for the isolation and purification of extrahepatic liver stem cells, but also supply a clue to obtain a readily available alternate source of cells for clinical hepatocyte therapy.

Abstract

AIM: The fears and concerns are associated with gastroscopy (EGD) decrease patient compliance. Conscious sedation (CS) and non-pharmacological interventions have been proposed to reduce anxiety and allow better execution of EGD. The aim of this study was to assess whether CS, supplementary information with a videotape, or presence of a relative during the examination could improve the tolerance to EGD.

METHODS: Two hundred and twenty-six outpatients (pts), scheduled for a first-time non-emergency EGD were randomly assigned to 4 groups: Co-group (62 pts): throat anaesthesia only; Mi-group (52 pts): CS with i.v. midazolam; Re-group (58 pts): presence of a relative throughout the procedure; Vi-group (54 pts): additional information with a videotape. Anxiety was measured using the "Spielberger State and Trait Anxiety Scales". The patients assessed the overall discomfort during the procedure on an 100-mm visual analogue scale, and their tolerance to EGD answering a questionnaire. The endoscopist evaluated the technical difficulty of the examination and the tolerance of the patients on an 100-mm visual analogue scale and answering a questionnaire.

RESULTS: Pre-endoscopy anxiety levels were higher in the Mi-group than in the other groups ($P < 0.001$). On the basis of the patients' evaluation, EGD was well tolerated by 80.7% of patients in Mi-group, 43.5% in Co-group, 58.6% in Re-group, and 50% in Vi-group ($P < 0.01$). The discomfort caused by EGD, evaluated by either the endoscopist or the patients, was lower in Mi-group than in the other groups. The discomfort was correlated with "age" ($P < 0.001$) and "groups of patients" ($P < 0.05$) in the patients' evaluation, and with "gender" (females tolerated better than males, $P < 0.001$) and "groups of patients" ($P < 0.05$) in the endoscopist's evaluation.

CONCLUSION: Conscious sedation can improve the tolerance to EGD. Male gender and young age are predictive factors of bad tolerance to the procedure.

INTRODUCTION

Esophagogastroduodenoscopy (EGD) is a safe and quick procedure, and can be carried out without sedation^[1]. However, it can evoke anxiety, feelings of vulnerability, embarrassment and discomfort^[2], and the fears and concerns associated with endoscopic procedure decrease patient compliance^[2-4]. Indeed, anxiety, discomfort, and pain are interrelated, and each may increase the others^[5], making EGD execution more difficult. Several methods can be used to reduce patient pre-procedural worries, such as psychological interventions using relaxation and coping techniques^[6,7], hypnosis^[8], relaxation music^[9], acupuncture^[10], educational materials including videotapes^[11], and presence of a family member during EGD^[12]. However, conscious sedation with benzodiazepines is the method most widely employed^[5]. Although usually safe, such medications are not free of adverse effects^[13-15], and the likelihood of sedative-related complications increases in the presence of high anxiety levels, requiring higher doses of drugs^[2]. It follows that the role of conscious sedation is not well defined, and its use varies from country to country: up to 98% in USA, less frequently in European countries, and quite rarely in Asia and South America^[16]. The use of conscious sedation is also declining in the United Kingdom^[17], and many patients who receive detailed information about the advantages and risks of sedation choose to undergo EGD with pharyngeal anesthesia alone^[18,19]. In our endoscopy service, a standardized information sheet about EGD is given to all patients, and the examination is routinely performed with pharyngeal anesthesia alone.

This randomized prospective study was to evaluate if conscious sedation, additional information with a videotape, or the presence of a family member during the procedure could improve the tolerance to EGD and make the execution of EGD easier. In addition, particular emphasis was put on psychologic and procedure-related factors having a potential impact on the patient perception of tolerance.

MATERIALS AND METHODS

Study population

For six consecutive months, the first two outpatients daily referred for diagnostic EGD, fulfilling the eligibility criteria, were asked to enter the study. Inclusion criteria were age between 18 and 65 years, no prior experience of endoscopic examinations, and capability (evaluated by the endoscopist) of fully understanding and filling up the questionnaires of the study. Exclusion criteria were prior gastrectomy, psychiatric diseases or long-term psychiatric drug addiction, presence of neoplastic or other serious concomitant diseases, history of intolerance to benzodiazepines. On the whole, two hundred and eighty patients were asked to enter the study, and 228 of them were accepted. The patients were randomly assigned to four groups by a computer procedure. In the control group (Co-group), EGD was performed with topical pharyngeal anesthesia alone (100 g/L lidocaine spray). In the other three groups the following methods were used in addition to pharyngeal anesthesia: conscious sedation with i.v. midazolam 35 µg/kg (Mi-group); presence of a relative in the endoscopy room throughout the procedure (Re-group); additional information about the procedure using a videotape lasting for

about 10 min (Vi-group).

The study protocol was approved by the ethical committee of our hospital, and all patients gave their written consent to participate in the study.

Patients' assessments

Anxiety Since the anxiety experienced by patients undergoing EGD was hypothesized to be a factor related to potential discomfort, anxiety was measured by the Spielberger State-Trait Anxiety Inventory (STAI)^[20] in the validated Italian language version^[21]. Patients were asked to complete STAI before EGD. STAI is a 40-item questionnaire designed to measure state anxiety and trait anxiety. State anxiety is a temporary and situational anxiety, and trait anxiety is the tendency to awaken state anxiety under stress. Both kinds of anxiety were scored in the range of 20 to 80 points, a higher score indicated a greater anxiety. Before EGD, the patients had also to specify what they dreaded more about endoscopic examination, choosing among five items: fear of pain, fear of stifling, fear of complications, fear of endoscopic findings, and other.

Tolerance

Patients' assessment of tolerance to EGD was carried out at least 2 h after the end of the procedure. This interval was chosen to minimize the risk of persisting anterograde amnesia, which could potentially influence patient judgment. Patients assessed their tolerance answering the question: "how did you tolerate EGD?" ("well", "rather badly", "badly"), and rated the overall discomfort during EGD on an 100-mm visual analogue scale (0: no discomfort; 100: unbearable).

Endoscopist's assessment

All EGDs were carried out by the same endoscopist, using video endoscopes with a diameter of 9.8 mm (Fujinon video endoscopic system-Fujinon, Tokyo, Japan). Immediately after endoscopy, the operator recorded if EGD was completed, or it had to be interrupted, or it could be completed only after administration of sedatives (for Mi-group, after further sedatives in addition to midazolam previously administered). Moreover, he evaluated the ease of introduction of the instrument ("easy": no failed attempt of introduction; or "difficult": one or more failed attempts of introduction). Finally, he rated the discomfort caused to patients during EGD on an 100-mm visual analogue scale (0: no discomfort; 100: unbearable), and assessed the tolerance of the

patients grading it into three steps: "good", "poor", "very bad".

Parameters monitored

Blood oxygen saturation (SaO₂) and heart rate were continuously monitored during EGD. Desaturation was defined as a decrease in oxygen saturation below 90% for over 30 s. The occurrence of complications was recorded after each procedure. The duration of endoscopic examination was timed in all groups of patients. In Mi-group, the degree of sedation was evaluated using the Ramsay's scale^[22].

Statistical analysis

Characteristics of patients in the four groups were analyzed using one-way ANOVA and chi-square test. Endoscopic findings, tachycardia, motives of fear, answers of patients to the questions about their tolerance to EGD, ease of introduction of the instrument, and endoscopist's evaluation of tolerance of patients to EGD were compared in the four groups by using chi-square-test.

State and trait pre-endoscopic anxiety levels, and the discomfort rated by the patients and endoscopist on the 100-mm visual analogue scale were analyzed using one-way and two-way ANOVA. Two-way ANOVA was also used to evaluate the influence of sex, age, and anxiety levels on the discomfort caused by EGD. Linear-regression analysis was used to assess the relationship between the state and trait anxiety scores, as well as the correlation between patients' and endoscopist's evaluation of the discomfort caused by EGD. A general linear model (GLM) procedure was used to analyze the influence of sex, age, groups of patients, state anxiety, duration of EGD, and endoscopic findings on the degree of discomfort caused by EGD, assessed by either the endoscopist or the patients.

Results were considered statistically significant if *P* values were <0.05 (two-tailed test).

RESULTS

Two patients (1 in Co-group and 1 in Mi-group) were excluded from the study, as EGD was not completed. Two hundred and twenty-six patients (90 males and 136 females, mean age 38±10.62 years, range 19-63 years) could be evaluated. The four groups did not differ in age, endoscopic findings, and duration of the examination. The male: female ratio was lower in Mi-group than in the other groups (*P*<0.05) (Table 1).

Fourteen point five percent of patients in Co-group (6/62), 21.1% in Mi-group (11/52), 20.6% in Re-group (12/58), 16.6% in

Vi-group (9/54) had a heart rate higher than 100 beats/min before starting EGD. During EGD, the heart rate exceeded 130 beats/min for at least 30 seconds in 5, 2, 3, and 2 patients in the four groups, respectively. No complication occurred, and no case of oxygen desaturation was observed. According to Ramsay's scale, in Mi-group grade 2 sedation was reached in 50 patients, and grade 3 in 2 patients.

State anxiety scores before EGD were significantly higher in Mi-group than in the other groups ($P<0.001$), as well as trait anxiety scores ($P<0.001$) (Table 1). State and trait anxiety scores were strongly correlated ($P<0.001$).

In all groups the most frequent cause of fear before EGD was the fear of stifling (70 cases on the whole). The ease of introduction of gastroscope did not differ among the four groups, and the introduction resulted in difficulty just in one patient of Co-group and in 3 of Vi-group.

On the basis of patients' assessment, the tolerance to EGD was more frequently good when sedation was given: 80.7% of patients in Mi-group tolerated well gastroscopy, vs 43.5% in Co-group, 58.6% in Re-group, and 50% in Vi-group ($P<0.01$) (Table 2). Conversely, no significant difference among the four groups was observed in the evaluation of the endoscopist, who nevertheless found that the discomfort caused by EGD was lower in Mi-group than in Co-group ($P<0.05$) (Table 3). The degree of discomfort was lower in patients of Mi-group than in those of Co-group, but the difference was just close to threshold of significance, but did not reach it ($P=0.059$) (Table 3). The other comparisons among the groups did not show any difference in the degree of discomfort caused by EGD. The evaluations of the patients and those of the endoscopist were strongly correlated ($P<0.001$, $m=0.45$), even though the endoscopist underestimated the degree of discomfort (Figure 1).

Two-way ANOVA performed on the degree of discomfort assessed by the patients, evaluated for factors "gender" and

"groups of patients" corrected for age, trait anxiety and state anxiety, showed an inverse influence of the age (i.e. better tolerance for older individuals, $P<0.001$) and the factor "groups of patients" ($P<0.05$). Conversely, the degree of discomfort assessed by the endoscopist was significantly influenced by the factors "gender" and "groups of patients" ($P<0.001$ and $P<0.05$, respectively). The factors "gender" and "groups of patients" showed a true and constant interaction (interaction factor $P<0.01$), reflecting behaviors significantly different between males and females within the four groups, in particular in Co-group (Figures 2A, B).

Also the GLM procedure showed that age exerted the greatest influence on the discomfort caused by EGD in opinion of the patients (inverse correlation, $P<0.001$), whereas in opinion of the endoscopist the discomfort was mainly influenced by the gender (females tolerated EGD better than males, $P<0.001$) (Table 4).

**Figure 1** Linear regression of discomfort assessed by patients and endoscopist.

Co-G: control group Mi-G: midazolam group Re-G: relatives group Vi-G: video group A: Discomfort assessed by patients B: Discomfort assessed by endoscopist.

DISCUSSION

Although conscious sedation is the method most widely used to reduce anxiety in patients undergoing EGD, its actual role is still an unresolved problem. Very large differences in sedation practice existed among different countries, and sometimes among different units within the same country^[5]. To our knowledge, this is the first randomized trial comparing the efficacy in improving the tolerance to EGD of conscious sedation, the presence of a relative in the endoscopy room throughout the procedure, and additional information by using a videotape. Abuksis *et al.* demonstrated that previous endoscopy experience could reduce anxiety level and influence patients' compliance^[23], and other authors identified endoscope size as a significant variable in determining tolerance to the procedure^[24,25]. For these reasons, in our study all patients enrolled had no prior endoscopy experience, and all EGDs were carried out using gastroscopes with the same diameter.

Our results suggested that low-dose conscious sedation with midazolam could improve the tolerance to EGD, according to a previous trial reporting a lower discomfort in sedated patients than in controls^[26]. Conversely, the presence of a relative attending the procedure and the use of informative videotape did not seem to give the patients significant advantages over the controls. However, better tolerance and lower discomfort were found in Re-group and Vi-group than in Co-group by either the patients or the endoscopist. Although these findings did not reach the significance level, in our opinion they suggested that the method used in controls (pharyngeal anesthesia only) was the worst approach to perform EGD. Indeed, the multivariate analysis showed constant differences among the groups of patients in concern of the discomfort caused by endoscopy, highlighting the usefulness of preparatory interventions in improving the tolerance to EGD.

The presence of relatives has been proved helpful in several medical fields, such as to children during hospitalization and to women during childbirth^[27], but it is not a standard procedure in digestive endoscopy. At present, just one randomized study was published on this topic, and the results suggested that the

presence of a family member throughout endoscopy could represent a promising approach^[12]. Conversely, the usefulness of additional information to reduce the anxiety and to improve the compliance of patients has been widely investigated, but with conflicting results. Detailed information before endoscopy has been reported to reduce anxiety levels^[11,28], but other studies failed in demonstrating any usefulness of this approach^[29], and some authors found that the over-information about endoscopy could even increase anxiety levels^[30,31].

The evaluation of the discomfort expressed by the patients and the endoscopist showed a strong correlation in our study (Figure 1). However, the endoscopist rated the patient degree of discomfort as lower than the patients themselves. According to the observation of Watson *et al.* that both endoscopists and nurses underestimated the discomfort felt by the patients^[32]. Besides anxiety, in our experience age and gender also influenced significantly the tolerance to endoscopy. Indeed, high levels of discomfort during EGD have been recently reported to be associated with younger age and high levels of pre-endoscopic anxiety^[24]. Older patients were likely to tolerate endoscopy better than their younger counterparts as they had a decreased pharyngeal sensitivity^[33,34]. Unlike several studies reporting better tolerance in men^[26,35], we found that female gender was associated with better tolerance. However, this gender-specific finding has been disputed by other authors^[3,24,33].

Despite the effectiveness of conscious sedation shown in our study, we think it should be avoided whenever possible in clinical practice. The extensive use of sedation would require several extra-charges, including the cost of drugs, prolongation of the procedure time, need of monitoring cardiopulmonary functions, need of recovery room for post-procedure observation, and the impossibility for patients to return to work immediately after endoscopic examination^[36]. Furthermore, sedative drugs are not free of adverse effects. In our series, no complications and oxygen desaturation were observed, and low-dose midazolam induced just rarely significant alterations in cardiorespiratory parameters^[26]. Nevertheless, conscious sedation could cause hypoxemia, which may induce cardiopulmonary complications, and most complications associated with endoscopy were attributable to the medications given for the procedure rather than the procedure itself^[13-15]. For these reasons, we think that further studies incorporating cut-off points are necessary to identify the patients who are likely to tolerate diagnostic gastroscopy without sedation. Some other preparatory interventions might also be effective to reduce endoscopy-related anxiety^[37]. The intervention techniques we used might be incorporated into our endoscopic practice, as they are simple, quick, easy to reproduce, and their extensive use does not require additional extra-charges, and expose the patients to the risk of complications.

Abstract

AIM: Biliary stones are frequently encountered in areas endemic for opisthorchiasis in Thailand. The present study was to describe the prevalence and pathogenesis of these stones.

METHODS: Gallstones and/or common bile duct stones and bile specimens from 113 consecutive cholecystectomies were included. Bile samples, including sludge and/or microcalculi, were examined for *Opisthorchis viverrini* eggs, calcium and bilirubin. The stones were also processed for scanning electron microscopic (SEM) study.

RESULTS: Of the 113 cases, 82 had pigment stones, while one had cholesterol stones. The other 30 cases had no stones. Most of the stone cases (76%, 63/83) had multiple stones, while the remainder had a single stone. Stones were more frequently observed in females. Bile examination was positive for *O. viverrini* eggs in 50% of the cases studied. Aggregates of calcium bilirubinate precipitates were observed in all cases with sludge. Deposition of calcium bilirubinate on the eggshell was visualized by special staining. A SEM study demonstrated the presence of the parasite eggs in the stones. Numerous crystals, morphologically consistent with calcium derivatives and cholesterol precipitates, were seen.

CONCLUSION: Northeast Thailand has a high prevalence of pigment stones, as observed at the cholecystectomy, and liver fluke infestation seems involved in the pathogenesis of stone formation.

INTRODUCTION

Liver fluke infestation caused by *Opisthorchis viverrini* remains

a major public health concern in Southeast Asia^[1], particularly in Thailand where an estimated 6 million people are infected^[2]. This infection is associated with a number of benign hepatobiliary diseases, including cholangitis, obstructive jaundice, hepatomegaly, cholecystitis and biliary lithiasis^[3]. Both experimental and epidemiological evidence implicate liver fluke infestation in the etiology of bile duct cancer, i.e. cholangiocarcinoma^[1,4,5].

An association between liver fluke infection and biliary lithiasis is well-recognized. *Opisthorchis* worm and/or eggs have been observed in the stones of infected or previously treated individuals^[6], just as *Clonorchis sinensis* eggs were found in the stones of those with Chinese liver fluke infection^[7,8]. Several community-based studies in Northeast Thailand have shown a significant increase in the frequency of biliary sludge in people with a heavy infection^[9-11]. Since biliary sludge is a precursor of stone formation^[12-14], opisthorchiasis likely plays a role in the development of biliary stones in certain individuals. However, the mechanism of liver-fluke-associated stone development is unclear.

We report the incidence of stone types, its relationship with *O. viverrini* infection and bile/stone examinations. The potential pathogenesis of opisthorchiasis-associated stones, in patients from endemic areas of Thailand, is proposed.

MATERIALS AND METHODS

Patients

This study was carried out in Northeast Thailand, an area endemic for opisthorchiasis. The study population included 113 consecutive patients scheduled for cholecystectomy at Khon Kaen Regional Hospital from whom bile was obtained between 1990 and 1991. The gallbladder diseases associated with the cholecystectomies included cholelithiasis ($n = 71$), cholecystitis with cholangiocarcinoma ($n = 29$) and cholecystitis with other miscellaneous diseases ($n = 13$). None of the patients had any history of hemolytic anemia or severe thalassemia.

Patients ranged between 17 and 94 years of age (mean, 54.97 ± 14.65) (45 females, 68 males). The study was carried out in accordance with the principles embodied in the 1975 Helsinki Declaration. A signed informed consent was obtained from each patient.

Specimen collection and laboratory investigations

Gallstones and/or common bile duct stones and bile specimens were collected from each individual. Bile samples aspirated from the gallbladder were centrifuged at 3 000 r/min for 10 min, then examined for the presence of *O. viverrini* eggs. At least four pellet-smears per individual were examined before the specimen was considered negative for eggs.

For a demonstration of calcium and bilirubin, the bile smears were air-dried and fixed in 40 g/L formaldehyde. Calcium and bilirubin staining were performed using histochemical methods^[15]. Calcium was stained black, bilirubin deep green.

Five stones from each group with *Opisthorchis* egg-negative and -positive bile underwent scanning electron microscopic (SEM) study. Briefly, the stones were thoroughly washed in distilled water and dried. After mechanical breaking, the stones

were sputter-coated with gold (agar aids-PS3, UK) and observed under a Hitachi (Model S-3200N, Japan) scanning electron microscope and photographed.

Statistical analysis

The χ^2 -test was used to analyze the association between the frequency of gallstones and sex, disease association, parasite egg status and age groups. A *P* value <0.05 was considered statistically significant.

RESULTS

Cholesterol or pigment stones were classified by visual inspection. Cholesterol stones were white or yellow and crystalline in composition, pigment stones were black or black-brown and amorphous.

Of the 113 cases, 83 had stones while 30 had none. Most of the stone cases (98.8%, 82/83) had pigment stones, while only one had cholesterol stone(s). In addition, 63 of the 83 cases (75.9%) contained multiple stones, while the remainder had a single stone. Of the 29 cases with cholangiocarcinoma, 9 (31.0%) contained stones while the others with miscellaneous diseases had stones in 3 out of 13 (23.1%) cases. The prevalence of

stones in all of the sample groups was significantly higher in females (χ^2 -test, *P* = 0.028). No association between stones and age groups (stratified as < 40, 40-49, 50-59 and > 60 years) was found (χ^2 -test, *P* = >0.05).

Bile examination was positive for *O. viverrini* eggs in 57 of the 113 cases (49.6%) studied. The presence of parasite eggs was not associated with the frequency of stones or disease association (χ^2 -test, *P* = >0.05). Most of the eggs were embedded in mucous gel. Aggregates of calcium bilirubinate precipitates were observed in all cases with sludge. Three cases had clear deposits of calcium bilirubinate on the eggshell, seen by special staining. Specifically, calcium was stained immediately adjacent to the eggshell, while bilirubin was observed in the outer layer (Figure 1 A, B). Examples of parasite egg-associated microcalculi aggregation and stone development are shown in Figures 2A-D.

A SEM study demonstrated the presence of parasite eggs in the center of stones from all of the *Opisthorchis* egg-positive cases. Interestingly, 3 of the 5 egg-negative cases contained the parasite eggs in the stones. Numerous crystals, morphologically consistent with calcium derivatives and cholesterol precipitates, were observed. Typical SEM pictures of the stones are shown in Figures 3A, B.

Figure 1 Histochemical staining of biliary sludge for bilirubin (A) and calcium (B). Calcium appears as dark deposits on the *Opisthorchis* eggshell (arrow) and bilirubin precipitates are demonstrated in the outer layer (arrowhead). Normal parasite eggs without deposition are shown in the same field. (A = Fouchet stain, B = von Kossa stain).

Figure 2 Typical pictures showing the cascades of *Opisthorchis* egg-associated stone formation starting from aggregation of the eggs admixed with mucin (A), deposition of calcium bilirubinate on the eggshells (B), and formation of tiny stones (C & D). Original magnification, x100 (A & C) and x200 (B & D).

Figure 3 SEM micrographs of gallstones showing *Opisthorchis* eggs with typical musk-melon-eggshell surface in the nidi of the stones. Several crystalline structures consistent with calcium (Ca), bilirubin derivatives (Bi) and cholesterol (Ch) could be noted (AB). Higher magnification with highlighting calcium bilirubinate deposition on *Opisthorchis* eggshell and mucus is shown in Figure 3B.

Figure 4 Diagram showing the proposed pathogenesis of *Opisthorchis*-associated biliary stone.

DISCUSSION

Biliary lithiasis is a common indication for cholecystectomy in most parts of the world. However, the prevalence and types of stones differ geographically^[16-18]. Pigment stones, mostly containing calcium bilirubinate, generally constitute 10 to 27 percent of all gallstones in America and Europe, the predominant type was cholesterol stones^[19-21]. In contrast, the prevalence of pigment stones is high in Asia, accounting for $\leq 90\%$ of all stones in some parts of China^[22]. In our study, almost all the cases (98.8%) of biliary lithiasis involved pigment stones. This is probably the highest reported relative frequency of pigment stones found during cholecystectomy. It exceeds a report from Bangkok, Central Thailand, where pure cholesterol stones represent $\leq 32\%$ of stones^[23]. Stones in our study of Northeast Thailand, however, occurred more frequently in females than in males as in other countries^[19-20].

The association between certain parasitic infections and biliary stone formation is well documented^[7,24-27]. Our study demonstrated *Opisthorchis* eggs in the sludge from the gallbladder bile confirmed the sludge seen in other ultrasound studies performed in Northeast Thailand^[12-14]. However, our study failed to demonstrate the association between *O. viverrini* infection and the presence of stones, perhaps because of previous self-treatment with praziquantel, an anthelmintic widely used in Northeast Thailand^[2]. We collected the treatment data,

but they were not reliable as patients did not record when or how many times they took the medication before cholecystectomy. Moreover, re-infection is common in people in endemic areas.

SEM data from egg-negative patients revealed parasite eggs in the nidi of the stones, indicating these patients were previously infected. Budget constraints meant that only a limited number of cases were confirmed by SEM. More stones should be studied to test the validity of the findings.

The mechanism by which parasite infection enhances pigment stone formation is not clearly understood. The present study demonstrated *O. viverrini* eggs in the biliary sludge and gallstones in both bile smears and the SEM, while Riganti *et al.*^[6] observed both adult worms and eggs in the nidi of gallstones from two patients. Riganti *et al.* also demonstrated calcium bilirubinate in pigment stones, as previously reported in stones associated with *C. sinensis*^[7,8] and ascariasis^[8,27,28]. These observations have led investigators to conclude that parasite eggs and/or worms may directly stimulate stone formation^[6,8]. Our histochemical findings on the calcium and bilirubin coatings on the *O. viverrini* eggs support this hypothesis. The presence of calcium coating on the outer surface of the parasite eggshell suggests that the eggs may act as a nucleus for stone formation. This may be similar to peripheral calcification of existing cholesterol stones^[29]. Since calcium is an active element, and can precipitate several bile constituents including bilirubin, carbonate and phosphate - major components of pigment stones^[30]. The parasite eggs precipitated with calcium bilirubinate and admixed with mucin, which is abundant in a liver fluke infection^[3,25]. Mucin secreted by biliary epithelial cells has been recognized as an important local factor in gallstone pathogenesis^[31]. This orchestrated process can eventually produce mature pigment stones as generally described^[32].

Additionally, liver flukes that inhabit the bile ducts can partially obstruct the lumen leading to bile stasis and ascending cholangitis^[3]. *E. coli*, a common bacterial species infecting the biliary system^[23,33], releases β -glucuronidases, which can hydrolyze the glucuronic acid from the conjugated bilirubin^[34-36]. The resulting unconjugated bilirubin precipitates as calcium salts, which is the first step in pigment stone formation^[32,34]. Bile stasis is not only a condition for ascending infection but also induces stagnation of the bile components leading to stone formation^[37]. Heavy *Opisthorchis* infection can induce poor emptying of the gallbladder^[9-11]. In addition, our recent report has shown that severe fibrosis of the gallbladder wall is the main histopathology of chronic opisthorchiasis^[38]. These altogether support the role of this liver fluke in gallbladder stasis, ascending cholangitis and enhanced stone formation. From previous data and our own observations, a proposed pathogenesis of *Opisthorchis*-associated pigment stone formation

is presented in Figure 4.

In conclusion, Northeast Thailand has a high incidence of pigment stones compared to cholesterol stones at cholecystectomy. Our study clearly demonstrates that calcium bilirubinate precipitates on parasite eggshells both in light and SEM studies. This supports the role of *O. viverrini* infection in the pathogenesis of pigment stone formation.

Abstract

AIM: Achalasia is the best known primary motor disorder of the esophagus in which the lower esophageal sphincter (LES) has abnormally high resting pressure and incomplete relaxation with swallowing. Pneumatic dilatation remains the first choice of treatment. The aims of this study were to determine the long term clinical outcome of treating achalasia initially with pneumatic dilatation and usefulness of pneumatic dilatation technique under endoscopic observation without fluoroscopy.

METHODS: A total of 65 dilatations were performed in 43 patients with achalasia [23 males and 20 females, the mean age was 43 years (range, 19-73)]. All patients underwent an initial dilatation by inflating a 30 mm balloon to 15 psi under endoscopic control. The need for subsequent dilatation was based on symptom assessment. A 3.5 cm balloon was used for repeat procedures.

RESULTS: The 30 mm balloon achieved a satisfactory result in 24 patients (54%) and the 35 mm balloon in 78% of the remainder (14/18). Esophageal perforation as a short-term complication was observed in one patient (2.3%). The only late complication encountered was gastroesophageal reflux in 2 (4%) patients with a good response to dilatation. The mean follow-up period was 2.4 years (6 mo - 5 years). Of the patients studied, 38 (88%) were relieved of their symptoms after only one or two sessions. Five patients were referred for surgery (one for esophageal perforation and four for persistent or recurrent symptoms). Among the patients whose follow up information was available, the percentage of patients in remission was 79% (19/24) at 1 year and 54% (7/13) at 5 years.

CONCLUSION: Performing balloon dilatation under endoscopic observation as an outpatient procedure is simple, safe and efficacious for treating patients with achalasia and referral of surgical myotomy should be considered for patients who do not respond to medical therapy or individuals that do not desire pneumatic dilatations.

Dobrucali A, Erzin Y, Tuncer M, Dirican A. Long-term results of graded pneumatic dilatation under endoscopic guidance in patients with primary esophageal achalasia. *World J Gastroenterol* 2004; 10(22): 3322-3327

INTRODUCTION

Achalasia is an uncommon disorder of the esophagus characterized by clinical, radiologic and manometric findings. Dysphagia, regurgitation, weight loss and chest pain are among the most recognized clinical features of the disease. Manometrically it is distinguished by esophageal aperistalsis and incomplete relaxation of the lower esophageal sphincter (LES). Esophageal dilatation and a tapered deformity of the distal esophagus are presumably late radiological manifestations of the disease^[1,2]. The pathogenesis of achalasia remains unknown. Available data suggest hereditary, degenerative, autoimmune and infectious factors as possible causes for achalasia, the latter two are the most commonly accepted possible etiologies. The mean age of onset varies between 30 and 60 years with a peak incidence in the fifth decade. The incidence is 1.1 per 100 000 with a prevalence of 7.9 to 12.6 per 100 000^[2,3].

Although there is no definite cure for achalasia, the goals of treatment should be: 1) relieving the patient's symptoms, 2) improving esophageal emptying and 3) preventing development of a megaesophagus. The optimal treatment of achalasia includes several options and presents a challenge for most gastroenterologists. It can be treated by botulinum toxin injection, pneumatic dilatation or esophagomyotomy, but the most effective treatment options are graded pneumatic dilatation and surgical myotomy. All of these therapeutic modalities are aimed at removing the functional barrier at the lower esophageal sphincter level. Although high success rates have been reported for these therapeutic modalities, the fact remains that the esophageal propulsive force is not usually restored and therefore it is conceivable that a normal esophageal function can never be expected among these patients^[2,4,5].

The aim of our study was to evaluate the safety and efficacy of graded pneumatic dilation using two different size (3.0 and 3.5 cm) balloon dilators (Rigiflex) in patients with primary esophageal achalasia. We hereby report our experience, which indicates that pneumatic dilatation can be safely performed under direct endoscopic observation without fluoroscopic guidance and with only a short-term clinical monitoring in an outpatient setting prior to discharge.

MATERIALS AND METHODS

Patients

Forty-three consecutive patients (23 males and 20 females) were evaluated. The ages ranged from 19 to 73 years with a mean age of 43 years. All patients were referred because of typical symptoms of achalasia. All had dysphagia, but some also had regurgitation or pulmonary aspiration (Table 1). The diagnosis of achalasia was made on the basis of clinical, radiologic and manometric criteria. Barium esophagogram showed a distal narrowing of the esophagus (bird beak deformity) and variable degrees of dilation of the esophagus in most patients (93%). Mean esophagus diameter was 3.8 cm (range, 2-6.3 cm). Upper endoscopy was done in all patients to exclude secondary causes of achalasia. Computerized tomography of the chest was done in 12 patients over age 40 with significant weight loss over a short period (six months or less) to exclude mediastinal malignancy

causing pseudoachalasia.

Eligibility criteria for entry into the study required: a diagnosis of achalasia by manometry as defined above, absence of obstructive intrinsic or extrinsic esophageal lesions by X-ray and endoscopy, and Absence of esophageal or gastric carcinoma, a peptic stricture or a prior surgical fundoplication.

Symptoms of the patients were scored using a questionnaire requesting information regarding the presence and severity of their difficulty in swallowing solids and liquids on a 5 point subjective visual scale: 0 = no symptoms, 1 = mild, 2 = moderate, 3 = severe, 4 = very severe.

Table 1 Clinical characteristics and demographic data of patients [mean±SD, (min-max)]

Age (yr)	44±16 (19-73)
Gender (M/F)	23/20
Dysphagia	43 (100%)
Chest pain	5 (11%)
Regurgitation	34 (79%)
Pulmonary aspiration	9 (21%)
Mean duration of symptoms (mo)	35±21 (6-72)
Mean weight loss (kg)	7.7±2 (4-11)
LES pressure (mmHg)	
Before dilation	38.6±12 (19-66)
After dilation	11.8±8 (0-16)
Vigorous achalasia	1 (2.3%)
Esophagus diameter (cm)	3.8 (2-6.5)

Esophageal manometry

Esophageal manometry was performed in all patients with a four lumen polyvinyl catheter with Dent sleeve working with a pneumohydraulic capillary perfusion system (Synectic PC polygraph- Gastrosoft Inc. Upper GI edition, version 6.0). Manometric examinations were performed by the same author. LES was localised using the station pull-through technique. Other three orifices, located 5 cm apart and also oriented at 90° angles, for determination of the peristalsis and pressures, by placing the distal orifice 5 cm above the LES. The peristalsis was measured with 10 wet swallows of 5 mL of water, each at intervals of 60 s or more. Aperistalsis was the absolute manometric criterion required for the diagnosis of achalasia with increased LES pressure and incomplete/absent relaxation were the complementary findings^[7]. Incomplete relaxation was defined as the failure of LES pressure to drop to gastric baseline during a dry and /or wet swallow (Figure 1).

Technique of pneumatic dilation

All dilations were performed on outpatients. Dilations were

done by the same authors using the Rigiflex achalasia balloon dilators (Microvasive) in a graded manner. A 3.0 cm dilator was always used first. If there was still no symptomatic response, a 3.5 cm dilator was used after 6-8 wk. After clear liquid diet for 24 h and an overnight fast, an endoscope (Pentax EG-2940) was passed after application of a local anesthetic to the pharynx under conscious sedation (Midazolam 0.04 mg/kg iv) to evacuate the residual liquid from the esophagus and to insert a guide wire. The guide wire was placed into the duodenum via stomach under endoscopic guidance and endoscope was removed. A Rigiflex balloon dilator, which was marked with a thick coloured marker at the mid section of the balloon was passed over the guidewire to stomach and slightly inflated (less than 5 psi) to get a soft tube shaped form. Endoscope was reinserted and positioned proximally to adjust and control the position of the balloon in the esophagus. Balloon was withdrawn to esophagus and marked part of the balloon was located within the gastroesophageal junction under endoscopic control (Figure 2). The balloon was then inflated until 15 psi. and inflation was maintained for 60 s. Ischemic ring at the lower esophageal sphincter level was seen during dilatation through the transparent balloon. After repeating of the same inflation procedure one more time at the same session endoscopic dilatation was terminated and endoscope, balloon and guidewire were removed. Balloon dilator surface was checked to see if there was blood on it. The procedure was well tolerated by all patients.

Figure 2 Technique for pneumatic dilation under endoscopic control without fluoroscopy. The balloon was positioned so that its midsection was at the high pressure level (A). The balloon was inflated and the endoscopist observes with endoscope proximally to balloon (B). With successful dilatation the ischemic ring of dilated segment was diminished or disappeared (C).

Figure 1 Manometric samples from a normal individual (A) and a patient with achalasia (B). Figure A illustrates the normal peristaltic activity forwarding at cranio-caudal direction whereas figure B shows typical manometric findings of achalasia. Note the aperistalsis, weak and simultaneous contractions (mirror sign), and incomplete LES relaxation after swallow. Basal LES pressure is high (40 mmHg).

The severity of chest pain in patients was scored after the balloon dilation on a scale of 0-10 (0, absence of pain; 10 severest pain). Gastrograffin swallow was done few hours after dilation to exclude esophageal perforation. After an observation period of 6 h, patients were discharged and permitted to eat the next morning.

Second esophageal manometry and symptom scoring were performed in all patients with therapeutic response six weeks after pneumatic dilation to evaluate the efficacy of endoscopic balloon dilation.

The response to balloon dilation was considered excellent if there was no or very rare mild dysphagia, good if there was intermittent mild dysphagia, or poor if there was persistent daily mealtime dysphagia. The balloon therapy was considered successful if the patients had a good or excellent response.

Statistical analysis

Results were expressed as either percentages or mean \pm SD. Statistical analysis was performed using Chi-square test, Kendall's tau-b coefficient and Mann-Whitney U test as appropriate. $P < 0.05$ was considered statistically significant. The cumulative remission rates of the patients treated with balloon dilation were estimated by the Kaplan-Meier method and the difference between treatment groups was tested by the log rank test.

RESULTS

The clinical characteristics and demographic data of patients are shown in Table 1. The mean LES pressure was 37.6 \pm 12 mmHg. Relaxation failure of LES and aperistalsis with low amplitude simultaneous uniform waves were present in all patients. Only one of the 5 patients with retrosternal pain was diagnosed as a vigorous achalasia (2.3%) at esophageal manometry. The LES pressures and symptom scores of successfully dilated patients were decreased significantly one month after dilation, (37.6 \pm 12 vs 9.5 \pm 3) and (2.9 \pm 0.6 vs 0.8 \pm 0.6) respectively ($P < 0.01$) (Figure 3). There was no significant correlation between the parameters of age, sex, initial LES pressure, symptom score and barium study findings.

Chest pain was reported by all patients during the initial dilation, with a mean pain score of 7.2 \pm 2.3 (range, 4-10). Chest pain score was 8.1 \pm 1.8 in patients who were successfully dilated at the first session although score was 4.8 \pm 2.1 in patients with a poor response to initial balloon dilation ($P < 0.05$). Chest pain after the procedure usually lasted for 30-60 min and was substernal in nature, diminishing gradually over time and resolved completely within 2 to 6 h.

The results of balloon dilation are summarized in Table 2. A total of 65 dilations were performed in 43 patients for an average of 1.7 dilations per patient. The 3 cm balloon was always used first. Twenty-four patients (56%) were successfully dilated

with a 3 cm balloon only. Fourteen patients had an excellent response (32.5%) and 10 patients had a good response (23%) to 3.0 cm balloon dilation. Old age at the time of initial pneumatic dilation was significantly associated with a better clinical response to treatment as assessed by the need for subsequent treatments (Kendall's tau-b = 0.414, $P = 0.016$) (Table 3).

Eighteen patients (42%) with a poor response to 3.0 cm balloon were dilated with a 3.5 cm balloon at intervals of 6-8 wk. Nine patients had excellent, five had good and four patients had poor response to the second dilation with a 3.5 cm balloon.

Figure 3 Lower esophageal sphincter pressures (LESP) (A) and symptom scores (B) of patients with therapeutic response initially and at one month after pneumatic dilatation.

Patients with a poor response to the second dilation with a 3.5 cm balloon were dilated with a 3.5 cm balloon at the third time but all of them were symptomatic after a while and these patients were no longer treated with a larger balloon (4 cm), instead, surgical treatment was suggested. One patient who refused surgery had repeated dilation every 6 to 12 mo with a 3.5 cm balloon due to symptom recurrence.

The mean follow-up period in the entire group was 2.4 years (range, 6 mo -5 years). Among the 38 patients whose long term follow up information was available, 33 (87%) at six months were asymptomatic [Among them 23 (70%) required once and 10 (30%) required twice dilation]. At the end of the first year, 16 of 24 patients (66%) whose follow up information was available were asymptomatic. Among the 24 patients, 3 (12.5%) complained of mild intermittent dysphagia and 5 (21%) had intermittent severe dysphagia. The total number of asymptomatic patients and patients with mild dysphagia was 19 (79%) at the end of the first year. Among these, 10 patients (52%) required a second dilation.

Among patients whose follow up information was available at 3 years the 19, 13 were in remission (68%) (5 asymptomatic and 8 with intermittent mild dysphagia). Among patients whose follow up information was available at 5 years the 13, 7 were in remission (54%) (3 were asymptomatic and 4 with mild intermittent dysphagia). Among the total, 3 patients (44%) required once and 4 (56%) required twice dilation (Figure 4). Figure 5 shows the Kaplan-Meier plot for the two treatment groups of patients who were dilated once or twice. The cumulative one, three and five year remission rates were higher in patients dilated twice but this difference was not statistically significant (Log rank $\chi^2 = 2.10$, $P = 0.1471$).

Figure 4 Percentage of patients with excellent and good response to dilatation at 6 mo, 1, 3 and 5 years.

Figure 5 Kaplan-Meier plot for the two treatment groups of patients who were dilated once² or twice¹. The cumulative one, three and five year remission rates were higher in patients dilated twice but this difference was not statistically significant (Log rank $\chi^2 = 2.10$, $P = 0.1471$).

Gastrograffin swallow done immediately after balloon dilation revealed esophageal perforation in one patient (2.3%) (a 60 years old female) with persistent chest pain and surgical therapy was required. There were no other immediate complications. Reflux esophagitis as a late complication was observed in two of the patients who had a good response to dilatation during the follow up period (4%).

Blood on the balloon after dilatation was a common finding. There was no statistically significant correlation between bloody dilator and dilatation success ($P > 0.05$).

DISCUSSION

This study analysed the effectiveness of pneumatic balloon dilation and the clinical outcome in patients with achalasia. Our results showed that once or twice pneumatic dilatation provided good results in the majority of patients with achalasia and long term results were 79% at 1 year and 54% at 5 years. Of the patients studied, 38 (88%) were relieved of their symptoms after one or two sessions. An initial pneumatic dilation was an effective single treatment with no further treatment needed in 57% of patients in a short term period. The remaining 43% of patients treated initially with pneumatic dilation needed additional treatments due to persistent or recurrent symptoms and only 11% of patients failing pneumatic dilatation were referred for surgery (4 with poor response to repeated dilations and 1 with perforation due to dilation). Four patients with a poor response to the second dilation with a 3.5 cm balloon were dilated with a 3.5 cm balloon the third time but all of them were symptomatic after a while and these patients were not treated with a larger balloon. Some studies have reported using a 3.5 cm balloon instead of a 3 cm balloons one as the initial balloon but others have used 3 cm for the initial dilatation^[8,9,11]. In our series application of the second pneumatic dilation increased the long term clinical benefit of pneumatic dilation from 30% at six months to 57% at 5 years, but this difference was not statistically significant ($P > 0.05$) (Figure 4). To some extent, our results about the clinical benefit of a single pneumatic dilatation and the use of the second dilatation for patients with persistent symptoms are in agreement with other studies. It has been shown that the overall efficacy of endoscopic balloon dilation was approximately 85%, with an excellent to good response for 3, 3.5 and 4 cm dilators being 70%, 87% and 93% respectively (9 studies; four prospective, five retrospective, 261 patients, a mean follow up of 1.9 years (range; 0.3 to 6 years)^[10-17] (Table 4). Approximately 50% (range, 17% to 75%) of all patients required repeat dilations, equaling to 1.2 to 2 dilations per patient. About one half of patients responded to a repeat dilation, with the remainder either proceeding to surgical management or deciding to live with their persistent symptoms. The reported overall long-term efficacy of pneumatic dilatation was 50-90% at 1 year and 60% at 5 years^[1]. The major adverse event with pneumatic dilatation was esophageal perforation with a 2% cumulative rate. The American Society for Gastrointestinal Endoscopy has recommended that if a single dilation session (size of the balloon dilator unspecified) does not produce satisfactory relief, a second attempt may be warranted and if this fails, surgery usually is indicated^[15].

The patient population undergoing initial dilation in this study was not large enough to compare the effect of age on the dilation success, but our results indicate that initial pneumatic dilation was more effective in older patients (χ^2 value: 8.215^a, $P = 0.016$, Kendall's tau-b 0.414, $P = 0.001$). This increased clinical benefit of pneumatic dilation in old patients has also been described by other investigators^[19,21,22]. There was no significant difference between the mean ages of the patients with and without remission at the end of 1 and 5 years although

the patients in remission at 5 years were older, $[43 \pm 16$ ($n = 19$) vs 48 ± 16 ($n = 5$) ($P > 0.05$) at 1 year and 53 ± 17 ($n = 7$) vs 37 ± 14 ($n = 6$) ($P > 0.05$), at 5 years respectively]. The efficacy of pneumatic dilatation was not influenced by initial LES pressure and esophageal diameter (Table 3).

After balloon dilation, the mean LES pressure was 11.8 ± 4 mmHg (range, 0-16 mmHg) and it represented 75% decrease of basal LES pressure. It has been shown that basal LES pressure decreased from 39% to 68% after dilation but these changes did not allways indicate a dilation success. In general, a decrement in LES pressure of more than 50% or an absolute end-expiratory LES pressure of less than 10 mmHg were more indicative of clinical success^[2]. Timed barium esophagogram or scintigraphy may correlate with symptomatic improvement in up to 72% of patients. In spite of this similarity, approximately one third of patients who noted complete relief showed less than 50% improvement in barium column height and esophageal diameter^[21].

Only one of 43 patients in our series had an esophageal perforation during treatment with pneumatic dilatation (2.3%). This complication rate is similar to those reported by other experienced groups^[9,19,20]. Gradual increase in dilator size based on symptomatic response and the use of inflation pressure between 10 to 15 psi can minimize the risk of perforation. Esophageal perforation may occur in up to 5% of all reported cases, with a possible increased risk if hiatal hernia is present. In our study gastrograffin swallow was performed in all patients. Using immediate contrast studies to exclude perforation became routine in the late 1970's, and using this approach has been recommended in several studies and text books. Some authors suggested that contrast studies were indicated only when there was clinical suspicion of perforation. It has been reported that an immediate contrast study may not always exclude a perforation which may become clinically evident several hours later^[5].

Less commonly, intramural hematoma, diverticula at gastric cardia, mucosal tears, reflux esophagitis, prolonged post-procedure chest pain, fever, hematemesis without changes in hematocrit and angina may occur after pneumatic dilatation. Objective assessment of gastroesophageal reflux after pneumatic dilation rarely has been studied. Abnormal 24 h pH scores have been documented in approximately 20% to 33% of patients after dilation. In spite of these abnormal scores, very few of these patients were symptomatic or developed endoscopic or clinical evidence of GERD related complications. It has been shown that postdilatation LES pressures and gastric emptying were similar between reflux and non-reflux groups^[2]. Since GERD related symptoms correlated poorly in achalasia patients, 24 h pH monitoring has been recommended for patients that developed frequent heartburn, reflux or chest pain in spite of an otherwise good clinical response to dilation. One of the important points of this study was the dilatation technique which did not require fluoroscopic control (see materials and methods). Our experience

shows that Rigidflex balloon can be successfully positioned across the gastroesophageal junction and inflated under direct endoscopic observation. This technique is as effective as conventional fluoroscopic technique and has an advantage to prevent patients and endoscopists from an additional X-ray. Furthermore we have seen that patient tolerability was very good and success rates were reasonable and comparable with others. Safety and efficacy of pneumatic dilation for achalasia without fluoroscopic control also have been shown by Lambroza and Levine^[16,18].

In a recently published interesting study, Cheng *et al.* evaluated the usefulness of temporarily placing of covered stents for 3-7 d versus pneumatic dilatation and found that the early and late (at one and three years respectively) relapse rates were quite low in the stent treated group versus the pneumatic dilatation treated one^[23]. The success of this method was suggested to be due to chronic tearing of the cardia muscularis which resulted in a diminished amount of fibrosis and so restenosis after the stent was withdrawn.

The results of our study suggest that pneumatic dilatation for achalasia without fluoroscopic guidance is a safe and effective treatment modality. A gradual increase in dilator size based on symptomatic response minimizes complications. Symptomatic patients with achalasia who are good surgical candidates should be given an option of graded pneumatic dilatation before surgery. Although surgical myotomy, once with a high mortality and long hospital stay, can now be performed laparoscopically with a similar efficacy to the open surgical approach, reduced morbidity and hospitalization time, referral of myotomy should be considered for patients who do not respond to medical therapy or individuals that do not desire pneumatic dilatations. The advantages of pneumatic dilatation over surgical myotomy are a brief period of discomfort, a very short hospital stay and consequently low exposure.

Abstract

AIM: A circannual variation in the onset of several acute diseases, mostly dealing with cardiovascular system, has been reported. The present study was to verify the possible existence of a seasonal variability in the onset of acute pancreatitis.

METHODS: All patients consecutively admitted to the Hospital of Ferrara, Italy, between January 1998 to December 2002, whose discharge diagnosis was acute pancreatitis, were considered. According to the time of admission, cases were categorized into twelve 1-mo intervals and in four periods by season. χ^2 test for goodness of fit and partial Fourier series were used for statistical analysis.

RESULTS: During the study period, 549 cases of acute pancreatitis were observed. A significant peak of higher incidence was found in March-May, both for total population, males and subgroups with and without cholelithiasis or alcoholism. Fourier analysis showed the existence of a circannual rhythmic pattern with its main peak in March (95% C.L.: February-April, $P = 0.005$), and a secondary one in September. Death occurred more frequently in December-February, compared to the other periods ($P = 0.029$), and chronobiologic analysis yielded a seasonal peak in November-December ($P < 0.001$).

CONCLUSION: This study shows the existence of a circannual variation in the onset of acute pancreatitis, with a significantly higher frequency of events in the spring, especially for patients with cholelithiasis or alcoholism. Moreover, events occurring during the colder months seem to be characterized by a higher mortality rate.

<http://www.wjgnet.com/1007-9327/10/3328.asp>

INTRODUCTION

Many studies have shown a circannual variation in the onset of several diseases mostly dealing with cardiovascular system, characterized by an abrupt onset, e.g., fatal pulmonary embolism^[1,2], ischemic and hemorrhagic stroke^[3,4] and rupture of aortic aneurysms^[5,6]. Seasonal specific patterns have also been reported

for a series of miscellaneous diseases characterized by an acute onset, treated by the Emergency Department, including paralysis of cranial nerves^[7], microcrystalline arthritis^[8], herpes zoster infection^[9], epistaxis^[10], urinary retention^[11]. In the last few years several studies have investigated gastroenterologic diseases, and seasonal etiological patterns have been reported for the onset of peptic ulcer^[12-15] and exacerbation of inflammatory bowel diseases^[16-18]. The aim of the present study was to determine by means of a validated chronobiological analysis, whether acute pancreatitis, a common but potentially harmful entity, might show a rhythmic seasonal variation as well.

MATERIALS AND METHODS

All cases of acute pancreatitis (International Classification of Diseases, 9th Revision, Clinical Modification, ICD9-CM code: 577.0-8) consecutively observed from 1 January 1998 to 31 December 2002 at the St. Anna Hospital of Ferrara, Italy, were considered for the study. Ferrara is a small town in northern Italy particularly well suited for epidemiological studies. It has a stable population of approximately 150 000 inhabitants, almost exclusively white. The only available hospital in this community is St Anna Hospital, which also serves as the sole teaching center for the School of Medicine. The day and month of each event were categorized both into four 3-mo periods (according to seasons) and into twelve 1-mo intervals. Diagnosis was always made on the basis of clinical features, physical examination, laboratory data (serum amylase, isoamylase, lipase, and urinary amylase), and instrumental examinations, when necessary. For all subjects with acute pancreatitis the presence or absence of the two leading specific risk factors (alcoholism and biliary tract disease), was carefully investigated.

For statistical analysis, two different methods were used: χ^2 test for goodness of fit and partial Fourier series. To investigate possible differences in frequency peaks, χ^2 test for goodness of fit was applied to the total sample population and subgroups by gender, comparing observed against expected events during the four intervals season^[19]. On the other hand, to verify the possible existence of a reproducible rhythmic pattern, cosinor analysis and partial Fourier series were applied to the time series, using specific commercially available software written for the Apple Macintosh computer^[20]. The program allows, among all the possible combinations of the periods chosen by the user, the selection of the harmonic or the combination of harmonics that best explain the variance of data. The percentage of rhythms (PR: percentage of overall variability of data about the arithmetic mean attributable to the fitted rhythmic function) and the probability value resulting from the F statistic used to test the hypothesis of zero amplitude, were chosen to be reported in the results as representative parameters of goodness of fit and statistical significance of each fitted function, respectively. The program was used to calculate the midline estimating statistic of rhythm (MESOR: the rhythm-adjusted mean over the time period analyzed) and the amplitude (half the distance between the absolute maximum and minimum of the function) of the best-fitting-curve. The program was also used to calculate peak (orthophase) and trough (bathypase) times of the fitted curves (times of occurrence of the absolute maximum and minimum) and the acrophase of each single harmonic change, together with the 95% confidence limits (CL). Significance

levels were always assumed for $P < 0.05$. Conventional statistical analysis was performed using Student's t test for unpaired data. Significance levels were always set at $P < 0.05$.

RESULTS

From January 1998 to December 2002, 549 consecutive cases of

acute pancreatitis were observed, 285 cases were males (51.9%) and 264 were females (48.1%), their mean age was 65 ± 17 years (difference between sexes $t = 2.7$, $P = 0.007$). Two hundred and eighty-six had cholelithiasis (52.1%) and 48 had chronic alcoholism (8.7%).

Deaths from acute pancreatitis were 18 (14 males and 5 females), accounting for 3.2%. Their mean age was 56 ± 16 years,

PR = percentage of rhythm (percentage of overall variability of data about arithmetic mean attributable to the rhythmic fitted function MESOR = midline estimated statistics of rhythm, the rhythm-adjusted mean over the time period analysed amplitude: half the distance between the absolute maximum and minimum of the function of the best-fitting curve 95% CL = 95% confidence limits NS = not significant, (when acrophase did not reach the significance level, 95% CL could not be given).

significantly lower than that of survived subjects (65 ± 17 years, $t = 2.20$, $P = 0.028$). Among the subgroups of fatal events, 3 had gallstones (16.6%, $\chi^2 = 1.91$ $P = 0.178$), and 4 had chronic alcoholism (22.2%, $\chi^2 = 3.78$ $P = 0.075$). Table 1 shows the monthly distribution by gender, and subgroups by risk factors. A peak of higher frequency of events was found in the period March-May for the total samples and in particular for males and subgroups of subjects with and without gallstones and chronic alcoholism (Table 2). The percentage of fatal events was significantly higher in December-February ($n = 9$, 17.3% of acute pancreatitis observed in that period, 50% of total deaths, $\chi^2 = 9.11$, $P = 0.029$, compared to the other periods).

Chronobiologic analysis (Table 3) showed the existence of a circannual rhythmic variation characterized by a main peak in March (PR 84.8, 95% CL: February-April, $P = 0.005$), and a secondary peak in September. This pattern was confirmed also for subgroups by gender (men: PR 75.4, 95% CL: February-April, $P = 0.027$), and (women: PR 73.3, 95% CL: February-April, $P = 0.035$). Moreover, a highly significant peak was noticed for fatal cases in late November (PR 97.1, 95% CL: October-December, $P < 0.001$). NO statistically significant trend for a peak in March was found for subgroups of subjects with or without cholelithiasis (respectively: PR 61.8, 95% CL: February-April, $P = 0.109$; and PR 69.9, 95% CL: February-April, $P = 0.052$).

DISCUSSION

Identification of patients with acute pancreatitis is important due to the increased risk of death.

To our knowledge, there was only one recent study in medical literature, which aimed to evaluate the seasonal variation in the onset of acute pancreatitis^[20]. In a total of 263 cases observed for a period of 9 years in a German hospital, no correlation between admissions and a specific month or season was found, other earlier reports were mostly hypotheses^[21,22]. Our study instead showed a clear seasonal variation in the onset of acute pancreatitis characterized by a higher frequency in the spring, with a maximum in March-May. This pattern was particularly evident for patients with cholelithiasis and chronic alcoholism. It is difficult to give an exhaustive explanation for such a temporal pattern. Seasonal and circannual patterns have been reported for the prevalence of *Helicobacter pylori* infection^[14], or for relapses of inflammatory bowel disease for hospital admissions^[15,23].

As for circadian aspects, some acute dramatic clinical events, e.g., variceal and gastrointestinal bleeding^[24-26] showed obvious circadian patterns. Daily variations of some biologic functions have also been found as possible co-factors in several gastrointestinal diseases, e.g., fibrinolysis in liver cirrhosis and esophageal varices^[27], electrical uncoupling and ectopic pacemaker activity in intestinal motor dysfunction^[28], melatonin and duodenal ulcer^[29,30], colonic motility in diverticular disease^[31] and rectal motor activity in constipation^[32].

At present we do not know enough about seasonal biological changes potentially affecting onset of acute pancreatitis, e.g., secretion of pancreatic enzymes, biliary acids. However, it is possible that variations in physiological functions with seasonal change may be associated with an increased risk of pancreatitis. Oxygen free radicals, for example, were known to be a meaningful index for the severity of pancreatitis^[33], but possible variations in free radical generation have not been investigated yet. Our results seemed to be able to identify a higher mortality for colder months (November-December). This is particularly interesting when considering that both the mean age of subjects and the incidence of risk factors (gallstones, alcoholism) in the subgroup of fatal cases were significantly lower compared with those in the subgroup of non fatal events. Thus, it seems that acute events of pancreatitis occurring in the colder months

may be more at risk in terms of severity and mortality. Further studies conducted on larger samples and addressed to other countries of different latitudes would be needed.

ACKNOWLEDGEMENTS

The authors thank Mr. Franco Guerzoni, from the Statistical Service of Ferrara St Anna Hospital, for his helpful assistance in collection of cases and analysis of data.

Abstract

AIM: To evaluate the significance of the composite score of reflux symptoms in the diagnosis of gastroesophageal reflux disease (GERD), and to determine the relationship of the composite score with reflux esophagitis (RE) and pathological gastroesophageal reflux (PGER).

METHODS: Upper digestive endoscopy and /or 24-h esophageal pH monitoring were performed in 244 subjects. Of these, 54 were consecutive patients attending our clinic with symptoms suggestive of GERD, and 190 were randomly selected from 2532 respondents who participated in our previous general population-based study on GERD. A standardized questionnaire was used to classify both the frequency and severity of typical symptoms of GERD (heartburn, acid and food regurgitation) using a 4-score scale, and the composite score of main reflux symptoms (score index: SI, range from 0 to 18) were calculated for every subject. RE was diagnosed according to the Savary-Miller criteria. Subjects with abnormal pH-metry (DeMeester score more than 14.7) were considered to have PGER. GERD patients were defined as the subjects with RE and/or PGER.

RESULTS: The sensitivity of SI in the diagnosis of GERD was inversely associated with SI, but the specificity tended to increase with increased SI. With the cut-off of 8, the SI achieved the highest accuracy of 70.0%, with a sensitivity of 78.6% and a specificity of 69.2% in diagnosing GERD, followed by the cut-off of 3, which had an accuracy of 62.1%, a sensitivity of 96.4% and a specificity of 34.6%. The prevalence of RE, PGER and GERD was strongly associated with increased SI ($P < 0.01$), but there was no significant association between the severity of RE and SI ($P > 0.05$). Among patients with RE, 69.2% had PGER, and 30.8% were confirmed to have negative findings of pH monitoring. Among patients with PGER, 52.9% were identified to have RE and 47.1% had negative endoscopic findings in esophagus.

CONCLUSION: According to the composite score of main reflux symptoms, the diagnosis of GERD can be made without further tests in most cases. However, 24-h esophageal pH monitoring and upper digestive endoscopy are still indicated in patients with mild and atypical symptoms.

INTRODUCTION

Gastroesophageal reflux disease (GERD) is a very common disorder both in China^[1-2] and Western countries^[3-8]. The disease results from the abnormal reflux of gastric contents into the distal esophagus causing symptoms in most patients and subsequent mucosal damage in some patients. It has been proved that chronic GERD tends to develop to Barrett's esophagus associated with an increased risk of esophageal adenocarcinoma^[9-13]. Heartburn and regurgitation are the typical symptoms of GERD, and 24-h esophagus pH monitoring and upper digestive endoscopy are the main methods to confirm the diagnosis. These examinations, however, are inconvenient and not universal in many hospitals of China, especially 24-h esophagus pH monitoring. Although the relationship between reflux symptoms and GRED were evaluated by some clinical studies, the results varied considerably because the symptoms were quantified by different criteria and methods^[3,14-16]. As far as we know, data about the relationship between the combination of main reflux symptoms and proven GERD are lacking. The aim of this study was to establish a standard system to quantify the severity and frequency of typical reflux symptoms, and to evaluate the role of the composite score of main reflux symptoms in the diagnosis of GERD, and to determine the association between the composite score and reflux esophagitis (RE), pathological gastroesophageal reflux (PGER), and GERD.

MATERIALS AND METHODS

Subjects

Two hundred and forty-four subjects were included in this study. Among these, 54 were consecutive patients (32 men and 22 women; mean age, 45.3 ± 13.2 years) who attended our clinic with symptoms suggestive of GERD and underwent both 24-h esophageal pH monitoring and upper digestive endoscopy. The remaining 190 subjects were randomly selected from 2532 respondents who were previously enrolled in our general population-based study on GERD, according to the composite score (score index, SI) of main reflux symptoms (Table 1), and who underwent 24-h esophageal pH monitoring (50 subjects) or/and upper digestive endoscopy (140 subjects). Patients with previous foregut surgery and other systemic disorders affecting the gastrointestinal motility were excluded. Five selected respondents (3 in the normal group and 1 in the mild symptom group) refused to participate in this study, 1 (normal group) had intolerance to pH monitoring, and 1 (normal group) did not complete the evaluation. All of the 7 incomplete respondents were replaced by our clinic patients with same gender, SI, and similar age (± 5 years). There were no appreciable differences in age or gender among these groups ($P > 0.05$).

Questionnaire

A standardized questionnaire based on our previous work was

Table 1 Gender and age distribution of 190 subjects in symptom severity groups

Severity of symptoms	Responders	Upper digestive endoscopy			24-h pH monitoring		
		Subjects	Men/Women	Mean age (yr)	Subjects	Men/Women	Mean age (yr)
Normal	2 102	40	17/23	45.5±9.9	15	8/7	45.3±10.4
Mild	332	40	20/20	46.1±14.4	15	6/9	46.5±13.3
Moderate	74	40	18/22	47.4±9.6	10	5/5	47.4±10.6
Severe	24	20	11/9	49.1±10.2	10	4/6	49.7±11.5
Total	2 532	140	66/74	47.0±11.0	50	23/27	47.2±11.5

Criteria of SI	Endoscopic examination		pH monitoring		Endoscopic or/and pH examination	
	Subjects	RE (%)	Subjects	PGER (%)	Subjects	GERD (%)
Normal (SI = 0-2)	40	0 (0.0)	15	0 (0.0)	55	0 (0.0)
Mild (SI = 3-7)	40	3 (7.5)	15	2 (13.3)	52	4 (7.69)
Moderate (SI = 8-12)	40	11 (27.5) ^b	10	4 (40.0) ^a	45	12 (26.7) ^b
Severe (SI ≥13)	20	13 (66.5) ^b	10	6 (60.0) ^b	24	13 (54.2) ^b

^a $P < 0.05$ and ^b $P < 0.01$ vs normal group.

used to classify both the frequency and severity of typical symptoms of GERD (heartburn, acid regurgitation and food regurgitation) for all subjects before pH monitoring and upper digestive endoscopy. Personal interviews were carried out in our clinic with patients and respondents.

Endoscopy

General upper digestive endoscopy was performed using a Pentax videoendoscope, and the same two gastrointestinal physicians made the diagnosis according to VHS videocassettes recorded.

Twenty-four hour esophageal pH monitoring

Twenty-four hour ambulatory esophageal pH monitoring was performed using a Synectic device. The pH electrode should be positioned 5 cm above the lower esophageal sphincter. Subjects were instructed to fill in diary cards regarding the time of meals, supine position and the time of symptoms experienced during the 24-h period. In addition, they were asked to press a button on the digital data logger at the beginning of each symptom episode. No restrictions were imposed on food and beverage intake or smoking.

Definitions

The following definitions for symptom categories and diseases were used. Only symptoms occurring in the past year before the interview were considered. Heartburn was defined as a burning pain or burning sensation behind the breastbone in the chest, acid regurgitation as a bitter or sour-tasting fluid coming into throat or mouth, food regurgitation as eaten foods coming into mouth. Heartburn, acid regurgitation and food regurgitation were considered to be the typical symptoms of GERD. Each of these symptoms was estimated according to its severity and frequency measured on a 4-score scale. Severity was assessed as follows: 0, none; 1, mild (could be ignored); 2, moderate (could not be ignored but did not affect lifestyle); 3, severe (affected lifestyle). The score of symptom frequency was estimated as follows: 0, none or less than one occasion per month on average; 1, several occasions (once to three times) a month; 2, several occasions (once to six times) a week; 3, one or more daily occasions. Based on the scores of severity and frequency of the main GERD symptoms, the composite score (SI: ranged from 0 to 18) of every subject was calculated. All subjects were grouped as follows: SI = 0-2, normal; SI = 3-7,

mild; SI = 8-12, moderate; SI ≥13, severe. Patients with symptomatic gastroesophageal reflux disease (SGERD) were defined as subjects with SI ≥ R3. Those with RE were defined as subjects whose endoscopic findings met Savary-Miller criteria, those with PGER as subjects with abnormal pH-metry (DeMeester score more than 14.7), those with GERD as subjects with RE and/or PGER.

Statistical analysis

Data were analyzed with descriptive statistics and expressed as mean ± SD. Median values and ranges were used for nonparametric variables. Relative proportions were calculated for the analysis of prevalence and relative frequencies. The comparison between groups was performed by means of parametric tests such as the Student's *t* test for dimensional variables and χ^2 test for non-dimensional variables. The critical two-tailed value of alpha was set at 0.05.

RESULTS

Relationship between SI and its diagnostic accuracy for GERD

Among the 54 outpatients with symptoms suggestive of GERD, 28 patients (51.9%) were identified as GERD (16 patients with RE, 12 patients with PGER, 10 patients with RE and PGER), and 26 patients (48.1%) were normal, based on the findings of upper digestive endoscopy and 24-h esophageal pH monitoring. Figure 1 summarizes the relationship between criteria and its diagnostic accuracy for GERD compared with the diagnosis of endoscopy and pH monitoring. The sensitivity was inversely associated with increased SI, but the specificity tended to be higher with increased SI. The SI ≥ 8 had the highest accuracy (70.0%) for diagnosing GERD with a sensitivity of 78.6% and a specificity of 69.2%, followed by SI ≥ 3 with an accuracy of 62.1%, a sensitivity of 96.4% and a specificity of 34.6%.

Relationship between SI and RE, PGER, GERD

As shown in Table 2, the rate of RE was the highest in the severe group, followed by moderate, mild and normal groups, and the results were similar to both PGER and GERD. The rate of RE, PGER and GERD was strongly associated with increased SI. In the severe and moderate groups, the frequency of RE, PGER and GERD was significantly higher than that of the normal group ($P < 0.05$ or $P < 0.01$).

Figure 2 Endoscopic photographs of some patients with RE. A: Female, 46 years old, SI = 12, grade I RE; B: Male, 50 years old, SI = 16, grade II RE; C: Male, 42 years old, SI = 12, grade III RE; D: Male, 51 years old, SI = 13, grade IV RE.

Figure 1 Relationship between SI and its diagnostic accuracy.

Figure 3 The relationship between RE and PGER.

Relationship between SI and degree of RE

RE was diagnosed in a total of 43 patients on the basis of endoscopic findings (16 cases were outpatients and 27 cases came from general subjects). Thirty patients were males and 13 were females. The mean age was 55.3 ± 6.8 years. Table 3 shows the relationship between SI and the severity of RE. The SI was similar among all groups (from grade I to grade IV, $P > 0.05$). Figure 2 illustrates endoscopic photographs of some patients with RE.

Table 3 Relationship between severity of symptoms and grade of RE

Severity of RE	Patients	SI (mean \pm SD)
Grade I	19	10.63 \pm 4.74
Grade II	13	11.32 \pm 5.26
Grade III	7	11.85 \pm 5.11
Grade IV	4	12.00 \pm 4.12

Relationship between RE and PGER

Of the 43 patients with RE, 26 patients underwent 24-h esophageal pH monitoring. Eighteen patients with RE (69.2%) complicated by PGER and 8 patients (30.8%) were confirmed to

have negative pH monitoring. Upper gastrointestinal tract endoscopy was performed in 34 patients with PGER, of them, 18 (52.9%) were identified to have RE, but the remaining 16 (47.1%) patients were proven to have a negative endoscopic finding in the esophagus. The results are summarized in Figure 3.

DISCUSSION

Gastroesophageal reflux disease is a common disease with many typical and atypical symptoms. A low pressure exerted by the lower esophageal sphincter (LES) and an increased frequency of transient LES relaxation might contribute to the development of GERD^[17-19]. Esophageal testing, particularly 24-h pH monitoring has become the key to make the diagnosis and to ensure adequate acid suppression or prior to surgical therapy^[20]. Although the test could yield accurate and reliable information, it is inconvenient for patients. The problem is whether all patients require 24-h esophageal pH monitoring to establish the diagnosis of GERD. If so, its use, however, is not popular and many hospitals in China are unable to perform this special testing. For these reasons, we are trying to develop a standard system to quantify the symptoms and to evaluate the accuracy of the combination of typical reflux symptoms in the diagnosis of GERD with the hope of eliminating the need for the monitoring.

Laboratory studies have demonstrated that there is a close relationship between classic reflux symptoms and esophageal acid exposure, but some clinical studies revealed that these symptoms were neither specific nor sensitive to the diagnosis of GERD^[15,21-23]. For example, Tefera and his colleagues^[21] reported that moderate or severe heartburn could be used to diagnose GERD with a sensitivity of 68.42% and a specificity of 62.96%, and moderate or severe regurgitation with a sensitivity of 56.76% and a specificity of 65.08%. There were some common grounds in these clinical studies. These symptoms were evaluated separately. The frequency of each symptom was quantified but the severity was not considered. In our study, every typical symptom was estimated by quantifying both the frequency and the severity, and a combination score (SI) of all symptoms was calculated for every subject to exclude those subjects with trivial symptoms and to improve the accuracy of SI in the diagnosis of GERD.

We found that the sensitivity of the composite score of main reflux symptoms in the diagnosis of GERD was inversely associated with increased SI, but the specificity tended to be higher with increased SI. SI ≥ 8 had the highest accuracy of 70.0% for diagnosing GERD with a sensitivity of 78.6% and a specificity of 69.2%, followed by SI ≥ 3 with an accuracy of 62.1%, a sensitivity of 96.4%, and a specificity of 34.6%. Because SI ≥ 3 had the highest sensitivity, this criterion is the common choice in epidemiological studies. With the highest accuracy, SI ≥ 8 is very useful for diagnosing GERD in clinical work. We, therefore, prompted to develop a criterion based on the main reflux symptoms. The standardized symptom questionnaire and the scoring techniques (system) are important for

gastroenterological doctors to estimate the patients with typical reflux symptoms, especially in hospitals or clinics without objective tests. We suggest that patients with $SI \geq 8$ may be treated pharmaceutically combined with life style counseling. If the symptoms have not improved after 6 to 12 wk, 24-h pH monitoring and/or endoscopic examination should be performed, and if necessary, barium radiographing and manometry should be done.

Our study showed that the prevalence of RE, PGER and GERD was strongly associated with increased SI, but no significant association was found between the severity of RE and SI, indicating that patients with more severe reflux symptoms tend to have GERD, but the grade of esophagitis could not be evaluated on the basis of the severity of typical symptoms.

The present study also revealed that almost one third of patients with RE (30.8%) were confirmed to have negative pH monitoring and half of patients with PGER (47.1%) had negative endoscopic findings in the esophagus, the results were similar to previous studies^[24-26]. Excessive bile exposure of esophageal mucosa was the main cause of RE with normal acid exposure^[27-29]. We suggest that endoscopy-negative reflux disease (ENRD) should be treated as endoscopy positive GERD because longterm acid exposure would rapidly damage esophageal mucosa.

Patients with atypical symptoms such as cough, asthma, hoarseness, chest pain, and ear, nose and throat symptoms were not included in this study because they always had their first visit at specialized services. According to some studies the prevalence of GERD in patients with atypical symptoms ranged from 25% to 80%. We suggest that diagnostic tests such as upper digestive endoscopy and 24-h pH monitoring are a necessity for patients with atypical symptoms.

In conclusion, developing a criterion based on the composite score of typical reflux symptoms is useful to the diagnosis of GERD. Symptom questionnaire and scoring techniques are an important step in this analysis. For patients with a moderate or severe composite score, the diagnosis of GERD can be made without further tests in most situations. However, 24-h esophageal pH monitoring is still needed in patients with mild and atypical symptoms.

Abstract

AIM: To investigate the clinical characteristics and prognostic factors of a consecutive series of patients with severe acute pancreatitis (SAP).

METHODS: Clinical data of SAP patients admitted to our hospital from January 2003 to January 2004 were retrospectively reviewed. Collected data included the age, gender, etiology, length of hospitalization, APACHE II score at admission, local and organ/systemic complications of the patients.

RESULTS: Of the 268 acute pancreatitis patients, 94 developed SAP. The mean age of SAP patients was 52 years, the commonest etiology was cholelithiasis (45.7%), the mean length of hospitalization was 70 d, the mean score of APACHE II was 7.7. Fifty-four percent of the patients developed necrosis, 25% abscess, 58% organ/systemic failure. A total of 23.4% (22/94) of the SAP patients died. Respiratory failure was the most common organ dysfunction (90.9%) in deceased SAP patients, followed by cardiovascular failure (86.4%), renal failure (50.0%). In the SAP patients, 90.9% (20/22) developed multiple organ/systemic failures. There were significant differences in age, length of hospitalization, APACHE II score and incidences of respiratory failure, renal failure, cardiovascular failure and hematological failure between deceased SAP patients and survived SAP patients. By multivariate logistic regression analysis, independent prognostic factors for mortality were respiratory failure, cardiovascular failure and renal failure.

CONCLUSION: SAP patients are characterized by advanced age, high APACHE II score, organ failure and their death is mainly due to multiple organ/systemic failures. In patients with SAP, respiratory, cardiovascular and renal failures can predict the fatal outcome and more attention should be paid to their clinical evaluation.

INTRODUCTION

Acute pancreatitis, as a relatively common pancreatic disease,

can be found in every part of the world with an incidence of 35-80 cases per 100 000 inhabitants per year^[1,2]. According to Atlanta Classification, acute pancreatitis is clinically classified into a mild or severe type depending on the presence of local and systemic complications^[3]. Severe acute pancreatitis (SAP) is characterized by high morbidity and mortality. The mortality of SAP patients varies from 7% to 47%^[4]. The factors most closely linked to a poor prognosis are pancreatic necrosis, infection and multiple organ/systemic failures, which are associated with a mortality of 50%^[4-7]; although in recent years this mortality rate has tended to decrease^[8]. Many attempts have been made to achieve an early prognosis of SAP. However, none seems to be reliable enough to justify its routine use.

In view of the high mortality associated with SAP, it is important to identify the cases that require close monitoring and aggressive resuscitation. The aim of this study was therefore to investigate the clinical characteristics and factors which could predict the outcome of patients with organ/systemic failure admitted to our hospital.

MATERIALS AND METHODS

Clinical data

From January 2003 to January 2004, the clinical histories of patients with acute pancreatitis (AP), admitted to the Department of Surgery, Ruijin Hospital of Shanghai Second Medical University, were retrospectively reviewed. The diagnosis of AP was established in cases with clinical presentations and biochemical findings when other causes were excluded. The severities of AP were assessed according to the Atlanta classification system^[3]. Etiology was divided into two groups: cholelithiasis and non-cholelithiasis. A biliary etiology was confirmed by ultrasonography, CT scan, ERCP, MRCP and operation. Pancreatic necrosis and abscess were defined by the findings on contrast-enhanced CT scan or in operation. The local and organ/systemic complications were defined according to the Atlanta classification system^[3, 9].

The patients with SAP were divided according to their outcomes into two groups: deceased group and survived group. The data recorded for each patient included age, gender, etiology, length of hospitalization, APACHE II score at admission and the presence and type of local and organ/systemic complications. The relationship between clinical characteristics, specific single or multiple organ/systemic failures with mortality was evaluated in above-mentioned two groups.

Statistical analysis

Results were expressed as mean±SD. Statistical studies were made using SAS 6.12. Continuous data were evaluated by *t* test, and categorized data were analyzed by Chi-square test or Fisher's exact test. To identify the risk factors for SAP, multiple logistic regression analysis with backward elimination was used. *P*<0.05 was considered statistically significant.

RESULTS

Of the 268 patients with AP, 35.1% (94/268) developed SAP. Of the 94 SAP patients, 23.4% (22/94) died. The patients in the deceased group were significantly older and had a higher

APACHE II score than those in the survived group. The length of hospitalization was significantly shorter in those with a fatal outcome. There was no difference in etiology or gender (Table 1).

Regarding the local complications, the incidences of necrosis and abscess were significantly higher in the survived group than those in the deceased group. No patient in the deceased group developed pseudocysts (Table 2).

Table 1 Comparison of clinical characteristics (mean±SD)

Characteristics	Survival (n = 72)	Deceased (n = 22)	Total (n = 94)
Mean age (yr) (range)	49.7±14.9 ^b (15-82)	62.8±14.4 (42-83)	52.7±15.8 (15-83)
Gender (male/female)	45/27	10/12	55/39
Etiology (biliary/non-biliary)	31/41	12/10	43/51
Hospitalization (d) (range)	84.4±65.3 ^b (8-253)	26.2±28.2 (1-94)	70.8±63.7 (1-253)
APACHE II score (range)	6.3±3.5 ^b (0-14)	12.5±6.8 (1-33)	7.72±5.2 (0-33)

^bP<0.01 vs deceased group.

Table 2 Comparison of local complications

Local complications	Survival (n=72)	Deceased (n=22)	Total (n=94)
Necrosis, n (%)	47 (5.3) ^b	7 (31.8)	54 (57.4)
Abscess, n (%)	23 (31.4) ^a	2 (9.1)	25 (26.6)
Pseudocyst, n (%)	11 (15.3)	0 (0)	11 (11.7)

^aP<0.05, ^bP<0.01 vs deceased group.

A total of 61.7% (58/94) patients with SAP developed organ/systemic failures. In the deceased group, 90.9% (20/22) patients showed multiple organ/systemic failures (maximum 5 organ/systemic failures), only 18.1% (13/94) patients showed multiple organ/systemic failures in the survived group (Tables 3, 4). With regard to the organ/systemic complications, we found that the deceased group experienced a significantly greater incidence of episodes of respiratory failure, acute renal failure, cardiovascular failure and hematological failure than the survived group (Table 4).

Table 3 Comparison of the number of organ/systemic failure

Number of organ/ systemic failure	Survival (n=72)	Deceased (n=22)	Total (n=94)
1, n (%)	23 (31.9) ^a	2 (9.1)	25 (26.6)
2, n (%)	10 (13.9)	6 (4.5)	16 (17.0)
3, n (%)	3 (4.2) ^a	4 (18.2)	7 (7.4)
4, n (%)	0 (0) ^b	7 (31.8)	7 (7.4)
5, n (%)	0 (0) ^a	3 (13.6)	3 (3.2)
Total, n (%)	36 (50.0) ^b	22 (100.0)	58 (61.7)

^aP<0.05, ^bP<0.01 vs deceased group.

As for the frequency of different specific single organ failures, pulmonary failure occurred in 35.1% (33/94) patients, cardiovascular failure in 22.3% (21/94) patients, gastrointestinal failure in 19.1% (18/94) patients, hepatic failure in 15.9% (15/94) and renal failure in 14.9% (14/94) patients. The incidences of neurologic and hematological failures were relatively lower, only in 8.5% (8/94) patients respectively (Table 5).

Logistic regression analysis was carried out for the independent prognostic factors including all the variables studied. Respiratory failure, cardiovascular failure and renal failure were found to be independent prognostic factors of the mortality in SAP patients (Table 6).

Table 4 Comparison of the features of organ/systemic failure

Organ/systemic failure	Survival (n=72)	Deceased (n=22)	Total (n=94)
Multiple organ/systemic failures n (%)	13 (18.1) ^b	20 (90.9)	33 (35.1)
Respiratory n (%)	13 (18.1) ^b	20 (90.9)	33 (35.1)
Renal n (%)	3 (4.2) ^b	11 (50.0)	14 (14.9)
Gastrointestinal n (%)	11 (15.3)	7 (31.8)	18 (19.1)
Hepatic n (%)	12 (16.7)	3 (13.6)	15 (15.9)
Neurologic n (%)	6 (8.3)	2 (9.1)	8 (8.5)
Cardiovascular n (%)	2 (2.8) ^b	19 (86.4)	21 (22.3)
Hematological n (%)	2 (2.8) ^b	6 (27.3)	8 (8.5)

^bP<0.01 vs deceased group.

Table 5 Frequency of organ/systemic failure

Organ/systemic	Number of organ/systemic failure	Frequency (%)
Respiratory	33	35.1
Renal	14	14.9
Gastrointestinal	18	19.1
Hepatic	15	15.9
Neurologic	8	8.5
Cardiovascular	21	22.3
Hematological	8	8.5

Table 6 Independent factors of the logistic regression model

Variable	OR	OR 95% confidence interval	P
Respiratory failure	186.5	9.942-999.0	0.006
Cardiovascular failure	29.9	2.243-999.0	0.021
Renal failure	118.7	3.784-999.0	0.029
Hospitalization, days	0.957	0.908-0.989	0.037

DISCUSSION

Most deaths of SAP patients were mainly related to multiple organ/systemic failures^[10]. Regarding the survival time, patients died more often of multiple organ/systemic failures in the first few days after admission^[5,11]. In the early phase of SAP, multiple organ/systemic failures seemed to be caused by cytokine and inflammatory mediators released due to systemic inflammatory response syndrome, and sterile pancreatic necrosis might even occur^[12]. Early deaths of SAP patients were commonly associated with multiple organ/systemic failure, accounting for 40-60% of mortality, and over the past decade this proportion has not declined^[13]. The present study showed that in the deceased group 90.9% (20/22) patients developed multiple organ/systemic failure and 50% (11/22) patients died within 2 wk after admission.

Previous studies^[14-16] showed that in SAP patients, organ/systemic failure occurred in 72-90.3%, single organ failure in 24.7-37%, multiple organ failure in 35-65.6%. Among the single organ failures, respiratory failure was the most common organ/systemic complications (39.1-63%), followed by cardiovascular failure (23-37.7%), hepatic failure (20.7%) and renal failure (8.5-13%). The present data showed that organ failure occurred in 61.7% (58/94) patients, single organ failure in 26.6% (25/94) patients, and multiple organ failure in 38.3% (36/94) patients. Respiratory failure was the most common single organ failure (35.1%, 33/94), followed by cardiovascular failure (22.3%, 21/94), gastrointestinal failure (19.1%, 18/94), hepatic failure (15.9%, 15/94) and renal failure (14.9%, 14/94). In a recent study, five independent prognostic factors for hospital mortality in SAP patients were the age and chronic health situation of the patients and organ failures (renal, respiratory and cardiovascular)^[4]. In our study, respiratory failure, cardiovascular failure and renal failure were shown to be the independent prognostic factors of

mortality by multivariate logistic analysis, which are consistent with the reports by Fernandez-Cruz *et al.* and Halonen *et al.*^[6,17]. Apparently, the development of one of the above-mentioned complications is by far the worst prognostic factor in SAP, closely related to mortality.

Up to now, the development of pancreatic necrosis and infection has been considered as an important factor in the occurrence of multiple organ/systemic failure and subsequent death^[6,18,19]. There are even studies relating the site and extent of necrosis to the outcome and development of multiple organ failures^[18,20]. In other studies, infected pancreatic necrosis and combined of organ/systemic failures were the most significant causes for hospital mortality of SAP patients^[1,21]. The mortality rate of SAP patients was 7-47% (that of sterile necrotizing pancreatitis patients was 6-13% and SAP patients with infected necrosis was 14-80%)^[4,22-26]. Conversely, there was a higher proportion of patients with necrosis and abscess in the survived group in our study. Using logistic regression analysis failed to identify necrosis and abscess as independent prognostic factors for mortality, although statistically significant difference was found between survived and deceased groups. This suggested that, rather than the development of necrosis or abscess itself, necrosis and abscess were not correlated with an increased mortality. The main factor indicating a poor prognosis in SAP was the development of multiple organ/systemic failures^[27,28].

Although there was a higher incidence of pseudocysts in the survived group, no statistically significant difference was found compared with the deceased group. This observation must be made cautiously, because 50% (11/22) of the patients in deceased group died within 2 wk, which might be too short to develop a pseudocyst. In addition, in many patients the only complication was a pseudocyst, so they were classified as having SAP according to the Atlanta Criteria, although their clinical recovery was excellent^[3]. Patients with pseudocysts may develop complications, but since it takes at least 4 wk to develop a pseudocyst, it has no effect on early mortality.

Our results did not show that age was an independent poor prognosis factor in mortality, which was consistent with previous studies, but in contradiction to other investigators^[4,6]. When deaths due to complications of acute pancreatitis were analyzed, the mortality rate was not significantly different between the young and elderly groups. Moreover, the complication rate and the proportion of patients with SAP (judged by the number of prognostic signs) were not higher in the elderly. Thus the severity of acute pancreatitis was not intrinsically due to advanced age when the influence of other secondary factors was not taken into consideration.

In conclusion, SAP patients are characterized by advanced age, high APACHE II score at admission, development of organ/systemic failure, and their death is mainly due to multiple organ/systemic failures. In SAP patients, respiratory, cardiovascular and renal failures can predict their fatal outcome and more attention should be paid to their clinical evaluation.

Abstract

AIM: Leakage from oesophageal anastomosis is associated with substantial morbidity and mortality. This study presented a novel, safe and effective double stapled technique for oesophago-enteric anastomosis.

METHODS: The data were obtained prospectively from hospital held clinical database. Thirty nine patients (26 males, 13 females) underwent upper-gastrointestinal resection between 1996 and 2000 for carcinoma ($n = 36$), gastric lymphoma ($n = 1$), and benign pathology ($n = 2$). Double stapled oesophago-enteric anastomosis was performed in all cases.

RESULTS: No anastomotic leak was reported. In cases of malignancy, the resected margins were free of neoplasm. Three deaths occurred, which were not related to anastomotic complications.

CONCLUSION: Even though the reported study is an uncontrolled one, the technique described is reliable, and effective for oesophago-enteric anastomosis.

INTRODUCTION

Leakage is a major problem associated with oesophago-enteric anastomosis. The anastomosis may be hand sewn or stapled^[1-4]. Even though there is no proven advantage between either techniques, basic principles of anastomosis surgery- tension free, good vascularity, and good mucosal apposition apply to both. A technique of double stapled anastomosis avoids stretch at oesophageal side of anastomosis and circumvents damage to vascularity.

MATERIALS AND METHODS

The double stapled oesophago-enteric reconstruction was performed as follows. The oesophagus was mobilized in the standard way to above the proposed level of division. A transverse incision was made in the anterior wall of the oesophagus at least 3 cm above the proximal extent of the tumour in those cases undergoing surgery for malignancy (Figure 1). An appropriately sized circular stapler (CA Ethicon) was selected based on the oesophageal diameter. A 2-0 polypropylene suture was placed through the 'eye-hole' situated in the plastic spike that fits the head of the circular stapler. The

polypropylene suture should be tied such that around 5 cm of suture with the attached needle remained attached to the spike attached to the circular stapler head. The transverse anterior oesophagotomy should be of sufficient size to allow insertion of the stapler head with attached spike - see step 7 (Figure 2). The circular stapler head with spike and attached needle were placed through the oesophagotomy into the proximal oesophagus (Figure 3). The suture needle was brought out through the anterior oesophageal wall 2 cm proximal to the oesophagotomy. The oesophagus was then cross-stapled and divided transversely below the site of needle puncture but above the oesophagotomy. The suture attached to the spike was used to pull the spike and axis of the circular stapler head through the anterior wall of the oesophagus, around 2 cm proximal to the transverse staple line (Figure 4). The spike was then removed from the stapler head. Resection of the gastric or oesophago-gastric specimen was then completed. The distal conduit (either distal stomach or jejunal limb) was prepared and mobilized to allow a tension free anastomosis. The body of the circular stapler was introduced into the lumen of the efferent conduit through an appropriately placed enterotomy (Figure 5). The circular stapler head was engaged with the body of the circular stapler gun. The gun was closed and fired creating a double stapled oesophago-enteric anastomosis (Figure 5). A naso-gastric tube was fed across the oesophago-enterostomy after completion of the anastomosis.

Figure 2 Transverse anterior oesophagotomy. Stapler head spike with attached needle inserted through oesophagotomy into proximal oesophagus.

Figure 3 Placement of a circular stapler head with spike and attached needle. Needle was used to puncture anterior oesophagus 2 cm above the oesophagotomy. The oesophagus was then cross-stapled between the needle puncture site & the oesophagotomy.

Figure 4 Suture used to drive head spike through oesophageal wall above transverse suture line.

Figure 5 Introduction of the circular stapler body into the lumen of efferent conduit.

RESULTS

All patients were operated on by or under the direct supervision of a consultant surgeon with an upper gastrointestinal interest. Patients with malignancy underwent pre-operative staging with thoraco-abdominal computed tomography scan. Laparoscopy was used in selected instances. In elective cases, mechanical bowel preparation was employed. Thoracic epidural anaesthesia was employed for post-operative pain relief. Patients were kept nil by mouth for 5 d post-operatively. If the post-operative course was uneventful, fluids were introduced on d 5. Water

soluble contrast studies were not routinely used to assess anastomotic integrity unless there was clinical indication.

Data were obtained prospectively from the hospital-held clinical database.

Thirty-nine patients (26 males, 13 females) underwent upper gastrointestinal resection (total gastrectomy $n = 24$, Ivor-Lewis oesophago-gastrectomy $n = 15$) between 1996 and 2000. Indication for surgery was carcinoma ($n = 36$), gastric non-Hodgkin's lymphoma ($n = 1$), revision of a neo-gastric jejunal pouch ($n = 1$), gastric infarction secondary to volvulus ($n = 1$). The median age was 67 (36-82) years. Patient ASA grades were: ASA-1 $n = 12$, ASA-2 $n = 14$, ASA-3 $n = 9$, ASA-4 $n = 3$, ASA-5 $n = 1$. The median operative time for total gastrectomy was 175 (120-240) min and was 240 (180-360) min for Ivor-Lewis oesophago-gastrectomy. The median transfusion requirements were 2 (0-7) units for both procedures. The resection margins were free of tumour on histopathological examination in all cases of malignancy.

Morbidity and mortality rates are shown below (Tables 1-3). Risk adjusted morbidity and mortality rates were calculated using the physiological and operative scoring system for enumeration of morbidity and mortality (POSSUM) and Portsmouth POSSUM (P-POSSUM) models^[5,6].

Table 1 Morbidity and mortality of oesophago-gastrectomy (n , %)

	Total patients ($n = 15$)	POSSUM prediction	P-POSSUM prediction
Morbidity	5 (33)	63	-
Mortality	2 (14)	18	6

Table 2 Morbidity and mortality of total gastrectomy (n , %)

	Total patients ($n = 15$)	POSSUM prediction	P-POSSUM prediction
Morbidity	6 (25)	48	-
Mortality	1 (4)	16	9

Table 3 Analysis of morbidity

	Oesophagogastrctomy (n)	Total gastrectomy (n)
Chest infection	2	5
Chylothorax	1	-
DVT/PE	1	1
Anastomotic leak	-	-
Wound sepsis	1	-

Three deaths occurred, two post oesophago-gastrectomy and one post total gastrectomy. The deaths after oesophago-gastrectomy were shown at post-mortem to be due to left ventricular failure and myocardial infarction respectively. The patient who died after total gastrectomy deteriorated suddenly on the 10th post-operative day tolerated diet for three days. Symptoms, blood gases and electrocardiogram were compatible with a pulmonary embolus. Permission for a post-mortem was refused. No anastomotic leaks occurred on clinical grounds.

DISCUSSION

Anastomotic leakage following oesophago-enteric reconstruction may result in significant morbidity and mortality. The standard principles governing any gastro-intestinal anastomosis apply in dealing with the oesophagus. The anastomosis should be tension-free, well vascularized and there should be accurate mucosal apposition. Oesophageal anastomoses may be hand sewn (in one, two or even three layers) or stapled^[1-4]. There is no proven advantage to either the hand sewn or stapled technique.

Stapled anastomoses might be associated with a higher rate of subsequent benign stricture formation^[7]. The stapled technique that is commonly used requires a purse string suture in the cut end of the proximal oesophagus to retain the head of the circular stapler. The anastomosis is completed by a single firing of the circular stapler.

It is the authors' contention that the oesophageal purse string may be a contributory factor to subsequent anastomotic related complications (leak and stricture). This is based on the observation that the distal oesophagus is stretched over the head of the circular stapler, and therefore possibly devascularized by the purse string suture. To avoid the use of a purse string, a double stapled oesophago-enteric anastomotic technique has been devised.

This paper described a novel technique of oesophago-enteric anastomosis using a double stapled technique. Whilst this was an uncontrolled study, the technique has proved reliable and to date has not resulted in any anastomotic leaks. Whilst this study cannot implicate the use of a proximal oesophageal purse string suture as a factor in anastomotic leakage, it is interesting to speculate whether the double stapled anastomosis does allow improved anastomotic healing through omission of

a purse string suture. The technique described merits further evaluation either in the setting of a larger uncontrolled study or more preferably in the context of a randomised trial.

Abstract

AIM: To assess *Helicobacter pylori* (*H. pylori*) seroprevalence in a cohort of Greek patients with lung cancer.

METHODS: Seventy-two lung cancer patients (55 males and 17 females, aged 58.2 ± 11.7 years) and 68, age and gender-matched, control subjects were enrolled. All subjects underwent an enzyme-linked immunosorbent assay IgG serologic test for *H. pylori* diagnosis.

RESULTS: A correlation between age and *H. pylori* IgG level was detected for both lung cancer patients ($r = 0.42$, $P = 0.004$) and controls ($r = 0.44$, $P = 0.004$). Seropositivity for *H. pylori* did not differ significantly between patients with lung cancer and controls (61.1% vs 55.9%, $P > 0.05$). Concerning the mean serum concentration of IgG antibodies against *H. pylori*, no significant difference between the two groups was detected (32.6 ± 19.1 vs 27.4 ± 18.3 U/mL, $P > 0.05$).

CONCLUSION: No significant association between *H. pylori* infection and lung cancer was found.

Philippou N, Koursarakos P, Anastasakou E, Krietsepi V, Mavrea S, Roussos A, Alepopoulou D, Iliopoulos I. *Helicobacter pylori* seroprevalence in patients with lung cancer. *World J Gastroenterol* 2004; 10(22): 3342-3344

<http://www.wjgnet.com/1007-9327/10/3342.asp>

INTRODUCTION

Helicobacter pylori (*H. pylori*) infection of the gastric mucosa affects approximately 50% of the world's population^[1]. It seems to be the main cause of chronic antral gastritis^[2] and is strongly associated with peptic ulcer disease^[3], gastric cancer^[4], and gastric MALT-lymphoma^[5]. In the past few years, a variety of extradigestive disorders, including cardiovascular, skin, rheumatic and liver diseases, have also been associated with *H. pylori* infection^[6,7]. As regards respiratory diseases, an increased *H. pylori* seroprevalence has been found in active bronchiectasis^[8], chronic bronchitis^[9,10] and active pulmonary tuberculosis^[11]. The activation of inflammatory mediators by *H. pylori* seems to be the common pathogenetic mechanism underlying the observed associations^[12].

It is well known that the prevalence of lung cancer in peptic ulcer patients is increased 2 to 3 fold compared with findings in ulcer-free controls^[13-18]. The major factor underlying this association seems to be the impact of cigarette smoking on both diseases. However, a recent pilot study, in a small number of patients, showed that *H. pylori* infection, *per se*, might be implicated in lung cancerogenesis^[19]. It suggested that the prolonged release of gastrin and cyclooxygenase (COX)-2 in *H. pylori* infected patients might account for the stimulation of lung cancer growth and tumor neoangiogenesis^[19]. However, insufficient information is available on the prevalence of *H. pylori* infection in lung cancer patients.

Therefore, in order to further investigate the relationship between *H. pylori* infection and lung cancer, we assessed *H. pylori* seroprevalence in a cohort of Greek patients with lung cancer and control subjects.

MATERIALS AND METHODS

Study subjects

The present study was conducted at the 9th Department of Pulmonary Medicine, "Sotiria" Chest Diseases Hospital (Athens, Greece). The local ethics committee approved the study and written informed consent was obtained from each participant. Following a predefined protocol, between March 1, 2002 and April 30, 2001, 104 consecutive patients with, histologically verified, primary lung cancer were recruited from our department. Exclusion criteria were: (1) prior *Helicobacter* eradication therapy, (2) consumption of acid suppressive drugs or antibiotics in the preceding 6 mo and (3) a history of vagotomy or operations of the upper gastrointestinal tract. A total of 32 patients were excluded. Therefore, 72 patients were eligible for analysis.

Controls were selected randomly from subjects who attended courses designed for public health education during the period of the study. Exclusion criteria for controls were: (1) a known history of lung cancer and (2) a known history of gastrointestinal tract pathology. Finally, we selected 68 controls out of 99 healthy subjects and we matched them with the patients for sex, age (within 2 years) and socioeconomic status.

Methods

All subjects enrolled (lung cancer patients and controls) underwent an enzyme-linked immunosorbent assay (ELISA) IgG serologic test for *H. pylori* diagnosis (HEL-P test, Park Co, Athens, Greece), in accordance with the manufacturer's guidelines. A positive, borderline or negative result was assigned when the concentration of IgG antibodies against *H. pylori* was greater than 25, between 20 and 25 and less than 20 U/mL respectively. The specificity and sensitivity of the serology test, validated in our local population, were 95% and 85% respectively.

Statistical analysis

Results are expressed as mean \pm SD. Significance of difference between groups was assessed by unpaired Student's *t*-test for continuous variables and χ^2 -test for proportions. Correlation coefficients between variables were determined using conventional

Pearson's correlation analysis. Statistical analysis was performed using SPSS program (SPSS Inc, IL, USA) and *P*-values were two-tailed analyzed. *P* less than 0.05 was considered statistically significant.

RESULTS

The demographic data of both patients and controls are shown in Table 1. There was no statistical difference in age or gender between the two groups. The majority of lung cancer patients were current cigarette smokers (60 patients, 83.3%) or ex-smokers (10 patients, 13.9%) and only 2 patients (2.8%) had never smoked. On the other hand, 40 out of 68 control subjects (58.8%) were never-smokers, 20 (29.4%) were current and 8 (11.8%) were previous smokers.

A correlation between age and *H. pylori* IgG level was detected for both lung cancer patients ($r = 0.42$, $P = 0.004$) and controls ($r = 0.44$, $P = 0.004$). Among the lung cancer patients, 44 (61.1%) were anti-*H. pylori* IgG positive, 2 (2.8%) had borderline values and 26 (36.1%) were seronegatives. Of the control subjects 38 (55.9%) were anti-*H. pylori* IgG positive, 2 (2.9%) were borderline and 28 (41.2%) were seronegatives.

H. pylori seropositivity did not differ significantly between patients with lung cancer and controls ($P > 0.05$) (Table 1). Concerning the mean serum concentration of IgG antibodies against *H. pylori* no significant difference between the two groups was detected ($P > 0.05$).

Table 1 Demographic data and *H. pylori* serologic parameters

Parameter	Control (n = 68)	Lung cancer (n = 72)	<i>P</i>
Age (yr)	54.8±12.1	58.2±11.7	0.79
Male gender (%)	73.5	76.3	0.88
<i>H. pylori</i> IgG level (U/mL)	27.4±18.3	32.6±19.1	0.18
<i>H. pylori</i> IgG seropositivity (%)	55.9	61.1	0.23

DISCUSSION

Data in literature on the relationship between *H. pylori* infection and lung cancer are poor. Recently, Gocyk *et al.* carried out a pilot study in a sample of 50 Polish patients with lung cancer and showed an increased *H. pylori* seroprevalence (89%). Moreover, they proposed that the seropositive patients might be considered for *H. pylori* eradication in order to reduce the hypergastrinemia and COX-2 expression^[19], provoked by this bacterium. As both overexpression of COX-2 in lung tissue^[20-22] and increased serum levels of gastrin^[23] have been reported in lung cancer patients, a pathogenetic link between *H. pylori* infection and lung cancer seems to exist.

Our study is the first one focusing on seroprevalence of *H. pylori*, in a relatively large population of Greek patients with lung cancer. According to our results, *H. pylori* seroprevalence in lung cancer patients did not differ significantly from that of the control subjects. The age-related pattern of infection, which in our study was detected for both lung cancer patients and controls, was common in developed countries and explained by the cohort effect^[24]. The socioeconomic status, which was related with both *H. pylori* infection and risk of lung cancer, was similar between the two groups. Tobacco use could be another confounding factor. Cigarette smoking was the most important etiologic factor of lung cancer and seemed to fully account for the, observed in previous studies, association between peptic ulcer and lung cancer^[13-18]. However, data on the relationship between *H. pylori* infection and smoking habits are controversial. The prevalence of *H. pylori* infection in smokers has been variously reported as low^[25], normal^[26], and high^[27]. In the present study, we did not match patients with

control subjects in smoking habits. As the relation between smoking and *H. pylori* infection has not been clarified yet, the possible impact of cigarette smoking on both lung cancer and *H. pylori* infection should be regarded as a potential study limitation.

The present study did not focus on the potential pathogenetic mechanisms underlying a possible association between *H. pylori* infection and chronic bronchitis. This association might reflect either susceptibility induced by common factors or a kind of causal relationship between these diseases. As far as we know, there are no common factors implicated in the susceptibility to both lung cancer and *H. pylori* infection. However, we can not rule out this possibility, as the predisposing conditions to *H. pylori* infection have not been clarified yet. With regard to the aetio-pathogenetic role of *H. pylori* infection in lung cancer development, it has been suggested that the prolonged release of gastrin and cyclooxygenase (COX)-2 in *H. pylori* infected patients might stimulate lung cancer growth and lead to tumor neoangiogenesis^[19]. The spilling or inhalation of *H. pylori* or its exotoxins into the respiratory tract might also lead to their accumulation in lung tissue. However, as far as we know, neither identification of *H. pylori* species in human bronchial tissue, nor isolation of *H. pylori* from bronchoalveolar lavage (BAL) fluid has been achieved yet^[24]. Studies estimating the relative risk of developing lung cancer for *H. pylori* infected patients and the effect of *H. pylori* eradication on the natural history of chronic bronchitis are also needed to further investigate these hypotheses.

In conclusion, the present study suggests that *H. pylori* seroprevalence in lung cancer patients did not differ significantly from that of control subjects. Our results should be confirmed in a larger number of patients. Further studies are needed to clarify the pathogenetic mechanisms, if those exist, underlying a possible association between these two diseases.

Abstract

AIM: To identify the prognostic factors with regard to survival for patients with brain metastasis from primary tumors of the gastrointestinal tract.

METHODS: Nine hundred and sixteen patients with brain metastases, treated with whole brain radiation therapy (WBRT) between January 1985 and December 2000 at the Department of Radiation Oncology, University Hospital Freiburg, were analyzed retrospectively.

RESULTS: Fifty-seven patients presented with a primary tumor of the gastrointestinal tract (esophagus: $n = 0$, stomach: $n = 10$, colorectal: $n = 47$). Twenty-six patients had a solitary brain metastasis, 31 patients presented with multiple brain metastases. Surgical resection was performed in 25 patients. WBRT was applied with daily fractions of 2 Gray (Gy) or 3 Gy to a total dose of 50 Gy or 30 Gy, respectively. The interval between diagnoses of the primary tumors and brain metastases was 22.6 mo vs 8.0 mo for patients with primary tumors of the colon/rectum vs other primary tumors, respectively ($P < 0.01$, log-rank). Median overall survival for all patients with brain metastases ($n = 916$) was 3.4 mo and 3.2 mo for patients with gastrointestinal neoplasms. Patients with gastrointestinal primary tumors presented significantly more often with a solitary brain metastasis than patients with other primary tumors ($P < 0.05$, log-rank). In patients with gastrointestinal neoplasms ($n = 57$), the median overall survival was 5.8 mo for patients with solitary brain metastasis vs 2.7 mo for patients with multiple brain metastases ($P < 0.01$, log-rank). The median overall survival for patients with a Karnofsky performance status (KPS) ≥ 70 was 5.5 mo vs 2.1 mo for patients with KPS < 70 ($P < 0.01$, log-rank). At multivariate analysis (Cox Model) the performance status and the number of brain metastases were identified as independent prognostic factors for overall survival.

CONCLUSION: Brain metastases occur late in the course of gastrointestinal tumors. Pretherapeutic variables like KPS and the number of brain metastases have a profound influence on treatment outcome.

INTRODUCTION

The metastatic dissemination of a solid tumor to the brain is generally associated with a poor prognosis^[1]. The most common primary tumors metastasizing to the brain are breast and lung cancer, whereas patients with other primary tumors, e.g. tumors of the gastrointestinal tract, rarely present with brain metastases^[2-4]. Furthermore, within the group of gastrointestinal tumors, the incidence of brain metastases shows notable differences. They are extremely rare in esophageal tumors^[5,6], but more common in rectal cancer. Few literatures concerning this group of patients are available and therefore prognosis and hence treatment strategies remain controversial.

We retrospectively evaluated patient-, tumor- and treatment-related variables in patients with brain metastases of primary tumors of the gastrointestinal tract (i.e. epithelial tumors of the esophagus, stomach, colon, sigma, and rectum) who were treated with whole brain radiation therapy (WBRT) at our institution. The aim of the study was to identify the prognostic factors with regard to the endpoint survival.

MATERIALS AND METHODS

The records of all patients with brain metastases, who were treated with WBRT at our institution between January 1985 and December 2000, were analyzed retrospectively. Brain metastases were detected by contrast-enhanced cerebral computed tomography (CT) ($n = 43$) or magnetic resonance imaging (MRI) ($n = 14$).

WBRT was performed in 16 patients with cobalt⁶⁰ gamma rays, and in 41 patients with 6 MV photons of a linear accelerator. During the study period two fractionation schemes were used: conventional fractionation with daily fractions of 2 Gray (Gy), five days per week to a planned total dose of 50 Gy ($n = 42$) and since 1997 hypofractionation with daily fractions of 3 Gy, five days per wk to a planned total dose of 30 Gy ($n = 15$). None of the patients underwent a chemotherapy during WBRT.

The recursive partitioning analysis (RPA) was used to classify the patients with brain metastases^[7]. Class I contained all patients with a Karnofsky performance status (KPS) ≥ 70 , age < 65 years, a controlled primary tumor and no extracerebral metastases, Class III contained all patients with a KPS < 70 , and Class II contained all other patients.

All patients alive at the time of analysis were censored with the date of last follow-up. The endpoint of the study was overall survival. Survival was calculated from the first day of radiotherapy using the method of Kaplan and Meier. Survival curves were compared using the log-rank test. All factors with a P -value ≤ 0.1 at univariate analysis were entered into a multivariate analysis using the proportional hazards model.

RESULTS

Patient characteristics

Fifty-seven (6.2%) of the 916 patients presented with brain metastases from a cancer of the gastrointestinal tract. The exact localization of the primary tumor is shown in Table 1. None of the patients had an esophageal tumor, the most common primary site was rectum ($n = 24$) and colon/sigma ($n = 23$). In all patients, histology obtained either from the primary tumor, brain metastases or from extracerebral metastases, was adenocarcinoma.

Table 1 Site of primary tumor within gastrointestinal tract¹

Site of primary tumor	<i>n</i> (%)
Esophagus	0 (0)
Stomach	10 (17.5)
Colon	17 (30)
Sigma	6 (10.5)
Rectum	24 (42)

¹Esophagus, stomach, colon, sigma, rectum.

Thirty patients were males, 27 females. Their median age at diagnosis was 65 years (range: 30-80 years). Twenty-nine patients (51%) had a KPS ≥ 70 . Twenty-six patients (46%) had a solitary brain metastasis, 31 (54%) had multiple lesions. Location of the metastases is shown in Table 2. Gross total resection was performed in 25 patients (19 patients with single metastasis, six patients with multiple metastases).

Table 2 Location of brain metastases

Location	<i>n</i> (%)
Single lesion	26 (100)
Frontal	4 (15)
Temporal	1 (4)
Parietal	6 (23)
Occipital	1 (4)
Cerebellum	14 (54)
Brainstem	0 (0)
Multiple lesions	31 (100)
Supratentorial	20 (64)
Infratentorial	3 (10)
Both	5 (16)
Unknown	3 (10)

All patients presented with extracerebral metastases, mostly of the lung and/or the liver. Grouped according to the RPA classes, none of the patients met the criteria for class I. Twenty-nine patients (51%) met the criteria for class II. Twenty-eight patients (49%) presented with a KPS < 70 , and therefore belonged to RPA class III.

Patients with a primary tumor of the gastrointestinal tract presented with a solitary brain metastasis significantly more often (46%) than patients with other primary tumors (30%) ($P < 0.05$, χ^2). In patients with a primary tumor of the gastrointestinal tract, 25% (14 of 43 patients) had a solitary metastasis localized in the cerebellum, whereas the localization of solitary metastases in the cerebellum in patients with other primary tumors was 5% (42 of 805 patients). This difference was statistically significant ($P < 0.01$). Other locations of brain metastases were not significantly different between these two groups.

The time from the diagnosis of primary tumors to the diagnosis of brain metastases was 16.3 mo, 27 mo, and 20 mo in patients with gastric carcinoma, colon carcinoma, and rectum carcinoma, respectively, and showed no statistically significant difference. Compared with patients with other primary tumors, patients

with primary tumors of the colon/rectum had a significant longer interval between the diagnoses of primary tumors and brain metastases (22.6 mo vs 8.0 mo, respectively, $P < 0.01$).

Survival data

The median overall survival (OS) time for patients with a primary tumor of the gastrointestinal system was 3.2 mo and showed no significant difference compared to the overall survival time of 3.5 mo for patients with brain metastases and other primary tumors (Figure 1). OS rate for patients with gastrointestinal tumors was 49%, 30%, and 7%, at 3, 6, and 12 mo, respectively. Within the group of gastrointestinal tumors, patients with a primary tumor of the stomach, colon/sigma, and rectum had a median OS time of 2.7, 5.2, and 3.2 mo, respectively. This was not a statistically significant difference.

Prognostic factors

The potential prognostic factors tested for significance in univariate analysis were sex, age ($\geq < 65$ years), pretherapeutic performance status (KPS $\geq < 70$), number (single vs multiple) and distribution of brain metastases (Table 2), extracerebral tumor activity (yes vs no), resection status (operation yes vs no), and fractionation scheme (conventional fractionation vs hypofractionation). The fractionation scheme (2 Gy daily, 50 Gy total dose vs 3 Gy daily, 30 Gy total dose) showed no statistical significance for OS.

Three factors had a P -value ≤ 0.1 in univariate analysis and were entered into multivariate analysis: pretherapeutic performance status, number of brain metastases, and resection status. Concerning the OS, patients with a KPS ≥ 70 had a median OS time of 5.5 mo vs 2.1 mo for patients with a KPS < 70 ($P < 0.01$) (Figure 2). The same values were found by comparing the patients in RPA class II vs RPA class III. The median OS time for patients with a solitary metastasis was 5.8 mo and 2.7 mo for patients with multiple metastases ($P < 0.01$) (Figure 3). The median OS time for patients with resection of brain metastasis was 6.6 mo and 2.7 mo for patients without resection ($P < 0.01$).

Figure 1 Overall survival according to primary tumor.

Figure 2 Overall survival according to KPS (≥ 70 vs < 70).

Figure 3 Overall survival according to the number of brain metastases (solitary vs multiple).

In the first multivariate model limited to pretherapeutic variables, the number of brain metastases (single vs multiple, relative risk [RR] 0.63, 95% confidence interval [KI] 0.45-0.88) and the KPS (≥ 70 vs <70 , RR 0.59, 95% KI 0.42-0.82) turned out to be independent prognostic factors. In the second multivariate analysis we added the therapeutic variable 'resection'. The KPS and the number of brain metastases were still independent prognostic factors (RR 0.59, 95% KI 0.43-0.79, $P < 0.01$ and RR 0.65, 95% KI 0.45-0.90, $P < 0.05$ respectively), whereas resection status was not a prognostic factor.

DISCUSSION

In our series, 6.2 % of the patients treated with WBRT presented with a primary tumor located in the gastrointestinal tract. None of the 916 patients had a primary esophageal carcinoma. Brain metastases from esophageal carcinoma were extremely rare, with a reported incidences of approximately 1-5% in autopsy series^[8,9], and approximately 1-4% in clinical series^[5,6,10,11].

In ten patients the primary tumor was a gastric carcinoma. The majority of publications on brain metastases from gastric carcinoma were case reports^[12]. Two large studies found 0.7% of 3 320 patients, and 0.16% of 8 080 patients with gastric carcinoma to have brain metastases^[13,14]. In an autopsy series by Poser and Chernik, 5 of 46 patients (10.8%) with gastric carcinoma had brain metastases^[2]. The rarity of brain metastases both from esophageal and gastric cancer might result from the grim prognosis of these tumor entities^[15]. In esophageal cancer, brain metastases tended to occur in patients with large primary tumors^[5], usually implicating a short overall OS time. The low incidence in clinical trials might further result from an inadequate diagnostic evaluation, and symptoms indicating brain pressure like nausea and vomiting might be attributed to the primary tumor^[14]. The reason for the relatively high incidence of brain metastases from gastric cancer in our group is not clear. Gastric carcinoma is rare in Europe compared to Asian countries. In half of our patients gastric carcinoma was a gastric cardia carcinoma, and recent studies suggested, that they were distinct from adenocarcinomas of the esophagus and stomach regarding epidemiological and biological factors^[16-18]. These differences could possibly be associated with other pathways of metastatic spread, resulting in a relatively higher incidence of brain metastases.

Forty-seven patients had a primary colorectal carcinoma. The incidence of brain metastases in colorectal cancer ranged 2-10% in clinical studies^[19-21]. As observed in other studies^[14,21,22], the majority of primary tumors in our patients were located in the distal parts of the colon, i.e. sigma and rectum (64%). Significantly more patients with colorectal primary tumors presented with cerebellar metastases compared to patients with other primary tumors (25% vs 5%, respectively, $P < 0.01$). Studies by Wronski and Alden confirmed this finding, with a frequency for infratentorial location of 35% and 55%, respectively^[21,23]. The relative over-representation of cerebellar metastases in

colorectal carcinoma might be due to tumor spread by way of the vertebral system (i.e. Batson's plexus), bypassing the lungs^[24]. The two other possible routes of hematogenous dissemination of colorectal cancer to the brain were via the rectal vein plexus to the inferior vena cava, bypassing the liver, or via the portal veins to the liver and lung and then to the brain^[20,25]. The incidence of pulmonary metastases in our patients with colorectal cancer was 50% (23/46 patients), which was clearly higher than the approximately 30% for patients with metastatic colorectal cancer^[26], an observation also made in others^[19-21]. Presumably the rectal plexus of veins, draining into the inferior vena cava and subsequently the lung are also an important route for tumor spread to the brain.

The interval between the diagnosis of primary tumor and brain metastases in our study group for patients with gastric and colorectal carcinoma was significantly longer (22.6 mo) than that for patients with other primary tumors (8.0 mo). Although only few larger studies on patients with colorectal carcinoma and brain metastases are available to date, all reported a late onset of brain metastases, with a period ranging 21-36 mo between detection of primary tumors and diagnosis of brain metastases^[19-21,23,27-29] (the larger studies on gastric cancer did not give detailed information on this topic^[13,14,30]). Corresponding to the late onset of brain metastases in the clinical course of gastric and colorectal tumors, all of our patients had further extracerebral metastases (consequently none of our patients was qualified for RPA-class I). The high rate of extracerebral metastases was confirmed by most authors^[19-23,28,31,32] and even represented the most important prognostic factor in the study of Nieder *et al.*^[31].

Although the onset of brain metastases in our patients with gastrointestinal tumors was late, and the systemic disease was advanced, its median OS time was not statistically different from the median OS time of patients with brain metastases of other primary tumors (3.2 vs 3.5 mo, respectively). It was comparable to the median OS time for patients with brain metastases and colorectal carcinoma or gastric carcinoma treated with WBRT seen by others, which ranged from 2.0 to 3.6 mo for colorectal carcinoma^[20,22,23,32] and approximately 2 mo for gastric carcinoma^[13,14]. Hasegawa, in contrary, found a shorter survival time in a radiosurgically treated series of patients with gastrointestinal tumors compared to patients with other primary tumors^[27]. Several authors described a longer median OS time of approximately 9 mo for patients who underwent surgical resection of brain metastases as a sole treatment or followed by radiotherapy^[21,22,27,32,33]. Whereas resection of brain metastases seemed to be a favorable prognostic factor in our patients in univariate analysis, it was not statistically significant in multivariate analysis.

The independent factors correlated with a better prognosis in our multivariate analysis were a KPS ≥ 70 , and the presence of a solitary brain metastasis. It has been widely accepted that the pretherapeutic performance status is one of the most powerful predictive factors for the survival of patients with brain metastases^[7,34-38] which could be validated for patients with brain metastases from gastrointestinal tumors in our study group. The more favourable prognosis for patients with primary tumors of the gastrointestinal system presenting with a solitary brain metastasis was also found by Farnell *et al.*^[32], whereas others only found the surgical resection of brain metastases to be associated with a better survival^[19,23,27]. In our second multivariate analysis, including the therapeutic variable 'resection' status could not be identified as an independent prognostic factor, as mentioned above. In order to diagnose brain metastases in an early phase, in which a resection could still be possible, discrete symptoms hinting cerebral tumor spread should be taken seriously.

A basic problem concerning treatment recommendations for patients with brain metastases of gastrointestinal tumors is that to date only few retrospective studies with a relatively small

number of patients are available. Therefore, the results concerning the prognostic factors should be regarded with caution. The different prognostic factors from each study should be kept in mind when considering a therapeutic concept for individual patients.

In conclusion, brain metastasis is a late event in the course of gastrointestinal tumors, and it occurs later as in patients with other primary tumors. However, the overall survival time is comparable to patients with brain metastases from other primary tumors. Independent prognostic factors in our group were KPS and the number of brain metastases.

Abstract

AIM: To study the developmental regularities and heterogeneity of mast cells (MC) in human fetus duodenum and the distribution and developmental regularities of substance P(SP), calcitonin gene-related peptide (CGRP)-immunoreactive (IR) peptidergic nerves in fetus duodenum, as well as the relationship between MC, SP and CGRP-IR peptidergic nerves.

METHODS: Duodena from 21 cases of human fetus and one term infant were stained by hematoxylin-eosin (HE), toluidine blue (TB) and immunohistochemical avidin-biotinylated peroxidase complex (ABC) method.

RESULTS: Lobe-shape intestinal villi in duodenum were already developed at the twelfth week. At the 21st wk, muscular mucosa appeared gradually, and four layers were observed in the wall of duodenum. TB staining showed that the granules in the immature MC were pale violet, while the mature MC were strong violet in color by TB staining. Connective tissue MC (CTMC) appeared occasionally in submucosa and muscular layer of duodenum at the 16th wk. While the mucosa MC (MMC) appeared at the 18th wk. At the 22nd wk, both CTMC and MMC were activated, and distributed in the surrounding blood vessels and ganglions. The verge of some MC were unclear, and showed degranular phenomena. At the 14th wk, SP and CGRP-IR nerve fibers and cells appeared in the myenteric and submucous plexuses in small intestine, and the responses were turn strongly. Neurons were light to deep brown, and nerve fibers were present as varicose and liner profiles. On the corresponding site of serial sections, SP and CGRP immunohistochemical reactions were coexisted in one nerve fiber or cell. Some of MC showed SP and CGRP-IR positive staining.

CONCLUSION: There are two heterogeneous kinds of MC in duodenum, MMC and CTMC. MC might play an important role in regulating blood circulation and sensation.

INTRODUCTION

Previous microscopic anatomy studies have shown that somatic and visceral nerves are both widely approached to MC. MC and nerve cells interact with each other by connecting with a lemma or degranular style, so that they could regulate microenvironments. As far as organizations are concerned, the anatomic relation means interaction with function, but no studies are available about the development and distribution of MC and developmental regularities of SP, CGRP-IR nerves and cells in human fetus duodenum. BY investigating the relationship between MC and nerve- endocrine- immunological network^[1-3], we observed the histological changes in human fetus duodenum with HE staining, the developmental regularities and heterogeneity of MC with TB special staining, neuropeptide SP, CGRP by ABC methods, the relations between neuropeptide and MC. The study provided morphology data of the functional significance of mast cells in human fetus duodenum.

MATERIALS AND METHODS

Tissue specimens

Twenty-one fetuses of 3-9 mo old and one dead term infant were randomly collected within 1-5 h after birth, in which 10 were males and 11 were females. Duodena were taken out (near to bulbs), and fixed in 40 g/L formaldehyde for 12 h, cut into 10 mm×5 mm×3 mm, then embedded in paraffin and cut into 5μm thick serial section.

TB special staining

The paraffin embedded sections were deparaffined in serial xylene, dehydrated by alcohol solvents and mounted by xylene transparent neutral gum, then examined by microscopy and photographed.

Immunohistochemistry

The reactions were carried out according to the ABC method as previously reported^[4]. Briefly, the paraffin sections were deparaffined in xylene and graded alcohol. Sections were incubated at room temperature for 10 min with 30 mL/L H₂O₂ solution to block endogenous peroxidase activity. After washed with phosphate buffered saline (PBS) 3 times for 5 min each, slides were digested with trypsin, treated with 3 g/L Triton X-100, followed by incubation with antibodies SP (1:2 000, Sigma) or CGRP (1:1 000, Sigma) at 37 °C for 2 h and at 4 °C for 24 h. The sections were then incubated with biotin-conjugated IgG (diluted in PBS, 1:100) for 2.5 h at room temperature and washed with PBS 3 times for 5 min each, followed by incubation with the streptavidin-peroxidase complex for 1 h. At last, chromogen 3,3'-diaminobenzidine tetrahydrochloride (DAB) (1:50, Wuhan Boster) was added to visualize the reaction products of peroxidase.

The specific neuropeptide antibodies were replaced by PBS or normal rabbit serum for the negative controls. Adult duodenum tissue sections were used as positive controls, which showed immunoreactivity for SP and CGRP.

The results were judged as follows. Pale-yellow was

negative (-), shallow brown was weak positive (+), brown was moderately positive (++), and deep brown was strongly positive (+++).

RESULTS

HE staining

The histological differentiations were found in lobe-shape intestinal villi in duodenum at the 12nd wk. At the 15th wk, duodenal glands of mucous cells were formed in the submucosa. At the 21st wk, muscular mucosa appeared with 4 layers in the wall of duodenum gradually.

TB special staining

The experiments showed that CTMC in submucosa and muscular layer appeared by staining with 5 g/L toluidine blue with 500 mL/L alcohol dyeing for 5 min, but MMC in mucous layer appeared by staining with 5 g/L toluidine blue with one equivalent hydrochloric acid for 5 d. At the 16th wk, CTMC appeared occasionally in submucosa. But the time of MMC appearance was at the 18th wk. The granules in immature MC were pale violet, and strong violet in the mature MC as detected by TB special staining. CTMC in intermuscular appeared fusiform and cell bodies were small. MC in mucosa and submucosa layer were round or oval in shape and cell bodies were large (Figure 1A). With the increase of gestational age, the number of MC in duodenal wall increased gradually. At the 22nd wk, the two types of MC were activated and distributed in the surrounding blood vessels and ganglions. The verge of some MC was unclear, which might be a degranular phenomenon (Figure 1B). MC were closed together with connective tissue cells and there existed lemma connection in fetus duodenal mucous and submucous layer connective tissues.

Figure 1 MC in submucous layer at the 21st wk (A) and in mucous layer at the 27th wk (B) of duodenum (TB×400).

Immune phenotype

The degree of positive SP-immunoreactivity (SP-IR) and CGRP-immunoreactivity (CGRP-IR) and their distribution in neurons and nerve fibers (NF) in fetus duodenum had no sex difference. At the 14th wk, SP-IR positive neurons appeared occasionally in the myenteric plexuses of duodenum and neuron cell bodies showed fusiform, few SP-IR-NF appeared

in submucosal layer. But nerve plexuses of CGRP-IR appeared at the 16th wk. Diffused SP and CGRP-IR neurons were appeared in submucous at the 21st wk, pale-brown neuron cell bodies were round or oval in shape and nuclei were negative (Figure 2B). SP-IR-NF response to reinforcement (+ to ++) was found in myenteric connective tissue, showing string pearls in shape. A few CGRP-IR-NF appeared in submucous (+), were showing point line in shape. With the growth of gestational age, nerve fibers were mainly distributed in connective tissue of mucous, submucous and myenteric layers. Nerve plexus density increased, and staining turned deep gradually. The dark black positive nerve plexuses were identified (+++) in fetus duodenum after 34th wk, showing network structures and obvious varicosity (Figure 2B). On the corresponding site of serial sections, SP-IR and CGRP-IR materials were partially coexisted in nerve fibers and neurons. In serial sections of TB histochemistry and ABC immunohistochemistry staining, about 10% MC were SP-IR positive, and less MC were CGRP-IR positive. Some of SP, CGRP-IR-NF positive cells were coexisted with MC, while some were closely contacted.

Figure 2 CGRP-IR (+) nerve fiber in duodenum submucous layer at the 21st wk (A) (ABC×100) and SP-IR (++) neuron in duodenum submucous layer and myenteric nerve plexuses at the 28th wk (B) (ABC×200).

DISCUSSION

The results of our experiment showed that there were two kinds of MC in connective tissue of fetus duodenum, namely MMC and CTMC, which possessed heterogeneity. Our results are consistent with Wang *et al.*^[5]. It might be related to many factors such as local microenvironment. The activated MC were localized around cells, small vessels and ganglions in submucosa, showing that MC were related with those cells and tissues. Surface of some MC boundary was not clear. MC showed degranulation, which means that the cells were releasing active media and affecting peripheral environments and cells, so we considered that MC might take part in allergic and other physiological activities during fetus development and maturation of its surrounding tissues and organs. With electron microscope, Li *et al.*^[6] observed MC cytoplasm in intestinal mucosa lamina propria had electron dense round granules and electron-lucent inequality of size vesicles, which

were phenotype of activated MC. MC were important effector cells. It conducted the signal of inflammation cells, and induce the occurrence of mucosa correlated diseases^[7-9]. Previous studies have shown the severity of gastrointestinal allergic diseases, such as *Hp* infection, stomach reflow in duodenum, neuro-psychical factor leading gastro-intestinal functional dyspepsia related with MC, and the more serious the disease, the more obviously increased the numbers of MC^[10,11]. MC could release inflammatory medium, secretory cytokines (IL-2, TNF- α), biologically active molecules through phospholipase A₂ pathway in earlier period of various kinds of enteritis, which could evoke physiological injuries in the intestinal^[12-14]. With the growth of gestational age, the number of MC in bowel wall connective tissue increases gradually, suggesting that MC play an important regulatory role in developing tissue cells in duodenum.

Our experiment showed that the SP-IR and CGRP-IR peptidergic nerves plexus appeared at different time. Owing to the difference of local microenvironments in gastrointestinal tract, various kinds of peptidergic nerves appeared in different time. This difference was decided by local microenvironments of neural crest cells on the way of migration or after its presence. The occurrence of peptidergic nerves was determined by interaction of microenvironmental factors and crest cells. Since different investigators used different specimen source, they adopted different methods and techniques, the detection rate of positive nerve fibers and neurons was different. for example, Larsson *et al.*^[15] reported that CGRP-IR-NF was not observed in fetus duodenum mucosa membrane. But Yang *et al.*^[16] reported that developing fetus from the 13th week showed mild CGRP-IR-NF in myenteric nerve plexus of duodenum. There were differences in the distribution of SP and CGRP peptidergic nerve plexus at the same gestational age. We found that the distribution and response of SP-IR-NF was slightly higher than those of CGRP-IR-NF in myenteric nerve plexus, but CGRP-IR-NF mainly existed in connective tissue of mucosa and submucosa layers, showing that there was a difference in distribution of peptidergic nerve fibers in the same individual organ. They were closely connected with the presence of digestive tract peptidergic nerve. SP peptidergic nerves exist mainly in duodenum myenteric connective tissue. It could activate cholinergic nerve of gastrointestinal tract, cause neurilemma depolarization in myenteric nerve plexus and increase the effect of acetylcholine, resulting in contraction of digestive tract smooth muscle and secretion of glands^[17]. CGRP peptidergic nerves exit mainly in mucous and submucous layers. It is probably related to differentiation of duodenal epithelium and excretion of duodenal gland. CGRP could expand blood vessels of gastrointestinal tract and increase capillary permeability. CGRP could inhibit smooth muscles of gastrointestinal tract and cause relaxation of circular and longitudinal muscles and decrease duodenum vermication^[18]. Previous studies have reported that decrease of the level of serum CGRP might be related to *Hp* infection, leading to occurrence of duodenal ampulla ulcer^[19]. By observing adjacent sections, we found there was partial concordance in localization of SP-IR and CGRP-IR positive neurons. Therefore it is possible that SP and CGRP neurotransmitters coexist in peptidergic nerves. In previous studies, besides the coexistence of CGRP, cells of SP, somatostatin, vasoactive intestinal peptide (VIP) and neuropeptide Y were also coexisted in thymus, sensory ganglion and other organs^[18,20,21]. Because SP, CGRP peptidergic nerve fibers project very extensive in central nervous system, it is possible that these neuropeptides together with nervous system produce an important effect on sensation, movement, endocrine and other aspects. Gastrointestine SP, CGRP could regulate stability of MC, which might play an important role in keeping homeostasis the occurrence and development of

many pathologic alternations.

There are a lot of MC in connective tissue of human duodenum. Meanwhile, there also existed a huge nervous system, including rich peptidergic neurotransmitters^[22,23]. Those made it possible to connect adequate information between MC and nervous system. Gastrointestinal mucous MC are next to gastrointestinal nervous system. It provides double directions of channel between center nervous system and intestinal tract. Thus nervous system can influence physiological functions of gastrointestinal tract. MC could also stimulate intestinal neurons and smooth muscle cells by releasing various kinds of media^[24,25]. By electron microscopy some researchers found lemma connection was existed between MC plasmalemma and axon of nonmyelinated nerve fibers in enteron mucosa, form "plywood structure" and synaptic connection^[6,26]. As far as organ is concerned, that MC closely contacted with nerves in anatomy means interaction of function by releasing certain active substances, such as histamine, nitrogen monoxide *etc.*, as transmitters; On the other hand, nerves could affect MC growth and development. Animal experiments confirmed that the number of MMC and CTMC could be increased by nerve growth factor (NGF), moreover, NGF receptors have been discovered on the surface of MC in rat belly^[27]. It has been confirmed that SP and VIP are coexisted in MC^[28]. Jia *et al.*^[29-31] observed MC in mouse submandibular glands or tongue, and found that most of the MC were SP-IR positive, and 14% MC were CGRP-IR positive. In our studies, we observed that about 10% MC in the wall of fetus duodenum were SP-IR positive, but fewer MC were CGRP-IR positive, indicating that MC in different species and organs contain different peptidergic activity substances. Thus, MC in fetus duodenum possess heterogeneity, whose physiological significance needs further research.

Abstract

AIM: To observe the protective effect of rhIL-1 β on pancreatic islets of alloxan-induced diabetic rats.

METHODS: Protection of rhIL-1 β on pancreatic islets of alloxan-induced diabetic rats ($n = 5$) was demonstrated with methods of immunohistochemistry and stereology. The concentration of serum glucose was measured by GOD method and that of serum insulin by RIA.

RESULTS: The concentration of serum glucose increased but that of insulin decreased after administration of alloxan (150 mg/kg), and the volume density and numerical density of the islets were zero. In rhIL-1 β pretreated rats, although the concentration of serum insulin decreased (from 11.9 ± 3.0 mIU/L to 6.1 ± 1.6 mIU/L, $P < 0.05$), that of glucose was at normal level compared with the control group. As compared with alloxan group, the concentration of serum glucose in rhIL-1 β pretreated rats decreased (from 19.4 ± 8.9 mmol/L to 12.0 ± 4.0 mmol/L, $P < 0.05$) and the volume density increased (0/L to 1/L, $P < 0.05$).

CONCLUSION: rhIL-1 β pretreatment may have protective effect on the islets of alloxan-induced diabetic rats.

INTRODUCTION

The cytokine interleukin-1 β (IL-1 β) can not only promote immunological reaction but also regulate neuro-endocrine system^[1]. Previous studies found that IL-1 β could stimulate the central adrenergic system, promote production of PG, and downregulate glucose metabolism^[2].

Diabetes mellitus implicates many organs and tissues. It has been found that IL-1 β decreases serum glucose in experimental

animals and may potentially be therapeutic for diabetes mellitus^[3,4]. In this experiment, we observed changes in serum glucose and insulin in alloxan induced diabetic rats treated with IL-1 β . In addition, we detected the variation of volume density and numerical density of insulin positive pancreatic islets by ABC immunohistochemistry and stereology.

MATERIALS AND METHODS

Animals

Twenty male Sprague-Dawley rats weighing 200 to 300 g were housed in a temperature-controlled room (24 ± 1 °C) with a 12-h light-dark cycle. The rats were provided with ordinary rat chow and water and divided into 4 groups ($n = 5$, every group): (1) Control group, each rat was injected with 2 mL saline every other day for 3 times, then injected with 2 mL saline on the 7th d; (2) rhIL-1 β group, each rat was injected with 1×10^4 U rhIL-1 β in 2 mL saline every other day for 3 times, then injected with 2 mL saline on the 7th d; (3) rhIL-1 β pretreated group, each rat was injected with 1×10^4 U rhIL-1 β in 2 mL saline every other day for 3 times, then was injected with 150 mg/kg alloxan in 2 mL saline on the 7th d; (4) Alloxan group, each rat was injected with 2 mL saline every other day for 3 times, then injected with 150 mg/kg alloxan in 2 mL saline on the 7th d.

Reagents

Guinea pig anti-rat insulin antibody and SPA-HRP were prepared by Professor Yun-Long Zhu (Department of Physiology) and Professor Cai-Fang Xue (Department of Parasitology) of our university respectively. DAB was purchased from Sigma.

Tissue preparation

Forty-eight hours after last injection of alloxan or saline, rats were anesthetized with ether and sacrificed by cervical dislocation. The blood was collected into heparinized tubes (50 kU/L) and centrifuged (3 000 g, 10 min, at room temperature). Plasma was aspirated and stored at -70 °C until assayed as described below. The pancreas was also removed and fixed in Bouin's solution overnight. Each piece was embedded in paraffin and 4- μ m sections were prepared.

Immunohistochemistry

Four-micrometer sections from rat pancreas were employed for immunohistochemical analysis. Several dilutions of the antibody were tested to find the optimal staining concentration before the entire series was processed. The staining procedure was carried out as previously reported, but without protease treatment. Briefly, (1) the sections were deparaffinized in xylene, hydrated in ethanol, and blocked with 3 mL/L H₂O₂ in methanol for 30 min to remove endogenous peroxides, then treated with 30 mL/L normal goat serum for 40 min and rinsed in 0.01 mol/L PBS. (2) The sections were incubated at 4 °C for 24 h with primary antibody, guinea pig anti-rat insulin antibody (1:1 000 dilution, final concentration 5 mg/L); (3) then with secondary antibody, SPA-HRP (1:200 dilution), at room temperature for 1 h. (4) Peroxidative reaction was performed using DAB as chromogen. The sections were washed three times for 10 min after incubation.

All slides were stained at the same time and under identical conditions. Primary antibodies were replaced by irrelevant antibodies and normal guinea pig serum as specific antibody control. Primary antibody was replaced by PBS as negative control. Primary antibody was omitted as blank control.

Detection of serum glucose and insulin

The concentration of serum glucose was measured by routine GOD method^[5] and the concentration of serum insulin was measured by RIA^[6,7]. Every sample was measured three times and the results were displayed as mean±SD.

Morphometry

Five specimens from each group were used for morphometric analysis of slides processed for light microscopy. Two sections from each specimen were then selected and five different regions of each section were chosen for the measurement of volume density and number density by double blind method.

Statistical analysis

The results were calculated by the following formula; $N_v = 2/3 \times \pi \times NA \times U$ ($AT \times A$); $V_v = A/AT$. Data were analyzed by χ^2 test. A *P* value of less than 0.05 was considered statistically significant.

RESULTS

Insulin expression in rat pancreas

There were more insulin immunoreactive cells in pancreas of control group and rhIL-1 β group than in alloxan group. Immunoreactive cells were mainly located in the central region

of the pancreas. Insulin immunopositive cells had dark-brown reaction products in the cytoplasm mostly and nuclei were not stained (Figure 1A, B). The number of insulin immunopositive cells in alloxan group decreased remarkably and there were only a few positive cells in each pancreatic islet (Figure 1C). The number of insulin immunopositive cells in rat pancreas of rhIL-1 β pretreated group decreased slightly compared with that of control group and rhIL-1 β group, whereas, the number of insulin immunopositive cells in rat pancreas of rhIL-1 β pretreated group increased remarkably compared with that of alloxan group (Figure 1D).

Destructive effect of alloxan on rat pancreatic B cells

The concentration of serum glucose increased significantly but that of insulin decreased remarkably after administration of alloxan (150 mg/kg) for 48 h compared with those of control rats. At the same time, the volume density and numerical density of the islets were zero (Table 1).

Stimulatory effect of rhIL-1 β on insulin secretion

Compared with control group rats, the concentration of serum insulin in rhIL-1 β group rats increased significantly whereas that of glucose was at normal level. Immunohistochemistry and stereology data showed that there were no significant differences in the number density and volume density of the pancreatic islets between rhIL-1 β group rats and control rats (Table 1).

Protective effect of rhIL-1 β on pancreatic islets of alloxan-induced diabetic rats

In rhIL-1 β pretreated group, when the rats were injected with

Figure 1 Insulin immunoreactive cells in pancreas. ABC method $\times 264$ A: control group. B: rhIL-1 β pretreated rat. C: alloxan-induced diabetic rat. D: rhIL-1 β pretreated alloxan-induced diabetic rat.

Table 1 Protective effect of rhIL-1 β on pancreatic islets of alloxan-induced diabetic rats

Group	Serum glucose (mmol/L, <i>n</i> = 5)	Serum insulin (mIU/L, <i>n</i> = 5)	Volume density (/L, <i>n</i> = 50)	Number density (/μm ² , <i>n</i> = 50)
Control	8.4±0.3	11.9±3.0	0.6±0.7	5.2±4.1
Alloxan	19.4±8.9 ^a	4.7±1.0 ^a	0 ^a	0 ^a
rhIL-1 β	8.0±1.3	20.0±6.6 ^a	0.6±0.5	5.6±5.3

^a*P*<0.05 vs control.

alloxan for 48 h, although the concentration of serum insulin decreased significantly, that of glucose was at normal level compared with control group rats. Immunohistochemistry and stereology data showed that there were no significant differences in the number density of the pancreatic islets between rhIL-1 β pretreated rats and control rats, whereas the volume density decreased markedly in rhIL-1 β pretreated group (Table 1).

DISCUSSION

Interleukin 1 β (IL-1 β) is a multi-functional cytokine synthesized mainly by mononuclear/mo cells and is a key factor in the cytokine network^[8,9]. IL-1 β has many biological functions^[9-21]. Previous study showed that IL-1 β could decrease the serum glucose level and might be potentially a new drug for diabetes therapy^[2-4]. In our experiment, when the rats were injected with alloxan (150 mg/kg) for 48 h, the concentration of serum glucose increased significantly, and that of insulin decreased remarkably. At the same time immunohistochemistry and stereology data showed that the value of number density and volume density of the pancreatic islets were zero. In rhIL-1 β pretreated group, when the rats were injected with alloxan for 48 h, although the concentration of serum insulin decreased significantly, that of glucose was at normal level compared with control group rats. Immunohistochemistry and stereology data showed that there were no significant differences in the number density of the pancreatic islets between rhIL-1 β pretreated rats and control rats, whereas the volume density decreased remarkably in rhIL-1 β pretreated rats. Our results suggest that rhIL-1 β has protective effect on pancreatic islets of alloxan-induced diabetic rats and provide the experimental evidence that rhIL-1 β may be a new therapeutic drug for diabetes.

Abstract

AIM: To identify the new alternative splicing variants of human CYP2D6 in human extratumoral liver tissue with RT-PCR and sequencing.

METHODS: Full length of human *CYP2D6* cDNAs was amplified by reverse transcription-polymerase chain reaction (RT-PCR) from a human extratumoral liver tissue and cloned into pGEM-T vector. The cDNA was sequenced. Exons from 1 to 4 of human *CYP2D6* cDNAs were also amplified by RT-PCR from extratumoral liver tissues of 17 human hepatocellular carcinomas. Some RT-PCR products were sequenced. Exons 1 to 4 of *CYP2D6* gene were amplified by PCR from extratumoral liver tissue DNA. Two PCR products from extratumoral liver tissues expressing skipped mRNA were partially sequenced.

RESULTS: One of the *CYP2D6* cDNAs had 470 nucleotides from 79 to 548 (3' portion of exons 1 to 5' portion of exon 4), and was skipped. Exons 1 to 4 of CYP2D6 cDNA were assayed with RT-PCR in 17 extratumoral liver tissues. Both wild type and skipped mRNAs were expressed in 4 samples, only wild type mRNA was expressed in 5 samples, and only skipped mRNA was expressed in 8 samples. Two more variants were identified by sequencing the RT-PCR products of exons 1 to 4 of *CYP2D6* cDNA. The second variant skipped 411 nucleotides from 175 to 585. This variant was identified in 4 different liver tissues by sequencing the RT-PCR products. We sequenced partially 2 of the PCR products amplified of *CYP2D6* exon 1 to exon 4 from extratumoral liver tissue genomic DNA that only expressed skipped mRNA by RT-PCR. No point mutations around exon 1, intron 1, and exon 4, and no deletion in *CYP2D6* gene were detected. The third variant was the skipped exon 3, and 153 bp was lost.

CONCLUSION: Three new alternative splicing variants of CYP2D6 mRNA have been identified. They may not be caused by gene mutation and may lose CYP2D6 activity and act as a down-regulator of CYP2D6.

INTRODUCTION

Over 90% medications are metabolized by cytochrome P450 (CYP) family of liver isoenzymes^[1]. The most important enzymes are CYP1A2, 3A4, 2C9/19, 2D6 and 2E1. Although CYP2D6 accounts for <2% of the total CYP liver enzyme, nevertheless it mediates metabolism in 25% of drugs in clinical use such as antipsychotics, antidepressants, beta-blockers, antiarrhythmic agents and opiates^[2]. CYP2D6 exhibits an extensive polymorphism^[3]. Over 40 *CYP2D6* allelic variants have been reported^[4].

Pre-mRNA splicing involves precise removal of introns from pre-mRNA, such that exons are spliced together to form mature RNAs with intact translation reading frames. Splicing requires exon recognition, followed by accurate cleavage and rejoining, which are determined by the invariant GU and AG intronic dinucleotides at the 5' (donor) and 3' (acceptor) exon-intron junctions, respectively^[5]. Human genes typically contain multiple introns, and in many cases the exons can be joined in more than one way to generate multiple mRNAs, encoding distinct protein isoforms. This process named alternative splicing is a major mechanism for modulating the expression of cellular and viral genes and enables a single gene to increase its coding capacity, allowing synthesis of several structurally and functionally distinct protein isoforms^[6-9].

CYP2D subfamily comprises *CYP2D6* gene and pseudogenes, i.e. *CYP2D7P* and *CYP2D8BP*. Six mRNA splice variants of *CYP2D* have been identified in human liver^[10], breast^[11], lung^[12], and brain tissues^[13]. Variants a and b retain intron 5 and 6, respectively; variant b' has missed the 3' 91 bp portion of exon 6; variant c has missed exon 6; variant d retains 57 bp portion of intron 6; variant e retains the 3' portion of intron 6 and has missed the 61 bp fragment at the 3' end of exon 6. Forms b' and c are variants of *CYP2D6*, and forms d, c, b, b' are variants of *CYP2D7P*^[10-13]. All of these CYP2D splice variant mRNAs disrupt open reading frames. If they are translated, they would not have CYP2D6 function.

Three new pre-mRNA alternative splicing variants of human *CYP2D6* in human extratumoral liver tissue were identified by RT-PCR and sequencing.

MATERIALS AND METHODS

Materials

Moloney murine leukemia virus (M-MuLV) reverse transcriptase was supplied by MBI Fermentas AB, Lithuania. Random hexamer primers, T4 DNA ligase and pGEM-T vector system were supplied by Promega Corp. PCR primers, DNA sequence primers, dNTPs and Taq DNA polymerase were synthesized or supplied by Shanghai Sangon Biotechnology Co. DNA sequencing kit was purchased from Perkin-Elmer Corp. Diethyl pyrocarbonate (DEPC) was from Sigma Chemical Co. DNA gel extraction kit was from Hangzhou V-gene Biotechnology Ltd. Other chemical reagents used were all of analytical purity from commercial sources. Extratumoral liver tissue samples were collected from patients undergoing hepatocellular carcinoma resection at affiliated hospitals of Zhejiang University School of Medicine and stored at -70 °C.

Cloning and sequencing of human CYP2D6 cDNA from a human extratumoral liver tissue

Total RNA was extracted from a human extratumoral liver tissue from a Han nationality Chinese with AGPC method^[14]. RT-PCR amplifications were described before^[15,16]. Two specific 28 mer oligonucleotide PCR primers were designed according to cDNA sequence of *CYP2D6* reported by Gonzalez *et al.*^[10] (GenBank accession no. NM_000106). The sequence of sense primer (*CYP2D6* F) corresponds to base position of -39 to -12, i.e. 5'-AGGTGTGTCTCGAGGAGCCCCATTGGTA-3', with a restriction site of *Xho*I (underlined), and the antisense one (*CYP2D6* R), corresponds to base position from 1 503 to 1 530, i.e. 5'-TGGCTAGGGATCCGGCTGGGGACTAGGT-3', with a restriction site of *Bam*HI (underlined). The anticipated PCR products were 1.569 kb in length. PCR was performed at 94 °C for 5 min, then 35 cycles, each at 94 °C for 60 s, at 62 °C for 60 s, at 72 °C for 2 min, and a final extension at 72 °C for 10 min. An aliquot (10 µL) from PCR was subjected to electrophoresis in a 10 g/L agarose gel. The PCR products were ligated with pGEM-T vector, and transformed into *E. coli* DH5α. The *CYP2D6* cDNA cloned in pGEM-T was sequenced by dideoxy chain-termination method marked with BigDye with primers of T7 and SP6 promoters and a specific primer of 5'-ACCTCATGAATCACGGCAGT-3' (nt 1 069 to 1 088) on Perkin-Elmer-ABI Prism 310 automated DNA sequencer.

RT-PCR and sequencing analysis of liver transcripts of CYP2D6 exons 1 to 4

Transcripts of *CYP2D6* exons 1 to 4 were assayed with RT-PCR using 17 extratumoral liver tissues from Han nationality Chinese, with *CYP2D6* F and *CYP2D6* 4R primer: 5'-GCAGAAAGCCCGACTCCTCTTCA-3' (nt 638 to 661). Simultaneously the beta-actin (GenBank accession no. NM_001101) cDNA fragment was amplified in the same Eppendorf tube as an internal control^[17]. The sequences of sense and antisense primers used for amplification of beta-actin cDNA fragment were 5'-TCCCTGGAGAAGAGCTACGA-3' (nt 776 to 795) and 5'-CAAGAAAGGGTGTAACGCAAC-3' (nt 1 217 to 1 237) respectively. The anticipated PCR products of *CYP2D6* exons 1 to 4 were 700 bp in length, and those of beta-actin were 462 bp. PCR was performed at 94 °C for 3 min, then 35 cycles, each at 94 °C for 30 s, at 62 °C for 30 s, at 72 °C for 45 s, and a final extension at 72 °C for 7 min. An aliquot (10 µL) from PCR was subjected to electrophoresis in a 17 g/L agarose gel. Several RT-PCR products of *CYP2D6* exons 1 to exon 4 were shorter than the anticipated full length of 700 bp. The shorter RT-PCR products were separated by agarose gel electrophoresis and extracted using DNA gel extraction kit according to the manufacturer's instructions, and then sequenced by dideoxy chain-termination method marked with BigDye with primer of *CYP2D6* F on Perkin-Elmer-ABI Prism 310 automated DNA sequencer.

Sequencing identification of exon 1 to exon 4 of CYP2D6 gene

Genomic DNA of human extratumoral liver tissues expressed full length of *CYP2D6* exons 1 to 4 only (3 samples), or only exons skipped (2 samples) or both of full length and skipped ones (3 samples) were extracted according to the methods reported by Gross-Bellard *et al.*^[18]. The segment of *CYP2D6* gene from exons 1 to 4 was amplified with *CYP2D6* F and *CYP2D6* 4R primers. The anticipated PCR products were 2043 bp (from 1581 to 3623) in length. Two PCR products from extratumoral liver tissues that only expressed skipped mRNA were partially sequenced by RT-PCR.

RESULTS

Identification of a new alternative splicing variant from a cDNA clone

During cloning of *CYP2D6* cDNA, a 1.1 kb RT-PCR product was obtained, which was much shorter than anticipated 1.57 kb (Figure 1).

Figure 1 Electrophoresis of RT-PCR products of *CYP2D6* cDNA. Lane 1: 1 kb DNA marker, 2: Amplification of 1.1 kb in size, 3: Amplification of full length of 1.57 kb.

Figure 2 Partial sequences of the cloned human *CYP2D6* cDNA. The upper sequence represents the sense strand and the underside sequence represents the sequenced anti-sense strand.

Figure 3 Representative electrophoresis of RT-PCR products of exons 1 to 4 of *CYP2D6* from human liver tissues and HepG2 cells with beta-actin as internal control (464 bp). Lane 1: 100 bp marker, lane 2: A sample having both full length of 700 bp and shorter 300 bp, lane 3: A sample having only shorter ones (300 bp), lane 4: HepG2 cells having no *CYP2D6* expressed, lane 5: A sample having only full length 700 bp of exons 1 to 4 of *CYP2D6*.

Figure 4 Partial sequences of two alternative splicing variants of *CYP2D6*. A: Part of skipped exon 1, exon 2, exon 3, and part of exon 4. B: Skipped exon 3.

Figure 5 Comparison of sequences of *CYP2D6* cDNA, *CYP2D7* BP and 3 new *CYP2D6* alternative splicing variants, f, g, h. The different bases compared with wild type *CYP2D6* are indicated in boldface and “_”, and the border of exons is indicated by “!”. The skipped parts are indicated by “-”.

The cDNA obtained was then inserted into pGEM-T vector and sequenced. Compared with human wild type *CYP2D6* cDNA sequence reported by Kimura *et al.*^[19] (GenBank accession no.M33388), there were 470 nucleotides from 84 to 553, i.e., the 3' end portion 97 bp of exon 1 (180 bp), exon2, exon 3, and the 5' end portion 48 bp of exon 4 (161 bp) were skipped in the

cDNA shorter in length (Figures 2, 5). Substitution, insertion and deletion occurred in 13 base pairs, i.e. 620A→G, 712G→T, 1196T→G, 1401T→G, 1405C→G, 1408A→G, 1410T→C, 1432C→T, 1433A→C, 1435G→C, 1400 insG, 1442T→C, 1443T→A, 1449C del, 1457G→C. This cDNA had a premature stop codon at codon 96 and was named variant f.

RT-PCR analysis of transcripts of CYP2D6 exons 1 to 4 in 17 liver extratumoral tissues and HepG2 cells, two more new alternative splicing variants were identified by sequencing

In 17 liver tissues, 4 samples expressed both wild type and skipped mRNA, 5 samples expressed only wild-type mRNA, and 8 samples expressed only skipped mRNA. Representative electrophoresis of RT-PCR products of exons 1 to 4 of *CYP2D6* from human extratumoral liver tissues and HepG2 cells with beta-actin as internal control are shown in Figure 3.

The sequencing data of RT-PCR products demonstrated that the second variant lost 411 nucleotides (137 amino acid residues) from 177 to 587, i.e., the 3' end portion 4 bp of exon 1 (180 bp), exon 2, exon 3, and the 5' end portion 83 bp of exon 4 (161 bp) and gained a base substitution 100 C→T, resulting in one amino acid exchange P34S, as compared with the human wild type *CYP2D6* cDNA sequence reported by Kimura *et al.*^[19] (GenBank accession no.M33388) (Figure 4A, 5). This variant was identified in 4 different extratumoral liver tissues by sequencing RT-PCR products and was named variant g.

The third variant had skipped exon 3, losing 153 bp from nucleotides 353 to 505 or 51 amino acid residues from 117 to 167, and had 2 base substitutions 100 C→T and 336 T→C, resulting in one changed amino acid P34S and a samesense mutation 112F, respectively. This variant was named variant h (Figure 4B, 5).

Figure 6 Electrophoresis of PCR products from genomic DNA amplified using *CYP2D6* F and *CYP2D6* 4R primers. Lane 1: λ /EcoRI and HindIII marker, lanes 2-4: PCR products from livers expressing full and short length RT-PCR products, Lanes 5, 6: PCR products from livers expressing full length RT-PCR products, Lanes 7, 8: PCR products from livers expressing only short length RT-PCR products.

No mutation events around splicing sites of exon 1 and exon 4 nor gene deletion from exon 1 to exon 4 of *CYP2D6* gene

The segment of *CYP2D6* gene at exons 1 to 4 was amplified with *CYP2D6* F and *CYP2D6* 4R primers by PCR. All amplified products from 8 samples gave anticipated 2.04 kb in length but no 0.3 kb PCR products as predicted from the possibility that the shorter cDNA was originated from deleted mutations in *CYP2D6* gene rather than due to alternative splicing (Figure 6). Two PCR products from extratumoral liver tissues expressed only skipped exon were purified and partially sequenced. One showed 3 mutations, i.e., 1719 (nt 100) C→T in exon 1, resulting in P34S, 3280 (nt 408) G→C in exon 3, and samesense mutations 136 V, 3056 G→C in intron 2. Another one showed 3 mutations, i.e., 1719 (nt 100) C→T in exon 1, resulting in P34S, 1958 T→C in intron 1, and 3056 G→C in intron 2.

DISCUSSION

The mechanism of exon missed in cDNA may include gene deletion, alternative splicing, template sequence recombination present in PCR amplification^[20-22], and retroviral recombination^[23-25]. One or several exons missed entirely could ascribe to alternative splicing. The first mechanism of formation of recombinant molecules during PCR is mediated by premature termination of chain synthesis. Therefore, a short extension time or increased

dissociation of polymerases from the template may promote recombination. The optimum values to minimize recombinant molecule formation could prolong the extension time and could be achieved using 30 or 34 amplification cycles respectively. The second mechanism is template switching, it implicates that a fragment elongating on one template, can continue this elongation on another homologous template. The high template concentrations could facilitate template switching and *de novo* synthesize recombinant molecules. We performed PCR with lower template concentrations, 1 min/kb extension, and 32 to 35 amplification cycles to minimize the PCR recombination. During synthesis of the first DNA strand, reverse transcriptase could switch templates from one to other copy of RNA, a phenomenon known as copy-choice. The term 'template switching' implies that the nascent DNA strand is transferred from one RNA (the 'donor') to the other (the 'acceptor'). This process depends on a ribonuclease (RNase H) activity, carried by reverse transcriptase, which could degrade the RNA template once it has been copied^[26]. The RNA recombination is a very rare event. In this study, MMLV without RNase H activity was used and skipped mRNA was found in 12 out of 17 liver tissues by RT-PCR assay. Variant g was identified in 4 different extratumoral liver tissues by sequencing RT-PCR products. These facts indicated that the exon missed variant g did not come from PCR recombination or retroviral recombination. PCR amplification and sequencing identification of exon 1 to exon 4 of *CYP2D6* gene from genomic DNA indicated that the exon missed variant g came from neither gene mutation around splicing sites of exon 1 and exon 4 nor gene deletion.

Burset *et al.*^[27] analyzed canonical and non-canonical splice sites in mammalian genomes, and found that 99.24% contained canonical dinucleotides GT and AG for donor and acceptor sites, respectively, 0.69% contained GC-AG, 0.05% contained AT-AC and only 0.02% contained other types of non-canonical splice sites. Some non-canonical splice sites seemed to be involved in immunoglobulin gene expression and the others in alternative splicing events.

CYP2D6 gene has 9 exons and 8 introns. All alternative splicing *CYP2D* reported are located in exon 6 to exon 7. No alternative splicing in exon 1 to exon 4 has been reported. We identified 3 new alternative splicing *CYP2D6* cDNA in exon 1 to exon 4 in human extratumoral liver tissues. The skipped mRNA was not an unusually phenomenon, for 12 samples expressed skipped mRNA in 17 human liver tissue, whereas 9 samples expressed wild-type mRNA in this study.

We cloned a cDNA variant of human *CYP2D6*, the variant f with some exons skipped. The five nt 5'-CAACG-3', located at the boundary of partially skipped exons 1 and 4 (Figure 6). It looked as the 3' end portion of skipped exon 1 or the 5' end portion of exon 4. If we looked it as the 3' end portion of the skipped exon 1, then the splicing donor and acceptor sites would be CT-CG, which were not found as splice site pairs^[27]. If we looked it as the 5' end portion of exon 4, then there would be 470 nucleotides from 79 to 548, i.e., the 3' end portion 102 bp of exon 1 (180 bp), exon 2, exon 3, and the 5' end portion 43 bp of exon 4 (161 bp) were skipped. The splicing donor and acceptor sites would be the non-canonical splice sites: CA-AG^[27].

CYP2D gene exists in a number of structurally polymorphic haplotypes and also comprises several variants of *CYP2D7P* and *CYP2D8P* pseudogenes. *CYP2D6* is highly homologous to *CYP2D7* and *CYP2D8* pseudogenes. The characteristic base substitution, insertion and deletion of the variant f from 1401 to 1457 in exon 9 indicated that this exon was derived from *CYP2D7BP*^[28] (GenBank accession no.X58468). So this cDNA clone may be transcribed from *CYP2D6**36 (Trivial name: *CYP2D6Ch2* or *CYP2D6*10C*) gene, which has gene conversion to *CYP2D7* in exon 9^[29]. Johansson *et al.*^[29] using allele-specific polymerase chain reaction analysis of genomic DNA from 90 Chinese individuals revealed that *CYP2D6**10 (*CYP2D6Ch1*)

allele was the most common one, *CYP2D6**36 was not a common allele^[30] and so we got an alternative splicing variant from this allele only once.

Another alternative splicing *CYP2D6* cDNA, variant g, has 7 bp 5'-GCTTCGA-3', which locates at the boundary of partially skipped exons 1 and 4 (Figure 6). It can be regarded as the 3' end portion of skipped exon 1 or the 5' end portion of exon 4. The splicing donor and acceptor sites would be CC-GA or GC-CC which have not been found as splice site pairs^[27]. If we regarded it as the skipped nucleotides from 175 to 585, then 411 nucleotides (137 amino acid residues), i.e., the 3' end portion 6 bp of exon 1 (180 bp), exon 2, exon 3, and the 5' end portion 81 bp of exon 4 (161 bp) were skipped. The splicing donor and acceptor sites would be the non-canonical splice sites: GA-TC^[27]. As this variant has been identified in 4 different liver tissues by RT-PCR products sequencing, it could not be the RT-PCR artificial ones.

The third variant, variant h, having skipped the entire exon 3, would use the most common non-canonical GC-AG splice sites (Figure 6). It has an amino acid change of P34S which is a common polymorphism occurring in *CYP2D6**4, 10, 14, 36, 37. This variant might come from *CYP2D6**10, the most common allele in Chinese.

The cDNA sequence of *CYP2D6* is differed from that of *CYP2D7P* at nucleotides 629 to 639, *CYP2D6*^[19] was AGG AGGGACTG whereas *CYP2D7P*^[28] was AGGGAGGGATCG (Figure 6). All sequencing data of the alternative splicing cDNA and PCR products originated from related genomic DNA showed the characteristics of *CYP2D6*, so they were all derived from *CYP2D6* but not from *CYP2D7P*.

Variant f has premature stop codon at codon 96, which would cause loss of its enzyme activity. According to the homology modeling study of human CYP2 family enzyme reported by Lewis^[31], the substrate could recognize site (SRS) 1 of human *CYP2D6* located between amino acid residues 101 and 123 and the SRS2 located between amino acid residues 204 to 215. Variant g which lost 137 amino acid residues from 58 to 194, would lose SRS1, and might not have *CYP2D6* activity. Variant h having skipped the entire exon 3, would lose 51 amino acid residues from 117 to 167, where part of SRS1 located. It might not have *CYP2D6* activity.

All 3 *CYP2D6* splice variants might not have *CYP2D6* function. But the possibility of the expression of proteins with novel function(s) could not be excluded. The splice variants might have a role in the posttranscriptional down-regulation of the expression of *CYP2D6*. Formation of variant mRNAs at the expense of full-length mRNAs would ultimately result in a diminished expression of *CYP2D6* protein.

Three new *CYP2D6* pre-mRNA alternative splicing variants in human extratumoral liver tissues have been identified. Further work is needed to clarify if they are commonly existed in liver tissue or only in extratumoral liver tissue, and their relation with hepatocellular carcinoma as well.

Abstract

AIM: To investigate the antiangiogenic effects of endostatin on colonic carcinoma cell line implanted in nude mice and its mechanism.

METHODS: Nude mice underwent subcutaneous injection with LS-174t colonic carcinoma cell line to generate carcinoma and were randomly separated into two groups. Mice received injection of vehicle or endostatin every day for two weeks. After the tumor was harvested, the tumor volumes were determined, and the expressions of CD34, VEGF and Flk-1 were examined by immunohistochemical method.

RESULTS: Tumor volume was significantly inhibited in the endostatin group (84.17%) and tumor weight was significantly inhibited in the endostatin group (0.197 ± 0.049) compared to the control group (1.198 ± 0.105) ($F = 22.56$, $P = 0.001$), microvessel density (MVD) was significantly decreased in the treated group (31.857 ± 3.515) compared to the control group (100.143 ± 4.290) ($F = 151.62$, $P < 0.001$). Furthermore, the expression of Flk-1 was significantly inhibited in the treated group (34.29%) compared to the control group (8.57%) ($\chi^2 = 13.745$, $P = 0.001$). However no significant decrease was observed in the expression of vascular endothelial growth factor (VEGF) between these two groups ($\chi^2 = 0.119$, $P = 0.730$).

CONCLUSION: Endostatin can inhibit tumor growth and angiogenesis by blocking Vegf/Flk-1 pathway. This experiment provides the theory basis for developing a new anti-carcinoma drug through studying the properties of anti-angiogenesis inhibitors.

INTRODUCTION

Angiogenesis is the process of sprouting of capillaries from

preexisting blood vessels. The overall process is a complex one that involves many biological functions and cell types. Previous researches since 1970s have demonstrated that tumor angiogenesis is required for the growth and metastasis of primary solid tumor. Endothelial cell activation, migration, and proliferation are major cellular events in this process. All of these processes are under the tight regulation of factors that either “promote” or “inhibit” angiogenesis. When the balance of these factors is disturbed, angiogenic factors can be released from tumor cells, such as vascular endothelial growth factor (VEGF)^[1] and basic fibroblast growth factor (bFGF), and migrate to the nearby blood vessel endothelia, signal the activation of the angiogenic response. Tumor cells also produce anti-angiogenic factors including angiostatin, endostatin. Administration of endostatin in tumor-bearing mice has been shown to keep the primary tumor in a dormant state^[2]. But the mechanisms are still unclear. One mechanism is that endostatin in combination with the endothelial cells to form a compound with tyrosine activity and thereby inducing apoptosis of endothelial cells. The other is that endostatin functions as a ligand for the integrin family of adhesion receptors on the surface of endothelial cells and is associated with MMP family^[3]. So, in order to explore the mechanism of endostatin, we provided data that endostatin showed a broad antitumor effect, which might be a result of its inhibitory mechanism on tumor angiogenesis.

MATERIALS AND METHODS

Materials

Endostatin donated from Hefei Sunny Biology-technology Institute, was a 20 ku C-terminal fragment of collagen X VIII. Human endostatin was cloned and expressed in *Escherichia coli* and purified by gene cloning technology by Gene Med Ltd.

Colon cancer cell line HL-174T was purchased from Shanghai Cellular Research Institute. The cells were cultured in 1640 medium supplemented with 100 mL/L fetal bovine serum at 37 °C in 50 mL/L CO₂ and the culture media were changed twice a week and observed in the invert microscope to assay the reproduction situation. All reagents and media for cell culture were obtained from GIBCO.

Methods

Subcutaneous xenograft models Tumor cells were implanted (0.5×10^6 cells/animal) subcutaneously using a 27-gauge needle in the back region of BALB/C-nu/nu female mice of 6-8 wk old. Tumor volume was measured every 3 d using a slide gauge. Tumor volumes were measured as the product of (length × width) × $\pi/6$. Mice were fed with a standard rodent diet for two weeks, and 14 of 20 mice with a similar tumor volume were selected and divided into two groups randomly. Animals of each group were treated once daily with a 0.1 mL (2 mg/mL) ip bolus injection of endostatin in saline or saline alone for 14 d. Upon termination of the efficacy portion of endostatin (3 d after drug withdrawal), the animals were euthanized, and the tumor was harvested from the animals and the volume was weighted. The tumors were submitted for immunohistochemical test.

Evaluation of MVD, VEGF and VEGFR/flk-1 expression in tumors Five- μ m paraffin embedded sections of the tumors were evaluated by immunohistochemistry. The sections were stained with anti-CD34 antibody (DAKO, 1:2 000) and polyclonal anti-VEGF antibody and polyclonal anti-Flk-1 antibody that could recognize VEGF isoforms and their receptors, following avidin-biotin complex methods.

Microvessel density was assessed by light microscopy in areas of invasive tumors containing the highest number of capillaries and small venules per area (neovascular "hot point"). Areas of the highest neovascularization were found by scanning the tumor sections at a low magnification ($\times 100$) and identified with the greatest number of distinct CD34 stained (brown) microvessels per area. Necrotic areas within tumors, where microvessels were sparse, were not included in the vessel counts. After the area of the highest neovascularization was identified, individual microvessels were counted under $\times 400$ field. A brown-stained endothelial cell or a endothelial cell cluster clearly separated from adjacent microvessels, tumor cells, and other connective-tissue elements, considered a single, countable microvessel. Vessel lumens were not necessary for a structure to be defined as a microvessel, and red cells were not used to define a vessel lumen. Results were expressed as the number of microvessels identified within 10 fields ($\times 400$).

VEGF was assessed by light microscopy ($\times 100$) in the areas of invasive tumor cells. VEGF expression was determined on adjacent serial visual fields and scored by a pathologic doctor. The number of positively and negatively stained cells was counted in 10 continuous visual fields. If more than 5% cells were brown stained, they were considered as positive, otherwise negative. The results were expressed as mean \pm SD.

Flk-1 was assessed by light microscopy ($\times 400$) in the areas of microvessel endothelial cells. The number of endothelial cells stained positively was counted in 10 continuous visual fields. Over 5% positively stained endothelial cells were determined as positive and else negative. The results were expressed as mean \pm SD.

Statistics

The analysis of variance test was used to compare the differences in tumor weight and MVD between the treated and control groups. The Chi-squared test was used to compare the differences in the expression of VEGF or VEGFR2/Flk-1 between the treated and control groups. The difference was considered statistically significant if the *P* value was less than 0.05. All the data were analyzed with SAS 6.22 by the statistical office of the Second Military Medical University.

RESULTS

Inhibition of tumor growth by endostatin

To determine the efficacy of endostatin on tumor growth, the volume of tumors were measured every three days after endostatin was used and tumors were weighed immediately after they were harvested. The tumor growth in the mice treated with endostatin was inhibited by 84.17% in volume. The growth of the tumors was stopped 3-5 d after using endostatin except two of them. The growth of primary colon tumor was significantly inhibited by endostatin (Figure 1). The tumor weight of the treated group was significantly less than that of the control group ($F = 22.56$; $P = 0.0005$) (Table 1).

Effects of endostatin on angiogenesis in primary tumors

Immunohistochemical analysis showed a significant inhibition of angiogenesis in the tumors treated with endostatin ($P < 0.05$) (Table 1). The MVD of tumors was significantly different ($F = 151.62$, $P = 0.001$) between the two groups, the treated group had a significant lower MVD.

Figure 1 Changes in volume of tumors transplanted in dorsal skinfold chambers in nude mice.

Table 1 Reduction in tumor mass and MVD after endostatin treatment (mean \pm SD)

	Control	Endostatin	<i>F</i>	<i>P</i>
Mass	1.198 \pm 0.105	0.197 \pm 0.049	22.56	^a <i>P</i> = 0.0005
MVD	100.143 \pm 4.290	31.857 \pm 3.515	151.62	^b <i>P</i> = 0.0001

^a*P* = Mass difference between Control group and Endostatin group, ^b*P* = MVD difference between Control group and Endostatin group.

Table 2 Expression of VEGF and VEGFR2/Flk-1 in tumor after Endostatin treatment

	Positive	Negative		χ^2	<i>P</i>
Control-VEGF (1)	65	5	(1) vs (2)	0.119	0.730
Endostatin-VEGF (2)	66	4			
Control-Flk-1 (3)	64	6	(3) vs (4)	13.745	^a <i>P</i> = 0.001
Endostatin-Flk-1 (4)	46	24			

^a*P* = Flk-1 difference between Control group and Endostatin group.

Selectivity and potency of endostatin on VEGF and Flk-1

Immunohistochemical analysis showed that endostatin had a potent inhibition on Flk-1 expression ($\chi^2 = 13.745$, $P = 0.001$) but no inhibition on VEGF expression in tumor cells (Table 2). There was a significant difference in the tumors of treated mice and control mice after staining of endothelial cells with Flk-1 monoclonal antibody (Table 2) but no difference in the tumor tissue stained with VEGF between the two groups (Table 2).

DISCUSSION

Angiogenesis is a fundamental process by which new blood vessels are formed. It is essential in reproduction, development, and wound repair. Under these conditions, angiogenesis is highly regulated, turned on for brief periods and then completely inhibited. However some diseases are driven by persistently unregulated angiogenesis. Tumor growth is one of these kinds of diseases. Tumor growth and metastasis are angiogenesis-dependent. A tumor must continuously stimulate the growth of new capillary blood vessels for the tumor itself to grow. MVD was significantly high in colon cancer tissues compared with normal colon tissues^[4]. Tumor cells get oxygen and nutrition through angiogenesis. The Phenomena were also observed in other cancers, for example, breast carcinoma^[5] lung cancer^[6] prostate cancer^[7] and pancreatic tumor^[8], etc.

Endostatin, a 20-kD C-terminal cleavage product of collagen XVIII, was originally identified by O'Reilly *et al.*^[2] as a tumor-derived, highly active, and endothelial specific angiogenic inhibitor^[9]. Recombinant endostatin has been shown to inhibit

the growth of a wide variety of tumors in mice, with no toxic side effects observed. Importantly, tumors treated with several cycles of endostatin did not develop drug resistance and become dormant, which persisted even when the endostatin therapy was discontinued^[10]. In our experiment, we found that the tumor growth slowed down or even stopped three days after usage of endostatin, but when the treatment was stopped the tumor began to grow rapidly. So endostatin must be used continuously to prevent tumor growth. It is difficult for the patients to accept the treatment in their whole lifetime, so further research is necessary for the usage of endostatin. At present, the molecular mechanism of endostatin action remains unknown. There are some theories which are supported by various studies.

Our results showed that endostatin blocked the VEGF-VEGFR/Flk-1 pathway to inhibit the angiogenesis of colon tumor in nude mice. VEGF pathway is the only well-defined signaling pathway known to be required for the normal development of vasculature as well as for the pathologic angiogenesis that accompanies cancer and other disease states^[11,12]. The VEGF family of growth factors comprises at least five members, i.e., VEGF, placenta growth factor (PGF), VEGF-B, VEGF-C^[13], and VEGF-D. The VEGF pathway is initiated when VEGF binds to its receptors in endothelial cells. The three best characterized VEGF receptors are termed VEGF receptor 1 (VEGFR1/Flt-1) and VEGF receptor 2 (VEGFR2/Flk-1/KDR) and VEGF receptor 3 (VEGFR3/Flk-4). VEGFR1 and VEGFR2 are highly related transmembrane tyrosine kinases that use their ectodomains to bind to VEGF^[14,15]. These binding in turn, activate the intrinsic tyrosine kinase activity of their cytodomains, initiating intracellular signaling. VEGFR3 is expressed almost exclusively by the lymphatic endothelium, thus being considered as a major regulator of lymphangiogenesis^[16]. The blockade of VEGF by using a soluble VEGFR-3 extracellular domain could inhibit tumor lymphangiogenesis^[17]. While PlGF could bind selectively to VEGFR1, VEGF-C and VEGF-D could bind to both VEGFR3^[18,19] and VEGFR2. The corresponding receptor(s) for VEGF-B is VEGFR1. VEGF/VEGFR2 pathway is the most important for tumor angiogenesis, growth and metastasis. In our studies, we found VEGFR2 was obviously down-regulated in the endostatin group compared to the control group, but the expression of VEGF was not changed in both groups. So we think that endostatin can block the VEGF/VEGFR2 pathway by binding to VEGFR2, thus inhibiting the neovascularization.

Endostatin could function as a ligand for the integrin family of adhesion receptors on the surface of endothelial cells^[20]. Integrins are potential targets for endostatin function and they are important in endothelial cell biology and angiogenesis. The endostatin-integrin interaction is of functional significance *in vitro*, and the immobilized endostatin supports endothelial cell survival and migration in an integrin-dependent manner. Soluble endostatin in turn could inhibit integrin-dependent endothelial cell functions, such as cell migration^[20].

Matrix metalloproteinases (MMPs), a family of extracellular and membrane-associated endopeptidases, collectively digest almost all extracellular matrix and basement membrane components, thus playing an important role in tumor progression. Endostatin could prevent the fragmentation of pro-MMP-2 that is associated with reduction of catalytic activity. Endostatin had no effect on MMP-8 as shown by collagenase activity assays^[3]. Endostatin could block the activation and activities of certain tumor-associated pro-MMPs, such as pro-MMP-2, -9, and -13, which may explain at least in part, the antitumor effect of endostatin^[3,21].

Inhibition of angiogenesis has been shown to be an effective strategy in cancer therapy in mice. However, its widespread application has been hampered by difficulties in the large-scale production of antiangiogenic proteins. This limitation may be resolved by *in vivo* delivery and expression of antiangiogenic

genes. A recombinant adenovirus that could express murine endostatin that was biologically active *in vitro* as determined in endothelial cell proliferation assays, and *in vivo* by suppression of angiogenesis induced by VEGF has been constructed^[22]. Persistent high serum levels of endostatin were achieved after systemic administration of the vector to nude mice, which resulted in a significant reduction of the growth rates and the volumes of metastatic brain tumor^[23]. If the method can be used safely in clinic, it can effectively resolve the recurrence and overgrowth of tumors during the rest periods. Different targets have been found and effective results were achieved in gene therapy. An adenoviral vector carrying Tie2 gene, an endostatin-specific receptor tyrosine kinase, was constructed and tested in established primary tumor, a murine mammary carcinoma or a murine melanoma, which could significantly inhibit the growth rate of both murine mammary carcinoma and melanoma by 64% and 47%, respectively. So the potential of vector-mediated antiangiogenic gene therapy as a component is a very novel and effective strategy in cancer therapy^[24,25].

Synergy between endostatin and chemotherapy^[26] can be used to eradicate spontaneous tumor and metastases of colon cancer or other angiogenesis dependent diseases. Tumor necrosis was demonstrated only in animals receiving the combination therapy, but not when each agent was applied as monotherapy. The results suggested that these synergistic treatment modalities might provide a novel and effective tool for future therapies of metastatic cancer. Synergy between endostatin and interventional therapy is another way to inhibit the neovascularization. Endostatin can be sent directly to the microvessels around the tumor and destroy the tunica intima of vessels to starve the tumor to death. Other strategies also were used to block the VEGF/VEGFR pathway to inhibit the tumor growth. VEGF-trap is a potent blocker against the angiogenesis of the tumor and could result in stunted and almost completely avascular tumors. VEGF-Trap-mediated blockade may be a hopeful way for tumor treatment^[27]. More and more attention has been paid to the effectiveness and carrier and medication methods are paid more and more attention throughout the world. Endostatin may provide a novel and effective tool for future therapies of cancer^[28,29].

Abstract

AIM: To characterize the protein files in blood from same patients with esophageal squamous cell carcinoma (ESCC) before and after operation at the high-incidence area for ESCC in Henan Province, China.

METHODS: Two-dimensional electrophoresis, silver staining and ImageMaster 2-DE analysis software were applied to the determination of protein files in the blood obtained from normal controls and ESCC patients before and after operation.

RESULTS: A total of 655, 662 and 677 protein spots were identified, respectively, from the normal controls and ESCC patients before and after operation. No significant difference in the number of protein spots was observed between the normal group and ESCC patients. A total of seven protein spots were identified with a dramatic difference among the samples before and after operation. Six protein spots were up-regulated and one protein spot was down-regulated in the group after operation compared with those in normal and before operation. Three protein spots were further characterized by matrix-assisted laser desorption/ionization time of flying mass spectrometry (MALDI-TOF-MS). The proteins from these three spots were identified as serum amyloid A (SAA), amyloid related serum protein and haptoglobin.

CONCLUSION: Serum amyloid A, amyloid related serum protein and haptoglobin may be related with ESCC and/or surgery. The significance of these proteins needs to be further characterized. The present study provides informative data for the establishment of serum protein profiles related with ESCC.

INTRODUCTION

Esophageal squamous cell carcinoma (ESCC) is one of the six most common malignant diseases in the world with a remarkable geographical distribution. The ratio between the high- and low-incidence areas could be as high as 500:1. The prognosis of ESCC is very poor, the five-year survival rate is only about 10% for the patients at late or advanced stage. China is a country with the highest incidence and mortality rate of ESCC in the world. There are about 300 000 new ESCC patients identified all over the world each year, half of them occur in China. Linzhou City (formerly Linxian County) and its neighbouring counties in Henan Province have been well-recognized as the highest incidence area in the world, the average incidence ratio of males and females is 161 and 103 per 100 000, respectively^[1]. ESCC remains the leading cause of cancer related-deaths in these areas. Unclear molecular mechanism, and lacking of sensitive and specific biomarkers for early diagnosis may be the reasons for the unchanged ESCC incidence pattern^[2].

Many studies have been focused on gene level for early diagnosis of ESCC. However, because alterations in DNA and RNA may or may not induce similar protein changes, genetic changes could not reflect the stage and progression of the disease directly and objectively^[3]. Proteomics based on two-dimensional electrophoresis and mass spectrometry is a new method for identification of cancer-specific protein markers^[4]. In this study, we analyzed the serum protein changes in ESCC patients before and after operation and compared them with normal controls by proteomic methods to find the specific ESCC-related proteins.

MATERIALS AND METHODS

Blood samples

Blood samples were collected from ESCC patients in Yaocun Esophageal Cancer Hospital of Linzhou, Henan Province. Of the ESCC patients, there were 4 males and 2 females with an average age of 63 years (range, 52-74 years). All the blood samples were collected two times from each patient, just before and one week after the operation. The control blood samples (10 mL/subject) were collected in our laboratory from the normal people with matched ages as the patients. There were not any abnormalities identified by physical and biochemical examinations in volunteers of the control group.

Reagents

Electrophoresis reagents, including 400 g/L acrylamide solution, *N*, *N*-methylenebisacryl amide, *N*, *N*, *N*', *N*'-tetramethylethylenediamine, urea, tris-base, glycine, glycerol, 3-[(3-cholannidopropyl)-dimethylammonio]-1-propanesulfonate (CHAPS), sodium dodecyl sulfate (SDS), dithiothreitol (DTT), ammonium persulfate, bromophenol blue, immobiline drystrips, immobilized pH gradient buffer and silver nitrate were from Amersham Pharmacia Biotechnology Inc. (Uppsala, Sweden). Iodoacetamide was from Acros (New Jersey, USA), sequence grade trypsin was from Washington Biochemical Corporation and trifluoroacetic acid (TFA) was from Fluka (Switzerland). All other reagents were of analytical grade.

Serum concentration detection

Serum samples were thawed and diluted by dH₂O as 1:5 (2 μ L serum was added to 8 μ L dH₂O), 1:10 (2 μ L diluent was added to 18 μ L dH₂O), 1:200 (4 μ L diluent was added to 796 μ L dH₂O) respectively, up to 1:10 000 dilution and then 800 μ L 1:10 000 diluent was added to 200 μ L protein assay reagent and absorbance was measured at 595 nm, finally the concentration of protein in serum was calculated.

First dimensional electrophoresis (Isoelectric focusing, IEF)

Precast IPG strips (pH 3-10 linear, 18 cm, Amersham Pharmacia Biotechnology Inc.) was used in the first dimension. A total amount of 250 μ g proteins was diluted to a total volume of 350 μ L with the buffer (8 mol/L urea, 20 g/L CHAPS, 5 g/L IPG buffer 3-10, 20 mol/L DTT and a trace of bromophenol blue). After being loaded on IPG strips, IEF was carried out according to the following protocol: rehydration for 6 h at 0 V, 10 h at 30 V, 1 h at 500 V, 1 h at 1 000 V and 7 h at 8 000 V. The current was limited to 50 μ A per gel.

Second dimensional electrophoresis (SDS-polyacrylamide gel electrophoresis, SDS-PAGE)

After IEF separation, the strips were immediately equilibrated for 2 \times 15 min with equilibration solution (50 mmol/L Tris-HCl, pH 6.8, 6 mol/L urea, 300 g/L glycerol and 20 g/L SDS). Then 20 mmol/L DTT was included in the first equilibration solution, and 20 g/L iodoacetamide was added in the second equilibration step to alkylate thiols. Thirteen percent SDS-PAGE gels were handled to become 1 mm thick. The strips were held in place with 5 g/L agarose dissolved in SDS/Tris running buffer and electrophoresis was carried out at constant power (2.5 W/gel for 40 min and 15 W/gel for 6 h) and temperature (20 $^{\circ}$ C) using Ettan Dalt II system (Amersham Pharmacia Biotechnology Inc.).

Silver staining

Gels were stained with silver nitrate according to the instructions of the silverstaining kit^[5] (Amersham Pharmacia Biotechnology Inc.).

Gel scanning and image analysis

Protein profiles were obtained in normal controls and ESCC patients before and after operation through correcting the background to detect, match and quantify the spots by ImageMasterTM two-dimensional Elite analysis software (Amersham Biosciences).

In-gel protein digestion

Individual protein spots were excised from the gel by Ettan spot picker (Amersham Pharmacia Biotechnology Inc.), destained with the solution (15 mmol/L potassium ferricyanide, 50 mmol/L sodium thiosulfate) and washed till opaque and colorless with 25 mmol/L ammonium bicarbonate/500 g/L acetonitrile. After being dried with vacuum concentrator (SpeedVac Plus, USA), the gel was rehydrated with 3-10 μ L of trypsin solution (10 ng/ μ L) at 4 $^{\circ}$ C for 30 min, followed by incubation at 37 $^{\circ}$ C overnight. Tryptic peptides were eluted and dried on SpeedVac vacuum concentrator.

Protein identification by MALDI mass spectrometry

The protein spots were analyzed by matrix-assisted laser desorption/ionization time of flying mass spectrometry (MALDI-TOF-MS) and SWISS-PROT database^[6].

RESULTS

A total of 655, 662 and 677 protein spots were identified, respectively, from the normal control and ESCC patients before and after operation. No significant difference in number of protein spots was observed between normal group and ESCC patients. A total of seven protein spots were identified with a dramatic difference among the samples before and after operation. Six protein

spots were up-regulated and one protein spot was down-regulated in the group after operation compared with those in normal and before operation. Of these six protein spots, three spots were further characterized by MALDI-TOF-MS. The proteins from these three spots were identified as serum amyloid A (SAA), amyloid related serum protein and haptoglobin (Figures 1, 2).

DISCUSSION

In the present study, we found that serum amyloid A (SAA) and its isoform amyloid related serum protein, and haptoglobin were significantly increased after operation in ESCC patients compared with those in normal and pre-operation by mass spectrum. It indicated that these proteins might be related with ESCC and/or surgery. Although the literatures have reported that these acute-phase proteins are associated with tumors, such as colon cancer, the changes of these proteins may be more concerned with stress response, for example, the trauma by operation. The significance for these proteins needs to be further characterized. Although two-dimensional electrophoresis coupled with mass spectrometry is a powerful tool for screening and identification of cancer-specific protein markers, it costs time and money. The present study provided informative data for the establishment of serum protein profiles related with ESCC.

SAA is an acute-phase protein existing as various isoforms in a molecular mass range of 11-14. It is derived mainly from two genes, SAA1 and SAA2^[7], mapped at chromosome 11p15.4-15.1^[8]. In normal individuals, SAA is produced by hepatocytes in the liver. After its production, it is secreted into serum and rapidly binds to high-density lipoproteins, 90% of the protein particles are bound to high-density lipoprotein. A review of the literature showed that only a low level of SAA could be found in the sera of healthy individuals^[9], but during the acute-phase response, its level in the blood could elevate 1 000-fold after various injuries, including trauma, infection, inflammation and neoplasia^[10,11].

Recently, many studies have shown that high SAA protein level is present in the serum of patients with disseminated cancer, reflecting the extent of malignant diseases, and inversely correlated with patient survival^[12]. The mechanism is not clear. The mode of involvement of SAA in metastatic processes has not been elucidated. Several proposed functions for SAA proteins are compatible with the mechanism of tumor cell invasion and metastasis. These include inhibition of malignant cell attachment to extracellular matrix (ECM) proteins^[13,14], induction of the expression of enzymes degrading the ECM^[15] and induction of adhesion, migration, and tissue infiltration of cells^[16-18]. Moreover, SAA contains functional arginine-glycine-aspartic acid (RGD) -like and tyrosine-isoleucine-glycine-serine-arginine (YIGSR) -like adhesion motifs^[19], and the peptides containing these motifs could inhibit tumor cell invasion, metastasis, and angiogenesis^[20,21]. Cumulatively, these findings, together with our observation of SAA alterations in blood after operation, imply that SAA may play a role in one or more steps of tumor progression or regression.

Glojnaric *et al.*^[22] indicated that although the presence of colorectal carcinoma caused an increase in serum levels of all the acute phase reactants studied, SAA protein showed the most powerful reaction in pre-operative disease stage, with the mean value of 330 mg/L as compared to the normal values of <1.2 mg/L obtained in 30 healthy adults. SAA protein concentration increased to 487 mg/L after surgery and declined during the post-operative clinical course until the sixth chemotherapy cycle, but never returned to the normal range. In the later chemotherapy cycles, the mean SAA protein increased to 163 mg/L, probably as a result of the disease relapse. According to the statistical relations among exact confidence intervals for proportions, SAA protein showed the best specificity for colorectal carcinoma of all the acute phase proteins studied (83-100%) and also a sensitivity of 100%. They concluded that SAA protein seems to be a

Figure 1 Representative of two-dimensional electrophoresis profiles and three-matched protein spots (arrows) analysis of the sera from esophageal squamous cell carcinoma patients before (A) and after (B) operation with different acidity from pH 3 to pH 10. Norm: normalization, Vol: volume, BkGnd: background, Eq: equality.

Figure 2 Representative of two-dimensional electrophoresis patterns of sera protein from the same esophageal squamous cell carcinoma patient before (A) and after (B) operation and the normal subject (C) with different acidity from pH 3 to pH 10. A', B' and C' are the magnification of A, B and C, respectively, for the sera protein with marked difference.

reliable parameter, which could be recommended for clinical routine as a non-specific tumor marker for colorectal carcinoma. Haptoglobin is an acute phase protein capable of binding haemoglobin and may play a role in modulating many aspects of the acute phase response^[23]. The complex of haptoglobin with haemoglobin is metabolized in the hepatic reticuloendothelial system^[24]. Biosynthesis of haptoglobin occurs not only in the

liver, but also in adipose tissue and in lung, providing antioxidant and antimicrobial activity^[25]. Changes in the measured concentrations of haptoglobin in serum may help to assess the disease status of patients with inflammations, infections, malignancy, *etc*^[26]. Dynamic detection of haptoglobin in leukemia patient plasmas showed that haptoglobin level increased obviously in leukemia patients than that in normal persons and

dropped gradually with the improvement of diseases.

In conclusion, serum amyloid A, amyloid related serum protein and haptoglobin may be related with ESCC. The significance of these proteins needs to be further characterized. The present study provides informative data for the establishment of serum protein profiles related with ESCC.

Abstract

AIM: To investigate the number, size, and status of lymph nodes within the mesorectum and to explore the prognostic significance of lymph node micrometastases in patients with rectal cancer.

METHODS: Thirty-one patients with rectal cancer undergone total mesorectal excision between October 2001 and October 2002 were included. Mesorectal nodes retrieved from the resected specimens were detected with a combination of haematoxylin and eosin (HE) staining and immunohistochemistry (IHC). The relations between lymph node metastases, micrometastases and postoperative recurrence were analyzed.

RESULTS: A total of 548 lymph nodes were harvested, with 17.7 ± 8.2 nodes per case. The average number of metastatic nodes in HE-positive patients and micrometastatic nodes in IHC-positive patients was 5.2 ± 5.1 per case and 2.2 ± 1.3 per case, respectively. The mean size of all nodes and metastatic nodes was 4.1 ± 1.8 mm and 5.2 ± 1.7 mm in diameter, respectively. The mean size of micrometastatic nodes was 3.9 ± 1.4 mm in diameter. The size of the majority of mesorectal nodes (66.8%), metastatic nodes (52.6%), and micrometastatic nodes (79.5%) was less than 5 mm in diameter. During a median follow-up period of 24.6 ± 4.7 mo, 5 patients (16.7%) had recurrence, of them 2 died and 3 survived. Another case died of tumor unrelated cause and was excluded. All 5 recurrent cases had 3 or more nodes involved, and one of them developed only lymph node micrometastases. The mean number of both metastatic and micrometastatic nodes per case differed significantly between the recurrent and non-recurrent groups ($P < 0.01$ and $P = 0.01$, respectively).

CONCLUSION: The majority of lymph nodes, metastatic, and micrometastatic lymph nodes within the mesorectum are smaller than 5 mm in diameter. The nodal status and the number of lymph nodes involved with tumor metastases and micrometastases are related to the rapid postoperative recurrence.

INTRODUCTION

Lymph node involvement is one of the most important factors in determining the prognosis of patients with rectal cancer^[1-6]. Patients with lymph node involvement were found to suffer from more advanced diseases according to the tumor-node-metastasis (TNM) classification system^[6], and up to 30% of them eventually developed recurrences after a potentially curative resection^[7,8]. In contrast, some patients without positive lymph nodes also had postoperative recurrences or developed metastatic diseases, which were reported to be associated with lymph node micrometastases missed by conventional pathological examination^[9-13].

Lymph node spread of rectal cancer generally follows an anatomical route from the proximity to distance along the main supplying vessels of the rectum^[14,15]. Lymph nodes contained in the mesorectum are thereby the earliest and most frequent ones that might be involved when tumor spread occurs^[14-16]. Although reports have emphasized the importance of regional lymph nodes in the prognosis of rectal cancer^[11,2,17-21], few studies available have investigated the number and size of lymph nodes within the rectal mesentery^[22,23]. The clinical significance of mesorectal lymph node metastases and micrometastases remains to be fully acknowledged^[22,23]. This study was conducted to examine the number, size, and status of lymph nodes within the mesorectum, and to investigate the prognostic value of lymph node metastases, especially lymph node micrometastases, in patients with rectal cancer.

MATERIALS AND METHODS

Patients

From October 2001 to October 2002, 31 patients with rectal cancer undergone total mesorectal excision (TME) at the Department of Gastroenterological Surgery of West China Hospital were included. There were 18 males and 13 females, with an average age of 55 (32-72) years. Of them, 7 cases were patients with high rectal cancer (above the peritoneal reflection) and 24 cases were patients with lower rectal cancer (below the peritoneal reflection). Three tumors were highly differentiated, 20 moderately differentiated, and 8 poorly differentiated. All patients received standard preoperative examination and the diagnosis of rectal adenocarcinoma was made by fibrocolonoscopy and confirmed by pathological biopsy before surgery. All operations were carefully performed by skillful surgeons following the principle of TME^[24], and the rectal specimens resected were collected prospectively.

Specimen processing

After removal, the specimens were routinely processed with neutral buffered 100 mL/L formalin solution for 24 h, and immersed in lymph node revealing solution (LNRS) for 6 h or more^[25]. Later, they were washed thoroughly with running

water. Fat tissues in the specimens were dissected carefully at intervals of 2-3 mm from upward down to the level of distant transaction along the runway of the superior rectal artery (SRA). Lymph nodes stood out as white, and chalky nodules against the background of yellow fat were harvested and recorded.

Pathological examination

After retrieval, each lymph node was embedded separately in paraffin. The block was then sectioned serially at intervals of 20-40 μm , with each section of 4 μm in thickness. Two sections sampled randomly from 10 representative levels were subjected to haematoxylin and eosin (HE) staining. For nodes diagnosed negatively by HE staining, another 3 sections were further singled out, one for HE re-examination, the other two for immunohistochemistry (IHC).

Immunohistochemistry was performed using labelled streptavidin biotin method (LsAB). Briefly, all sections were deparaffinized and rehydrated. Then, they were immersed in 30 mL/L H_2O_2 for 20 min to block the endogenous peroxidase activity. Sections were then incubated with 100 mL/L normal goat serum for 20 min, followed by incubation with mouse monoclonal anti-human cytokeratin (CK) 20 antibody (Neomarkers, Lab Vision Corporation, CA, USA) (1:50) at 4 $^{\circ}\text{C}$ overnight. After that, the sections were washed with phosphate buffered solution (PBS) (0.01 mol/L, pH 7.2) and sequentially incubated with biotinylated goat anti-mouse IgG, and streptavidin biotin horseradish peroxidase complex following the manufacturer's instructions (HistostainTM-SP Kits, Zymed laboratories Inc., San Francisco, CA, USA). Staining was developed by immersing slides in 0.5 g/L 3,3'-diaminobenzidizing tetrahydrochloride (DAB) with 3.3 mol/L H_2O_2 . All slides were counterstained with haematoxylin, dehydrated and mounted. Yellowish staining of the tumor cell cytoplasm was taken as positive. Previously confirmed rectal adenocarcinoma tissue served as positive control, and substitution of the primary monoclonal antibody with PBS was used as negative control. Tumor micrometastases were occult diseases generally missed by HE staining while detected by IHC, and were characterized as single cell or small cluster of cells showing malignant morphology.

Follow-up

All patients were regularly followed up to now. The follow-up

interval was every 3 mo after surgery during the first year and every 6 mo thereafter. The time of recurrence and the cause of death were inquired and recorded.

Statistical analysis

The *t* test for difference in mean values and χ^2 test for difference in frequencies were performed using SPSS 10.0 software package. $P < 0.05$ was considered statistically significant.

RESULTS

Micrometastases and number of lymph nodes

A total of 548 mesorectal lymph nodes were retrieved from the 31 specimens, with 17.7 ± 8.2 lymph nodes per case. HE staining detected 114 lymph nodes positive in 22 patients (71.0%). The average number of metastatic lymph nodes in HE-positive patients was 5.2 ± 5.1 per case. IHC re-examination of the remaining negative nodes revealed 39 lymph nodes (9.0%) positive with tumor micrometastases from 18 cases (58.1%). Among them, 5 cases (16.1%) with 10 nodes positive with IHC staining were previously assumed free of metastatic diseases. The average number of micrometastatic lymph nodes in IHC-positive patients was 2.2 ± 1.3 per case.

Micrometastases and size of lymph nodes

The average diameter of all the 548 lymph nodes was 4.1 ± 1.8 mm. The mean size of 114 metastatic lymph nodes (5.2 ± 1.7 mm in diameter) was significantly larger than that of 39 micrometastatic lymph nodes (3.9 ± 1.4 mm in diameter) ($P < 0.01$). Of all the lymph nodes, 92 (16.8%) were ≤ 2 mm in diameter, with 4 metastatic and 3 micrometastatic lymph nodes; 182 (33.2%) ≥ 5 mm, with 54 metastatic and 8 micrometastatic lymph nodes; and 274 (50.0%) with a size between 2 mm and 5 mm in diameter, with 56 metastatic and 28 micrometastatic lymph nodes (Table 1). It was noted that the majority of lymph nodes (66.8%) were < 5 mm in diameter, and 52.6% of the metastatic nodes and a higher proportion of the micrometastatic nodes (79.5%) were < 5 mm in diameter also.

Lymph node metastases and micrometastases and prognosis

All the 31 patients were successfully followed-up. Patients with lymph node metastases received regular chemotherapy after surgery. However, during a median follow-up period of 24.6 ± 4.7 mo, one

Table 1 Size of lymph nodes (LNs) and status of tumor metastases and micrometastases

Size of LNs (mm)	No. of LNs				Positive ratio (%)

<i>P</i>	0.135	0.003	0.01	0.000	0.000

patient died of tumor unrelated cardiovascular disturbance 24 mo post operation and was excluded from the analysis. Among the five cases (16.7%) with lower tumor recurrences, 3 cases were localized in the pelvic floor, one case spread to the lung, and one case with both pelvic and liver involvements. Two of them died and the other three remained alive. All the recurrent patients shared the characteristics of having 3 or more lymph nodes involved with tumor metastases and/or micrometastases. Of them, one case with mere lymph node micrometastases also developed local recurrence 17 mo after operation (Tables 2, 3). Comparison analysis showed that both the number of metastatic and micrometastatic lymph nodes between the recurrent and non-recurrent groups differed significantly ($P < 0.01$ and $P = 0.01$, respectively), although such a statistical difference was not found between them in reference to the total number identified per case (Table 4).

DISCUSSION

The nodal status is the single powerful predictor of survival in rectal cancer^[1,2,20,21]. Both the number and location of lymph nodes involved have significant impacts on the outcome of patients with rectal cancer^[6,15,21,26]. However, the nodal staging accuracy is not easy to make^[27-29]. Factors contributing to this dilemma include the mount of mesentery resected, diligence for search of nodes paid, number of histological slices investigated, and methods of pathological examination employed^[30-33]. There are still wide variations regarding the minimum number of lymph nodes to be examined for a reliable node-negative diagnosis, the reported recommendations were 6 to 17 lymph nodes^[34-36]. The non-uniform extent of lymph nodes collected for investigation made the results incomparable between authors, and the absence of consensus on the number of lymph nodes contained in the mesentery worsened the situation further^[36,37].

It was established that the lymphatic spread of rectal cancer followed an anatomical way along which the normal lymphatic fluid drains^[14,15]. As a consequence, lymph nodes contained in the mesorectum are the earliest and the most frequent ones that might be involved when the dissemination of tumor cells takes place^[14-16]. Focused examination of the mesorectal lymph nodes, thereby, could identify most metastases and micrometastases in the first place^[15], though skip metastases might exist in a few cases^[38,39]. However, available data have provided little information on the lymph nodes enveloped within the mesorectum^[22,23]. The number and size of lymph nodes, and their tumor status remain to be defined.

Recently, Canessa *et al.*^[22] recovered 168 mesorectal lymph nodes from 20 cadavers and found that the mean number was 8.4 per specimen. They searched the lymph nodes from the division

of the superior rectal artery which excluded the lymph nodes that lie above it, i.e., the lymph nodes along the main trunk of it, that should otherwise be referred to 'mesorectal' nodes by strict definition^[40]. Also in another study on cadavers, an average of 24.9 pelvic lymph nodes were identified from 7 fresh specimens, which included 13.6 mesorectal lymph nodes per case^[23]. Their study employed modified LNRS to facilitate the identification of lymph nodes in the mesorectum. Therefore, the lymph nodes they retrieved outnumbered those in previous study markedly^[23]. In the current study, the LNRS was also used to help identify lymph nodes embedded in the mesorectal fat. A mean number of 17.7 lymph nodes per case were dissected. The majority of them (82.2%) were located along the superior rectal artery. The sizes of 66.8% of the total lymph nodes, 59.8% of the metastatic lymph nodes and 79.5% of the micrometastatic lymph nodes were <5 mm in diameter. The minimal size of lymph nodes found was 0.7 mm in diameter. These lymph nodes, especially those with a diameter ≤ 2 mm, were at great risk of being missed in routine pathological sampling with only naked speculation and manual palpitation^[41-43]. By further examining the HE-negative nodes with IHC staining, we identified 39 nodes positive with tumor micrometastases from 18 cases (58.1%). Of interest, 10 nodes with micrometastatic diseases in 5 cases (16.1%) were previously assumed free of tumor spread by routine pathological examination. Thus this group of patients was upstaged.

The superior sensitivity of IHC to HE staining in detecting micrometastases in colorectal cancer has been well recognized^[44-47]. Although its sensitivity remained ten times lower compared to reverse transcriptase polymerase chain reaction (RT-PCR) techniques, IHC is probably more specific and reliable, in that it allows examining the morphology of stained cells and differentiating from that of non-specific background staining^[44-46]. There are still many controversies regarding the prognostic significance of micrometastases in colorectal cancer^[10,11,47-54]. It was argued that although the application of IHC technique had the added ability to identify overt diseases missed by HE staining, it offered little prognostic information on the postoperative recurrence and long year survival^[10,49-52]. On the contrary, authors favoring the detection of lymph node micrometastases stated that it was not only one of the major concerns for the proper staging of diseases, but also of prognostic relevance to the outcome of patients with rectal cancer, thus suggesting helpful in the early planning of a multimodality treatment protocol for indicated patients^[11,53,54].

Choi *et al.*^[50] retrospectively reviewed 1 808 lymph nodes from 93 Dukes' B colorectal tumors with IHC staining and found that 54 lymph nodes (3.0%) from 29 cases (31.2%) harbored micrometastatic diseases. However, the five-year survival analysis showed no significant difference between the micrometastatic group and non-micrometastatic group. Yasuda *et al.*^[11] employed

IHC method and examined a total of 1 013 lymph nodes from 12 recurrent and 30 non-recurrent patients with histologically determined Dukes' B colorectal cancer. Micrometastases were confirmed in 59 lymph nodes (16%) from 11 cases (92%) in the recurrent group, and 77 lymph nodes (12%) from 21 cases (70%) in the non-recurrent group. They further demonstrated that micrometastases in four or more lymph nodes occurred more frequently in the recurrent group than in the non-recurrent group (58% vs 20%, $P < 0.05$), and micrometastases to N2 or higher nodes occurred more frequently in the recurrent group also (92% vs 47%, $P < 0.01$). Afterwards they concluded that the number and level of positive micrometastatic lymph nodes were both significantly correlated with postoperative recurrence of histologically determined Dukes' B colorectal cancer^[11].

In the present study, 5 patients with rectal cancer developed recurrences. The rate of recurrence was 16.7% within two years after curative operation. All patients suffering from recurrent diseases had three or more mesorectal nodes involved with tumor metastases and/or micrometastases, one patient with lymph node micrometastases developed recurrence also. It was noted that both the number of metastatic and micrometastatic lymph nodes differed significantly between the recurrent and non-recurrent groups ($P < 0.01$ and $P = 0.01$, respectively), implying that lymph node micrometastases and the number of lymph nodes involved might also correlate with the outcome of patients with rectal cancer, while the prognostic value of lymph node metastases was confirmed.

In summary, by using the LNRS to facilitate identifying lymph nodes, and with a combination of HE and IHC to detect tumor metastases and micrometastases, we have provided a detailed description of both the number and size of lymph nodes enveloped in the mesorectum, as well as their tumor status with metastases and micrometastases in rectal cancer. The rapid recurrence of tumor after a cure-intended surgery is related to the tumor status of mesorectal lymph nodes. The presence of lymph node micrometastases and the number of lymph nodes involved might have some value for the prediction of tumor recurrence in rectal cancer^[11,47,48,53,54], now that the importance of lymph node metastases has been widely acknowledged^[1-6,19,21]. However, it is too cursory to draw a convincing conclusion, concerning the small samples included and only short-term outcome investigated in the current study. Future multi-central large-sample controlled studies are needed to clearly define the role of lymph node micrometastases in the prognosis of patients with rectal cancer.

Abstract

AIM: To investigate the expression of CD34 and c-kit (receptor of stem cell factor) in cholangiocarcinoma.

METHODS: Fifteen cases of intrahepatic cholangiocarcinoma and 17 cases of extrahepatic cholangiocarcinoma were studied in this experiment. Using Envision detection system, paraffin-embedded sections of the resected cholangiocarcinoma tissue were stained with antibodies against CD34 and c-kit, respectively. The sections were counterstained with hematoxylin, and the results were examined under light microscope. Normal tonsil and mammary tissues were used as positive controls for CD34 and c-kit, respectively.

RESULTS: CD34 was positive in all sections, but only in capillary endothelial cells of tumor tissue. No cholangiocarcinoma cells were positive for CD34. In one case of extrahepatic cholangiocarcinoma, a few tumor cells (about 5%) were immunoreactive with c-kit.

CONCLUSION: CD34 or c-kit positive cells in liver tissue may represent liver stem cells, as they can differentiate into mature biliary cells *in vitro*. The expression of c-kit by some cholangiocarcinoma cells suggests that cholangiocarcinoma might originate from liver stem cells. However, other mechanisms of hepatocarcinogenesis, such as de-differentiation of mature cholangiocytes, may also exist.

INTRODUCTION

Two theories are available to explain the process of hepatocarcinogenesis, one is de-differentiation of mature liver cells (hepatocytes and cholangiocytes), the other is maturation arrest of liver stem cells^[1]. In normal liver, putative liver stem cells may exist at terminal bile ductules (canal of Hering) and periductular area^[2,3]. In rodent animals, when damage and loss of hepatocytes and/or cholangiocytes are combined with impaired regeneration of the mature cells, liver stem cells may be activated. They proliferate and differentiate towards both hepatic and biliary lineages^[2,4-7]. Activation of liver stem cells has been observed in various human liver diseases, such as acute liver necrosis^[8], hemochromatosis^[9], chronic cholestatic diseases^[10], alcoholic liver diseases^[9] and chronic viral hepatitis^[9,11,12]. In human liver focal nodular hyperplasia^[13], hepatic adenoma^[14], hepatocellular

carcinoma^[15] and hepatoblastoma^[16], some tumor cells have also been detected to express the specific markers of liver stem cells, indicating their possible stem cell origin. In animals, cholangiocarcinoma can also originate from liver stem cells^[17].

CD34 and c-kit are two hemopoietic markers, but in periductular area and occasionally within bile ducts, CD34 and c-kit positive cells were also found^[18]. CD34 or c-kit positive cells in human liver can be isolated with immunomagnetic separation techniques, and these isolated cells are able to differentiate into biliary epithelial cells *in vitro*^[18]. Thus, CD34 and c-kit positive cells in human liver may represent liver stem cells. In this study, the expression of CD34 and c-kit in human cholangiocarcinoma was investigated.

MATERIALS AND METHODS

Specimens

Paraffin-embedded specimens from 32 cases of resected cholangiocarcinoma at Sun Yat-Sen Memorial Hospital were studied in this experiment. They included 18 male and 14 female patients, ranging from 24 to 80 years old (mean and medium 64 years old). Fifteen cases had the tumor located in intrahepatic bile duct (IBD), 4 cases in common hepatic bile duct (CHBD) and 13 cases in common bile duct (CBD). Some clinical characteristics of the patients are summarized in Table 1.

Immunohistochemistry

Each paraffin-embedded specimen was cut consecutively into 6 sections. Three sections of CD34 and 3 sections of c-kit were stained with Envision detection system (DAKO, Denmark). CD34 retrieval was performed by heating the sections in 10 mmol/L citrate buffer (pH 6.0). In brief, the tissue sections were incubated with peroxidase blocking reagent (DAKO) for 5 min, incubated with CD34 (monoclonal mouse anti-human, IgG₁, kappa, ready to use; DAKO) for 10 min or c-kit (polyclonal rabbit anti-human, 1:50; DAKO) for 30 min at room temperature. Then, the sections were incubated with peroxidase labelled polymer conjugated to goat anti-rabbit or goat anti-mouse immunoglobulin for 30 min at room temperature, incubated with diaminobezidine (DAB) chromogen for 5 min, counterstained with hematoxylin and mounted with coverslip. Between each of these steps, the sections were rinsed gently with Tris-HCl buffer. Normal human tonsil and mammary tissues were used as positive controls for CD34 and c-kit, respectively. Negative control was performed at the same conditions by omitting incubation with the first antibody. The stained tissue sections were examined under light microscope.

RESULTS

CD34 and c-kit were positive in the staining of capillary endothelial cells in tonsil and ductal cells in normal mammary tissues, respectively. Negative controls were all negative. Among the specimens of 32 cases of cholangiocarcinoma, CD34 was strongly positive in the staining of all capillary endothelial cells and negative in tumor cells (Figure 1). However, c-kit was positive in the staining of tumor cells in 1 case of cholangiocarcinoma originating from common bile duct (case 32, Table 1). This was an 80 years old patient with moderately differentiated cholangiocarcinoma, and about 5% of the tumor cells were positively stained at cell

membrane and cytoplasm (Figure 2). The positive result was repeatedly identified in several sections from the same specimen.

F: Female; M: Male; CBD: Common bile duct; CHBD: Common hepatic bile duct; IHBC: Intrahepatic bile duct.

Liver stem-like cells are small and oval in shape with relatively large oval nuclei. They are immunoreactive for OV-6 (rat oval cell marker), cytokeratin (CK) 8 and CK 18 (both are epithelial cell markers), CK 7 and CK 19 (both are biliary cell markers), CK 14, and chromogranin-A^[15,19]. Liver stem-like cells are heterogeneous, and could be classified into 3 types based on their differentiation characteristics. Type I represents the most undifferentiated cells, type II the progenitor cells differentiating towards biliary lineage, and type III the progenitor cells differentiating towards hepatic lineage^[19]. In human liver, these liver stem-like cells have been found in focal nodular hyperplasia, hepatic adenoma, hepatocellular carcinoma and hepatoblastoma^[13-16].

CD34 and c-kit are two markers of hemopoietic stem cells. However, recently in normal human liver, c-kit was detected in canal of Hering where the putative liver stem cells may exist^[3]. In patients with fulminant hepatic failure, over expression of c-kit was detected in activated liver stem-like cells^[20]. CD34 was also identified in rat liver stem-like cells^[21]. Using immunomagnetic separation method, CD34 and c-kit positive cells were isolated from human liver. These cells were able to proliferate and differentiate into both biliary epithelial and endothelial cells *in vitro*^[18]. This suggested that CD34 and c-kit positive cells in

liver might represent biliary progenitor cells, biliary and endothelial cells might share the same progenitor cells. Among the 12 cases of hepatoblastoma, Ruck *et al.* reported that CD34 was found to be immunoreactive with both tumor cells and endothelial cells in 1 case of small cell hepatoblastoma, and this indicated the possible stem cell origin of hepatoblastoma^[22].

In this study, a few tumor cells in 1 of 32 cases of cholangiocarcinoma were immunoreactive with c-kit, and this suggested their possible origin of biliary stem cells.

Figure 1 A: Immunohistochemical staining of cholangiocarcinoma with antibody against CD34. Arrowhead indicates strongly positive capillary endothelial cells. B: Immunohistochemical staining of cholangiocarcinoma with antibody against c-kit (Envision, original magnification: $\times 400$). Arrowhead indicates positive tumor cells.

As putative liver stem cells possibly exist in terminal bile ductules (canal of Hering), intrahepatic cholangiocarcinoma is supposed to originate from liver stem cells more likely than extrahepatic cholangiocarcinoma. However, the cells with stem cell characteristics may not only exist in intrahepatic bile ducts, but also in extrahepatic bile ducts. In embryonic development of rat liver, both intra- and extrahepatic bile ducts originated from AFP- and albumin-containing hepatoblasts^[23]. The remnant of embryo liver stem cells may also exist in extrahepatic bile ducts. In human, it was observed that hepatocellular carcinoma could also develop from extrahepatic bile ducts^[24-26]. These tumors might originate from liver stem cells in extrahepatic bile ducts by maturation arrest. Thus, extrahepatic cholangiocarcinoma that was immunoreactive with c-kit in this experiment might also originate from putative liver stem cells.

Based on animal experiments, different carcinogenic regimens might act on different level of cells in hepatic lineage and produce hepatic carcinoma by different mechanisms^[27]. Diethylnitrosamine acted on mature hepatocytes and induced hepatocellular carcinoma by de-differentiation. Furan injured bile duct progenitor cells and induced cholangiocarcinoma by maturation arrest. 2-acetylaminofluorene acted on ductular bipolar progenitor cells and induced hepatocellular carcinoma by maturation arrest. In choline deficiency models, the periductular stem cells could be activated to induce hepatocellular carcinoma by maturation arrest. The exact causes of human cholangiocarcinoma are still unclear, and there may be more than one mechanism of its carcinogenesis. In this study, only a few tumor cells in 1 case of cholangiocarcinoma were c-kit immunoreactive, and we could

not draw a sound conclusion. Tumor cells may lose their markers of stem cells during maturation arrest. Thus, further researches, such as increasing the number of cases and discovering new biliary progenitor cell markers, are needed to answer if human cholangiocarcinoma originates from stem cells.

Abstract

AIM: To describe the epidemiological features of peptic ulcer disease in Wuhan area during 1997-2002, to analyze the sex, age and occupation characteristics, as well as the geographic distribution of peptic ulcer disease, and to determine the effective methods of preventing and controlling peptic ulcer disease.

METHODS: In the early 1980s, the peptic ulcer disease registry system was established to collect the data of peptic ulcer disease in Wuhan area. Here we performed a statistically detailed analysis of 4876 cases of peptic ulcer disease during 1997-2002.

RESULTS: The morbidity of peptic ulcer disease between males and females was significantly different ($\chi^2 = 337.9$, $P < 0.001$). The majority of peptic ulcer diseases were found at the age of 20 to 50 years. Because of different occupations, the incidence of peptic ulcer disease was different in different areas.

CONCLUSION: The incidence of peptic ulcer disease is highly associated with sex, age, occupation and geographic environmental factors. By analyzing the epidemiological features of peptic ulcer disease, we can provide the scientific data for prevention and control of peptic ulcer disease.

INTRODUCTION

During 1997 to 2002, 21693 patients had a gastroscopy in Outpatient Department of the Renmin Hospital in Wuhan University, of them, 4876 were diagnosed as peptic ulcer disease. Factors that increased the risk of serious peptic ulcer disease included older age, history of peptic ulcer disease, gastrointestinal hemorrhage, dyspepsia and previous non-steroidal anti-inflammatory drug-associated (NSAID) intolerance, as well as poor living conditions^[1]. Furthermore, the epidemiological factors were important reasons leading to peptic ulcer disease. To explore the epidemiological features of peptic ulcer disease in

Wuhan area, we performed a statistical analysis of the data about sex, age, occupation and geographic environmental distribution.

MATERIALS AND METHODS

A total of 21 693 patients with gastrointestinal symptoms received a gastroscopy in Outpatient Department of the Renmin Hospital of Wuhan University, of them, 4 876 were diagnosed as peptic ulcer disease. The patients were classified according to gastric ulcer (GU), duodenal ulcer (DU), complex ulcer (CU), sex, age, occupation and geographic environment and a database was set up. All the data were checked and analyzed using the SPSS statistical software.

RESULTS AND DISCUSSION

Peptic ulcer disease mainly refers to the chronic ulcer which occurs in stomach and duodenum, because the formation of ulcer is linked to the digestive function of gastric acid-pepsin^[2]. Peptic ulcer disease is a worldwide common disease, but the incidence of peptic ulcer disease in different countries and regions is obviously different. The incidence of peptic ulcer disease has not been exactly investigated in China. Therefore, we performed a statistically detailed analysis of the data in Wuhan area from 1997 to 2002.

There were 4 876 cases of peptic ulcer disease out of 21 693 patients, and the incidence was 22.5%. Among the 4 876 cases diagnosed as peptic ulcer disease by gastroscopy, 3 899 males (79.9%) and 977 females (20.1%) had peptic ulcer disease. The sex ratio (males to females) was 3.95:1. Among the patients with peptic ulcer disease, 3 397 had duodenal ulcer disease, 1066 had gastric ulcer disease and 413 had complex ulcer disease. Duodenal ulcer diseases accounted for 69.6%, gastric ulcer diseases accounted for 21.9% and complex ulcer diseases accounted for 8.5%. The ratio of the three was 8.2:2.6:1. The data of the sex, age, occupation characteristics and geographic distribution of peptic ulcer disease are shown in Tables 1-4.

Table 1 Sex ratio of six different age groups in 4 876 cases of peptic ulcer disease

Age (yr) group	Duodenal ulcer	Gastric ulcer	Complex ulcer	Peptic ulcer
10-	3.66	5.00	10.00	3.96
20-	5.13	4.03	6.13	4.93
30-	4.12	4.63	7.53	4.39
40-	2.65	5.82	3.04	3.26
50-	2.53	5.56	2.86	3.37
60-	3.43	5.70	6.75	4.39
Mean	3.59	5.12	6.05	4.05

Sex difference

The incidence of peptic ulcer disease in males was always higher than that in females in different age groups. From Table 1, we could see that the sex ratio in duodenal ulcer disease was 2.53-5.13:1, the maximum ratio was 5.13, and the average ratio was 3.59. The sex ratio in gastric ulcer disease was 4.03-5.82:1, the maximum ratio was 5.82, and the average ratio was 5.12. The cases of complex ulcer disease were so few that they had no

statistic significance. After analyzing the trend of the mortality of peptic ulcer disease from 1952 to 1980 in Western Germany, we found that the general trend of mortality of males was descending but there was a fluctuating ascending, and the general trend of mortality of females was steadily ascending^[3]. Since the early 1960s in America, the incidence of the peptic ulcer disease in males has slightly decreased, but that of females has shown the increasing trend, and the difference of sex has gradually lessened^[4]. Mortality from non-perforated ulcer decreased markedly, while that from perforated ulcer decreased slightly, similar trends were observed in men and women^[5]. We carried out a statistical analysis of the data according to the different age groups ($\chi^2 = 337.9$, $P < 0.001$). From Table 2 and Figure 1, we could see that the incidence of peptic ulcer disease between males and females was significantly different.

Table 2 Comparison of sex among six different age groups in 4 876 cases of peptic ulcer disease

Gender	Age(yr) group					
	10-	20-	30-	40-	50-	60-
Male	190	858	1 340	880	576	282
Female	48	174	305	270	171	65

$\chi^2 = 337.9$, $P < 0.001$.

Age distribution

People who suffered from peptic ulcer disease could be found out at whatsoever ages, but the majority of patients with peptic ulcer disease were adults. Our data indicated that the youngest patient was 9 years old, the oldest was 73 years old, 78.7% of the patients were between 20 and 50 years old, the peak age of incidence was between 30 and 40 years old in duodenal ulcer disease patients. In gastric ulcer disease patients, the youngest was 11 years old, and the oldest was 75 years old, 82.9% of the patients were between 20 and 50 years old, 92.2% of the patients were between 30 and 60 years old, and the peak age of incidence was between 30 and 40 years old. People with gastric ulcer disease were older than those suffering from duodenal ulcer

disease. The incidence of peptic ulcer disease in patients between 40 and 60 years old was obviously higher than that in patients between 10 and 30 years old. The actual number of peptic ulcers in the elderly decreased, however the percentage of elderly with peptic ulcer against total population increased^[6]. The age distribution of complicated ulcer disease was basically similar to that of gastric ulcer disease. The incidence of peptic ulcer disease was 22.5% in Wuhan area, the ratio of duodenal ulcer to gastric ulcer was 3.2:1, and the ratio of different age groups was 1.24-5.1:1. From Figure 2, we could see that the incidences of duodenal ulcer disease and gastric ulcer disease were not significantly different after 50 years old. Huang *et al.*^[7] found that peptic ulcer disease in children over 6 years old was mainly primary ulcer, the majority of them were duodenal ulcer, and the clinical symptoms of the peptic ulcer were similar to those in the adults. It was reported that 72-80% of peptic ulcer disease in Hunan and Guangdong provinces in China occurred in patients between 20 and 50 years old, which was similar to the results of the reports from India^[8]. The location of duodenal ulcer disease was on anterior wall and greater curvature of bulb, but in gastric ulcer disease was on gastric angle and antrum, and the peak age of incidence was 21 to 50 years^[9]. The results of our investigations were basically similar to them.

Figure 1 Age and sex distribution of peptic ulcer disease in Wuhan area, China.

Figure 2 Age distribution of 4 876 cases of peptic ulcer disease in Wuhan area.

Social occupation factors

The sex difference and age distribution of peptic ulcer disease in different occupations were basically the same. The data of our study were divided into four parts, each from the workers, farmers, students and cadres, respectively. From Table 4, we know that the incidence of peptic ulcer disease among farmers was the highest, moderate in workers and the lowest in students. The incidence of duodenal ulcer disease was also very high among these special occupations such as drivers, firefighters and so on, which was similar to the report of Sonnenbeg *et al.*, who found the incidence of duodenal ulcer disease was very high among the firefighters, pilots and shift workers^[10,11]. The

study results from Western Germany indicated that the consumption of body's energy was a dangerous factor for the development of peptic ulcer disease^[11]. This may be related to social factors such as busy working, heavy mental stress and so on. It was reported that the occurrence, recurrence of peptic ulcer disease were closely associated with psychological contradiction, emotional-hindering and defective character. Depress, anxiety, fear, emotional irritability and cognitive disorganization were significantly increased in the integrated stress management program (ISMP) group in comparison with the progressive muscle relaxation (PMR) group, and the incidence of peptic ulcer disease was higher in the ISMP group than in the PMR group^[12]. In addition, irregular meal, over-eating, and fast-eating might cause injuries to the digestive tract mucosa, leading to the occurrence of peptic ulcer disease^[13]. Peptic ulcer disease was more common in the working age groups. To any kind of occupation, age between 20 and 50 years was a period in which people were widely connected with society and participation in assorted social activities more frequently than ever. Heavy social psychological stress, frequent mobility and irregular working were extremely important factors in the formation of peptic ulcer disease. The increasing incidence of peptic ulcer disease in females was related to more and more social activities that females participated in gradually^[14].

Geographic and environment factors

Environmental factors played a role in peptic ulcer disease^[15]. The positive detectable rate of peptic ulcer disease in Han nationality was higher than that in Korea nationality at Yanbian area^[16]. Thors *et al.*^[17] demonstrated that peptic ulcer mortality and disease risk were particularly high in subjects born after the turn of the century and subsequent generations. Since 1945, a very rapid economic development has been achieved with the advent of electricity and refrigeration, clean water and food; The condition in Iceland changed from being anti-hygienic and poor to being rich and clean, the morbidity of peptic ulcer disease has decreased. The rise and fall in peptic ulcer during the 20th century might be caused by factors early in life in the generations born during these years with crowding and poor hygiene before living conditions and socio-economic status were improved. The incidence of peptic ulcer disease as reported was between 16% and 33% from different regions in China. The results from Hunan and Gansu Provinces indicated that the ratio of duodenal ulcer disease to peptic ulcer disease was 2.7-6.2:1 in the inpatient department during the same period. The peptic ulcer disease is very prevailing in all over China, but there is an increasing trend from the north to the south in region distribution. Furthermore, the morbidity of peptic ulcer disease is also different in different countries, and duodenal ulcer disease turns up more frequently than gastric ulcer disease in the majority of Western countries. The study report in Japan indicated that the incidence of gastric ulcer disease was higher than that of duodenal ulcer disease. The incidence of duodenal ulcer disease and gastric ulcer disease was almost equal to that in Norwegian. In respect to ethnicity, Bengali speaking Hindus showed high probability for gastric ulcers in both sexes^[18]. The detecting rates of peptic ulcer disease in Han and Hui nationalities were 13.42% and 10.66% respectively. Among peptic ulcer diseases 44.4% were duodenal ulcer disease, and 50.63% were gastric ulcer disease, the ratio being 0.88:1. The detecting rate of peptic ulcer in Han nationality was higher than that in Hui nationality, and gastric ulcer disease occurred

more often than duodenal ulcer disease in China. The regional difference in the type and level of peptic ulcer disease revealed that geographic and environmental factors probably played an important role in the development of peptic ulcer disease. Additionally, the incidence of peptic ulcer disease in the transition period between autumn and winter or between winter and spring was higher than that in other periods. The change of climate factors was also associated with occurrence of peptic ulcer disease; with the change of temperature and atmosphere, patients with peptic ulcer disease would appear gastroperiodynia.

In conclusion, the occurrence of peptic ulcer disease is highly associated with sex, age, occupation, geographic and environmental factors. By analyzing the epidemiological characteristics of peptic ulcer disease, we can provide the scientific data for prevention and control of peptic ulcer disease.

Abstract

AIM: To determine whether 2-(3-carboxy-1-oxopropyl) amino-2-deoxy-D-glucose (COPADG), a derivative of D-amino-glucose, inhibited the growth of human esophageal cancer cell line Eca-109.

METHODS: Effects of COPADG on Eca-109 cells cultured in RPMI 1640 medium were examined by a tetrazolium-based colorimetric assay (MTT assay).

RESULTS: COPADG inhibited the growth of Eca-109 cells in a dose- and time-dependent manner; the maximum inhibition rate was 83.75%.

CONCLUSION: COPADG can directly inhibit the proliferation of Eca-109 cells, which may serve as the experimental evidence for development of new drugs for esophageal cancer therapy.

INTRODUCTION

2-(3-carboxy-1-oxopropyl) amino-2-deoxy-D-glucose (COPADG, structure is shown in Figure 1) is a derivative of D-glucose, a monose derivative of degraded chitosan. Previous researches have discovered that some amino-D-glucose derivatives are capable of inducing leukemia K562 cells to differentiate into macrophages^[1], but their efficacy in inducing apoptosis of tumor cells remains unclear. We conducted this study to determine whether COPADG could inhibit the proliferation of human esophageal cancer cell line Eca-109, to provide experimental evidence for new drug development for esophageal cancer therapy.

MATERIALS AND METHODS

Materials

COPADG, synthesized by the Lanzhou Institute of Chemical

Physics of Chinese Academy of Sciences, was dissolved in distilled water, filter-sterilized with 0.22 μ m filter disc, and stored at 4 °C until use. Eca-109 cells were purchased from Shanghai Institute of Cell Biology of Chinese Academy of Sciences. RPMI 1640 medium, agarose, trypsin and fetal bovine serum (FBS) were obtained from Gibco BRL Company, and the reagents for MTT assay were purchased from Sigma Chemical Co. Ltd.

Cell culture

Eca-109 cells growing in logarithmic phase were cultured in RPMI 1640 medium supplemented with 100 mL/L heat-inactivated FBS, 100 μ g/mL penicillin and 100 μ g/mL streptomycin. The cells were maintained in a humidified atmosphere containing 50 mL/L CO₂ at 37 °C. The medium was replaced every 48 h.

MTT colorimetric assay

MTT assay^[2] was based on the enzymatic reduction of the tetrazolium salt MTT in viable and metabolically active cells. Cells at 85% to 100% confluency were harvested with the mixture of 2.5 g/L trypsin and 0.2 g/L EDTA solution and seeded into a 96-well plate at a density of 4×10^3 /well, followed by incubation of the cells with COPADG at varied concentrations (0.01-0.09 mol/L) for different lengths of time (24-96 h, Table 1). The control cells were treated in the same way except that incubation was performed with sterile PBS instead of COPADG. After treatment, the medium was replaced by fresh medium and the cells were incubated for 4 h with 5 mg/mL MTT, which was dissolved in 150 μ L of 100 g/L DMSO and kept for 1 h. The optical densities at 490 nm (A_{490nm}) in the 96-well plates were determined using a microplate reader. Cell growth inhibition was estimated with the following formula: Growth inhibition (%) = $1 - A_{490nm}(\text{treated cells}) / A_{490nm}(\text{control cells}) \times 100\%$.

Statistical analysis

Results were expressed as mean \pm SD. Each experiment was repeated at least three times. Statistical differences between each group were determined by single-factor analysis of variance and correlation analysis using SPSS 11.0 statistical software.

Figure 1 Chemical structure of 2-(3-carboxy-1-oxopropyl) amino-2-deoxy-D-glucose.

RESULTS

COPADG could effectively inhibit the growth of Eca-109 cells, the maximum inhibition rate was 83.75%. The inhibition exhibited

Table 1 Inhibitory effect of COPADG on the proliferation of esophageal cancer cell line Eca-109 (mean±SD)

Concentration (mol/L)	A_{490nm}			Inhibitory rate (%)		
	24 h	48 h	72 h	24 h	48 h	72 h
0 (Control)	1.505±0.090	1.686±0.067	1.745±0.077	12.76	20.81	31.29
0.01	1.313±0.053 ^b	1.336±0.057 ^b	1.199±0.083 ^b	12.76	20.81	31.29
0.03	0.958±0.028	0.966±0.086	0.900±0.056	36.35	42.68	48.42
0.05	0.400±0.064 ^{b,c}	0.429±0.065 ^{b,a}	0.384±0.050 ^{b,c}	73.42	74.57	77.99
0.07	0.383±0.045	0.360±0.039	0.342±0.037	74.55	78.66	80.44
0.09	0.355±0.046 ^c	0.362±0.053 ^c	0.280±0.039 ^a	76.41	78.54	83.75

At the same time point, $P < 0.01$ vs the control group; ^b $P < 0.01$ vs 0.03 mol/L; ^a $P < 0.05$, ^c $P > 0.05$ vs 0.07 mol/L.

an obvious time- and dose-dependent manner when the COPADG concentrations were below 0.05 mol/L, and higher concentrations tended to induce gradually stabilized inhibition, suggesting a saturation of the effects of COPADG (Table 1, Figure 2).

**Figure 2** Inhibition of Eca-109 cell growth by COPADG.

DISCUSSION

COPADG is a derivative of D-glucose, which is a low-molecular-weight compound with multiple biological activities and a monosaccharide derived from chitosan through release of an acetyl group followed by degradation of the residual group. D-glucose is the intermediate during the synthesis of protein-polysaccharide macromolecules, and distributed in almost every human tissue as a part of the structural components of cell membrane and tissues. From the biological standpoint, D-glucose not only is involved in hepatic and renal detoxification against toxic agents, but also acts to stimulate the anti-inflammatory response and enhance the synthesis of protein-polysaccharides. Studies^[3,4] have also shown that D-glucose could inhibit tumor cell growth, and partial derivatives of D-glucose could potentially induce differentiation of tumor cells. Some D-amine-glucose derivatives were able to induce leukemia K562 cells to differentiate into macrophages^[5], but this effect failed to be observed in human hepatocellular carcinoma cell line^[1]. Currently, COPADG has become a new focus of interest in cancer therapy.

By conducting this study, we aimed to test whether COPADG, the newest derivative of D-glucose, had any effect on the proliferation of human esophageal cancer cells. MTT assay showed that COPADG could effectively inhibit Eca-109 cell

proliferation, in a marked time- and dose-dependent manner below the concentration of 0.05 mol/L; the maximum inhibition rate was 83.75%. The inhibition, however, became stable when the concentrations were higher than 0.05 mol/L, indicating that the effects of the drug might be saturated at this concentration.

The development of cancer has been considered to be the combined results of unrestricted cell proliferation and impairment of normal cell apoptosis^[6]. These concepts provide a basis for the development of new strategies for cancer treatment. Agents with antiproliferative properties and proapoptotic effects have been widely investigated as potential chemotherapeutic options^[7,8].

Conclusion, COPADG has obvious time- and concentration-dependent inhibitory effects against the proliferation of human esophageal cancer cell line Eca-109 *in vitro*, but whether this effect can be achieved in other cell lines still awaits further examination, which may also be necessary to clarify the mechanism underlying this effect.

Abstract

We report a case of caudate lobe hemangioma with an atypical CT enhancement pattern. In the present case, hemangioma exhibited a very subtle discontinuous peripheral rim enhancement at the post-enhanced arterial phase, and the peripheral enhanced zone had a moderately increased enhancement degree and with widened enhancement thickness during the portal-phase and delayed-phase. The slow enhancement rate for this caudate lobe hemangioma was due to sluggish perfusion by the small feeding arteries of caudate lobe branches as demonstrated by angiography.

Chen HC, Lee CM, Chen CS, Wu CH. A case of atypical caudate lobe hemangioma mimicking hepatocellular carcinoma: CT and angiographic manifestations. *World J Gastroenterol* 2004; 10 (22): 3382-3384

<http://www.wjgnet.com/1007-9327/10/3382.asp>

INTRODUCTION

Cavernous hemangioma is the most common benign hepatic tumor and usually presents with a typical enhancement pattern when studied by dynamic spiral computed tomography (CT). However, there are a small number of hemangiomas that exhibit atypical enhancement patterns due to the presence of intralesional non-enhanced or less-enhanced components^[1-4]. Herein, we report a case of hepatitis B and C with an atypical caudate lobe hemangioma that preoperatively was misdiagnosed as a hepatocellular carcinoma because the caudate lobe mass was supplied by small caudate lobe arteries with very sluggish perfusion, resulting in a slow enhancement rate and atypical enhancement patterns when studied by dynamic CT. CT imaging features and corresponding angiographic findings of the atypical caudate lobe hemangioma were provided.

CASE REPORT

An asymptomatic 58-year-old woman was found incidentally to have a hepatic mass in the caudate lobe by ultrasound study during a health examination. She was a known hepatitis B carrier (serum positive HBsAg) for 10 years and also known as a hepatitis C carrier (positive IgG anti-HCV) for 1 year. Laboratory evaluation demonstrated normal liver and renal function. The counts of red blood cells, white blood cells, and platelets, coagulation function test, urinalysis, and serum biochemistry profile analysis were normal. The serum alpha-

fetoprotein level was not elevated. Abdominal ultrasound detected a 4.0 cm×4.6 cm inhomogeneous hyperechoic mass situated at the caudate lobe.

Pre- and post-contrast triphasic spiral CT scans were subsequently performed with intravenous administration of a total of 100 mL of contrast material at an injection rate of 2 ml/s via a power injector. Hepatic arterial-phase, portal-phase and delayed-phase were obtained 35, 75 and 180 seconds, respectively, after the injection of contrast material. Pre-contrast CT revealed a well-circumscribed, low attenuation (attenuation value of 40 HU) ovoid mass (measuring approximately 4.0 cm×4.6 cm in dimension) occupying the caudate lobe. The mass exhibited a very faint discontinuous peripheral rim enhancement (attenuation value of 76 HU) at the arterial-phase (Figure 1A), with a moderately increased enhancement degree (attenuation value of 110 to 114 HU) and widened enhancement thickness for the enhanced peripheral zone during the portal-phase and delayed-phase (Figures 1B, C). Minimal enhancement (attenuation value of 61 HU) was also noted in the central portion of the mass during the delayed-phase.

The patient also received a conventional angiographic examination for further evaluation of the caudate lobe mass. Selective proper hepatic angiography showed two small, slightly tortuous, but not enlarged caudate lobe arteries deriving from the right and left hepatic arteries and supplying the caudate lobe mass. Very faint peripheral tumor stains were detected during the late arterial phase (Figure 2A) and parenchymal phase. However, there were no persistent, dense tumor stains at the late venous phase. During the angiographic study, 4 mL of lipiodol (iodized oil) was also slowly injected into the proper hepatic artery and showed several foci of spotty lipiodol retention in the peripheral and central portions of the caudate lobe mass (Figure 2B).

The patient underwent caudate lobe excision under the presumptive diagnosis of hepatocellular carcinoma based on the imaging findings. Pathological examination revealed a cavernous hemangioma occupying the caudate lobe. Only several small foci of organizing thrombi within the hemangioma were discovered.

DISCUSSION

Cavernous hemangioma is the most common benign hepatic tumor. The vast majority of hepatic hemangiomas present with a typically initial intense peripheral nodular enhancement with gradual central fill-in enhancement when studied by dynamic CT study, and it is easy to differentiate from other hepatic tumors. However a small number of hemangiomas could exhibit atypical enhancement patterns due to the presence of intralesional non-enhanced thrombosis, fibrotic, degenerated or calcified components^[1,4]. In addition, variable vascularity of hemangiomas could also influence the lesion's enhancement rate and result in atypical enhancement patterns^[2-4]. An atypical hemangioma may mimic a malignant hepatic tumor, causing diagnostic confusion, especially in patients at risk of malignancy.

Previous investigators^[2-4] have observed that atypical enhancing hemangiomas were more common for smaller lesions than for larger lesions. Approximately 15.6% to 22.2% of

Figure 1 CT images were obtained from an asymptomatic 58-year-old woman with an atypical hepatic hemangioma. A: A 4.0 cm×4.6 cm caudate lobe mass, which exhibits a subtle, discontinuous peripheral thin-rim enhancement (attenuation value of 76 HU) shown by post-contrast triphasic CT scan at the arterial-phase. B and C: A moderately increased enhancement degree and a widened enhancement thickness for the enhanced peripheral zone (attenuation value of 110 to 114 HU) in the caudate lobe mass shown by post-contrast triphasic CT scans at the portal-phase and delayed-phase.

Figure 2 Peripheral tumor stains during the late arterial phase and foci of spotty lipiodol retention in the peripheral and central portions of the caudate lobe mass. A: Peripheral tumor stains during the late arterial phase. B: Foci of spotty lipiodol retention in the peripheral and central portions of the caudate lobe mass.

hemangiomas smaller than 2 cm in diameter might have an atypical enhancement pattern of low or iso-attenuation during the post-enhanced arterial and portal venous phases by dynamic CT^[2-4]. However, atypical enhancement patterns of large hemangiomas were very rare. Yun *et al.*^[2] reported that only 2.2% of hemangiomas larger than 2 cm in diameter presented with atypical enhancement patterns. These reports were correlated with the concept that the presence of typical peripheral nodular enhancement required larger blood supply vessels for hemangiomas and this was associated more with a larger lesion size. Thus, a hemangioma fed by small, not-enlarged supply arteries may fail to exhibit a typical enhancement pattern.

In this present case, although the caudate lobe hemangioma was larger than 4 cm in diameter, the angiograms showed that it was supplied by slightly tortuous, but un-enlarged feeding arteries due to its unique location on an independent hepatic segment of the caudate lobe that only receives the small diameter caudate arterial branches derived from the proximal portion of right and left hepatic arteries. So, this caudate lobe hemangioma failed to exhibit a typical initial peripheral nodular enhancement due to the absence of large feeding arteries. Moreover, the small caudate arteries with their sluggish perfusion also resulted in a slow enhancement rate for the caudate lobe hemangioma. On the post-enhanced arterial-phase, a very faint discontinuous peripheral rim enhancement was noted. During the portal-phase, there was a moderately increased enhancement degree for the enhanced peripheral zone, but the degree of enhancement was not as high as intra-hepatic vessels. At the delayed-phase, complete centripetal fill-in enhancement was not present in the hemangioma, but only a subtle enhancement of the intralesional central portion was noted. The enhancement pattern in the caudate lobe hemangioma thus simulated a well-differentiated hepatocellular carcinoma with delayed pseudocapsule

enhancement, because a well-differentiated hepatocellular carcinoma might usually only possess a slightly increased arterial supplement and is not fed by markedly enlarged vessels^[5]. Therefore, both a well-differentiated hepatocellular carcinoma and a hemangioma with small feeding arteries may exhibit a similar enhancement pattern on dynamic CT study. However, the thickness of pseudocapsules in a hepatocellular carcinoma was thinner than that of the enhanced peripheral rim in a hemangioma. Furthermore, the increased enhancement degree and the increased enhancement thickness of the intra-lesional peripheral rim also provided a diagnostic clue for the hemangioma with a slow progressive central fill-in enhancement. In contrast, a hepatocellular carcinoma usually exhibited contrast medium washout during the delayed-phase.

MR imaging is superior to CT study to improve diagnostic confidence for hepatic hemangiomas. CT has a sensitivity of 62-88% and a specificity of 84-100% (100% when enhancement is isoattenuating to the aorta) for detection of the typical globular enhancement in hemangiomas^[6]. However, MR imaging has a higher sensitivity of 98% and a specificity of 98% for detection of the hemangiomas^[7]. Some atypical hemangiomas can be diagnosed by MR imaging study. Nevertheless, some atypical hemangiomas will still remain uncertain at MR study due to the presence of intralesional thrombosis, calcified, hyalinized or cystic components that results in the loss of its characteristic appearance of markedly high signal intensity on heavy T2-weighted imaging and present with atypical enhancement patterns on post-enhanced study^[8]; and these cases will require biopsy and histopathologic examination.

Except that hemangiomas can exhibit peripheral rim enhancement, the presence of peripheral rim enhancement could also be observed in hepatic metastatic lesions^[9].

However, the peripheral rim enhancement in a metastatic lesion often has a serrated margin and not a lobular margin as seen in a hemangioma. Thus, in the present case, the caudate

lobe hemangioma had an enhanced peripheral rim with a lobular margin and not a serrated margin allowing it to be differentiated from a metastatic lesion.

As in the present case of a hepatitis carrier at risk for malignancy, CT and MR imaging were considered as complementary imaging study for detection of the malignant hepatic masses. Kang *et al.*^[10] reported that although MR imaging study had a higher sensitivity of 95% than that of CT study with a sensitivity of 88% for detection of the hepatocellular carcinomas. However, there was no significant difference in the diagnostic specificity between MR study (97%) and the CT study (98%).

Intra-arterial lipiodol injection has also been used to increase detection of small hepatic neoplasms. Lipiodol retention with a spotty and/or nodular type distribution in the peripheral or central portions of hepatic hemangiomas has been described by Moon *et al.*^[11]. However, the presence of spotty lipiodol retention has also been observed in other hepatic tumors, such as focal nodular hyperplasia, metastases and hepatocellular carcinoma. Hepatocellular carcinomas tended to exhibit a peripheral distribution of lipiodol accumulation, rather than a central distribution of lipiodol deposition as seen in hemangiomas. In this present case, conventional angiography failed to demonstrate the typical “cotton-wool” appearance of puddling of contrast material within the large vascular spaces and persisting into the venous phase of a caudate lobe hemangioma. The absence of persistent tumor stains in the hemangioma may be due to its unique location in the hepatic caudate lobe where there is a rapid venous drainage to the adjacent portal vein and inferior vena cava. In such a situation, it is difficult to distinguish a hemangioma from a hepatocellular carcinoma based only on conventional angiographic imaging findings. Whereas, intra-arterial lipiodol injection demonstrated spotty lipiodol retention at the intralesional peripheral and central portions, with a “cotton wool” appearance, and suggested a diagnosis of hemangioma. In addition, the number of lipiodol retention foci was also more pronounced than the number of contrast material stains as seen on conventional angiograms, because the lipiodol materials could be retained in the ectatic and tortuous vascular channels of the hemangioma, thus decreasing its venous washout degree via the portal vein and inferior vena cava. Therefore, intra-arterial lipiodol injection is able to help in the diagnosis of a hemangioma with a rapid venous drainage.

In conclusion, the presence of slow progressive peripheral rim enhancement persisting to the delayed phase, associated with the presence of central distributed spotty lipiodol retention in a caudate lobe mass should give rise to a suspicion of the possibility of hepatic hemangioma. This report emphasizes that a hepatic hemangioma in this unique caudate lobe location can

present with an atypical enhancement pattern and resembles a hepatocellular carcinoma. Thus, we recommend that when studying a caudate lobe lesion, a longer post-enhanced delayed time (more than 3 min) is required on CT, in order to reflect its actual vascularity characteristics. In addition, further evaluation by MR study with a long echo time of 150 to 180 ms is also necessary to confirm the diagnosis of a cavernous hemangioma in order to prevent inappropriate therapeutic decision making.

Abstract

We report an 80-year-old man who presented with spontaneous regression of hepatocellular carcinoma (HCC). He complained of sudden right flank pain and low-grade fever. The level of protein induced by vitamin K antagonist (PIVKA)-II was 1 137 mAU/mL. A computed tomography scan in November 2000 demonstrated a low-density mass located in liver S4 with marginal enhancement and a cystic mass of 68 mm×55 mm in liver S6, with slightly high density content and without marginal enhancement. Angiography revealed that the tumor in S4 with a size of 25 mm×20 mm was a typical hypervascular HCC, and transarterial chemoembolization was performed. However, the tumor in S6 was hypovascular and atypical of HCC, and thus no therapy was given. In December 2000, the cystic mass regressed spontaneously to 57 mm×44 mm, and aspiration cytology revealed bloody fluid, and the mass was diagnosed cytologically as class I. The tumor in S4 was treated successfully with a 5 mm margin of safety around it. The PIVKA-II level normalized in February 2001. In July 2001, the tumor regressed further but presented with an enhanced area at the posterior margin. In November 2001, the enhanced area extended, and a biopsy revealed well-differentiated HCC, although the previous tumor in S4 disappeared. Angiography demonstrated two tumor stains, one was in S6, which was previously hypovascular, and the other was in S8. Subsequently, the PIVKA-II level started to rise with the doubling time of 2-3 wk, and the tumor grew rapidly despite repeated transarterial embolization with gel foam. In February 2003, the patient died of bleeding into the peritoneal cavity from the tumor that occupied almost the entire right lobe. Considering the acute onset of the symptoms, we speculate that local ischemia possibly due to rapid tumor growth, resulted in intratumoral bleeding and/or hemorrhagic necrosis, and finally spontaneous regression of the initial tumor in S6.

INTRODUCTION

According to previous reports, spontaneous regression (SR)

of malignant tumors is estimated to occur once in 60 000-100 000 cancer patients^[1]. Neuroblastomas and urinary bladder cancers are well-known to regress spontaneously. However, in hepatocellular carcinoma (HCC) only 30 cases of SR have been reported in the English-language literature^[2-7]. Among them, there has been only 1 report of 2 cases of recurrent HCC after SR^[4]. In both cases, however, the new lesion developed at a different site in the liver while the preexisting HCC was regressing, suggesting that multicentric hepatocarcinogenesis was involved in the recurrence. In this paper, we present a case of spontaneously regressing HCC, which recurred locally during the course of 8 mo. Four months later, a new lesion developed at a different site in the liver, possibly through intrahepatic metastasis from the original tumor, and progressed rapidly. We discussed the possible mechanisms of SR in HCC.

CASE REPORT

An 80-year-old man was admitted to our hospital on November 14, 2000 due to right flank pain and low-grade fever, which continued for a day and worsened gradually. He drank 350 mL of beer every day but had no history of the use of herbal medicines.

His blood pressure was 170/104 mmHg and body temperature was 37.2 °C. There was no remarkable physical finding. The laboratory data on admission revealed that his white blood cell count and C-reactive protein (CRP) were elevated to 10 600/mm³ and 6.2 mg/dL, respectively. Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) also were elevated to 201 IU/L and 234 IU/L, respectively. The level of alfa-fetoprotein (AFP) was within the normal limit, but protein induced by vitamin K antagonist (PIVKA)-II was 1 137 mAU/mL. His serum was negative for hepatitis B surface antigen and positive for hepatitis C antibody.

Enhanced computed tomography (CT) on admission demonstrated 2 hepatic tumors (Figure 1A). One was a low-density mass located in liver S4 with marginal enhancement. The other was a cystic mass of 68 mm×55 mm in S6 with slightly high density content but without marginal enhancement. Angiography demonstrated that the right hepatic lobe was supplied by the replaced right hepatic artery. A celiac arteriogram showed tumor stain in S4 with a size of 25 mm×20 mm, which was diagnosed as typical HCC (Figure 2A). Transarterial chemoembolization was performed using an emulsion of 3.2 mL Lipiodol (iodized oil manufactured by Andre Guerbert, Aulnay-sous-Bois, France) and 32 mg epirubicin^[8]. The super mesenteric arteriogram, on the other hand, demonstrated that the tumor in S6 was hypovascular (Figure 2B). Because this image was atypical of HCC, no therapy was given.

Low-grade fever disappeared on the second day of admission and the white blood cell count, CRP and transaminases became almost normal on the eighth day. Because the patient wanted to undergo an operation for gallbladder stones, preoperative evaluation for cholecystectomy was carried out. In December 2000, just before the operation, a CT scan showed that Lipiodol was accumulated in the tumor in S4 and that the cystic mass in S6 was decreased in size spontaneously, down to 57 mm×44 mm (Figure 1B). During the operation in December 2000, microwave coagulation was performed for HCC in S4. The surface of the cystic tumor in S6 was dark red and needle aspiration revealed bloody fluid, which was diagnosed cytologically as class I. Because there was no evidence of malignancy, we did not give any treatment for this lesion.

After the operation, the tumor in S6 continued to decrease in size (Figure 1C), whereas the tumor in S4 was treated successfully with a 5 mm margin of safety around it. The PIVKA-II level fell to the normal limit in February 2001. A CT scan in July 2001 revealed that the tumor was decreased further in size but demonstrated an enhanced area at the posterior margin of the tumor (Figure 1D). Furthermore, the PIVKA-II level increased slightly. In November 2001, a CT scan demonstrated that the enhanced area extended to the surrounding area of the cystic tumor (Figure 1E). Histological evaluation by tumor biopsy from the lesion in S6 revealed a well-differentiated HCC (Figure 1F). The celiac arteriogram in November 2001 showed that the previous tumor stain in S4 disappeared. The super mesenteric arteriogram demonstrated 2 tumor stains; one was in S6, which was previously hypovascular, and the other was in S8 (Figure 2D).

Subsequently, transarterial embolization with gel foam (TAE) was repeated but the tumor resisted therapy, with rapid invasion and intrahepatic metastasis. In February 2003, the

patient died of bleeding into the peritoneal cavity from the tumor that occupied almost the entire right lobe (Figure 3).

DISCUSSION

To our knowledge, there has been only 1 report of 2 cases of recurrence of HCCs after SR^[4]. In both cases, the recurrent HCCs developed at different sites in the liver before the preexisting HCC regressed completely, suggesting that multicentric hepatocarcinogenesis, rather than intrahepatic metastasis, was likely to have been involved in the recurrence. However, in our case, evidence of local recurrence in the regressing tumor was observed by CT scan before the newly developed lesion in S8 was found by angiography. In addition, when local recurrence was detected by CT scan, the serum PIVKA-II level started to rise again. This clinical course suggests that the new lesion in S8 might be due to intrahepatic metastasis from the locally recurrent tumor in S6, rather than multicentric hepatocarcinogenesis.

Figure 1 Enhanced computed tomography (CT). A: A low-density mass located in liver S4, with marginal enhancement and a cystic mass of 68 mm×55 mm in S6. B: Lipiodol accumulation in the tumor in S4 and the cystic mass in S6. C: Microwave coagulation performed for HCC in S4 during cholecystectomy. D: Further decrease in tumor size and enhanced area at the posterior cystic lumen of the tumor. E: Extension of the enhanced area to the surrounding area of cystic tumor. F: A well-differentiated HCC shown by histological evaluation.

Figure 3 Clinical course of the patient. TAE: transarterial embolization with gel foam.

In previous reports, some authors made a definitive diagnosis by histological study after tumor resection but others suspected SR based on the following up radiological findings and the tumor markers^[2-7]. In this case, the PIVKA-II level was 1 137 mAU/mL on the first admission and decreased dramatically to 103 in 1 mo. However, at that point we were not certain whether this was due to SR of the HCC in S6 or to transarterial chemoembolization for a typical HCC in S4. In addition, a diagnosis of class I by tumor aspiration cytology in S6 prevented us from performing S6 segmentectomy, in view of evidence-based medicine. We could not make a definitive diagnosis of the tumor in S6 until it showed radiological signs of recurrence and was proven histologically to be HCC.

The precise mechanism of SR of HCC remains unclear, but various factors have been speculated to play a role, such as alcohol withdrawal^[9], androgen withdrawal^[10], and intake of herbal medicine^[2,11,12]. Secondary bacterial infection in the tumor has also been supposed to cause SR through the stimulation of cytokine production^[13,14] and fever^[15]. Because of the hypervascular nature of HCC, another important factor might be an insufficient blood supply to the tumor, possibly due to rapid natural tumor growth^[16,17], spontaneous arterial thrombosis^[18], or gastrointestinal bleeding^[19,20]. In our case, there was no history of alcohol or androgen withdrawal or the use of herbal medicines. The initial symptoms of right flank pain and fever suddenly appeared and lasted for only a day. Laboratory data showed that the levels of transaminases were elevated on admission but almost normalized in about a week. In addition, angiography clarified that the tumor in S6 was hypovascular. Furthermore, this tumor was cystic with slightly high density content, from which bloody fluid was obtained. These clinical manifestations suggest that the acute onset of the symptoms was due to local ischemia, leading to intratumoral bleeding or hemorrhagic necrosis, and as a result, causing SR.

In this case, the PIVKA-II level after recurrence showed a logarithmic increase throughout the entire clinical course, except that it stabilized for one month after each TAE. The doubling time of the PIVKA-II level, which is thought to reflect the tumor doubling time, was calculated to be 2-3 wk. This indicates that the recurrent tumor grew very rapidly, compared with the average natural growth rate of HCC reported previously^[21,22]. The PIVKA-II level was elevated to 1 137 mAU/mL on the first admission, decreased along with SR of the tumor in S6, and rose again after recurrence. It has been reported that HCCs with high PIVKA-II levels during the initial stage show aggressive behaviors and a poor prognosis. Therefore, we speculate that the initial tumor in S6 grew as fast as the recurrent tumor and this rapid growth itself might be the cause of insufficient blood supply to the tumor, finally inducing SR, as suggested in previous reports^[16,17].

Abstract

AIM: To evaluate the association between *CYP1A1* and *GSTs* genetic polymorphisms and susceptibility to esophageal squamous cell carcinoma (SCC) and esophageal adenocarcinoma (ADC) in a high risk area of northwest of France.

METHODS: A case-control study was conducted to investigate the genetic polymorphisms of these enzymes (*CYP1A1**2C and *GSTP1* exon 7 Val alleles, *GSTM1**2/*2 and *GSTT1**2/*2 null genotypes). A total of 79 esophageal cancer cases and 130 controls were recruited.

RESULTS: *GSTM1**2/*2 and *CYP1A1**1A/*2C genotype frequencies were higher among squamous cell carcinomas at a level close to statistical significance (OR = 1.83, 95% CI 0.88-3.83, *P* = 0.11; OR = 3.03, 95% CI 0.93-9.90, *P* = 0.07, respectively). For *GSTP1* polymorphism, no difference was found between controls and cases, whatever their histological status. Lower frequency of *GSTT1* deletion was observed in ADC group compared to controls with a statistically significant difference (OR = 13.31, 95% CI 1.66-106.92, *P* < 0.01).

CONCLUSION: In SCC, our results are consistent with the strong association of this kind of tumour with tobacco exposure. In ADC, our results suggest 3 distinct hypotheses: (1) activation of exogenous procarcinogens, such as small halogenated compounds by *GSTT1*; (2) contribution of *GSTT1* to the inflammatory response of esophageal mucosa, which is known to be a strong risk factor for ADC, possibly through leukotriene synthesis; (3) higher sensitivity to the inflammatory process associated with intracellular depletion of glutathione.

INTRODUCTION

One of the highest incidences of esophageal cancer in Europe is observed in the Northwest of France^[1-4]. There are two predominant histological forms of this cancer: squamous cell carcinoma (SCC) and adenocarcinoma (ADC)^[4,5]. Recent epidemiological observations showed an important decrease in the incidence of SCC whilst ADC was slightly increased^[2,4].

In Western countries, smoking tobacco and drinking alcohol are the main risk factors for SCC. For ADC, exogenous risk factors are not well known. A link was found between this pathology, esophageal reflux and Barrett's esophagus^[5].

Tobacco smoke contains many carcinogens such as polycyclic aromatic hydrocarbons (PAH) and *N*-nitrosamines that can be activated or deactivated by phase I (cytochromes P-450) and phase II enzymes (glutathione S-transferases). Cytochromes P450 (CYP) are a widely expressed enzyme family, some members of which present genetic polymorphisms (e.g. *CYP1A1*, *2E1*, *2D6*). *CYP1A1* is expressed in esophageal mucosa, which means that activation of tobacco carcinogens can happen *in situ*^[6]. Benzo[a]pyrene is activated by *CYP1A1* to diol-epoxide, which is a reactive and carcinogenic product. Four main genetic polymorphisms are described for *CYP1A1*. One of the most studied is Ile/Val polymorphism in exon 7 (*CYP1A1**2C allele). One study reported that Val-type could be associated with a higher aryl hydrocarbon hydroxylase activity^[7].

Many studies have reported the association of *CYP1A1* polymorphisms with lung cancer^[8], particularly with SCC of the lung^[9,10]. The level of DNA adducts was found to be linked to *CYP1A1**2C polymorphism^[11]. All these results suggest that susceptibility to tobacco-related cancers could be modified by *CYP1A1* polymorphisms.

The glutathione S-transferases are a family of phase II enzymes, which catalyse the conjugation of many endogenous and exogenous electrophilic compounds to glutathione. *GSTM1* and *GSTP1* are able to detoxify benzopyrene diol-epoxide^[12], whereas *GSTT1* can conjugate oxidised lipids and halogenated compounds^[12]. Both *GSTM1*, *P1* and *T1* are expressed in esophageal mucosa^[13,14]. *GSTP1* is the mainly expressed GST in this tissue^[15]. *GSTP1* presents a substitution polymorphism in exon 7 that results in a substitution of Ile by Val at amino acid position 104^[16]. Val variants were found to have a lower activity towards 1-chloro-2, 4-dinitrobenzene^[17]. *GSTM1* and *GSTT1* present deletion polymorphisms (*GSTM1**2/*2 and *GSTT1**2/*2), which are currently at about 50% and 20% among Caucasians, respectively^[18,19]. *GSTM1**2/*2 polymorphism has been found to increase the frequency of chromosome aberrations after tobacco-specific *N*-nitrosamine exposure *in vitro*^[20]. Many studies have shown that this deletion increases the susceptibility conferred by the *CYP1A1**2C allele for tobacco-associated cancer^[21]. While *GSTT1**2/*2 genotypes have not been clearly

associated with susceptibility to tobacco-linked cancers, an interaction with *GSTM1**2/*2 has often been found^[22,23].

The aim of our work was to evaluate the susceptibility conferred by *CYP1A1* and *GSTs* genetic polymorphisms to SCC and ADC of esophagus in a high risk European area.

MATERIALS AND METHODS

Controls and cases were from the geographic area of Basse-Normandie, France. Patients were recruited after endoscopic and histologic diagnosis of primary esophageal cancer. All cases were newly diagnosed and previously untreated patients. Controls were required to be free of any chronic diseases, having no cancer history and living in Basse-Normandie. They were matched with cases in sex and age. Alcohol and tobacco consumption were also evaluated during the recruitment of cases and controls by means of a questionnaire.

The research protocol was approved by the Comité Consultatif pour la Protection des Personnes dans la Recherche Biomédical en Basse-Normandie. A 20 mL sample of venous blood was taken and DNA extraction was performed by phenol/chloroform method.

The primer sequences and product sizes of each gene amplification are shown in Table 1. *GSTM1* and *GSTT1* multiplex PCR was performed according to the Lin *et al.* method^[24], with some modifications. A final mixture volume of 25 µL was prepared containing 0.100 µg of DNA, 0.25 µmol/L of dNTP, 0.4 µmol/L of primer for *GSTM1*, 0.8 µmol/L of primer *GSTT1*, 0.8 µmol/L of primer albumin, 5 µL of 10× buffer, 2 mmol/L of MgCl₂ and 0.5 U per sample of DNA Gold *Taq* polymerase (Applied Biosystem, Coutaboeuf, France). The first step was performed for 15 min at 95 °C followed by 35 cycles: at 94 °C for 1 min (denaturation), at 58 °C for 1 min (annealing), at 72 °C for 1 min (elongation). PCR ended a final extension for 10 min at 72 °C. PCR products were visualised on 20 g/L agarose gel with ethidium bromide staining.

Table 1 Primer sequences and length of PCR products

GSTP1 PCR restriction fragment length polymorphism (rflp) was performed using a method adopted by Harries *et al.*^[16] with slight modifications. The final mixture (40 µL) was prepared containing 0.100-0.500 µg of DNA, 0.25 µmol/L of dNTP, 0.25 µmol/L of each of the primers, 1.25 µmol/L of MgCl₂, 4 µL of 10× buffer, 4 µL of DMSO, 1.5 U of *Taq* polymerase (Eurobio, Les Ulis, France). Briefly, the samples were denatured at 94 °C for 5 min and submitted to 30 cycles of amplification as follows: for 30 s at 94 °C (denaturation), for 30 s at 55 °C (annealing), for 30 s at 72 °C (extension) and a final extension at 72 °C for 5 min. PCR product of 12 µL was digested by 5 U Alw26 I restriction enzyme (Eurogentec, Seraing, Belgium) for 12 h at 37 °C. Migration was performed on low melting 40 g/L agarose gel (Eurobio, Les Ulis, France), stained with ethidium bromide, in order to separate the 85 and 91 bp fragments.

*CYP1A1**2C polymorphism was determined by PCR-RFLP

as previously described^[8].

Each PCR analysis was performed twice in double blind.

Statistical analysis

Chi-square test and *P* value estimation were performed using Stata software (STATA Corporation, college Station, TX). Odds ratio was also evaluated using StataO software and adjusted for age, sex and histological type.

RESULTS

The populations of controls and cases are described in Table 2. The patient group consisted of 52 SCCs and 27 ADCs. The mean ages for cases and controls were 62 and 56 years respectively. Unfortunately, we obtained tobacco and alcohol exposure data for only 48 cases. This was insufficient to allow us to study interaction between exposure and polymorphisms. As it could be expected, the vast majority of SCCs were smokers (93%, all with more than 20 years of tobacco consumption) and heavy drinkers (86% drinking more than 229 g/wk). Fewer ADCs were smokers (78%, of which 67 % with more than 20 years of tobacco consumption) and only 50% were heavy drinkers (Table 2).

Table 2 Description of control and case populations

	Control n (%)	Case n (%)	SCC n (%)	ADC n (%)
Male	87 (0.67)	69 (0.87)	44 (0.85)	25 (0.93)
Female	43 (0.33)	10 (0.13)	8 (0.15)	2 (0.07)
Mean age (yr)	56 [19; 87]	62 [40; 85]	60 [40; 78]	66 [51; 85]
Tobacco duration ^{1,2} (years of smoking)				
Non-smokers	66 (0.66)	6 (0.13)	2 (0.07)	4 (0.22)
1-19	13 (0.13)	2 (0.04)	0 (-)	2 (0.11)
+20	21 (0.21)	40 (0.83)	28 (0.93)	12 (0.67)
Alcohol consumption ^{3,4} (g of ethanol per week)				
0-228	11 (0.64)	13 (0.28)	4 (0.14)	9 (0.50)
228.5 -/+ 470	6 (0.36)	35 (0.72)	26 (0.86)	9 (0.50)

¹Tobacco duration (year); ²Data were available for 77% of controls, 61% of cases, including 58% of SCC and 67% of ADC; ³Alcohol consumption (gram of ethanol per week); ⁴Data for alcohol consumption were available for only 13% of controls, 61% of cases, including 58% of SCC and 67% of ADC.

Frequencies of the different genetic polymorphisms in the control group were 0.06 for *CYP1A1**A/*2C (no homozygous *2C/*2C subject was found), 0.45 and 0.07 for Ile/Val and Val/Val *GSTP1* genotypes, 0.49 for *GSTM1**2/*2 and 0.26 for *GSTT1**2/*2 (Tables 3, 4).

A high frequency of *CYP1A1**1A/*2C genotype was found in SCC cancer patients (Table 3). However, the difference did not reach statistical significance (with a *P* value of 0.06). The ADC patient group did not show any significant difference compared to the control group.

*GSTM1**2/*2 genotype (*GSTM1* null) was increased among the cases compared to the controls, particularly among SCC patients (Table 4), but this difference was not statistically significant (OR = 1.83; 95% CI = 0.88-3.83). The distribution of *GSTM1**2/*2 genotype among ADCs did not differ from the controls.

The frequency of *GSTT1**2/*2 genotype (*GSTT1* null) was not different between cases and controls (Table 5). However, the ADC group showed a greatly decreased frequency of *GSTT1**2/*2 genotype (4%) compared to the control population (26%) and SCCs (29%) (OR = 13.31, 95 % CI = 1.66-106.92).

Distribution of the *GSTP1* genotype did not differ between SCC, ADC and control groups (Table 6).

DISCUSSION

Esophageal cancer presents a very variable incidence in different regions and ethnic groups. In France, different levels of environmental exposure to carcinogens could not fully explain this high variability^[25-27], a fact which suggests a genetic susceptibility. Many epidemiological studies have established that exposure to tobacco smoke and alcohol is a major risk factor for SCC in Western countries, whereas ADC is not strongly linked to exogenous factors. As far as we know, only one study concerning the genetic susceptibility to esophageal cancer was performed among Caucasians^[28]. Moreover, the cases for this study were recruited in a low risk area in Europe.

The repartition of different polymorphisms in our control group agrees with available data for a Caucasian population^[8,16,18,19,29]. Recently, frequencies of these polymorphisms among a healthy population were evaluated and published by International Collaborative Study on Genetic Susceptibility to Environmental Carcinogens (GSEC)^[18].

Among SCC cases, *CYP1A1**2A/*2C frequency was increased when compared to controls and adjusted OR was 3.03 (95% CI 0.93-9.90), however this result was not statistically significant (*P* = 0.067). The deletion of *GSTM1* gene was also more frequent among SCC cases when compared to controls (63% and 49% respectively, OR = 1.83; 0.88-3.83). But this result was also not statistically significant (*P* = 0.108). *CYP1A1**2A/*2C and *GSTM1**2/*2 genotypes were found to increase the risk of SCC in a previous study in an Asian population, particularly among cases with higher tobacco consumption. However, some studies did not find *CYP1A1* and *GSTM1* gene polymorphisms to be related to SCC. No association was found between other genetic polymorphisms studied (*GSTT1*, *GSTP1*) and esophageal SCC, which is in accordance with the data in literature^[24,30,31]. It should be emphasized that, concerning *GSTT1*, our study is the first report about a Caucasian population.

No differences were found among ADC cases regarding the

frequencies of *CYP1A1*, *GSTM1* and *GSTP1* polymorphisms when compared to controls. This observation is in accordance with the weak association of tobacco smoke, alcohol consumption and ADC. In the ADC group, an unexpected protective effect of *GSTT1* deletion was found (OR = 13.31; 95% CI 1.66-106.92). Such results have been previously described for other sites such as renal or prostate carcinoma^[32,33]. It is well known that the risk of renal carcinoma is increased by exposure to small halogenated compounds such as dichloromethane or trichloroethylene. Activation of these compounds in electrophilic species implies *GSTT1*^[29], which could explain these results. However, to our knowledge, no studies have demonstrated a role of small halogenated compounds in esophageal ADC carcinogenesis. Exposure to these compounds is possible through occupational factors, chlorinated tap water consumption or tobacco smoke. The latter, which is a weakly associated risk factor for ADC, contains methyl chloride^[34]. However, our present data did not allow us to estimate exposure to halogenated compounds in our population.

Another hypothesis is that GST could participate in chronic inflammation through leukotriene synthesis^[35]. In particular, leukotriene A4 to C4 (LTC4) conversion requires GST activity. Inflammation is a major etiologic factor for ADC and leukotrienes have been found to be mediators implicated in this process^[5]. Furthermore, leukotriene LTD4, which is biosynthesized from LTC4, was found to induce contraction of the oesophagus and lower esophageal sphincter in animal models^[35,36]. This phenomenon is likely to be involved in gastro-oesophageal reflux, which constitutes the strongest risk factor for ADC. However, though *GSTT1* is also expressed in esophageal mucosa^[14], it remains unclear whether this enzyme contributes to LTC4 synthesis in this tissue.

The association between susceptibility to cancer and *GSTT1* genotypes could be also explained by depletion in intracellular glutathione in the presence of *GSTT1* enzyme. In this case, cells would be more sensitive to radical species produced during the inflammatory process observed among adenocarcinoma patients.

In conclusion, our study shows a different pattern of susceptibility to SCC and ADC of esophagus in a European high risk population. Whereas a slight susceptibility to SCC could be conferred by *CYP1A1**1A/*2C and *GSTM1**2/*2 genotypes, a high frequency of *GSTT1**1/*1 genotype was found among ADC. These results are consistent with the association of SCC with tobacco exposure, as other tobacco-related cancers such as lung cancer were found to be moderately linked to *CYP1A1**2C allele and *GSTM1**2/*2 genotype. In ADC, our results suggest 3 distinct hypotheses. (1) The activation of exogenous procarcinogens, such as small halogenated compounds (to which ways of exposure remain to be identified), by *GSTT1*. Unlike tobacco, the evaluation of exposure to small halogenated compounds remains difficult because of the wide distribution of these compounds. (2) The contribution of *GSTT1* to the inflammatory response of esophageal mucosa, which is known to be a strong risk factor for ADC, possibly by way of leukotriene synthesis. (3) Higher sensitivity to the inflammatory process associated with intracellular depletion of glutathione. A new study focusing on esophageal ADC with a larger recruitment would allow us to investigate these issues.

ACKNOWLEDGEMENTS

We thank Dr Dominique Arsène and Pr Marc Gignoux (Services de Gastroentérologie et de Chirurgie Digestive, CHU de Caen) for assistance in case recruitment. We thank Jacques Marnay and Dr Jacques Chasles (Laboratoire d'Anatomie Pathologique, Centre François Baclesse, Caen) for help in the histological

diagnosis of tumors. We thank Marie Ingouf, Jocelyne Dannetot and Anne Leclerc for technical assistance.

Abstract

AIM: To explore the effect of DNA methyltransferase, demethylase and methyl-CpG binding protein MeCP2 on the expressions and methylation of hMSH2 and proto-oncogene in human gastric cancer.

METHODS: Paired samples of primary gastric cancer and corresponding para-cancerous, non-cancerous gastric mucosae were obtained from surgically resected specimens of 28 patients. Transcription levels of Dnmt1, mbd2, MeCP2, p16^{INK4A}, hMSH2 and c-myc were detected by using real-time PCR or RT-PCR. Promoter methylation of p16^{INK4A}, c-myc and hMSH2 genes was assayed by methylation-specific PCR (MSP) and sequencing (mapping). Their relationships were analyzed by Fisher's exact test using the software SPSS.

RESULTS: The average mRNA level of Dnmt1 gene from cancerous tissue was higher and that of mbd2 gene from cancerous tissue was lower than that from non-cancerous tissue, respectively. mbd2 was lower in cancerous tissue than in non-cancerous tissue in 14 (50.0%) of patients but higher in 3 cases (10.7%) of non-cancerous gastric tissue ($P < 0.001$). c-myc expression was up-regulated in cancer tissues ($P < 0.05$). The up-regulation of mbd2 was found in all patients with hypomethylated c-myc. The transcriptional levels of p16^{INK4A} and MeCP2 genes did not display any difference between gastric cancerous and matched non-cancerous tissues. There were down-regulation and hypermethylation of hMSH2 in cancer tissues, and the hypermethylation of hMSH2 coexisted with down-regulated transcription. However, the transcription level of the above genes was not associated with biological behaviours of gastric cancers.

CONCLUSION: The up-regulation of proto-oncogene may be the consequence of epigenetic control of gene expression by demethylase, and mbd2 is involved in the regulation of hMSH2 expression in human gastric cancer.

INTRODUCTION

Methylation of gene regulatory elements, a well-known epigenetic change, acts as an important alternative to genetic alteration for gene inactivation. DNA methyltransferase (Dnmt) and DNA demethylase are the enzymes potentially affecting promoter methylation status. Human DNA demethylase has been cloned^[1]. The inactivity of demethylase may play a role in production and maintenance of regional DNA hypermethylation, which frequently results in reduced expression of tumor suppressor genes in human cancers.

Gastric cancer is the second most common malignant tumor in Asia, with a much higher incidence than in Western countries. During gastric carcinogenesis, hypomethylation of c-myc and c-Ha-ras proto-oncogenes was frequently seen^[2,3], however the average level of mRNA for Dnmt1 was significantly higher in gastric cancers than in corresponding non-cancerous mucosa^[4]. mbd2 has been proposed to be a DNA demethylase, and the average level of mbd2 mRNA was significantly lower in gastric cancer than in non-cancerous mucosa. But there was no significant association between DNA demethylase mRNA level and malignant potential in gastric cancers^[5]. The mRNA expression levels for pro-methylation of Dnmt1, Dnmt3a and Dnmt3b and mbd2 are not the critical determinant of tumor-specific promoter hypermethylation of hMLH1, p16^{INK4A} or CDH1 in gastric cancer^[6]. However, little is known about the relationship between mbd2 or Dnmt1 and the methylation status of proto-oncogene or hMSH2, another important mismatch repair (MMR) gene. Furthermore, up-to date, there has not been any report about methyl-CpG binding protein MeCP2 associated with tumor-related genes in gastric cancer.

In the present study, we examined the methylation and transcriptional level of tumor-related genes including p16^{INK4A}, hMSH2 and c-myc, and detected the expression of Dnmt1, mbd2 and MeCP2. We therefore analyzed their relationship in normal and cancerous stomach tissues.

MATERIALS AND METHODS

Patients

Paired samples of histologically verified primary gastric cancer and corresponding para-cancerous (3-5 cm from cancer margin) and non-cancerous gastric mucosae were obtained immediately from surgically resected specimens of 28 patients (C1-C28) treated at Renji Hospital, Shanghai, China. A complete written informed consent was obtained from all patients. They were all diagnosed pathologically by HE-stained sections and classified according to WHO's histological classifications of gastric carcinoma. The histological characteristics in para-cancerous area were chronic gastritis or intestinal metaplasia, and dysplasia was present in ten cases. The clinico-pathological features of each patient were reviewed and recorded (Table 1). The mean age of patients (19 men and 9 women) at resection was 58 (range 45-79) years. A portion of the tissues (approximately 1-3 g) was snap-frozen on dry ice and kept in liquid nitrogen until used for DNA or RNA extraction. Other portions were used for histological examination.

RNA extraction and reverse-transcription polymerase chain reaction (RT-PCR)

First, mRNA expression of tumor-related genes in cancerous, para-cancerous and non-cancerous tissues from each patient was detected by using RT-PCR and real-time PCR. Total RNA was extracted using a commercial kit (Trizol) according to the manufacturer's instructions (Gibco BRL). RT reactions using 5 µg of total RNA in 20 µL of reaction buffer were performed with Superscript II reverse transcriptase (Life Technologies, Inc). mRNA transcription levels of mbd2, MeCP2, p16^{INK4A} and c-myc genes were evaluated by using RT-PCR. The sequence and PCR reaction for each primer are shown in Table 2. For control of RT-PCR, a 612 bp fragment of β-actin cDNA was also amplified. At the end of 40 cycles, reaction products were separated electrophoretically on a 3% agarose gel and stained with ethidium bromide for visual confirmation of PCR products. The density of bands in RT-PCR in each lane was normalized to the amount of total RNA as determined by the density of the band in RT-PCR for β-actin^[7]. RT-PCR analysis

was repeated at least thrice.

Real-time quantitative PCR for Dnmt1 and hMSH2

mRNA levels of Dnmt1 and hMSH2 were measured using a real-time quantitative PCR system. Relative quantitation using the comparative Ct method with the data from ABI PRISM 7700 sequence detection system (version 1.6 software) was performed according to the manufacturer's protocol.

Real-time PCR was also performed with Taqman β-actin to normalize each of the extracts for amplifiable human DNA. The results were expressed as the ratio of copies of each gene to β-actin, respectively. The Ct values were measured, and the average Ct value of triplicate samples was calculated. Alteration of mRNA expression was defined as a 3-fold difference in the expression level^[8]. The primers and the Taqman fluorogenic probes for Dnmt1, hMSH2 and β-actin were provided by Jikang Company, Shanghai, China.

The sequences of all primers and probes, as well as PCR programs are shown in Table 3.

Methyl-specific PCR (MSP) for p16^{INK4A} and c-myc genes

To amplify the promoters of p16^{INK4A} and c-myc genes, we carried out bisulfite modification^[9] and MSP.

Bisulfite could convert unmethylated cytosine residues to uracil, but methylated cytosines remained non-reactive. PCR amplified uracil as thymine while methylated cytosines were only amplified as cytosines. Two micrograms of total genomic DNA (from at least two independent treatments corresponding to RT-PCR experiments) were isolated by using QIAamp DNA blood mini kit (QIAGEN Inc.), then denatured by NaOH and modified by sodium bisulfite solution (2.35 mol/L) containing hydroquinone (40 mmol/L) freshly prepared. The bisulfite-treated DNA was desalted using Wizard DNA clean up kit (Promega) and amplified by PCR using primers specific for methylated and unmethylated p16^{INK4A} and c-myc promoters. PCR reaction buffer contained 0.1 mmol/L dNTP, 2.0 mmol/L MgCl₂, and 0.5 μmol/L primers. PCR products were directly loaded onto 3% agarose gels and electrophoresed. The gel was stained with ethidium bromide and directly visualized under UV illumination. Furthermore, the primers for wild-type p16^{INK4A} and c-myc were used to monitor complete conversion of DNA obtained in the bisulfite reaction.

Bisulfite modification and sequencing (mapping) for hMSH2

Primers were designed in the region without CpG dinucleotides to amplify both methylated and unmethylated alleles in hMSH2. The PCR products were recovered using QIA quick gel extraction kit (Gibco). Direct sequencing was performed by using ABI PRISM BigDye terminator kit (PE Biosystems, Foster City, CA). The products of sequencing PCR included 22 CpG sites in promoter of hMSH2 gene.

The sequences of all primers and PCR programs are shown in Table 2.

Statistical analysis

Results were representative of at least three independent experiments performed in triplicate and presented as mean±SD. Comparisons between groups were made using Student's paired *t* test. Their relationship was analyzed by Fisher's exact test using the software SPSS.

RESULTS

Expressions of Dnmt1, mbd2 and MeCP2 genes in cancerous and non-cancerous gastric tissues

After quantitative PCR, the specific products visually confirmed on agarose gels were about 101- and 96 bp, and no non-specific products were obtained upon amplification of Dnmt1 and β-actin, respectively. In all cancerous, para-cancerous and non-cancerous tissues, their mRNA expressions were detected, and 32.2% (9/28) of cancerous tissues over-expressed Dnmt1, and the copies of Dnmt1 were higher than in non-cancerous tissues (5.08 vs 1).

mbd2 was expressed in all samples. However, mbd2 was down-regulated in 50% (14/28) of gastric cancer tissues, up-regulated in 10.7% (3/28) cases, and no significant change in 3.39% (11/28), respectively. Average value of mbd2 mRNA expression was lower in cancerous tissues than in non-cancerous tissue (Figures 1, 2). In 11 patients, mbd2 mRNA level in gastric cancer was particularly low, being reduced by 50% or more when compared with that in the corresponding non-cancerous mucosae. However, we did not find association between expressions of MeCP2 and Dnmt1 and mbd2.

In addition, we did not find the association of overall aberrant methylation and expressions of Dnmt1, MeCP2, mbd2 with the age of patients.

Examination of mRNA expression of tumor-related genes and status of promoter methylation in primary gastric cancers

Figure 1 shows the results from RT-PCR and real-time PCR,

and Figure 2 shows the relative mRNA levels of each gene after normalization with the signal of β-actin. These data demonstrated that the expressions of p16^{INK4A} and hMSH2 (data not shown) were down-regulated in cancerous tissues from 11 cases (39.3%) and 10 cases (35.7%) respectively, but there was no significant difference between cancerous and non-cancerous tissues. As shown in Figure 2, c-myc transcription level was up-regulated in 14 patients with gastric cancer, and the mean value of expression in cancerous tissues was greater than that in non-cancerous tissues (*P*<0.05).

Figure 1 mRNA expression of p16^{INK4A}, c-myc, mbd2 and MeCP2 in cancerous (lanes 1, 4, 7 and 10), para-cancerous (lanes 2, 5, 8 and 11) and non-cancerous (lanes 3, 6, 9 and 12) tissues from patients with gastric cancer by using RT-PCR.

Figure 2 Density of bands from RT-PCR in each lane normalized to the total RNA as determined by the density of bands in RT-PCR for β-actin. Assuming β-actin was 4 562.39 units (pixels of brightness), the calculation [4 562.39/(density of actin)]×(density of each gene) equals each gene normalized to β-actin. Data shown are representative of three separate experiments. ^a*P*<0.05.

To determine whether the expression of p16^{INK4A}, hMSH2 and c-myc genes in gastric cancer was associated with methylation, we selected the samples from cancerous, para-cancerous and non-cancerous tissues in ten patients for MSP or genomic bisulfite sequencing. Each tissue showed a positive 150 bp and a 151 bp band for methylated and unmethylated specific primer sets for p16^{INK4A}, indicating that the p16^{INK4A} gene was partially methylated in human gastric cancer. The methylated bands for the p16^{INK4A} gene in the cancerous and para-cancerous tissues were consistently stronger than the products of non-cancerous tissues (Figure 3A). Regarding c-myc gene, the methylated product (131 bp) was significantly lower and the unmethylated product (132 bp) was higher in cancerous and para-cancerous tissues than in non-cancerous tissues. Figure 3B displays representative examples of MSP products analyzed by electrophoresis on an agarose gel.

Bisulfite genomic sequencing of the representative PCR products of hMSH2 showed that all cytosines at non-CpG sites were converted to thymine. This excluded the possibility that successful amplification could be attributable to incomplete bisulfite conversion. Interestingly, methylation occurred at the -166 CpG site only (Figure 4).

Taken together, the results from MSP, sequencing, RT-PCR and real-time PCR indicated that hypermethylation of hMSH2

might be induced, inactivation and activation of c-myc were associated with its hypomethylation in human gastric cancer.

Figure 3 Hypermethylation of p16^{INK4A} promoter (A) and hypomethylation of proto-oncogene c-myc promoter (B) in gastric cancer tissue indicated by MSP. U: unmethylation-specific PCR; M: methylation-specific PCR.

Figure 4 Methylation analysis of hMSH2 gene promoter by bisulfite sequencing. The arrows indicate the changes of CG to TG in promoters of non-cancerous and para-cancerous tissue, but CG remained in cancerous tissues.

Correlation between mRNA expression of Dnmt1, mbd2 and DNA methylation

Dnmt1 was not associated with the methylation status of p16^{INK4A} or c-myc gene.

Among Dnmt1 down-regulated cases, 6 (60%) had over-expression of c-myc in cancerous tissues. In the cancer cases with up-regulated mbd2, all 3 had an expression of c-myc. We also found that there was a positive correlation in the expression of c-myc and mbd2 ($r=0.59$, $P=0.026$), MeCP2 ($r=0.64$, $P=0.02$), but c-myc had no positive correlation with Dnmt1.

In contrast to cancer tissues, all normal tissues had a positive association of p16^{INK4A} with MeCP2 ($r=0.483$, $P=0.02$) or mbd2 ($r=0.483$, $P=0.027$).

Among the 10 cases with down-regulated hMSH2, 6 cases had a decreased mbd2 mRNA, but there was no significant association between expressions of Dnmt1 and hMSH2.

Association of Dnmt1, mbd2 and histological change

There was no significant association between Dnmt1, mbd2 mRNA level and clinico-pathological parameters of the tumors, such as histological differentiation, size of tumor and lymph node metastasis. These data failed to indicate their aberrant expression as an early event in gastric cancer.

DISCUSSION

Generally, the global DNA methylation level is lower in cancer cells than in normal cells, and some loci tend to show hypomethylation of proto-oncogene in human gastrointestinal cancers^[10]. Recent studies demonstrated that DNA methylation could contribute to inactivation of tumor suppressor genes, a key event in tumorigenesis of a wide spectrum of human tumors^[11,12].

Three enzymes are responsible for DNA methylation. The carboxy-terminal domain of Dnmt1 could catalyse the methylation of DNA containing hemi-methylated CpG dinucleotides more

efficiently than unmethylated DNA *in vitro*^[13]. DNA demethylase was first identified by Szyf's group, and they demethylated both fully methylated and hemimethylated DNA, showing dinucleotide specificity, and could demethylate mCpG in different sequence contexts^[5]. The shortest form of methyl-CpG binding domain (MBD)2, mbd2b, has been proposed to be a DNA demethylase which has been cloned and characterized^[14]. MeCP2 is the first true member of the family of proteins that could selectively recognize methylated CpG^[15]. It is a single polypeptide characterized by an MBD and a transcriptional repression domain^[16,17]. Aberrant methylation in tumor-related genes was frequently detected in gastric intestinal metaplasia of both cancer and non-cancer patients, suggesting their early involvement in the multi-step progression of gastric carcinogenesis^[18]. However, little is known about the relationship of Dnmt1, demethylase, MeCP2 with tumor-related genes.

We found that the average mRNA level of Dnmt1 gene in cancerous tissue was higher and that of mbd2 gene was lower than that in non-cancerous tissue. Regarding Dnmt1 expression, these results are consistent with a study by Kanai^[4]. On the other hand, Patra found that MBD2 protein expression was significantly higher in benign prostatic hyperplasia BPH-1 cells and deficient in prostate cancer cell lines and in BPH tissues^[19]. For mbd2, our result is consistent with another experiment of gastrointestinal cancer^[3]. They suggested that the average levels of demethylase mRNA expression normalized to GAPDH mRNA were significantly lower in colorectal (0.81 ± 0.55) and gastric (2.88 ± 0.23) cancers than in the non-cancerous mucosae (1.90 ± 0.16 and 5.11 ± 0.34 , respectively, $P<0.0001$). However, up to date, we have not found any report about the expression of MeCP2 in gastric cancer. Darwanto found that colonic mucinous adenocarcinomas showed a strong MeCP2 expression^[20], and Muller observed a higher expression level of MeCP2 mRNA in breast cancer tissues than in non-cancerous tissues^[21].

Previous studies indicated that the mRNA expression level for Dnmt1 and mbd2 was not a critical determinant of promoter hypermethylation of tumor-suppressor gene p16^{INK4A} in gastric cancer^[6,22]. Regarding the hMLH1, the result was different in different studies^[6,23]. During gastric carcinogenesis, hypomethylation of c-myc proto-oncogene is common, and it has not been linked to Dnmt1, mbd2 or MeCP2, or hMSH2. In the present study, we demonstrated that there was a positive association of mbd2 and c-myc proto-oncogene in gastric cancerous tissues. The up-regulation of mbd2 was found in all patients with hypomethylated c-myc. The correlation of mbd2 expression with unmethylation of c-myc promoter suggests that c-myc may be a target for demethylation by the enzymes.

Another interesting gene we tested was hMSH2. The second important finding in this study was the decrease of mbd2 mRNA in most patients with down-regulated hMSH2, but we did not find any correlation between hMSH2 and Dnmt1 or MeCP2. It suggests that mbd2 is also involved in the regulation of hMSH2 expression in human gastric cancer. We did not test the promoter region of hMLH1 gene, because the promoter was not associated with Dnmt1^[6,23] and mbd2^[6] in human gastric cancer.

In addition, the data from our study demonstrated that the transcription level of Dnmt1, mbd2 and MeCP2 might not be associated with biological behaviours in human gastric cancer. Kanai also suggested there was no significant association between DNA demethylase mRNA level and malignant potential in gastric cancers^[5]. Although the mbd2 expression was lower both in early and in advanced cancers, we could not demonstrate a definitive relationship between the histology and mbd2 expression due to the small number of patients studied.

In conclusion, the up-regulation of proto-oncogene may be the consequence of epigenetic control of gene expression by demethylase, and mbd2 is also involved in the regulation of hMSH2 expression in human gastric cancer.

Abstract

AIM: To investigate the value of transabdominal ultrasonography (US) in the preoperative staging of gastric cancer.

METHODS: A total of 198 patients with gastric cancer underwent preoperatively transabdominal US, depth of tumor infiltration was assessed in 125 patients, and lymph node metastasis was assessed in 106 patients.

RESULTS: The staging accuracy of transabdominal US was 55.6%, 75.0%, 87.3% and 71.1% in T1, T2, T3 and T4 carcinomas, respectively. The overall accuracy was 77.6%. The detection rate for pancreatic invasion and liver invasion was 77.4%, 71.4%, respectively. The sensitivity, specificity, accuracy of transabdominal US in assessment of lymph node metastasis were 77.6%, 64.1%, 72.6%, respectively. Various shapes such as round, ovoid, spindle were encountered in benign and malignant lymph nodes. Majority of both benign and malignant lymph nodes were hyperechoic and had a distinct border. Benign lymph nodes were smaller than malignant lymph nodes in length and width ($P = 0.000$, 0.005). Irregular shape, fusional shape, infiltrative signs, inhomogenous echo were seen mainly in malignant lymph nodes ($P = 0.045$, 0.006 , 0.027 , 0.006).

CONCLUSION: Transabdominal US is useful for preoperative staging in gastric cancer, although it is difficult to differentiate benign from malignant lymph nodes.

INTRODUCTION

Gastric cancer is one of the most prevalent malignant tumors^[1,2]. An accurate preoperative staging is helpful for the prediction of prognosis and establishment of the individualized therapy. Although endoscopy and upper gastrointestinal series with double-contrast study have significantly improved the diagnostic accuracy in gastric cancer, they neither allow the assessment of the depth of tumor infiltration nor visualize perigastric lymph nodes^[3,4]. Currently, endoscopic ultrasonography (EUS) has

been considered as a useful modality for the preoperative staging of gastric cancer, and the accuracy of EUS in the assessment of the depth of tumor infiltration and lymph node metastasis is 67-92% and 63-78%^[5-11], respectively. However, EUS procedure is relatively complex, and can not be performed successfully in some patients, due to marked obstruction of gastric lumen caused by tumor or noticeable discomfort during examination.

Transabdominal ultrasonography (US) is applied widely in clinical practice. When condition of patients is suitable, transabdominal US can detect lymph nodes with a diameter of 5 mm, and the normal wall of fluid-filled stomach after the patients drank water can be described as a 5-layer structure^[12-14], which contributes to the assessment of the depth of tumor infiltration. Literature on the preoperative staging with transabdominal US is sparse^[15,16]. The aim of our study was to further assess the accuracy and limitations of transabdominal US in preoperative staging of the depth of tumor infiltration and lymph node metastasis.

MATERIALS AND METHODS

Between January 2000 to July 2003, 198 patients with gastric cancer confirmed by endoscopic biopsy underwent transabdominal US preoperatively. Patients with preoperative transabdominal US findings and detailed operative and pathological findings were included in this study. The depth of tumor infiltration was assessed in 125 patients (78 males, 47 females, ranged 27-78 years). Lymph node metastasis was assessed in 106 patients (66 males, 40 females, ranged 31-78 years).

All patients were required to drink water to fill stomach for the assessment of the depth of tumor infiltration. Transabdominal US was performed 3-5 min after 500-700 mL boiled water was drunk. Patients were examined usually in the supine position. Sitting position, left or right lateral decubitus position might be taken for visualization of lesions according to different locations of tumors.

The wall of fluid-filled stomach is described as a 5-layer structure^[12-14]. The innermost hyperechoic layer (the first layer) corresponds to the superficial mucosa, the second hypoechoic layer corresponds to the deep mucosa, the third hyperechoic layer corresponds to the submucosa plus the acoustic interface between the submucosa and muscularis propria, the fourth hypoechoic layer corresponds to the muscularis propria minus the acoustic interface between the submucosa and muscularis propria, the fifth hyperechoic layer corresponds to the subserosal fat and serosa.

According to the TNM (UICC) classification^[17], the depth of tumor infiltration was divided into 4 categories. T1 = tumor confined to mucosa or submucosa. For mucosal carcinoma, tumor located in the first and second layers, the third layers (submucosa) was intact; for submucosal carcinoma, layers 1 to 3 were interrupted or thickened and the fourth and fifth layers were normal sonographically (Figure 1A). T2 = tumor invading muscularis propria (the fourth layer) which became thickened, and the fifth layer was intact sonographically (Figure 1B). T3 = tumor invading serosa (the fifth layer), with interruption

Figure 1 Sonograms of T1-T4 carcinoma. A: Submucosal carcinoma (T1) in gastric antrum. Arrow indicates segmental thickening of layers 1-3 of the posterior wall, triangle indicates normal layers 4-5. B: T2 carcinoma. The posterior wall of Gastric body is thickening. Arrow indicates the third hyperechoic layer is obliterated and the fourth hypoechoic layer is thickening, triangle indicates normal layer 5. C: T3 carcinoma. Tumor located in the greater curvature of stomach (STO) is hypoechoic with disappearance of wall all layer (arrow). D: T4 carcinoma. Sonogram shows tumor located in antrum (AN) infiltrating duodenum. Arrow indicates the segmental wall thickening of duodenal bulb.

or disappearance of all layers of wall sonographically (Figure 1C). T4 = tumor invading adjacent organs which had an indistinct border and was indistinguishable from involved organs sonographically (Figure 1D).

Assessment of regional lymph node metastasis was performed in a fasting state before water was drunk for evaluation of tumor infiltration. Regional lymph nodes around the following organs or structures were examined: stomach, liver, pancreas, gallbladder, aorta, hilum of spleen, comma hepatic aorta, superior mesenteric artery, celiac artery, and recorded number, size, shape, border, and echogenicity of lymph nodes.

Lymph nodes with a length of 5 mm or greater were considered metastatic. Regional lymph node staging was classified as N0 (no lymph node metastasis) and N+ (lymph node metastasis).

Lymph nodes detected with transabdominal US were divided into 3 groups according to their shapes: regular, irregular, fusional. Regular lymph nodes were classified into 3 categories of shape: spindle: width \leq half the length of the lymph node; ovoid: width \leq three quarters of the length of the lymph node; round: width $>$ three quarters of the length of the lymph node^[18].

The followings were considered as "infiltrative signs" of lymph nodes: ill-defined border, indistinguishable from the adjacent structures or loss of movement.

Sonographic examinations were performed with commercially available real time image units (Toshiba 6000, Aloka 2000, DU-6), and transducer frequency varied between 3.5-6.0 MHz.

Data were analyzed with SPSS10.0 software. $P < 0.05$ was considered statistically significant.

RESULTS

Assessment of depth of tumor infiltration

Table 1 summarizes the findings of transabdominal US and operative or pathological findings in 125 patients with gastric cancer. The accuracy of transabdominal US in staging of T1 carcinomas was 55.6%, 75.0% in T2 carcinomas, 87.3% in T3

carcinomas, and 71.1% in T4 carcinomas. The overall accuracy was 77.6%.

Tumors were overstaged in 8 patients. T1 carcinoma was overstaged as a T2 carcinoma in 3 patients and as a T3 carcinoma in 1 patient (Figure 2), and T2 carcinoma was overstaged as a T3 carcinoma in 4 patients. Tumors were understaged in 20 patients. T3 carcinoma was understaged as a T2 carcinoma in 7 patients. T4 carcinoma was understaged as a T2 carcinoma in 2 patients and as a T3 carcinoma in 11 patients.

Invasion of adjacent organs confirmed by operative or pathologic findings was as follows (Table 2): pancreas (31 patients), liver (7 patients), spleen and hilum of spleen (3 patients), transverse colon (3 patients), diaphragm (2 patients), and duodenum (9 patients). The detection rate for pancreas and liver invasion with transabdominal US was 77.4% and 71.4%, respectively, whereas the detection rate for the invasion of other organs was low.

Figure 2 Mucosal carcinoma (T1) was overstaged as a T3 carcinoma with transabdominal US. Sonogram of gastric body shows hypoechoic wall thickening with ulcer (arrow), loss of wall five-layer structure (triangle).

Table 1 Accuracy of transabdominal US in assessing the depth of tumor invasion in 125 patients

Stage	n	Staged by operative and pathological findings			
		T1	T2	T3	T4
T1	7	5	0	0	0
T2	34	3	12	7	2
T3	80	1	4	48	11
T4	38	0	0	0	32
Accuracy (%)	55.6 (5/9)	75.0 (12/16)	87.3 (48/55)	71.1 (32/45)	

Table 2 Detection rate of tumor invasion with transabdominal US

Involved organs	n	Cases detected with transabdominal US	Detection rate (%)
Pancreas	31	24	77.4
Liver	7	5	71.4
Spleen and hilum of spleen	3	1	33.3
Transverse colon	3	1	33.3
Diaphragm	2	0	0
Duodenum	9	4	44.4

Assessment of regional lymph node metastasis

Accuracy of assessment of regional lymph metastasis Swollen lymph nodes were found pathologically in 106 patients. Lymph node metastasis was confirmed in 67 of 106 patients. Swollen lymph nodes were detected in 66 of 106 patients with transabdominal US. All lymph nodes detected sonographically had a length of 5 mm or greater, and were considered as metastatic. Of the 66 patients, lymph node metastasis was confirmed by pathological examination in 52 patients, and swollen lymph nodes were benign in the remaining 14 patients. No swollen lymph nodes were detected sonographically in 40 of 106 patients, and lymph node metastasis was confirmed in 15 of these 40 patients. The sensitivity of transabdominal US in the assessment of lymph node metastasis was 77.6% (52 of 67 patients). The specificity was 64.1% (25 of 39 patients). The accuracy was 72.6% (77 of 106 patients) (Table 3).

Table 3 Accuracy of transabdominal US in assessing lymph node metastasis in 106 patients

Diagnosis with transabdominal US	Pathological findings (n)	
	N+	N0
N+	52	14
N0	15	25

Sensitivity: 77.6% (52/67); Specificity: 64.1% (25/39); Accuracy: 72.6% (77/106).

Sonographic features of benign and malignant lymph nodes

All lymph nodes in 14 of 66 patients with swollen lymph nodes detected with transabdominal US were confirmed benign (lymph

node without metastasis), and transabdominal US detected 46 lymph nodes in these patients. All lymph nodes in 11 of 52 patients with lymph node metastasis were confirmed malignant (metastatic), and transabdominal US detected 48 lymph nodes in these patients. Forty-six benign lymph nodes had a mean length of 1.26 cm and a mean width of 0.84 cm, 48 malignant lymph nodes had a mean length of 1.79 cm and a mean width of 1.25 cm. According to size, shape, echogenicity, and border, sonographic features of these benign and malignant lymph nodes were further analyzed (Table 4). The length and width of benign lymph nodes were significantly smaller than those of malignant lymph nodes ($P = 0.000, 0.005$). Sonographic features such as irregular or fusional shape, infiltrative signs, and inhomogenous echoes were found mainly in malignant lymph nodes (Figure 3). There was a significant difference between benign and malignant lymph nodes ($P = 0.045, 0.006, 0.027, 0.006$).

Table 4 Sonographic features of 46 benign and 48 malignant lymph nodes

B: Sonogram shows fusional-shaped lymph node (arrow) (4×3 cm) adjacent to the stomach (STO), invading adjacent tissues and having an indistinct border.

DISCUSSION

Assessment of the depth of tumor invasion in gastric cancer

Compared with the operative and pathological findings, the accuracy of transabdominal US for T1, T2, T3, T4 was 55.6%, 75.0%, 87.3%, 71.1%, respectively, and the overall accuracy was 77.6% (Table 1).

Although the accuracy of transabdominal US in staging of T1 carcinoma was low (55.6%), T2, T3, and T4 staging results were compared favorably with those of EUS T staging. Lim *et al.*^[15] reported the accuracy of staging in early-stage carcinoma was 66.7% (10 of 15 patients) with transabdominal US. In the study of Segura *et al.*^[16], the accuracy of transabdominal US for T1, T2, T3, T4 was 100%, 50%, 87%, 81%, respectively. Due to the small number of patients with early stage carcinoma (2 patients), the results of T1 staging required further investigation.

In our study, the accuracy for T3 carcinomas was the highest (87.3%) among the four groups with different depths of infiltration. The normal serosal layer was a thin and smooth hyperechoic band sonographically. When tumor invaded into the serosal layer, this band was interrupted or disappeared, which could be assessed easily with transabdominal US.

In our study, the accuracy for T1 carcinomas was most unfavorable (55.6%) because of overstaging in 4 patients, of which 3 had ulcerative carcinoma. Similarly, misdiagnosis was made in 4 patients with T2 carcinoma due to overstaging as a T3 carcinoma, and these 4 patients also had ulcerative carcinoma. Previous studies showed that the hyperechoic submucosal layer became hypoechoic because of inflammation or edema around the tumor, which was similar to echogenicity of muscularis propria and tumor. It was difficult to differentiate 3 layers with transabdominal US^[19], so T1 carcinoma might be overstaged as T2 carcinoma (tumor invading muscularis propria). On the other hand, the ulcer in gastric cancer may cause gastric wall fibrosis and scar, which lead to wall thickening, loss of wall layers, and even interruption or disappearance of serosal layer, therefore, overstaging as T3 carcinoma may occur in T1 or T2 carcinoma (Figure 2). Difficulties in differentiation between tumors and peritumor inflammation or scar may be an important source of overstaging^[5,6,15,20-23].

As shown in Table 1, misdiagnosis was made in T1 and T2 carcinomas because of overstaging. On the contrary, misdiagnosis was made in T3 and T4 carcinomas because of understaging. The possible reasons for understaging were as follows: (1) The procedure did not practise adequately, because transabdominal US was technically difficult to perform and may fail to guarantee a correct diagnosis for tumors locating in gastric fundus, greater curvature or cardia^[15]. Tumors in 8 of 20 understaged patients located in the above locations, respectively. (2) Location of involved organs also affected the diagnosis, because it was difficult to clearly visualize hilum of spleen, diaphragm, and the tail of pancreas. Invasions of the tail of pancreas (4 patients), diaphragm (2 patients), spleen and hilum of spleen (2 patients) were not detected with transabdominal US. (3) Microscopic tumor invasion undetected with transabdominal US was another cause of understaging^[6], which occurred in 2 patients with T3 carcinoma.

Assessment of adjacent organ invasion with transabdominal US

The fact that gastric cancer invaded into adjacent organs would decrease surgical resectability, so it is important to assess preoperatively if organs are invaded by gastric cancer.

In our study, the followings were taken as the diagnostic criteria for gastric cancer invading into organs: interruption of the serosal layer of gastric wall, indistinguishable from adjacent organs, tumor and organs moving synchronously slow or no moving as breath changed.

Pancreas was the most common organ invaded by tumor, the detection rate in this study was 77.4%. In 3 of 7 patients undetected by transabdominal US, pancreas was invaded slightly, and the boundary between pancreas and tumor seemed to exist on sonogram, thus leading to understaging. In the remaining 4 patients, the tail of pancreas was invaded, which was not detected by transabdominal US due to interference of bowel gas and ribs.

The detection rate for liver invasion was higher (71.4%). Tumors invading liver located in anterior wall of stomach or lesser curvature and were close to the liver. The relationship between tumor and liver could be visualized clearly by using ultrasonographic beam through liver without interference of bowel gases.

Transverse colon was invaded in three patients, of them, correct diagnosis was made in 1 patient because complete circumference of transverse colon was invaded and marked tumor was detected. In two others undetected by transabdominal US, transverse colon was slightly invaded and bowel gases interfered severely. Correct diagnosis was made preoperatively in 1 of 3 patients with spleen and its hilum invasion. None was diagnosed preoperatively for diaphragm invasion. Spleen and its hilum, and diaphragm could not be observed completely with transabdominal US, leading to the low detection rate.

Correct diagnosis was made preoperatively in 4 of 9 patients with duodenum invasion. It was necessary to fill duodenum by drinking water for the assessment of duodenum. Because tumor caused gastric lumen obstruction, duodenum was not filled adequately and visualized clearly, leading to misdiagnosis of duodenum invasion.

Assessment of lymph node metastasis and differentiation between benign and malignant lymph nodes

The sensitivity of transabdominal US for lymph node metastasis was 77.6%, and the false positive rate was 13.2% (14 of 106 patients). The results showed transabdominal US did not permit the differentiation between benign and (metastatic) malignant lymph nodes in gastric cancer (Figures 4, 5).

Benign swollen lymph nodes due to immune reaction in patients with tumor are misdiagnosed easily as malignant lymph nodes. According to the analysis of sonographic features of lymph nodes (Table 4), benign lymph nodes were smaller than malignant lymph nodes in length and width ($P = 0.000, 0.005$). From Table 5, if the length ≥ 1.1 cm or 1.6 cm was defined as diagnostic criteria of malignant lymph nodes, the sensitivity was 81.3% and 47.9%, respectively, and the specificity was 56.5% and 76.1%, respectively. Hence the criteria could not differentiate benign from malignant lymph nodes. If the length ≥ 2.1 cm or the width ≥ 1.6 cm was defined as diagnostic criteria of malignant lymph nodes, the sensitivity was 33.3% and 29.2%, respectively, and the specificity was 95.7% and 93.5%, respectively. This result showed that lymph node with a length ≥ 2.1 cm or width ≥ 1.6 cm increased significantly the probability of metastasis. From the literature and our study, although benign lymph nodes were smaller than malignant lymph nodes, it is clear that there was a considerable overlap in size between benign and malignant lymph nodes; therefore, the value of lymph node size is limited for discriminating benign lymph nodes from malignant lymph node^[18,24,25].

In our study (Table 2), benign and malignant lymph nodes in round shape were encountered most commonly (Figures 4, 5) and spindle and ovoid lymph nodes were also seen, there was no significant difference between two kinds of lymph nodes. Malignant lymph nodes in irregular shape were mostly seen, and all fusional-shaped lymph nodes were malignant (Figure 3), there was a significant difference between benign and malignant lymph nodes ($P = 0.045, 0.006$). It was reported that

Figure 4 Differentiation between benign and metastatic lymph nodes. A: Benign lymph nodes. Sonogram shows multiple small lymph nodes (arrow) adjacent to the lesser curvature of stomach (STO). These hypoechoic lymph nodes are 5-8 mm, and misdiagnosed as metastatic with transabdominal US; Pathologic examination confirms that all these lymph nodes are reactive and noncancerous. B: Metastatic lymph nodes. Sonogram is similar to figure A. Multiple hypoechoic small lymph nodes (arrow) adjacent to the lesser curvature of stomach (STO) are 5-9 mm, and confirmed metastatic by pathologic examination.

Figure 5 Differentiation between benign and metastatic lymph nodes. A: Benign lymph nodes. Sonogram shows multiple hypoechoic lymph nodes (arrow) adjacent to the greater curvature of stomach (STO). Of them, the largest is 1.8 cm with a distinct border. These lymph nodes are misdiagnosed as metastatic with transabdominal US. Pathologically, all these lymph nodes are reactive and noncancerous. B: Metastatic lymph node. Sonogram shows hypoechoic lymph node (arrow) adjacent to the lesser curvature of stomach (STO) with 1.6 cm in size and a distinct border. Pathologic examination confirms this lymph node is metastatic.

abdominal malignant lymph nodes were round or ovoid in shape, conversely, benign lymph nodes in people who were healthy or affected by benign disease were spindle or flat in shape^[9,18,24,26-30]. However in our study, both benign and malignant lymph nodes were mostly round in shape, and round shape did not allow the correct differentiation between benign and malignant lymph nodes. Immune reaction caused by tumor was different from that caused by benign diseases such as hepatitis or entities, which may be a cause for difficulties in differentiation between benign and malignant lymph nodes.

In our study the majority of benign and malignant lymph nodes had a distinct border (Figure 5), without statistical difference between them (Table 4). "Infiltrative signs" of lymph nodes were seen only in malignant lymph nodes ($P = 0.027$), which were typical and helpful for diagnosing malignant lymph nodes. Heintz *et al.*^[31] reported that both benign and malignant lymph nodes had an indistinct or distinct border by studying surgical resection specimens of patients with esophageal and gastric carcinomas. The study reported by Akahoshi *et al.*^[29,32] showed that malignant lymph nodes had a distinct border.

Table 4 shows that both benign and malignant lymph nodes were hypoechoic mostly (Figures 3-5), and the small number of lymph nodes was hyperechoic. There was no difference between benign and malignant lymph nodes. Inhomogenous echogenicity was seen only in malignant lymph nodes, there was a significant difference between benign and malignant lymph nodes ($P = 0.006$) and majority of inhomogenous lymph nodes were 2 cm greater in length. Contradictory data were published for echogenicity of lymph nodes. Heintz *et al.*^[31] stressed that echogenicity did not allow the correct differentiation

between benign and malignant lymph nodes. Other authors^[24,33] reported that most malignant lymph nodes were hypoechoic, and most benign lymph nodes were isoechoic or slightly hyperechoic. The different results might result from different patients studied.

In our study, the following 4 sonographic features were taken as the diagnostic criteria of malignant lymph nodes (Table 5): irregular shape, fusional shape, infiltrative signs, and inhomogenous echo. The sensitivity of the criteria was lower than 20 percent, and the specificity was higher than 90 percent. One of these 4 features was helpful to suggest malignant, however the similar sonographic features were observed in abdominal tuberculosis. Differential diagnosis was made on the basis of medical history.

Table 5 Diagnostic results of 46 benign and 48 malignant lymph nodes

Criterion	Sensitivity (%)	Specificity (%)
Length ≥ 1.1 cm	81.3 (39/48)	56.5 (26/46)
≥ 1.6 cm	47.9 (23/48)	76.1 (35/46)
≥ 2.1 cm	33.3 (15/48)	95.7 (44/46)
Width ≥ 1.1 cm	50.0 (24/48)	84.8 (39/46)
≥ 1.6 cm	29.2 (14/48)	93.5 (43/46)
Irregular	16.7 (8/48)	95.7 (44/46)
Fusional	16.7 (8/48)	100 (46/46)
Infiltrative signs	12.5 (6/48)	100 (46/46)
Inhomogenous	16.7 (8/48)	100 (46/46)

Swollen lymph nodes were found pathologically in 106 patients. But no swollen lymph nodes were detected with transabdominal US in 40 of 106 patients, and lymph nodes metastases were confirmed pathologically in 15 of these 40 patients. Missing lymph nodes were associated with the size of lymph nodes mainly. Lymph nodes less than 5 mm in size were usually undetectable with transabdominal US. In addition, obesity and bowel gas were unfavorable for detection of lymph nodes.

In conclusion, transabdominal US is useful for preoperative staging of gastric cancer, especially for assessment of advanced gastric cancer invasion. Although it is difficult to differentiate benign from malignant lymph nodes, typical sonographic features might contribute to diagnosis.

Abstract

AIM: To analyze the factors influencing the prognosis of patients with gastric cancer after surgical treatment, in order to optimize the surgical procedures.

METHODS: A retrospective study of 2 613 consecutive patients with gastric cancer was performed. Of these patients, 2 301 (88.1%) received operations; 196 explorative laparotomy (EL), 130 by-pass procedure (BPP), and 1 975 surgical resection of the tumors (891 palliative resection and 1 084 curative resection). The survival rate was calculated by the actuarial life table method, and the prognostic factors were evaluated using the Cox regression proportional hazard model.

RESULTS: Of the patients, 2 450 (93.8%) were followed-up. The median survival period was 4.6 mo for patients without operation, 5.2 mo for EL, 6.4 mo for BPP, and 15.2 mo for palliative resection ($P = 0.0001$). Of the patients with surgical resection of the tumors, the overall 1, 3 and 5-year survival rates after were 82.7%, 46.3% and 31.1%, respectively, with the 5-year survival rate being 51.2% in patients with curative resection, and 7.8% for those with palliative resection. The 5-year survival rate was 32.5% for patients with total gastrectomy, and 28.3% for those with total gastrectomy plus resection of the adjacent organs. The factors that independently correlated with poor survival included advanced stage, upper third location, palliative resection, poor differentiation, type IV of Borrmann classification, tumor metastasis (N_3), tumor invasion into the serosa and contiguous structure, proximal subtotal gastrectomy for upper third carcinoma and D₁ lymphadenectomy after curative treatment.

CONCLUSION: The primary lesion should be resected as long as the local condition permitted for stage III and IV tumors, in order to prolong the patients' survival and improve their quality of life after operation. Total gastrectomy is indicated for carcinomas in the cardia and fundus, and gastric cancer involving the adjacent organs without distant metastasis requires gastrectomy with resection of the involved organs.

INTRODUCTION

Although the mortality rate of gastric cancer has been dramatically decreased in the western country since 1930^[1], cancer of the stomach remains the second most frequent malignancy in the world^[2,3], and an estimate of more than 1 million new cases were identified worldwide in 1997^[4]. From 1990 to 1992, the mortality rate of gastric cancer in China remained at a high level of 25.2/100 000, taking up 23.2% of the total cancer-related death, and claiming the largest death toll in cancer patients^[5]. As the generally acknowledged primary treatment modality for gastric cancer, surgical interventions^[6-9] give rise to many controversies concerning (1) the decision on palliative resection, by-pass procedure or avoidance of operation for advanced gastric cancer (including stage III_B or IV), (2) the optimal extent to be resected in patients with gastric cancer in the upper third, by total gastrectomy (TG) or proximal subtotal gastrectomy (PSTG), and (3) the optimal surgical resection for gastric cancer involving the neighboring organs. The aim of this retrospective study was to analyze the factors influencing the patients' prognosis after surgical treatment, curative or palliative, of gastric cancer, and find answers to above questions.

MATERIALS AND METHODS

Clinical data

This study included 2 613 patients with primary gastric cancer admitted in Department of Oncology, Affiliated Union Hospital of Fujian Medical University, during the period of June 1972 to June 2000. There were 2 059 male and 554 female patients whose ages ranged from 19 to 85 years with a mean of 55.6 ± 2.48 years. The tumors were found in the gastric cardia and fundus in 871 cases, in the gastric body in 544 cases, in the gastric antrum in 1 069 cases and involving the entire stomach in 129 cases. The dimension (maximum diameter) of the tumor was smaller than 3 cm in 254 cases, between 3.1 and 6 cm in 1 290 cases and more than 6 cm in 1 069 cases. The tumors were histologically classified according to WHO classification criteria, and staged according to the TNM system used since 1989 in China^[10], as listed in Table 1.

Table 1 Histological classification of the tumors in the 2 613 patients with gastric cancer

Histological classification	Number	Percentage (%)
Well differentiated adenocarcinoma	528	20.2
Moderately differentiated adenocarcinoma	1102	42.2
Mucinous adenocarcinoma	560	21.4
Poorly differentiated adenocarcinoma	277	10.6
Others	146	5.6
Borrmann's classification		
Type I	179	6.9
Type II	477	18.3
Type III	1683	64.4
Type IV	129	4.9
Early-stage cancer	145	5.6

Methods

Of all those patients, 312 had not received any previous surgical intervention, and 2 301 (88.1%) had undergone operations. Among the patients with a history of previous operations, 196 had explorative laparotomy (EL), 130 had by-pass procedure (BPP), 1 975 underwent surgical resection of the tumor, of whom 891 received palliative resection. The tumor resection was considered palliative on the basis of the presence of residual tumor or distant metastasis or both at the end of surgery. A total of 1 084 patients underwent curative resection, making up 54.9%. The surgical procedure was defined as curative when no grossly visible tumor tissue (metastasis or lymph node involvement) remained after the resection and the resection margins were histologically normal.

In all the 1 975 surgical patients, distal subtotal gastrectomy (DSTG) was performed in 894 patients, total gastrectomy (TG) in 615, and proximal subtotal gastrectomy (PSG) in 466. Among the patients undergoing curative resection, limited D₁ nodal dissection was performed in 159 patients (during the period of 1 972 to 1 979), extended D₂/D₂⁺ in 846 and extended D₃ in 79. The clinical data of the 1 975 patients with surgical tumor resection are shown in Table 2. Metastases involving such organs as the esophagus, spleen, pancreas, colon and the duodenum were identified in 439 patients.

Table 2 Clinical data of the 1 975 patients with surgical resection of the tumor

Characteristics	Number	Percentage (%)
Type of resection		
Radical resection	1 084	54.9
Palliative resection	891	45.1
Depth of invasion (T)		
Mucosa/submucosa (PT ₁)	145	7.3
Muscularis (PT ₂)	347	17.6
Serosa (PT ₃)	978	49.5
Serosa and contiguous structure (PT ₄)	505	25.6
Lymph node involvement (N)		
N ₀	207	10.5
N ₁	343	17.4
N ₂	936	47.4
N ₃	489	24.7
Stage		
I _A	125	6.3
I _B	131	6.6
II	251	12.7
III _A	404	20.5
III _B	442	22.4
IV	622	31.5
Type of nodal dissection (radical resection)		
D ₁	159	14.7
D ₂ /D ₂ ⁺	846	78.0
D ₃	79	7.3

The 5-year cumulative survival was calculated after both curative and palliative tumor resection by actuarial life-table method. Statistical analysis was carried out by using Chi-square test and Wilcoxon rank sum test. Multivariate analysis was applied using the Cox regression proportional hazard model. The SPSS 10.0 for Windows was used for all the statistical analyses.

RESULTS

Among the 2 613 patients with gastric cancer, 163 failed to be followed-up with the follow up rate of 93.8%. Postoperative complications arose in 189 cases with an incidence of 9.6%. Death within one month after operation occurred in 41 cases (2.1%).

The survival rate was calculated in 1 498 patients with surgical resection, curative and palliative, of the tumors. Univariate and multivariate analyses were used to evaluate 5-year survival rate with respect to the main clinicopathologic and treatment variables after both curative and palliative treatment. The overall 5-year survival after surgical resection (operative mortality excluded) was 31.6%, 51.2% for curative treatment, and 7.8% for palliative resection; 91.1% for stage I_A, 86.7% for stage I_B, 51.1% for stage II, 34.5% for stage III_A, 29.1% for stage III_B, and 5.9% for stage IV (Figure 1, Table 3). The median survival period was 4.6 mo after NO, 5.2 mo after EL, 6.4 mo after BPP, and 15.2 mo after palliative resection ($P = 0.0001$). The 5-year survival rate was 32.5% for patients with total gastrectomy, and 28.3% for those with total gastrectomy plus resection of the adjacent organs. Univariate and multivariate survival analyses showed that the variables independently correlated with poor survival included advanced stage, upper third location, palliative resection, poorly differentiated adenocarcinoma, type IV of Borrmann classification, tumor metastasis (N₃), tumor invasion into the serosa and contiguous structure, proximal subtotal gastrectomy for upper third carcinoma and D₁ lymphadenectomy after curative treatment (Table 4).

Figure 1 Survival curves of the 1 498 patients of different clinical stages undergoing surgical resection (radical and palliative) with operative death excluded.

DISCUSSION

Surgical treatment of gastric cancer has been universally recognized as the most effective way of treatment, and the 5-year survival rate of curative resection in this study reached 51.2%. Although curative resection for gastric cancer is most effective, most cases are in stage III and IV on identification in China^[11-13], as seen from the high rate of 74.9% in this study, and many of them were ineligible for radical treatment. Ekbom *et al.*^[14] reported that BPP in advanced cases only resulted in the average survival period of 5.9 mo, and none of the patients survived for more than one year, similar to the results of without tumor resection^[15]. The average survival periods of patients without operation, with EL and BPP in China, as reported by

National Gastric Cancer Cooperation Organization, were 4.1, 4.7, and 5.5 mo, respectively^[11], comparable with our findings (4.6, 5.2, and 6.4 mo, respectively, $P>0.05$). In this study, the survival period after palliative resection was 15.2 mo with a 5-year survival rate reaching 7.8%, significantly higher than that in patients without operation or with EL and BPP ($P<0.01$). Therefore, for stage III and IV gastric cancer, resection of the primary focus should be performed as much as possible. After the resection, the patient's condition might be improved to tolerate postoperative chemotherapy, immunotherapy and comprehensive treatment by traditional Chinese medicine, and the survival period of the patients might consequently be prolonged and quality of life improved^[16-20].

There is still controversy over the impact of the extent of resection for tumors located in the upper third of the stomach (including cardia and fundus)^[21]. Some researchers^[22-25] advocate the performance of PSG so as to possibly retain the stomach even partially, and proper digestive function. It also enables patients to avoid the late stage complications following TG. However, Fujimaki and Lin discovered in their respective research that the rate of lymphatic metastasis of group 5 and 6 might reach up to 24.0% to 29.0% in some cases^[26,27]. It is difficult to eliminate all tumor tissues without performing TG. The incidence of postoperative regurgitant esophagitis is high and volume of residual stomach is small, and TG may overcome these defects to improve the 5-year survival rate^[28-31]. According to the review of our 28-year experience with the treatment of gastric cancer, two types of resection for cancer of the cardia (the upper 1/3 location) irrespective of the tumor stage contributed to a 5-year survival rate after TG of up to 32.5%, while the 5-year survival rate after PSG was only 20.1%, showing significant difference ($P<0.05$). Following great improvements in surgical techniques, postoperative care and measures of digestive tract reconstruction, postoperative complication and death rate have been remarkably decreased^[32-34]. The incidence of complication was only 12.7% and death rate 2.9% in the 615 patients receiving TG in this study. In recent years, we attempted routine TG for treating cancer of the upper 1/3 location as long as the patients' general condition permitted, and of all gastrectomy cases, 31.1% were received TG in the study.

In approximately 15.5-22.3% of patients with advanced gastric cancer, the malignancy had already invaded the neighboring organs when the diagnosis was established^[11,35,36], requiring critical decisions on the treatment for the best interests of the patients. In this study, 439 cases (22.9% of those with surgical resection) had combined resection of the involved organs, and the total 5-year survival rate was 28.3%. In these cases extensive radical resection of gastric cancer combined with resection of the spleen and the body and tail of pancreas was found to produce the best therapeutic effect, yielding a 5-year survival rate of 43.2%. For treatment of 28 cases of advanced gastric cancer involving multiple neighboring organs, left upper abdominal evisceration (LUAE) and resection of the total stomach, lower end of esophagus, left lobe of liver, spleen, body and tail of pancreas, transverse colon and partial suprarenal gland were performed, resulting in a 5-year survival rate of up to 16.7%. One of the patients has survived for 10 years. Pessimism toward gastric cancer invading nearby organs is not reasonable. For gastric cancer with metastasis to adjacent organs, but without incurable factors such as liver metastasis, peritoneal dissemination (P₂ and P₃) and widespread nodal involvement, complete excision of the invaded organs should be performed as much as possible, irrespective of the number or site of the invaded organs. Cure is possible in some cases of advanced gastric cancer. In cases with incurable factors, partial resection of the involved organs is not recommended, as it almost invariably fails to prolong the patients' survival in comparison with simple resection of the primary focus of gastric cancer, but increases the sufferings of the patient and prolongs the operation time.

Palliative operation to resect the primary focus might be a better alternative, for it not only relieves obstruction, hemorrhage and pain, but also prepares favorable condition for other postoperative treatments and at the same time, improves the quality of life and prolongs the survival period of the patient.

Abstract

AIM: In recent years, studies have suggested that Epstein-Barr virus (EBV) is associated with HCC. The present study was to determine the prevalence of EBV in HCC patients, and whether EBV acted synergistically with hepatitis viruses in HCC carcinogenesis.

METHODS: Liver tissue 115 HCC patients and 26 non-carcinoma patients were studied. Polymerase chain reaction (PCR) was performed to detect EBV *Bam*HI W DNA, EBV LMP1 DNA, HBV X DNA, and HBV S DNA. Reverse transcription PCR (RT-PCR) was performed to detect HCV RNA and HDV RNA. Immunohistochemistry was performed to detect LMP1, HBsAg, HBcAg and HCV. The positive ratios were compared between HCC group and control group by χ^2 test.

RESULTS: Totally, 78 HCC samples whose β -globulin DNA was positively detected by amplified PCR were selected. PCR was performed in all cases for EBV DNA and HBV DNA. RT-PCR was performed in 18 cases for HCV RNA and HDV RNA. EBV *Bam*HI W and EBV LMP1 were positive in 18 and 6 cases, respectively. HBV X gene and HBV S gene were positive in 42 and 27 cases respectively. HCV was positive in one of the 18 cases, and none was positive for HDV. The positive rates were 28.2% (22 of 78) for EBV DNA (*Bam*HI W and/or LMP1) and 56.4% (44 of 78) for HBV DNA (X gene and/or S gene) respectively. In addition, 12 cases were positive for both EBV DNA and HBV DNA. Among the 26 cases in the control group, 2 cases were positive for EBV *Bam*HI W, 4 positive for HBV X gene and 3 positive for HBV S gene. The positive rates were 8.0% (2 of 26) and 23.1% (6 of 26), respectively, for EBV DNA and HBV DNA. The result of DNA sequencing of *Bam*HI W was 100% homologous with the corresponding sequence of B95-8. There was significant difference in EBV infection rate between HCC patients and controls ($\chi^2 = 4.622$, $P < 0.05$). The difference in HBV infection rate was also significant ($\chi^2 = 8.681$, $P < 0.05$). However, there was no obvious correlation between HBV and EBV in HCC patients ($\chi^2 = 0.835$, $P > 0.05$). LMP1, HBV (HBsAg, HBcAg) and HCV were detected positively in 25, 45 and 6 of 78

cases of HCC tissues respectively. In the 26 control cases, the corresponding positive cases were 2, 4 and 0. The difference in EBV infection rate between HCC patients and control cases was statistically significant ($\chi^2 = 6.02$, $P < 0.05$). The difference in HBV infection rate was also statistically significant ($\chi^2 = 10.03$, $P < 0.05$). In the 25 cases with positive LMP1 expression, 6 were in the nuclei of tumor cells, 9 in the cytoplasm of tumor cells and 10 in mesenchymal lymphocyte cytoplasm.

CONCLUSION: The existence of EBV infection in HCC tissues suggests that EBV may be involved in the hepatocellular carcinogenesis in China. HBV infection may be a major cause of HCC. There is no correlation between EBV and HBV in the development of HCC. The prevalence of HCV infection is low in our area, and HDV appears not to play a direct role in hepatocellular carcinogenesis.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most frequent malignant tumors. It possesses the characteristics of high malignancy, rapid progress and poor prognosis. In recent years, studies have suggested that Epstein-Barr virus (EBV) is associated with HCC although opposite results have been subsequently reported. The present study was to determine the prevalence of EBV in hepatocellular carcinoma (HCC) patients, and whether EBV acted synergistically with hepatitis viruses in HCC carcinogenesis.

MATERIALS AND METHODS

Patients and tissue samples

HCC samples from 115 patients, which were resected in the First Affiliated Hospital of Medical College, Shantou University and Shantou Central Hospital between October 1997 and October 2001, were fixed in 40 g/L neutral formaldehyde and embedded in paraffin. Of these, 78 samples satisfied the criteria that their β -globulin DNA presented positive. The patients consisted of 59 men and 19 women. Their ages ranged from 22 to 76 years (average 50.2 ± 2.4 years). According to the Edmondson (1956) HCC morphology standard, two, 34, 30 and 12 cases belonged to the levels I, II, III and IV, respectively. AFP was detected in 48 cases; the level was lower than 0.14 ng/mL in four cases, between 0.14 ng/mL and 5.6 ng/mL in 14 cases and higher than 5.6 ng/mL in 12 cases. Anti-hepatitis B virus (HBV) assay was performed by enzyme-linked immunosorbent assay (ELISA) in 62 cases, and 54 were positive. Anti-hepatitis C virus (HCV) assay was carried out in 58 cases and anti-EBV EA-IgA and VCA-IgA assays in 43 cases. The control group consisted of 20 cases with hepatolithiasis and lobectomy of liver, three cases with hepatic adenoma and three cases with hepatocyte focal nodular hyperplasia. HBV was positive in 10 cases. HCV and EBV were negative in all cases.

Reagents

Taq DNA polymerase, dNTP mixture, AMV reverse transcriptase XL, RNase inhibitor, random primer and DNA marker were purchased from TaKaRa® Biotechnology Co., Ltd (Dalian, China). The Trizol total RNA separating medium was purchased from Gibco® Co., Ltd (Grand Island, NY, USA). LMP1 monoclonal antibody (Clone CS1-4), HBsAg monoclonal antibody (Clone ZMHB5), HBcAg polyclonal antibody, the immediately-used-type of the second generation immunohistochemistry Elivision™ plus broad spectrum test kit were from Maixin Co., Ltd (Fuzhou, China). Rat-anti-human HCV monoclonal antibody (Clone TORDJI-22) was from Zhongshan Biotechnology Co. Ltd (Beijing, China).

PCR, DNA sequencing and RT-PCR

We downloaded the gene sequences of EBV, HBV, HCV and hepatitis D virus (HDV) from the GenBank. Each included four strains, and the homogeneity was compared among the strains by the Vector NTI suite7 software. The primers were designed by Oligo software (Table 1, LMP1^[1] and β -globulin^[2] primer sequences were adopted from literature) within the homogeneous gene regions, and synthesized in Shenggong Co., Ltd (Shanghai, China). The positive controls of EBV, HBV and HCV were, respectively, B95-8 cell line, PSDHBV-1 (HBV complete sequence plasmid, 7.8 k) and an HCV-positive serum. The HDV positive control could not be obtained. Fetal liver tissues served as the negative controls. Blank control was established. Primers flanking β -globulin gene were used as a positive control for DNA preservation. Full details of the sequences and genome coordinates of primers and amplification programs of PCR are given in Table 1. The PCR products were electrophoresed in 15 g/L agarose gel, stained with ethidium bromide (Et-Br), and photographed under a UV-transilluminator. After being retrieved and purified, PCR product was ligated with pMD 18-T vector, and then transfected *E.coli* competent cells. The clones were selected and identified. Sequencing of the positive clones was performed by Shenggong Co., Ltd. Bacteriophage M13 cloning vector was used to ligate the fragments. RNA extracts were prepared from paraffin sections. The tissue specimens were deparaffinized with xylene,

then washed with ethanol. RNA was extracted using TRIZOL total RNA separating medium. Reverse transcription was performed using AMV reverse transcriptase XL with cDNA synthesis performed for 1 h at 42 °C. Then nested PCR was carried out using the resulting cDNA as template. The detail is shown in Table 1.

Immunohistochemistry

We used a two-step method according to the instructions provided with the reagent kits. LMP1 located in nucleus or cytoplasm. HCV located in nucleus. HBsAg located in cytoplasm. HBcAg located in nucleus or cytoplasm. Positive cells were defined when there were clear small particles or granuloreticular reddening in cytoplasm or nucleus. The positive control was the positive tissue section provided by the company. Negative control was the sample of lobectomy of liver due to hepatolithiasis. Blank control was tissue section without addition of the first antibody.

Statistical analysis

The positive ratios were compared between HCC group and control group by means of χ^2 test. $P < 0.05$ was considered as statistically significant. The statistical software used was SPSS 10.0.

RESULTS

PCR and RT-PCR

Totally, 78 HCC samples whose β -globulin DNA was positively detected by amplified PCR were selected; PCR and RT-PCR were performed in all cases for EBV and HBV, and in 18 cases for HCV and HDV. EBV *Bam*HI W and EBV LMP1 were positive in 18 and six cases, respectively. HBV X gene and HBV S gene were positive in 42 and 27 cases respectively. HCV was positive in 1 of the 18 cases, and none was positive for HDV. The positive rates were 28.2% (22 of 78) for EBV DNA (*Bam*HI W and/or LMP1) and 56.4% (44 of 78) for HBV DNA (X gene and/or S gene) respectively. In addition, 12 cases were positive for both EBV DNA and HBV DNA. Among the 26 cases in the control group, 2 cases were positive for EBV *Bam*HI W, four

Figure 1 Results of PCR. P, positive control; N, negative control; B, blank control; M, marker of molecular mass. The sizes of the six bands of the marker are 2 000 bp, 1 000 bp, 750 bp, 500 bp, 250 bp, 100 bp, respectively. A: β -Globulin (Positive: Lanes 2-4, 210 bp), B: LMP1 (Positive: Lanes 3 and 4, 337 bp), C: *Bam*HI W (Positive: Lanes 1-6, 130 bp), D: X gene (Positive: Lanes 2-4, 232 bp), E: S gene (Positive: Lanes 1-8, 198 bp), F: HCV (Positive: Lane 4, other lanes are nonspecific, 142bp), G: HDV (All are negative, Lane 5 is nonspecific).

positive for HBV X gene and three positive for HBV S gene. The positive rates were 8.0% (2 of 26) and 23.1% (6 of 26), respectively, for EBV DNA and HBV DNA (Figures 1A-G). The result of DNA sequencing of *Bam*HI W was 100% homologous with the corresponding sequence of B95-8 (Figure 2). There was significant difference in EBV infection rate between HCC patients and controls ($\chi^2 = 4.622$, $P < 0.05$). The difference in HBV infection rate was also significant ($\chi^2 = 8.681$, $P < 0.05$). However, there was no obvious correlation between HBV and EBV in HCC patients ($\chi^2 = 0.835$).

Figure 2 Sequencing results.

Immunohistochemistry

The immunohistochemical detection was performed for LMP1, HBV (HBsAg, HBcAg) and HCV in tissues of 78 cases of HCC, with 25, 45 and six cases positive, respectively. In the 26 control cases, the corresponding positive cases were two, four and zero. The difference in EBV infection rate between HCC patients and control cases was statistically significant ($\chi^2 = 6.02$, $P < 0.05$). The difference in HBV infection rate was also statistically significant ($\chi^2 = 10.03$, $P < 0.05$). In the 25 cases with positive LMP1 expression, six presented in the nuclei of tumor cells, nine in the cytoplasm of tumor cells and 10 in mesenchymal lymphocyte cytoplasm (Figures 3A-H).

DISCUSSION

EBV is considered as the first virus associated with human

malignancies including Burkitt's lymphoma^[3], T cell lymphoma^[4], parotid lymphoepithelioma^[5,6], nasopharyngeal carcinoma^[7], Hodgkin's disease^[8], gastric carcinoma^[9] and breast carcinoma^[10]. The virus proteins including EBNA1, 2, 3A, 3C, and LMP1 take part in the virus transformation and immortalization. Whether EBV has relation to HCC and whether it plays a role in the genesis of HCC has become the research focus of this field in recent years. However, the results so far are conflicting.

In Japan, Sugawara *et al.*^[11-13] found that the positive rate of EBNA1 in HCC was 37% and that cells infected by EBV could facilitate the replication of HCV. The positive rate of *Bam*HI W in HCC was 33% detected by PCR. Among patients with positive *Bam*HI W, anti-HCV positive rate was 40% and HBsAg positive rate was 14%, whereas the control subjects were all negative for anti-HCV and HBsAg. Moreover, EBV DNA load in HCC tissues was 1 000 times that in peripheral blood mononuclear cells of the healthy EBV-seropositive individuals. The authors concluded that EBV accelerates the onset of HCC and plays a role in oncogenesis of HCC, probably by promoting HCV replication, exacerbating inflammatory processes in liver tissue, promoting the proliferation of carcinoma cells or directly influencing tumorigenic potential. In China, Cheng *et al.*^[14] used EBV to transform the hepatitis C virus from an HCV positive patient to permanent lymphoblastoid cell lines. They found that HCV might exist and remain functional in a cultured cell line for a long period with the help of EBV. However, Chu *et al.*^[15] studied 41 cases of HCC from Los Angeles area in the United States, for evidence of EBV infection. Among these patients, one was positive for EBER1 by *in situ* hybridization, and none was positive for LMP1 and EBNA4 by PCR. The authors concluded that there is no association between EBV and genesis of HCC. In addition, later studies carried out in Germany, United Kingdom and The Netherlands^[16-19] reported very low detection rates of EBV in HCC patients, further suggesting that EBV has little relation to hepatocellular carcinogenesis.

In our study, EBV DNA was detected in 28.2% of the HCC tissues by PCR while the positive rate of HBV DNA was 56.4%. HCV RNA was detected in 5.6% of the HCC tissues by RT-PCR while HDV RNA was not detected in all of 18 cases. The positive rate of LMP1 was 32.1% of the HCC tissues by immunohistochemistry. The positive signals of LMP1 were mainly localized in tumor cells. The infection rate of EBV was significantly higher in HCC patients than in control patients.

Figure 3 Results of immunohistochemistry. A: Positive-control of LMP1 from the tonsil tissue. The cytoplasm of lymphocytes showed positive signals. $\times 400$, B: Immunohistochemical staining with anti-LMP1 antibody of an HCC specimen. The positive signals were localized in the cytoplasm and membrane of neoplasm cells. $\times 100$, C: Immunohistochemical staining with anti-LMP1 antibody of an HCC specimen. The positive signals were localized in the cytoplasm and membrane of neoplasm cells. $\times 400$, D: Immunohistochemical staining with anti-LMP1 antibody of an HCC specimen. The positive signals were localized in the nuclei of neoplasm cells. $\times 400$, E: Immunohistochemical staining with anti-LMP1 antibody of an HCC specimen. The positive signals were localized in the interstitial lymphocytes but no clear positive signals were present in the adjacent neoplasm cells. $\times 400$, F: Immunohistochemical staining with anti-HBsAg antibody of an HCC specimen. The positive signals were localized in the cytoplasm of neoplasm cells. $\times 400$, G: Immunohistochemical staining with anti-HBsAg antibody of an HCC specimen. The positive signals were localized in the cytoplasm and nuclei of neoplasm cells. $\times 400$, H: Immunohistochemical staining with anti-HCV antibody of an HCC specimen. The positive signals were localized in the nuclei of neoplasm cells. $\times 400$.

These results are similar to those obtained by Sugawara *et al.* Moreover, we observed LMP1 expression in cytoplasm of interstitial lymphocytes in a large proportion of HCC tissues. Experiments *in vitro* have demonstrated that EBV can infect human B-lymphocytes, combine with C3d receptor on the surface of B lymphocyte and enter the cells, escape from the immune surveillance of the host, and then transform the cells. We postulate that EBV, which infects lymphocytes, can promote the genesis and development of HCC in an unidentified way.

Why the results of Sugawara *et al.* and ours are different from those of others? Previous studies produced controversial results on whether EBV played a role in the genesis and development of malignant tumors like breast cancer^[20-23],

esophageal cancer^[24,25], gastric cancer and colorectal cancer. It has been reported that the correlation between EBV and tumor incidence is stronger in Japan and Taiwan than in the western countries. Therefore, we assume that the significance of EBV in HCC may vary because of regional and racial differences. Further studies are required to reveal the underlying mechanism by which EBV contributes to hepatocellular carcinogenesis.

It has been confirmed that HBV and HCV play a certain part in hepatocellular carcinogenesis. Our study showed that EBV and HBV had no synergistic action in HCC, which is consistent with the report by Yuan *et al.*^[26]. Because the infection rate of HCV in our region is much lower than that in Japan, the issue whether HCV interacts with EBV in hepatocellular carcinogenesis

should be studied further. HDV is one kind of defective virus that can deteriorate the patient's condition if co-infected with HBV. It has been suggested that HDV also plays a role in hepatocellular carcinogenesis to some extent. But our study did not support such a point of view.

The method using paraffin-embedded samples for a retrospective molecular epidemiological study may be affected, to some extent, by sample processing and conservation. In this experiment, β -globulin gene was selected as an inner control in PCR amplification. Some cases in which DNA had been seriously degraded were excluded in order to reduce the false-negative rate. To increase the detectable rate, several indexes were used for each virus. *Bam*HI W is regarded as a sensitive index as it repeats 7 to 12 times in EBV genome. LMP1, as a major virus transform protein, is detected in tumors that are related to EBV such as nasopharyngeal carcinoma, Burkitt's lymphoma and other tumors. The primers and reaction conditions are also the important factors. We took advantage of the Internet and biology software to process sequence search, primer design and reaction condition simulation, and achieved a good performance.

The relationship between EBV and the malignant tumors including HCC is very complex and controversial. More studies with larger sample sizes are required to draw a scientific and precise conclusion. If the hypothesis that there is a relation between EBV and HCC comes into existence, then, research and development of EBV vaccines will become a more significant issue, and gene therapy aiming at EBV will be an important approach in the treatment of HCC.

Abstract

AIM: To investigate the expression of cysteine-rich61 (Cyr61), connective tissue growth factor (CTGF) and nephroblastoma overexpressed gene (Nov) in hepatocellular carcinoma (HCC), and to evaluate the relationship between Cyr61, CTGF and Nov genes expression with invasion and metastasis of HCC.

METHODS: Thirty-one HCC specimens were divided into small hepatocellular carcinoma (SHCC), nodular hepatocellular carcinoma (NHCC), solitary large hepatocellular carcinoma (SLHCC) according to their diameter and number of nodes. Reverse transcription polymerase chain reaction (RT-PCR) was used to detect the mRNA expression levels of Cyr61, CTGF and Nov genes in 31 resected specimens of hepatocellular carcinoma and para-cancerous normal liver tissues semi-quantitatively and the relation between their expression levels and clinical pathological parameters were compared.

RESULTS: The expressions of Cyr61 and CTGF mRNA in carcinoma tissues were significantly higher than those in para-cancerous normal liver tissues ($P < 0.01$). The expressions of Cyr61 and CTGF mRNA in HCC with venous invasion were higher than those in HCC without venous invasion. CTGF expression in HCC Edmondson's grade III-IV was significantly higher than that in HCC Edmondson's grade I-II ($P = 0.022$). There was no obvious correlation between Nov mRNA and clinical-pathological features. Compared to NHCC, SLHCC had better cell differentiation, easier capsule formation, less microscopic venous invasion, milder liver cirrhosis. The expressions of Cyr61 and CTGF mRNA in NHCC were significantly higher than those in SLHCC and SHCC.

CONCLUSION: Cyr61 and CTGF genes may play an important role in hepatocellular carcinogenesis and correlate with recurrence and metastasis of hepatocellular carcinoma. SLHCC has better biological behaviors than NHCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignant cancers in the world, and the fourth most common cause of death from cancer, the second-leading cause of cancer death in China, which alone accounts for 53% of all liver cancer deaths worldwide. Although HCC resection plays an important role in improving HCC prognosis, it has been generally accepted that the high incidence of recurrence and metastasis is the most crucial prognostic factor in patients with HCC^[1]. The high recurrent rate in the liver with mainly intrahepatic metastatic spread remains a major obstacle to further improvement in the long-term survival after curative HCC resection^[2]. The mechanism of recurrence and metastasis of hepatocellular carcinoma is very complicated, and includes cell adhesion, matrix degradation, cell migration and angiogenesis^[3-7].

CCN gene family is a group of growth factor-inducible immediate-early genes, including cysteine-rich61 (Cyr61), connective tissue growth factor (CTGF), nephroblastoma overexpressed gene (Nov), Wnt-1 induced secreted protein 1 (WISP-1), WISP-2, WISP-3^[8,9]. CCN proteins are secreted extracellular matrix (ECM)-associated proteins that regulate cellular processes, such as adhesion, migration, mitogenesis, differentiation and survival^[10]. They also regulate more complex biological processes such as angiogenesis, chondrogenesis, tumorigenesis, fibrotic and vascular diseases^[11-13]. Cyr61 gene was originally identified as an immediately-early gene of mouse 3T3 fibroblasts, and was also found to be expressed in developing mouse cartilaginous elements and placental tissues^[14]. CTGF was originally identified in the conditioned culture medium of human umbilical vein endothelial cells, and revealed to be induced by transforming growth factor in human skin fibroblasts. Nov gene was identified as an aberrantly expressed gene in avian nephroblastomas induced by myeloblastosis-associated viruses. The overexpression of Nov gene was reported relative to human Wilms' tumors.

Taking cues from clinical observations and results of our laboratory researches, we have hypothesized that solitary large hepatocellular carcinoma (SLHCC) possesses relatively better biological behaviors^[15]. Furthermore, we have preliminarily proved our hypothesis by a series of researches^[16]. The clinical pathological features of SLHCC were better than nodular hepatocellular carcinoma (NHCC) and the molecular biological study also suggested that SLHCC possessed better molecular pathological features.

Cyr61, CTGF and Nov gene may overexpress in HCCs. In this report, we studied the expressions of Cyr61, CTGF and Nov genes in HCCs and para-cancerous normal liver tissues, to clarify whether these genes might play an important role in the recurrence and metastasis of HCCs. Furthermore, we examined the expressions of Cyr61, CTGF and Nov genes in SLHCC, NHCC and SHCC and compared their differences.

MATERIALS AND METHODS

Patients and tissue preparation

Thirty-one fresh HCC specimens and corresponding para-cancerous liver tissues were obtained by surgical resection at

Xiangya Hospital between March 2002 and March 2003. The patients with HCC consisted of 26 men and 5 women and the age of them ranged from 21 to 69 years (mean, 48 years). The patients were classified as SHCC (tumor largest diameter ≤ 5 cm for a single tumor nodule or the sum of diameters ≤ 5 cm for two tumor nodules), SLHCC (a single tumor nodule and tumor largest diameter >5 cm), NHCC (the nodules of tumor ≥ 2 , only two tumor nodules and the sum of diameters ≤ 5 cm were excluded). Furthermore, we divided 31 specimens into six groups: tumors <5 cm diameter and ≥ 5 cm, grade I-II and grade III-IV, liver cirrhosis and no liver cirrhosis, capsule formation and no capsule formation, microscopic portal vein tumor thrombosis and no microscopic portal vein tumor thrombosis. All specimens were examined under a microscope after haematoxylin and eosin (HE) staining.

RNA extraction and RT-PCR

Total RNA was isolated using Trizol reagent (GIBCO BRL, USA) and cDNA was synthesized from RNA by M-MLV reverse transcriptase (Promega, USA) with oligo-dT primers (Sango Technology, China). The primer sequences of Cyr61, CTGF and Nov genes were as follows: Cyr61, upstream: 5'-ACTTCATGGTCCCAGTGC GC-3', downstream: 5'-AAATCCGGGTTTCTTTCACA-3'; CTGF, upstream: 5'-GCAGGCTAGAGAAGCAGAGC-3', downstream: 5'-ATGCTTTCATGCTGGTGCAG-3'; Nov, upstream: 5'-AGCATGCAGAGTGTGCAGAG-3', downstream: 5'-GGTGTGCCACTTACCTGTCC-3'; β -actin, upstream: 5'-CTGCAATCCGAAAGAAGCTG-3', downstream: 5'-ATCTTCAAACCTCCATGATG-3'. The conditions of PCR were as follows: after an initial denaturation at 94 °C for 2 min, 30 cycles of denaturation at 94 °C for 30 s, annealing at 54 °C for 1 min and extension at 72 °C for 1 min. The bands representing amplified products were analyzed by Stratagene Eagle-eye scanner. Expressions of Cyr61, CTGF and Nov genes were presented by the relative yield of the PCR products of the target sequence to that of the β -actin gene.

Statistical analysis

The results of RT-PCR were statistically analyzed using the Student's *t* test. Fisher's exact test was used to determine the relationship between the expressions of Cyr61, CTGF and Nov genes and clinicopathological characteristics of HCCs. SPSS11.0 software was used. $P<0.05$ was considered statistically significant.

RESULTS

Expression of Cyr61, CTGF and Nov mRNA in HCC and para-cancerous liver tissues

The expressions of Cyr61 and CTGF mRNA in HCC tissues were significantly higher than those in para-cancerous normal liver tissues. The expression of Nov gene was higher than that in para-cancerous normal liver tissues (Table 1). The difference in Nov gene expression between these two groups did not reach statistical significance. The expressions of Cyr61, CTGF and Nov genes are shown in Figure 1.

Table 1 Expression of Cyr61, CTGF and Nov mRNA in HCC and para-cancerous liver tissues (mean \pm SD)

	<i>n</i>	Cyr61	CTGF	Nov
HCC	31	2.34 \pm 0.46 ^b	2.21 \pm 0.34 ^b	1.56 \pm 0.21
Para-cancerous	31	0.48 \pm 0.29	0.65 \pm 0.33	0.89 \pm 0.64

^b $P<0.01$ vs para-cancerous tissues.

Between the groups with different pathological characteristics, the expressions of Cyr61, CTGF and Nov genes were significantly different. Especially, the differences between the two groups with and without microscopic portal vein tumor thrombosis were of great significance. Moreover, CTGF expression was significantly different between Edmondson's grades I-II and III-IV. The relationship between the expression of Cyr61, CTGF, Nov mRNA and clinicopathological features of HCC patients is shown in Table 2.

Clinical and pathological features of three types of HCC

Thirty-one HCC specimens were divided into SLHCC, SHCC and NHCC according to their diameter and number of nodules. Liver cirrhosis, microvascular invasion, capsule formation, Edmondson's classification of HCC were studied in each group. NHCC group had a higher incidence of microvascular invasion compared with SLHCC and SHCC ($P<0.05$). Only 8.3% of NHCCs were classified as Edmondson's grade I-II, while 62.5% of SLHCC and 63.6% of SHCC were classified as Edmondson's grade I-II. The differentiation of NHCC was significantly poorer than that of SLHCC and SHCC ($P<0.05$). The other three pathological features of SLHCC and SHCC were also better than NHCC but did not reach statistical significance. No statistical difference in the five pathological features was observed between SLHCC and SHCC (Table 3).

Figure 1 Expressions of Cyr61, CTGF and Nov mRNA in hepatocellular carcinoma A and D : Cyr61 mRNA expression, product size 100 bp; B and E : CTGF mRNA expression, product size 105 bp; C and F: Nov mRNA expression, product size 106 bp; M, DNA marker; T, tumor; P, para-cancerous normal liver tissues; T₁, NHCC; T₂, SLHCC; T₃, SHCC. PCR product of β -actin was 360 bp.

^a*P*<0.05 vs NHCC.**Expression of Cyr61, CTGF and Nov mRNA in three types of HCCs**

The expression of Cyr61 mRNA in NHCC was significantly higher than that in SLHCC and SHCC (*P* = 0.024 and *P* = 0.031, respectively). The expression of CTGF mRNA in nodular HCC was also significantly higher than that in SLHCC and SHCC (*P* = 0.016 and *P* = 0.027, respectively). No statistical difference in the expression of Nov gene among NHCC, SLHCC and SHCC was observed (Table 4).

DISCUSSION

All members of the CCN gene family possess a secretory signal peptide at the N terminus, indicating that they are secreted proteins. Several lines of evidence supported a role of CCN molecules in tumorigenesis^[8].

Cyr61 is a secreted, 40-kDa, cysteine-rich and heparin-binding protein coded by a growth factor-inducible immediate early gene^[14]. Recently, it has been reported as an angiogenic inducer that can promote tumor growth and vascularization^[17]. A mechanistic framework for the biological properties of Cyr61 has been provided by the finding that Cyr61 binds to integrin α_vβ₃, which represents the first molecularly defined receptor for any member of the CCN family^[18]. Interaction of α_vβ₃ with Cyr61 may account for its promotion of chemotaxis and growth factor-mediated DNA synthesis as well as cell adhesion since integrins have been known to modulate cell migration and growth factor signaling in other systems^[16,17]. In a direct interaction between the two molecules, Cyr61-mediated adhesion and migration of cultured endothelial cells were specifically inhibited by the peptide RGDS and/or antiintegrin α_vβ₃^[19-23]. In addition to its integrin-binding property, Cyr61 appears to be localized to its site of synthesis by associating with the ECM, possibly by binding to heparin-like molecules. This interaction could limit the extent of Cyr61 diffusion so that its site of action is in close proximity of its site of synthesis^[24]. In our study, the expression of Cyr61 gene in HCC tissue was markedly higher than that in para-cancerous normal liver tissues, indicating that Cyr61 may play an important role in hepatocellular carcinogenesis.

CTGF is a cysteine-rich mitogenic peptide that was originally identified as a growth factor secreted by vascular endothelial cells^[25]. It was selectively induced in fibroblasts after activation with TGF^[26]. A previous study demonstrated the coordinate expression of TGF1 and CTGF in granulation beds during wound

^a*P*<0.05 vs SLHCC.

repair, and found that dermal fibroblasts in scleroderma lesions overexpressed CTGF^[27]. In addition to contributing to TGF- β -mediated AIG, CTGF could interact synergistically with EGF, PDGF, IGF-I, or bFGF, suggesting that it activates the receptors and/or signaling pathways used by other growth factors^[28,29]. Consistent with its profibrotic properties, CTGF has been found to be overexpressed in pancreatic cancers, mammary tumors, and melanomas^[30-32]. In our study, the expression of CTGF gene in HCC tissue was obviously higher than that in para-cancerous normal liver tissues, indicating that CTGF might play an important role in hepatocellular carcinogenesis.

Nov gene was first recognized as an overexpressed gene in nephroblastomas induced by myeloblastosis-associated virus type 1^[33]. Unlike the other members of this family, Nov gene expression was associated with quiescence and transcriptionally downregulated upon expression of p60 v-src in RSV-infected CEF^[34]. It has been reported that overexpression of normal Nov gene in CEF has an inhibitory effect on cell growth, whereas expression of an amino-terminal truncated form of Nov gene was able to induce morphological transformation^[35,36]. Therefore, Nov is a negative regulator of cell growth, the amino-truncation of which would result in oncogenic activation^[37,38]. Also, Koliopoulos *et al.*^[42] reported that Nov was a ligand of integrins $\alpha_v\beta_3$ and $\alpha_5\beta_1$, and acted directly upon endothelial cells to stimulate pro-angiogenic activities, thus inducing angiogenesis *in vivo*. While, in our study, the expression of Nov gene in HCC and para-cancerous normal liver tissues had no difference. The diagnostic significance of Nov gene expression in HCC needs to be further investigated with more samples.

Metastasis and invasion of HCC is a multistep process, the molecular and cellular mechanisms of which have not been fully understood^[39]. They may involve matrix degradation, cell motility, angiogenesis, *etc.* CCN proteins could regulate biological processes such as angiogenesis, chondrogenesis, tumorigenesis, fibrotic and vascular diseases^[4-6,40]. Numerous *in vitro* studies indicated that Cyr61 protein was related to angiogenesis^[41]. Overexpressions of Cyr61, CTGF and Nov genes have been found in metastatic lesions of esophageal cancer, breast cancer, colon tumors, lung cancer and osteosarcoma^[42-45]. In the present study, we statistically analyzed the clinical and pathological parameters. No significant correlation was found among the parameters of age, sex, cause of liver diseases. Cyr61 and CTGF mRNA levels in patients with portal vein tumor thrombosis were significantly higher compared to those in patients without portal vein invasion. Moreover, CTGF mRNA level in Edmondson's grade III-IV was significantly higher than that in Edmondson's grade I-II. These results indicated that Cyr61 and CTGF had a close relationship with invasion and metastasis of HCC.

Previous studies have shown that SLHCC is different from other types of HCC in pathological features and invasiveness^[16]. Coordinated with this, the relatively better pathological features of SHCC were found in this study. The differentiation of SLHCC was much better than that of NHCC, and microvascular invasion was observed more frequently in NHCC compared with SLHCC. No statistical difference in pathological features was observed between SHCC and SLHCC. In addition, the transcription level of Cyr61 and CTGF in NHCC was much higher than that in SLHCC and SHCC, while no statistical difference was observed between SLHCC and SHCC. The lower transcription of Cyr61 and CTGF mRNA in SLHCC was probably due to the relatively better molecular pathological features of SLHCC.

Our findings indicate that Cyr61 and CTGF genes are related to tumorigenesis of HCC, and may enhance the invasion and metastasis of HCC. Its molecular basis remains to be elucidated. What are the most important factors regulating the expression level of CCN family and how does CCN gene family regulate effector protein will be the subjects of our future studies. When

the upstream and downstream signaling pathways are understood, those findings will provide new potential tools for the prognosis or prevention of invasion and metastasis of HCC.

Abstract

AIM: Peroxisome proliferator-activated receptor γ (PPAR γ) is known to regulate growth arrest and terminal differentiation of adipocytes and is used clinically as a new class of antidiabetic drugs. Recently, several studies have reported that treatment of cancer cells with PPAR γ ligands could induce cell differentiation and apoptosis, suggesting a potential application as chemopreventive agents against carcinogenesis. In the present study, 3 different kinds of PPAR γ ligands were subjected to the experiments to confirm their suppressive effects on liver carcinogenesis.

METHODS: Three PPAR γ ligands, pioglitazone (Pio) (200 ppm), rosiglitazone (Rosi) (200 ppm), and troglitazone (Tro) (1 000 ppm) were investigated on the induction of the placental form of rat glutathione S-transferase (rGST P) positive foci, a precancerous lesion of the liver, and liver cancer formation using a diethylnitrosamine-induced liver cancer model in Wistar rats, and dose dependency of a PPAR γ ligand was also examined.

RESULTS: PPAR γ ligands reduced the formation of rGST P-positive foci by diethylnitrosamine and induction of liver cancers was also markedly suppressed by a continuous feeding of Pio at 200 ppm.

CONCLUSION: PPAR γ ligands are potential chemopreventive agents for liver carcinogenesis.

INTRODUCTION

Carcinogenesis is a complex process that has been divided into three stages: initiation, promotion and progression^[1]. These three stages of tumor formation have been characterized in many mammalian tissues, particularly in the liver^[2,3]. According to the concept of multistage carcinogenesis, clones of cells

arise with increasing autonomy from normal growth regulation at each stage of development, and from these selected populations of cells, neoplasms ultimately develop^[4]. The placental form of rat glutathione S-transferase (rGST P) positive foci is thought to be preneoplastic lesions of the liver^[5-12].

Peroxisome proliferators-activated receptor γ (PPAR γ), a nuclear hormone receptor, provides a strong link between lipid metabolism and regulation of gene transcription. PPAR γ is known to regulate growth arrest and terminal differentiation of adipocytes, and a group of PPAR γ activators are now widely prescribed and form a new class of antidiabetic drugs. Several specific ligands have been identified, such as the thiazolidinedione groups, including pioglitazone (Pio), rosiglitazone (Rosi), and troglitazone (Tro), 15-deoxy-prostaglandin J2, and certain polyunsaturated fatty acids^[13]. PPAR γ is expressed in various organs including adipose tissue, breast epithelium, small intestine, lungs, and liver^[13]. Several studies have reported that treatment of cancer cells with PPAR γ ligands could induce cell differentiation and apoptosis, suggesting a potential application as chemopreventive agents against carcinogenesis^[14].

In present study, 3 different kinds of PPAR γ ligands were subjected to the experiments to confirm their suppressive effects on liver carcinogenesis in the rat model. In experiment 1, we investigated the effects of 3 PPAR γ ligands, Pio, Rosi, and Tro, on the development of rGST P-positive foci that were induced by diethylnitrosamine (DEN)^[6]. Dose dependency of the PPAR γ ligand was also examined. In experiment 2, a long-term carcinogenesis study of DEN was conducted^[15]. Our findings indicate that PPAR γ ligands are potential chemopreventive agents for liver carcinogenesis.

MATERIALS AND METHODS

Chemicals and animals

DEN was purchased from Beijing Chemical Reagents Company (Beijing, China). Three different PPAR γ ligands, Pio, Rosi, and Tro, were kindly provided by GlaxoSmithKline (BN, United Kingdom). To prepare experimental diets, each PPAR γ ligand was mixed with a powdered basal diet and stored at 4 °C until use. Fresh diets were provided to the rats once a week, and the dietary intake and body mass (bm) for each group of rats were measured every week. Concentrations of PPAR γ in experimental diets were 200 and 1 000 ppm for Pio and Tro, respectively. For Rosi, various concentrations in the diet, ranging from 0.88 to 500 ppm, were used to evaluate the dose-response effect of PPAR γ ligands on the formation of rGST P-positive foci. Fifteen-week-old male Wistar rats were purchased from Peking University Health Science Center (Beijing, China) and housed in a ventilated, temperature-controlled room (23±1 °C) with a 12-h light/dark cycle. After a period of 1-week acclimatization to the housing environment and the basal diet, groups of rats were fed either the basal diet or the experimental diet containing one of the PPAR γ ligands, from sixteen weeks of age until termination.

Induction of rGST P-positive foci (Experiment 1)

Rats were divided into 8 experimental groups, 4 DEN treated and

4 vehicle-treated. In DEN-treated cases (groups 1-4, Figure 1A), groups of 10 rats were fed diets without ligands (basal diet, group 1) or with a PPAR γ ligand (experimental diet, groups 2-4), beginning 1 wk prior to the subcutaneous injection of DEN as described below and continued until the end of the experiment. Starting at sixteen weeks of age (experimental wk 1), rats in each group were administered DEN subcutaneously twice, at 1-week intervals at a dose of 20 mg/kg bm in saline. In the vehicle-treated groups (groups 5-8, Figure 1A), groups of 5 rats were fed the basal diet (group 5) or experimental diet (groups 6-8) and given subcutaneous injections of an equal volume of saline without DEN. Four weeks after the first administration of DEN or saline, all rats were killed at experimental week 5. In a separate experiment, dose-dependent effect of Rosi, within the range of 0.67-500 ppm in diet, on formation of rGST P-positive foci was also examined. The entire liver was removed, and fixed in 40 g/L neutralized formaldehyde overnight at 4 °C. Then the liver sections were embedded in paraffin. Immunohistochemical staining was performed on sections by the peroxidase-antiperoxidase method, using the antibody against the rGST P. Sections were counterstained with haematoxylin. The number of rGST P-positive foci (consisting of single to several GST P positive cells, indicating preneoplastic lesions) was expressed as per cm² of liver sections^[16].

Induction of liver tumors (Experiment 2)

As in Experiment 1, rats were fed either the experimental diet or the basal diet, starting 1 wk prior to the injection of DEN or vehicle. A total of 80 rats were divided into 4 experimental groups, 2 DEN treated and 2 vehicle treated. For the former, groups of 30 rats were fed diets without ligands (basal diet) or with PPAR γ ligands (basal diet + pioglitazone 200 ppm), beginning 1 wk prior to the subcutaneous injection of DEN as described below and continued until the end of the experiment (Figure 1B). Starting at 16 wk of age (experimental week 1), rats in each group were administered DEN subcutaneously 6 times at 1-wk intervals at a dose of 20 mg/kg bm in saline. In the vehicle-treated groups, groups of 10 rats were fed the basal diet or experimental diet (basal diet + pioglitazone 200 ppm) and given subcutaneous injections of an equal volume of saline without DEN (Figure 1B). All surviving animals were killed 60 wk after the first injection of DEN. Livers were removed and fixed in 10% neutralized formalin as described above. The number, size, and location of liver tumors detected macroscopically or by stereomicroscopic observation were determined. Diameters were measured in 3 dimensions, and tumor size was calculated by (height + width + length)/3.

Histologic analysis of liver slices

Liver slices were embedded in paraffin blocks according to the standard procedures. In the case of liver tumors, lesions were resected, fixed in neutralized 40 g/L formaldehyde overnight at 4 °C, and embedded in paraffin blocks according to the standard procedures. Some of the tumors were bisected, and a half was frozen in liquid nitrogen and stocked at -80 °C until used for the frozen section preparation and RNA extraction. The other half was embedded in paraffin blocks as described above. Paraffin sections were prepared at 3.0- μ m thickness, stained with H & E, and subjected to histologic analysis.

Immunohistochemical analysis of liver tumors

Paraffin-embedded sections were deparaffinized and subjected to immunohistochemical staining using rabbit alpha fetoprotein polyclonal antibody (Novus Biologicals, Inc.) and rabbit PPAR γ polyclonal antibody (Santa Cruz Biotechnology, Inc.) following the manufacturer's instructions. The primary alpha fetoprotein (AFP) antibody was diluted at 1:200 and the PPAR γ antibody

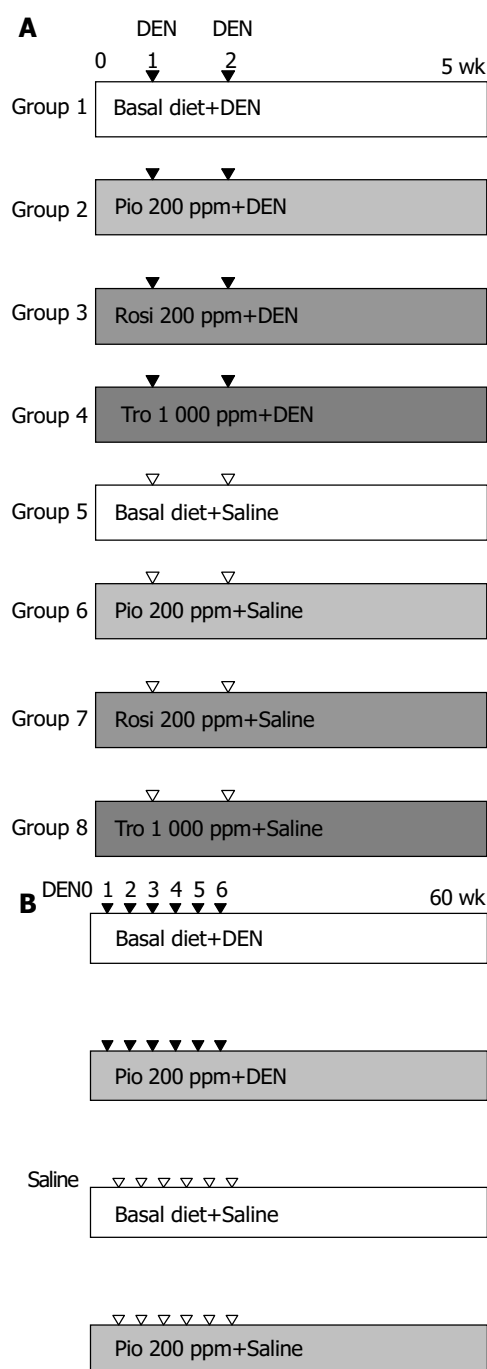

Figure 1 Experimental design for evaluation of chemoprevention efficacy of PPAR γ ligands against liver carcinogenesis. A: In the short-term study of rGST P-positive foci, groups of male Wistar rats were fed experimental diets containing 0 or 200 or 1 000 ppm of PPAR γ ligands from 1 wk prior to exposure to DEN at 20 mg/kg bm until the termination. B: For liver tumor study, groups of animals were given the basal diet or experimental diet containing 200-ppm Pio continuously from 1 wk prior to exposure of animals to DEN, IP, at 1 to 6 experimental weeks at 20 mg/kg bm until the termination.

to 1:400. To confirm the specificity of PPAR γ staining, addition of an excess amount of the N-terminal peptide of PPAR γ , used for immunization, was also carried out.

RT-PCR analysis for PPAR γ and β -actin expressions

RNA extraction from liver tumors and surrounding normal liver tissues was carried out as follows. Serial sections were prepared at 7- μ m thickness from frozen tissues, lesions were microdissected by scraping with a razor blade under microscopic observation,

and RNA was extracted using TRI reagent (Sigma). Extracted RNA was transcribed to cDNA using Oligo(dT)12-18 primer and SuperScript II RT (Invitrogen, Carlsbad, CA) and subjected to semiquantitative reverse-transcriptase (RT)-PCR analysis to quantify messenger RNA (mRNA) expression levels of the PPAR γ gene. PCR primers designed to amplify the 299-bp fragment of the PPAR γ gene were 5'-AGGATTCATGAC-CAGGGAGTT-3' (forward) and 5'-TCTGCCTGAGGTCT-GTCATCT-3' (reverse). For the internal control, expression of the β -actin gene for each sample was also quantified as above by amplifying the 138-bp fragment using a primer set: 5'-AGACTTCGAGCAGGAGATGGC-3' (forward) and 5'-AAGAAGGAAGGCTGGAAAAGA-3' (reverse). PCR amplification was carried out at 94 °C for 30 s, at 59 °C for 30 s, and at 72 °C for 45 s using MasterMix kit (tw-biotech, China) under the reaction conditions recommended by the manufacturer, and PCR cycles were set at 30 and 25 cycles for PPAR γ and β -actin, respectively. PCR products were run on 20 g/L agarose gels and visualized by ethidium bromide staining. In addition, the amount of PCR products was also quantified in real-time PCR using Taq RT-PCR kit (Ambion Inc.) and Smart cycler system (Cepheid, Sunny Vale, CA). Experiments were repeated at least twice, which gave similar results.

Statistical analysis

Statistical analysis for rGST P-positive foci and liver tumor multiplicity were conducted using the *t*-test (SPSS 10.0 for Windows). Other statistical analyses for liver tumor incidences and the distribution of tumor sizes were performed using the χ^2 -test (SPSS 10.0 for Windows). Differences were considered significant when *P* values were <0.05.

RESULTS

Effect of PPAR γ ligands on formation of rGST P-positive foci

One animal in the DEN+ 200-ppm Rosi-treated group and 4 in the DEN+1000-ppm Tro-treated group died within a few days after the injection of DEN, which were not included in the effective number of rats. Based on the diet consumption, the daily intake of PPAR γ ligands was estimated to be approximately 25 mg/kg bm (200 ppm in diet) for Pio and Rosi and 125 mg/kg bm (1 000 ppm in diet) for Tro. The mean body weight of rats given DEN was slightly decreased but stayed within 10% of the control value (data not shown). Administration of PPAR γ ligands alone did not significantly alter the body mass within the observation period of 5 wk (data not shown). After the administration of DEN, rats fed with the basal diet without a PPAR γ ligand developed 7.5 ± 3.1 rGST P-positive foci per cm² of liver sections by experimental wk 5. Treatment with 200-ppm Pio, 200-ppm Rosi, and 1000-ppm Tro significantly

reduced that to 2.5 ± 1.2 , 1.7 ± 1.1 , and 5.6 ± 2.3 , respectively (Table 1). This suppressive effect was observed in a dose-dependent manner within the range of 0.88 to 500 ppm of Rosi (Figure 2). Histologic analysis of a total of 40 liver sections of rGST P-positive foci (10 liver sections of rGST P-positive foci each from groups 1, 2, 3, and 4) revealed no significant histologic change. No rGST P-positive foci were induced by feeding experimental diet or basal diet alone without DEN administration.

Figure 2 Dose-dependent suppression of the formation of rGST P-positive foci by rosiglitazone. As clearly demonstrated, Rosi suppressed the formation of rGST P-positive foci in a dose-dependent manner within the range of 0.88-500 ppm in diet (^a*P*<0.05, ^b*P*<0.01).

Effects of PPAR γ ligands on induction of liver tumors

Five animals treated with DEN+200 ppm Pio died before the termination without tumor development, which were not included in the effective number. With administration of DEN, body weight gradually decreased to approximately 90% of the vehicle-treated group by experimental wk 18, but the difference stayed within 10% of the control mass throughout the experimental period. Data for incidences, multiplicities (average numbers of tumors per animal), histologic features of liver tumors, and size distribution of tumors are summarized in Table 2. Administration of 200-ppm Pio almost halved the incidence of liver tumors, and the multiplicity was also significantly reduced by Pio treatment. As to the size, only 38% (3 of 8) of tumors observed in the Pio-treated group were more than 2 mm in diameter, and 38% (3 of 8) were less than 1 mm. In contrast, 76% (19 of 25) of those in rats without Pio treatment were more than 2 mm in diameter, and only 8% (2 of 25) were less than 1 mm (*P*<0.05). All of the lesions developed in both Pio-treated and untreated groups were diagnosed as hepatocellular carcinoma. No liver tumors were observed in the rats fed with the basal diet alone or diet with 200-ppm Pio (data not shown).

Table 1 Effect of PPAR γ ligands on the multiplicity of DEN-induced rGST P-positive foci in male Wistar rats (mean \pm SD)

Experimental group	DEN	Diet	No. of rats	No. of rGST P-positive foci/cm ² of liver sections
Group 1	+	Basal diet alone	10	7.5 \pm 3.1
Group 2	+	Basal diet+pioglitazone 200 ppm	10	2.5 \pm 1.2 ^a
Group 3	+	Basal diet+rosiglitazone 200 ppm	9	1.7 \pm 1.1 ^a
Group 4	+	Basal diet+troglitazone 1000 ppm	6	5.6 \pm 2.3 ^a
Group 5	-	Basal diet alone	5	0
Group 6	-	Basal diet+pioglitazone 200 ppm	5	0
Group 7	-	Basal diet+rosiglitazone 200 ppm	5	0
Group 8	-	Basal diet+troglitazone 1000 ppm	5	0

^a*P*<0.05 vs group 1.

Table 2 Effect of PPAR γ ligands on the incidence, multiplicity, and size of DEN-induced liver tumors in male Wistar rats (mean \pm SD)

Experimental group	Incidence(%) ¹	Histology		Tumor size(mm) ¹		
		Hepatocarcinoma	Multiplicity	0-1	1-2	>2
DEN+basal diet	13/30 (43)	25	0.83 \pm 1.22	2	4	19
DEN+pioglitazone 200 ppm	5/25 (20) ^a	8	0.32 \pm 0.75 ^a	3	2	3 ^a

¹Statistical analysis was conducted using χ^2 test. ^a P <0.05 vs DEN+basal diet group.

Histologic findings and immunohistochemical staining of liver tumors

Liver tumors in both Pio-treated and untreated rats demonstrated no appreciable histologic differences on H & E staining or AFP immunostaining. Furthermore, no variation was observed in PPAR γ expression levels in tumors developed in Pio-treated and untreated rats. Addition of an excessive antigenic PPAR γ N-terminal peptide used for immunization before incubation of the sections with the antibody blocked the staining completely (data not shown).

Expression of PPAR γ mRNA in liver tumors

RNA samples from 2 liver tumors and 1 normal liver sample from both Pio-treated and untreated groups were subjected to semiquantitative RT-PCR analysis. No products were amplified without reverse transcriptase (data not shown). Liver tumors and normal tissue from both Pio-treated and untreated animals expressed PPAR γ mRNA as shown in Figure 3, and the relative amounts, normalized to β -actin mRNA, were almost equivalent in liver tumors as compared with normal liver tissue in both groups. Real-time PCR analysis also gave similar results (data not shown).

Figure 3 Expression of PPAR γ mRNA in liver tumors. Lanes 1 and 4: normal liver tissues; lanes 2, 3, 5, and 6: liver tumor tissues; lane 7: water.

DISCUSSION

In the present study of short- and long-term effects, clear evidence was obtained for preventive influence of the 3 different PPAR γ ligands, Pio, Rosi, and Tro, on rat liver carcinogenesis induced by DEN. In the short-term experiment, all 3 significantly suppressed the formation of rGST P-positive foci, the effect of the former 2 was particularly strong. Because this suppression was proved to be dose dependent, we considered the inhibitory effect of PPAR γ ligands on the formation of rGST P-positive foci to be due to pharmacologic actions rather than nonspecific toxicity. There were no significant differences in histopathologic features of rGST P-positive foci. In this context, the fact that the compounds reduced the formation of rGST P-positive foci without otherwise affecting their pathology is important. In the long-term carcinogenic experiment, the single PPAR γ ligand investigated also significantly suppressed the induction of liver tumors.

Our results are in good agreement with those from Rumi

et al.^[17], which demonstrated an inhibitory effect of PPAR γ on cell growth through PPAR γ activation. Our study has an advantage of the suppressive effect of rGST P-positive foci and liver tumors using 3 PPAR γ ligands in the rat model, including the dose-dependent experiments. In addition, PPAR γ could play roles in apoptosis, cell-cycle control through regulating p21^{waf/cipl}^[18]. Antiinflammatory activity of PPAR γ could also be involved in its suppression of liver carcinogenesis^[19]. However, the results of Hosokawa *et al.*^[20] and Kim *et al.*^[21], showing clofibrate, a peroxisome proliferator, enhanced liver carcinogenesis in their rat model in which GST-P-positive cells induced by DEN were changed to GST-P-negative cells on subsequent treatment with peroxisome proliferator, need to be taken into account. Now we have no reasonable explanation for the discrepancy.

In conclusion, PPAR γ ligands have substantial suppressive effects on liver carcinogenesis without affecting the histologic features of preneoplastic lesions or tumors. Although the molecular mechanisms underlying the inhibitory influence still remain largely unsolved, PPAR γ ligands may be potential chemopreventive agents against liver carcinogenesis.

Abstract

AIM: To prepare the human hepatocellular carcinoma (HCC)-targeted liposome microbubbles and to investigate their immunological properties.

METHODS: Human hepatocarcinoma specific monoclonal antibody HAb18 was attached to the surface of home-made liposome microbubbles by static attraction to prepare the targeted liposome microbubbles. The combination of HAb18 with liposome microbubbles was confirmed by the slide agglutination test and immunofluorescent assay. Their immunological activity was measured by ELISA. Rosette formation test, rosette formation blocking test and immunofluorescent assay were used to identify the specific binding of targeted liposome microbubbles to SMMC-7721 hepatoma cells, and cytotoxicity assay was used to detect their effect on human hepatocytes.

RESULTS: The targeted liposome microbubbles were positive in the slide agglutination test and immunofluorescent assay. ELISA indicated that the immunological activity of HAb18 on the liposome microbubbles was similar to that of free HAb18. SMMC-7721 cells were surrounded by the targeting liposome microbubbles to form rosettes, while the control SGC-7901 gastric cancer cells were not. Proliferation of SMMC-7721 cells and normal human hepatocytes was not influenced by the targeted liposome microbubbles.

CONCLUSION: The targeted liposome microbubbles with a high specific biological activity have been successfully prepared, which specifically bind to human hepatocarcinoma cells, and are non-cytotoxic to hepatocytes. These results indicate that the liposome microbubbles can be used as a HCC-targeted ultrasound contrast agent that may enhance ultrasound images and thus improve the diagnosis of HCC, especially at the early stage.

INTRODUCTION

Targeted ultrasound imaging is a promising method of imaging diagnosis^[1]. This technique can significantly improve the

sensitivity and specificity of ultrasonic diagnosis. At present, several targeted ultrasound contrast agents that can enhance imaging of specific tissues, such as thrombus-specific and inflammatory tissue-specific targeted ultrasound contrast agent, have successfully been developed abroad^[2-15], while study on hepatocellular carcinoma-targeted ultrasound contrast agent has not been reported.

In this study, liposome microbubbles containing fluorocarbon gases were prepared in our laboratory. Then human hepatocarcinoma specific monoclonal antibody HAb18 was attached to the surface of home-made liposome microbubbles to prepare targeted liposome microbubbles. Finally the immunological properties of targeted liposome microbubbles were investigated.

MATERIALS AND METHODS

Materials

Human hepatocarcinoma specific monoclonal antibody HAb18 was kindly provided by Research Centre of Cell Engineering, the Fourth Military Medical University. Rabbit anti-mouse serum was purchased from Beijing Zhongshan Biotechnology Co., Ltd, China. FITC conjugated sheep anti-mouse IgG and HRP conjugated sheep anti-mouse IgG were purchased from Huamei Bioengineering Company, China. MTT was purchased from Sigma. Human hepatoma cell line SMMC-7721 and human gastric carcinoma cell line SGC-7901 were maintained in our laboratory. Primary cultures of normal human hepatocytes were established from human liver tissue collected from person who died in accident.

Preparation of liposome microbubbles

The lipid film prepared previously in our laboratory and some mediators were mixed in proportion^[16]. Then the resulting mixture was sonicated, into which perfluoropropane gas was injected. The concentration and size of the microbubbles were measured under microscope. Zeta potential of the microbubbles was determined by the Chongqing Comed Nanopharma Co., Ltd, China.

Preparation of targeted liposome microbubbles

Human hepatocarcinoma specific monoclonal antibody HAb18 was added to the liposome microbubble suspension in proportion and mixed for 2 h at pH4.0, 4 °C^[17]. After the mixture was separated into 2 distinct layers, the lower layer was discarded and the upper layer was washed three times with phosphate-buffered saline (PBS) to elute the free HAb18.

Identification of targeted liposome microbubbles

Slide agglutination test A drop of rabbit anti-mouse serum or normal saline was mixed with a drop of targeted liposome microbubbles or liposome microbubbles respectively for about 5 min. The results were observed under a ×100 field of microscope.

Immunofluorescent assay A 100 μL of FITC conjugated sheep anti-mouse IgG was put into 200 μL of targeted liposome microbubbles and mixed for 30 min at 4 °C. After the mixture was separated into 2 distinct layers, the lower layer was discarded and the upper layer was washed three times with PBS to elute the free FITC conjugated sheep anti-mouse IgG. Then the microbubbles were observed under fluorescence microscope.

Assessment of immunological activity of targeted liposome microbubbles

SMMC-7721 cells (1×10^5) were placed in each well of a 96-well ELISA plate and cultured overnight. The cells were fixed in 0.25 g/L glutaraldehyde for 20 min. A 30 g/L of defatted milk powder was added and incubated for 1 h at 37 °C. Different concentrations of targeted liposome microbubbles or free HAb18 were added and incubated for 1.5 h at 37 °C. HRP conjugated sheep anti-mouse IgG was added and incubated for 1.5 h at 37 °C. O-phenylenediamine (OPD) and H_2O_2 were added and incubated for 10 min at 25 °C. A 2 mmol/L of H_2SO_4 was added to terminate the reaction. The optical absorbance (A) value at 490 nm was detected with ELISA.

Specific binding of targeted liposome microbubbles to SMMC-7721 cells

Rosette formation test^[18] Log phase SMMC-7721 cells and SGC-7901 cells were digested with 2.5 g/L trypsin. The isolated cells were adjusted to a concentration of 2×10^5 /mL in PBS respectively. One hundred μ L of targeted liposome microbubbles or liposome microbubbles was added to 200 μ L of SMMC-7721 or SGC-7901 cell suspension and mixed for 30 min at 25 °C. The resulting mixture was observed under microscope and the cells that formed rosette were counted.

Rosette formation blocking test SMMC-7721 cells were mixed with different concentrations of HAb18 for 30 min at 25 °C. The mixture was centrifuged and washed with PBS to elute free HAb18. Then targeted liposome microbubbles were added to cell suspension and mixed for 30 min at 25 °C. Cells forming rosette were counted under microscope.

Immunofluorescent assay one hundred μ L of targeted liposome microbubbles combined with FITC conjugated sheep anti-mouse IgG and 200 μ L of SMMC-7721 cells or SGC-7901 cells were mixed for 30 min at 25 °C. The suspension was observed under fluorescence microscope.

Cytotoxicity assay of targeted liposome microbubbles

SMMC-7721 cells or human hepatocytes (1×10^5 per well) were added into a 96-well culture plate. About three hours later different concentrations of targeted liposome microbubbles were added, while PBS was used as control. Three wells were used for each concentration. They were cultured in a CO_2 incubator at 37 °C for 48 h, then MTT (2 g/L, 50 μ L/well) was added and incubated at 37 °C for 6 h. The medium was discarded, and 100 μ L/well DMSO was added. The culture plate was shaken for 10 min and the optical absorbance (A) value at 570 nm was detected with ELISA.

RESULTS

Preparation of liposome microbubbles

The average diameter of liposome microbubbles ranged from 2 to 5 μ m, the concentration was 7×10^9 bubbles/mL (Figure 1). The mean zeta potential was -71.2 mV. Animal experiment demonstrated that the microbubbles could significantly enhance the ultrasound images of several tissues.

Figure 1 Light micrograph of liposome microbubbles under a $\times 200$ field of microscope.

Preparation and identification of targeted liposome microbubbles

The average diameter of targeted liposome microbubbles was similar to that of liposome microbubbles. HAb18 did not affect the size of microbubbles. The concentration was 5×10^8 bubbles/mL.

After rabbit anti-mouse serum was added, targeted liposome microbubbles agglutinated (Figure 2), but liposome microbubbles did not. While normal saline (NS) did not lead to agglutination of two kinds of microbubbles.

The surfaces of targeted liposome microbubbles gave out bright yellow-green fluorescence after they were stained with fluorescent agents (Figure 3), whereas liposome microbubbles did not give out any fluorescence.

Figure 2 Direct agglutination of targeted liposome microbubbles in the presence of rabbit anti-mouse serum.

Figure 3 Immunofluorescence staining of targeted liposome microbubbles with FITC conjugated sheep anti-mouse IgG. Targeted liposome microbubbles were stained in yellow-green under a $\times 400$ field of fluorescence microscope.

Assessment of immunological activity of targeted liposome microbubbles

ELISA indicated that the immunological activity of HAb18 on liposome microbubbles was similar to that of free HAb18. There were no significant differences in optical absorbance (A) value between free HAb18 ground and conjugated HAb18 ground (Figure 4).

Figure 4 Activity assay of free HAb18 and conjugated HAb18 on microbubbles by ELISA.

Specific binding of targeted liposome microbubbles to SMMC-7721 cells

After targeted liposome microbubbles and SMMC-7721 cells or SGC-7901 cells were mixed for 30 min, SMMC-7721 cells were surrounded by targeted liposome microbubbles to form rosettes and the rate of rosettes reached 90% (Figure 5), while SGC-7901 cells were negative. Rosettes were not observed in the mixture of liposome microbubbles and SMMC-7721 cells under microscope. After SMMC-7721 cells were pretreated with different concentrations of HAb18, the rate of rosettes declined significantly, even dropped to 0. Immunofluorescent assay indicated that SMMC-7721 cells were surrounded by the microbubbles and gave out bright yellow-green fluorescence to form rosettes (Figure 6), whereas control cells were negative.

Figure 5 Light micrograph of the binding of targeted liposome microbubbles to SMMC-7721 cells under a $\times 400$ field of microscope. SMMC-7721 cells were surrounded by targeted liposome microbubbles to form rosettes.

Figure 6 Immunofluorescent assay for identification of the binding of targeted liposome microbubbles to SMMC-7721 cells. SMMC-7721 cells were surrounded by the microbubbles and gave out bright yellow-green fluorescence.

Cytotoxicity assay of targeted liposome microbubbles

The result of MTT assay showed that the proliferation of human hepatocytes and SMMC-7721 cells were not influenced by targeted liposome microbubbles. There were no significant differences in average optical absorbance (A_{550}) value between experiment group and control group (Figure 7).

Figure 7 Effect of targeted liposome microbubbles on the proliferation of human hepatocytes and SMMC-7721 cells.

DISCUSSION

It has been nearly thirty years since the conception of ultrasound contrast imaging was suggested. Especially in recent years it has been developed rapidly and a number of ultrasound contrast agents have been described, but most of these are nontargeted. Now several targeted contrast agents that can bind to a specific acceptor have been developed^[2-15,19], and it has been demonstrated that such agents can enhance ultrasound images of chosen target tissues. Skyba *et al.*^[17,20-25] observed that ultrasound could induce intravascular microbubble destruction and bioeffects, and found that the application of ultrasound to thin-shelled microbubbles flowing through small microvessels ($<7\ \mu\text{m}$ in diameter) could produce vessel wall ruptures and the microspheres in vessel could go out through the ruptured walls. Thus antibody-loaded ultrasound contrast microbubbles could also cross the ruptured microvessels and bind specifically to the target tissues.

At present, hepatocellular carcinoma (HCC) is one of the most common malignant tumors with a high incidence and mortality in the world^[26]. This cancer severely threatens our health and needs to be diagnosed as early as possible, but differential diagnosis of HCC at its early stage is still difficult. So it is important to find a specific and sensitive diadynamic method for it. Studies^[27] have demonstrated that human hepatocarcinoma specific monoclonal antibody HAb18 could specifically bind to hepatocellular carcinoma cells and can be used for site targeting. If the antibody was used as a target carrier to prepare targeted ultrasound contrast agent, the contrast agent could assemble in a higher concentration of hepatoma tissues and the aim of target imaging could be achieved.

In this study, we prepared and identified targeted liposome microbubbles and investigated their immunological properties. The results indicated that human hepatocarcinoma specific monoclonal antibody HAb18 was firmly attached to the surfaces of liposome microbubbles by static attraction and the immunological activity of HAb18 on liposome microbubbles was similar to that of free HAb18. These demonstrate that it is feasible to prepare targeted liposome microbubbles by static attraction. This method is simple and inexpensive. Moreover, the activity of the antibody can be retained completely. Besides, in order to investigate the properties of targeted liposome microbubbles bound specifically to target cells, rosette formation test and rosette formation blocking test as well as immunofluorescent assay were performed. These tests indicated that targeted liposome microbubbles could bind to human hepatocarcinoma cells specifically and effectively, and the binding was mediated by HAb18.

In order to evaluate the safety of targeted liposome microbubbles, we performed cytotoxicity assay. The result indicated the microbubbles did not influence the proliferation of human hepatocytes and SMMC-7721 cells. These results lay a good foundation for further study.

Abstract

AIM: To determine the effect of metastatic hepatoma cells on lymphangioma-derived endothelium, and to establish *in vitro* model systems for assessing metastasis-related response of lymphatic endothelium.

METHODS: Benign lymphangioma, induced by intraperitoneal injection of the incomplete Freund's adjuvant in BALB/c mice, was embedded in fibrin gel or digested and then cultured in the conditioned medium derived from hepatoma H22. Light and electron microscopy, and the transwell migration assay were used to determine the effect of H22 on tissue or cell culture. Expressions of Flt-4, c-Fos, proliferating cell nuclear antigen (PCNA), and inducible nitric oxide synthase (iNOS) in cultured cells, and content of nitric oxide in culture medium were also examined.

RESULTS: The embedded lymphangioma pieces gave rise to array of capillaries, while separated cells from lymphangioma grew to a cobblestone-like monolayer. H22 activated growth and migration of the capillaries and cells, induced expressions of Flt-4, c-Fos, PCNA and iNOS in cultured cells, and significantly increased the content of NO in the culture medium.

CONCLUSION: Lymphangioma-derived cells keep the differentiated phenotypes of lymphatic endothelium, and the models established in this study are feasible for *in vitro* study of metastasis-related response of lymphatic endothelium.

INTRODUCTION

Metastasis of most cancers occurs primarily through the lymphatic system, and is responsible for the majority of cancer deaths. But tumor-associated lymphatic system has been overshadowed by the greater emphasis placed on the blood vascular system^[1]. This scenario is changing rapidly after the identification of lymphangiogenic vascular endothelial growth factor C^[2]. The traditional view that lymphatic capillaries are passive participants in metastasis is currently being challenged, and recent studies indicate the importance of lymphatic vessel

activation in tumor dissemination^[3-5].

Better understanding of the lymphatic endothelial properties and their alteration in cancer may develop a new way to therapeutic intervention^[6,7]. *In vitro* experiments have been proven to be valuable, expeditious and easy of quantification in providing initial information on angiogenesis, a potentially important oncotherapy target^[8]. However such *in vitro* models have not been well established for revealing metastasis-related response of lymphatic endothelium. Therefore, the aim of our study was to determine the effect of metastatic hepatoma cells on lymphangioma-derived endothelium, and to establish *in vitro* model systems for assessing metastasis-related response of lymphatic endothelium.

MATERIALS AND METHODS

Animals and reagents

BALB/c mice of either gender, 2 mo old and weighing 22-25 g, were provided by Laboratory Animal Research Center, Fourth Military Medical University (FMMU, Xi'an, China). A mouse ascitic hepatoma cell line, H22, was obtained from Institute of Digestive Diseases, FMMU. Reagents for *in vitro* culture of lymphatic endothelium included incomplete Freund's adjuvant, Hanks' balanced salt solution (HBSS), M199 medium and fetal calf serum (FCS), which were purchased from Gibco Company (Carlsbad, California, USA), bovine fibrinogen, thrombin, gelatin, endothelial cell growth supplement (ECGS), heparin, collagenases I and II, which were products of Sigma Company (Saint Louis, Missouri, USA). The sABC and sABC-AP kits for immunohistochemical staining were purchased from Boster Company (Wuhan, China). Polyclonal anti-Flt-4 antibodies, monoclonal anti-iNOS antibody, anti-c-Fos antibody, and anti-PCNA antibody were products of Santa Cruz Company (Santa Cruz, California, USA). Nitric oxide (NO) detection kit was purchased from Nanjing Jiancheng Bioengineering Institute (Nanjing, China). Millicell culture plate inserts (12.0 µm) for transwell cell migration test were purchased from Millipore Corporation (Billerica, Massachusetts, USA).

Preparation of conditioned medium of H22

Hepatoma H22 cells were inoculated into abdominal cavity of 5 BALB/c mice for passage. To verify the capability of spontaneous lymphatic metastasis of H22, the generated carcinomatous ascites was transplanted into hindlimb claw pad of 10 healthy BALB/c mice and the lymph nodes in groin were harvested 10 d later for pathological examination. The conditioned medium of H22 (H22 CM) was prepared as a mixture of sterile ultra-filtrate of H22 ascites and M199 medium at the ratio of 1:5, supplemented with 150 mL/L FCS. The control medium was M199 medium supplemented with 150 mL/L FCS.

Induction of lymphangioma

Twenty healthy animals of BALB/c strain were intraperitoneally injected twice, with a 15-d interval, with 200 µL of the emulsified (1:1 with HBSS) incomplete Freund's adjuvant and killed one month later. Multicentric and clearly delimited white neoplasm on the abdominal surface of the diaphragm, varying in size from 3 to 15 mm², was collected for the following experiments. Histopathological examination of the tumors in our preparative experiment and other previous studies^[9] confirmed that this

neoplasm was benign lymphangioma.

Tri-dimensional lymphangioma culture

The lymphangioma masses were washed by HBSS, and cut into 1-mm² pieces. HBSS containing 3 g/L bovine fibrinogen was added into 48-well culture plates (0.5 mL/well), and fibrin gel clotting was induced by addition of 10 μ L 50 kU/L thrombin. A piece of lymphangioma was then placed on gel surface, and additional 0.5 mL fibrinogen solution and 10 μ L thrombin were added to embed the tissue. H22 CM was then added into 24 wells (as an experimental group), and the control medium into another 24 wells (as a control group). The gels were incubated, with culture medium changed every other day, at 37 °C with 50 mL/L CO₂ in air, and examined daily under an inverted microscope. To perform a quantitative analysis, images were taken every second day under same conditions (in brightness, contrast, and magnification), and measured by a computer-assisted image analysis system of Quantimet 570. For electron microscopy, six gels from each group were fixed two weeks later with 10 g/L glutaraldehyde in 0.1 mol/L sodium phosphate buffer, post-fixed with 10 g/L OsO₄ in s-collidine buffer, dehydrated in graded ethanol, and embedded in Epon. Ultrathin sections were cut and stained with lead citrate and examined with a JEM-200EX transmission electron microscope.

Primary cell culture

Lymphangioma masses were mechanically broken, and washed in M199 medium, supplemented with 100 kU/L penicillin. The tissues were then incubated for 30 min at 37 °C in HBSS containing 0.5 g/L collagenases (1:1 mixture of type I and II), and washed with a medium containing 150 mL/L FCS to stop digestion. Cells were centrifuged at 700 r/min, resuspended in M199 medium supplemented with 150 mL/L FCS, and equally seeded on 10 g/L gelatin-coated cover slips in a 24-well plate. To allow cell attachment, the plates were put still for one hour in an incubator at 37 °C with 50 mL/L CO₂ in air. Then the wells were gently washed to remove floating cells, and refilled with 2 mL H22 CM (24 wells) or 2 mL control medium (24 wells). Attached cells were cultured routinely, and examined daily under a phase-contrast microscope.

Immunocytochemical testing

Six days after primary cell seeding, the cover slips were fixed with 40 g/L formaldehyde in PBS for 20 min, with 2 g/L Triton X-100 in PBS, and incubated with 200 mL/L normal goat serum. Polyclonal anti-Flt-4 antibodies, monoclonal anti-iNOS antibody, anti-PCNA antibody and anti-c-Fos antibody were used as primary antibodies, and biotin-labeled goat anti-rabbit IgG antibodies as second antibodies. Streptavidin and biotinylated horseradish peroxidase complex (sABC) and DAB were used for anti-Flt-4 and anti-iNOS antibodies, and sABC-AP (alkaline phosphatase) and BCIP/NBT for anti-PCNA and anti-c-Fos antibodies.

Nitric oxide detection

The content of NO in fresh H22 CM and control medium was indicated by determining the total concentration of nitrite/nitrate by using the colorimetric method, according to the instructions provided with the NO detection kit. After primary cells were equally seeded and cultured with 2 mL H22 CM or control M199 medium for 48 h, the levels of NO in the two media were detected again. For an empty control, the two media were added into an empty plate, which was then incubated at 37 °C for 48 h before NO detection.

Transwell migration assay

Primary cells from lymphangioma were cultured to a confluent monolayer with a complete endothelium growth medium

(M199 supplemented with 100 mg/L heparin, 30 mg/L ECGS and 150 mL/L FCS), subjected to serum starvation for 4 h by switching the culture medium to M199 medium without growth factors or serum, trypsinized and suspended (1×10^8 cells/L) in serum-free M199 medium. Transwell migration assays were performed in Millicell inserts, with 1 g/L gelatin-coated 12 μ m filter membrane, in a 24-well culture plate. H22 CM and the control medium were added, respectively, into 12 wells of the plate, and 0.5 mL of suspended cells was placed in chambers of the inserts. After 4-h incubation at 37 °C, the medium in the insert chamber was aspirated, and cells on the upper surface of the filter membrane were removed with a cotton swab. Cells on the lower surface were fixed, stained with hematoxylin and counted in 5 high-power fields per chamber under light microscope.

RESULTS

Basic feasibility of the assay

Spontaneous lymphatic metastasis of transplant H22 tumor was found in all 10 animals as demonstrated by pathological examination of the groin lymph nodes (Figure 1). H22 CM could be easily prepared, and stored for the entire experiments to ensure the continuity of the different parts of the assay. The induction of lymphangioma was also confirmed to be a simple and well duplicable procedure, and could provide adequate original tissues for the following experiments.

Figure 1 Metastatic H22 tumor in the groin lymph node ($\times 100$).

Effect of H22 CM on lymphangioma culture

Lymphangioma embedded in the fibrin gels gave rise to capillaries when cultured 3-4 d in both H22 CM and control M199 media. Neo-branches of the micro-vessels with obvious lumina were generated every day. Under the effect of H22 CM, rather straight capillaries stretching out to the fringe of the gel were generated, and the number of branching in micro-vessels increased more rapidly (Figure 2). Transmission electron microscopy revealed that the ultrastructure of the capillaries was plasmalemma invagination of a single cell, or formed by cytoplasmic flaps joined by overlapping contacts and specialized tight junction complexes (Figure 3). End-to-end intercellular contacts were rare. No typical Weibel-Palade body was distinguished in the cytoplasm.

Effect of H22 CM on primary cell activation

Primary cell culture was successfully established on gelatin-coated cover slips. When cultivated in H22 CM, the cells proliferated, albeit at a low rate with a doubling time of about 36-60 h, and reached sub-confluence in 6 d. At this stage, the lymphangioma cells showed appearance like cobblestone, the classical morphology of endothelial cells. In contrast, when cultured in the control M199 medium, the cells showed no obvious proliferation after attachment. Correspondingly, immunocytochemical staining for Flt-4, PCNA, and c-Fos were positive in cells cultured in H22 CM (Figure 4), but negative in cells cultured in the control medium.

Figure 6 Transwell migration assay. A: Cells on lower surface of the filter membrane of the Millicell insert ($\times 400$); B: Migration cell number in H22 CM (1) and the control medium (2).

Effect of H22 CM on NO production

Immunostaining showed the expression of iNOS in lymphangioma cells after culture in H22 CM, and significantly increased content of NO in the culture medium (Figure 5). In contrast, cells cultured in the control M199 medium did not express iNOS, and the level of NO was rather low in the control medium.

Effect of H22 CM on cell migration

When cultured in the complete medium, the lymphangioma cells grew to a confluent monolayer in 8–10 d, and showed specialized cobblestone morphology, which further confirmed the nature of the cells. In transwell migration assay, the number of the cells on the lower surface of the filter membrane in H22 CM was significantly greater than in control medium (Figure 6).

DISCUSSION

The ascitic hepatoma H22 is a cell line with high potential of spontaneous lymphatic metastasis^[10], which was also verified in our experiments, and has been generally used in various experimental studies in oncology^[11–14]. It is proven to be a convenient and feasible tumor model for *in vitro* assessment on metastasis-related response of lymphatic endothelium.

The difficulty in isolation of lymphatic endothelium, especially from the animals commonly used in oncological experiments such as mice and rats, has limited studies on its reactions in tumorous environments. We used induced lymphangioma to solve this problem. When cultured in the fibrin gel, lymphangioma sprouts capillaries with ultrastructure similar to that of lymphatic vessels^[4,15]. Moreover, gelatin-anchorage dependent primary cell culture, and cobblestone morphology of confluent or subconfluent monolayer, are also specialized phenotype of lymphatic endothelium^[16,17]. Finally, positive expression of Flt-4 (also known as VEGFR-3), a marker of lymphatic endothelium in proliferation^[18,19], confirmed the

nature of the endothelium. These findings prove that lymphangioma is a proper original tissue for *in vitro* assay on lymphatic endothelium or lymphangiogenesis.

Despite the possible lymphangiogenic effect of fibrin^[20], H22 CM induced a faster formation of capillary network from lymphangioma in fibrin gels. Moreover, in primary cell culture, H22 CM showed similar capability to the complete growth medium in activating proliferation of lymphatic endothelial cells. Immunostaining for the common proliferating nuclear marker, PCNA^[21], and early-response gene signaling factor, c-Fos^[22], further confirmed the microscopic findings. Our results accord with the opinion on lymphatic vessel activation in cancer.

Endogenous NO is one of the key factors in the control of dilation of the lymphatic micro-vessels^[23,24]. The expression of iNOS in cancers is related to lymph node metastasis^[25,26]. iNOS is also evenly distributed throughout the cytoplasm of lymphatic endothelial cells^[27–29]. Our study demonstrates sustained expression of iNOS in cultured lymphatic endothelium and marked increase of NO levels in the culture medium under the effect of H22 CM, suggesting that dilation of lymphatics may be important for cancer invasion and metastasis.

There have been rare assays on lymphatic endothelial cell migration, which is an important event that initiates and coordinates lymphangiogenesis^[30]. Results from our study suggest that some soluble factors in H22 CM activate migration of lymphatic endothelial cells and tropistic lymphangiogenesis. The coadjuvant models established in our experiment are useful for further studies on migration inhibitors.

To our knowledge, this study is the first of its kind that bridges the gap between *in vivo* and *in vitro* studies on lymphatic endothelium and lymphangiogenesis. Both the culture medium and gel matrix in the experiment can be manipulated pharmacologically, which allows us to evaluate the activity of either soluble or solid-phase lymphangiogenesis inhibitors. Moreover, this spontaneous lymphatic metastasis

model of transplant H22 tumor will be helpful to determine whether inhibition of lymphangiogenesis is a realistic therapeutic strategy for inhibiting tumor dissemination and metastasis.

Abstract

AIM: To establish the DNA methylation patterns of the promoter CpG islands of 14 "drug-resistance" genes in hepatocellular carcinoma (HCC).

METHODS: The methylation specific polymerase chain reaction in conjunction with sequencing verification was used to establish the methylation patterns of the 14 genes in the liver tissues of four healthy liver donors, as well as tumor and the paired non-cancerous tissues of 30 HCC patients.

RESULTS: While 11 genes (ATP-binding cassette, sub-family G (WHITE), member 2 (*ABCG2*), activating transcription factor (*ATF2*), beta-2-microglobulin (*B2M*), deoxycytidine kinase (*DCK*), occludin (*OCLN*), v-raf-1 murine leukemia viral oncogene homolog (*RAF1*), ralA binding protein 1 (*RALBP1*), splicing factor (45 kD) (*SPF45*), S-phase kinase-associated protein 2 (p45) (*SKP2*), tumor protein p53 (Li-Fraumeni syndrome) (*TP53*) and topoisomerase (DNA) II beta (*TOP2B*)) maintained the unmethylated patterns, three genes displayed to various extents the hypermethylation state in tumor tissues in comparison with the normal counterparts. The catalase (*CAT*) was hypermethylated in tumor and the neighboring non-cancerous tissue of one case (3.3%). Both glutathione S-transferase pi (*GSTpi*) (80%, 24/30 in tumor and 56.7%, 17/30 in the paired non-cancerous tissues) and cystic fibrosis transmembrane conductance regulator, ATP-binding cassette (sub-family C, member 7) (*CFTR*) (77%, 23/30 in tumor and 50%, 15/30 in the paired non-cancerous tissues) genes were prevalently hypermethylated in HCC as well as their neighboring non-cancerous tissues. No significant difference in the hypermethylation occurrence was observed between the HCC and its neighboring non-cancerous tissues.

CONCLUSION: Hypermethylation of promoter CpG islands of both *CFTR* and *GSTpi* genes occurs prevalently in HCC, which may correlate with the low expression of these two genes at the mRNA level and has the profound etiological and clinical implications. It is likely to be specific to the early phase of HCC carcinogenesis.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most threatening malignancies, occurring prevalently in China^[1]. Its poor prognostic prospects have not only been attributed to the rapid advancing nature as well as the notorious metastasizing potential of the primary lesions, but also resulted from its refractoriness to the conventional chemotherapeutic practices^[2-4]. Altered expression of the crucial genes, even prior to the relevant treatment, is common in cancer cells, including HCC. The intrinsic drug resistance, reflected by the changes in the expression profile of the key genes in relevant pathways, including apoptosis, cell cycle progression, DNA repairs, etc., is common in cancer cells, which certainly contributes to the more rapid growth ability of cancerous cells than the normal counterparts, in the adverse environments in particular. Furthermore, cancer cells can also acquire resistance to chemotherapeutic remedies during treatment. It has been regarded as the key mechanism for the post-remission return of the full-blown cancer of same origin. Therefore, a long-standing challenge in cancer field is the underlying mechanisms of the drug resistance nature of tumors. The genetic defects leading to the intrinsic drug resistance have been well-established, but the mechanisms at the epigenetic levels, DNA methylation in particular resulting in the changes in expression, have only gained the justified recognition recently^[5].

Over 50% of the protein coding genes are marked with the CpG rich segment at their 5' end, the methylation status of which profoundly affects the transcription status of the genes^[6]. Biochemically, the methylated CpG affects the sequence-specific DNA-protein interactions by eliminating the otherwise binding of the transcription factors to their cognate cis-elements, while unfolding the cascade of reactions leading to chromatin condensation initiated by the binding to the methylated CpG by members of the methyl CpG binding protein family (MBD). Hypermethylation of the promoter CpGs has been linked to the long-term transcription-silencing status of DNA segments, including genes as well as the transposon-like-repetitive sequences in cells^[7,8]. The genome-wide hypomethylation has been regarded contributive to activation of transcription of the otherwise silenced transposon like repetitive sequences (such as the Alu and LINE repeats in mammals) and instrumental to the transposition mediated loss of the genome stability during cell transformation^[9-11]. The CpG islands of several tumor suppressor genes, which are hypomethylated and express in normal cells, became frequently hypermethylated in almost all the cancers investigated, contributing to the loss of function of the tumor suppressor genes in cancer. On the other hand, the reverse processes, such as hypomethylation of CpG islands may also result in transcription activation of the otherwise inert genes^[12].

In our previous studies on HCC^[13], we have assessed a number of genes in the category of “drug-resistance” genes, including the O-6-methylguanine-DNA methyltransferase (*MGMT*) gene encoding an enzyme responsible for the cell’s resistance to the alkylating type of chemotherapeutic drugs, and mutL homolog 1, colon cancer, nonpolyposis type 2 (*hMLH1*), a mismatch repairing gene^[14]. The former is frequently methylated while the later maintains the unmethylated status in HCC tissues in comparison with the normal liver tissues. In this study, we extended our profiling efforts in the same group of HCC patients to other 14 “drug-resistance” genes, 13 of which were touched for the first time. This specifically oriented survey to “drug-resistance” should provide valuable insights into our understanding of the underlying mechanisms for the development of intrinsic resistance of HCC to chemotherapeutic drugs, and have important etiological implications to carcinogenesis of HCC.

MATERIALS AND METHODS

Tissue samples and DNA preparation

With the informed consent of all patients and approval of the ethics committee, the samples of tumors were collected from HCC patients ($n = 30$) during operation. The pathological classification of tumor tissues was carried out, and the stage of each case was graded according to the WHO classification^[15]. Total genomic DNA was extracted from frozen tissue specimens (50-100 mg) according to a standard protocol with some modifications^[16,17]. Frozen pulverized powders of the specimens were re-suspended with 2 mL lysis buffer containing 50 mmol/L Tris-HCl pH 8.0, 50 mmol/L EDTA, 10 g/L SDS, 10 mmol/L NaCl plus 100 µg/mL boiling-treated RNase A (Sigma, USA). Following 1-h incubation at 37 °C, proteinase K (Roche, USA) was added to the cellular lysates for a final concentration of 100 µg/mL, and the digestion was carried out at 55 °C for 2 h. Organic extractions with a half volume of phenol/chloroform/isoamyl alcohol (1:1:0.04) were repeatedly carried out until no visible interphase remained after centrifugation. DNA was precipitated from the aqueous phase in the presence of 0.3 mol/L NaOAc (pH 7.0) and two and a half volumes of ethanol, washed once in 700 mL/L ethanol, dissolved at 65 °C for 30 min with 0.2-0.4 mL TE (10 mmol/L Tris-HCl pH 7.4 and 1 mmol/L EDTA) and stored at 4 °C until use. The DNA concentrations were calculated according to the $A_{260\text{ nm}}$ readings.

Bioinformatics search for “drug-resistance” genes

We used “drug resistance” as the key word to search from the NCBI LocusLink database (<http://www.ncbi.nlm.nih.gov/LocusLink/list.cgi>). The sequence of the coding region (63 targets) plus 5 kb segments at each ends were downloaded, and subjected to search for the existence of the CpG island. The parameters were set as OBS/EXP (the minimum average observed to expected ratio of C plus G to CpG) = 0.6, MINPC (the minimum average percentage of G plus C) = 50, and LENGTH (the minimum length that a CpG island has to be) = 200 bp (<http://www.ebi.ac.uk/emboss/cpgplot/>). Thirty six genes were found containing the promoter CpG island (Table 1). Among this list 14 genes were selected for the methylation profiling, as they represent in different categories for the functions and properties (Table 2). The primer pairs (Table 3) for methylation specific polymerase chain reaction (MSP) in this report were designed according to the same principle with assistance of the web server for identification of the CpG islands (<http://www.ebi.ac.uk/emboss/cpgplot/index.html>) and the primer design software (http://micro-gen.ouhsc.edu/cgi-bin/primer3_www.cgi) (Table 3).

Bisulfite treatment of DNA and MSP

The methylation status of the promoter CpG islands of the 14 genes in all sample DNAs were analyzed by MSP on the sodium-bisulfite converted DNA^[16,17]. The primer pairs for MSP and the genes’ genome access on GenBank are detailed in Table 3. In detail, 2 µg DNA in 50 µL TE was incubated with 5.5 µL of 3 mol/L NaOH at 37 °C for 10 min, followed by a 16 h treatment at 50 °C after adding 30 µL of fresh-prepared 10 mmol/L hydroquinone and 520 µL of freshly prepared 3.6 mol/L sodium-bisulfite at pH 5.0. The DNA was desalted using a home-made dialysis system with 10 g/L agarose. Then, the DNA (approximately 100 µL) was denatured at 37 °C for 15 min with 5.5 µL of 3 mol/L NaOH, followed by ethanol precipitation with 33 µL 10 mol/L NH₄OAc and 300 µL ethanol. After washing with 700 mL/L ethanol, the gently dried DNA pellet was dissolved with 30 µL TE at 65 °C for 10 min. The DNA sample was finally stored at -20 °C until further use. PCR reaction was carried out in a volume of 15 µL with 50 ng or less template DNA with JumpStart Taq polymerase (Sigma, USA). An initial denaturation step at 94 °C for 4 min was followed by 35 cycles of reaction at 94 °C for 20 s, variable annealing temperature (Table 3) for 20 s and 72 °C for 25 s, and a final extension at 72 °C for 5 min. The PCR products were separated by 12 g/L ethidium bromide containing agarose gel electrophoresis with 1×Tris Acetate EDTA (TAE) buffer and visualized under UV illumination. To verify the PCR results, representative bands from each target were gel-purified and cloned into T-vector (Buocai, Shanghai, China), followed by automatic DNA sequencing provided by Buocai. Only verified results are presented in this report.

The M. Sss I treated DNA from the normal liver tissue was used in the MSP procedure as the control template. The DNA from the liver tissue of the healthy liver donor^[14,16] was batch cleaved with *EcoRI*, followed by M. Sss I treatment overnight according to the manufacturer’s instruction (New England Biol., Boston, USA). The purified DNA was bisulphate treated as usual, and subjected to MSP with the primer pairs for 11 genes where no methylated alleles were detected in both cell lines and HCC tissues.

Cell culture and semi-quantitative reverse transcription^[18]

The established cell lines, BEL-7402 (human hepatocellular carcinoma cell line, No. TCHu68, Cell Bank in Shanghai),

Table 2 The “drug resistance” genes in this study

Resistance mechanism	Genes and ref.	Function
Plasma membrane transporters/pump decrease or increase to concentration	ABCG2	Belongs to the abc transporter family, appears to play a major role in the multidrug resistance phenotype of MCF-7 breast cancer cell line. When over-expressed, the transfected cells become resistant to mitoxantrone, daunorubicin and doxorubicin, display diminished intracellular accumulation reduce intracellular drug of daunorubicin, and manifest an ATP-dependent increase in the efflux of rhodamine
	CFTR	Belongs to the abc transporter family. MRP subfamily, involved in the transport of chloride ions
	RALBP1	Activates specifically hydrolysis of GTP bound to RAC1 and CDC42. Mediates ATP-dependent transport of S-(2,4-dinitrophenyl)-glutathione (DNP-SG) and doxorubicin(DOX) and is the major ATP-dependent transporter of glutathione conjugates of electrophiles (GS-E) and DOX in erythrocytes. Can catalyze transport of glutathione conjugates and xenobiotics, and may contribute to the multidrug resistance phenomenon
Transcription factor and/or tumor suppressor	ATF2	Belongs to the bZIP family, ATF subfamily, binding the cAMP response element (CRE) (consensus sequence: 5'GTGACGT(A/C)(A/G)-3') as a transcription activator
	TP53	Acts as a tumor suppressor in many tumor types, involved in cell cycle regulation as a transcription activator that acts to negatively regulate cell division by controlling a set of genes required for this process
The enzymes involved in drug activation or inactivation metabolism abnormality	CAT	Belonging to the catalase family ,serves to protect cells from the toxic effects of hydrogen peroxide
	GSTP1	Belongs to the GST superfamily. Pi family; Conjugation of reduced glutathione to a wide number of exogenous and endogenous hydrophobic electrophiles
	TOP2B	Control of topological states of DNA by ATP-dependent breakage, passage and rejoining of double-stranded DNA
	DCK	Required for the phosphorylation of several deoxyribonucleosides and certain nucleoside analogs widely employed as antiviral and chemotherapeutic agents
Cell signaling alteration and cell cycle checkpoints alteration	RAF1	Belongs to the Ser/Thr family of protein kinases. RAF subfamily. Involved in the transduction of mitogenic signals from the cell membrane to the nucleus as a part of the Ras-dependent signaling pathway from receptors to the nucleus
	SKP2	Involved in regulation of G1/S transition as substrate recognition component of the SCF (SKP1-CUL1-F-box protein) E3 ubiquitin ligase complex which mediates the ubiquitination and subsequent proteasomal degradation of target proteins involved in cell cycle progression, signal transduction and transcription
Unclear mechanisms	B2M	Beta-2-microglobulin is the beta-chain of major histocompatibility complex class I molecules, Containing 1 immunoglobulin-like domain
	OCLN	May play a role in the formation and regulation of the tight junction (TJ) paracellular permeability barrier
	SPF45	Involved in nuclear mRNA splicing, via spliceosome

Note: All the information in this table was obtained from the web site of the OMIM section of the locus link (<http://www.ncbi.nlm.nih.gov/LocusLink/>) and GeneCards(<http://bioinfo.weizmann.ac.il/cards/>).

SMMC-7721 (human hepatocellular carcinoma cell line, No. TCHu13, Cell Bank in Shanghai), Hep3B (human hepatocellular carcinoma cell line, ATCC Number: HB-8064), HepG2 (human hepatocellular carcinoma cell line, ATCC Number: HB-8065), HCCLM3 (human hepatocellular carcinoma cell line, Cell Bank in Zhongshan Hospital, Shanghai), and L02 (immortalized normal liver cell line, No GNHu6, Cell Bank in Shanghai) were cultured in DEME medium plus 100 mL/L new born calf serum at 37 °C in a 50 mL/L CO₂ atmosphere.

Total RNA from various HCC cell lines was extracted using the TriPure isolation reagent kit (Roche, USA). Reverse transcription was subsequently carried out using the superscript II RNase H-reverse transcriptase kit. β -actin was used as an internal control in separate reaction. The *GSTpi* cDNA primers (sense: 5'-GGAGACCTCACCTGTACCA-3'; anti-sense: 5'-GGGCAGTGCCTTACATAGT-3') were the same as in a previously published paper^[19]. The primer sequences and reaction conditions are listed in Table 4. RT-PCR products were visualized under UV illumination after electrophoresis in 1.2% agarose, followed by the densitometric quantification.

Statistics

The methylation data were dichotomized as 1 for the co-existence of the methylated and unmethylated alleles; 2, for methylated allele only; and 0 for the unmethylated for both

alleles to facilitate statistical analysis using contingency tables. The statistic analyses for the association between the methylation profile of the gene and each of the clinical-pathological parameters were carried out with the statistics package (<http://www.R-project.org/>). Both Pearson's Chi-square test with Upton's adjustment and Fisher's exact test (<http://www.R-project.org/>) were used to deal with the sample cells with the low expected values. The relative frequency with a 95% confidence interval ($P < 0.05$) for a binomial distribution was calculated for the tumors and the paired non-cancerous tissues.

RESULTS

Our previous efforts^[14,16] provided an HCC specific altered pattern in DNA methylation of 11 among 44 genes by MSP in conjunction with sequencing verification. Among that list, there were several genes that might be classified as the drug resistance related genes, i.e., the *hMLH1* and *MGMT* genes. The former maintained the unmethylated status and the later displayed hypermethylation in liver cancer. Although the impact of the tumor specific changes in methylation pattern of the *MGMT* gene has not been fully evaluated experimentally, it remains desirable to establish the methylation profile of more genes in the category of “drug resistance”. Such efforts should provide new insights into the underlying mechanisms as well

as the capability of predicting HCC patient's intrinsic profile of drug resistance, based upon the changes in DNA methylation pattern of the genes involved.

Bioinformatics search for the "drug-resistance" genes

Sixty three genes were revealed from NCBI LocusLink database from the searching with "drug-resistance" as the key words (<http://www.ncbi.nlm.nih.gov/LocusLink/list.cgi>). To identify the genes falling into the category of CpG island containing genes, the sequence of the coding region plus 5 kb each upstream and downstream was downloaded and subjected to the analysis with CpG island identification software (<http://www.ebi.ac.uk/emboss/cpgplot/>). Forty four genes were found containing one or more CpG islands, but only 36 genes really had the promoter embedded in a CpG island (Table 1). Hence, transcription of these 36 genes is likely to be subjected to the control of the DNA methylation status. From these genes, 14 genes representing different functions and mechanisms in "drug-resistance" (Table 2) were selected for methylation profiling; three genes encoding the various membrane transporters: *ABCG2*, *CFTR*, and *RALBP1*, two encoding the transcription factors, *ATF2*, and *TP53*, four encoding the enzymes mediating the drug activation or inactivation: *CAT*, *GSTpi*, *TOP2B* and *DCK*, two encoding the proteins involved in signaling or cell-cycle progression: *RAF1* and *SKP2*, and three with unknown underlying mechanisms: *B2M*, *OCLN* and *SPF45*.

Technological consideration

MSP is the most popular method for methylation profiling of any given targets in human cancers for both its easiness and sensitiveness. Based upon the distinguished difference in sensitivity of the methyl-cytosine from the cytosine to be

converted to uridine by bisulphate treatment: the later is amenable, but the former is resistant, the methylation status of the target fragments can be determined by parallel PCR reactions with one pair of the primers in which the CG in the wide-type sequence is maintained for detection of methylated allele, and the other in which the CG is replaced with TG for the unmethylated allele. However, inherent with the PCR-type assays, there are compelling reasons to eliminate both false positive and negative PCR reactions. As 13 genes in this list except for the *GSTpi* gene had not been subjected to MSP previously, we carried out optimization of the PCR reaction with a panel of five established cell lines. For those targets, only the unmethylated allele was detected, MSP with the DNA from the normal liver tissue was carried out, showing that all 14 genes were unmethylated. To ensure that failure to detect the methylated allele was not false negative artifact in PCR reaction, we *in vitro* methylated the DNA from the normal liver with M. Sss I methyl-transferase that was capable of transferring methyl to the fifth carbon atom of the cytosine in the CpG dinucleotides, followed by methylation profiling. As shown in Figure 1, while no methylated allele was detected with the methylation targeted primers with the liver DNA, the M. Sss I treated DNA led to the positive PCR reaction, indicating that the PCR condition used for the tumor samples was capable of detecting the methylated targets, including *ABCG2*, *ATF2*, *B2M*, *DCK*, *RAF1*, *RALBP1*, *SPF45*, *SKP2*, *TP53*, and *TOP2B* genes (panels 1-10, respectively). As the rest four genes were heterozygously methylated in some of liver cancer cell lines, it indicated that the PCR reactions specific to the methylated allele was acceptable (for instance, lane 11 for *OCLN*, Figure 1), the *in vitro* methylation by M. Sss I testing was exempted. To eliminate the false negative results, the representative PCR bands were subjected to T-cloning

and sequencing verification. Only the data, the bands of which had the correct identity in sequence, were regarded informative.

Figure 1 MSP testing with the M. Sss I treated normal liver tissue DNA. The *in vitro* methylated DNA from the normal liver tissue was used for MSP along with the untreated. Panels: 1, *ABCG2*; 2, *ATF2*; 3, *B2M*; 4, *DCK*; 5, *RAF1*; 6, *RALBP1*; 7, *SKP2*; 8, *SPF45*; 9, *TOP2B*; and 10, *TP53*. The PCR conditions for *OCLN* gene were assessed by PCR in three liver cancer cell lines, 7721, 7402, and Hep3B (panel 11). U, unmethylated allele; M, methylated allele, NL, normal liver tissue; *the DNA size marker: DL-2000.

The methylation profiles of 14 genes in HCC

By MSP analysis, 13 genes displayed a uniform unmethylated status in the liver tissues from all four healthy donors, while the *RAF1* gene was heterozygous in one case, but fully unmethylated in the rest three cases. In all 30 cases of HCC, the following 11 genes: *ABCG2*, *ATF2*, *B2M*, *DCK*, *RAF1*, *RALBP1*, *SPF45*, *SKP2*, *TOP2B*, *OCLN* and *TP53* maintained the same unmethylated status in both HCC tissues and the paired non-cancerous tissues (Figure 2), indicating no DNA methylation mediated changes in the control of the expression of these 11 genes in HCC. The remaining three genes displayed in varying degree hypermethylation in HCC tissues (Figure 2 and Table 4). Since hypermethylation of the *CAT* gene rarely occurred (3.3%) (Figure 2), its impacts on the HCC pathology might be rather trivial. Both *GSTpi* and *CFTR* genes were prevalently hypermethylated in HCC and their neighboring non-cancerous tissues (80% and 56.7%, and 77% and 50%, respectively, Table 4), highlighting the possibility that inactivation of transcription of these two genes may indeed occur in HCC, and have certain etiological significance.

It has been well recognized that the so-called non-cancerous cells pathologically defined may have already suffered from certain genetic lesions as the corresponding cancerous tissues. Inclusion of the neighboring non-cancerous tissues in this study made it possible to analyze our results from the stage-specific perspective of carcinogenesis. As shown in Table 5, no significant difference was detected in the occurrence of hypermethylated *GSTpi* and *CFTR* genes between HCC and the paired non-cancerous tissues ($P > 0.05$) (Table 4). If the neighboring non-cancerous tissues have indeed suffered from the early stage genetic and/or epigenetic lesions, the methylation changes of these two genes might occur at the early stage of HCC carcinogenesis.

To correlate the hypermethylated status with the transcription silencing of *GSTpi* gene, we carried out MSP analysis of this gene and semi-quantitative RT-PCR for its expression in five

established liver cancer cell lines. As shown in Figure 3, three liver cancer cell lines (i.e. HepG2, Hep3B and L-02) were fully methylated, and did not express *GSTpi*, while SMMC-7721 and HCCLM3 cell lines were heterozygously methylated, and expressed a detectable level of *GSTpi* mRNA. Therefore, the general notion stands correct in this case, that the hypermethylated status of the promoter CpG island is inversely correlated with the long-term transcription silencing state of the gene.

Glutathione-S-transferases (GSTs) are a family of phase II detoxification enzymes that catalyze the conjugation of glutathione to a wide variety of endogenous and exogenous electrophilic compounds, including subclasses of carcinogens and cytotoxic therapeutic drugs^[20,21], so that the cells are protected from DNA damages^[22]. Furthermore, the *GSTpi* isoform also regulates the mitogen-activated protein (MAP) kinase pathway that participates in cellular survival and death signals via protein: protein interactions with c-Jun N-terminal kinase 1 (JNK1) and apoptosis signal-regulating kinase (ASK1)^[23]. Therefore, GSTs serve two distinct roles in the development of drug resistance to both substrate-type and other types of chemotherapeutic drugs via direct detoxification as well as acting as inhibitors of the MAP kinase pathway^[24].

The cystic fibrosis trans-membrane conductance regulator (CFTR) belongs to the ABC transporter superfamily, and regulates the chloride permeability mainly in epithelial cells. Its defects may contribute to cystic fibrosis, a common autosomal recessive disorder among the Caucasian population, which affects multiple organs, including lung, pancreas, liver, sweat gland, reproductive system and intestine. *CFTR* gene has high expression level of transcripts in epithelial cells in pancreas and nasal polyps; low in lung, liver, and kidney; and undetectable in brain and fibroblasts^[25]. It functions as a cAMP-regulated chloride channel, a conductance regulator by an autocrine mechanism involving ATP and/or chloride efflux, and an inhibitor of epithelial Na⁺ channels when chlorides are released^[26]. The involvement of *CFTR* gene in drug resistance is implicated by observation that the forced over-expression of *CFTR* gene confers the multiple drug resistance to NIH 3T3 cells^[27], a similar behavior to the founding member of this family, multiple drug resistance 1 (MDR1), which was identified three decades ago, for its etiological role in the cellular resistance to the multiple chemotherapeutic drugs. The unmethylated status of *CFTR* gene in the normal liver tissues suggested that its expression may be necessary for the physiological activities of hepatocytes. Although whether this gene is expressed in HCC has not been tested, the possibility does remain for the functional loss of this gene in HCC, indicated by the prevalent hypermethylation of its promoter CpG islands.

Therefore, lacking of expression of these two genes, implicated by the hypermethylated state of the promoter CpG islands, may make the cells more susceptible to the carcinogenic insults, a feature associated with the proneness to the malignant state of cells. Hypermethylation of the promoter CpG islands may reflect the long-term silencing state of transcription of both *GSTpi* and *CFTR* genes in HCC, which may offer growth advantages of the malignant cells over their normal counterparts *in vivo*. Indeed, the hypermethylation of both genes was an early phase event, as no statistically significant difference in the hypermethylation frequency between the paired neighboring non-cancerous and HCC tissues was observed (Table 5). Nevertheless, the hypermethylated status of these two genes may not be all bad, as the HCC with the hypermethylated alleles of these two genes (if either or both genes did not express) may be more sensitive to the relevant chemotherapeutic drugs than their unmethylated counterparts. Indeed, in a recent report, a better response to chemotherapy was achieved in breast cancer patients lacking *GSTpi* expression than the expressing counterparts^[28].

Figure 2 Methylation profiles of the promoter CpG islands of 24 genes in HCC. Both electrophoretic patterns of the representative PCR products of each of 14 targets and the sequencing verification of one representative PCR product were presented. To indicate the methylation status, the sequenced data are aligned with the wild-type sequence. *, size markers, the bands of 250 bp and 100 bp were shown. U, unmethylated; and M, the hypermethylated. Panels: 1, *ABCG2*; 2, *ATF2*; 3, *B2M*; 4, *CAT*; 5, *CFTR*; 6, *DCK*; 7, *GSTpi*; 8, *OCLN*; 9, *RAF1*; 10, *RALBP1*; 11, *SKP2*; 12, *SPF45*; 13, *TOP2B*; and 14, *TP53*.

Table 4 The hypermethylation for each gene in each of HCC patient samples

Figure 3 Methylation status of the promoter CpG Island correlated the expression state of the GSTpi gene in liver cancer cell lines. Both methylation status (panel 1) and mRNA level (panel 2) of the GSTpi gene in SMMC-7721 (lane 1), Hep3B (lane 2), HepG2 (lane 3), HCCLM3 (lane 4) are determined and presented. *, size markers, the bands of 250 bp and 100 bp are shown. U, unmethylated; and M, the hypermethylated. The density of the bands (indicated in panel 3) for the internal control β-actin and the GSTpi gene were densitometrically recorded, where the density of the β-actin in SMMC-7721 cells was arbitrarily taken as 100%. The band-ratio of the GSTpi over the β-actin genes were calculated and summarized in the table and plot (panel 3).

Table 5 The early stage-specific change in methylation

Gene	C/M	N/M	P
GSTpi	24/30	17/30	0.052
CFTR	23/30	16/30	0.058

DISCUSSION

Drug resistance of cancers represents a formidable challenge in cancer management, and the underlying mechanisms of its

formation remain poorly defined. Both genetic and epigenetic defects can result in changes in expression of the “drug-resistance” genes in tumors. DNA methylation state of the promoter CpG islands has been demonstrated as a useful indicator for the transcriptional silencing state of the relevant genes. In this study, we determined the methylation profile of the genes at the focal point, classified as the drug-resistance type in DNA database in HCC, one of most devastating human cancers in Far East Asia, including China.

To identify suitable targets for such a study, we carried out

the search with key word “drug resistance” from the LocusLink part of the human genome database. Among 63 entries (<http://www.ncbi.nlm.nih.gov/LocusLink/list.cgi>), 44 (approximately 70%) fall into the category “the CpG island containing genes”, of which, 36 genes have their promoter embedded in the CpG island (Tables 2, 3). Hence, the DNA methylation mediated mechanism likely exerts the important control of over expression of this type of genes, the key function of which is somehow linked to the drug-resistance of cancer cells. Finally, 14 genes were selected for the methylation profiling in HCC. Although 11 genes maintained the unmethylated state in all the tissue samples tested, including four cases of the liver tissues from the healthy liver donors, 30 HCC tissues and their neighboring non-cancerous tissues, three genes, *CAT*, *GSTpi* and *CFTR*, exhibited to various degrees the hypermethylation status in HCC. *CAT* was only hypermethylated in one (3.3%) case. Both *GSTpi* and *CFTR* genes were prevalently hypermethylated (Figure 2 and Table 4) in both HCC and the paired non-cancerous tissues. There was no significant difference in occurrence of the hypermethylated status between the HCC and the paired non-cancerous tissues, indicating that the hypermethylation of these two genes is likely to be the early rather than the late phase events behind the same rationale described previously^[14]. This observation would strengthen the notion that the DNA methylation mediated transcription silencing of these two genes may promote carcinogenesis of HCC, by failing to protect the cells from both intracellular and extracellular genotoxic insults. On the other hand, this may offer certain advantages from the angle of the chemotherapeutic treatment of HCC. It is probably true that the HCC with hypermethylated *GSTpi* and *CFTR* genes may respond to the relevant chemotherapies better than the unmethylated counterparts. To further evaluate this hypothesis, both retrospective and prospective clinical studies specifically addressing the association between the chemotherapeutic responses of the HCC and the methylation state of the promoter CpG islands of the drug resistance genes, including *GSTpi*, *CFTR* and *MGMT*^[14] genes with a larger cohort of HCC patients are underway.

Abstract

AIM: To establish the methylation profile of the promoter CpG islands of 31 genes that might play etiological roles in colon carcinogenesis.

METHODS: The methylation specific PCR in conjunction of sequencing verification was used to establish the methylation-profile of the promoter CpG islands of 31 genes in colorectal cancer ($n = 65$), the neighboring non-cancerous tissues ($n = 5$), colorectal adenoma ($n = 8$), and normal mucosa ($n = 1$). Immunohistochemically, expression of 10 genes was assessed on the home-made tissue microarrays of tissues from 58 patients. The correlation of tumor specific changes with each of clinical-pathologic features was scrutinized with relevant statistic tools.

RESULTS: In comparison with the normal mucosa of the non-cancer patients, the following 14 genes displayed no tumor associated changes: breast cancer 1, early onset (*BRCA1*), cadherin 1, type 1, E-cadherin (epithelial) (*CDH1*), death-associated protein kinase 1 (*DAPK1*), DNA (cytosine-5-)-methyltransferase 1 (*DNMT1*), melanoma antigen, family A, 1 (directs expression of antigen MZ2-E) (*MAGEA1*), tumor suppressor candidate 3 (*N33*), cyclin-dependent kinase inhibitor 1A (p21, Cip1) (*p21^{WAF1}*), cyclin-dependent kinase inhibitor 1B (p27, Kip1) (*p27^{KIP1}*), phosphatase and tensin homolog (mutated in multiple advanced cancers 1) (*PTEN*), retinoic acid receptor, beta (*RAR- β* , Ras association (RalGDS/AF-6) domain family 1 C (*RASSF1C*), secreted frizzled-related protein 1 (*SFRP1*), tissue inhibitor of metalloproteinase 3 (Sorsby fundus dystrophy, pseudoinflammatory) (*TIMP3*), and von Hippel-Lindau syndrome (*VHL*). The rest 17 targets exhibited to various extents the tumor associated changes. As changes in methylation of the following genes occurred marginally, their impact on the formation of colorectal cancer were trivial: adenomatous polyposis coli (*APC*) (8%, 5/65),

Ras association (RalGDS/AF-6) domain family 1A (*RASSF1A*) (3%, 2/65) and cyclin-dependent kinase inhibitor 2A, alternated reading frame (*p14^{ARF}*) (6%, 4/65). The following genes exhibited moderate changes in methylation: O-6-methylguanine-DNA methyltransferase (*MGMT*) (20%, 13/65), mutL homolog 1, colon cancer, nonpolyposis type 2 (E. coli) (*hMLH1*) (18%, 12/65), cyclin-dependent kinase inhibitor 2A (melanoma, p16, inhibits CDK4) (*p16^{INK4a}*) (10%, 10/65), methylated in tumor 1 (*MINT1*) (15%, 10/65), methylated in tumor 31 (*MINT31*) (11%, 7/65). The rest changed greatly in the methylation pattern in colorectal cancer (CRC): cyclin A1 (*cyclin a1*) (100%, 65/65), caudal type homeobox transcription factor 1 (*CDX1*) (100%, 65/65), *RAR- α* (85%, 55/65), myogenic factor 3 (*MYOD1*) (69%, 45/65), cyclin-dependent kinase inhibitor 2B (p15, inhibits CDK4) (*p15^{INK4b}*) (68%, 44/65), prostaglandin-endoperoxide synthase 2 (prostaglandin G/H synthase and cyclooxygenase) (*COX2*) (72%, 47/65), cadherin 13, H-cadherin (heart) (*CDH13*) (65%, 42/65), CAAX box 1 (*CXX1*) (58%, 38/65), tumor protein p73 (*p73*) (63%, 41/65) and Wilms tumor 1 (*WT1*) (58%, 38/65). However, no significant correlation of changes in methylation with any given clinical-pathological features was detected. Furthermore, the frequent changes in methylation appeared to be an early phase event of colon carcinogenesis. The *in situ* expression of 10 genes was assessed by the immunohistochemical approach at the protein level: *CDH1*, *CDH13*, *COX2*, *cyclin A1*, *hMLH1*, *MGMT*, *p14^{ARF}*, *p73*, *RAR- α* , and *TIMP3* genes in the context of the methylation status in colorectal cancer. No clear correlation between the hypermethylation of the promoter CpG islands and the negative expression of the genes was established.

CONCLUSION: The methylation profile of 31 genes was established in patients with colon cancer and colorectal adenomas, which provides new insights into the DNA methylation mediated mechanisms underlying the carcinogenesis of colorectal cancer and may be of prognostic values for colorectal cancer.

INTRODUCTION

Colorectal carcinoma (CRC) is the third most common malignancy in the developed countries, with an annual incidence approximately 35-50/100 000^[1,2]. The risk factors of CRC include Western diet (low fiber, high fat diet), family history, smoking, obesity and inflammatory colorectal diseases. As a whole, China falls into the low incidence country in the world, with the relative incidence of CRC rates being the 4th-6th of the total malignances and the 2nd-3rd of those in the digestive system in China. However, CRC

occurrence exhibits an increasing trend, with an average 4.2% increase per year in the last two decades^[3]. CRC is the 3rd common malignancy in Shanghai and occurs more frequently in China (<http://www.caca.org.cn/zlyy/shanghai/index.asp>). Clinically and pathologically, CRC has been grouped as the sporadic (approximately 80% cases) and hereditary types of diseases (roughly 20% in the total).

Both activation of proto-oncogenes (e.g. the *CDH13* gene) and inactivation of tumor suppressor genes (e.g. the *APC*, *p53* and genes responsible for the mismatch repaired activity in cells) attributed to genetic defects have been proved instrumental to carcinogenesis of colorectal cancer. The well-known adenoma-carcinoma sequence of the genetic defects by Volgestein has gained both experimental supports and general recognition. However, the predicted accumulation of genetic events has not been substantiated in sporadic colorectal adenocarcinomas, and the expected increase in the number of genetic events in aging tissues has not materialized^[4]. Both observations are indeed at odds with the exponential increase in the incidence of colorectal cancer with age. Therefore, alternative mechanisms must be accounted for such a shortfall, which is associated with DNA methylation mediated control of the expression of critical genes overseeing cell growth, apoptosis, as well as cell cycle progression.

Addition of the methyl group at the fifth carbon of cytosine of CpGs is the only covalent DNA modification in vertebrate^[5]. Such epigenetic signatures in parental cells are passed to the daughter cells at high fidelity, by a similar semi-conserved mechanism during duplication of the genetic information. The hypermethylated status of CpGs can affect the DNA-protein interaction by eliminating the otherwise occurring DNA-protein interactions involved with the methylation-sensitive transcription factors, while unfolding a cascade of reactions toward the condensed chromatin that is initiated with binding to the methylated CpG by members of the methylated CpG binding protein family^[6]. Cancer specific changes in methylation occur widely in all the cancers tested^[7]. The global demethylation of DNA has been linked to the increased genome instability as the otherwise transcription-/ transposition-silenced repetitive sequences in normal cells are reactivated by DNA demethylation^[8,9]. Paradoxically, local hypermethylation (at the promoter CpG island) has been well established for inactivation of tumor suppressor genes and caught great attention. However, the local demethylation in human tumors has also been recently reported to be associated with transcription reactivation of the silenced genes in normal tissues, such as the *MAGEA1* gene in hepatocellular carcinoma^[10]. In view of the fact that the majority of the promoter CpG island containing genes (50% of the protein-coding genes fall into this category) have not been properly looked in the context of the tumor biology, methylation profiling remains valuable for new insights into the etiological mechanism.

CRC is one of the first few types of cancers for methylation profiling^[11,12]. Learnt from the rather extensive survey with more than 30 targets, a so called "CpG island methylation (CIM)" phenomenon has been reported, i.e., a clustering occurrence of multiple hypermethylated targets including upto a dozen of tumor suppressor genes^[11]. In this study, we recruited 65 CRC tissues, eight colorectal adenomatous tissues, five neighboring non-cancerous tissues and one normal mucosa tissue from Shanghai Cancer Hospital for a middle scale methylation profiling with the promoter CpG islands of 31 genes, aiming, to establish the methylation profile of CRC patients in China, and to assess the association between the methylation status and expression profile of the genes *in situ*. Our results presented in this report should provide some new insights into the role of the epigenetic mechanism in CRC carcinogenesis.

MATERIALS AND METHODS

Clinical-pathological profiles of CRC patients

With the informed consent of all patients and approval of the ethics committee, tumor tissues were obtained during surgery from 65 CRC patients at the Cancer Hospital of Fudan University in 1996-2003. They were 39 patients with sporadic colorectal cancer (SCRC), 10 with hereditary non-polyposis colorectal cancer (HNPCC) fulfilling Amsterdam criteria of IGC and Japanese criteria, and 16 in the category of Bethesda CRC. In addition, tissues were taken from the neighboring non-cancerous mucosa (at least 5-10 cm away from the tumorous lesions) of five patients. A cecum sample was obtained from a 68-year old female patient with inflammatory pseudotumor. In addition, Bethesda CRC concomitant adenomatous samples from six patients and sporadic colon adenomatous samples (one was cancer concomitant) from two patients were taken.

All samples were freshly obtained and cut into two parts. One was buried into an optimal cutting temperature compound (OCT, Miles Inc, USA), and put into fluid nitrogen for storage. The rest was fixed in formalin, embedded in paraffin and then cut into 4-5 μ m sections for routine pathological diagnosis.

Clinical-pathological features including the age and gender of patients, the tumor site histological type, Duke's stages, differentiation grades (only moderate and poor differentiation), lymph node metastasis status, and more than 3 years follow-up results (36 cases) are shown in Table 1. The clinical-pathologic data of the eight adenomas are shown in Table 2.

Table 1 Clinical-pathologic profiles of the CRC cases in this study

Clinical-pathologic features		Number of cases
Gender	Male	37
	Female	28
Age (yr)	Median	60
	Range	28-85
Tumor site	Left colon and rectum	43
	Right colon	22
Histological types	Adenocarcinoma	51
	Mucinous carcinoma	5
	Other types combined ¹	9
Differentiation	Moderate	51
	Poor	14
Follow-up (3 yr)	Survival	27
	Deceased	9
Duke's stage	A	6
	B	15
	C	30
	D	14

¹Other types combined included the mixed squamous cell carcinoma, carcinoid carcinoma, etc.

Table 2 Clinical-pathologic profiles of adenomas and neighboring tumor-free mucosae

Clinical-pathologic features		Adenoma	Mucosa
Gender	Male	4	2
	Female	4	4
Age (yr)	Median	60	68
	Range	34-83	47-76
Tumor site	Left colon	6	4
	Right colon	2	2
Histological type	Tubular	3	
	Tubulovillous	5	
Dysplasia	Light-moderate	8

DNA preparation and methylation specific PCR analysis

Genomic DNA was extracted from frozen tissues by the protein precipitation method^[13]. Frozen tissue block was cut into 10-20 µm sections, put into a 1.5 mL Eppendorf tube, and then incubated at 37 °C in the cellular lysis buffer with proteinase K (SABC, Shanghai) for a final concentration of 100 µg/mL. The digestion was carried out at 55 °C for at least 2 h. After centrifuged, the upper liquid was collected and the protein precipitation mix was added. After centrifuged, 1:1 isopropanol was added. The deposition was washed with 750 mL/L ethanol, and naturally dried. The DNA pellet was washed once with 700 mL/L ethanol and dissolved with TE (10 mmol/L Tris HCl, pH 7.4 and 1 mmol/L EDTA), and stored at a concentration of 1 mg/mL at 4 °C.

The primers for methylation specific PCR (MSP) (Table 3) were adopted as the previously published works^[10,14] or designed with the assistance of the web server for the CpG islands identification (<http://www.ebi.ac.uk/emboss/cpgplot/index.html>) and the primer design software (http://micro-gen.ouhsc.edu/cgi-bin/primer3_www.cgi). DNA treatment and PCR reaction were carried out by the previously described method^[10,14,15]. In detail, 10 µg DNA in 50 µL TE was incubated with 5.5 µL of 3 mol/L NaOH at 37 °C for 10 min, followed by a 16 h treatment at 50 °C after 30 µL of freshly prepared 10 mmol/L hydroquinone and 520 µL of freshly prepared 3.6 mol/L sodium-bisulfite at pH 5.0 were added. The DNA was desalted using a home dialysis system with 10 g/L agarose. The DNA in the desalted sample (approximately 100 µL in volume) was denatured at 37 °C for 15 min with 5.5 µL of 3 mol/L NaOH followed by ethanol precipitation with 33 µL 10 mol/L NH₄OAc and 300 µL ethanol. After washed with 700 mL/L ethanol, the gently dried DNA pellet was dissolved with 30 µL TE at 65 °C for 10 min. DNA samples were finally stored at -20 °C until further use. The sample of 50 ng of DNA was reserved for PCR reaction. PCR reaction was carried out in a volume of 15 µL with 50 ng or less template DNA with FastStart Taq polymerase (Roche, Germany) as follows. After an initial denaturing step for 3 min at 94 °C, 35 cycles at 94 °C for 30 s, at varying temperatures with primer pairs for 30 s and at 72 °C for 30 s, were carried out. The PCR products were separated by 12 g/L ethidium bromide containing agarose gel electrophoresis with 1×TAE and visualized under UV illumination. To verify the PCR results, representative bands from each target were gel-purified. Then the PCR products were sequenced directly or cloned into T-vector (Promega, USA) followed by automatic DNA sequencing provided by Bioasia (Shanghai, China). Only verified results were presented in this report.

Immunohistochemistry analysis on a home made tissue microarray

The paraffin embedded tissues from 58 cancer cases were made into the tissue microarray paraffin blocks, followed by sectioning. For each sample, the H&E stained sections were first reviewed and marked for the picked point. At least 4 points of cancer tissue and 1 point of normal mucosa tissue were taken from the different positions on the paraffin block. The diameter of our tissue microarray punch was 1 mm. We put about 40-80 tissue dots in one array. To identify the tissue put into the array, all the made tissue microarray sections were stained with H&E and reviewed by two pathologists independently.

The immunostaining was performed with each of 10 commercially available antibodies (Table 4) using DAKO Envision system/3,3'-diaminoben-aidine (DAB) staining. The result was scored by conjunction with both staining intensity and the percentage of positive staining cells. Each sample was given an intensity score (0-3) and a percentage of cell positive score (0=less than 5%, 1=5-25%, 2=25-50%, 3=50-75%, 4=more than 75%). An overall immunohistochemistry score was calculated by multiplying the intensity and percentage of cell

positive scores. Scores of 1-4 were recorded as +, 6-8 as ++, and 9-12 as +++.

Table 4 Antibodies for immunohistochemical analysis

Antibody name	Expression location	Company	Catalogue No.
CDH1	Membrane/Cytoplasm	Antibody Diagnostica INC.	M-0536
CDH13	Cytoplasm	Santa Cruz	sc-7940
COX2	Cytoplasm	Santa Cruz	sc-1746
Cyclin a1	Nuclear	Novocastra Lab.	NCL-CYCLINA
hMLH1	Nuclear	PharMingen	G168-15
MGMT	Cytoplasm	DAKO	M3610
p14 ^{ARF}	Nuclear/Cytoplasm	Santa Cruz	sc-8340
p73	Cytoplasm	Santa Cruz	sc-17823
RAR	Nuclear/ Cytoplasm	Santa Cruz	sc-552
TIMP3	Cytoplasm	Oncogene	IM43T

Statistical analysis

A comparison of the proportion was performed using Pearson ² test or the Fisher's exact method. Analysis of methylation status vs protein expression was performed using the contingency coefficient.

RESULTS

Among the 65 CRC patients, there were 39 SCRCs, 10 HNPCCs and 16 colorectal carcinoma in Bethesda category. In addition, eight colorectal adenomas, five non-cancerous mucosa tissues and one normal mucosa sample were also recruited for this study.

Twenty four genes among the 31 targets studied in this study were previously analyzed in liver cancer^[10] and astrocytoma (unpublished data) in this and other laboratories. They were *APC*, *BRCA1*, *CDH1*, *CDH13*, *DAPK1*, *hMLH1*, *p14^{ARF}*, *p15^{INK4b}*, *p16^{INK4a}*, *p27^{KIP1}*, *p73*, *PTEN*, *RAR-b*, *RASSF1A*, *RASSF1C*, *VHL* and *WT1*. The *CDX1*, *COX2*, *CXX1*, *MINT1*, *MINT31* and *TIMP3* genes have also been studied in colon cancer, the methylation pattern of which was found altered in CRC^[16] so that the relevant inter-study comparison of the methylation behaviors should be possible. In this list, there were genes with the proven roles in as well as those lacking any obvious association with the carcinogenesis of human tumors. For the later group, hypermethylation of the myogenetic lineage-specific transcription factor: MYOD1, occurs more frequently in aging tissues than its younger counterparts^[17]. In the category of cancer associated genes, the tumor suppressor genes made up the major part. There were proteins operating in the RB1/p16^{INK4a} pathway: p14^{ARF}, p15^{INK4b} and p16^{INK4a}, as well as the three cyclin-dependent kinase inhibitors: p21^{WAF1}, p27^{KIP1}^[18] and p57^{KIP2}^[19]. The rest in this subset were the p53 analogue, p73^[18,20], the two alternative forms of a tumor suppressors in the Ras mediated signal transduction pathway: RASSF1A and RASSF1C^[21], VHL^[22], APC^[23], PTEN^[6], N33 as well as the Wilms tumor 1 gene, WT1^[24]. Also included were the genes encoding the cell membrane proteins or nuclear receptors acting actively in intercellular interactions: e.g. melanoma specific antigen A1 (MAGEA1)^[25], and cadherins, CDH1^[26] and CDH13^[26]. One gene implicated in signal transduction was *cyclin A1*^[27]. The gene encoding O-6-methylguanine-DNA methyltransferase, *MGMT*^[28] was also included, which plays a key role in the cellular responses to alkylating agents and heavy metal stresses. The genes acting in DNA repair process were *hMLH1*^[29] and *BRCA1*^[30] as well as the gene acting in apoptosis, *DAPK1*^[31].

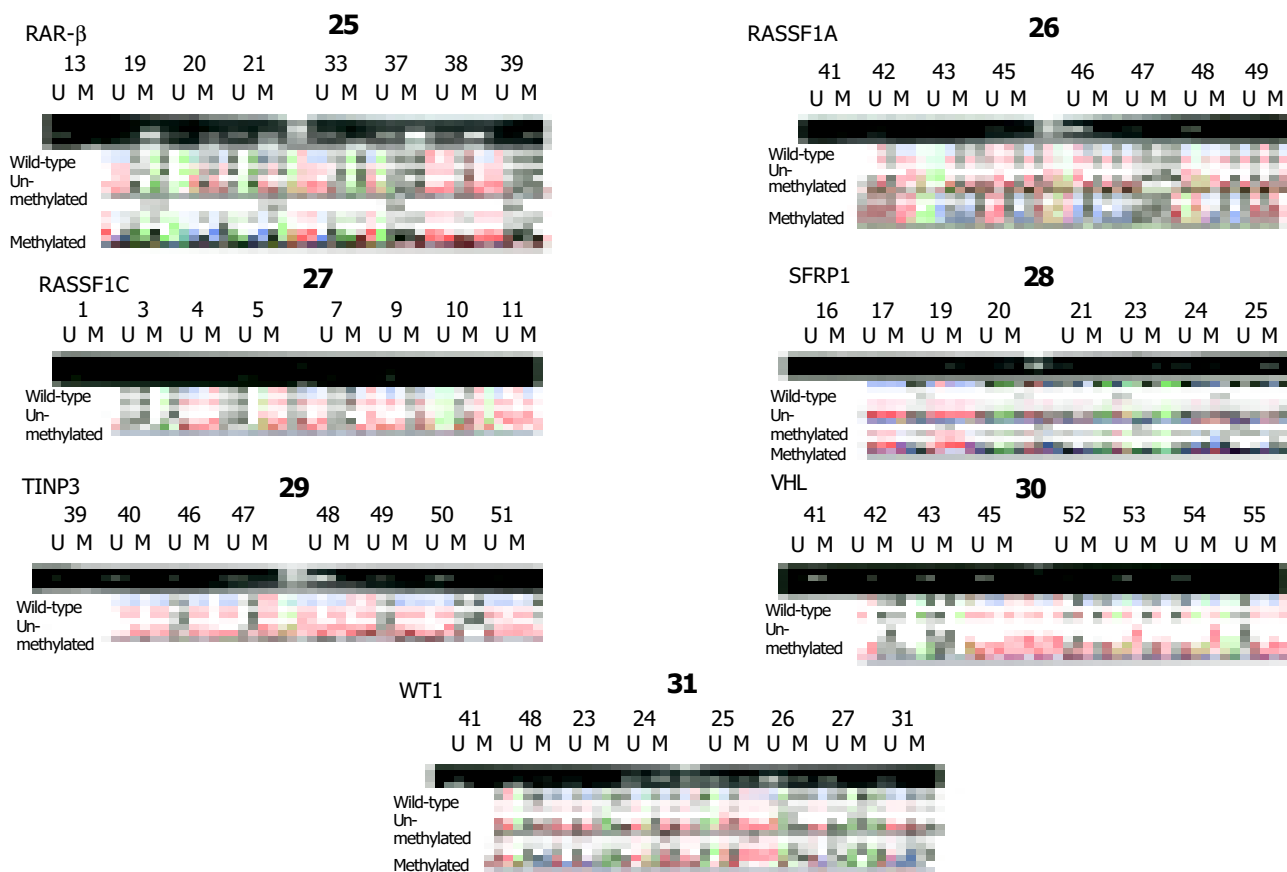

Figure 1 Methylation profiles of the promoter CpG islands of 31 genes in CRC. Both electrophoretic patterns of the representative PCR products of each of 31 targets (indicated respectively, at the top of figures) and the sequencing verification of the one representative PCR product are presented. To indicate the methylation status, the sequenced data are aligned with the wild-type sequence. ¹Size markers, the bands of 250 bp and 100 bp are shown. U, the unmethylated; M, hypermethylated. Panels: 1, *APC*, 2, *BRCA1*, 3, *CDH1*, 4, *CDH13*, 5, *CDX1*, 6, *COX2*, 7, *CXX1*, 8, *cyclin A1*, 9, *DPAK1*, 10, *DNMT1*, 11, *hMLH1*, 12, *MAGEA1*, 13, *MGMT*, 14, *MINT1*, 15, *MINT31*, 16, *MYOD1*, 17, *N33*, 18, *p14^{ARF}*, 19, *p15^{INK4b}*, 20, *p16^{INK4a}*, 21, *p21^{WAF1}*, 22, *p27^{KIP1}*, 23, *p73*, 24, *PTEN*, 25, *RAR-β*, 26, *RASSF1A*, 27, *RASSF1C*, 28, *SFRP1*, 29, *TIMP3*, 30, *VHL*, and 31, *WT1*.

Genes displayed no changes in methylation profile in tumor samples

As shown in Figure 1 and summarized in Figure 2, by comparing with the normal mucosa of non-cancerous samples, the following 14 genes did not display any tumor associated changes: *BRCA1* (panel 2), *CDH1* (panel 3), *DPAK1* (panel 9), *DNMT1* (panel 10), *MAGEA1* (panel 12), *N33* (panel 17), *p21^{WAF1}* (panel 21), *p27^{KIP1}* (panel 22), *PTEN* (panel 24), *RAR-β* (panel 25), *RASSF1C* (panel 27), *SFRP1* (panel 28), *TIMP3* (panel 29) and *VHL* genes (panel 30). The *MAGEA1* gene was the only target that tends to be demethylated and transcription-activated in tumors, as we previously demonstrated in hepatocellular carcinoma (HCC)^[10]. But the hypermethylated state of its promoter CpG islands maintained in all the samples tested. The likely explanations for such no-change-type-observations were the following: no changes in expression of this set of genes occurred in CRC, and the changes in expression indeed occurred, but the DNA methylation mediated mechanisms was not involved.

It should be pointed out that our no change conclusion as to both *N33* and *TIMP3* genes was at odds with the previous report where both genes were hypermethylated rather frequently in CRC^[32]. Whether it was attributed to the inherent difference between patient groups in different studies remains to be clarified.

Genes displayed changes in methylation profile in tumor samples

To score the changes in each CRC case, the methylated status in the mucosa tissue of the non-cancerous patients was taken as the reference, any deviation from which was scored as positive (increasing methylation extent) or negative (decrease

in methylation extent).

Seventeen genes in this list displayed to various extents the tumor associated changes. As shown in Figures 1, 2, the changes of the following genes occurred marginally, and their impact on CRC looked trivial: *APC* (panel 1) (8%, 5/65), *RASSF1A* (3%, 2/65) (panel 26) and *p14^{ARF}* (6%, 4/65) (panel 18). It was surprising to see that the extremely low frequency in hypermethylation of the *RASSF1A* gene in CRC, which was hypermethylated in a wide range of the human tumors, including hepatocellular carcinoma^[10,14], astrocytoma (unpublished results) and other tumors^[33,34].

The following genes displayed significant alterations in methylation pattern deviated from that of the mucosa of the non-cancer tissues, including those with the moderate levels of changes: *MGMT* (20%, 13/65, panel 13), *hMLH1* (18%, 12/65, panel 11), *p16^{INK4a}* (10%, 10/65, panel 20), *MINT1* (15.4%, 10/65, panel 14), *MINT31* (11%, 7/65, panel 15); and with a great level of changes: *COX2* (72%, 47/65, (panel 6), *cyclin A1* (100%, 65/65, panel 8) and *CDX1* (100%, 65/65, panel 5), *RAR-β* (85%, 55/65, panel 25), *MYOD1* (69%, 45/65, panel 16), *p15^{INK4b}* (68%, 44/65, panel 19), *CDH13* (66%, 43/65, panel 4), *CXX1* (58%, 38/65, panel 7), *p73* (63%, 41/65, panel 23) and *WT1* (58%, 38/65, panel 31, Figure 1). In this list, while changes in methylation pattern of the majority of targets, were compatible with the previously reported frequencies in CRC patients in the Western countries^[7,11,35,36], there was a noticeable difference. For instance, we have found the *p15^{INK4b}* was significantly methylated in CRC (68%, 44/65), while this gene was not methylated at all in a similar study in USA^[35].

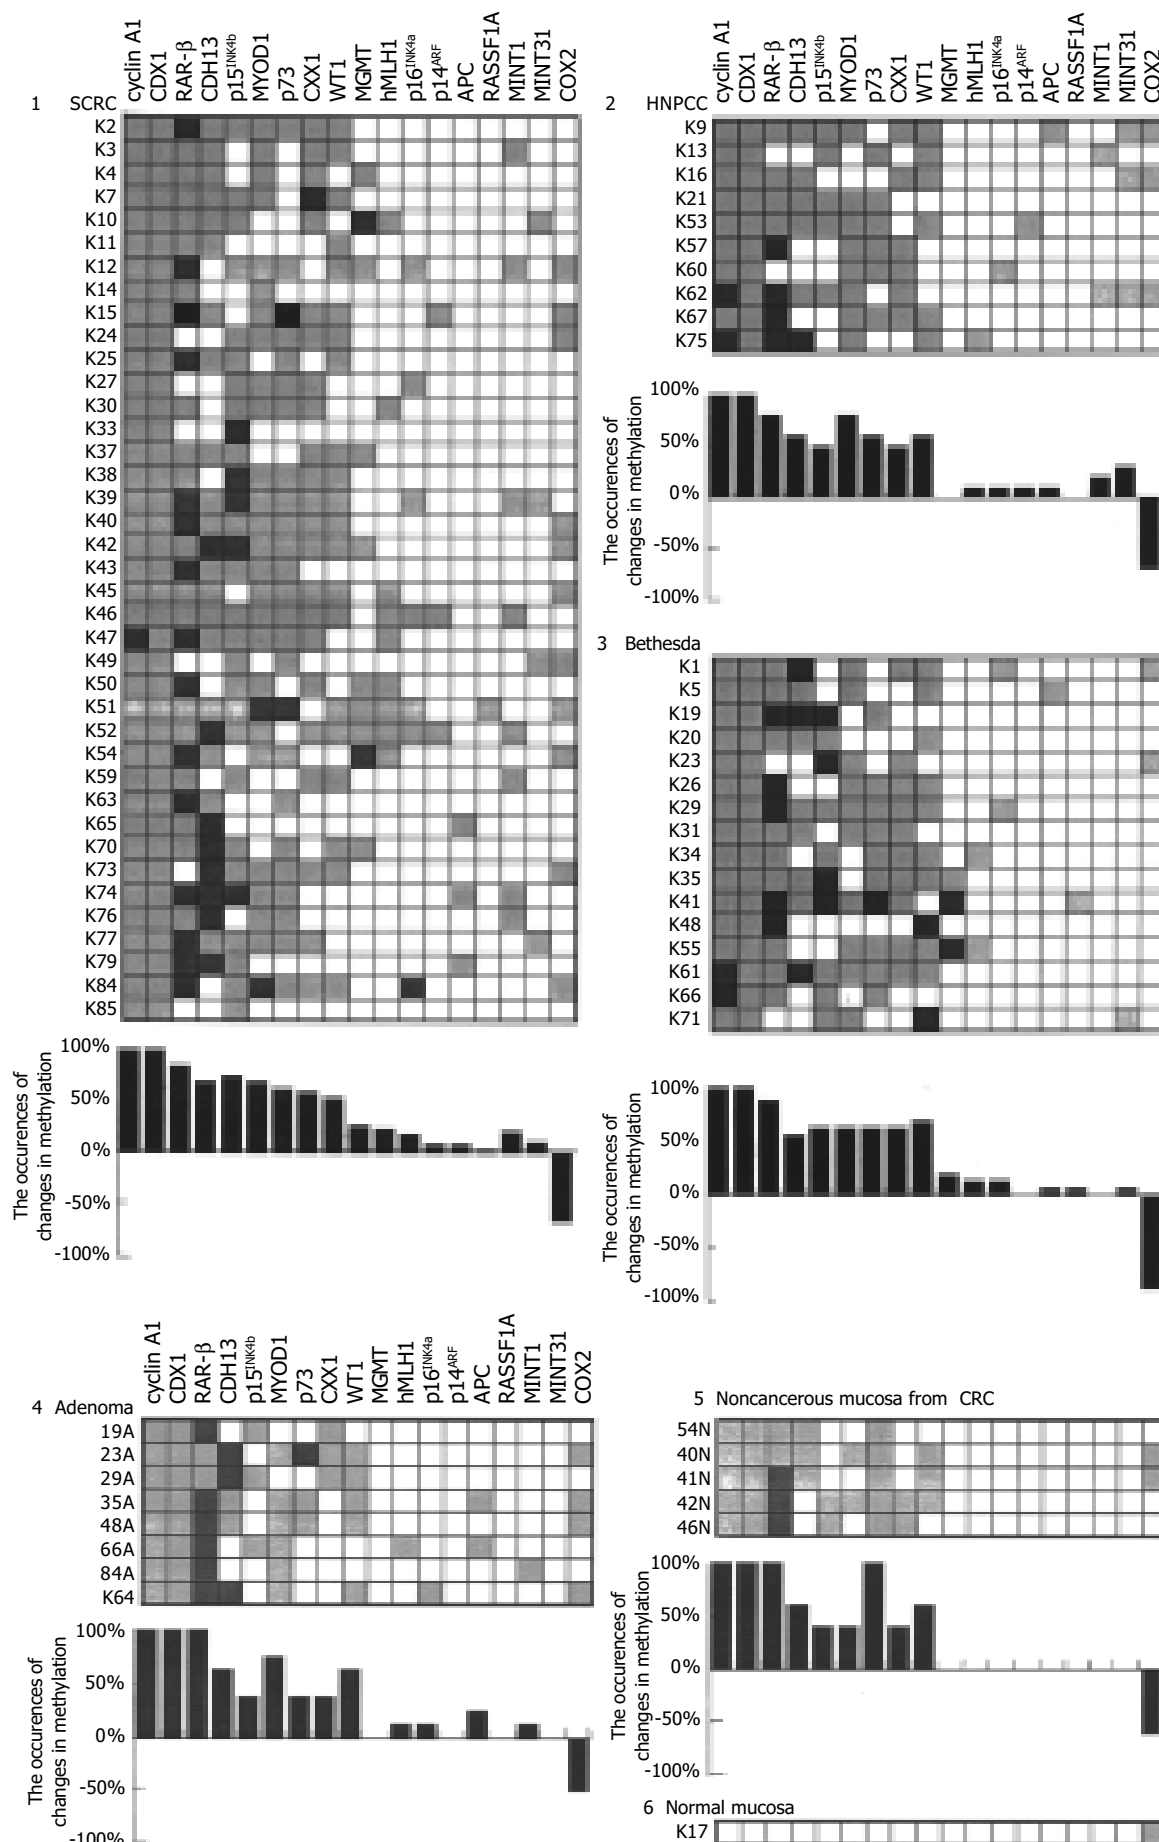

Figure 2 Changes in methylation pattern of genes in CRC and other relevant tissues. The frequency (%) of the hypermethylated targets among the total cases was calculated, and the frequency of the changes in the methylation pattern is presented in the plot as well as in the attached table. Panels: 1, SCRC, 2, HNPCC, 3, Bethesda, 4, Adenoma, 5, Non-cancerous mucosa from CRC patients and 6, the normal mucosa from a non-cancerous patient.

It was also our intention to correlate the methylation pattern with the clinical-pathological features of CRC patients. Subjected to the stringent statistic analysis ($P < 5\%$), none of the comparisons displayed any significant correlation. For instance, there was no statistic significance between the methylation changes of any given genes among different subgroups of CRC: SCRC and HNPCC as well as against other cohorts of tissues, such as colorectal adenoma and adjacent mucosa. This was likely to attribute to the small sample size. Although there was a decent number for SCRC ($n = 39$), the sample sizes for other subgroups were rather small: 10 HNPCCs, 16 Bethesda CRCs, eight adenomas, five non-cancerous mucosae and one normal mucosa.

It has been well recognized that the so-called non-cancerous cells pathologically defined may have already suffered some genetic lesions as the corresponding cancerous tissues, the outcome of the earlier events of carcinogenesis. The scenario of the genetic events from the normal mucosa to the full-blown CRC within the context of the well defined clinical and pathological parameters has been well characterized^[37]. In this study, we included samples of non-cancerous mucosa from five CRC patients, adenomatous samples from eight patients and tumorous tissues from 65 CRC cases including 39 SCRCs, 10 HNPCCs and 16 Bethesda CRCs, which enabled us to determine whether the changes in methylation pattern in CRC were specific to the early or late phases of carcinogenesis. Judged by the no difference in methylation pattern between the non-cancerous mucosa and adenoma and/or CRC (Figures 1, 2) (the same rationale used in our previous work on the hepatocellular carcinoma^[10]), we suggested that the high frequent changes in methylation pattern of the genes might be the early rather than the late phase events during carcinogenesis of CRC.

CRC was among the first few types of human cancers subjected to the rather intensive DNA methylation profiling, where changes in methylation in tumor samples were classified as the aging related as well as the cancer specific^[17,38,39]. For instance, the *MYOD1* was found also hypermethylated more frequently in the aged healthy epithelia tissues than their younger counterparts^[17]. Also from the studies of CRC, the concordant methylation profile of multiple genes was firstly reported, called "CpG island methylation phenotype (CIMP)", short for CpG island methylator phenotype^[11]. It implies that the unknown genetic mechanism (s) operating in CRC may contribute to the clustering profile of the DNA methylation of the multiple genes together. Among the 65 CRC cases, the distribution in occurrence of changes in the multiple genes was as following, 1, 3, 5, 7, 12, 11, 11, 7, 4, 1, and 3 cases, for assuming the methylation change of from 2, progressing step by step to 12 genes, respectively (Figure 3), with the 7 gene group as the peak.

In situ expression profile of 10 genes in CRC

Hypermethylation of the promoter CpG islands could reflect

the transcriptional silencing status of the gene. However, exceptions also were reported, suggesting the involvement of other mechanisms in the control of the gene transcription. To verify this notion, we immunostained 10 target proteins *in situ* on the home-made tumor tissue arrays, where the tissue blocks from 58 CRC samples along with several controls of the non-cancerous mucosa from the cancer patients were present. The results were scored from the negative (-), to positive: ranging from + to ++++. With the expression level in the non-cancerous mucosa as reference, the relative level of expression of each protein in the context of the methylation state of the promoter CpG islands of the genes was assessed. As shown in Figure 4 and summarized in Table 5, the unmethylated states of the promoter CpG islands of the following genes were indeed positively correlated with the expression levels of the genes. Among the cases of the fully unmethylated targets, expression of each protein \geq one + level occurred very frequently: for the *CDH13*, 73% (16/22); *RAR-b*, 100% (8/8); *COX2*, 80% (35/44); *p73*, 60% (12/20); *hMLH1*, 75% (35/47); *p14^{ARF}*, 100% (51/51); *TIMP3*, 80% (46/58) and *CDH1*, 98% (57/58). The only exception was *MGMT*, only 25% (2/8) of the unmethylated cases expressed this protein, suggesting the mechanisms other than DNA hypermethylation being involved. For the CRC cases with the heterozygous methylated status (u/m), expression of each proteins was: *CDH13*, 50% (14/28); *cyclin A1*, 70% (37/53); *RAR-*, 79% (22/28); *COX2*, 100% (14/14); *p73*, 54% (19/35); *MGMT*, 24% (11/46); *hMLH1*, 36% (4/11) and *p14^{ARF}*, 100% (2/2), respectively. For the CRC cases with the fully methylated targets, the expression profile of the genes was as the following: *CDH13*, 38% (33/58), *cyclin A1*, 80% (4/5), *RAR-*, 85% (17/20) and *MGMT*, 50% (2/4). Except for the *CDH13*, which expressed less frequently in the methylated than the unmethylated containing cases, the expression frequency was not significantly less prevalently in the methylated cases, even higher as far as the *MGMT* was concerned. Therefore, the correlation between the methylation status and level of expression of these 10 genes was not in a good agreement with the conventional notion.

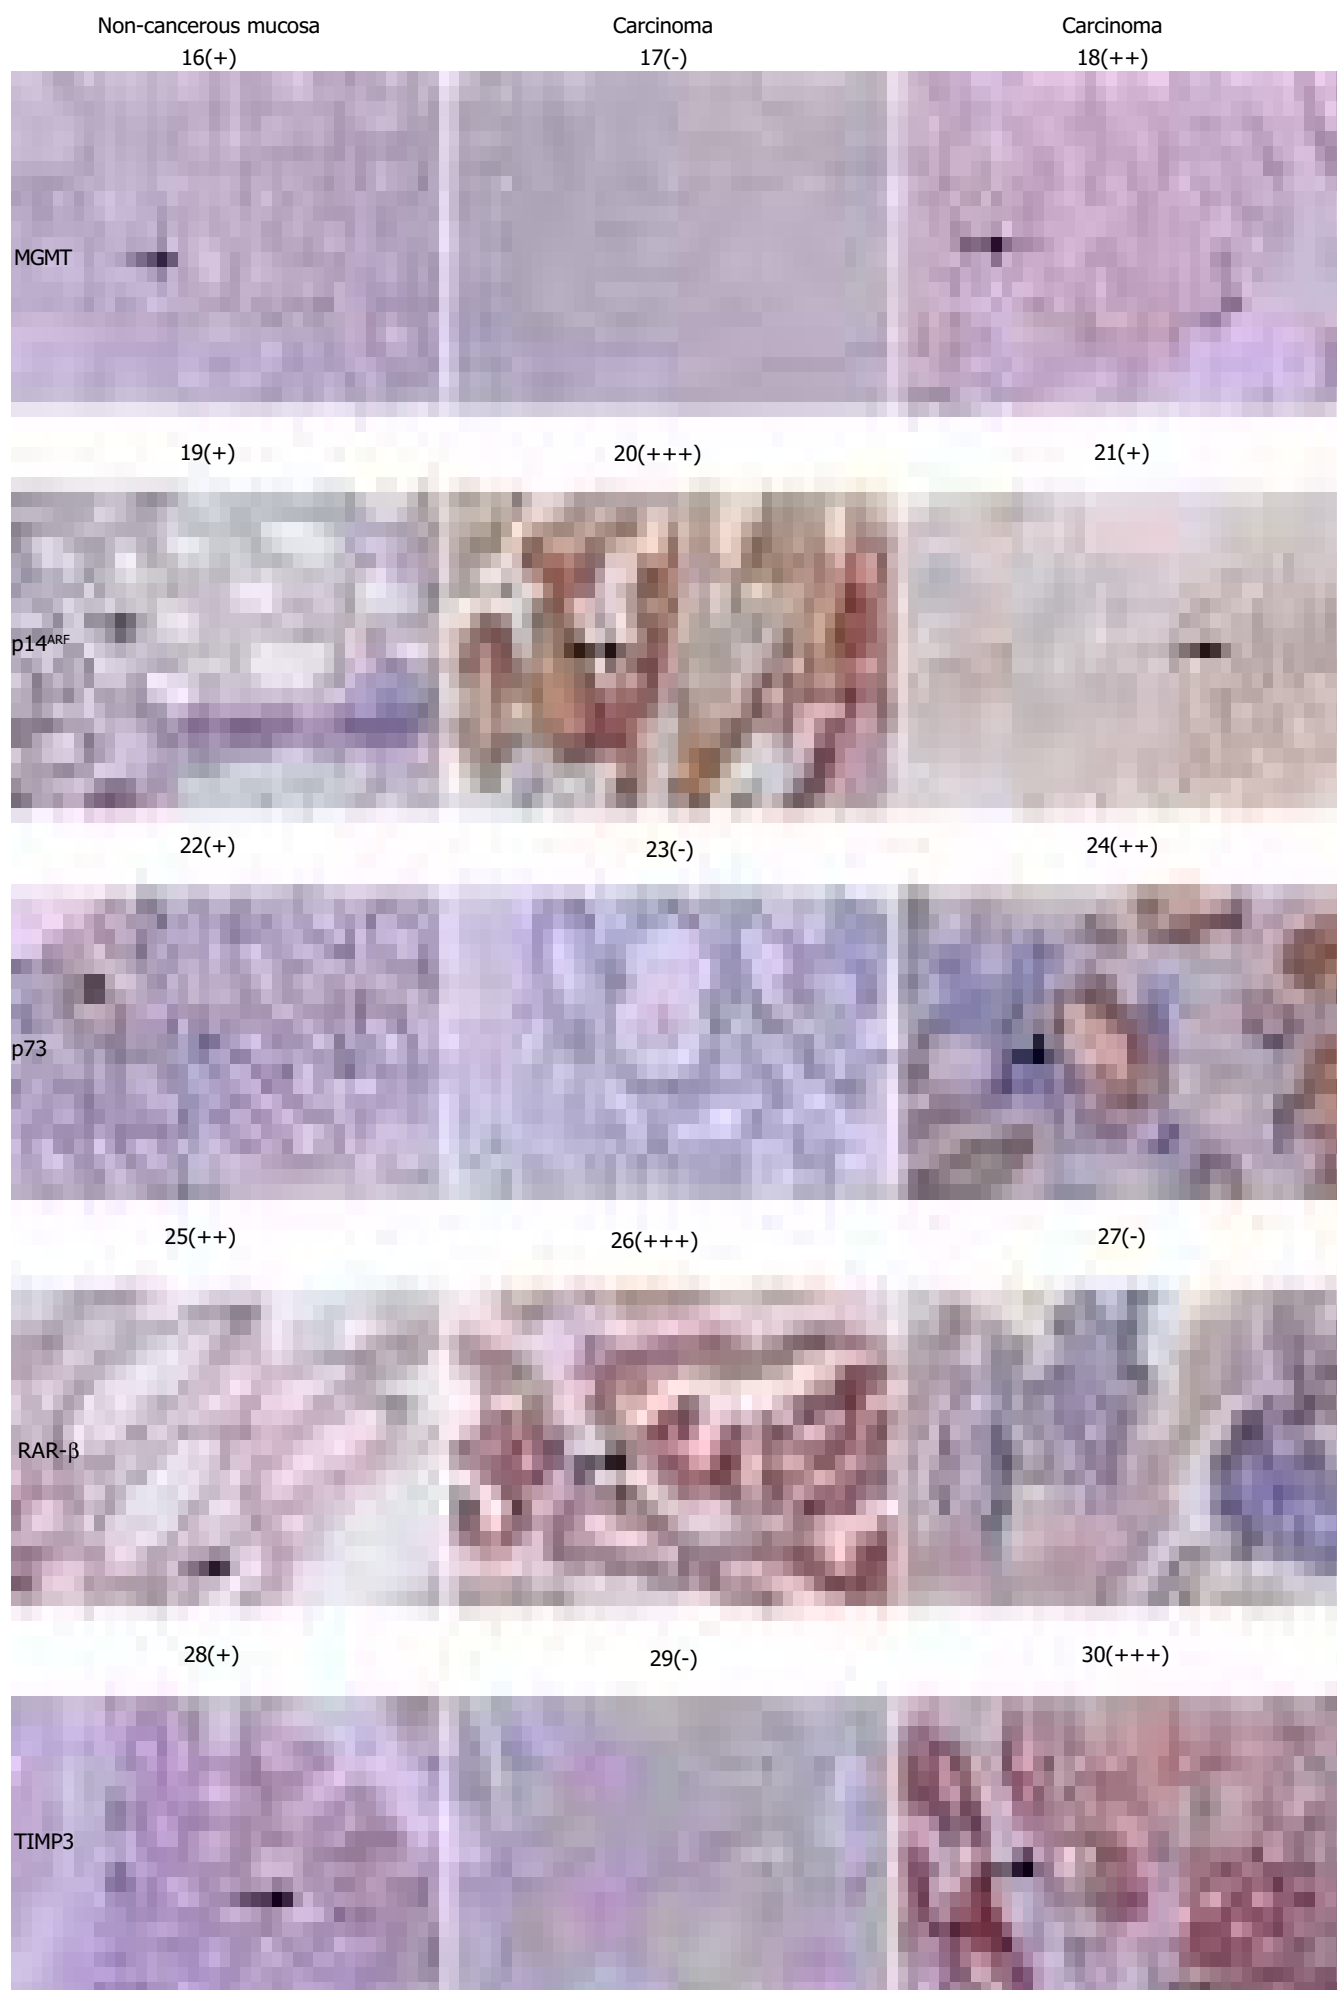

Figure 3 Concordant behavior of the multiple methylated loci in CRC.

Table 5 Expression profile of the genes in the context of DNA methylation status

Methylation status	Positive rate % (Positive cases/the total cases)									
	CDH13	Cyclin a1	RAR-	COX2	P73	MGMT	hMLH1	p14ARF	TIMP3	CDH1
U	73 (16/22)	/	100 (8/8)	81 (35/43)	60 (12/20)	24 (11/46)	74 (35/47)	100 (51/51)	80 (46/58)	98 (57/58)
U/M	50 (14/28)	70 (37/53)	79 (22/28)	93 (14/15)	54 (19/35)	25 (2/8)	36 (4/11)	100 (2/2)	/	/
M	38 (3/8)	80 (4/5)	85 (17/20)	/	/	50 (2/4)	/	/	/	/
Total	57 (33/58)	71 (41/58)	84 (47/56)	84 (49/58)	53 (31/58)	26 (15/58)	67 (39/58)	100 (53/53)	79 (46/58)	98 (57/58)
Non-cancerous mucosa	+	/	++	/	+	+	++	+	+	++

Figure 4 Immunochemical assessment of the expression level of each of 10 target genes. Both the protein targets (left site to) and sample identities (top down) of the immuno-chemical stained picture are indicated. The signs: -, +, ++, and +++ in bracket are used to provide the quantitative reference in pictures below. The areas pointed by the arrows are the regions showing the immunostaining data quantified.

DISCUSSION

In this study, 31 targets were selected to be studied, 65 cases of CRC, 8 cases of adenoma, five cases of non-cancerous mucosa from the cancer patients and one case mucosa from the non-cancerous patient. As far as the number of genes was concerned, this study is rather extensive, and it is the first of such a kind with CRC patients in China, and in Shanghai in particular.

Changes in methylation pattern of the promoter CpG islands are very common in CRC

By taking the methylation profile of the mucosa from the non-cancerous patient as the reference, CRC associated changes in methylation pattern were a very extensive event, 17 among of 31 targets assumed the altered patterns, the following 14 changed in more than 20% of CRC cases as a whole: *MGMT* (20%, 13/65), *hMLH1* (18%, 12/65), *p16^{INK4a}* (10%, 10/65), *MINT1* (15.4%, 10/65), *MINT31* (11%, 7/65), *COX2* (72%, 47/65), *cyclinA1* (100%, 65/65), *CDX1* (100%, 65/65), *RAR-* (85%, 55/65), *MYOD1* (69%, 45/65), *p15^{INK4b}* (68%, 44/65), *CDH13* (66%, 43/65), *CXX1* (58%, 38/65), *p73* (63%, 41/65) and *WT1* (58%, 38/65) genes. Furthermore, there was only one case assuming the methylation changes with three genes (Figure 3), no less than 76.3 % of cases assumed changes in methylation more than seven targets (49/65), 86% more than six targets (56/65), 93.8% more than five targets (61/65). This observation indeed supports the concept, "CpG island methylator phenotype", for that changes in methylation pattern in CRC indeed tend to be clustered. As a similar survey with the astrocytoma showed that less 26.4% patients assumed no more than two gene (among 31 targets being surveyed), and the occurrence of changes in methylation pattern for at least five, six and seven targets was 41.51%, 20.75 and 9.43% in a cohort of 56 astrocytoma patients (unpublished data). The high incidence of changes in CRC may be partly attributed to the fact that colorectal epithelial cells were much amenable to the environmental challenges.

Except for the genes that have been proved in the category of tumor associated genes, such as *p16^{INK4a}*, *p15^{CDKN4b}*, *p14^{ARF}*, *p27^{KIP1}*, *WT1*, *VHL*, *RB*, *p73*, *APC*, *N33*, *PTEN* and *BRCA1*, the *MAGEA1* and *RAR-* genes have not been studied in CRC. While the *MAGEA1* gene displayed the homozygously methylated state in all samples tested, the *RAR-* gene indeed changes its methylated state from the unmethylated in the normal mucosa toward the hypermethylated state at a significantly higher frequency in CRC, over 85% (55/65). The retinoic acid receptor (*RAR*) gene is a putative tumor suppressor gene on chromosome 3p24, where a high incidence of loss of heterozygosity (LOH) is detected in many types of tumors. Retinoic acid suppresses cancer cell growth through binding to *RARs*, especially *RAR-*, indicating a critical role in mediating anticancer effects. Selective loss or down-regulation of the *RAR* mRNA and protein has been reported in prostate cancers. The DNA methylation mediated silencing of this gene has been suggested as an etiological factor for carcinogenesis of prostate cancer^[40]. This result indicates that the *RAR-* hypermethylation may be the mechanism of expression silencing in these tumor cells^[41]. However, its etiological significance in carcinogenesis of CRC remains to be clarified.

The following genes: *CXX1*, *CDX1*, *SFRP1*, *MINT1* and *MINT31* were initially identified as the CRC associated hypomethylated genes by an approach at the genome level^[16]. Except for the *SFRP1* gene that was not methylated with all the samples being tested, the rest targets were indeed hypermethylated to varying extents in CRC (Figures 1, 2). Tumor suppressor gene *RASSF1A* was inactivated predominantly by promoter methylation and rarely by somatic mutations. Wagner *et al.*^[34] investigated *RASSF1A* promoter methylation in colorectal

cancer and detected *RASSF1A* methylation in 80% (4/5) colorectal cancer cell lines and 45% (13/29) primary colorectal cancers. But we found that the frequency of *RASSF1A* methylation was extremely low in CRC although we previously found this gene was hypermethylated (100%) in HCC^[14].

Does the methylation profile of the promoter CpG islands of the genes correlate with the expression of the genes?

Although it has been generally accepted that the hypermethylated status of the promoter CpG islands represents the long-term transcription silencing state of the genes, its credential has not been thoroughly checked in clinical samples, due to various limiting factors, including availability and inherent diversity of the cell types in the actual samples. In this study, we immunostained the genes with antibodies to assess the expression of 10 genes in a home-made tissue array. For both homozygously and heterozygously unmethylated samples, nine of 10 targets (except for *MGMT*) expressed at a detectable level of more than 60% cases. It was generally fit with the expectation. For the fully methylated CRC, only four targets were involved, among which the profile of the *CDH13* gene met the expected profile. The expression frequency (38%, 3/8) in methylated samples was significantly lower than heterozygously methylated (50%, 14/28), and homozygously unmethylated (73%, 16/22). The profiles of the other three targets did not comply with the role at all. Both *cyclin A1* and *RAR-* genes expressed equally well as the CRC samples of m/u type. Furthermore, it was paradoxically found that the *MGMT* gene expressed more prevalently in the methylated CRC cases (50%, 2/4) than its counterparts (u/m: 25%, 2/8 and u: 25%, 11/46). As we have previously shown in astrocytoma cell lines, the methylated status of the promoter CpG islands inversely correlated with the expression of the *MGMT* gene (unpublished data), this rather unexpected observation should be looked into further. In conclusion, despite the general roles that have been followed as to the inverse correlation between the methylation state of the promoter CpG islands and expression, the exception is also distinguishingly noticeable. Therefore, it should be very cautious in correlating the methylated status with the expression profile of the genes.

Demethylation of the COX2 gene correlates with the increased frequency in its expression

Cyclo-oxygenase 2 (*COX2*), an inducible isoform of prostaglandin H synthase, which mediates prostaglandin synthesis during inflammation, and is selectively over-expressed in colon tumors, is thought to play an important role in colorectal carcinogenesis^[42]. Its expression in the normal epithelial cells is low, but can be induced by a variety of stressing agents, including tumor promoters and inflammatory cytokines. In the list of the genes displaying changes in methylation, it was noticed that the *COX2* gene was the only target that displayed CRC associated demethylation, i.e., from the heterozygous methylated state to fully demethylated in 47 among 65 cases being studied (72%) (Figures 1, 2). The *COX2* gene did not express in the control non-cancerous tissues, indicating that it seems less likely to have the physiological role in normal colon epithelial cells. Although there was no increase in the frequency of expression in CRC from the heterozygously to the fully unmethylated CRC cases (Figure 2), the fact that over 82% CRC cases expressed this gene was indeed supportive.

Tumor type specificity of the methylation profile

It has been well established that the methylation profile as an inheritable epigenetic signature in any given cells reflects both history of cell differentiation and the chronicle of aging, in addition to those closely associated with the biological profiles

of tumors^[6,43,44]. It is desirable to identify the changes, specific to one type of tumor from the others, otherwise our efforts to use the DNA methylation pattern, as the biomarkers for tumor diagnosis would be severely constrained. Therefore, we compared the methylation patterns in HCC^[10,14] with those in CRC. As shown in Figure 5, there were methylation changes common to both HCC and CRC i.e., the *p73* gene: 73% in HCC vs 62.5% in CRC and the *MYOD1* gene: 57.8% in HCC vs 69.23% in CRC. The following changes were more prevalent in CRC than in HCC: the *cyclin A1* gene: 100% in CRC vs 53.85% in HCC; the *WT1* gene: 58.46% in CRC vs 30.77% in HCC; and the *CDH13* gene: 64.62% in CRC vs 23.08% in HCC. The following two genes were more frequently hypermethylated in HCC than in CRC: the *RASSF1A* gene: 100% in HCC vs 3.08% in CRC; and the *p16^{INK4a}* gene: 53.85% in HCC vs 15.38% in CRC. Although little is known about the mechanisms underlying the tumor specific methylation profiles of CRC vs those of HCC, the distinct profiles of CRC vs HCC should have the profound implication in the future diagnostic tools to differentiate these two common human cancers.

Figure 5 Tumor specific methylation pattern: CRC verse HCC.

In conclusion, the altered promoter CpG island methylation patterns of 17 genes are the common and distinguished hallmarks specific to the early phase of colon carcinogenesis, although no significant correlation has been detected between the changes in the methylation patterns with any given clinical-pathological features. The correlation between the methylated state of the promoter CpG islands and the expression of the corresponding genes has not been proved as close as previously suggested. Our observations from this rather extensive methylation-profiling maneuver would provide new insights into the role of the DNA methylation mediated control in the colon carcinogenesis as well as the clues for the development of robust diagnostic and prognostic tools for colorectal cancer.

Abstract

AIM: To investigate the inhibitory effect of phosphorothioate anti-sense oligodeoxynucleotides (PASODN) on colorectal cancer LS-174T cells *in vitro* and the mechanism of inhibition of telomerase activity in these cells.

METHODS: PASODN were used to infect LS-174T cells and block human telomerase RNA (hTR) through anti-sense technology. The inhibitory effect of PASODN was evaluated by colony-forming inhibition assay and growth curve. Changes of telomerase activity in LS-174T cells were detected by polymerase chain reaction-enzyme-linked immunosorbent assay (PCR-ELISA), and the level of apoptosis was analyzed by flow cytometry (FCM) assay.

RESULTS: PASODN showed a dose and time-dependent inhibition of cell proliferation. The optimal dosage of PASODN was 10 $\mu\text{mol/L}$. The colony-forming efficiency was 10.3% in PASODN group after 10 d, whereas that in phosphorothioate mis-sense oligodeoxynucleotides (PMSODN) group with the same concentration and in PBS group (blank control) was 49.1% and 50.7%, respectively. PCR-ELISA results indicated that telomerase activity in the PASODN group was obviously inhibited in comparison with in the control groups ($P < 0.01$, $t = 3.317$ and 3.241 , $t_{0.01(20)} = 2.845$). Meanwhile, before the number of cells was decreased, the morphological changes were observed in the cells of PASODN group. The cells in PASODN group showed the apoptotic peak at 72 h after infection, whereas the control group did not show.

CONCLUSION: Specific sequence oligonucleotides can inhibit telomerase activity and lead to cell apoptosis, suggesting a novel treatment strategy for malignant tumors induced by telomerase.

INTRODUCTION

Telomerase, a ribonucleic acid-protein complex, adds hexameric

repeats of 5'-TTAGGG-3' to the ends of telomeres to compensate for the progressive loss in malignant tumor cells^[1,2]. Because of its preferential expression in malignant tumors and lack of expression in normal tissues^[3-5], the idea that telomerase is a potential target of cancer therapy has been widely accepted^[6,7]. From the theoretical point of view, telomerase-associated therapeutic approach to telomerase-positive tumors is the anti-telomerase cancer therapy that directly inhibits telomerase activity, resulting in apoptotic cell death or growth arrest. Two major components of the telomerase holoenzyme complex: human telomerase RNA (hTR) and catalytic subunit (human telomerase reverse transcriptase, hTERT), are considered as the therapeutic targets^[8]. Since the growth of majority, or even parts of malignant tumors depends on telomerase, the strategy of anti-telomerase cancer therapy is necessary and important. In this study, we investigated the inhibitory effect of PASODN on colorectal cancer cells.

MATERIALS AND METHODS

Human colorectal cancer cell line LS-174T was obtained from Shanghai Institute of Cell Biology (Shanghai, China). Oligonucleotides were synthesized in Shenggong Company (Shanghai, China). The sequences of oligonucleotides were as follows: PASODN: 5'-TTAGGG-3', and PMSODN: 5'-TGTGAG-3'. Telomerase PCR-ELISA kit (No. 1854666) was purchased from Roche Company.

Cell culture

Colorectal cancer LS-174T cells were cultured in RPMI 1640 (GIBCO, UK) supplemented with 100 mL/L charcoal-stripped FCS (GIBCO, UK), 500 units/mL penicillin and 0.1 $\mu\text{g/mL}$ streptomycin (SIGMA, USA) at 37 °C with a humidified atmosphere containing 50 mL/L CO₂. The medium was changed every 48 h. Cell cycle was 12 h approximately. Cells in logarithmic phase were used in all experiments.

Selection of optimal concentration of PASODN

The LS-174T cells (100 cells/mL in each well) were transferred to 24-well plates and cultured in 500 μL of RPMI 1640. Wells were divided into six groups with different final concentrations of PASODN: 0, 1, 2.5, 5, 10 and 20 $\mu\text{mol/L}$, respectively, the first one acted as a control. The medium was changed every other day. Ten days later, the cells in each well were stained with Giemsa and the colony-forming units were counted (consisting of more than 50 cells) under a phase contrast microscope. The optimal concentration of PASODN was screened according to the relative rate of inhibition of colony forming according to the formula: the relative rate of inhibition of colony-forming (%) = (1 - number of clone in experiment group / number of clones in control group) $\times 100\%$.

Inhibition of colony formation

Logarithmic phase cells were digested, suspended and calculated, and then suspension was transferred to 6-well plates. Cell concentration was 400 cells/mL in each well. Wells were divided into: PASODN group, PMSODN group, and PBS group. The

later two groups acted as controls. Twenty hours after the cells were adhered, RPMI 1640 was removed and wells were washed with 2.5×PBS. Cells were incubated with 2 mL of RPMI 1640 culture medium containing 10 μmol/L PASODN, 10 μmol/L PMSODN and PBS (same volume). Medium was changed every other day. The incubation was terminated 10 d later. The colony-forming units were stained by Giemsa dye and counted. Colony-forming efficiency = (unit number / cell number) × 100%.

Inhibition of cell proliferation

LS-174T cells (10×10^3 cells/mL in each well) were transferred to 24-well plates. Wells were divided into three groups and the cells were treated as mentioned above in 1 mL of RPMI1640 culture medium. Medium was changed every other day. The number of cells in each group was counted every day, and morphological changes were observed. The growth curve of the cells was obtained 13 d later.

Variation of telomerase activity detected by PCR-ELISA and silver staining assay

PCR-ELISA was performed following the manufacturer's instructions. All solutions were provided by the kit from Roche.

Briefly, the cells were digested, collected and centrifuged at 800 r/min for 10 min seven days after treatment with the reagents mentioned above. The supernatant was discarded. A total volume of 200 mL of the refrigerated lysis medium was added into a tube and placed on ice for 30 min. The cells were centrifuged at 16 000 g for 20 min at 4 °C. Then 100 mL of the supernatant was removed into a new tube. The telomere sequence was amplified in a 50 mL PCR system containing 25 mL of reaction solution, 2 mL of supernatant, 23 mL of triple-distilled water. PCR amplification was performed in the 9600 thermal cycler (PEPKIN ELMER): one cycle of primer extension at 25 °C for 30 min, 2 cycles of the inactivation at 94 °C for 5 min, 3-32 cycles of amplification at 94 °C for 30 s, at 50 °C for 30 s, at 72 for 90 s. The amplification products were stored at 4 °C.

The hybridization and ELISA were carried out as described below.

Denaturation solution and PCR products were incubated at room temperature for 10 min, 225 mL of hybridization solution was added and mixed thoroughly. Then 100 mL of the mixture was put in a 96-wells plate (provided by the kit), and the plate was vibrated (300 r/min) while it was incubated at 37 °C for 2 h. All the mixture was removed and the plate was rinsed 3 times. One hundred mL of anti-DIG peroxidase was added to each well, vibrated (300 r/min) and incubated at room temperature for 30 min. The solution was completely removed and each well was rinsed 5 times, 100 mL of substrate solution was added and incubated at room temperature for 15 min. Then the substrate solution was reserved, 100 mL stop solution was added into each well to terminate the discoloration development. The absorbance of the samples was measured (ΔSA value) at 450 nm and at 690 nm within 30 min after termination of the reaction. If the value of ΔSA of the sample was higher than '0.2 $\Delta SA_{450\text{nm}} - \Delta SA_{690\text{nm}}$ ', then the telomerase in the sample was regarded as positive. The final value was expressed as mean±SD, a statistical treatment was performed by using *t* test.

FCM analysis

Cells in logarithmic phase were incubated with 10 μmol/L PASODN for 72 h and subsequently harvested by trypsinization, beated upon with PRMI 1640 culture containing serum, and centrifuged at 1 000 r/min for 10 min. The supernatant was removed. The cells were fixed with 700 mL/L cold ethanol. FCM analysis of the DNA content was performed on a flow cytometer (FACS Calibur™ B.D USA).

Statistical analysis

The data were expressed as mean±SD. Analysis of data was performed using student's *t* test. *P*<0.01 was considered as statistically significant.

RESULTS

Optimal concentration of PASODN

Although colony formation in LS-174T cells was inhibited by PASODN at the lower concentrations (1, 2.5, 5 μmol/L) in a dose-dependent manner, 10 μmol/L seemed the best concentration and the relative rate of inhibition was 82.8% (slightly lower than that in 20 μmol/L group) (Table 1).

Table 1 Selection of optimal concentration of PASODN

Clones	Concentration of PASODN (μmol/L)					
	0	1	2.5	5	10	20
Mean	64.7	51.5	41.0	24.7	11.1	8.4
Inhibitive rate (%)	0	20.4	36.6	61.8	82.8	87.0

Effect of PASODN on colony formation

The colony-forming efficiency of cells treated with PASODN was 10.3%, which was significantly lower than that in PMSODN group (*P*<0.01, *t* = 3.174) and PBS group (*P*<0.01, *t* = 3.263). No significant difference was observed between PMSODN group and PBS group (Table 2).

Table 2 Colony-forming efficiency in each group (mean±SD)

	PASODN (10 μmol/L)	PMSODN (10 μmol/L)	PBS (same volume)
Mean±SD	41.2±5.5	196.3±13.5	202.8±8.5
Efficiency (%)	10.3	49.1	50.7
vs PASODN		<i>P</i> <0.01	<i>P</i> <0.01

Effect of PASODN on growth and morphology of LS-174T cells

No significant effect was observed during the initial 5 d, but a time-dependent effect was observed during the subsequent days (Table 3 and Figure 1). The growth inhibition was observed obviously from the 7th d, which reached the peak from the 11th to 13th d. But PMSODN had no evident effect on cell growth. Under microscopy, obvious morphological changes were observed in the cells of experiment group as follow. Cells turned round, cell membranes shrank, and nuclei were concentrated at the karyothecae. The number of cells was very small and cells did not compact with each other. On the other hand, cells in other groups grew bloomy and tightly (Figure 2).

Table 3 Variation of telomerase activity (mean±SD)

Group	SA	<i>P</i>
PASODN	0.18±0.12	
PMSODN	1.89±0.24	<0.01
PBS	1.98±0.25	<0.01

Figure 1 Curve of cell growth with time.

Figure 2 Changes in cell morphology and distribution. A: PMSODN group (10×40); B: PASODN group (10×40); C: PMSODN group (10×10); D: PASODN group (10×10).

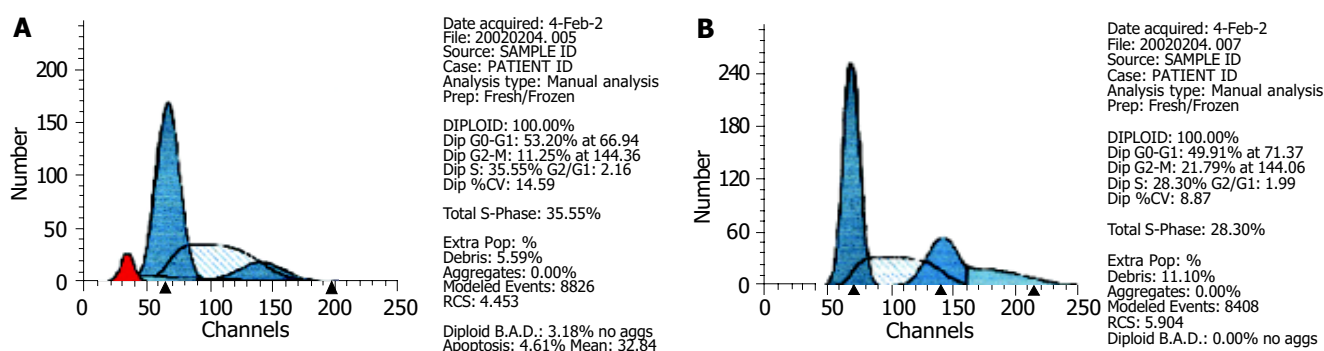

Figure 3 Cell cycle after 72 h of treatment with PASODN(A) and PMSODN(B) detected by FCM.

Variation of telomerase activity

Telomerase activity in PASODN group had no change. The ΔSA value of telomerase activity in PASODN group was significantly different from that in the other two control groups ($P < 0.01$, $t = 3.317$ and 3.241 , $t_{0.01(20)} = 2.845$) (Table 3).

Results of FCM

FCM analysis showed that the proportion of cells in G_0/G_1 and S phases increased appreciably 72 h after 10 $\mu\text{mol/L}$ PASODN treatment, but no difference was observed between experiment and control groups (Table 4). A hypo diploid apex representing the apoptotic cells, was found before the apex of G_0/G_1 in the experiment group (Figure 3A), but not in control group (Figure 3B).

Table 4 Effect of PASODN on LS-174T cell cycle

Groups	G_0/G_1	G_2/M	S
Control	49.91	21.79	28.30
PASODN	53.20	11.25	35.55

DISCUSSION

With the development of living conditions, the incidence of colorectal cancer has been going up year by year. Colorectal

cancer is not sensitive to traditional chemotherapy^[9]. So, it seems important to exploit potent and nontoxic drugs in this field. Telomerase activity has been reported to express in cancer but not in most normal somatic cells, suggesting that telomerase might be an important target for chemotherapy. Telomerase consists of an RNA component (hTR) that binds to telomere and a protein component (hTERT) that acts as a reverse transcriptase. In our opinion, targeting the template region of hTR with anti-sense reagents (such as oligonucleotides) may offer more advantages than targeting hTERT gene. It has been reported that the expression of telomerase activity depends on Watson-Crick base pair between hTR gene and telomere^[10]. This accessibility and indispensability make hTR an ideal and convincing target for oligonucleotides.

PASODN exerted its inhibitory effect on LS-174T cells both at the cellular and molecular levels, whereas no such effects were observed in the control groups. Moreover, the inhibitory effect was time and dose-dependent. The inhibitory effect of PASODN on the cells had a certain latent phase. The growth curve showed that the inhibitory effect of PASODN on the growth of LS-174T cells was obvious on the seventh day, and reached the greatest value from the 11th to 13th d. Besides, the growth curve combined with the result of telomerase activity showed that after telomerase activity turned negative (on the 7th d), the cells could still continue to cleavage a certain number

of times, and the phenomenon might be the “retarded effect” of telomerase inhibitor treatment.

In conclusion, specific oligonucleotide sequences can inhibit telomerase activity and lead to apoptotic cell death. The intrinsic existence of hTR in malignant tumors makes telomerase an ideal target for anti-sense reagent attack. But, we must pay attention to the fact that hTR also exists in normal somatic cells^[11,12]. How to improve the tumor-affinity to oligonucleotids is still a problem. The lag phase^[13] indicated that anti-telomerase inhibitors were unlikely to produce acute anti-proliferative effects. However, with researches going on in the field of telomerase and the advanced experiences of oligonucleotides in other molecular fields^[14-16], the trial in animals and humans will be taken in near future.

Abstract

AIM: To investigate the anticancer activity of Honokiol on RKO, a human colorectal carcinoma cell line *in vitro* and *in vivo*, and to evaluate its possible use in clinic.

METHODS: *In vitro* anticancer activity of honokiol was demonstrated by its induction of apoptosis in tumor cells. We analyzed cell proliferation with MTT assay, cell cycle with flow cytometer, DNA fragment with electrophoresis on agarose gels. To test the mechanism of honokiol-induced apoptosis, Western blotting was used to investigate the factors involved in this process. The pharmacokinetics study of honokiol was tested by high phase liquid chromatography. In *in vivo* study, Balb/c nude mice were incubated with RKO cells. Honokiol was injected intraperitoneally every other day into tumor bearing Balb/c nude mice.

RESULTS: Our results showed that honokiol induced apoptosis of RKO cells in a time- and dose-dependent manner. At 5-10 $\mu\text{g/mL}$ for 48 h, honokiol induced apoptosis through activating Caspase cascades. Pharmacokinetics study demonstrated that, honokiol could be absorbed quickly by intraperitoneal injection, and maintained in plasma for more than 10 h. In nude mice bearing RKO-incubated tumor, honokiol displayed anticancer activity by inhibiting tumor growth and prolonging the lifespan of tumor bearing mice.

CONCLUSION: With its few toxicity to normal cells and potent anticancer activity *in vitro* and *in vivo*, honokiol might be a potential chemotherapy candidate in treating human colorectal carcinoma.

INTRODUCTION

In traditional Chinese medicine, Houpu (*Magnolia officinalis*) has long been one of the important herbs. It is widely used by Chinese people in treating thrombotic stroke, typhoid fever,

anxiety and nervous disturbance^[1] when used in combination with other herbs. With its major active constituent extracted from the bark of Houpu, honokiol has been found having a variety of pharmacological effects, such as anti-inflammatory^[2], antithrombotic^[3], anti-arrhythmic^[4], antioxidative^[5] and anxiolytic effects^[6]. Recently, honokiol has been reported to exhibit a potent cytotoxicity by inducing cell apoptosis in rat and human leukemia cells^[7,8], human fibrosarcoma cells^[9], human squamous lung cancer CH27 cells^[10] and human SVR angiosarcoma cells^[11], yet there has been no report on honokiol in the treatment of human colorectal carcinoma.

Previous studies have shown that honokiol can induce apoptosis with characteristic morphological changes and DNA fragments, involvement of Caspase family and Bcl-2 family^[10]. It could reduce tumor volume of SVR angiosarcoma in nude mice^[11]. However, it is still unclear whether honokiol can be used as a monomer in clinic. In this study, we chose colorectal carcinoma cells to investigate its possible application in clinical practice.

MATERIALS AND METHODS

Cell line and reagents

Human colorectal cell line RKO was provided by the Cancer Institute of Zhejiang University. Cells were maintained in RPMI-1640 medium (Gibco BRL) supplemented with 100 mL/L heat-inactivated fetal bovine serum (Si-Ji-Qing Biotechnology Co, Hangzhou, China), 100 U/mL penicillin and 100 $\mu\text{g/mL}$ streptomycin at 37 °C in a 50 mL/L CO₂ atmosphere. Antibodies used in this study including Caspases-3, -9 and pan-actin were purchased from NeoMarkers, Fremont, CA, USA. Honokiol was obtained from the National Institute for Pharmaceutical and Biological Products, Beijing, China. The drug was dissolved in dimethyl sulfoxide (DMSO) at the stock concentration of 10 g/L. It was further diluted in culture medium at the final DMSO concentration <1%. 3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide (MTT) was purchased from Sigma Chemical Corporation, USA. Six weeks old female Balb/c mice and female BALB/c nude mice (weighing 20±2 g each) were provided by the Experimental Animal Center of Zhejiang University.

Cell proliferation assay

Cells (1×10^4 in 100 μL) were seeded on 96-well plates in triplicate. Following a 24-h culture at 37 °C, the medium was replaced with fresh medium at various concentrations of honokiol in a final volume of 200 μL . Cells were incubated at 37 °C for 68 h^[12,13]. Then 50 μL of MTT (2 mg/mL in PBS) was added to each well, incubated for an additional 4 h, the plate was centrifuged at 1 000 r/min for 10 min, then the medium was removed. MTT formazan precipitate was dissolved in 100 μL of DMSO, shaken mechanically for 10 min and then read immediately at 570 nm in a plate reader (Opsys MR, Denex Technology, USA).

Morphological changes and detection of DNA fragmentation

RKO cells were exposed to a variety of concentrations of honokiol for 24 h, then examined under reverse microscope

(Olympus) and imaged with a digital camera. To detect DNA fragments, the cells were collected and lysed with lysis buffer containing 50 mmol/L Tris-HCL (pH 7.5), 20 mmol/L EDTA, and 10 g/L NP-40. Then 10 g/L SDS and RNase (5 μ g/mL) were added to the supernatants, and incubated at 56 °C for 2 h, followed by incubation with proteinase K (2.5 μ g/mL) at 37 °C for 2 h. After the DNA was precipitated by addition of both ammonium acetate (3.3 mol/L) and ethanol (99.5 %), it was dissolved in a loading buffer. DNA fragmentation was detected by electrophoresis on 15 g/L agarose gels and was visualized with ethidium bromide staining.

Cell cycle analysis by FCM

Honokiol-treated RKO cells and vehicles were fixed with 700 mL/L alcohol for 15 min at 4 °C, then stained with 1.0 μ g/mL propidium iodide (PI, Sigma, USA). The red fluorescence of DNA-bound PI in individual cells was measured at 488 nm with a FACSCalibur (Becton Dickinson, USA) and the results were analyzed using ModFit 3.0 software. Ten thousand events were analyzed for each sample.

Western blot assay

RKO cells (5×10^6) were lysed by 4 g/L trypsin containing 0.2 g/L EDTA, then collected after washed twice with phosphate-buffered saline (PBS, pH 7.4). Total protein extracts from the cells were prepared using cell lysis buffer [150 mmol/L NaCl, 0.5 mol/L Tris-HCL (pH 7.2), 0.25 mol/L EDTA (pH 8.0), 10 g/L Triton X-100, 50 mL/L glycerol, 12.5 g/L SDS]. The extract (30 μ g) was electrophoresed on 120 g/L SDS-PAGE gel and electroblotted onto polyvinylidene difluoride membrane (PVDF, Millipore Corp., Bedford, MA) for 2 h in a buffer containing 25 mmol/L Tris-HCL (pH 8.3), 192 mmol/L glycine and 200 mL/L methanol. The blots were blocked with 50 g/L nonfat milk in TBST washing buffer for 2 h at room temperature and then incubated at 4 °C overnight with anti-caspase-3 and -9 antibodies (NeoMarkers), all of which were diluted 1:400 in TBST. After washed at room temperature with washing buffer, they were labeled with peroxidase-conjugated secondary antibodies.

Cell toxicity on primary cells

Primary human fibroblast cells were derived from fresh skin^[13]. Human monocytes were isolated from umbilical blood by Ficoll-Hyque separation method while seeded in 96-well microplates at the concentration of 5 μ g/mL phytohemagglutinin (PHA)^[14]. HUVECs isolated from fresh human umbilical cords were inoculated into 96-well microplates at 5 000 cells/well^[15]. Following treatment with the concentrations of 5, 10, 20, 40 μ g/mL of honokiol for 24 h, cell viability was estimated by trypan blue exclusion. Three wells were measured at each time point/concentration. Six wells were measured for each concentration of test compound. All toxicity experiments were at least repeated three times.

Pharmacokinetics study

For intraperitoneal (ip) pharmacokinetics study, honokiol was mixed with PEG400/dextrose by 7:3 in volume at a concentration of 20 g/L. Thirty Balb/c mice received honokiol by i.p. at a dose of 250 mg/kg. Blood samples were collected as described^[16]. The plasma concentrations were tested by the total fluorescence intensity at 290 nm with high phase liquid chromatograph (HPLC, HEWLETT PACKARD)^[17]. Chromatography was carried out using a Hypersil C18 column (5 mm \times 100 mm \times 2.1 mm) with a flow rate of 0.2 mL/min. Pharmacokinetic parameters were estimated by Modkine programs (Biosoft, UK).

In vivo efficacy evaluation

Effect of honokiol on ascites formation in Balb/c nude mice
Five Balb/c nude mice in each group were transplanted with

1×10^7 RKO cells by ip. Honokiol was dissolved in PEG400/Tween 20 (9:1 by volume). Honokiol-treated group was intragastrically administered 2 mg of honokiol per mice on d 0, 2, 4, 6, 8 and 10 after inoculation of RKO cells. While the control group was given the same volume of PEG400/Tween20. Animals were regularly monitored for the appearance of peritoneal bulge and body weight.

Effect of honokiol on solid tumor growth in Balb/c nude mice
RKO cells (5×10^6) were injected subcutaneously at the axilla of Balb/c nude mice. When tumors became visible about one week after implant, the animals were randomized into four groups: Adriamycin-treated, honokiol-treated, vehicle and control. All mice received ip injection on days 8-11, 14-17, 21-24 and 28-31. Each mouse of honokiol-treated group received 80 mg/(kg/d) of honokiol suspended in PEG400/dextrose (7:3 by volume) intraperitoneally, while vehicle given equivalent solvent of PEG400/dextrose. Adriamycin dissolved in saline was injected ip at a dose of 2 mg/kg. Mice of control group were given the same volume of saline. Tumor growth was monitored with calipers every other day, and tumor volume was calculated using the modified ellipsoid formula: $A/6 \times A \times B^2$, where A is the longer axis and B is the axis perpendicular to A (Figure 1)^[18].

Figure 1 Chemical structure of honokiol (C₁₈H₁₈O₂, MW = 266.33).

Statistical analysis

Values were given as mean \pm SD. Statistical comparisons were made by Student's *t*-test, and *P*<0.05 was taken as significant.

RESULTS

Inhibition of RKO cell proliferation

Cells treated with honokiol resulted in a dose- and time- dependent cytotoxicity in RKO cells. As shown in Figure 2A, honokiol-mediated cytotoxicity occurred at the concentration of 5 μ g/mL and above. A significant decrease in cell number was seen at 10 μ g/mL. The concentration leading to a 50% decrease in cell number (IC₅₀) was about 12.47 μ g/mL. Moreover, treatment of RKO cells with 5 μ g/mL or 10 μ g/mL of honokiol resulted in a significant growth inhibition at various time points (Figure 2B).

Morphological changes and DNA fragmentation detection in RKO cells

According to MTT results, we chose 5, 10, 15 μ g/mL of honokiol to detect molecular changes. Under an inverted phase contrast microscope, honokiol-treated cells exhibited morphological features of apoptosis (Data not shown): rounded and granulated morphology, some vacuoles coming from cytoplasm, cell shrinkage and eventually detached from culture plates. In honokiol-treated cells, a degradation of chromosomal DNA into small internucleosomal fragments was evidenced by the formation of 180-200 bp DNA ladders on agarose gels (Figure 3), hallmark of cells undergoing apoptosis. No DNA ladders were detected in the samples isolated from control cultures. These results indicated that honokiol induced an apoptotic cell death in RKO cells.

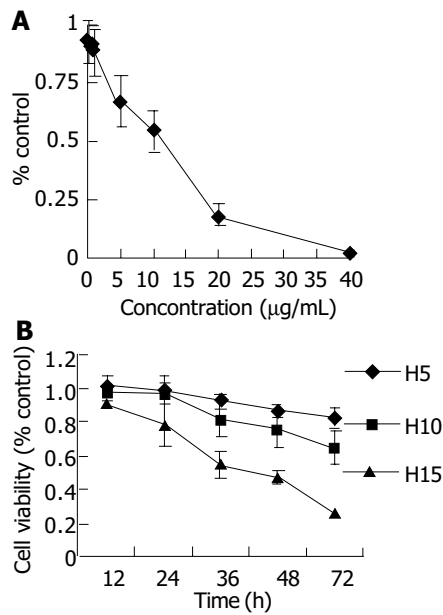

Figure 2 Concentration- and time-dependent inhibition of RKO cells exposed to honokiol shown by MTT assay. (A) RKO cells were plated in quadruplicate in 96-well plates and treated with increasing concentrations of honokiol for 68 h. (B) RKO cells treated with 5, 10 and 15 µg/mL of honokiol were tested at different time points.

Figure 3 Differences in vehicle or honokiol induced apoptotic DNA laddering of RKO cells. lane 1: control; lane 2: 5 µg/mL; lane 3: 10 µg/mL; lane 4: 15 µg/mL.

Effect of honokiol on cell cycle analysis of RKO cells

RKO cells were exposed to increasing concentrations of honokiol (5-15 µg/mL) for 48 h, and the growth of cells was analyzed with flow cytometry. In the absence of honokiol, the cell populations were at G1, S, and G2/M phases (Figure 4), accompanied with increased concentrations of honokiol by a concomitant increase of the G1 phase (Table 1). From Figure 4, the peak areas of subdiploid were enlarged with increased concentrations of honokiol. This observation led to a suggestion of G1 arrest. DNA fragmentation was seen when the cells were exposed to honokiol at 10 µg/mL and above (14.10% and 20.31%, respectively).

Table 1 Effect of honokiol on cell cycle distribution and apoptosis of RKO cells

Groups	Cell cycle distribution (%)			Apoptosis (%)
	G0/G1	S	G2/M	
Control	44.45	45.10	10.14	0.27
5 µg/mL	48.03	42.37	9.60	4.51
10 µg/mL	54.04	40.30	5.66	14.10 ^a
15 µg/mL	58.94	39.36	1.70	20.31 ^b

^a*P*<0.05, ^b*P*<0.01 vs corresponding control group. Cell cycle distribution was determined after 48 h of treatment in each group. The tabulated percentages were an average calculated on the results of three separate experiments. The results were represented by mean±SD (*n* = 3).

Caspase -3 and -9 expression by Western blot

Since Caspases are the main factors in the apoptotic pathway, we investigated whether Caspases were involved in inducing apoptosis of RKO cells treated with honokiol. Cells induced for 48 h were analyzed for protein expression by Western blot. The results showed that Caspase-3 and -9 were up-regulated in a dose-dependent manner (Figure 5).

Effects of honokiol on primary cultured cells

As shown in Figure 6, honokiol had little cytotoxic effect on primary human fibroblast cells and human lymphocytes even up to 40 µg/mL. HUVEC cells after honokiol treatment resulted in a sharply dose-dependent cytotoxicity. These

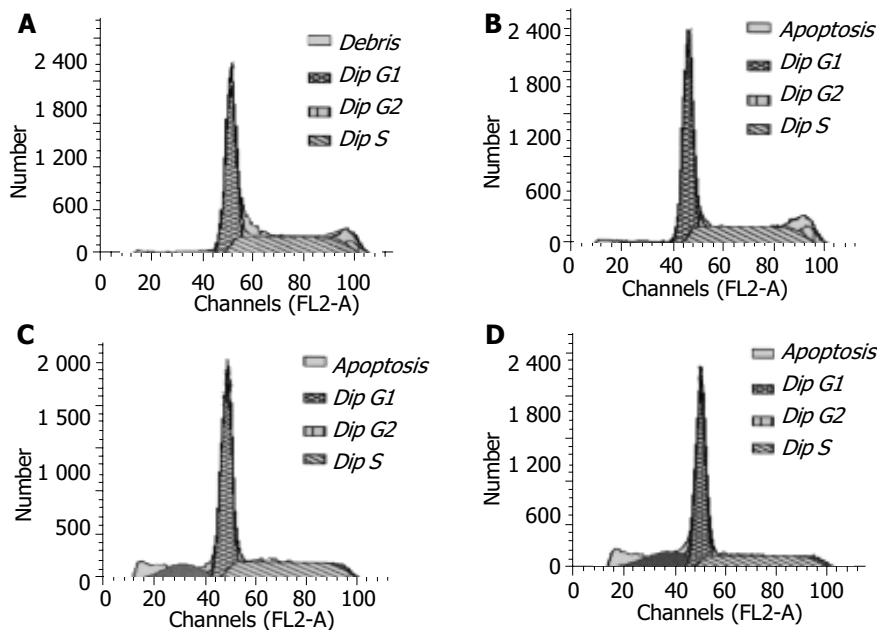

Figure 4 Apoptosis of RKO cells detected by FCM. (A) control; (B) 5 µg/mL; (C) 10 µg/mL; (D) 15 µg/mL.

results demonstrated that human fibroblast cells and lymphocytes were more resistant to the honokiol-mediated cytotoxicity than HUVECs.

Figure 5 Western blot analysis for the expression of Caspase-3 and -9 in human colorectal carcinoma cell line RKO cells. Lane 1: vehicle; lane 2: 5 µg/mL; lane 3: 10 µg/mL.

Figure 6 Cytocidal effect of honokiol on the growth of primary cultured human umbilical vein endothelial cells, primary human fibroblast cells and human lymphocytes.

Pharmacokinetics studies

The pharmacokinetics of honokiol was evaluated after intraperitoneal injection of 250 mg/kg to BALB/c mice. The maximum plasma concentration of honokiol was observed at 27.179 ± 6.252 min after administration (Figure 7). The plasma disappearance curve could best be described by a first-order absorption one-compartment model, with an absorption half-life of 10.121 ± 2.761 min, and an elimination half-life of 5.218 ± 0.461 h (Figure 7).

Figure 7 Honokiol concentration in plasma of BALB/c mice.

Inhibition of tumor growth in nude mice implanted with RKO cells

We studied the effect of honokiol on the growth of RKO tumor. There was significant inhibition of tumor growth by honokiol (Table 2). All the control mice developed peritoneal bulge and died by d 12. However, no peritoneal bulge was observed in 80% of the honokiol-treated animals and the mice survived for up to 30 d. These observations indicated the anti-tumor activity of honokiol *in vivo* (Table 2).

Table 2 Effect of honokiol on ascites growth of tumor in Balb/c nude mice

Group	Ascites	MST (d)	Dead (D)	Living (L)	Survival percentage (L/(D+L)×100%)
Control	5	10.7	5	0	0%
Honokiol	1	34.3	1	4	80%

MST: Mean survival time. RKO cells were transplanted intraperitoneally. Honokiol was administered 2 mg per mice on d 0, 2, 4, 6, 8, and 10 after tumor transplantation. The mice were monitored for peritoneal bulge and survived for up to 30 d. Control mice died by d 12 of RKO inoculation.

Inhibition of solid tumor growth in nude mice bearing RKO cells

From Figure 8, animals in control and vehicle groups showed a progressive increase in tumor volume, with a growth rate of 1627.6% and 1408.2% respectively on d 28. While in treated groups, tumor growth rate was increased to 968.9% in adriamycin group and 709.9% in honokiol-treated group. There was a significant difference between honokiol-treated group and its control (treated with PEG400/dextrose) ($P < 0.05$). Similar results were found between adriamycin-treated group and its control ($P < 0.05$). These data further confirmed that honokiol had an effective anticancer activity *in vivo*.

Figure 8 Effect of honokiol on the growth of xenografted RKO in Balb/c nude mice. The Y-axis represents tumor volume, X-axis represents time (day) after RKO cell inoculation.

Prolongation of life-span in nude mice bearing RKO solid tumor

The lifespan of mice in honokiol-treated group (80 mg/kg) was monitored and compared to the vehicle and adriamycin-treated group (Table 3). The mean survival time was 50.9 d in honokiol-treated group, with a significant prolongation compared to vehicle group (29.7 d, $P < 0.05$). The survival rate in honokiol-treated group was 176.7%, much higher than that in vehicle group ($P < 0.01$). There was no significant difference between control and vehicle groups and between adriamycin-treated and honokiol-treated groups. The results demonstrated that honokiol had a similar effect to adriamycin in prolongation of lifespan of tumor-bearing nude mice.

Table 3 Effect of honokiol on MST and T/C% in Balb/c nude mice bearing RKO-incubated tumor

Group	Number of mice	MST (d)	T/c (%)
Control	7	28.8	100
Vehicle	6	29.7	104.5
Adriamycin	7	46.2 ^a	160.4 ^b
Honokiol	7	50.9 ^a	176.7 ^b

MST, mean survival time. The survival rate (T/C%) was calculated according to the following equation: T/C (%) = [average survival period in the test group/average survival period in the control group]×100. ^a $P < 0.05$; ^b $P < 0.01$ vs vehicle or control.

DISCUSSION

Many anticancer drugs kill tumor cells by inducing apoptosis. Previous studies suggest that growth inhibition by honokiol resulted from the induction of apoptosis in several cell lines^[7-11]. A further study reported that in human squamous lung cancer cells, honokiol induced apoptosis by down-regulating Bcl-X_L and sequentially activating Caspase cascade^[10]. Our results confirmed this honokiol-mediated apoptotic progression in cultured RKO cells.

A variety of compounds with potent anticancer activity *in vitro* could not be used in clinic, one probable reason was due to their strong toxicities to normal cells^[17,18]. Therefore, we first investigated honokiol's effects on the toxicity of primary cultured human cells. Our data demonstrated that the IC50s were much higher in human fibroblasts and lymphocytes than in RKO cells, with the exception that HUVECs were more sensitive to honokiol. The safe doses for fibroblasts and lymphocytes could be up to 40 µg/mL (Figure 6), much greater than that for RKO and other tumor cells (data not shown). The phenomenon that primary cultured endothelial cells were more sensitive to honokiol might be related to the finding that honokiol had antiangiogenesis activity by inhibiting VEGF and its receptor 2 *in vitro*^[11]. In chemotherapy, antiangiogenesis is another important target besides apoptosis induction in tumor cells. Based on the fewer toxicity to normal fibroblasts and lymphocytes, we thus proposed that honokiol could be a safe and potent candidate of chemotherapy for colorectal cancer *in vivo*.

Another major obstacle was that many potent agents were poorly absorbed and quickly cleared *in vivo*, such as curcumin. Curcumin was difficult to absorb in the gastrointestinal tract and, even when systemically administered, it was rapidly cleared by hepatic metabolism^[11].

We then established two *in vivo* models with Balb/c nude mice bearing RKO cells, the ascitic tumor model and the solid tumor model. In RKO ascitic tumor model, honokiol exhibited a strong efficiency in prolonging the lifespan of ascitic tumor bearing mice and was highly effective on inhibiting intraperitoneal ascites in Balb/c nude mice. In our another model, honokiol also exhibited a potent efficiency in inhibiting solid tumor growth. In RKO incubated tumor bearing mice, honokiol at 80 mg/kg significantly inhibited the tumor growth and prolonged the lifespan compared to the vehicle ($P < 0.05$). The antitumor efficiency of honokiol was similar to that of the commonly used chemotherapy drug, adriamycin.

The results of the present study are encouraging because honokiol has shown significant inhibition of tumor growth *in vitro* and *in vivo*, as well as prolongation of lifespan in tumor-bearing mice *in vivo*. Together with its safety to human, honokiol might be a promising chemotherapy candidate in treating colorectal carcinoma or other cancers in clinic.

Abstract

AIM: To examine the serological response of patients with upper gastrointestinal diseases and *Helicobacter pylori* (*H pylori*) infection to two *H pylori* outer membrane proteins (OMPs) ($M_{18\ 000}$ and $M_{26\ 000}$) acquired by gene recombinant technique, and to determine the diagnostic significance of serological tests derived from these OMPs.

METHODS: Recombinant vectors encoding the two *H pylori* OMPs were used to transform and express in BL21 (DE3) *E.coli*. After purification with Ni^{2+} -NTA agarose resin, colloid gold kits were prepared with purified recombinant proteins to detect *H pylori* infection and *H pylori*-associated diseases by the immunity-marker technology. We selected 150 patients with *H pylori* infection and digestive symptoms without previous treatment, including chronic gastritis ($n = 60$), duodenal ulcer ($n = 30$), gastric ulcer ($n = 30$), and gastric cancer ($n = 30$). As controls, 33 *H pylori*-negative healthy volunteers were also recruited. Serum samples were collected from all subjects, and the antibodies to specific proteins of *H pylori* were tested with the colloid gold test kits. The sensitivity, specificity and accuracy of the colloid gold tests were evaluated, by using the combination of standard diagnostic methods (^{13}C urea breath test and bacteria culture) and classic enzyme-linked immunosorbent assay (ELISA) as reference.

RESULTS: After purification with Ni^{2+} -NTA agarose resin, the purity of recombinant fusion proteins was about 95%. The recombinant fusion proteins were recognized by the specific monoclonal antibodies against the two *H pylori* OMPs, as demonstrated by the ELISA. Of the 150 serum samples from patients infected with *H pylori* 141 (94.0%) responded positively to the recombinant protein with $M_{26\ 000}$, while the seropositive rates were 95.0%, 96.7%, 96.7% and 90.0% for patients with *H pylori*-associated chronic gastritis, duodenal ulcer, gastric ulcer, and gastric cancer respectively. The sensitivity, specificity, and accuracy of the colloid gold kit with $M_{26\ 000}$ protein were 94.0%, 97.0%, and 94.5%, respectively. Compared with the classic ELISA, bacteria culture and ^{13}C urea breath test results in detecting *H pylori*

infection, there was no significant difference ($P > 0.05$). For the colloid gold kit with $M_{18\ 000}$, the seropositive rates were 52.0%, 40.0%, 40.0%, 53.3% and 86.7%, respectively, in *H pylori*-infected patients, and those with *H pylori*-associated chronic gastritis, duodenal ulcer, gastric ulcer, and gastric cancer. There was a significant difference ($P < 0.05$) in seropositivity between patient with gastric cancer (86.7%) and those with other diseases (43.3%).

CONCLUSION: The two colloid gold kits derived from the recombinant OMPs are useful tools either for detecting *H pylori* infection, or for, predicting *H pylori*-associated gastric malignancy.

<http://www.wjgnet.com/1007-9327/10/3464.asp>

INTRODUCTION

Since the initial report of an unidentified curved bacillus located on the gastric epithelium of patients with chronic active gastritis, the discovery of *Helicobacter pylori* (*H pylori*) and its association with a number of gastrointestinal diseases has revolutionized gastroenterology. It has attracted the interest of scholars in gastroenterology and microbiology. Infection of gastric mucosa with *H pylori* could be found in approximately 50% of the world population^[1], its association with peptic ulcer disease, chronic gastritis, mucosa-associated lymphoid tissue lymphoma, and gastric adenocarcinoma has been well documented over the past two decades^[2-19]. Moreover it was also found in some extradigestive diseases^[20-36]. The direct evidence of carcinogenesis was recently demonstrated in an animal model^[37,38], so this organism has been recently categorized as a class I carcinogenetic factor by the World Health Organization. It is obviously important to detect and eradicate *H pylori* infection.

The routine detecting methods including invasive and non-invasive tests have differences in sensitivity and specificity, each with their indication and characteristics in clinical practice^[39-48]. Because of great quantity of serum samples especially in epidemiological studies, enzyme linked immunosorbent assay (ELISA) is the widely used test^[49-52]. Antigens used in ELISA are divided into three kinds. The first is the total cell of microbacteria sonicated by ultrasonic wave, which is easy to be confused with *Helicobacter*, campylobacter, or a diverse range of other bacteria and incur to intercourse response with each other in detecting *H pylori* infection. The second is the partly purified antigens, with greatly increased specificity and decreased intercourse response, but *H pylori* could not be cultured in great quantity without special apparatus and conditions. The last is the recombinant purified antigen by gene recombinant technique. To date, many genes of OMP of *H pylori* have been amplified by scholars with polymerase chain

reaction from *H pylori* chromosomes and inserted into the compatible sites of expression vectors by using T₄ DNA ligase. Moreover recombinant vectors could be expressed in *E.coli*^[53-62], but a few reports are available on lower-molecular-mass OMP application to the detection of *H pylori* infection and diagnose *H pylori*-associated diseases. In order to acquire a great amount of purified 18 000, 26 000 OMP of *H pylori*, we constructed recombinant vectors containing genes encoding with M_r18 000, 26 000 OMP of *H pylori* expressed in *E.coli* respectively and identified the antigenicity of expressed products^[63]. So we prepared the colloid gold kits with purified recombinant proteins by antigen-antibody reaction and gold-marked technique to determine whether they were capable of detecting *H pylori* infection and *H pylori*-associated diseases.

MATERIALS AND METHODS

Material

Well-characterized strains of BL21/pET32a (+)/Omp₂₆, BL21/pET32a (+)/Omp₁₈ were constructed, expressed and identified by the Department of Microbiology. The expression fusion proteins were recognized by the corresponding monoclonal antibody with M_r18 000, 26 000 OMP of *H pylori* and the animal's serum immunized with recombinant fusion proteins respectively. After purification using Ni²⁺-NTA agarose resin columniation, the purity of recombinant fusion proteins was about 95%. ¹³C urea breath test was purchased from Headway Company, Ni²⁺-NTA agarose resin columniation was obtained from QIAGEN Company, ultrasonic liquid (50 mmol/L NaH₂PO₄, 300 mmol/L NaCl, PH 7.0), abluent (50 mmol/L phosphate, 300 mmol/L NaCl, 20 mmol/L imidazole, pH 7.80) and lavation (50 mmol/L phosphate, 300 mmol/L NaCl, 250 mmol/L imidazole, pH 7.80) were provided by the Institute of Viral Hepatitis of Chongqing University of Medical Sciences.

Sample collection

Sera were collected from 150 patients with gastrointestinal symptoms and *H pylori* infection in the Outpatient Clinic of the Gastroenterology Department of the University Hospital during Jan. 2002 to Dec. 2002 including 60 cases of gastritis, 30 cases of gastric ulcer, 30 cases of duodenal ulcer and 30 cases of gastric cancer diagnosed by gastroscopy. Sera from 31 healthy volunteers without *H pylori* infection were collected as control. All testee were forbidden to take H₂-antagonists, corticosteroids, proton pump inhibitors and antibiotics within 4 wk.

Expression of recombinant plasmid

Single bacterial colonies (BL21/pET32a (+)/Omp₁₈, BL21/pET32a (+)/Omp₂₆) were picked and cultured respectively in 2 mL LB broth containing 100 mg/L of ampicillin, at 300 r/min at 37 °C overnight. On the next day, BL21 *E.coli* strains containing recombinant plasmids were grown until mid-log phase (Absorbance at 600 nm = 0.5 to 1.0), and then induced to express recombinant fusion proteins in 100 mL LB by adding 1 mmol/L IPTG for 4 h. Following induction, bacteria were harvested by centrifugation at 12 000 r/min for 15 min, and stored at -20 °C for SDS-PAGE analysis.

Immunoblot analysis of recombinant fusion protein

Due to C end of recombinant fusion antigens with six histidines, recombinant fusion antigens were purified with Ni²⁺-NTA agarose resin. Briefly, 500 mL of cultivated bacteria suspension was prepared, centrifuged, resuspended with the buffer liquid (50 mmol/L phosphate, 300 mmol/L NaCl, pH 7.0), and sonicated by ultrasonic wave with the energy of 600 W×35% for 40 min, and ultracentrifuged for 15 min at 10 000 g at 4 °C. The sonicated recombinant fusion antigens were purified using Ni²⁺-NTA agarose

resin with abluent (50 mmol/L phosphate, 300 mmol/L NaCl, 20 mmol/L imidazole, pH 7.80) and lavation (50 mmol/L phosphate, 300 mmol/L NaCl, 250 mmol/L imidazole, pH 7.80), and quantified. The antigenicities of expressed recombinant fusion proteins were determined by immunoblotting. Following electrophoretic transfer of SDS-PAGE-separated (150 g/L acrylamide) recombinant fusion proteins to 0.45 µm pore size PVDF membrane, and after a 30-min wash in tris-saline blotting buffer, antigen-impregnated PVDF strips were incubated with the sera from patients infected with *H pylori* and anti-Omp₁₈ or anti-Omp₂₆ antibody for 2 h at RT. After washed, the proteins were detected by incubating the strips in alkaline phosphatase-conjugated goat anti-man IgG and alkaline phosphatase-conjugated goat anti-mice IgG antibody for 1 h at RT.

Colloid gold test of *H pylori* OMP

With gold marker and special antigen-antibody reaction technique, *H pylori* infection could be detected using the antigen-antibody-antigen method. The recombinant fusion proteins were impregnated in nitrocellulose membrane (NC) as a detecting strip, the recombinant fusion proteins were marked with gold as a colored reagent by which the special antibody of patient serum to *H pylori* could be detected in seconds. The criteria of the test were as follows: Negative (-): antigen-impregnated NC membrane was not recognized by patient serum, non-special antibody to *H pylori* in patient serum, so there was only an aubergine strip in mass-control district, and not in detecting district simultaneously. Positive (+): antigen-impregnated NC membrane was recognized by patient serum, special antibody to *H pylori* in patient serum. In mass-control and detecting district, there were aubergine strips. If there was no aubergine strip in mass-control district, errors might occur in experiment course. The colloid gold test paper is shown in Figure 1.

Figure 1 Colloid gold test paper.

Diagnostic criteria of the test

The sensitivity, specificity and accuracy of the colloid gold kits were evaluated on the basis of the serum ELISA results taken as reference with combined of standard diagnostic methods (¹³C urea breath test, bacteria culture as the gold standard). Patients were defined as *H pylori* infection if one out of two validated tests of ¹³C urea breath test and culture was positive, and as non-*H pylori* infection if two tests were negative. Patients infected with *H pylori* were determined as false negative if the colloid gold kits were negative; patients without *H pylori* infection were determined as false positive if the colloid gold kits were positive. Based on the above results, the applied value of the colloid gold kit in clinical practice was evaluated.

RESULTS

Analysis of recombinant fusion protein

After pET32a (+)/Omp₁₈ and pET32a (+)/Omp₂₆ were transfected into BL21 *E.coli* strains, the strains with high expressions of fusion proteins were selected and grown respectively until mid-log phase (Absorbance at 600 nm = 0.4 to 0.6), and then

induced to express recombinant fusion proteins by adding of 1 mmol/L IPTG for 4 h. Following induction, bacteria were harvested by centrifugation at 12 000 g for 5 min, resuspended in protein-buffer and seethed for 5 min. Their molecular mass was M_r 38 000 and 46 000 respectively by 150 g/L SDS-PAGE gel analysis. After the recombinant bacteria were sonicated by ultrasonic wave and ultracentrifuged (10 000 g, 15 min, 4 °C), the levels of soluble fusion proteins in the supernatant were about 18.96% and 26.38% of total cellular protein respectively. After purification by Ni^{2+} -NTA agarose resin columniation, the purity was about 95%. Recombinant fusion proteins were all recognized by the corresponding monoclonal antibody with M_r 18 000, 26 000 OMP of *H pylori* and the animal's serum immunized with recombinant fusion proteins respectively. The results showed recombinant fusion proteins could provide excellent antigenicity.

Detection of *H pylori* infection by colloid gold kit

Sera from 150 patients with gastrointestinal symptoms and *H pylori* infection including 60 cases of gastritis, 30 cases of gastric ulcer, 30 cases of duodenal ulcer and 30 cases of gastric cancer examined by gastroscopies, and sera from 33 healthy volunteers without *H pylori* infection were assayed using the colloid gold kits with M_r 18 000, 26 000 respectively (Table 1, Figure 2). The results were as follows. Ninety-four percent of patients infected with *H pylori* showed response to recombinant protein with M_r 26 000, while 95%, 96.7%, 96.7% and 90.0% of patients with *H pylori*-infected chronic gastritis, gastric ulcer, duodenal ulcer, and gastric cancer showed responses (Table 2). There was no significant difference between the conventional examined methods and the colloid gold kits ($P>0.05$), indicating that the prevalence of infection diagnosed by both methods was similar. To specific recombinant protein with M_r 18 000, 52.0% of patients showed response, while 40.0%, 40.0%, 53.3% and 86.7% of patients with *H pylori*-infected chronic gastritis, gastric ulcer, duodenal ulcer, and gastric cancer respectively showed responses (Table 3). Moreover there was a significant difference ($P<0.05$) in the detecting rates of *H pylori* infection between patients with gastric cancer (86.7 %) and those with other diseases (43.3%). Based on the classic ELISA, bacteria culture and ^{13}C urea breath test results, the sensitivity, specificity, and accuracy of the colloid gold kit with M_r 26 000 protein were 94.0%, 97.0%, and 94.5%, respectively.

Table 2 Detecting results of diseases infected with *H pylori* using colloid gold kit with M_r 26 000 OMP

Disease	Patients	yr	Positive	Negative
Gastritis	60	50.3±15.9	57	3
Gastric ulcer	30	57.3±13.2	29	1
Duodenal ulcer	30	46.5±14.2	29	1
Gastric cancer	30	64.7±17.4	27	3

Table 3 Detecting results of diseases infected with *H pylori* using colloid gold kit with M_r 18 000 OMP

Disease	Patients	yr	Positive	Negative
Gastritis	60	50.3±15.9	24	36
Gastric ulcer	30	57.3±13.2	12	18
Duodenal ulcer	30	46.5±14.2	16	14
Gastric cancer	30	64.7±17.4	26	4

DISCUSSION

M_r 18 000, 26 000 OMP of *H pylori* are commonly expressed in all *H pylori* strains examined so far. Furthermore, no cross-reaction has been shown when antibodies (polyclonal and monoclonal) to low-molecular outer membrane proteins were used to screen closely related species of *Helicobacteria*, campylobacteria, or a diverse range of other bacteria^[64]. In our study, *H pylori* 18 000, 26 000 OMP were successfully expressed in *E.coli* with good antigenicity. With marked gold and special antigen-antibody reaction technique, *H pylori* infection could be detected by the antigen-antibody-antigen method. Recombinant fusion proteins were impregnated in NC membrane as a detecting strip, and marked with gold as a colored reagent by which the special antibody to *H pylori* could be determined in seconds. At first the recombinant proteins were prepared in large quantities, purified and regulated. Due to the diameter size of grained gold would affect directly the result of test, the diameter of grained gold was adjusted to 40-60 nm, at the same time the concentration of antibody was adjusted in order to acquire steady and reliable products marked with gold. A test detecting IgG antibodies to *H pylori* was thus constructed.

Sera were collected from 150 patients with gastrointestinal symptoms and *H pylori* infection and from 33 healthy volunteers without *H pylori* infection used as controls during one year. The detecting results using colloid gold kit were as follows. Ninety-four percent of patients infected with *H pylori* showed response to recombinant protein with M_r 26 000, 95.0%, 96.7%, 96.7% and 90.0% of patients with *H pylori*-infected chronic gastritis, gastric ulcer, duodenal ulcer, and gastric cancer, showed responses to specific proteins with M_r 26 000 respectively. There was no significant difference between the routine examined methods and colloid gold kits ($P>0.05$). 52.0% of patients infected with *H pylori* showed response to recombinant protein with M_r 18 000, while 40.0%, 40.0%, 53.3% and 86.7% of patients with *H pylori*-infected chronic gastritis, gastric ulcer, duodenal ulcer, and gastric cancer respectively, showed responses to specific proteins with M_r 18 000, moreover there was a significant difference ($P<0.05$) in the detecting rates of *H pylori* infection between gastric cancer (86.7 %) and other diseases (43.3%). The results showed that colloid gold kits with M_r 26 000 proteins of *H pylori* could be used as a conventional examination method. Based on the classic ELISA, bacteria culture and ^{13}C urea breath test results, the sensitivity, specificity, and accuracy of the rapid test kit with M_r 26 000 protein were 94.0%, 97.0%, and 94.5%, respectively, and a significant association was found between the serologic response to M_r 18 000 OMP antigen and malignant outcome of *H pylori* infection. The two colloid gold kits with

M_r 26 000, 18 000 proteins of *H pylori*, could be used to detect *H pylori* infection and *H pylori*-associated diseases, and to predict the risk of peptic ulcer or malignancy. The results mentioned above were consistent with those reported^[65-67].

All strains of *H pylori* could express low-molecular-mass OMP, which stimulates the body to produce corresponding antibodies, moreover the antibodies produced are related to the corresponding molecular size of antigens and immuno-status of the body. Decrease of the antibodies was associated with the corresponding molecular size of the antibodies. So the results showed that the responses of patients infected with *H pylori* to recombinant proteins with M_r 26 000 were stronger (94.0%) than that (52.0%) to recombinant proteins with M_r 18 000, while the growth of gastric cancer was associated with much more factors and stages. All pathogenic factors may act on the pre-carcinoma stage alone or together with each other in the model of chronic gastritis-atrophic gastritis-intestinal metaplasia-atypical hyperplasia-gastric cancer. Chua *et al.*^[68] compared the seroprevalence of antibodies with various *H pylori* antigens in Singaporeans with gastric adenocarcinoma and the normal Singaporean population using both conventional immunoglobulin (Ig) G ELISA and Western blot immunoassay, and found that strains of *H pylori* including antigens with M_r 19 500 and seronegative antigens with M_r 35 000 could provide their potential for carcinogenesis. Immunoreactive species-specific M_r 19 500 OMP of *H pylori* is actually Lpp20, while its actual molecular mass is 18 000 OMP. So *H pylori* strains based on carcinogenic potential could provide a basis for selective surveillance and eradication therapy. Low-molecular-mass OMP could lead to the 12th gene mutation of C-Ha-ras, and amplify p²¹ protein expressed by ras gene and c-met protein could also be overexpressed. Therefore the detecting rate of low-molecular-weight OMP of *H pylori* in gastric cancer is higher than other OMP. In our study, the detecting rate of M_r 26 000 OMP of *H pylori* in gastric cancer was similar to that of M_r 18 000 OMP. The results showed low-molecular-weight OMP could be used, not only in vaccine target candidates, but also in detection of gastric cancer in highly risk patients with *H pylori* infection. In a nutshell, the colloid gold kit constructed with M_r 18 000, 26 000 OMP of *H pylori* could detect anti-*H pylori* IgG-antibody. Compared with other methods, this method not only provides a rapid, simple and painless test, but also gives a reliable specificity, especially in diagnosis of gastrointestinal tumors. The colloid gold kit based on marked gold and special antigen-antibody reaction technique is a rapid diagnostic kit, only a few minutes are required to complete an assay, and no special instruments are needed. Compared with other immunoassay techniques, the colloid gold kit has following advantages. It is based on the antigen-antibody reaction on membranes, its detecting time is much shorter than ELISA, at the same time colloid gold is red in color, so there is no need to add other colored reagents, moreover, the products marked with gold are more stable than those marked with enzyme. The colloid gold kit evaluated in our study enables a simple, rapid, noninvasive, and accurate diagnosis of *H pylori* infection, and is an ideal test method for screening patients with gastrointestinal tumors.

Abstract

AIM: The role of the sphincter of Oddi (SO) in ethanol (ETOH)-induced pancreatitis is controversial. Our aim was to characterise the effect of ETOH on basal and stimulated SO motility.

METHODS: SOs removed from white rabbits were placed in an organ bath (Krebs solution, pH7.4, 37 °C). The effects of 2 mL/L, 4 mL/L, 6 mL/L and 8 mL/L of ETOH on the contractile responses of the sphincter were determined. SOs were stimulated with either 0.1 µmol/L carbachol, 1 µmol/L erythromycin or 0.1 µmol/L cholecystokinin (CCK).

RESULTS: ETOH at a dose of 4 mL/L significantly decreased the baseline contractile amplitude from 11.98±0.05 mN to 11.19±0.07 mN. However, no significant changes in the contractile frequency were observed. ETOH (0.6%) significantly decreased both the baseline amplitude and the frequency compared to the control group (10.50±0.01 mN, 12.13±0.10 mN and 3.53±0.13 c/min, 5.5±0.13 cycles(c)/min, respectively). Moreover, 0.8% of ETOH resulted in complete relaxation of the SO. Carbachol (0.1 µmol/L) or erythromycin (1 µmol/L) stimulated the baseline amplitudes (by 82% and 75%, respectively) and the contractile frequencies (by 150% and 106%, respectively). In the carbachol or erythromycin-stimulated groups 2-6 mL/L of ETOH significantly inhibited both the amplitude and the frequency. Interestingly, a 4-5 min administration of 6 mL/L ETOH suddenly and completely relaxed the SO. CCK (0.1 µmol/L) stimulated the baseline amplitude from 12.37±0.05 mN to 27.40±1.82 mN within 1.60±0.24 min. After this peak, the amplitude decreased to 17.17±0.22 mN and remained constant during the experiment. The frequency peaked at 12.8±0.2 c/min, after which the constant frequency was 9.43±0.24 c/min throughout the rest of the experiment. ETOH at a dose of 4 mL/L significantly decreased the amplitude from 16.13±0.23 mN to 14.93±0.19 mN. However, no significant changes in the contractile frequency were observed. ETOH at a dose of 6 mL/L inhibited both the amplitudes and the frequencies in the CCK-stimulated group, while 8 mL/L of ETOH completely relaxed the SO.

CONCLUSION: ETOH strongly inhibits the basal, carbachol, erythromycin, and CCK-stimulated rabbit SO motility. Therefore, it is possible that during alcohol-intake the

relaxed SO opens the way for pancreatic fluid to flow out into the duodenum in rabbits. This relaxation of the SO may protect the pancreas against alcohol-induced damage.

INTRODUCTION

It is well documented that ethanol (ETOH) can cause acute pancreatitis^[1,2], but the mechanisms by which alcohol causes this severe pancreatic injury are not clear. Two main hypotheses have been put forward to explain the role of the sphincter of Oddi (SO) in ETOH induced pancreatitis. One is the obstruction-hypersecretion theory which holds that ETOH induces spasm of the SO and can increase the pressure in the pancreatic ductal system, which may lead to the disruption of small pancreatic ducts. Therefore, pancreatic juice can enter the parenchyma evoking acute pancreatitis^[3,4]. The other is the duodenopancreatic reflux theory which believes that ETOH reduces the SO motility, thus, the reflux of bile, activated enzymes, or other substances into the pancreatic ducts may cause pancreatitis after alcohol ingestion^[5,6]. Despite these contradictory theories, no data are available concerning the effect of alcohol on physiologically (postprandial)-stimulated SO motility.

Cholecystokinin (CCK) is generally regarded as the major hormone regulating postprandial SO motility. This regulatory effect of CCK is rather complex. CCK could directly stimulate SO motility in guinea pigs^[7], opossum^[8], rabbits^[9-11] and dogs^[12]. On the other hand, CCK could induce acetylcholine (ACh) and vasoactive intestinal peptide release from pre- and postjunctional sites in the enteric nervous system via CCK_A and CCK_B receptors in the canine gastrointestinal tract, which suggests an indirect effect of CCK^[13]. Others have also demonstrated that the contractile response of the guinea pig SO to CCK consists of a direct effect and an indirect effect mediated by ACh release from postganglionic parasympathetic neurons^[7,14].

Motilin is also a key peptide regulating phasic contractile activity of the stomach, duodenum, SO, and gallbladder^[15]. This regulation is mediated by the migrating myoelectric complex of the gastrointestinal tract^[16]. Motilin provoked an increase of the SO spike activity in a dose-dependent manner in rabbits^[17]. Erythromycin, a motilin agonist, has been found to stimulate interdigestive motility of the duodenum and SO in dogs^[18], Australian opossum^[19] and also in humans^[20]. However, there are no available data concerning the effect of erythromycin on rabbit SO motility.

The parasympathetic nervous system plays an important role in the stimulation of gastrointestinal motility after a meal. The parasympathetic neurotransmitter ACh and its analogues have been shown to stimulate SO motility in different species^[21]. Furthermore, ACh can be released from postganglionic parasympathetic neurons after hormonal stimuli, as described above.

In this study our aim was to characterise the effects of ETOH on the basal and differently stimulated SO motility in rabbits.

MATERIALS AND METHODS

Ethics

The present experiments conformed to the European Guiding Principles for Care and Use of Experimental Animals. In addition, the experimental protocol applied was approved by the local ethical boards of the Universities of Szeged and Debrecen, Hungary.

Isometric tension measurements

Isometric tension measurements were described in detail previously^[22]. Biliary SO muscle rings of approximately 6 mm long from adult male New Zealand white rabbits weighing 2–2.5 kg were prepared. The papilla Vateri was eliminated and the ampullary part of the muscle rings of approximately 3 mm long were mounted horizontally on two small L-shaped glass hooks, of which one was connected to a force transducer (SG-O2, Experimetria, Budapest, Hungary) attached to a six channel polygraph (R61 6CH, Mikromed, Budapest, Hungary) for measurement and recording of isometric tension as described^[22]. One muscle ring was prepared from one animal. The experiments were carried out in an organ bath (5 mL) containing Krebs bicarbonate buffer (in mmol/L: NaCl 118.1, KCl 4.7, MgSO₄ 1.0, KH₂PO₄ 1.0, CaCl₂ 2.5, NaHCO₃ 25.0, glucose 11.1) which was maintained at 37 °C and aerated continuously with carbogen (50 mL/L CO₂/950 mL/L O₂).

Experimental protocol

The muscle rings underwent brief experimental protocols as follows. Phasic activity of SO: contractile frequencies and their amplitudes were measured over 50 min in each experiment. The initial tension was set at 10 milliNewtons (mN) and the rings were allowed to equilibrate for over 30 min. After that amplitudes and frequencies were recorded for 60 min. In the first 10 min, baseline phasic activity was measured. From the second 10 min, phasic activities were stimulated with 0.1 µmol/L carbachol, 1 µmol/L erythromycin or 0.1 µmol/L CCK. During the last 40 min, ETOH was administered at the doses of 2 mL/L, 4 mL/L, 6 mL/L and 8 mL/L for equal periods (4 times, 10 min). The control SOs received no treatments.

Drugs and chemicals

All laboratory chemicals (including ions, carbachol, erythromycin, CCK and ETOH) were obtained from Sigma Chemical Company (Budapest, Hungary). CCK and carbachol were dissolved in Krebs solution, while erythromycin was dissolved in dimethyl sulfoxide.

Data and statistical analysis

Parameters producing the data for evaluation were as follows. The *amplitude of contractions* (mN) was referred to as the difference between peak contractions and relaxations. The average of the amplitudes was calculated every minute (results were expressed as mean±SE, *n* = number of frequencies in a minute). The *frequencies of contractions* (c/min) were calculated every minute. Statistical analysis was performed for 10 min of each of the experiments using either Student's *t*-test (when the data consisted of two groups) or ANOVA (when three or more data groups were compared). Results were expressed as mean±SE, *n* = 5, *P* < 0.05 was considered statistically significant.

RESULTS

Effect of ETOH on basal SO motility

The amplitudes and frequencies of the basal SO motility were stable during the control experiments (11.98±0.04 mN and 5.37±0.07 c/min, respectively). ETOH (2 mL/L) had no effects on the baseline amplitudes and frequencies. When ETOH was administered at a dose of 4 mL/L, the baseline amplitude was significantly decreased *vs* the control (11.19±0.07 mN and 11.98±0.05 mN, respectively) (Figure 1A, B). However, no significant changes in the contractile frequency were observed *vs* the control (Figure 1C, D). ETOH (6 mL/L) significantly decreased both the baseline amplitude and frequency *vs* control (10.50±0.01 mN, 12.13±0.10 mN and 3.53±0.13 c/min, 5.50±0.17 c/min, respectively). ETOH (8 mL/L) completely relaxed the SO within 10 s. Therefore, neither the frequencies nor the amplitudes could be detected during the last 10 min of the experiments.

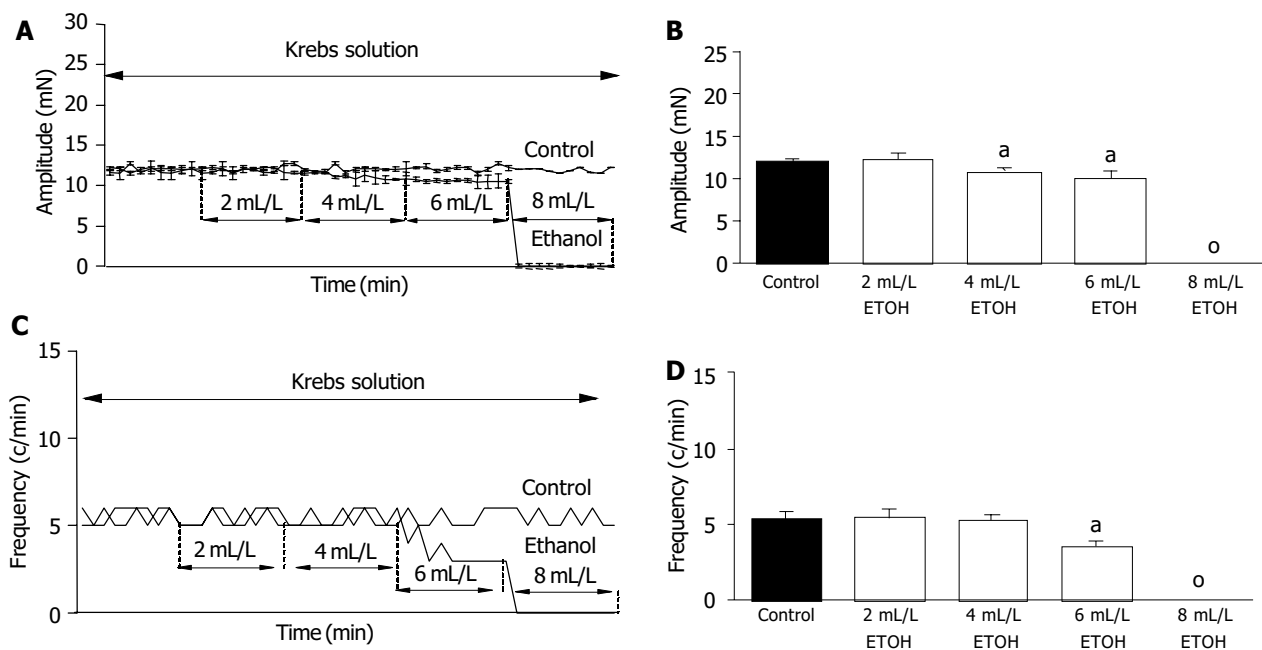

Figure 1 Basal SO motility inhibited by ETOH. Sphincter of Oddi (SO) was exposed to increasing doses of ethanol (ETOH; 2 mL/L, 4 mL/L, 6 mL/L and 8 mL/L). Each concentration of ETOH was administered for 10 min. A: Effect of ETOH on the baseline amplitude. Representative experiments of the control and the ETOH-treated groups are shown. B: Summary of the effect of ETOH on the baseline amplitude. mean±SE, *n* = 5, ^a*P* < 0.05 *vs* the control; o: no contractile activity. C: Effect of ETOH on the contractile frequency. Representative experiments of the control and the ETOH-treated groups are shown. D: Summary of the effect of ETOH on the contractile frequency. mean±SE, *n* = 5, ^a*P* < 0.05 *vs* the control; o: no contractile activity.

Effect of ETOH on carbachol-stimulated SO motility

Carbachol (0.1 $\mu\text{mol/L}$) stimulated the baseline amplitude by 82% and the contractile frequency by 150%. This carbachol-stimulated SO motility was stable during the experiment (Figure 2A-C). ETOH (2 mL/L) significantly inhibited both the amplitude and frequency vs the carbachol-stimulated group (19.42 ± 1.16 mN, 20.81 ± 0.49 mN and 12.32 ± 0.16 c/min, 12.91 ± 0.10 c/min, respectively) (Figure 2A-D). ETOH (4 mL/L) further reduced the amplitude (13.92 ± 0.49 mN) and the frequency (9.24 ± 0.21 c/min) of the SO motility. ETOH (6 mL/L) decreased the contractile frequency of the SO by 50% (4.61 ± 0.46 c/min). However, it did not modify the amplitude frequency (12.23 ± 0.22 mN). Interestingly, a 4.20 ± 1.47 min administration of 6 mL/L ETOH suddenly and completely relaxed the SO.

Effect of ETOH on erythromycin-stimulated SO motility

Erythromycin (1 $\mu\text{mol/L}$) stimulated the baseline amplitude by 75% and the contractile frequency by 106%. This erythromycin-stimulated SO motility was constant over the experiment. ETOH (2 mL/L) significantly inhibited both the amplitude and the frequency vs the carbachol-stimulated group (19.10 ± 0.25 mN, 19.65 ± 0.45 mN and 9.66 ± 0.29 c/min, 10.45 ± 0.20 c/min, respectively). ETOH (4 mL/L) significantly decreased both the amplitude (16.27 ± 0.33 mN) and the frequency (8.32 ± 0.22 c/min), (Figure 2E-H). Administration of 6 mL/L ETOH caused a further decrease in the amplitude and frequency (11.85 ± 0.41 mN and 4.10 ± 0.37 c/min, respectively). Similar to that seen in the carbachol-stimulated group, a 4.10 ± 0.55 min administration of 6 mL/L ETOH suddenly and completely relaxed the SO.

Effect of ETOH on CCK-stimulated SO motility

CCK (0.1 $\mu\text{mol/L}$) stimulated the baseline amplitude from 12.37 ± 0.05 mN to 27.4 ± 1.82 mN within 1.60 ± 0.24 min. After this peak, the amplitude decreased to 17.17 ± 0.22 mN and was constant during the experiment. The frequency peaked at 12.8 ± 0.2 c/min, after which the constant frequency was 9.43 ± 0.24 c/min throughout the rest of the experiment. ETOH (2 mL/L) mildly decreased the amplitude frequency (16.13 ± 0.23 mN and 17.05 ± 0.14 mN), but had no effect on the contractile frequency of the SO (9.32 ± 0.15 mN and 9.50 ± 0.31 mN). ETOH (4 mL/L) further decreased the amplitude frequency from 16.13 ± 0.23 mN to 14.93 ± 0.19 mN, but still had no effect on the contractile frequency of the SO (9.82 ± 0.23 c/min). ETOH (6 mL/L) further decreased the amplitude and frequency of the SO to 12.13 ± 0.11 mN and 7.26 ± 0.27 c/min, respectively. ETOH (8 mL/L) resulted in complete relaxation of the SO within 10 s (Figure 2 I-L). After this time neither frequencies nor amplitudes could be detected during the remaining part of the experiments.

DISCUSSION

It has been widely known for a long time that ETOH may evoke acute pancreatitis^[23]. The role of SO in the pathogenesis of alcohol-induced acute pancreatitis has also been suggested^[3,6]. However, the effect of ETOH on SO is controversial. On the one hand, it has been demonstrated that ETOH reduces the SO pressure^[3,6]. On the other hand, alcohol was found to induce spasm of the SO^[24,25]. These contradictory results indicate that much more information is needed to clarify the effect of ETOH on SO motility.

To investigate these issues, we tested the effect of four different concentrations of ETOH on the resting SO motility. ETOH (2 mL/L) had no effect on the basal SO motility. This result is in accordance with the findings of Cullen *et al.*^[26]. They reported that ETOH at a dose of 2 mL/L had no significant effect on the baseline amplitude and the contractile frequency of SO in opossum. ETOH (4 mL/L) mildly decreased the baseline amplitude of the spontaneously contracting SO, but had no effect on the contractile frequency. When ETOH concentration

was elevated to 6 mL/L, both the baseline SO contractile amplitude and the frequency were decreased (13%, 34% respectively), while 8 mL/L of ETOH completely relaxed the SO.

Next we tested the effect of different doses of ETOH on physiologically stimulated SO motility (carbachol, erythromycin and CCK). We tested 3 different stimuli at the ED₅₀ doses. Carbachol was used to mimic the activity of parasympathetic nervous system, while CCK and a motilin receptor agonist erythromycin were administered to mimic neurohumoral stimuli.

Carbachol (0.1 $\mu\text{mol/L}$) stimulated the frequency (150%) and the amplitude (82%) of SO contractions. ETOH (2 mL/L) decreased the baseline amplitude and frequency of the carbachol-stimulated SO by the same rate (12%). ETOH (4 mL/L) decreased the amplitude of SO motility to the basal level, but the frequency still remained elevated. A 4-5 min administration of 6 mL/L ETOH completely relaxed the SO. These results demonstrate that ETOH may inhibit the activity of SO motility stimulated by the parasympathetic nervous system in a dose-dependent manner. Moreover, we can conclude that ETOH has a stronger effect on the contractile amplitude than on the frequency of SO.

The effect of ETOH was almost the same on erythromycin-stimulated as on carbachol-stimulated SO. ETOH (2 mL/L) mildly decreased the baseline amplitude and frequency by 10%. ETOH (4 mL/L) decreased both the amplitude and the frequency of erythromycin-stimulated SO. A 4-5 min administration of 6 mL/L ETOH completely relaxed the SO, as it was found during carbachol-stimulation.

Finally, the effect of ETOH was tested on CCK-stimulated SO motility. CCK stimulated the baseline amplitude and the contractile frequency of SO by 39% and 74%, respectively. ETOH (2 mL/L) mildly decreased the baseline amplitude (6 mL/L), but had no effect on the frequency of the SO. ETOH (4 mL/L) further decreased the baseline amplitude. Interestingly, 4 mL/L ETOH still had no effect on the contractile frequency. When the concentration of ETOH was increased to 6 mL/L, both the baseline amplitude and the contractile frequency of SO were decreased (29% and 23% respectively). ETOH (8 mL/L) immediately and completely relaxed the SO as it was seen during the study of unstimulated SO.

Taken together, ETOH inhibited the basal and neurally (carbachol), humorally (erythromycin, a motilin agonist) and neurohumorally (CCK) stimulated SO motility in a dose-dependent manner. Viceconte *et al.*^[6] suggested that alcohol might cause a hormone-mediated relaxation, but they could not exclude a nervous or direct mechanism. Cullen *et al.*^[26] demonstrated that 2 mL/L ETOH could decrease the frequency of H₂O₂-stimulated SO motility. These findings suggest that the main effect of alcohol is direct, independent of a specific neural and/or humoral pathway. Interestingly, we have to note that the inhibitory effect of ETOH was more pronounced during carbachol or erythromycin stimulation than during CCK stimulation. Therefore, we could not totally exclude a marginal specific effect of ETOH. There is no data available concerning the effect of low doses of ETOH on the SO in human. However, gastric absorption accounted for 30% of ETOH administered with food^[27], therefore, during a low alcohol-concentrated-fluid (2-5%) intake, small doses of alcohol may be found around the SO. These findings need further investigation.

The inhibitory effect of ETOH on SO motility may have an important pathophysiological role. ETOH has been found to increase basal pancreatic flow rate and protein output^[28,29], thus, elevating the intraluminal pressure in the pancreatic ductal system. The relaxation of SO opens the way for pancreatic fluid to flow out into the duodenum, thus, preventing the pancreas from the damage by the elevated intraluminal pressure during acute ETOH administration. It is hard to believe, that a duodeno-pancreatic reflux against the high pancreatic-juice-flow could play a decisive role in the pathogenesis of alcohol-induced

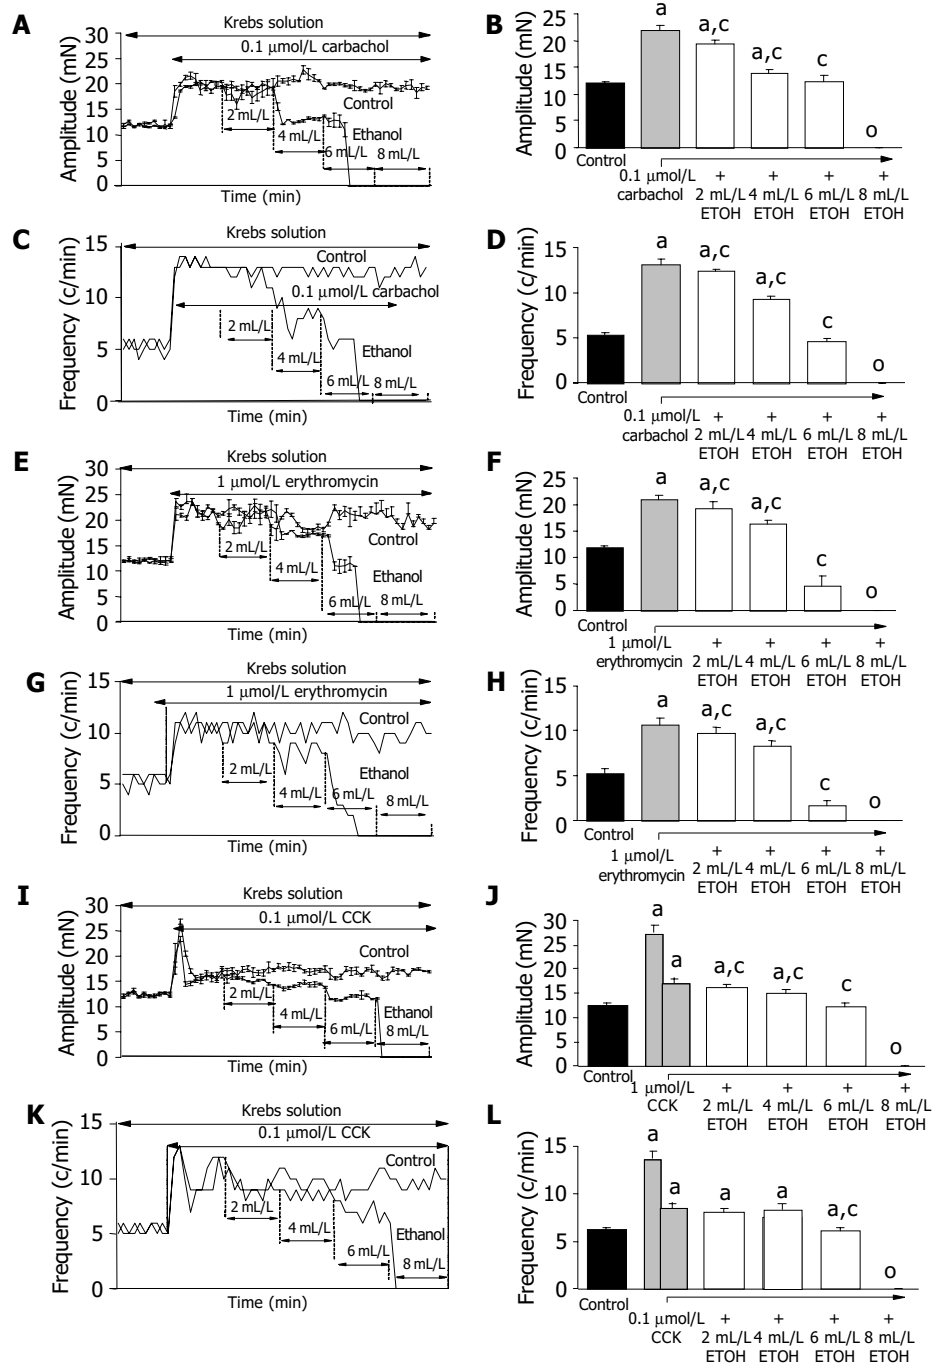

Figure 2 Effect of ETOH on carbachol, erythromycin, CCK stimulated SO motility. All of the SOs were stimulated by 0.1 $\mu\text{mol/L}$ carbachol for 40 min. Different concentrations of ETOH were administered as described in Figure 1. A: Effect of ETOH on the carbachol-stimulated baseline amplitude. Representative experiments of the control (carbachol-treated) and the ETOH-carbachol-treated groups are shown. B: Summary of the effect of ETOH on the carbachol-stimulated baseline amplitude. mean \pm SE, $n = 5$, $^aP < 0.05$ vs control, $^cP < 0.05$ vs the carbachol-stimulated group, o: no contractile activity. C: Effect of ETOH on the contractile frequency. Representative experiments of the (carbachol-treated) and the ETOH-carbachol-treated groups are shown. D: Summary of the effect of ETOH on the carbachol-stimulated contractile frequency. mean \pm SE, $n = 5$, $^aP < 0.05$ vs control, $^cP < 0.05$ vs the carbachol-stimulated group, o: no contractile activity. E: Effect of ETOH on the erythromycin-stimulated baseline amplitude. Representative experiments of the control (erythromycin-treated) and the ETOH-erythromycin-treated groups are shown. F: Summary of the effect of ETOH on the erythromycin-stimulated baseline amplitude. mean \pm SE, $n = 5$, $^aP < 0.05$ vs the control, $^cP < 0.05$ vs the erythromycin-stimulated group, o: no contractile activity. G: Effect of ETOH on the contractile frequency. Representative experiments of the control (erythromycin-treated) and the ETOH-erythromycin-treated groups are shown. H: Summary of the effect of ETOH on the erythromycin-stimulated contractile frequency. mean \pm SE, $n = 5$, $^aP < 0.05$ vs the control, $^cP < 0.05$ vs the erythromycin-stimulated group, o: no contractile activity. I: Effect of ETOH on the carbachol-stimulated baseline amplitude. Representative experiments of the control (CCK-treated) and the ETOH-CCK-treated groups are shown. J: Summary of the effect of ETOH on the CCK-stimulated baseline amplitude. mean \pm SE, $n = 5$, $^aP < 0.05$ vs the control; o: no contractile activity. In the 0.1 $\mu\text{mol/L}$ CCK-treated group, the first column represents the peak amplitude of contractile frequencies. The second column represents the constant amplitudes after the peak. $^aP < 0.05$ vs the constant amplitude of the CCK-treated group. K: Effect of ETOH on the contractile frequency. Representative experiments of the (CCK-treated) and ETOH-CCK-treated groups are shown. L: Summary of the effect of ETOH on the CCK-stimulated contractile frequency. mean \pm SE, $n = 5$, $^aP < 0.05$ vs the control; o: no contractile activity. In the 0.1 $\mu\text{mol/L}$ CCK-treated group, the first column represents the peak of frequencies. The second column represents the constant frequencies after the peak. $^cP < 0.05$ vs the constant frequency of the CCK-treated group.

acute pancreatitis. Furthermore, it is also well documented that SO relaxants^[30-32] and endoscopic sphincterotomy^[33,34] have beneficial effects during acute pancreatitis, which argue against the duodeno-pancreatic reflux theory. All in all, we think that the response of SO motility to ETOH administration is protective against pancreatic injury rather than harmful to the pancreas.

In conclusion, ETOH can strongly inhibit the basal, carbachol, erythromycin, and CCK stimulated SO motility in rabbits, and it is possible that SO opens the way for the pancreatic fluid to flow out into the duodenum. This relaxation of the SO may prevent the pancreas against alcohol-induced damage.

Abstract

AIM: To investigate the prognostic significance of *c-Kit* gene mutation and DNA ploidy in gastrointestinal stromal tumors (GISTs).

METHODS: A total of 55 cases of GISTs were studied for the expression of *c-Kit* by immunohistochemistry, and the *c-Kit* gene mutations in exons 9, 11, 13, and 17 were detected by polymerase chain reaction-single strand confirmation polymorphism (PCR-SSCP) and denaturing high performance liquid chromatography (D-HPLC) techniques. DNA ploidy was determined by flow cytometry.

RESULTS: Of the 55 cases of GISTs, 53 cases (96.4%) expressed *c-Kit* protein. The *c-Kit* gene mutations of exons 11 and 9 were found in 30 (54.5%) and 7 cases (12.7%), respectively. No mutations were found in exons 13 and 17. DNA aneuploidy was seen in 10 cases (18.2%). The *c-Kit* mutation positive GISTs were larger in size than the negative GISTs. The aneuploidy tumors were statistically associated with large size, high mitotic counts, high risk groups, high cellularity and severe nuclear atypia, and epithelioid type. There was a tendency that *c-Kit* mutations were more frequently found in aneuploidy GISTs.

CONCLUSION: DNA aneuploidy and *c-Kit* mutations can be considered as prognostic factors in GISTs.

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal neoplasms of the gastrointestinal tract. The term, GIST, was first introduced in the 1980s to include a group of nonlymphomatous, nonepithelial tumors of the gut^[1]. With the advent of immunohistochemistry, CD117 (c-Kit) negative tumors, such as schwannomas, leiomyomas, and leiomyosarcomas, were excluded from the noncommittal term of "gastrointestinal stromal tumors". Recently, based on immunophenotypic and ultrastructural similarities, it is widely accepted that the precursor cells in GISTs are the interstitial cells of Cajal (ICCs)^[2]. Immunohistochemically, GISTs are typically positive for *c-Kit* and CD34, but negative for S-100 protein, desmin, and may express smooth muscle actin in 20% to 40% of cases^[3].

Yet despite their recognition as a distinct pathologic entity, because GISTs are widely diverse in terms of clinical presentation, morphology, and biologic behavior, the prediction of malignancy on the basis of pathologic features is often difficult. Many studies have analyzed the prognostic relevance of a variety of parameters such as anatomical location, mucosal invasion, tumor necrosis, and high cellularity, rather often leading to conflicting conclusions^[1,4-6]. However, two morphologic features have emerged as fairly reliable predictors of outcome: mitotic rate and tumor size^[4,7-12]. A consensus conference held at National Institutes of Health in April 2001 provided both an evidence-based definition and a practical scheme for assessing the risk (very low risk, low risk, intermediate risk, and high risk) of aggressive clinical behavior^[13]. Recently, a prognostic significance of *c-Kit* mutations was suggested by several clinicopathologic studies^[14-17]. The largest series has shown that *c-Kit* mutation in exon 11 was more common in large tumors, and that the presence of this mutation was an adverse prognostic factor^[14].

The conceptual evolution of GISTs and *c-Kit* mutation has been the subject of numerous previous articles. However, DNA ploidy studies in relation to *c-Kit* mutation are not well established. The purpose of this study was to examine the *c-Kit* mutations and DNA ploidy in GISTs to evaluate them as the prognostic factors.

MATERIALS AND METHODS

Histological review

The cases included in this study were retrieved from patients who were diagnosed as GISTs and treated at Korea University Hospitals between January 1997 and August 2003. The clinical history and postoperative courses were obtained from the review of clinical records. The tumor size in greatest dimension and the location were taken from the pathology reports. Histological slides were reviewed by two of the authors (Kim, I and Lee, JH) in all of the cases. The tumor cell type was determined by light microscopic study. The spindle cell type had a predominant fusiform morphology. Both cytoplasm and nuclei were elongated and aligned within the microscopic field. The epithelioid cell type had a predominantly spherical morphology. The nuclei were round and tended to be centrally placed within tumor cells. The number of mitosis was determined by counting the mitotic activity in 50 adjacent high-power fields (HPF) at a magnification of $\times 400$. The cytologic atypia of the tumor cells was determined to be mild, moderate, or severe. The cytologic atypia was assessed within the most proliferative area. Mild atypia indicated that the tumor cells were histologically benign or mildly atypical. Moderate atypia indicated that the tumor cells had moderately enlarged hyperchromatic or vesicular nuclei with or without prominent nucleoli and some nuclear irregularity. Severe atypia indicated that the tumor cells had enlarged irregular, hyperchromatic, or vesicular pleomorphic nuclei with prominent nucleoli. The cellularity was scored as low if the cell count was below 1 000/mm², intermediate for a range from 1 000 to 2 000 cells per mm², and high if exceeding 2 000 cells/mm². Tumor necrosis was determined to be present or absent. Tumor hemorrhage was determined to be present or absent. The growth pattern was determined to be expansive or invasive. GISTs were reclassified as very low, low, intermediate, and high risk groups for their estimated potential for aggressive clinical behavior as suggested by NIH consensus^[13].

Immunohistochemistry

Representative sections from each lesion were subjected to immunohistochemical staining by using the avidin-biotin-peroxidase complex (ABC) method. The target differentiation antigens visualized by the monoclonal and polyclonal antibodies were *c-Kit* (1:400; Dako, Glostrup, Denmark), CD34 (1:200; Neomarker, CA, USA), smooth muscle actin (SMA, 1:200; Dako, Glostrup, Denmark), and S-100 protein (1:400; Neomarker, CA, USA). The tumors were designated as positive when more than 10% of the tumor cells showed a positive reaction for CD34, SMA and S-100 protein. Positive reactions were classified by using the following criteria for *c-Kit*: (-) negative, if <10% cells were stained; (+), if 10-50% cells were immunoreactive; (++) if 51-100% cells were immunoreactive. The tumors which showed positive reaction for CD34 and/or *c-Kit* protein with or without SMA and S-100 protein were included in GISTs.

DNA extraction

DNA was extracted from the formaldehyde-fixed, paraffin-embedded tissue sections by using standard methods with proteinase K digestion and phenol/chloroform purification.

Polymerase - chain reaction - single strand confirmation polymorphism (PCR-SSCP)

PCR primers were designated to amplify exons 9, 11, 13, and 17 (Table 1). PCR was carried out with the following conditions: 50 μ L total reaction volume, with 5 μ L template, 5 μ L of each oligonucleotide primer, 10 μ L dNTP, 10 μ L ddH₂O, 2 μ L Taq polymerase, 8 μ L Mg²⁺ and 5 μ L 10 \times PCR buffer. Cycling conditions were as follows: an initial penetration at 95 $^{\circ}$ C for 4 min, 38 cycles each at 94 $^{\circ}$ C for 1 min, at 56 $^{\circ}$ C for 1 min, at 72 $^{\circ}$ C for 1 min, followed by one cycle at 72 $^{\circ}$ C for 10 min. PCR products were visualized by gel electrophoresis in 1.7 g/L agarose. Then the PCR products were subjected to 80 g/L non-denaturation polyacrylamide gel electrophoresis with 50 g/L glycerin and silver nitrate staining.

Table 1 Primer sequence for *c-Kit* exons 9, 11, 13, and 17 and the corresponding annealing temperature (T_A) and the size of expected PCR size products

<i>c-Kit</i> exon No.	Primers	Primer sequence 5'->3'	T _A ($^{\circ}$ C)	Product size (bp)
9	hEx9-F	TTCCTAGAGTAAGCCAGGG	53	298
	hEx9-R	AATCATGACTGATATGGT		
11	hEx11-F	CAGGTAACCATTTATTTGT	53	326
	hEx11-R	TCATTGTTTCAGGTGGAAC		
13	hEx13-F	ATCAGTTTGCCAGTTGTGCT	53	250
	hEx13-R	TTTATAATCTAGCATTGCC		
17	hEx17-F	GTTTCACTCTTTACAAGT	53	277
	hEx17-R	TTACATTATGAAAGTCACAGGAAAC		

Denaturing high performance liquid chromatography (D-HPLC)

To enhance heteroduplex formation, the untreated PCR products (5-7 μ L) were denatured at 95 $^{\circ}$ C for 5 min followed by gradual reannealing to room temperature for over 30 min. Samples were analyzed in WAVE DHPLC. The gradient was formed by mixing buffer A (0.1 mmol/L TEAA) and buffer B (0.1 mol/L TEAA, 250 g/L acetonitrile). The analysis was carried out at a flow rate of 0.9 mL/min and buffer B gradient increase of 20 g/L per minute for 4 min. Oven temperature for optimal heteroduplex separation under partial DNA denaturation was determined for each amplified fragment by using WAVE Marker software. The most important criteria for assigning the presence of a sequence alteration in each DHPLC fragment were the numbers and the shape of elution peaks in comparison with a wild-type subject elution profile used as reference. To allow the detection of heteroduplex DNA molecules in homozygous patients, those

amplicons were pre-mixed with sequence-confirmed wild-type PCR controls. The mixed samples were then denatured at 94 $^{\circ}$ C for 5 min and cooled for over 45 min at room temperature, before D-HPLC analysis.

DNA ploidy

Nuclear suspensions from the selected tissue blocks, previously used in the immunohistochemical study, were prepared in each case. Three 50- μ m thick sections from the tissue block were dewaxed in xylene and rehydrated in a sequence of decreasing concentrations of alcohol. After being washed in Dulbecco's phosphate buffered saline (DPBS), the tissue was incubated in 2 g/L pepsin (Sigma Chemical Company, St. Louis, USA) at 37 $^{\circ}$ C water bath for 2.5 h. Then, the samples were neutralized by citrate buffer and treated with trypsin at 37 $^{\circ}$ C water bath for 10 min. After RNase treatment at 37 $^{\circ}$ C water bath for 30 min, the samples were stained with propidium iodide at 4 $^{\circ}$ C for 30 min. By using a FACS analyzer, the DNA histograms were obtained.

Statistical analysis

The data were analyzed with Chi-square and *t* tests by using SPSS 10.0 program.

RESULTS

Clinicopathologic characteristics

There were 25 males and 30 females. The mean age of the patients at the time of diagnosis was 60 (range: 29-80) years. The locations of tumors were as follows: one in the esophagus, 43 in the stomach, 10 in the small intestine (including duodenum), and one in the mesentery. The symptoms of patients were as follows: 24 cases of abdominal pain, 11 cases of gastrointestinal bleeding, 4 cases of palpable mass and 12 cases of nonspecific. The mean diameter of tumors was 5.29 (range: 0.4-17.0) cm. Three patients showed liver metastasis at the time of surgery. Two patients received re-operation due to recurrence. One patient had a local gastric recurrence after 17 mo and the other had a local duodenal recurrence after 33 mo.

Patients included in this study were diagnosed to have a GIST by a variety of histologic criteria. Spindle cell lesions occurred with or without an epithelioid component, the most common tumor lesions showed interlacing fascicles of spindle cells. Some lesions showed a palisaded morphology resembling peripheral neurilemmomas, but storiform, fascicular, or mixed growth patterns were seen. Some of them were composed of round and epithelioid cells appearing with perinuclear shrinkage of cytoplasm. In some tumors or parts of tumors, there was a mixture of epithelioid cells and spindle cells. Fifteen (27.3%) tumors were epithelioid cell type, whereas the remaining 40 (72.7%) were spindle cell type (Figure 1). The mitotic index ranged from 0 to 100 (mean: 11.4). The degree of cytologic atypia was mild in 27 (49.1%) patients, moderate in 21 (38.2%), and severe in 7 (12.7%). The degree of cellularity was low in 11 (20.0%) patients, intermediate in 37 (67.3%), and high in 7 (12.7%). Necrosis was present in 11 (20.0%), and hemorrhage was present in 17 (30.9%) tumors. Expansive growth was found in 30 (54.5%), and invasive growth in 25 (45.5%) tumors.

Correlation of risk groups and clinicopathologic parameters

Tumors were divided into very low (10/55, 18.2%), low (26/55, 47.3%), intermediate (4/55, 7.3%) and high risk (15/55, 27.3%) groups by NIH consensus^[13]. Correlation of risk groups and other clinicopathologic parameters is shown in Table 2. Higher risk (intermediate and high risk) groups showed more frequent necrosis, more severe nuclear atypia and higher cellularity than lower risk (very low and low risk) groups which were statistically significant. The epithelioid cell type was more frequent in higher risk group.

Figure 1 Histological features of various cell types of gastrointestinal stromal tumors and immunohistochemical staining for *c-Kit*. $\times 200$. A: Spindle cell type; B: Epithelioid type; C: $>50\%$ tumor cells are positive for *c-Kit*; D: 10-50% tumor cells are positive for *c-Kit*.

Figure 2 *c-Kit* mutations in exon 11 by denaturing high performance liquid chromatography. A: Normal; B: mutation.

Table 2 Comparison of clinicopathologic parameters according to the risk groups of gastrointestinal stromal tumors

Parameter	Risk group	Very low and low ($n = 36$)	Intermediate and high ($n = 19$)	<i>P</i>
Cellularity	Low	11	0	0.019
	Intermediate	22	15	
	High	3	4	
Nuclear atypia	Mild	22	5	0.019
	Moderate	12	9	
	Severe	2	5

Results of immunohistochemistry

A positive reaction for *c-Kit* protein was obtained in 53 (96.4%), CD 34 in 53 (96.4%), SMA in 17 (30.9%), and S-100 protein in 3 (5.5%). Among 53 *c-Kit* positive cases, 10 cases (18.9%) were (+) and 43 cases (81.1%) were (++) (Figure 1).

Correlation of *c-kit* mutation with clinicopathologic parameters

Thirty cases (54.5%) showed mutations of *c-Kit* in exon 11 (Figure 2). Among 30 cases, 16 cases showed mutations by both PCR-SSCP and D-HPLC methods, 9 cases by PCR-SSCP, and 5 cases by D-HPLC method. Seven cases (12.7%) showed mutations of *c-Kit* in exon 9. Among them, 3 cases showed mutations by both

PCR-SSCP and D-HPLC methods, 3 cases by PCR-SSCP, and 1 case by D-HPLC method. Two cases showed mutations of both exons 9 and 11. No mutations were found in exons 13 and 17. The mutation-positive GISTs belonged to the large tumors (Table 3), but the association with the other parameters was not significant.

Table 3 Comparison of clinicopathologic parameters according to *c-Kit* mutations

Parameter	Mutations		<i>P</i>
	Negative ($n = 20$)	Positive ($n = 35$)	
Sex (M:F)	11:9	14:21	0.283
Age (mean, yr)	58.2	61.0	0.360
Mean tumor size (cm)	3.8	6.2	0.020
Mean mitoses counts	7.8	13.4	0.360
Risk group: Very low/low	14	22	0.592
Intermediate/high	6	13	
Cellularity: Low	5	6	
Intermediate	13	24	0.741

	Present	8	
Tumor cell type	Spindle	13	0.330
	Epithelioid	7	

Correlation of *c-kit* mutation with *c-kit* expression

Among 10 *c-Kit* (+) cases, 6 cases showed mutations of *c-Kit* in exon 9 or 11. Among 43 *c-Kit* (++) cases, 31 cases showed mutations of *c-Kit* in exon 9 or 11. The rate of *c-Kit* mutations was higher in *c-Kit* (++) group than that in *c-Kit* (+) group ($P=0.05$).

Correlation of DNA aneuploidy with clinicopathologic parameters

Ten cases (18.2%) were DNA aneuploidy (Figure 3). The tumors with aneuploidy were associated with the larger tumor size, high mitotic counts, higher risk groups, high cellularity, and severe nuclear atypia, and epithelioid cell type (Table 4).

Figure 3 DNA aneuploidy in gastrointestinal stromal tumors.

Table 4 Comparison of clinicopathologic parameters according to DNA ploidy

Parameter	Diploid (n = 45)	Aneuploid (n = 10)	P
Sex (M:F)	21:24	4:6	0.702
Age(mean, yr)	60.8	56.1	0.225

Correlations of *c-kit* mutation and DNA aneuploidy with metastasis or recurrence

Three metastatic GISTs showed *c-Kit* mutation. Among them, two cases showed mutations in exon 11, and the other one showed mutation in exon 9. Two of these 3 tumors had DNA aneuploidy. Among two recurrent GISTs, only one case showed mutation in exon 11, and the two cases were DNA diploidy.

Correlation of *c-kit* mutation with DNA aneuploidy

Correlation of *c-Kit* mutation with DNA ploidy state was analyzed (Table 5). There was a tendency that *c-Kit* mutations were more frequent in aneuploid tumors than in diploid ones, but not statistically significant ($P=0.063$).

Table 5 Correlation of *c-Kit* mutation and DNA ploidy

DNA ploidy ¹	<i>c-Kit</i> mutation	
	Negative	Positive
Diploid	19	26
Aneuploid	1	9

¹ $P=0.063$.

DISCUSSION

It has been reported that GISTs are strongly and nearly consistent *c-Kit* positive, and associated with the mutations of the *c-Kit* gene. Approximately 40% to 50% of GISTs, mostly the malignant variants, had mutations in the juxtamembrane domain (exon 11) of the *c-Kit* gene^[14-16], although some studies found mutations in only 15%^[18] or the others in as many as 80%^[19] of the analyzed cases. Lack of mutations in exon 11 in a significant portion of GISTs may suggest that mutations may occur in other domains of the *c-Kit* gene. However, no mutations were found in exon 17 (kinase domain) in a large group of GISTs studied^[14], which was the area where *c-Kit* mutations occur in mastocytoma^[20] and seminoma^[21]. Recently, new mutational hotspots were identified as a result of comprehensive sequencing of *c-Kit* cDNA obtained from 13 GISTs, which were negative for exon 11 mutations. Mutations in exon 9 and exon 13 were detected in 6 (46%) and 2 (15%) of them, suggesting that such mutations may be relatively common in GISTs^[19].

In this study, we analyzed 55 GISTs. Thirty cases (54.5%) showed mutations of *c-Kit* in exon 11 and 7 cases (12.7%) showed mutations in exon 9. No mutations were found in exon 13 and exon 17. The *c-Kit* mutation positive GISTs were large in size, and all three metastatic GISTs showed mutations, but the association with other clinicopathologic factors was not evident. The rate of *c-Kit* mutations was higher in *c-Kit* (++) group rather than in *c-Kit* (+) group.

The factors related to the tumor biology might usefully complement the clinical and morphological data. Thus, DNA aneuploidy has been claimed to allow a sensitive and specific discrimination between benign and malignant tumors of the gastrointestinal tract and to correlate with their prognosis^[22-28]. However, in other reports, aneuploidy could not be used as a diagnostic criterion of malignancy, but was associated with a mere tendency to an adverse outcome^[29,30]. In our study, 10 cases (18.2%) showed DNA aneuploidy. The aneuploid GISTs were associated with large tumor size, high mitotic counts, higher risk groups, high cellularity, severe nuclear atypia and epithelioid type. These results suggest that DNA aneuploidy represents high risk groups of GISTs suggested by NIH consensus^[13].

In conclusion, there is a tendency that *c-Kit* mutations are more frequent in aneuploid GISTs. Therefore, DNA ploidy and *c-Kit* mutations might be closely related.

Abstract

AIM: To study the changes of quantitative expression, adhering activity and genomic density polymorphism of complement types in erythrocytes (CR1) of patients with gallbladder carcinoma and the related clinical significance.

METHODS: Polymerase chain reaction (PCR), *Hind*III restriction enzyme digestion, quantitative assay of CR1 and adhering activity assay of CR1 in erythrocytes were used.

RESULTS: The number and adhering activity of CR1 in patients with gallbladder carcinoma (0.738 ± 0.23 , 45.9 ± 5.7) were significantly lower than those in chronic cholecystitis and cholelithiasis (1.078 ± 0.21 , 55.1 ± 5.9) and healthy controls (1.252 ± 0.31 , 64.2 ± 7.4) ($P < 0.01$). The number and adhering activity of CR1 in patients with chronic cholecystitis and cholelithiasis (1.078 ± 0.21 , 55.1 ± 5.9) were significantly lower than those in healthy controls (1.252 ± 0.31 , 64.2 ± 7.4) ($P < 0.05$). There was a positive correlation between quantitative expression and adhering activity of CR1 ($r = 0.79$, $P < 0.01$). Compared with those on preoperative day (0.738 ± 0.23 , 45.4 ± 4.9), the number and adhering activity of CR1 in patients with gallbladder carcinoma decreased greatly on the third postoperative day (0.310 ± 0.25 , 31.8 ± 5.1) ($P < 0.01$), and on the first postoperative week (0.480 ± 0.25 , 38.9 ± 5.2) ($P < 0.01$), but they were increased slightly than those on the preoperative day ($P > 0.05$). The number and adhering activity of CR1 recovered in the second postoperative week (0.740 ± 0.24 , 46.8 ± 5.9) ($P < 0.01$) and increased greatly in the third postoperative week (0.858 ± 0.35 , 52.7 ± 5.8) ($P < 0.01$) in comparison with those on the preoperative day and in the first postoperative week. The number and adhering activity of CR1 of gallbladder carcinoma patients with infiltrating, adjacent lymphogenous and distant organ metastases were significantly lower than those of gallbladder carcinoma patients without them ($P < 0.01$). No difference was observed between the patients with gallbladder carcinoma and healthy individuals in the spot mutation rate of CR1 density gene ($\chi^2 = 0.521$, $P > 0.05$). The distribution of expression was 67.8% in high expression genomic type, 24.8% in moderate expression genomic type, and 7.4% in low expression genomic type. The number and adhering activity of CR1 high expression genomic type

gallbladder carcinomas (0.749 ± 0.22 , 42.1 ± 6.2) were significantly lower than those of healthy individuals (1.240 ± 0.29 , 63.9 ± 7.2), and were also significantly lower than those of healthy individuals (0.921 ± 0.23 , 54.8 ± 7.1), but no difference was observed between the number and adhering activity of CR1 lower expression genomic type gallbladder carcinomas (0.582 ± 0.18 , 44.3 ± 5.5) and those of healthy individuals (0.610 ± 0.20 , 45.8 ± 5.7) ($P > 0.05$).

CONCLUSION: Defective expression of CR1 in gallbladder carcinoma is mostly acquired through central peripheral mechanisms. The changes in CR1 quantitative expression and adhering activity are consanguineously related to the development and metastasis in gallbladder carcinoma.

INTRODUCTION

Carcinoma of the gallbladder is the most common neoplasm in biliary tract, and its incidence has been rising in recent years^[1-4]. The C3b receptors (CR1, Cd35) on erythrocytes serve as the primary transport system for immune complexes from peripheral blood of the liver^[5-8], and CR1 plays an important role in this system, the rate of clearance of immune complexes from the circulation is directly related to the number of CR1 molecules expressed on erythrocytes^[9-11]. However, there are few reports on the changes of genomic density polymorphism of complement types in erythrocytes of patients with gallbladder carcinoma. We previously demonstrated the altered levels of cellular immunity and humoral immunity in patients with gallbladder carcinoma, and the effects of radical cholecystectomy on nutritional and immune status in patients with gallbladder carcinoma^[12-15]. In this study, we reported the changes in quantitative expression, adhering activity and genomic density polymorphism of complement types in erythrocytes (CR1) of patients with gallbladder carcinoma.

MATERIALS AND METHODS

Patients

A total of 33 patients with gallbladder carcinoma were admitted to the First Affiliated Hospital of Sun Yat-Sen University from August 2000 to August 2002. Those were 16 men and 17 women aged from 50 to 70 years (median, 52.7 years). Nineteen patients were preoperatively diagnosed as polypoid, cholelithiasis and chronic cholecystitis, and diagnosed as gallbladder carcinoma by frozen sections after surgery. Fourteen patients were diagnosed as gallbladder carcinoma preoperatively, of them, 4 patients had radical cholecystectomy, 7 patients had U-tube drainage operation, 3 patients cholecystectomy. Direct invasion or distant metastasis was found in 10 patients during operation, simple gallbladder carcinoma in 15 patients, both gallbladder carcinoma and cholelithiasis in 18 patients. The patients with gallbladder

carcinoma were grouped according to the staging system of Nevin^[16], the number of cases on stages I, II, III, IV and V was 7, 11, 5, 7 and 11, respectively. Tumor size ranged from 1.8 cm to 6 cm in diameter (median, 2 cm), 23 patients had tumors smaller than 2 cm in diameter, 10 patients had tumors larger 2 cm in diameter.

No therapy was administered to patients preoperatively. Meanwhile, 90 patients with cholecystitis or cholecystolithiasis had cholecystectomy, including 44 patients with cholecystitis and 46 patients with cholelithiasis. No severe systemic diseases were found, such as, myocardial infarction, cerebral vascular accidents, uncontrollable diabetes mellitus, Hypertension. Their disease was stable in a period of one month. All the surgical specimens were examined histologically, and classified into hyperplasia, atypical hyperplasia (mild, moderate and severe) according to Gong *et al.*^[17]. A total of 59 patients exhibited epithelial hyperplasia, 10 patients had mild dysplasia, 10 patients moderate dysplasia, 11 patients severe dysplasia. Normal controls were 30 healthy individuals (18 men and 12 women) aged from 56 years to 72 years (median 61.7 years).

Methods

Quantitative expression, adhering activity and genomic density polymorphism of complement types in erythrocytes (CR1) patients with gallbladder carcinoma were assessed preoperatively (1 wk before surgery), and on d 3, 7, 14 and 21 postoperatively.

Genomic determination of CR1 (Cd35) density polymorphism on erythrocytes^[18]

DNA samples DNA was extracted using the following simplified protocol. Following lysis of erythrocytes, nucleated cells from 10 mL of blood were incubated in 3.5 mL of 10 mmol/L Tris, 2 mmol/L EDTA buffer pH7.5, containing 0.4 mol/L NaCl, 7 g/L sodium dodecylsulfate and proteinase K (30 mg/L) for 16 h at 37 °C, 1 mL of 6 mol/L NaCl was added. After vortexed and ethanol-precipitated, the pellets were washed three times in 700 mL/L ethanol and solubilized in 10 mmol/L Tris, 1 mmol/L EDTA buffer pH7.5.

Sequencing

A construct in pUC-18 containing *Hind* III-kpn fragments from the introns located within the first and second exons of the short consensus repeat d2 from the long homologous repeat D of CR1 was sequenced. Sequencing was performed using the modified Sanger method with a commercial T₇ DNA polymerase kit.

Primers

Primers were designed based on the analysis of internal homologies within the CR1 gene and homologies with other human sequences obtained from the EMBL databank using the Bisanse software. The 5' primer was from base 4 415 to base 4 435 from the CR1 cDNA sequence. The 3' primer was 75 to 55 from the *Hind* III monomorphic restriction site in the introns. The latter primer was chosen due to the presence of five mismatches between the CR1 intron sequence and the consensus *Hind* III 1.9 ku repetitive sequence. Primers were synthesized on a 380 Applied Biosystem apparatus. Twenty base oligonucleotides were recovered from the solid phase by rinsing the column with 250 g/L ammonium. After incubation at 55 °C for 16 h, ammonium was expelled through evaporation using a Speed-Vac apparatus. Primers were used without further purification.

Amplification and agarose gel electrophoresis

PCR was performed using a Techne PHC-I apparatus with the Taq polymerase.

Amplified DNA was precipitated and then digested using the *Hind* III restriction enzyme, and separated by electrophoresis in 20 g/L agarose gels. Gels were analyzed under UV illumination. The genomic density polymorphism of complement type 1 (CR1)

in erythrocytes was classified into three types: high expression genomic type (1.8 Kb1), moderate expression type (1.8 kb, 1.3 Kb and 1.5 Kb) and low expression genomic type (1.3 Kb, 0.5 Kb).

Quantitative expression of CR1 in erythrocytes of patients with gallbladder carcinoma

EBC enzyme-linked immunosorbent assay This assay was based on the method of Cornillet *et al.*^[18]. All RBCs in the assay were routinely glutaraldehyde-fixed. Finally, 20 µL of S/BSA were added to each well, followed by 20 µL of substrate. The plates were incubated at 37 °C for 90 min with gentle agitation every 15-20 min to ensure the maximum contact of RBC with substrate. Subsequently, 100 µL of S/BSA was added to each well, the plate was centrifuged at 1 800 r/min for 90 s and 100 µL of supernatant was transferred to a clean microtitre plate for readings in a plate reader at 405 nm (Dynatech MR5000; Dynatech Billingshurst, Suaaex, UK). In each case, a mean of the readings obtained for the RBC without first antibody (the blank controls) was subtracted from the other readings obtained, in order to correct nonspecific phosphatase-like activity within RBC membranes. Duplicate values were obtained for each RBC sample with each antibody. Black control values were obtained for both the antimouse conjugates and for the anti-rabbit conjugates.

Adhering activity of CR1 in erythrocytes of patients with gallbladder carcinoma

A 50 µL of 1×10⁸/mL RBC suspensions was added to each well, then added and 50 µL of plasma itself and 100 µL of 1×10⁶/mL tumor cells, mixed completely, stained. Fields were examined (×640), 5 RBC combined each tumor cell were labeled as a flower, tumor cell flowers were assessed.

Statistical analysis

For each variable, multiple analysis of variance for repeated measurements was used to compare the values measured before operation with those measured at four subsequent time points. The results were presented as mean±SE based on the mixed model of repeated measurement analysis. Statistical analysis was performed with SAS software. *P*<0.05 was considered statistically significant.

RESULTS

The number and adhering activity of CR1 in patients with gallbladder carcinoma, chronic cholecystitis and cholecystolithiasis and healthy individuals

As shown in Table 1, the number and adhering activity of CR1 in patients with gallbladder carcinoma (0.738±0.23, 45.9±5.7) were significantly lower than those in patients chronic cholecystitis and cholecystolithiasis (1.078±0.21, 55.1±5.9) and healthy individuals controls (1.252±0.31, 64.2±7.4) (*P*<0.01). In Table 2 the number and adhering activity of CR1 in patients with chronic cholecystitis and cholecystolithiasis were significantly lower than those in healthy controls (*P*<0.05). There was a positive correlation between quantitative expression and adhering activity of CR1 (*r* = 0.79, *P*<0.01).

In the series of epithelial pathologic changes including hyperplasia, atypical hyperplasia, carcinoma *in situ* or invasive carcinoma, the number and adhering activity of CR1 decreased gradually (Table 3), and there was a positive correlation between quantitative expression and adhering activity of CR1 (*r* = 0.77, *P*<0.01). In Table 4 compared with those on the preoperative day (0.738±0.23, 45.4±4.9), the number and adhering activity of CR1 in patients with gallbladder carcinoma decreased greatly on the third postoperative day (0.310±0.25, 31.8±5.1) (*P*<0.01) and in the first postoperative week (0.480±0.25, 38.9±5.2) (*P*<0.01), but they were increased slightly than those on the preoperative

day ($P>0.05$). In comparison with those on the preoperative day and in the first postoperative week, the number and adhering activity of CR1 recovered in the second postoperative week (0.740 ± 0.24 , 46.8 ± 5.9) ($P<0.01$), and increased greatly in the third postoperative week (0.858 ± 0.35 , 52.7 ± 5.8) ($P<0.01$).

The number and adhering activity of CR1 in gallbladder carcinoma patients with infiltrating, adjacent lymph node and distant organ metastases were significantly lower than those in gallbladder carcinoma patients without metastasis (Table 5, $P<0.01$).

Table 1 The number and adhering activity of CR1 in different groups before operation (mean \pm SE)

Changes of genomic density polymorphism of CR1 in patients with gallbladder carcinoma

The distribution of genomic density polymorphism of CR1 in patients was 67.8% in high expression genomic type, 24.8% in moderate expression genomic type, 7.4% in low expression genomic type. Compared with healthy controls, no difference was observed between the patients with gallbladder carcinoma and healthy in the spot mutation rate of CR1 density gene ($\chi^2 = 0.521$, $P>0.05$). The number and adhering activity of CR1 high expression genomic type gallbladder carcinomas (0.749 ± 0.22 , 42.1 ± 6.2) were significantly lower than those in healthy individuals (1.240 ± 0.29 , 63.9 ± 7.2). The number and adhering activity of CR1 moderate expression genomic type gallbladder carcinomas (0.641 ± 0.19 , 34.2 ± 5.1) were also significantly lower than those in healthy individuals (0.921 ± 0.23 , 54.8 ± 7.1), but no difference was observed between the number and adhering activity of CR1 lower expression genomic type gallbladder carcinomas (0.582 ± 0.18 , 44.3 ± 5.5) and those of healthy individuals (0.610 ± 0.20 , 45.8 ± 5.7) ($P>0.05$).

DISCUSSION

The immune functions of erythrocytes have been studied at gene levels^[5-8]. RBCs are the major cellular component of the peripheral blood and occupy 50% of the total blood volume^[9]. Normal RBC cytosol contains the majority of natural killer enhancing factors and other factors, such as PIF. Damaged RBC could produce tumor necrosis factor inducing factor. RBCs appear to have an important regulating role in immune function, and RBC activity involves in regulating multiple cytokines such as IL-2, IL-3, CSF, IL-6, TNF- α , TNF. CD44 and CD58 expressed by RBC could serve as the center in controlling immune status, which can directly affect the development and progression of tumors^[8-11]. The changes of CR1 quantitative expression and adhering activity are consanguineously related to the development and metastasis of liver carcinoma.

In our study, the number and adhering activity of CR1 high expression genomic type gallbladder carcinomas were significantly lower than those in healthy individuals, indicating that defective expression of CR1 in gallbladder carcinoma is mostly acquired through central peripheral mechanisms.

Gallbladder carcinoma is often associated with cholecystolithiasis and cholecystitis in 40-100% of cases^[19-28]. Although no carcinogenic substance has so far been isolated from the bile or the stones in patients with cholecystolithiasis and cholecystitis, many scholars suggested that gallstone might play a role as a chronic injury factor to induce a series of epithelial pathologic changes^[29-38]. Gong *et al.*^[17] reported that in 150 consecutive cholecystectomy specimens for detection of cholelithiasis or cholecystitis, 76.68% exhibited epithelial hyperplasia, 16.89%

atypical hyperplasia, 1.32% carcinoma *in situ* and 2.11% invasive carcinoma. Simple epithelial hyperplasia was found in the mucus adjacent to invasive carcinoma. With the passage of time, a significant number of atypical hyperplasias presumably would progress to a higher grade lesion, becoming carcinoma. Toyonaga *et al.*^[39] reported that in 200 consecutive cholecystectomy specimens for detection of cholelithiasis or cholecystitis, 83% simple epithelial hyperplasias, 13.5% atypical hyperplasias and 3.5% carcinomas *in situ*. In general, a significant number of atypical hyperplasias presumably would progress to a higher grade lesion, 80% atypical hyperplasias could become pre-cancer lesions. Albores-Saavedra *et al.*^[11] results showed that cholelithiasis or cholecystitis produced a series of epithelial pathologic changes, such as simple epithelial hyperplasia, atypical hyperplasia and carcinoma *in situ*, which represented the precancer lesion of gallbladder carcinoma. The probable sequence of events appear to be as follows. Hyperplasia has been found to have atypical hyperplasia which in turn may progress to neoplasia. With the passage of time, a significant number of atypical hyperplasias presumably would progress to carcinoma *in situ* and invasive carcinoma^[24]. So almost all scholars have suggested that a small number of hyperplasias of the gallbladder would evolve toward *in situ* carcinoma which finally becomes invasive carcinoma^[40]. In our study, the number and adhering activity of CR1 in patients with gallbladder carcinoma were significantly lower than those in patients with chronic cholecystitis and cholelithiasis and healthy individuals ($P < 0.01$). The number and adhering activity of CR1 in patients with chronic cholecystitis and cholelithiasis were significantly lower than those in healthy individuals. There was a positive linear correlation between quantitative expression and the adhering activity of ECR1 ($r = 0.79$, $P < 0.01$). Compared with data the on preoperative day, the number and adhering activity of CR1 in patients with gallbladder carcinoma decreased greatly on the third postoperative day and in the first postoperative week, indicting that surgery plays an injurious role in the disorder of RBC and cytokine functions^[12,41,42]. The number and adhering activity of CR1 recovered in the second postoperative week, and increased greatly in the third postoperative week.

The number and the adhering activity of CR1 in gallbladder carcinoma patients with infiltrating, adjacent lymph node and distant organ metastases were significantly lower than those in patients without metastasis. This study demonstrates CR1 can be used as an immune therapy for gallbladder carcinoma.

Abstract

AIM: To investigate the effect of dermatan sulfate (DS) derivatives on platelet surface P-selectin expression and blood activated protein C (APC) activity in patients with inflammatory bowel disease (IBD), and to clarify the anti-inflammatory mechanism of DS derivatives.

METHODS: Dermatan sulfate (DS) was sulfated with chlorosulfonic acid to prepare polysulfated dermatan sulfate (PSDS). The major disaccharides of DS and PSDS were determined by ^1H nuclear magnetic resonance spectroscopy (^1H -NMR) and ^{13}C -NMR. Both DS and PSDS were depolymerized with hydrogen peroxide. The fragments were separated by gel filtration chromatography. The effects of DS derivatives on P-selectin expression were assayed by ELISA method, and blood APC activity was assayed by the synthetic chromogenic substrate method.

RESULTS: The major disaccharides of DS and PSDS were IdoA-1 \rightarrow 3-GalNAc-4-SO₃ and IdoA-2SO₃-1 \rightarrow 3-GalNAc4, 6-diSO₃, respectively. Compared with the adenosine diphosphate stimulated group and IBD control group, DS and its derivatives all had significant inhibitory effects on P-selectin expression ($P<0.01$), but there was no difference between DS-derived oligosaccharides (DSOSs) and PSDS-derived oligosaccharides (PSDSOSs). The experiments on APC activity showed that DS and its derivatives all enhanced APC activity. The most active DSOS was the one with a relative molecular weight (M_r) of 4 825, which enhanced the APC activity from 106.5 \pm 11.5% to 181.8 \pm 22.3% ($P<0.01$). With the decrease of M_r , the activity of DSOSs decreased gradually. The effect of PSDS on APC activity enhancement was more significant than that of DS, and the APC activity was raised to 205.2 \pm 22.1% ($P<0.01$). All the PSDSOSs were more active than DSOSs on the basis of comparable M_r . With the decrease of M_r , the activity of PSDSOSs increased gradually, and the

most active PSDSOSs was PSDSOS₃ with M_r of 2 749, which enhanced the APC activity to 331.2 \pm 27.8% ($P<0.01$), then the activity of PSDSOSs decreased gradually.

CONCLUSION: DS and its derivatives can significantly inhibit P-selectin expression on platelet surface, but the effect has no correlation with DS molecular mass and sulfation. The effect of DS or its derivatives on APC activity at molecular level involves complex mechanisms that depend on the molecular mass, the degree of sulfation, and the heterogeneous composition of DS. On the same molecular size, the higher the degree of DS sulfation, the more significant the effect on enhancing APC activity.

INTRODUCTION

Inflammatory bowel disease (IBD) is a chronic non-specific intestinal inflammation. Recent researches have revealed a number of links between inflammation and coagulation, patients with IBD may be at increased risk of having venous thromboembolism^[1-9]. Abnormal platelet activity has been reported in patients with ulcerative colitis (UC) and Crohn's disease (CD), and plays an important role in inflammation aggravation^[10-12]. P-selectin, a membrane glycoprotein expressed on activated platelets and endothelial cells, plays a crucial role in thrombosis and inflammatory response^[13]. P-selectin antagonism could decrease thrombosis and inflammation in animal models of venous thrombosis prophylaxis^[14]. The protein C anticoagulant pathway appears to be the major pathway involved in the cross link between inflammation and coagulation. Activated protein C (APC) contributes to systemic anticoagulant and anti-inflammatory activities^[15], and may reduce organ damage by inhibiting thrombin generation and leukocyte activation^[16]. To inhibit the release of P-selectin and enhance APC activities are helpful for the treatment of IBD and related thrombosis^[17].

Dermatan sulfate (DS) is a member of the family of structurally complex, sulfated and linear polysaccharides called glycosaminoglycans (GAGs). It is mainly composed of [4- α -L-IdoA-1 \rightarrow 3- β -D-GalNAc-1]_n and [4- α -L-GlcA-1 \rightarrow 3- β -D-GalNAc-1]_n, and their derivatives with sulfate groups at C-2 of L-IdoA, C-4 or/and C-6 of D-GalNAc (IdoA, iduronic acid, GalNAc, N-acetyl-galactosamine, GlcA, glucuronic acid). The relative molecular weight (M_r) of natural DS is within 15 ku to 45 ku^[18]. Polysulfated DS is the sulfated product of DS reacting with chlorosulfonic acids. DS-derived oligosaccharides (DS-Oligs) are the oligosaccharides from depolymerizing DS and PSDS. DS is an important glycosaminoglycan found in a wide variety of tissues

in animals. Recently, growing evidence has suggested that DS, like the better studied heparin and heparan sulfate, is an important cofactor in a variety of cell behaviors^[18]. Many of the biological activities of DS proteoglycans are associated with their glycosaminoglycan structure^[19]. In addition to its anticoagulant and antithrombotic activities^[20,21], DS has also been reported possessing anti-inflammatory activities^[22-24]. The mechanisms of anti-inflammation of DS are unknown. To the author's knowledge, the relationships between the molecular structure of DS-Oligs and their effects on P-selectin and APC activity have not been studied. The present study was designed to observe the effects of DS-Oligs with different M_r and structure on platelet surface P-selectin expression and blood APC activities in patients with IBD, and to clarify the anti-inflammatory mechanisms of DS in the treatment of IBD.

MATERIALS AND METHODS

Materials

Dermatan sulfate was donated by Dongying Tiandong Biochemical Industrial Co. Ltd and 300 mL/L hydrogen peroxide (H_2O_2) was purchased from Laiyang Fine Chemical Reagent Co. Ltd. Adenosine diphosphate (ADP) was purchased from Sigma Co., USA. Superdex-30 was purchased from Amersham Biosciences. Human P-selectin ELISA kit (96 tests) and protein C CSA were purchased from Shanghai Sun Diagnostics, China.

Preparation of DS-Oligs

PSDS was prepared by the reaction of DS with chlorosulfonic acids. DS and PSDS were degraded by oxidative depolymerization with hydrogen peroxide^[25] respectively. All DS-Oligs were obtained from the products separated by gel filtration chromatography with Superdex 30 column (26 mm×1 200 mm), and the DS-Oligs were eluted with 0.25 mol/L ammonium bicarbonate and dried with lyophilization.

Determination of the relative molecular weight of DS-Oligs

The relative molecular weight (M_r) of the Oligs was determined by high performance liquid chromatography (HPLC)^[26].

¹H-NMR and ¹³C-NMR analysis of DS and PSDS

¹H-NMR and ¹³C-NMR spectra of DS and PSDS were assayed using a 600 MHz instrument as previously described^[27].

Patients and controls

Ten healthy blood-donors served as a control group and blood samples from 10 IBD patients, including five patients with UC and five patients with CD were used for experiments.

Collection of blood samples

Blood used to prepare platelets was collected in silicone-coated tubes containing 32 g/L sodium citrate as anticoagulant just before preparation and analysis.

Preparation of isolated platelets (IP)

Nine milliliter of blood with sodium citrate as anticoagulant blood was centrifuged at 500 r/min for 20 min at room temperature to obtain platelet rich plasma (PRP). The upper PRP was taken out, and the remaining plasma was centrifuged at 3 000 r/min for 15 min again and the platelet poor plasma (PPP) was obtained. The PRP was diluted with PPP to the platelet density of 3.0×10^8 cells/mL for P-selectin test.

Preparation of P-selectin standard calibration curve

Standard P-selectin was diluted to 80, 40, 20, 10, 5 and 2.5 ng/mL with assay buffer, and then added to the standard wells. The

standard curve was tested according to the test kit manufacturer's instructions.

Measurement of P-selectin in IP by ELISA

A total of 225 μ L of afore mentioned PRP was added to tubes, 30 μ L of saline was added to the control group and adenosine diphosphate (ADP) control tubes, and then 30 μ L of 2.50 mg/mL DS, PSDS and DS-Oligs saline solution were added to the sample tubes. All the tubes were incubated for 10 min at 37 °C. Then 25 μ L of 4.68 μ mol/L ADP solution was added to the ADP and sample tubes and an equal volume of saline was added to the blank control tubes. Then all the tubes were incubated for 5 min at 37 °C, followed by centrifugation for 15 min at 3 000 r/min, and finally the P-selectin in the upper solution was tested by ELISA according to the test kit manufacturer's instructions.

Specimen collection and preparation for APC test

Five milliliter of venous blood, containing 32 g/L sodium citrate as an anticoagulant, was collected from ten patients with IBD and the sample was centrifuged immediately. The plasma was collected and stored at 2-8 °C until use.

Preparation of protein C activity standard calibration curve

Normal plasma was dissolved in 200 μ L of buffer and the APC activity was defined as 200%. The solution was diluted three times to make the activities 100%, 50% and 25%, respectively. The activity of buffer was 0% criterion. Twenty five microliters of the four standards was added to the standard wells of the test plate, then 50 μ L of activator at the concentration of 0.1 mg/mL was added to activate protein C. These points were determined according to the manufacturer's instructions at 405 nm. The absorbance (A_{405nm}) was plotted versus the known percentage of standard APC activity to give a standard curve.

Detection of APC activity

APC activity in the plasma pre-incubated with DS and its derivatives was determined according to test kit manufacturer's instructions with minor modifications. Fifty microliters of DS and its derivatives solution at the concentration of 0.20 g/L was used to produce 50 μ L of activator. The APC enhancement by 50 μ L of DS at the concentration of 0.20 g/L was defined as 100%. Fifty microliters of buffer served as a blank control without any activator. The APC activities of the DS-Oligs were calculated according to the calibration curve.

Statistical analysis

Data were expressed as mean \pm SD. Student's *t* test and one-way analysis of variance were used for statistical analysis according to the data obtained. *P* values less than 0.05 were considered statistically significant.

RESULTS

Analysis of ¹H-NMR and ¹³C-NMR spectra of DS and PSDS

The ¹H-NMR and ¹³C-NMR spectra of DS and PSDS and the main disaccharides in their structure are shown in Figure 1. The major disaccharide sequence in DS was IdoA-1 \rightarrow 3-GalNAc-4-SO₃. In the ¹H-NMR spectra of PSDS (Figures 1B, D), the chemical shift of all the protons was shifted downfield in PSDS with respect to the DS. Similar effects could also be seen in the ¹³C-NMR spectra (Figures 1 A, C). The chemical shift of C-6 in GalNAc was shifted downfield (from 63.89 ppm to 68.60 ppm), while that of C-5 in GalNAc was shifted upfield (from 74.63 ppm to 69.98 ppm). The same phenomenon occurred in IdoA. The spectra showed that the hydroxyl group of C-6 in GalNAc and C-2 in IdoA of PSDS was sulfated, and the major disaccharide sequence was IdoA-2SO₃-1 \rightarrow 3-GalNAc4, 6-diSO₃.

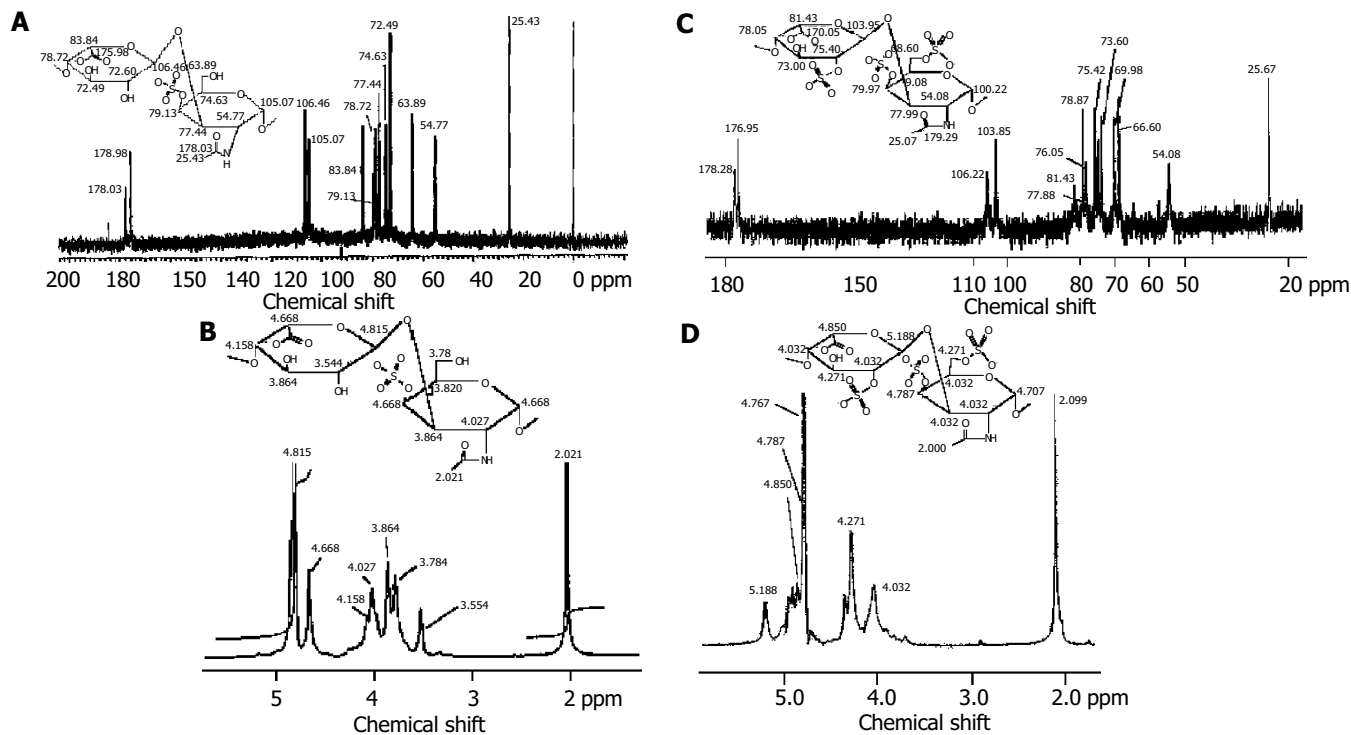

Figure 1 ^1H -NMR and ^{13}C -MNR spectra of DS and PSDS. A and B: ^{13}C -MNR and ^1H -NMR spectra of DS and the chemical shift of major disaccharides in DS; C and D: ^{13}C -MNR and ^1H -NMR spectra of PSDS and the chemical shift of the major disaccharides in PSDS.

Figure 2 Fragment size separation of DS-Oligs. The products were separated on a Superdex 30 size exclusion column (26 mm×1 200 mm) at a flow rate of 0.5 mL/min in 0.25 mol/L ammonium bicarbonate. Elution profiles were monitored by carbazole assay. A and B: depolymerized products of DS and PSDS.

Fractionation of DS-Oligs

The DS-Oligs prepared from DS and PSDS degradation and separated by gel filtration chromatography are shown in Figure 2. The peaks numbered were DS-Oligs collected for the experiments on P-selectin and APC, and their M_r are listed in Table 1.

Table 1 M_r of DS-Oligs

DS oligosaccharides	M_r	PSDS oligosaccharides	M_r
DSOS ₁	4 825	PSDSOS ₁	4 959
DSOS ₂	3 926	PSDSOS ₂	4 280
DSOS ₃	2 254	PSDSOS ₃	2 749
DSOS ₄	1 696	PSDSOS ₄	2 107
DSOS ₅	1 309	PSDSOS ₅	1 594
DSOS ₆	1 038	PSDSOS ₆	1 021
DSOS ₇	709	PSDSOS ₇	785

Effects of DS derivatives on the expression of platelet surface P-selectin

Expression of platelet surface P-selectin on IP of IBD control group was significantly increased from 13.92 ± 1.69 ng/mL (control group) to 23.95 ± 2.51 ng/mL, and the ADP group showed a

significant increase in P-selectin expression after stimulation with ADP ($P < 0.01$). All DS and its derivative groups showed a significant decrease in P-selectin expression compared with the ADP-stimulated group and IBD control group ($P < 0.01$), but no significant differences could be seen as compared with the control group, and between DSOS and PSDSOS groups (Figure 3).

Figure 3 Effects of DS derivatives on expression of P-selectin on IP surface. Bars I, II, III, IV and V represent control group, IBD control group, ADP group, DS group and PSDS group, respectively. Groups 4 to 10 represent DS-Oligs from 1 to 7 listed in Table 1. ^b $P < 0.01$ vs control group; ^a $P < 0.05$, ^d $P < 0.01$ vs IBD control group; ⁱ $P < 0.01$ vs ADP group ($n = 10$ for each group).

Effects of DS derivatives on APC activity

The experimental results showed that all DS and its derivatives enhanced APC activity. The most active DSOS was DSOS₁ with M_r of 4 825, which enhanced the APC activity from $106.5 \pm 11.5\%$ (DS group) to $181.8 \pm 22.3\%$ ($P < 0.01$). With the decrease of M_r , the activity of DSOSs decreased gradually. PSDS was more active than DS, which enhanced the APC activity from $106.5 \pm 11.5\%$ (DS group) to $205.2 \pm 22.1\%$ ($P < 0.01$). On the same molecular size basis, PSDSOSs were more active than DSOSs. With the decrease of M_r , the activity of PSDSOSs increased, and the most active one was PSDSOS₃ with M_r of 2 749, which enhanced the APC activity to $331.2 \pm 27.8\%$, then decreased gradually (Figure 4).

Figure 4 Effects of DS and its derivatives on APC activity. Bars I and II represent DS group and PSDS group, respectively. Groups 2 to 8 represent DS-Oligs from 1 to 7 listed in Table 1. ^b $P < 0.01$ vs DS group, ^d $P < 0.01$ vs PSDS group ($n = 10$ for each group).

DISCUSSION

IBD is a gastrointestinal disorder of unknown aetiology. Current research has paid attention to platelet dysfunction as a possible contributor to the disease, and the prevalence of IBD seems to be lower among patients with coagulation disorders^[28]. Platelets play a crucial role in hemostasis and inflammatory response. Normally, platelets circulate in a quiescent state, but after stimulation with agonists, such as thrombin, ADP and epinephrine, platelets begin to express P-selectin and release inflammatory mediators and factors, thereby promoting hemostasis^[29]. P-selectin acts as a cell-adhesion molecule in activated platelets and endothelial cells, and its main actions are to adhere to neutrophils and monocytes^[30] and to facilitate diapedesis. It has been reported that DS acts as a ligand to bind to P-selectin, and the sulfation plays an important role in the interactions between L- or P-selectin and DS^[31,32]. Our results showed that DS, PSDS and their derivatives significantly inhibited the P-selectin expression on IP surface, but there was no difference between DS and PSDS, and the effect seemed to be independent of molecular weight.

The increased risk of thrombosis in IBD patients has been attributed to a hypercoagulable state^[33-37]. Investigations of the hypercoagulation state and clinical risk factors in patients with IBD are of interest because thromboembolism is a significant and serious complication in IBD patients, with a high morbidity and mortality. The incidence of arterial and venous thromboembolic disease in patients with UC and CD is between 1% and 8%, and was 39% in some postmortem studies^[38]. Deficiencies and functional abnormalities of protein C, antithrombin III and protein S are the well-recognized causes of thrombotic disease^[8,39]. Blood coagulation is carefully controlled *in vivo* by several anticoagulant systems. Protein C pathway is one of these natural anticoagulant systems. It could regulate the coagulation process through proteolytic cleavage and inactivation of the two cofactors in the coagulation cascade,

the activated forms of factor V and VIII^[40-42]. The response of UC to heparin therapy^[43] and the low risk of IBD in patients with hemophilia and von Willebrand's disease^[29] also suggested that thrombosis and vascular occlusion might be important in the pathogenesis of IBD.

DS has been widely used as an antithrombotic drug. Its anticoagulant activity may involve multiple mechanisms. One of the mechanisms is that DS could promote the inhibition of thrombin activity by heparin cofactor II^[44]. The present experiments were designed to investigate the relationships between the APC activity enhancement and structures of DS or its derivatives *in vitro*. The results showed that DS and its derivatives all enhanced APC activity. Furthermore, a variety of experiments based on enhancement of APC activity compared the activity of various DS derivatives and defined the influences of DS molecular size and degree of sulfation on this activity. Two important variables of DS derivatives are the relative molecular weight and the degree of sulfation of the molecules. To assess the influence of molecular size, we studied different DS and PSDS fragments with M_r ranging from 0.7 ku to 5.0 ku. A clear correlation between the molecular size of DS and PSDS fragments and the degree of APC activity enhancement was observed by the synthetic chromogenic substrate method. With the decrease of molecular weight, the activity of DS-Oligs increased, and then decreased gradually. DSOS with M_r of 4 825, containing 16 to 24 monosaccharide residues, had more significant activity than undegraded DS. The same tendency was observed on PSDSOSs. But the most active PSDSOS was PSDSOS₃ with M_r of 2 749 containing about 8 to 10 monosaccharide residues.

To study the influence of the sulfate groups in DS molecules on APC enhancement, a chemically modified DS with a high degree of sulfation was prepared and compared with its parent DS. PSDSOSs were also compared with DSOSs with comparable M_r . The APC activity enhancement of PSDSOSs was much higher than that of DSOSs.

In conclusion interactions between APC and DS-Oligs at the molecular level involve complex mechanisms that depend on the M_r , the degree of sulfation, and the heterogeneous composition of DS, and are of great importance in the development of new anti-thrombotic DS-derived drugs.

Abstract

AIM: To investigate the inhibitory effect of heparin-derived oligosaccharides (Oligs) on secretion of interleukin-4 (IL-4) and interleukin-5 (IL-5) from human peripheral blood T lymphocytes (PBTLs).

METHODS: Oligs were prepared by three different heparin depolymerization methods and separated by gel filtration chromatography. PBTLs from ten adult patients with allergic eosinophilic gastroenteritis were treated with phytahematoagglutinin (PHA) and Oligs. The supernatants from the cell culture of PBTLs were harvested and subjected to the determination of IL-4 and IL-5 contents by ELISA method.

RESULTS: At the concentration of 5 $\mu\text{g/mL}$, Oligs with different M_r had different effects on the secretion of IL-4 and IL-5. The tetrasaccharide with M_r of 1 142, produced by depolymerizing heparin with hydrogen peroxide, had the strongest inhibitory effect on the secretion of IL-4. It decreased the IL-4 content from 375.6 ± 39.2 ng/L (PHA group) to 12.5 ± 5.7 ng/L ($P < 0.01$). The hexasaccharide with M_r of 1 806, produced by depolymerizing heparin with β -elimination method, had the strongest inhibitory effect on the secretion of IL-5. It decreased the IL-5 content from 289.2 ± 33.4 ng/L (PHA group) to 22.0 ± 5.2 ng/L ($P < 0.01$).

CONCLUSION: The inhibitory activity of Oligs on the secretion of IL-4 and IL-5 from human PBTLs closely depends on their molecular structure, and there may be an essential structure to act as an inhibitor. The most effective inhibitors of IL-4 and IL-5 secretion are tetrasaccharides and hexasaccharides, respectively.

INTRODUCTION

Heparin is a highly sulfated, polyanionic glycosaminoglycan. It is composed of the trisulfated disaccharide unit [- *L*-iduronic acid-2-sulfate (IdoA2S) (1 \rightarrow 4)- α -*D*-glucosamine-*N*,6-disulfate (GlcNS6S)-], interrupted by irregular sequences containing undersulfated (or oversulfated) uronic acids and amino sugar residues, with an average relative molecular mass (M_r) of 12 000-15 000^[1]. In addition to its anticoagulatory effect, heparin has anti-inflammatory property, which has been used for treatment of ulcerative colitis and other inflammatory bowel diseases (IBD)^[2-15]. Although many studies have reported heparin's anti-inflammatory activities, there is little information available in literature about the specific oligosaccharide structures in heparin that inhibits the secretion of IL-4 and IL-5. IL-4 and IL-5 abnormalities have been reported to be consistent with the elevated IgE and eosinophilia in allergic eosinophilic gastroenteritis, suggesting that strategies targeting T lymphocytes may be efficacious in treatment of this kind of diseases^[16-19]. Here, we examined whether there was a relationship between the molecular weight of heparin-derived Oligs and their inhibitory effect on IL-4 and IL-5 secretion from PBTLs in allergic eosinophilic gastroenteritis.

MATERIALS AND METHODS

Drugs and reagents

Heparin sodium was donated by Dongying Tiandong Biochemical Industrial Co. Ltd, and 300 mL/L hydrogen peroxide (H_2O_2) was purchased from Laiyang Fine Chemical Regent Co, Ltd. Benzethonium chloride and (4-chloro)-benzyl chloride were purchased from Sigma Co., USA. Sodium nitrite was purchased from Jinan Chemical Reagents Co., Ltd. Superdex-30 was purchased from Amersham Biosciences. Human IL-4 and IL-5 ELISA kits (96 tests) were purchased from Bender Medsystems, USA. Phytahematoagglutinin (PHA) was purchased from Shanghai Yihua Medical Science and Technology Co., Ltd. RPMI 1640 culture medium was purchased from Gibco, Paisley, UK.

Preparation of Oligs

Heparin was degraded by oxidative depolymerization with hydrogen peroxide^[20], deaminative cleavages with nitrous acid^[21] and β -eliminative cleavages with alkaline^[22], respectively. All Oligs were obtained from the products separated by gel filtration chromatography with Superdex-30 column (26 mm \times 1200 mm), and the oligosaccharides were eluted with 0.25 mol/L ammonium bicarbonate and dried with lyophilization.

Determination of the relative molecular weight of Oligs

The M_r of Oligs was determined by high performance size exclusion chromatography (HPSEC) on two Ultrahydrogel 250 (7.8 mm \times 300 mm) columns in series. The calibration was based on low molecular mass heparin for calibration CRS (Batch No 1A, European Pharmacopoeia) standards with number average molecular mass (M_n) of 3 700. A refractometer (RI) detector connected in series to an ultraviolet (UV) spectrophotometer

set at 234 nm was used for detection, and 28.4 g/L solution of sodium sulphate (pH 5.0) was used as the mobile phase at a flow rate of 0.5 mL/min^[23].

T cell separation and culture

Twenty-five milliliters of edetic acid anticoagulant peripheral blood was taken from ten adult patients with allergic eosinophilic gastroenteritis, and then mixed with 25 mL of PBS (pH 7.4, containing 50 mL/L fetal bovine serum). The diluted peripheral blood was then laid on 50 mL of lymphocyte separating solution carefully and centrifuged for 20 min at 2 000 r/min at room temperature. The peripheral blood lymphocytes (PBL) were collected and washed two times with PBS and suspended in RPMI 1640 solution (containing 200 mL/L fetal bovine serum). One millilitre of PBL suspending solution was added to the column of Nylon cotton (5 mm×16 mm). Then 0.2 mL of RPMI 1640 (containing 200 mL/L fetal bovine serum) was added on the Nylon cotton surface to close the column. The column was incubated for 30 min at 37 °C in an incubator. After that, PBTLs were eluted with RPMI 1640 (containing 200 mL/L fetal bovine serum) solution and then centrifuged for 10 min at 2 000 r/min. PBTLs were diluted to the cell density of 1.0×10^6 cells/mL, and 0.2 mL of the diluted cell suspending solution was added to a well of 96-well plate as a blank control. Another well was added into 0.2 mL of diluted cell suspending solution containing 20 µg of PHA as PHA control group. Other wells were added into 0.2 mL of diluted cell suspending solution containing 20 µg of PHA and 1 µL of 1.0 mg/mL heparin and Oligs. The cells were incubated for 48 h at 37 °C in a humidified atmosphere containing 50 mL/L CO₂ in air.

Detection of cytokines

The cells were harvested and centrifuged for 10 min at 1 000 r/min at room temperature. IL-4 and IL-5 in the cell culture solution were assayed by ELISA according to the manufacturer's instructions.

Statistical analysis

Data were expressed as mean±SD. Student's *t* test and one-way analysis of variance were used for statistical analysis. *P* values less than 0.05 were considered statistically significant.

RESULTS

Figure 1 shows the Oligs prepared from heparin degradation and separated by gel filtration chromatography. The peaks numbered were Oligs collected for inhibiting IL-4 and IL-5 experiments, and their *M_r* is listed in Table 1.

Table 1 Oligs obtained from chromatography eluted solution and their *M_r*

Oligs produced by H ₂ O ₂ oxidation		Oligs produced by β-elimination		Oligs produced by degradation with HNO ₂	
Samples	<i>M_r</i>	Samples	<i>M_r</i>	Samples	<i>M_r</i>
Olig H1	6 032	Olig B1	6 621	Olig N1	6 680
Olig H2	3 206	Olig B2	3 375	Olig N2	3 150
Olig H3	2 381	Olig B3	2 447	Olig N3	2 334
Olig H4	1 786	Olig B4	1 804	Olig N4	1 747
Olig H5	1 142	Olig B5	1 344	Olig N5	1 047
Olig H6	632	Olig B6	702	Olig N6	609

The effect of Oligs on secretion of IL-4 showed that all the Oligs had inhibitory activities and Oligs prepared from different methods or with different *M_r* had different effects. First, the Olig prepared from H₂O₂ depolymerizing method, was Olig H5 with *M_r* of 1 142 (tetrasaccharides), which had the strongest inhibitory effect and decreased the IL-4 content from 375.6±39.2 ng/L (PHA group) to 12.5±5.7 ng/L (*P*<0.01). Second, among the Oligs

from β-eliminative cleavage heparin, Olig B5 with *M_r* of 1 344 (tetrasaccharides) had the strongest inhibitory activity and decreased the IL-4 content to 54.4±6.3 ng/L (*P*<0.01). Third, the Olig from nitrous acid deaminative cleavage heparin, was Olig N5 with *M_r* of 1 107 (tetrasaccharides), which had the strongest inhibitory activity and decreased the IL-4 content to 47.4±5.8 ng/L (*P*<0.01). Although all these Oligs were tetrasaccharides, they had different *M_r*, because the amount of sulfate groups in their structure was different. The IL-4 content in the heparin group was 152.4±17.9 ng/L, and the difference in inhibitory activities between Oligs and heparin group was significant (*P*<0.01, Figures 2A, 3A).

The inhibitory effect of Oligs on secretion of IL-5 and IL-4 was similar. But there were some differences. Firstly, the Oligs prepared from H₂O₂ oxidation method, were Olig H4 with *M_r* of 1 786 and Olig H5 with *M_r* of 1 142, which had strongest inhibitory activities. They decreased the IL-5 content from 289.2±33.4 ng/L (PHA group) to 31.7±5.6 ng/L and 35.5±4.4 ng/L, respectively (*P*<0.01). Secondly, among the Oligs from β-eliminative cleavage heparin, Olig B4 with *M_r* of 1 804 (hexasaccharides) had the strongest inhibitory activity and decreased the IL-5 content to 22.0±5.2 ng/L (*P*<0.01). Thirdly, among the Oligs from nitrous acid deaminative cleavage heparin, Olig N4 with *M_r* of 1 747 (hexasaccharides) had the strongest inhibitory activity and decreased the IL-5 content to 69.2±6.3 ng/L (*P*<0.01). The inhibitory activities of these Oligs were stronger than those of unfractionated heparin (*P*<0.01, Figure 2B). The strongest inhibitor was Olig B4 (Figure 3B).

Figure 1 Size separation of heparin oligosaccharides. A: heparin degraded with hydrogen peroxide; B: heparin degraded with β-eliminative cleavage; C: heparin degraded with nitrous acids. The reaction products were separated on a Superdex 30 size exclusion column (26 mm×1 200 mm) at a flow rate of 0.5 mL/min in 0.25 mol/L ammonium bicarbonate. Elution profiles were monitored by carbazole assay.

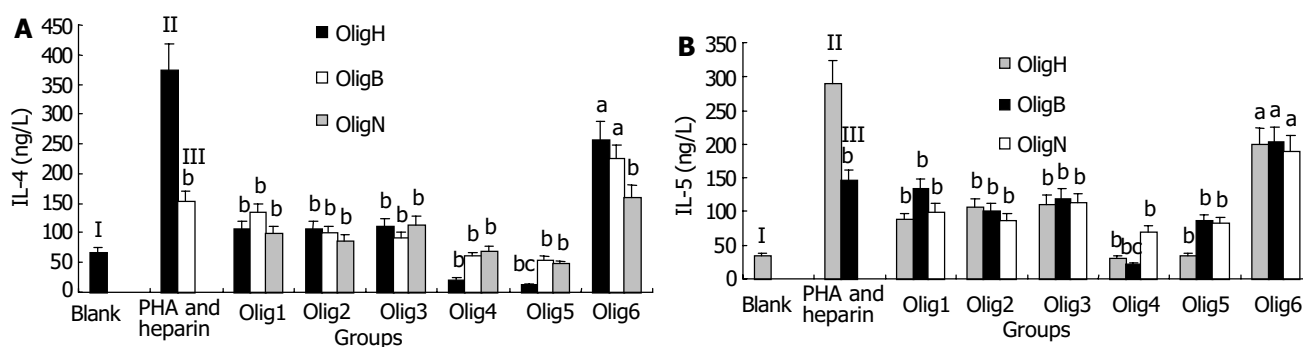

Figure 2 Content of IL-4 (A) and IL-5 (B) in PBTL culture solution of different groups. I, II and III represent blank control group, PHA control group and heparin group respectively. Olig1 to Olig 6 represent corresponding oligosaccharide samples described in Table 1 (from 1 to 6), respectively. ^a*P*<0.05, ^b*P*<0.01 vs PHA group; ^c*P*<0.05 vs Olig H4 group. (*n* = 10 for each group).

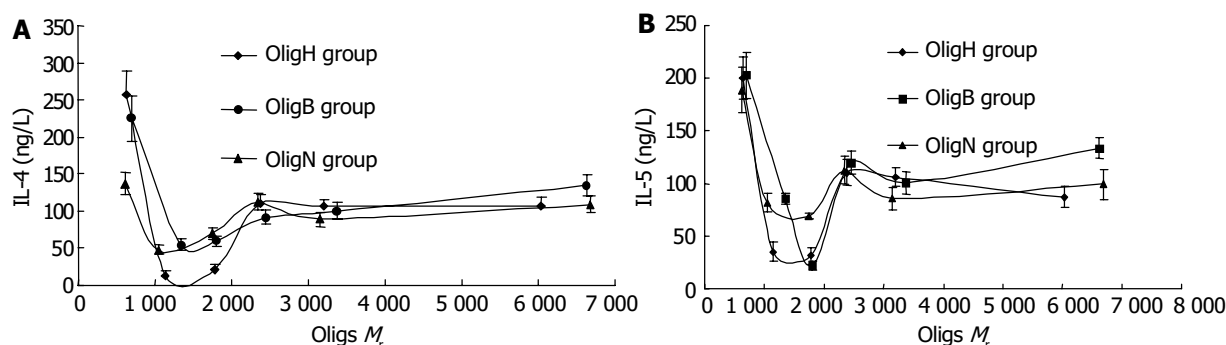

Figure 3 Relationship between M_r of Oligs and their activity on inhibiting IL-4 (A) and IL-5 (B) secretion. ^a*P*<0.05 vs Olig H4 group.

DISCUSSION

Allergic eosinophilic gastroenteritis is characterized by elevated total immunoglobulin E (IgE). IgE plays a significant role in allergic IBD by mediating the cross-linking of high-affinity Fc receptors (FcεRI) on mast cells, thus resulting in the release of a vast array of pro-inflammatory mediators including histamine, leukotrienes, and cytokines^[24] (Figure 4). In clinical studies, increased secretion of IL-4 and IL-5 by peripheral blood T cells has been reported in patients with eosinophilic gastroenteritis^[17]. Furthermore, T cells derived from the duodenum of patients with eosinophilic gastrointestinal disorder could preferentially secrete helper T cell 2 (Th2) cytokines that pre-dominantly include IL-4 and IL-5 when stimulated with milk proteins^[17]. IL-4 might play a critical role in mediating IgE-dependent allergic reactions, and regulation of IL-4 production or action might be useful for the prevention or therapy of immediate hypersensitivity disorders^[25-27]. IL-5, on the other hand, is most specific to the eosinophil lineage and responsible for the selective expansion of eosinophils and their release from bone marrow. Eosinophil granules contain a crystalloid core composed of major basic proteins (MBP) and a matrix composed of eosinophil cationic protein (ECP)^[28] (Figure 4). These cationic proteins share certain pro-inflammatory properties but differ in other aspects. MBP also triggers degranulation of mast cells and basophils. Triggering of eosinophils through engagement of receptors for cytokines could lead to the generation of a wide range of inflammatory cytokines, including IL-1, IL-3, IL-4, IL-5, IL-13, granulocyte-macrophage colony stimulating factor (GM-CSF), transforming growth factors (TGF), TNF-α, RANTES, macrophage inflammatory protein 1α, vascular endothelial cell growth factor, and eotaxin 1, indicating that they have the potential to modulate multiple aspects of the immune response^[29]. These findings imply that regulation of IL-5 production or action may also be useful for the prevention or therapy of allergy symptoms and inflammation.

Figure 4 Interactions among inflammatory cells in pathogenesis of allergic eosinophilic gastroenteritis. Broken arrows denote the inhibitory effect of heparin-derived oligosaccharides on the various targets shown. MBP: major basic protein; and ECP: eosinophil cationic protein.

Heparin is a kind of polyanionic polysaccharides. In addition to its anticoagulant activity, heparin has a wide range of biological activities, including inhibition of complement activation^[30], regulation of cell proliferation^[31], inhibition of angiogenesis and tumor growth^[32,33], and antiviral activity^[34,35]. Over the last decade, heparin and low molecular mass heparin have been used to treat IBD in clinical practice^[36-50]. The mechanisms by

which heparin is able to treat IBD include its ability to inhibit the recruitment of neutrophils, reduce production of pro-inflammatory cytokines^[51] and restore the high-affinity receptor binding to antiulcerogenic growth factor^[12,13]. The ability of heparin to inhibit neutrophil activation, adhesion, and chemotaxis was also found in a mouse model of IBD^[14], suggesting that balanced interactions between mast cells and neutrophils might be important for the development of IBD. Furthermore, unfractionated heparin has potent immunomodulatory effects^[52-57]. Administration of unfractionated heparin may therefore be rational in patients with ulcerative colitis or Crohn's disease resistant to conventional forms of treatment^[39,40]. The anti-inflammatory effects of heparin can be most probably attributed to its physical binding to a variety of heparin-binding proteins such as TNF- α , IL-4, IL-5, RANTES, secretory leukocyte protease inhibitor, neutrophil-derived elastase and cathepsin G, eosinophil-derived major basic protein, and L- and P-selectins^[58-61]. Alternatively, heparin has been shown to specifically inhibit the inositol 1,4,5-triphosphate signal transduction pathway, which is important for a vast array of inflammatory cellular responses^[62,63].

If heparin is to be used as an anti-inflammatory drug, the risk of inducing bleeding must be abrogated. It has been reported that the anti-inflammatory effects of heparin were independent of its anticoagulant activity^[64-67], especially when it was used for treatment of allergic inflammation. Partial chemical modifications of heparin, such as depolymerization or partial desulfation, are the aim to develop heparin-derived anti-inflammatory drugs. We degraded heparin and separated the fragments by gel filtration chromatography. The oligosaccharides obtained were used as anti-inflammatory reagents and the results were promising. The hypothetical mechanisms for anti-inflammatory effects, such as inhibiting secretion of IL-4 and IL-5, were studied. Our results showed that Oligs with different M_r had different activities on inhibiting the secretion of IL-4 and IL-5. The Oligs, which had the strongest inhibitory activities on IL-4 secretion, were tetrasaccharides, but they had different M_r corresponding to the production methods. That was because different methods caused different desulfation during the process of degradation. The same phenomenon occurred in inhibiting the secretion of IL-5, but the strongest inhibitors were hexasaccharides other than tetrasaccharides. The mechanism needs further studies.

Abstract

AIM: The optimal treatment for bile duct stones (in terms of cost, complications and accuracy) is unclear. The aim of our study was to determine the predictive factors for preoperative endoscopic retrograde cholangiopancreatography (ERCP).

METHODS: Patients undergoing preoperative ERCP (≤ 90 d before laparoscopic cholecystectomy) were evaluated in this retrospective study from the 1st of January 1996 to the 31st of December 2002. The indications for ERCP were elevated serum bilirubin, elevated liver function tests (LFT), dilated bile duct (≥ 8 mm) and/or stone at US examination, coexisting acute pancreatitis and/or acute pancreatitis or jaundice in patient's history. Suspected prognostic factors and the combination of factors were compared to the result of ERCP.

RESULTS: Two hundred and six preoperative ERCPs were performed during the observed period. The rate of successful cannulation for ERC was (97.1%). Bile duct stones were detected in 81 patients (39.3%), and successfully removed in 79 (97.5%). The number of prognostic factors correlated with the presence of bile duct stones. The positive predictive value for one prognostic factor was 1.2%, for two 43%, for three 72.5%, for four or more 91.4%.

CONCLUSION: Based on our data preoperative ERCP is highly recommended in patients with three or more positive factors (high risk patients). In contrast, ERCP is not indicated in patients with zero or one factor (low risk patients). Preoperative ERCP should be offered to patients with two positive factors (moderate risk patients), however the practice should also be based on the local conditions (*e.g.* skill of the endoscopist, other diagnostic tools).

INTRODUCTION

The rate of coexisting common bile duct stones (CBDS) in patients undergoing cholecystectomy for cholelithiasis is approximately 7-20%^[1-3]. The dramatic shift from conventional to laparoscopic cholecystectomy (LC) in the last 15 years has opened a large debate over the optimal management of patients with CBDS undergoing cholecystectomy^[4,5]. It is generally accepted that bile duct stones should be removed (even if asymptomatic), because they may be associated with severe complications such as pancreatitis and cholangitis. The management of coexisting CBDS may be surgical or endoscopic followed by surgery. Gallbladder preservation has also been suggested, however it has not become universal^[6]. A group of surgeons have recommended laparoscopic management of coexisting CBDS by intraoperative cholangiography or intraoperative ERCP and surgical removal of the stones^[7-9]. However, manipulation of the bile duct during LC is not popular among laparoscopic surgeons. Recent studies suggest that it can be done safely and does not prolong hospitalisation^[10,11], but minimal invasiveness and cost-effectivity remain questionable^[12].

ERCP is the most popular peri-LC bile duct imaging method. It is readily available, safe, highly accurate and has therapeutic potential, even in old patients^[13]. Furthermore ERCP offers the possibility to study bile duct anatomy, identify abnormalities of the bile ducts as well as being useful in the differential diagnosis of questionable lesions (*e.g.* malignancy). The role of new, less invasive imaging techniques (*e.g.* endoscopic ultrasound - EUS, magnetic resonance cholangiopancreatography - MRCP) is less well characterized^[14-16].

Routine preoperative ERCP may not be recommended, due to the low percentage of coexisting cholecysto-choledocholithiasis, a large number of negative investigations, and a small but significant risk of associated morbidity and high additional costs. Postoperative ERCP could reduce the number of unnecessary interventions and the majority of retained stones and postoperative leakages can be treated, although a second operation is required in case of failure. The development of more reliable predictors of CBD stones, based on the patient's clinical, biochemical and ultrasound (US) presentations, could allow a more appropriate use of preoperative ERCP (or EUS, MRCP). However, there is still no consensus as to which particular indicator, or set of indicators should be used, or as to the threshold values of various indicators^[3,17-22].

The aim of this study was to determine a precise and easily applicable clinical, biochemical and US (selection) criteria for patients who should undergo further investigation (preoperative ERCP) prior to LC/surgery.

MATERIALS AND METHODS

Patients who underwent preoperative ERCP from the 1st January 1996 to the 1st January 2003 (≤ 90 d before laparoscopic cholecystectomy) were evaluated in this retrospective study.

The indications for ERCP were one or more of the following: elevated serum bilirubin ($\geq 2 \times$ upper limit of normal - ULN) concentration, elevated liver function tests [LFT, $\geq 1.5 \times$ ULN: either aspartate-aminotransferase (AST), alanine-aminotransferase (ALT), alkaline phosphatase (ALP) or γ -glutamyl transpeptidase (GGT) activities], dilated bile duct (≥ 8 mm) and/or stones at US examination, coexisting acute pancreatitis and/or acute pancreatitis or jaundice in patient's history. The predictive values of age, sex and colic were also investigated. The majority of the ERCPs were performed by two expert endoscopists. Suspected prognostic factors and combination of factors were compared to the results of the ERCP.

Serum bilirubin concentration, AST, ALT, ALP and GGT activities were measured by Olympus AU600 (Olympus Co. Ltd, Shizuoka, Japan) autoanalyser at 37 °C. The enzyme activities were expressed in U/L and serum bilirubin concentration was given in $\mu\text{mol/L}$.

Statistical analysis

Sensitivity, specificity, positive and negative predictive values were calculated for individual factors (compared to all other cases) and for combination of factors. Student *t*-test with separate variance estimates was performed to test the demographic differences. χ^2 test and Fisher exact test were performed to compare between patients with a different number of suggested factors. $P < 0.05$ was considered statistically significant. For the statistical analysis Statistica 6.1 (Statsoft Inc, OK, USA) was used.

RESULTS

A total of 2985 ERCPs and 1248 LCs were performed in the Csolnoky F. Province Hospital between 1st January 1996 and the 31st December 2002. Using our selection criteria (a minimum of one positive factor) preoperative ERCP was performed in 206 patients (16.5%, Table 1). Seventy-seven percent of the patients were women and 23% men. The mean age of women was significantly lower ($P = 0.02$, Table 2). The mean waiting time between ERCP and LC was 17.3 d. Thirty-nine percent of the patients were operated within 3 d, almost 60% within one week.

Table 1 Number of ERCP and/or LC cases per year in the Csolnoky Ferenc Hospital, Veszprém, Hungary

Year	ERCP	LC	ERCP-LC
1996	373	99	15
1997	393	164	28
1998	375	140	27
1999	490	189	33
2000	558	183	36
2001	378	246	42
2002	391	227	25
Total	2 258	1 248	206
Average	423/yr	178	29/yr

Table 2 Preoperative ERCP, age and gender of patients ($n=206$)

Gender	<i>n</i> (%)	Mean age
Male	48 (23)	57.4
Female	158 (77)	51.0
Total	206 (100)	52.5

A successful cannulation was done in 200 patients (97.1%,

Table 3). CBD stones were found in 81 patients (39.3%), the stone/stones were removed endoscopically in 79 cases (97.5%). There was a tendency of increased frequency of CBD stones in men (24/48 = 50.0%) compared to women (57/158 = 36.1%, $P = 0.06$ by Fisher exact test), but CBD stones were equally common in elder (≥ 60 years) and younger (< 60 years) patients (50/128 = 39.1% vs 31/78 = 39.7%).

The results for each individual criterion are shown in Tables 4, 5. With the exception of jaundice or pancreatitis in the patient's history the positive predictive value of each criterion was high (58-72%). Sensitivity and specificity were compared to patients lacking the specific factor.

Table 3 Results of preoperative ERCPs performed prior to LC ($n = 206$)

ERCP finding	<i>n</i>	%
Common bile duct (CBD) stone	81	39.3
Negative	119	57.8
CBD not filled	6	2.9
Successful EST and duct clearance	79/81	97.5
Complication	3	1.5
-bleeding	1	0.5
-pancreatitis	1	0.5
-stone impaction	1	0.5

Table 4 Common bile duct stones in cases of different positive prognostic factors (PPF)

Factor	Number	Stone	Negative	Unsuccessful	%
Hyperbilirubinaemia (> 2)	61	44	16	1	72
Elevated ASAT/ALAT ($> 50\%$)	116	74	39	3	64
Elevated GGT/ALP ($> 50\%$)	134	79	52	3	59
Acute pancreatitis (AP)	26	18	7	1	69
AP in the anamnesis	20	4	16	0	20
Jaundice in the anamnesis	29	1	26	2	3
US: CBD ≥ 8 mm	53	38	14	1	71
US: bile duct stone	7	4	3	0	57
Biliary colic	106	62	42	2	58

Table 5 Total predictive value of different positive predictive factors (PPF) for common bile duct stone

Factor	PPV %	NPV %	Sensitivity %	Specificity %
Hyperbilirubinaemia	73.3	73.6	54.3	86.6
Elevated ASAT/ALAT	65.4	91.9	91.3	67.2
Elevated GGT/ALP	60.3	97.1	97.5	56.3
Acute pancreatitis (AP)	72.0	73.5	22.2	96.2
AP in the anamnesis	20.0	57.2	4.9	86.5
Jaundice in the anamnesis	3.7	53.7	1.2	78.2
US: CBD ≥ 8 mm	73.1	70.9	46.9	88.2
US: bile duct stone	57.1	60.1	4.9	97.5

A more realistic approach was to compare the predictive value in association with other factors. Table 6 demonstrates that the positive predictive value of the investigated factor was high in cases with (at least) two concurrently positive factors. The positive predictive value of two positive markers was 41-55%, again with the exception of pancreatitis or jaundice in the anamnesis.

Table 6 Predictive value of positive predictive factors (PPF) for CBD stones and effect of associated other factors, *n* (%)

Factor	Alone	One further factor	Two or more further factors
Hyperbilirubinaemia	0/3	1/5 (20)	43/53 (81)
Elevated ASAT/ALAT	1/11 (9)	13/32 (41)	60/73 (82)
Elevated GGT/ALP	1/24 (4)	16/35 (46)	62/75 (83)
Acute pancreatitis (AP)	-	0/3	18/23 (78)
AP in the anamnesis	1/12 (8)	0/3	3/5 (60)
Jaundice in the anamnesis	0/27	1/2 (50)	-
US: CBD \geq 8 mm	0/7	6/11 (55)	32/35 (91)
US: bile duct stone	0/1	-	4/6 (67)

The association between the number of positive factors and the presence of CBD stones is shown in Tables 7, 8. One factor alone was associated with a very low risk of CBD stone (1.2%). In patients with two, three and four or more positive factors, CBD stones were detected in 43.1%, 72.5% and 91.4% respectively. If we omitted history of jaundice and pancreatitis from the factors the corresponding data were 2.7% (1/41), 1.9% (1/54), 45.6% (23/48) and 82.3% (56/69) for patients with zero, one, two and three or more positive factors.

Table 7 Association between the number of positive predictive factors and ERCP findings (*n* = 206)

Number of positive factors	Number	Stone	Negative	Unsuccessful	%
1	84	1	80	3	1.2
2	46	19	25	2	43.1
3	40	29	11	0	72.5
≥ 4	36	32	3	1	91.4

$P < 0.00001$ for the whole group, $P < 0.00001$, between group 1 and groups 2, 3, 4, group 2 and group 4, $P = 0.008$, between groups 2 and 3, $P = 0.035$, between groups 3 and 4.

Table 8 Predictive value of predictive factors according to the number of positive factors

Number of positive factors	Number	PPV %	NPV %	Sensitivity %	Specificity %
1	84	1.2	-	-	-
2	46	43.1	98.7	95.2	76.1
3	40	72.5	84.0	59.1	90.5
≥ 4	36	91.4	72.0	40.2	98.4

$P < 0.00001$ for the whole group, $P < 0.00001$, between group 1 and groups 2, 3, 4 and group 2 and group 4, $P = 0.008$, between groups 2 and 3, $P = 0.035$, between groups 3 and 4.

DISCUSSION

Although laparoscopic cholecystectomy has become the treatment of choice for cholelithiasis, the treatment of coexisting cholecysto-cholecho-lithiasis is still controversial^[1,3,8,10,15,17]. The surgical management of CBD stones requires a skilled laparoscopic surgeon and the options of management include conversion to open CBD exploration, intraoperative or postoperative ERC. In contrast, no single non-invasive method is sensitive and/or specific enough to predict the presence of CBD stones. Individual findings are less important than the overall clinical presentation.

A number of methods have been used for the diagnosis of CBDS, including new and improved radiological techniques. However some of them are invasive, more expensive and require special equipment. A major advantage of ERCP is that it could

also offer a therapeutic possibility. Approximately 90-95% of CBDS could be managed endoscopically^[1,23], but it is expensive, technically demanding and is associated with small but significant morbidity.

The question is whether preoperative ERCP should be routinely indicated or whether it should be kept for selected cases only. Most of the studies concluded that routine preoperative ERCP was not indicated^[1,20,24]. One of the earliest studies is the well-known study from Neuhaus *et al.*^[24]. They performed routine preoperative ERCP in 288 prospective patients prior to LC. The rate of successful cannulation was 91.7%, and normal anatomy was found in 86%. CBDS were proved in 29 patients (11%), the stone was asymptomatic in 9 patients. Endoscopic sphincterotomy was performed in all cases and the stones were extracted in all but three patients. One additional patient was operated due to complications. In concordance with the reported rate of 6-13.2% in other studies^[1,14,20], coexisting cholecysto-cholecho-lithiasis was found in 6.5% of our LC patients (81 cases by preoperative ERCP).

The aim of this and previous studies was to determine a precise and easily applicable selection of clinical, biochemical and US criteria, which would enable the identification of patients with low risk of CBD stones (without the necessity for invasive procedures), and with higher risk of CBD stones who should undergo further preoperative investigation. The selection of patients was difficult. CBD stones were more common in patients with symptoms (e.g. jaundice, cholangitis, pancreatitis) and laboratory alterations including elevated serum bilirubin and liver function test. However, 8-10% of gallstone patients might have asymptomatic ductal stones^[3,25,26].

The positive predictive value of laboratory data for CBD stones was found to be 60-87% in various studies^[26,27]. In our study it was 57.1-73.3% in univariate analysis. However in most of the cases they were not individual parameters. In concordance with previous studies we could not identify jaundice and pancreatitis in the anamnesis as a predictor variable.

Traditional abdominal US is a valuable diagnostic tool. Although it is less sensitive (20-30%) in the detection of ductal gallstones, it provides important additional information about the degree of dilation of the bile ducts. The sensitivity of iv. cholangiography is also relatively low, moreover, it is associated with a severe risk of side effects. However, due to new non-ionic radiocontrast agents and radiological techniques, more and more research groups have started to routinely apply this technique again with improving results^[3]. Laparoscopic intraoperative cholangiography is a useful and reliable method, although its indication remains debated^[10,28]. The sensitivity of traditional CT is similar to that of US, but 3D helical techniques could offer an accuracy comparable to that of MRCP^[29]. MRCP and endoscopic US could approach the diagnostic value of ERCP^[14,15,30].

None of the aforementioned and analyzed factors is fit for the prediction of bile duct stones with sufficient certainty by itself. A combination of the prognostic factors is routinely applied. Several authors have constructed complicated scoring systems^[16,23,27]. However, most of these systems require highly specific and sophisticated softwares, and no universally accepted system exists. More practical is the use of suggested clinical scores based on routine clinical data (jaundice, pancreatitis, liver function tests, ductal dilation and/or stones in the choledochus on US) in everyday practice^[17,20]. Some authors also included the presence of small gallstones, old age and gender.

In concordance with our study, in the different studies based on large patient populations, CBDS/ductal stones or other pathologic deviations were found in 40-60% of ERCP cases performed on selected/restricted indications^[1,16,18,20]. Based on the prognostic factors, patients were usually divided into low,

medium and high-risk CBD stone groups.

Peter Cotton^[31] has presented his guidelines in the American Journal of Surgery. In his opinion the main constituents of the indications of preoperative ERCP were the following: positive predictive factors for CBD stones, the expertise of the endoscopist, and the pressure for laparoscopic intervention as opposed to open surgery. In concordance with our suggestion, he identified low, medium and high-risk patients for CBD stones based on the anamnesis, liver function tests, and ductal dilation on US. According to his conclusions, preoperative ERCP was not indicated for low-risk patients, while it must absolutely be performed in the high-risk group. As for the medium risk group, seemingly paradoxically, preoperative ERCP was only indicated, if the local endoscopist was mediocre. With an experienced endoscopist, preoperative intervention should be avoided, ERCP is to be performed only after the surgery, if the need arises.

Rieger *et al.*^[26] found CBD stones in 56 patients (53%) of the 106 ERCP performed in combination with 1140 LC. More than two-fold elevation in any liver function test, multiple abnormal laboratory tests, stones in the biliary tract on US, a more than 7 mm, dilated ductus choledochus were taken as positive predicting factors for preoperative ERCP. The multicenter study of Welbourn *et al.*^[32] in England also aimed to identify the exact indications of selective preoperative ERCP. The retrospective analysis of 306 preoperative ERC and 1396 LC showed that the predictive value of jaundice was 75%, that of pancreatitis 56%, while the predictive value of pathologic US or liver function tests was 48 %. In a prospective study of Sarli *et al.*^[3], 74 symptom-free, CBD stone patient data were evaluated. Positive US, biliary colic, elevated serum aminotransferase and alkaline phosphatase levels and the presence of multiple, smaller stones were associated with a higher risk, while acute cholecystitis and non-specific upper gastrointestinal complaints were associated with a lower risk. In our study jaundice, elevated LFTs and dilated choledochus or stones in the bile duct on US examination gave a similarly high positive predictive value in univariate analysis for bile duct stones.

In our opinion, the major shortcoming of the above studies is that they analyzed the effects of different predictive factors separately, which in accordance with our own findings, could easily result in misleading conclusions. Santucci *et al.*^[33] and Geron *et al.*^[7] came to the same conclusion, emphasizing the importance of the co-existence of several pathologic markers at the same time. Furthermore, the American Society for Gastrointestinal Endoscopy (ASGE) in its guideline^[29] favors the establishment of the aforementioned risk categories based on "simple clinical" data, such as clinical picture, laboratory findings and US. Interestingly, it recommends intraoperative (during the laparoscopic cholecystectomy) cholangiography to be performed even in low-risk/negative patients, followed by laparoscopic or endoscopic postoperative intervention, if required. In the medium-risk group endosonography or MRCP is recommended as the method of choice or, if these are not available, ERCP. According to the guideline, ERCP should be the first (therapeutic) intervention for high-risk patients.

In Hungary, ERCP is performed on a relatively high level and is generally available. Among the new imaging techniques, the availability of MRCP and endosonography is still limited. At the same time, due to financing reasons, ERCP turns out to be more cost-effective. The accessibility of intraoperative laparoscopic imaging techniques is also limited.

In summary, based on the literature and our own results, the following guideline can be established about the indications of preoperative ERCP.

The possibility of CBD stones should be considered after the evaluation of clinical, laboratory and US findings. Zero or one positive predictive factor indicates low risk, while the risk is high if three or more factors are present. Two positive

predictive factors suggest medium risk. In the low risk group preoperative ERCP is not recommended, LC is advisable without restrictions. In the high risk group the indication of preoperative ERCP is unambiguous. In the medium-risk population, preoperative ERCP is generally indicated. If available, MRCP can be a good alternative. In case of a highly qualified endoscopist, ERCP should be postponed until the surgery can be considered.

Abstract

AIM: To assess the possible effect of integrated traditional Chinese and Western medicine on severe acute respiratory syndromes.

METHODS: The current available randomized controlled trials of integrated traditional Chinese and Western medicine on SARS were identified through systematically searching literature in any languages or any types of publications. Additional studies of gray literature were also collected. The quality of studies was evaluated by two investigators independently based largely on the quality criteria specified CONSORT. Statistical analysis of the results was performed using RevMan 4.2.0 software developed by the Cochrane Collaboration.

RESULTS: Six studies ($n = 366$) fulfilling the inclusion criteria were found, of which the quality of one study was graded as B, the remaining five were graded as C. Two studies were performed with meta-analysis, the other four studies existed some heterogeneity for which meta-analysis could not be performed, a significant effect on lung infiltrate absorption was found in the treatment groups of these two studies [RR 6.68, 95% CI (2.93, 15.24), $P < 0.01$], there was no significant differences between the mortality [RR 0.86, 95% CI (0.22, 3.29), $P = 0.82$] and the average dosage of corticosteroid [WMD -39.65, 95% CI (-116.84, 37.54), $P = 0.31$]. The other three studies also showed significant differences in infiltrate absorption, including national drug No. 2. 3. 4 in combination with Western medicine [RR 5.45, 95% CI (1.54, 19.26)], compound formulas NO. 1 combined with Western medicine [WMD 0.24, 95% CI (0.02, 0.46)], compound formulas combined with Western medicine [RR 8.06, 95% CI (0.40, 163.21)]. Kangfeidian No.4 in combination with Western medicine had no significant effect on symptom improvement such as loss of dyspnea and cough [RR 1.50, 95%CI (0.41, 5.43)] and [RR 1.29, 95%CI (0.30, 5.43)].

CONCLUSION: Integrated traditional Chinese and Western medicines has some positive effects on lung infiltrate absorption in SARS patients, and is recommended as an adjunct treatment

for SARS. However, its effect on SARS requires further careful study due to limited available randomized control trials.

INTRODUCTION

Severe acute respiratory syndromes (SARS) is a readily transmissible new disease emerged in the 21st century that imposes a threat to international health^[1-3]. SARS is caused by a novel coronavirus, first identified in Hong Kong, United States of American and Germany. It is due to an infection with SARS associated coronavirus (SARS-CoV). The genome of SARS-CoV is 29 727 nucleotides in length and has 11 open reading frames, and its genome organization is similar to that of other coronaviruses^[4-7]. SARS is an acute respiratory illness with typical symptoms of fever, cough and difficult breathing. Besides, it may be associated with other symptoms, such as headache, muscular stiffness, myalgia, loss of appetite, malaise, chills, confusion, dizziness, rash, night sweat, nausea and diarrhea. SARS can be divided into 5 types and 4 stages. The 5 types are common type (typical type), mild type, severe type and more severe type. The four stages are potential stage (2-10 d), initial stage (1-7 d), developing stage (8-14 d), and recovery stage (1-14 d), which are classified based on the developing process of SARS patient conditions by the criteria of Western medicine. SARS can also be divided as initial stage (1-5 d), acute stage (3-10 d), critical stage (7-14 d) and recovery stage (10-18 d) based on the theory of traditional Chinese medicine^[8-11].

SARS demonstrates dramatically the global havoc that its epidemic had broken out worldwide including mainland China, Taiwan, Hong Kong, Vietnam, Singapore, Macao, North American and Europe when the first case was found in Foshan city, Guangdong Province, China on November 16, 2002. Airborne droplets from SARS patients are the main transmission routes. Based on the data from WHO. SARS epidemic appears to have peaked and is on the wane^[12,13]. A total of 916 SARS patients died in 8 422 cases and the mortality was about 11%. A total of 5 327 SARS patients occurred in mainland China and 349 of them died, the mortality was about 7%. A total of 1 755 SARS patients occurred in Hong Kong Special Administrative Region, China and 300 of them died, the mortality was about 17%. A total of 655 SARS patients occurred in Taiwan, China and 180 of them died, the mortality was 27%. The case fatality ratio was estimated to be less than 1% in persons aged 24 years or younger, 6% in persons aged 25 to 44 years, 15% in persons aged 45 to 64 years, and greater than 50% in persons aged 65 years and older^[14,15].

Western medicine for SARS

The treatment of SARS involves multiple disciplines, and current recommendations are mainly based on the methods of Western medicine including aliment therapy, respiratory

auxiliary ventilation, anti-infection and glucocorticoid therapy. The effectiveness for SARS was limited especially in the first and recovery stages. For example, in severe cases, corticosteroids and ribavirin (antiviral medication) were used, however there was no evidence to support their general or routine use at this stage and to confirm the risks and benefits of Western medicine in the treatment of SARS. Selective therapies included the use of antiviral agents, immunopotentiators and Chinese herbs^[8,9,11,15]

Chinese herbs in combination with western medicine for SARS

Traditional Chinese medicine (TCM) is a useful model for scientific therapies and has been practiced worldwide. Among the components of TCM, herbal agents possess complex biological activities. In the theory of TCM, herbs preparations might resolve toxin, eliminate pathological dampness, disperse the lung, invigorate the blood circulation and resolve the blood stasis, benefit Qi and nourish Yin^[16,17]. Based on this principle, Chinese practitioners suspected that SARS was caused by pestilential toxin, one of the important characteristics of SARS. Nine traditional Chinese patent medicines are optimized for controlling different symptoms of SARS. Compared with the simple treatment of Western medicine, Chinese medicine in combination with Western medicine for SARS may have better effects in that it may reduce the adverse events induced by anti-biotic and anti-virus treatments and other complications, shorten fever period and hospital stay, promote lung infiltrate absorption and decrease damage to the lung^[18-20]. The 5 kinds of herbs are Kangfeidian No.1,2,3^[29,34], compound formula No.1^[32], national drugs No.2,3,4^[31], compound herbs^[30], Kangfeidian No.4^[33]. Unfortunately, no strong evidence is available to demonstrate the benefits and risks of Chinese herbs in combination with Western medicine for SARS.

This review evaluated the possible effect of Chinese herbs in combination with Western medicine for SARS, summarized randomized controlled trials (RCT) and methods of integrated traditional Chinese and Western medicine for SARS, as well as a recommendation for future research.

MATERIALS AND METHODS

Data collection

A comprehensive searching strategy was used to identify all current relevant RCTs regardless of languages or types of publication (published, unpublished, in press, and in progress). We searched MEDLINE for relevant trials (1966 to 2003), EMBASE (1980 to 2003), CBM (Chinese Biomedical Database, 1981 to 2003), Chinese Cochrane Centre Controlled Trial Register (up to 2003), Cochrane Controlled Trial Register in Cochrane Library (issues 1 to 4, 2003), Current Controlled Trials and The National Research Register. The search terms were: "severe acute respiratory syndrome", "acute respiratory syndrome", "randomized-controlled-trial", "random allocation" "double blind method", "single blind method", "placebo", "herbs", "Chinese medicinal".

The references of relevant trials and reviews were identified and RCTs in the Database of Chinese Evidence-Based Medicine Center and in journals not included in this Database were manually searched. We also checked the citations of existing reviews and all studies identified by the above methods. The authors of identified literature and relevant specialists were contacted for additional information.

Types of studies and participants

Only randomized controlled trials of Chinese herbs in combination with Western medicine for SARS were included regardless of blinding, follow up, language or publication status. The followings were excluded such as clinical controlled trials of SARS patients that failed to allocate into either trial, control group, case study or animal experiments.

Only randomized controlled trials of Chinese herbs in combination with Western medicine for the diagnosis of SARS patients with standard criteria of WHO in 2003 were included. Moreover, those SARS patients complicated with other diseases such as diabetes, cardiovascular disease, hypertension, or cancers were also included. The suspected SARS patients and misdiagnosed patients were excluded.

Quality assessment

We screened the titles, abstracts, and keywords of every document retrieved to determine the quality of the papers. We retrieved the full articles for further assessment if the information given suggested that the study included diagnosed SARS patients; compared Chinese herbs in combination with Western medicine with placebo, Chinese herbs, Western medicine or any other active intervention; used random allocation to the comparison groups. Where differences in opinion existed, we would solve them through discussion. If we were unable to solve the disagreement through discussion, we would contact the authors for clarification.

The quality of each trial was assessed based largely on the quality criteria specified CONSORT^[21]. In particular, the following factors were assessed^[22,23] such as minimization of selection bias, minimization of performance bias, minimization of attrition bias, and minimization of detection bias. Based on these criteria, studies were subdivided into the following three categories^[23]: low risk of bias which met all quality criteria graded as A, moderate risk of bias which met one or more of the quality criteria graded as B, high risk of bias which did not meet one or more criteria graded as C.

Statistical analysis

Data were extracted independently by two investigators with a standardized form and analyzed using RevMan 4.2.0 software developed by the Cochrane Collaboration^[23,24]. Heterogeneity was tested using the *Z score* and the *Chi square*. Statistical significance was set at $P < 0.05$. We performed a meta-analysis for the data. The dichotomous data expressed as relative risk (RR). The continuous data expressed as weighted mean difference (WMD). We calculated the overall results based on the random effect model.

Hypothesis

When data were pooled, we hypothesized that all Western medicine interventions used in control and trial groups had the same effect on all the outcome measures indexed in this review.

RESULTS

Studies identified

The initial searching using the electronic search strategy listed above and manual searching yielded 650 studies. After scanned, 48 studies of Chinese herbs in combination with Western medicine for SARS were identified to meet the inclusion criteria. Most of the studies were published in Chinese. Of the 48 studies, one study of clinical report on the suspected SARS patients was excluded upon further scrutiny and the other 28 case reports and 9 case control studies were identified. There were 10 RCT studies identified. Because of some reasons, we did not obtain the complete report of studies. Further exclusion included one study identified as randomized sample, but not randomization allocation^[25], one study which compared Western medicine versus Western medicine for SARS^[26] and the other two studies which were duplicate publication^[27,28]. Finally, 6 RCT studies of Chinese herbs in combination with Western medicine fulfilling the inclusion criteria were identified^[29-34].

Six studies ($n = 366$) were included^[29-34]. The details of the designs of these studies are shown in Table 2. All six studies

were conducted in China. The median time of treatment was 17 d. Four studies reported the number of patients in common type and severe type^[29-31,34]; two studies performed a meta-analysis, the data were sufficient in quality, and similar^[29,34]. One study was Western medicine plus compound herbs^[32]; the other three studies were about Western medicine plus national drugs 2,3,4^[30-32] and Kangfeidian No.4^[33]. The constituents and dosage of Chinese herbs varied. Most of the studies with the heterogeneity of intervention prevented us from doing a meta-analysis and a meaningful subgroup analysis on Chinese herbs.

Study methodology

Most of the included studies had poor quality ('C')^[29-31,33,34] one study was graded as B^[32] (Table 1).

All of the studies claimed as randomization, but none of them described the method of randomization in details, and none of the studies referred allocation concealment. Of the six studies, one described its design in detailed randomization process and the baseline data were reported adequately^[32]. Two

studies were described as stratified randomization^[31,33] and the other three studies only mentioned 'randomization'^[29,30,34]. Withdrawals and loss of follow-up were not reported in six studies and none of the studies reported intention-to-treat analysis.

No adverse events of Chinese herbs were observed in the included studies. Only one study reported the quality of life as result index^[32]. The effect of integrated traditional Chinese medicine and Western medicine for SARS see Table 2.

Mortality

The mortality^[29-31,34] was reported in 4 studies.

National drugs No. 2. 3. 4 in combination with Western medicine did not show a significant difference on mortality compared to simple Western medicine (RR 0.41, 95% CI 0.04, 4.78).

Kangfeidian No. 1.2. 3 in combination with Western medicine was tested in two studies^[29,34] which used the same dosage and treatment time and had the same outcome. Compared to simple Western medicine, there was no significant effect on mortality [RR 0.86, 95% CI (0.22, 3.29), $P=0.82$, Table 3].

Table 1 Design of the RCTs of traditional Chinese medicine in combination with Western medicine for SARS

Study ID	Grade of method	Participants (case)				Trial interventions	Control interventions	Duration	Follow up	Main results
		Common type		Severe type						
Zhao CH 2003	C	51		26		Western medicine plus compound herbs of kangfeidian No.1,2,3.	Western medicine	14-21d	No	Mortality, lung infiltrate absorption, symptom improvement, dosage of glucocorticosteroids.
Wang BE 2003	C	Trial 13	Control 17	Trial 18	Control 12	Western medicine plus compound herbs.	Western medicine	10-20 d	No	Mortality, lung infiltrate absorption, Secondary infections, dosage of methypred nisolone, SO ₂ ,
Wang RB 2003	C	Trial 5	Control 7	Trial 30	Control 23	Western medicine plus national drug No.2,3,4.	Western medicine	14 d	No	Mortality, lung infiltrate absorption, Secondary infections, symptom improvement
Jiang ZY 2003	B	40				Western medicine plus compound herbs No.1,2,3.	Western medicine	21 d or so	Yes	Lung infiltrate absorption, symptom improvement, quality of life
Zhang SN 2003	C	63				Western medicine plus kangfeidian No.4	Western medicine	7 d	No	Dose of glucocorticoid, lung infiltrate absorption, symptom improvement
Zhang XM 2003	C	Trial 7	Control 9	Trial 24	Control 23	Western medicine plus compound herbs of kangfeidian No.1,2,3.	Western medicine	21 d	No	Mortality, lung infiltrate absorption, symptom improvement, dose of glucocorticoid, length of fever

Table 2 Results of meta-analysis of integrated traditional Chinese and Western medicine for SARS at the end of treatment

Comparison or outcomes	Study	Participants			Statistical method	Effect estimate
		Total	Trial	Control		
National drugs No.2.3.4 combined with Western medicine versus Western medicine

Lung infiltrate absorption

Six studies reported the effect of Chinese herbs in combination with Western medicine on the lung infiltrate absorption^[29,34]. Of the six studies, three reported that Chinese herbs in combination with Western medicine had a better effect than simple Western medicine^[29,31,34].

National drugs No. 2. 3. 4 in combination with Western medicine^[31] showed a significant difference in lung infiltrate absorption [RR 5.45, 95% CI (1.54, 19.26)]. Kangfeidian No. 1. 2. 3 in combination with Western medicine^[29,34] showed a better positive effect on lung infiltrate absorption [RR 6.68, 95% CI (2.93, 15.24), $P < 0.01$] (Table 3). In the original study^[34], $n = 31$ in treatment group, $n = 32$ in control group, 21 d after treatment with Kangfeidian No. 1. 2. 3 in combination with Western medicine, symptoms were improved by 87% in treatment group, and 56% in control group. In the original study, $n = 77$ ^[29], it was reported that the lung infiltrate absorption was less two days in treatment group. In treatment group $n = 22$, the basic absorption time (16 ± 8.8 d) and in control group $n = 6$, the basic absorption time (18.4 ± 8.2 d).

Compound formulas No 1. in combination with Western medicine^[32] showed no significant difference in lung infiltrate absorption between treatment group and control group [WMD 0.24, 95% CI (0.02, 0.46)]. Compound formulas in combination with Western medicine^[31] showed a positive effect on lung

infiltrate absorption [RR 8.06, 95% CI (0.40, 163.21)].

Dosage of glucocorticosteroids

Kangfeidian No. 1. 2. 3 in combination with Western medicine versus Western medicine^[29,34] for SARS showed no significant effect on the treatment group [WMD -39.65, 95% CI (-116.84, 37.54) $P = 0.31$] (Table 3).

Additional results

Kangfeidian No 4 combined with Western medicine versus Western medicine^[33] showed no significant effects on loss of dyspnea [RR 1.50, 95% CI (0.41, 5.43)] and loss of cough [RR 1.29, 95% CI (0.30, 5.43)] (Table 3).

DISCUSSION**Standard treatment and outcome index**

To assess accurately any potential benefits and risks in the treatment of SARS, treatment of Chinese herbs must be scientifically evaluated. Standard treatment and outcome index need to be developed, based on the principles used by the Chinese herb practitioners. For example, criteria for the dosage and components of compound herbs, duration of treatment, withdrawal and follow up, treatment protocols should be adjusted according to the conditions of patients^[35,36]. In the six

studies, none of them were standardized and one study described not any details on the dosage and components of compound herbs^[33]. Principal criteria for outcome index are another important issue to be taken into account, such as mortality, symptom improvement, lung infiltrate absorption, quality of life and adverse events. The six studies varied in outcome index.

Treatments to be tested should be selected and standardized so that potentially effective and important treatments are evaluated first. The best evidence should be systematically reviewed, summarized, and disseminated, which in turn would lead to evidence-based decision making in traditional Chinese medicine.

Long term studies

Most of the current studies had a short duration, ranging from 7 to 21 d and a small sample size. All studies did not report data on compliance and follow up. As a new kind of respiratory disease many unknown factors remain to be solved. SARS is likely to require a longer period of follow-up. Based on the current investigation, Chinese herbs may also be considered as an adjuvant treatment to improve the quality of life. Meanwhile, whether herbs have any toxic effects should also be considered and attention should be paid to their long-term adverse events. For example, adverse events should be monitored by a standardized effective reporting system in clinical trials and some severe adverse events should also be studied or observed by epidemiological studies.

Adequate randomization method

SARS is a sudden outbreak disease. It is somewhat difficulty for us to conduct RCT, particularly in acute or critical stage. The current six RCTs conducted suggest that it is a promising work. However, a well designed RCT requires a thorough understanding of randomization so that better research results could be achieved.

Randomization includes 3 important steps: namely sequence generation, allocation concealment and randomization implementation^[37]. Sequence generation is a method used to generate the random allocation sequence, including details of any restriction. Allocation concealment is to implement the random allocation sequence. Randomization implementation is to generate the allocation sequence. Well designed RCTs are required to evaluate Chinese herbs combined with Western medicine versus Western medicine.

Abstract

AIM: To determine the feasibility and safety of intraluminal brachytherapy in treatment of malignant obstructive jaundice (MOJ) and to evaluate the clinical effect of intraluminal brachytherapy on stent patency and patient survival.

METHODS: Thirty-four patients with MOJ were included in this study. Having biliary stent placed, all patients were classified into intraluminal brachytherapy group (group A, $n = 14$) and control group (group B, $n = 20$) according to their own choice. Intraluminal brachytherapy regimen included: HDR-¹⁹²Ir was used in the therapy, fractional doses of 4-7 Gy were given every 3-6 d for 3-4 times, and standard points were established at 0.5-1.0 cm. Some patients of both groups received transcatheter arterial chemoembolization (TACE) after stent placement.

RESULTS: In group A, the success rate of intraluminal brachytherapy was 98.0%, RTOG grade 1 acute radiation morbidity occurred in 3 patients, RTOG/EORTC grade 1 late radiation morbidity occurred in 1 patient. Mean stent patency of group A (12.6 mo) was significantly longer than that of group B (8.3 mo) ($P < 0.05$). There was no significant difference in the mean survival (9.4 mo vs 6.0 mo) between the two groups.

CONCLUSION: HDR-¹⁹²Ir intraluminal brachytherapy is a safe palliative therapy in treating MOJ, and it may prolong stent patency and has the potentiality of extending survival of patients with MOJ.

INTRODUCTION

Self-expanding metal stent, due to its minimal invasion, low risk of migration and efficient bile drainage, has been widely used for management of malignant obstructive jaundice (MOJ)^[1-11]. Although self-expanding metal stent seems to be the first choice in the palliation of MOJ, high rates of stent occlusion, which were mainly caused by tumor ingrowth or overgrowth, usually lead to jaundice recurrence^[12,13]. Therefore, treating underlying malignancy is critical to extend stent patency and patient

survival. Intraluminal brachytherapy is characterized by superiority in treatment of ductal or periductal tumor, thus preventing tumor from invading or compressing the duct. We designed a prospective study to evaluate the feasibility, safety of intraluminal brachytherapy in the treatment of MOJ and the clinical effect of intraluminal brachytherapy on stent patency and survival of patients.

MATERIALS AND METHODS

Study design

Patients were selected among those admitted to our department between November 2001 and September 2002 with the diagnosis of MOJ. Patients who had percutaneous transhepatic cholangiography and drainage (PTCD) followed by stent placement were included. Exclusion criteria were: (1) patients who were in end-stage MOJ; (2) serum total bilirubin concentration decreased to less than 100 $\mu\text{mol/L}$ or 50% of that before PTCD. After the nature of intraluminal brachytherapy was fully explained, patients were classified into two groups: group A with intraluminal brachytherapy and group B without intraluminal brachytherapy as control group, according to their own choice whether to receive the therapy. The study was performed with the approval of the institutional ethics committees. Written informed consent was obtained from all patients before treatment.

Methods of treatment

Venous blood samples were taken 1-3 d before PTCD for biochemical test. Intraluminal brachytherapy was routinely performed in group A within 1-3 wk after stent placement. Patients in group B did not receive the therapy. Some patients in both groups underwent transcatheter arterial chemoembolization (TACE).

Intraluminal brachytherapy: After stent placement, a 10 F external-internal drainage catheter or a 7 F long vascular sheath was placed, with its distal tip across the stricture. The applicator and sham source were placed through the drainage catheter or the sheath as a whole under fluoroscopic guidance. Irradiated volume was customized to extend 1 cm proximal and distal to the maximum length of the stricture as determined by cholangiography. Dwell positions were recorded, and therapy planning system (TPS) was connected to the remote afterloading microSelectron (Nucletron, Holland). After the sham source was manually removed, HDR-¹⁹²Ir (111-370 GBq) was driven by the remote afterloading system to the programmed locations (Figure 1). Fractional dose of 4-7 Gy was prescribed 0.5-1 cm from the source axis. The procedure was performed 3-4 times with an interval of 3-6 d. The drainage catheter or sheath was removed 1 wk later in case there were no complications related to the procedure.

Follow-up

The acute morbidity scoring criteria by Radiation Therapy Oncology Group (RTOG) and the late morbidity scoring criteria by Radiation Therapy Oncology Group/European Organization for Research and Treatment of Cancer (RTOG/EORTC) were used to evaluate the radiation toxicity^[14]. Follow-up of each patient was based on outpatient examinations, telephone interviews, and questionnaires.

Figure 1 HDR- ^{192}Ir (111-370 GBq) driven to the programmed locations. A: In the patient who had undergone left-lobe resection due to cholangiocarcinoma, hilar recurrence with bile duct dilation was shown by portal-phase CT scan (arrow). B: The stricture of bile duct was clearly shown by cholangiography during PTCd (arrow). C: An 8 mm×60 mm SMART stent was deployed across the stricture. D: The applicator and sham source were inserted through a 10 F internal-external drainage catheter. The dose distribution curves were obtained from the TPS (arrow).

Figure 2 Cholangiography, CT, or US before and after intraluminal brachytherapy. A: Bile duct dilation of left lobe caused by cholangiocarcinoma was shown by CT (arrow). B: Cholangiography showed hilar stricture (arrow). C: Intraluminal brachytherapy (fractional dose 7 Gy, total dose 21 Gy) was performed after an 8 mm×60 mm SMART stent insertion. D: CT follow-up 11 mo after intraluminal brachytherapy showed no progress of the tumor and no redilation of the bile duct (arrow).

In this study, stent patency period was defined as the interval between stent placement and obstructive jaundice recurrence. If occlusion did not occur during a patient's life time, the patency period was considered equal to the survival period but censored. Jaundice recurrence was defined as the symptom of jaundice recurred after it had subsided and met one of the followings: (1) cholangiography, CT or US demonstrated redilation of bile duct, (2) combined serum bilirubin concentration/total serum bilirubin concentration $\geq 35\%$ (Figure 2).

Statistical analysis

Comparisons between the two groups were performed with paired-samples *t* tests for metric data and χ^2 tests for frequencies. Stent patency and survival were evaluated according to the Kaplan-Meier method and compared with the log rank test. For all tests, a *P* value less than 0.05 was considered statistically significant.

RESULTS

Baseline data of patients

A total of 34 patients were enrolled in this study (18 male and 16 female; age range, 41-87 years; mean age, 62.0 years). Thirty-seven SMART stents (Cordis. Johnson & Johnson. USA) were placed and 28 TACE procedures were performed in these patients, 14 patients underwent intraluminal brachytherapy. In group A (*n* = 14), the causes of obstruction were cholangiocarcinoma (*n* = 7), gallbladder carcinoma (*n* = 2) and metastatic lymphadenopathy (*n* = 5, from stomach, colorectum or breast). In group B (*n* = 20), the causes of obstruction were cholangiocarcinoma (*n* = 9), gallbladder carcinoma (*n* = 2) and metastatic lymphadenopathy (*n* = 9, from stomach, colorectum or breast). The diagnosis was based on clinical, radiological findings or

histology. There were no differences between the two groups according to gender, mean age, preoperative serum bilirubin, alanine aminotransferase, alkaline phosphatase, albumin, hemoglobin concentration, obstructive duration, obstructive level, and times of TACE performed (Table 1).

Table 1 Baseline clinical characteristics of patients

Factor	Group A (<i>n</i> = 14)	Group B (<i>n</i> = 20)	<i>P</i>
Mean age (yr)	57.9±9.2	63.3±11.4	0.356
Gender			
Male	8	10	0.681
Female	6	10	
Mean total serum bilirubin concentration (μmol/L)	318±94	314±115	0.913
Mean alanine aminotransferase concentration (U/L)	71±52	106±107	0.261
Mean albumin concentration (g/L)	33.6±4.3	33.5±3.4	0.914
Mean alkaline phosphatase (U/L)	443±334	543±400	0.449
Mean hemoglobin concentration (g/L)	111±12	105±16	0.275
Mean obstructive duration (wk)	3.7±0.9	4.0±1.4	0.512

Performed	9	10	0.409
Not performed	5	10	

Intraluminal brachytherapy

A total of 52 procedures were programmed and 51 procedures were successfully performed, achieving the technical success rate of 98.0%. In 1 patient, a drainage catheter kink, which was caused by an acute angle on the drainage passage, resulted in the failure of driving HDR-¹⁹²Ir to scheduled position in the third procedure. The total dose of these 14 patients was 14-21 Gy. One patient developed nausea, one complained of abdominal upset, one developed diarrhea. One patient, who had undergone bilobectomy 4 mo before stent placement, developed hemobilia for a period of 4 d (Figure 3). The bleeding stopped soon after hemostatic was prescribed without transfusions. According to RTOG acute morbidity scoring criteria, 3 patients were classified into RTOG grade 1 acute morbidity, the others RTOG grade 0 acute morbidity. According to RTOG/EORTC late morbidity scoring criteria, 1 patient was classified into RTOG/EORTC grade 1 late morbidity, the others grade 0 late morbidity.

Figure 3 One patient undergoing bilenterostomy and ostomy, which was shown in irradiation region in intraluminal brachytherapy. A: Cholangiography indicated that jejunum was invaded by the malignancy (arrow). B: Jejunum and ostomy were in the irradiation region.

Stent patency and patient survival

The median follow-up time was 6.0 mo (range, 1-17 mo). In group B, 1 patient died 1 mo after stent placement of uncontrolled bleeding caused by tumor rupture, another one died 5 mo after stent placement due to cerebrovascular accident. The mean stent patency was 12.6 mo (median, 10.0 mo) with stent occlusion of 21.4% (3 of 14 patients) in group A, whereas the mean stent patency was 8.3 mo (median, 6.0 mo) with stent occlusion of 45.0% (9 of 20 patients) in group B. The stent patency of group A was significantly longer than that of group B ($P < 0.05$, Figure 4). The mean survival was 9.6 mo (median 7.0 mo) in group A and 6.4 mo (median 6.0 mo) in group B, showing no significant difference.

Figure 4 Stent patency of the two groups.

DISCUSSION

As a part of brachytherapies, intraluminal brachytherapy is defined as performing brachytherapy by inserting an applicator and radioactive source into a lumen (or cavity) such as

nasopharyngeal cavity, uterine cavity, esophagus, rectum and bile duct^[15]. The properties of this radiotherapeutic technique include^[16]: (1) Small source size enables itself to be very close to or contact with the target tissue. (2) The effective therapeutic range is 0.5-2.0 cm, which has little effect on normal tissue. (3) The absorbed dose is in inverse proportion to the square of the distance from radioactive source. With its irradiation extent confined to ductal wall and tissue adjacent to duct, intraluminal brachytherapy is a proper therapy for malignancy arising from a duct or adjacent to a duct. Because the absorbed dose falls off rapidly with increasing distance from the sources, intraluminal brachytherapy can deal with the malignancy without significantly affecting the adjacent normal tissues. To date, intraluminal brachytherapy not only has been the major therapeutics in treating the carcinoma of nasopharyngeal, uterine cervix, vagina, and endometrium^[17-20], but complementary to the treatment of carcinoma of esophagus, lung, and rectum^[21-23].

A number of isotopes were available for brachytherapy, including ²²⁶Ra, ⁶⁰Co, ¹³⁷Cs, ¹⁹²Ir and ⁹⁰Sr. With advantages of highly specific activity, relatively short half-life, easy to be shielded, and technical flexibility, ¹⁹²Ir is the most widely used brachytherapy source in clinical practice^[24]. According to the dose delivered per hour, brachytherapy can be classified into low dose rate (LDR, 0.4-2 Gy/h), median dose rate (MDR, 2-12 Gy/h) and high dose rate (HDR, >12 Gy/h). Among them, LDR and HDR are more frequently used. By comparison with LDR, HDR represents a technologic advance that offers the following advantages^[25]: (1) Improved physical dose delivery due to the short treatment time and negligible organ motion. (2) Improved radiation safety and protection with decreased exposure to personnel. (3) Reduced possibility of human error through computerized remote afterloading. (4) Increased efficiency because more patients can be treated with HDR per unit time. Additionally, while treating patients with MOJ by LDR, the applicator and radioactive source must be kept in the drainage catheter for several hours to several days, which may influence bile drainage and increase the risk of infection. The course of HDR therapy only needs several minutes, thus having no effect on bile drainage^[26]. For all the reasons mentioned above, we used HDR-¹⁹²Ir as the radioactive source in our study.

Intraluminal brachytherapy takes use of the drainage passage established during PTCD, making the procedure uncomplicated and inducing less damage. We only failed to complete the therapy in 1 patient in his third procedure. In this case we found an acute angle on the drainage passage. The narrow applicator lumen caused by the kink on the drainage catheter resulted in failure in radioactive source transmission. In patients who are scheduled to receive intraluminal brachytherapy, an acute angle should be avoided on the drainage passage during PTCD. Dose distribution of intraluminal brachytherapy is characterized by "inverse-square law" as we discussed before. In our study it was technically impossible to use instrument such as balloon-catheter to centralize the radioactive source in the bile duct, that is to say, the radioactive source usually located eccentrically in the lumen. The absorbed dose of bile duct wall close to the radioactive source is too high to be calculated by the "inverse-square law". Brambs^[27] investigated the bile duct tolerance in intraluminal brachytherapy in a swine model, and demonstrated that fractional dose of 7.5 Gy only caused slight fibrosis in the bile duct. Because the radiation damage in human is similar to that in swine, fractional dose of 7.5 Gy is deemed to be safe in clinical practice. As to other structures adjacent to bile duct such as hepatic artery, portal vein, duodenum, and pancreas, the distance between radioactive source and those structures makes the "inverse-square law" calculation possible. A tumor causing obstructive jaundice is thought to be at the advanced stage of the disease, the aim of the therapy is palliation rather than cure. Palliative

radiation therapy generally follows the regimen^[28]: the total dose of 20-30 Gy and the fractional dose of 5-10 Gy, with an intention to alleviate pain, maintain patency, stop bleeding, and reduce morbidity. In consideration of the poor clinical status of patients due to hyperbilirubinemia in our study, we prescribed fractional dose of 4-7 Gy with a total dose of 14-21 Gy, which was certainly tolerable. In this study, only 3 patients developed RTOG grade 1 acute morbidity, and 1 patient developed RTOG/EORTC grade 1 morbidity. One patient developed hemobilia for a period of 4 d without the need for transfusions. This patient had undergone bilenterostomy and the ostomy, which was shown to be invaded by the malignancy, was in irradiation region in intraluminal brachytherapy. One of the reasons for hemobilia is tumor necrosis. On condition that block of tumor tissue necroses before the supplying arteriole could occlude, tumor bleeding will occur. The other one is ostomy hemorrhage. Jejunum and ostomy are dose-limiting tissues susceptible to irradiation.

MOJ is usually caused by cholangiocarcinoma, gallbladder carcinoma, metastatic lymphadenopathy (from stomach, colorectum, or breast), and pancreatic carcinoma. TACE has limited effect on these malignancies in most cases because of their character of relative avascularity^[29]. Cholangiocarcinoma, gallbladder carcinoma, and pancreatic carcinoma have the tendency of invading bile duct, so the rate of stent occlusion due to tumor ingrowth or overgrowth is inevitably high^[30-32]. There is an increasing demand for efficient therapy to palliate these malignancies, so to prolong stent patency and patient survival. External-beam irradiation has been used to treat abdominal tumors for nearly a hundred years. Major deterrents to improved results with MOJ are the limited tolerance of the structures (liver, duodenum, stomach, and kidney) around the lesion, lack of clear definition of the lesion's location, poor clinical status of the patients, and respiration interfering with the irradiation field^[33]. Fortunately, intraluminal brachytherapy, with special dosimetric characteristics and accurate location, overcome all the above shortcomings. Intraluminal brachytherapy in MOJ can efficiently palliate the underlying malignancies with fewer morbidities. Dvorak^[34,35] and cooperators reported their experiences of HDR-¹⁹²Ir intraluminal brachytherapy in treatment of 2 groups of patients with MOJ after bile drainage. The causes of MOJ were cholangiocarcinoma and gallbladder carcinoma in one group, cholangiocarcinoma and pancreas carcinoma in the other. The mean survival of both groups was 9 mo. After stent placement and subsequent jaundice subsidence, the underlying malignancy could be controlled by intraluminal brachytherapy, and invasion and compression of the bile duct avoided. Bruha *et al.*^[36] reported that patients with MOJ treated with intraluminal brachytherapy using HDR-¹⁹²Ir, the mean stent patency in patients with cholangiocarcinoma and gallbladder carcinoma were 418 and 220 d, respectively. The result of our study showed that the mean stent patency of intraluminal brachytherapy group (12.6 mo) was significantly longer than the control group (8.3 mo). We attribute the effect on prolonging stent patency to the followings: (1) Prohibit tumor from growing through the mesh of the stent (ingrowth) (2) Prohibit tumor from growing over the edge of the stent (overgrowth) (3) In cases with hilar obstruction, intraluminal brachytherapy in ipsilateral duct can prevent tumor tissue from invading contralateral duct. Although not statistically significant, it appeared that the mean survival in group A (9.6 mo) was longer than in group B (6.4 mo). We speculated that the advantage of intraluminal brachytherapy in extending survival be more prominent on condition that the cases were expanded or the follow-up was prolonged.

In conclusion, because the special dosimetric characteristics of HDR-¹⁹²Ir and the high dose tolerance of bile duct, HDR-¹⁹²Ir intraluminal brachytherapy is a safe and feasible method in the

treatment of MOJ. HDR-¹⁹²Ir intraluminal brachytherapy may prolong stent patency and has the potentiality of extending survival of patients with MOJ.

Abstract

AIM: To clone and sequence the *cagA* gene fragment of *Helicobacter pylori* (*H. pylori*) with coccoid form.

METHODS: *H. pylori* strain NCTC11637 were transformed to coccoid form by exposure to antibiotics in subinhibitory concentrations. The coccoid *H. pylori* was collected. *cagA* gene of the coccoid *H. pylori* strain was amplified by PCR. After purified, the target fragment was cloned into plasmid pMD-18T. The recombinant plasmid pMD-18T-*cagA* was transformed into *E. coli* JM109. Positive clones were screened and identified by PCR and digestion with restriction endonucleases. The sequence of inserted fragment was then analysed.

RESULTS: *cagA* gene of 3 444 bp was obtained from the coccoid *H. pylori* genome DNA. The recombinant plasmid pMD-18T-*cagA* was constructed, then it was digested by *Bam*H I + *Sac* I, and the product of digestion was identical with the predicted one. Sequence analysis showed that the homology of coccoid and the reported original sequence *H. pylori* was 99.7%.

CONCLUSION: The recombinant plasmid containing *cagA* gene from coccoid *H. pylori* has been constructed successfully. The coccoid *H. pylori* contain completed *cagA* gene, which may be related to pathogenicity of them.

INTRODUCTION

Helicobacter pylori (*H. pylori*) is one of the common bacteria causing chronic infection, which infects more than 50% of the human population, causes chronic gastritis and plays an important role in the pathogenesis of gastroduodenal ulceration. *H. pylori* has also been suggested to be involved in the genesis of adenocarcinoma and MALT lymphoma of the stomach.^[1-5] *H. pylori* cells growing actively *in vitro* are curved rods, which evolve into metabolically active but nonculturable coccoid cells after prolonged incubation^[6-8]. In the stomach mostly spiral-shaped bacteria are found, but coccoid cells have been observed

in the more severely damaged regions of the gastric mucosa^[9,10]. Many scholars believed that coccoid *H. pylori* might lead to difficult recovery, easy relapse and epidemical transmission^[11]. But the pathogenicity of coccoid *H. pylori* is unclear at present. The cytotoxin-associated protein encoded by *cagA* (cytotoxin-associated gene A) is important virulence determined by *H. pylori*. *cagA*⁺ *H. pylori* strains have been linked to more severe gastric inflammation, peptic ulcer disease, and gastric cancer in adults^[12-15]. *CagA* gene is a mono-replicon and locates 3' region of *cag*-PAI (*cag* pathogenicity island), whose length varies from 3 400 bp to 4 000 bp. In order to probe into possible pathogenesis of coccoid *H. pylori*, the recombinant plasmid encoding *cagA* gene of coccoid *H. pylori* was constructed and detected for the sequence in this study.

MATERIALS AND METHODS

Materials

The strain NCTC11637 of *H. pylori* was afforded by Chinese center for disease control and prevention. JM109 *E. coli* strains were preserved by our laboratory, pMD-18T (T-Vector), restriction endonuclease enzymes (*Bam*H I, *Sac* I), T₄ DNA ligase, LA Taq DNA polymerase, DNA Extraction Kit and DNA purification reagent kit were provided by TaKaRa Company.

Bacterial culture and induction of coccoid forms *H. pylori* strains were grown on Columbia agar with 50 mL frozen-melting sheep blood, 100 mL/L fetal bovine serum, and Skirrow's antibiotic supplement in a microaerophilic atmosphere for 3 d at 37 °C, then the bacteria were suspended in brucella broth and supplemented with 0.02 mg/L of amphotericin, still were incubated at 37 °C for 3, 5, 7, and 10 d. Bacterial morphology was determined by light microscopy after Gram staining. The coccoid forms were collected and stored at -20 °C.

Extraction of genomic DNA *H. pylori* of coccoid form were added to a 1.5 mL microcentrifuge tube, rinsed once with phosphate-buffered saline (PH 7.2), and pelleted by centrifugation at 11 000 g. Genomic DNA was extracted by TaKaRa MiniBEST Bacterial Genomic DNA Extraction Kit, the DNA pellet was suspended in TE (10 mmol/L Tris-HCL, 1 mmol/L PH 8.0 EDTA), and stored at -20 °C.

Synthetic primers A single primer pair was used to amplify coccoid *H. pylori* *cagA* gene based on GenBank. The primers had a *Bam*H I site incorporated into the 5' end and a *Sac* I site at the 3' end and their sequences as follows (5'-3'): AAGGATCC ACTAACGAAACCATTGACCA (forward) and AAGAGCTCA GATTTTTTGGAACACCTT (reverse). The 5' region initiator and 3' end stop codon were banned.

PCR amplification PCR was performed in a 100 µL reaction mixture in 0.6-mL tube in an automatic thermal cycler (TP3000; TaKaRa BIO INC). The PCR mixture contained 10 µL of 10×PCR buffer, 1 µL of sample DNA, 10 µL of 2.5 mmol/L deoxynucleoside triphosphate, 4 µL of 10 µmol/L oligonucleotide primers, 0.5 µL of LA Taq polymerase, 74.5 µL of molecular-biology-grade distilled water. The mixtures were incubated for 1 min at 94 °C for initial denaturation of the target DNA and then subjected to 30 cycles of denaturation at 98 °C for 10 s, annealing at 55 °C for 30 s, and extension at 72 °C for 210 s. The amplified products (5 µL) were analyzed by electrophoresis on 10 g/L agarose gel

containing 0.1 µg of ethidium bromide per ml in TBE buffer. The PCR product was visualized under UV light and photographed. **Construction of recombinant plasmids** The PCR product was purified by TaKaRa PCR Fragment Recovery Kit. The purified product was cloned into the compatible sites of the T-vector pMD-18T by using T₄ DNA ligase at a molar ratio of 6:1 at 16 °C for 3 h. After the above product was transformed into *E. coli* JM109, pMD-18T/cagA was selected and identified by PCR and enzyme digestion.

Extraction of recombinant plasmid The single bacterial colony (JM109/pMD-18T/cagA) was picked, and cultivated in 3 mL LB broth containing 100 mg/L of ampicillin, at 300 r/min at 37 °C overnight, then recombinant plasmids were extracted according to manufacturer's instructions (TaKaRa MiniBest DNA Purification Kit), in the meantime, identified by PCR and restriction endonuclease enzyme digestion.

Sequence determination and homology analysis The sequence determination of cagA gene of recombinant plasmid was carried out by Takara Company, in the meantime, the sequence of gene and amino acid were analyzed by software sequence 3.0, and compared the homology based on the GenBank.

RESULTS

PCR amplification of coccoid *H. pylori* cagA gene

H. pylori with coccoid form cagA was amplified by PCR from the above primers and The PCR product was electrophoresed and visualized by 10 g/L agarose gel (Figure 1). It revealed that the size of cagA DNA fragment amplified by PCR was 3 444 bp, and was compatible with the expectant size.

Figure 1 10 g/L agarose gel electrophoresis of cagA DNA fragment amplified by PCR from coccoid *H. pylori*. Lane 1. PCR products, Lane M: λ-Hind III DNA marker.

Identification of recombinant vector by PCR

The plasmid was extracted from recombinant bacteria and conducted as template to amplify by PCR under the condition mentioned above. The PCR products were visualized by 10 g/L agarose gel electrophoresis (Figure 2). It indicated that recombinant plasmid contained the objective gene. At the same time, it was successful in transforming recombinant plasmid into JM109 *E. coli*.

pMD-18T/cagA identification by restriction enzyme digestion

Recombinant plasmid pMD-18T/cagA was digested by bi-

enzyme digestion with *Bam*H I and *Sac* I, then digestive product was visualized on 10 g/L agarose gel (Figure 3). It demonstrated that recombinant plasmid was digested to 3 444 bp and 2 692 bp DNA fragment, which contained the objective gene.

Sequence analysis of cloned cagA gene of coccoid

H. pylori Sequence of inserted DNA was analyzed with BcaBEST Primer M13-47/BcaBEST Primer RV-M using automatic sequence analyzer by Sanger dideoxy chain termination method. The result of analysis showed that the size of inserted DNA was about 3 444 bp and 99.7% affinity in comparison with DNA sequence published on GenBank (locus: AB015416). The sequence of partial vacA gene was showed in Figure 4.

DISCUSSION

Morphological conversion from spiral *H. pylori* to coccoid forms has been described under several suboptimal conditions. These conditions include aerobiosis, alkaline pH, high temperature, extended incubation, or treatment with proton pump inhibitor or antibiotics^[16-18]. This coccoid form conversion phenomenon, which has been thought to result in a viable but nonculturable form of the bacterium, is not exclusive to *H. pylori*, as it is common for other enteric pathogens. Controversy remains about the pathogenicity of coccoid *H. pylori*. Many investigators have suggested that the coccoid form of *H. pylori* represents a degenerative form with no infectious capability, but others believed that the coccoid form retains a weak metabolic activity, important structural components, and pathogenicity^[19-21]. Recently, successful infection with coccoid forms of *H. pylori* in animal models has been reported^[22-24]. These findings have highlighted the possible role of the coccoid forms in transmission of infection and morphological conversion of coccoids to the spiral form. It is well known that cagA is an important virulence factor of *H. pylori* and related to severe gastrointestinal diseases. However, the research of cagA gene of coccoid *H. pylori* is few at present. In order to observe cagA and vacA expression

during conversion to the coccoid form, Sisto *et al.*^[25] analyzed the expression of ureA, cagA, vacA genes after prolonged incubation in a liquid medium in 2000, the results showed that although the coccoid forms had decreased DNA and RNA levels after 31 d, they were not degraded and still expressed the urease, cytotoxic island and vacuolating toxin genes. So in conclusion, coccoid forms are therefore viable and may act as a transmissible agent that plays a crucial role in disease relapses after antibiotic therapy. She *et al.* explored the virulence and the potential pathogenicity of coccoid *H. pylori* transformed from spiral form by exposure to antibiotic in 2001, and found that the content of the protein with the molecular weight over M_r 74 000 decreased, but vacA, cagA, urea, ureB, hpaA gene remained to be preserved, so they concluded that the virulence and the proteins with molecular weight over M_r 74 000 in coccoid *H. pylori* decrease, but no deletion exists in amplification fragments from ureA, ureB, hpaA, vacA and cagA genes, and suggested that coccoid *H. pylori* may have potential pathogenicity. Furthermore, Monstein *et al.*^[26] confirmed that the transcription and translation of cagA and vacA gene might actively take place in coccoid *H. pylori* cells.

In order to research the cagA gene existence, and explore the possible mechanism of pathogenicity in coccoid *H. pylori*, we designed the specific primers based on cagA gene sequence reported in GenBank, and successfully amplified the cagA gene of coccoid *H. pylori* by PCR, then inserted into pMD-18T vector. The recombinant plasmids were successfully identified containing cagA gene fragment by PCR and enzyme digestion, and sequence determination confirmed that cagA gene existed in coccoid *H. pylori*, though existence of 0.3% difference with the reported sequence in GenBank. The reason for the discrepancy might be as follows: (1) the mutant base could come from the process of PCR amplification and sequencing, (2) *H. pylori* provided have the transformation ability, which could lead to *H. pylori* variation and genome reset. Our results also support the assumption that virulence-gene expression is differently regulated among *H. pylori* strains^[26].

In this study, the NCTC11637 strain with amphotericin for 3 d generated a high proportion of coccoid forms. Forms obtained after removal of bacterial clumps and amorphous debris by centrifugation at 600 r/min for 5 min were nearly 100% coccoid. Due to similar to the condition *in vivo* by antibiotic induction, the collected coccoid *H. pylori* still remained complete cellular structure, and their genome DNA lost was less, so some important virulent gene, such as vacA, cagA and so on, could exist in their cells. Once coccoid *H. pylori* live in suitable condition, they can recover their virulence and lead to the occurrence of diseases. Or coccoid *H. pylori* may revert helical form, and result in the transmission and/or relapse of diseases with the complete cagA gene.

Abstract

AIM: To set up a real-time fluorescent quantitative reverse transcription-polymerase chain reaction (RT-PCR) assay, to detect human telomerase reverse transcriptase (hTERT) messenger RNA in gastric carcinomas, and to evaluate quantitative determination of hTERT mRNA in the diagnostic value of gastric carcinomas, and to analyze the correlation between the expression level of hTERT mRNA and clinicopathological parameters in patients with gastric cancer.

METHODS: A real-time quantitative RT-PCR (RQ-PCR) based on TaqMan fluorescence methodology and the LightCycler system was used to quantify the full range of hTERT mRNA copy numbers in 35 samples of gastric carcinomas and corresponding adjacent non-cancerous tissues. The normalized hTERT (NhTERT) was standardized by quantifying the number of GAPDH transcripts as internal control and expressed as 100× (hTERT/GAPDH) ratio. Variables were analyzed by the Student's *t*-test, χ^2 test and Fisher's exact test.

RESULTS: NhTERT from gastric carcinomas and corresponding adjacent non-cancerous tissues was 6.27 ± 0.89 and 0.93 ± 0.18 , respectively ($t = 12.76$, $P < 0.001$). There was no significant association between gastric cancer hTERT mRNA expression level and patient's age, gender, tumor size, location and stage (p -TNM), but a significant correlation was found between hTERT mRNA expression level in gastric carcinomas and the degree of differentiation.

CONCLUSION: Quantitative determination of hTERT mRNA by RQ-PCR is a rapid and sensitive method. hTERT might be a potential biomarker for the early detection of gastric cancer.

INTRODUCTION

Telomerase is a reverse transcriptase that adds telomeric repeats to chromosomal ends to compensate for sequence loss during

DNA replication. Telomerase activity has been detected in about 85% of human cancer samples and is associated with cell immortalization and the acquisition of malignancy, but most normal tissues have low or no telomerase activity^[1]. Telomerase is one of the most widespread tumor markers at present. To date, the main assay to detect telomerase activity is telomere repeat amplification protocol (TRAP). TRAP is a qualitative or semi-quantitative assay, and can not accurately exhibit telomerase expression level, and needs functional ribonucleoproteins, including both reverse transcriptase activity and undegraded RNA. The presence of telomerase inhibitors, Taq polymerase inhibitors, proteases, or RNases in tissue extract may influence its detection and subsequently lower its sensitivity. With the cloning of both genes coding for human telomerase RNA (hTR) and human telomerase reverse transcriptase (hTERT), hTERT becomes the catalytic subunit of telomerase and is a rate-limiting determinant of the enzymatic activity of human telomerase, and only the expression of hTERT is closely associated with telomerase activity^[2-5], whereas the expression of hTR is widespread. The close relationship between hTERT mRNA expression and telomerase activity suggests that quantification of the mRNA expression of the hTERT gene could be used as an alternative to measure telomerase activity. In this study, we used real-time quantitative reverse transcription-polymerase chain reaction (RQ-PCR) to detect and quantify hTERT mRNA in samples of gastric carcinoma and corresponding non-cancerous tissues, and to evaluate the quantitative determination of hTERT mRNA in the diagnostic value of gastric carcinomas, and to analyze the correlation between the expression level of hTERT mRNA and clinicopathological parameters in patients with gastric cancer.

MATERIALS AND METHODS

Patients and samples

We analyzed tissues (gastric cancer and corresponding non-cancerous tissues) from surgically removed primary gastric cancer in Union Hospital and Tongji Hospital of Tongji Medical College of Huazhong University of Science and Technology from October 2002 to May 2003. All patients (25 males and 10 females, mean age 55.2 years, range 34-73 years) were at initial presentation and had no radiotherapy or chemotherapy history before surgery. All samples were examined histopathologically to confirm the diagnosis. Control tissues were the corresponding non-cancerous mucosa from the stomach of cancer patients, and excised beyond 5 cm from neoplastic lesions. Samples were stored at -80 °C until further analysis.

Reagents and instruments

TRIzol was the product of Omega. The reagents used for reverse transcription were purchased from Promega. The reagents used for PCR and PCR product purification, glyceraldehydes 3-phosphate dehydrogenase (GAPDH) quantification, and the primers and TaqMan probe of hTERT were all purchased from Shanghai Shenyong Company. Both T4 DNA ligase and PMD18-T vector were the products of TaKaRa. The other chemical reagents used in this study were ACS reagents of China. The fluorescent quantitative PCR instrumentation was the LightCycler system of Roche.

Real-time quantitative RT-PCR

We used a RQ-PCR assay based on TaqMan fluorescence methodology to quantify the full range of hTERT mRNA copy numbers^[6,7]. This method used a dual-labeled nonextendable oligonucleotide hydrolysis (TaqMan) probe in addition to the two amplification primers. The probe contained 6-carboxy-fluorescein (FAM) as a fluorescent reporter dye, and 6-carboxytetramethyl-rhodamine (TAMRA) as a quencher for its light emission spectrum. During the extension phase of PCR, the probe hybridized to the target sequence and was then cleaved due to the 5' to 3' exonuclease activity of *Taq* polymerase. The increase in the fluorescence signal of the reporter was proportional to the amount of specific PCR products, providing highly accurate and reproducible quantification. The number of PCR cycles to reach the fluorescence threshold was the cycle threshold (Ct). The Ct value for each sample was proportional to the log of the initial amount of input cDNA. By plotting the Ct value of an unknown sample on the standard curve, the amount of target sequences in the sample could be calculated.

To normalize the hTERT mRNA expression for sample-to-sample differences in RNA input, RNA quality, and reverse transcriptase efficiency, we amplified the housekeeping gene GAPDH. According to each standard curve, we got the copy numbers of GAPDH and hTERT, respectively. The ratio between copy numbers of hTERT and GAPDH represented the normalized hTERT (NhTERT) for each sample and could be compared with that of other samples^[8].

$$\text{NhTERT} = (\text{hTERT mRNA copies}_{\text{sample}} / \text{GAPDH mRNA copies}_{\text{sample}}) \times 100.$$

Primers and probes

According to GAPDH quantification reagents and the reference^[9], the nucleotide sequences of oligonucleotide TaqMan probes and primers are shown in Table 1.

RNA extraction and cDNA synthesis

According to the manufacturer's instructions, total RNA from frozen tumor and corresponding non-cancerous tissue specimens was isolated by disruption of 50–100 mg tissues in 1 mL of TRIzol. RNA was quantified spectrophotometrically, and its quality was determined by agarose gel electrophoresis and ethidium bromide staining. Only samples that were not degraded and showed clear 18 S and 28 S bands under ultraviolet light were used for real-time RT-PCR.

All samples were denatured for 10 min at 60 °C to melt secondary structure with the template and cooled immediately on ice for 5 min to prevent secondary structure from reforming. Total RNA (1–2 µg) was reverse transcribed in a total volume of 25 µL containing 1×RT buffer (Promega), 200 U of Moloney murine leukemia virus Reverse Transcriptase (M-MLV RT) (Promega), 20 U of RNasin (Promega), 0.2 µg random primer (Promega) and 1 mmol/L deoxynucleotides. The reaction was performed for

10 min at 25 °C, for 60 min at 42 °C and for 10 min at 70 °C. cDNA was stored at -20 °C until use.

Construction of recombinant plasmid calibrator

Pure hTERT fragments from classical RT-PCR were joined to PMD18-T vector by T4 DNA ligase, resulting in recombinant plasmid PMD18-hTERT. The recombinant plasmids were confirmed in including hTERT target fragments by sequencing, and extracted and purified. The recombinant plasmid DNAs at 10⁷ copies/mL were stored at -20 °C until use. GAPDH standard template was from the GAPDH quantification reagents.

LightCycler real-time PCR amplification

All PCR reactions were performed using the LightCycler System (Roche Diagnostics, Switzerland) in a total volume of 20 µL containing 1×*Taq* polymerase buffer, 4 mmol/L MgCl₂, 200 µmol/L deoxynucleotides, 300 nmol/L each primer, 150 nmol/L probe, 1 U *Taq* polymerase and 20 ng cDNA. Water instead of cDNA template was used for the negative controls. Both GAPDH and hTERT amplification were done in duplicate for each sample. The thermal cycling conditions were 5 min at 94 °C, followed by 40 cycles, each at 94 °C for 15 s and at 60 °C for 1 min for GAPDH or at 65 °C for 1 min for hTERT (two-step PCR). The number of GAPDH and hTERT transcripts in samples was calculated with the LightCycler software, using these standard curves.

Statistical analysis

Data were expressed as mean±SD. The Student *t*-test, χ^2 test and Fisher's exact test were used in this study. *P*<0.05 was considered statistically significant.

RESULTS

Standard curve construction

We used different concentrations of GAPDH and hTERT standard templates including 10⁴, 10⁵, 10⁶ and 10⁷ copies/mL to perform quantitative PCR and calculate the standard curves, respectively. The standard curves were: Ct_{GAPDH} = -3.86 log (GAPDH copies) +46.60; and Ct_{hTERT} = -3.42 log (hTERT copies) +37.31. The correlation coefficients were both -1.00 (Figure 1A, B).

hTERT mRNA expression levels in gastric cancer and corresponding adjacent non-cancerous tissues

The expression of hTERT mRNA in gastric carcinomas was analyzed by a highly sensitive RQ-PCR assay. hTERT mRNA expression was detectable not only in all 35 gastric carcinomas, but also in the corresponding non-cancerous gastric tissues (Figure 2). For each experimental sample, the amount of hTERT and GAPDH was determined from the appropriate standard curve. Then, hTERT amount was divided by the GAPDH amount to obtain NhTERT. NhTERT was significantly higher (*t* = 12.76, *P*<0.001) in tumor tissues (6.27±0.89) than in the corresponding non-cancerous tissues (0.93±0.18).

Table 1 Sequences of primers and probes used in this study

Gene and oligonucleotide	Sequence	PCR product size (bp)
GAPDH		
Upper primer	5'-GAAGGTGAAGGTCGGAGTC-3'	
Lower primer	5'-GAAGATGGTGATGGGATTTC-3'	226
Probe	5'-(FAM) CAAGCTTCCC GTTCTCAGCC (TAMRA)-3'

Correlation between hTERT mRNA expression level and clinicopathological parameters

The data obtained by RQ-PCR were analyzed in relation to clinicopathological parameters of the patients. All 35 corresponding non-cancerous gastric tissue samples expressed low detectable NhTERT, ranging from 0.06 to 2.11. In the 35 gastric carcinomas, NhTERT varied greatly, ranging from 0.28 to 90.55. NhTERT was categorized as low or high, using a cutoff at 5.39, which was the value that represented the median value of the expression distribution. Thus, 17 tumors (48.6%) showed low hTERT expression, whereas 18 tumors (51.4%) had high hTERT expression. We observed the statistical links between hTERT mRNA expression levels and the degree of differentiation ($P = 0.007$). Seventy-three point six percent (14 of 19) of poorly differentiated and undifferentiated tumors showed high NhTERT expressions, whereas 75% (12 of 16) of well and moderately differentiated tumors exhibited low NhTERT expressions. Poorly differentiated and undifferentiated tumors had higher hTERT mRNA expression levels than well and moderately differentiated tumors. No relationship was found between hTERT mRNA expression level and patients' age, gender, tumor size, tumor location and stage (pTNM). The results obtained are shown in Table 2.

Table 2 Relationship between hTERT mRNA expression level and clinicopathological parameters in patients with gastric cancer

Parameter	n	NhTERT		P
		Low (n = 17)	High (n = 18)

DISCUSSION

We used RQ-PCR based on TaqMan methodology for the accurate quantification of hTERT mRNA expression in gastric carcinomas. This assay has several marked advantages over the TRAP assay for cancer detection. It needs only a 95-bp fragment of hTERT mRNA, making the assay less sensitive to RNase activity and insensitive to proteases and protein inhibitors. The assay output is numerical rather than qualitative, allowing appropriate diagnostic statistics to be applied. It uses endogenous controls (GAPDH in this study) which allow correction for parameters like RNA input, RNA degradation, or RT inhibitors. Real-time PCR makes RNA quantification much more precise and reproducible, based on Ct values established in the early exponential phase of the PCR reaction (when none of the reagents is rate-limiting) rather than end point quantification of the amount of accumulated PCR product. It does not require post-PCR sample handling and the closed-tube method minimizes the risk for cross-contamination. These suggest that quantitative determination of hTERT mRNA by RQ-PCR is a powerful method to investigate the telomerase status and superior in specificity and sensitivity to the evaluation of telomerase activity by the TRAP assay. In addition, we used recombinant hTERT plasmid DNA to calculate the external standard curves, and found it was better for the quantification of mRNA than the recombinant RNA calibrator or endogenous standards^[10,11]. Theoretically, the slope of the standard curve should be -3.3 if 10-fold dilutions are used, but in practice a slope between -3.0 and -3.9 is probably acceptable as long as the correlation coefficient is >0.95. The standard curves we obtained in this study had acceptable slopes and correlation coefficients.

In this study, the level of hTERT mRNA estimated with RQ-PCR procedure was the average amount of transcripts in a whole

tissue sample and mainly depended on the number of hTERT-positive cells present in the tissue. hTERT mRNA was detected in 100% of gastric carcinoma RNAs, and also in all the corresponding non-cancerous gastric mucosa RNAs. The highest hTERT was detected in gastric cancer, whereas the lowest hTERT was found in non-cancerous gastric tissues. However, hTERT in samples of non-cancerous tissues was only approximately 14.8% of those found in the cancerous samples, and hTERT was significantly higher ($t = 12.76$, $P < 0.001$) in tumor tissues (6.27 ± 0.89) than in the corresponding non-cancerous tissues (0.93 ± 0.18). We believed that these were not in contradiction to the findings using TRAP with which telomerase activity could not be detected in most non-malignant gastric tissues and the positive rate of hTERT mRNA expression by means of *in situ* hybridization or classical RT-PCR in gastric carcinoma^[12-15]. The difference could be explained by the increased sensitivity of the RQ-PCR assay and the presence of residual malignant cells, inflammatory lymphocytes or tumor infiltrating activated cells. Our results showed real-time measurement of hTERT expression could discriminate gastric carcinoma from nonmalignant gastric tumors. This discrimination would be more distinct if the percentage of tumor cells was higher in the selected tissues.

No relationship was found in our study between hTERT mRNA expression level and patients' age, gender, tumor size, location and tumor stage (pTNM) ($P > 0.05$) and there were statistical links between hTERT mRNA expression levels and the degree of differentiation ($P = 0.007$). These suggest that the up-regulation of hTERT appeared to be an early event in gastric carcinogenesis. hTERT may play a critical role in gastric carcinogenesis and have potential as a biomarker in the telomerase status for the early detection of gastric cancer. Real-time quantitative analysis of hTERT mRNA in tissues, cancer cells in the blood, and plasma or serum of the patients with cancer before and after surgery, radiotherapy or chemotherapy may be helpful for early detection and diagnosis of cancer, and find out therapeutic effect and estimate prognosis^[16-21]. hTERT may become a target in gene therapy of cancer and inaugurate a new approach for cancer therapy.

In conclusion, monitoring hTERT mRNA expression with RQ-PCR analysis appears to be a new effective and sensitive method to better differentiate gastric cancer from nonmalignant gastric tumors. hTERT mRNA expression status may be used as a molecular marker of gastric cancer. These findings must be confirmed in a larger series of gastric cancer patients.

Abstract

AIM: To investigate the expression of NDRG2 and mutation of the entire coding region of NDRG2 in human liver and pancreatic cancers, and to further discuss the possible causes of NDRG2 distinct expression patterns.

METHODS: Reverse transcription-polymerase chain reaction (RT-PCR) was used to analyze the expression of NDRG2 mRNA in 37 fresh cancer specimens (including 8 cases of pancreatic cancer and 29 cases of liver cancer) and adjacent normal tissues collected from clinical operation. In addition, mutation analysis of the whole coding region of NDRG2 in these cancers was examined by polymerase chain reaction-single strand conformational polymorphism (PCR-SSCP).

RESULTS: Compared with adjacent normal tissues, the expression levels of NDRG2 mRNA in corresponding cancer tissues reduced significantly (pancreatic cancer: 0.680 ± 0.112 vs 2.089 ± 0.214 , $P < 0.01$) (liver cancer: 0.894 ± 0.098 vs 1.345 ± 0.177 , $P < 0.05$). Using PCR-SSCP, the mutation of the whole coding region of NDRG2 was not found in those cancer tissues where the expression of NDRG2 mRNA reduced markedly.

CONCLUSION: NDRG2 gene might express differently between normal tissues and cancer tissues, and might play an important role in the development of pancreatic cancer and liver cancer. Low expression of NDRG2 might be unrelated to the mutation of coding region of NDRG2.

INTRODUCTION

NDRG2, a new member of the N-Myc downstream-regulated gene (NDRG) family including NDRG1-4, was first discovered and cloned from normal human whole brain cDNA library by

subtractive hybridization in our laboratory^[1]. NDRG2 is located on chromosome 14q11.2, including 16 exons and 15 introns, and its cDNA is 2 024 bp in length^[2]. Studies from our laboratory and others have shown that NDRG2 was highly expressed in many normal tissues, especially in the brain, heart, skeletal muscle, and kidney, whereas low expressed or not detected in various tumors and tumor cell lines^[3,4]. This suggests that NDRG2 inactivation might play an important role in some tumor genesis or evolution, and NDRG2 might be a new cancer suppressor gene candidate. To date, no report on mutation analysis of NDRG2 in a variety of tumors has been presented. This study was conducted to determine whether the distinct expression of NDRG2 was related to gene mutation as most cancer suppressor genes. The expression of NDRG2 mRNA in 37 patients with liver cancer and pancreatic cancer was detected, and the mutation of the whole coding region of NDRG2 in normal and cancer specimens was analyzed by PCR-SSCP.

MATERIALS AND METHODS

Patients and tissue specimens

Thirty-seven fresh cancer specimens (including 8 cases of pancreatic cancer and 29 cases of liver cancer) and corresponding adjacent normal tissues were collected from patients who underwent surgery at First Affiliated Hospital of Xi'an Jiaotong University, Tangdu Hospital and Xijing Hospital between May 2003 and September 2003. All specimens were examined by microscope after haematoxylin and eosin (H&E) staining.

RNA isolation and RT-PCR

Total RNA was extracted from tissue specimens using TRIzol reagent (GIBCO BRL, USA) according to the manufacturer's instructions. Reverse transcription reaction was set up according to Promega's reverse transcription system protocol. cDNAs were then amplified by PCR using specific primers for human NDRG2: upstream primer 5'-GC GGA TCC ATG GCG GAG CTG CAG GAG GTC -3'; and downstream primer 5'-GC GAA TTC AAC AAG GGC CAT TCA ACA GGA GAC -3', about 1 200 bp. The primer sequences of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) which was used as an internal quantitative control for the amplification were as follows: upstream primer 5'-GCC TCA AGA TCA GCA AT -3'; downstream primer 5'-AGG TCC ACC ACT GAC ACG TT -3', 310 bp. Cycling condition for NDRG2 was at 94 °C for 5 min, followed by 32 cycles of 94 °C for 40 s, 59 °C for 50 s, and 72 °C for 60 s, and the cycling condition for GAPDH was at 94 °C for 5 min, followed by 30 cycles of 94 °C for 30 s, 57 °C for 30 s, and 72 °C for 30 s, and finally for 10 min at 72 °C. The PCR products were then analyzed and visualized on 12 g/L agarose gel containing 5 g/L ethidium bromides. Results were normalized by the ratio of band density of NDRG2 mRNA to GAPDH mRNA.

PCR-SSCP silver staining

According to cDNA sequence of NDRG2 gene, we designed by DNASTar analysis software and synthesized 6 pairs of primers covering the whole coding region of NDRG2 gene, with length of each PCR product around 150 to 370 bp, and PCR reaction

**Figure 1** Expressions of NDRG2 mRNA in human liver cancer and pancreatic cancer. A: Representative agarose gels of RT-PCR-amplified NDRG2. M: DNA molecular weight marker; N: Normal tissue; C: Cancer tissue; B: Relative amount of NDRG2 mRNA was evaluated by the ratio of band optical density of NDRG2/GAPDH and the expression was significantly decreased in cancer ($n=29$ for liver cancer, and 8 for pancreatic cancer respectively) vs normal tissues. ^a $P<0.05$, ^b $P<0.01$ vs normal.

conditions are described in Table 1. The PCR products were separated by electrophoresis on 12 g/L agarose gel to check the specificity of each PCR reaction. The products were mixed with the same amount of formamide-loading buffer (950 g/L formamide, 10 mmol/L EDTA, and 0.5 g/L bromophenol blue, 0.5 g/L xylene cyanol) and heated at 100 °C for 5 min, and loaded on 80 g/L non-denaturing polyacrylamide gel in 1× TBE buffer for 8–12 h at 40 V. After electrophoresis, the gel was fixed, silver-stained, and finally developed, photographed and analyzed. The sample was considered normal if the band position was the same as that of the normal tissue. Otherwise, it was abnormal.

Statistical analysis

Statistical analysis was performed by SPSS version 10.0. Data were expressed as mean±SD, and analyzed by Student's *t* test. $P<0.05$ was considered statistically significant.

RESULTS

RT-PCR data

We investigated the expression patterns of NDRG2 mRNA by RT-PCR in 37 cases of human cancers including 29 liver cancers and 8 pancreatic cancers. Figure 1A shows PCR products of representative agarose gels for NDRG2 and GAPDH in human liver cancer and pancreatic cancer. The size of the RT-PCR products was as predicted, 1 200 bp for NDRG2 and 310 bp for GAPDH. The levels of NDRG2 mRNA expression were quantified by the ratio of band optical density of NDRG2/GAPDH (Figure 1B). Compared with adjacent normal tissues, there were marked decreases in NDRG2 mRNA expression in liver cancer (0.894 ± 0.098 vs 1.345 ± 0.177 , $P<0.05$) and pancreatic

cancer (0.680 ± 0.112 vs 2.089 ± 0.214 , $P<0.01$).

PCR-SSCP analysis

The PCR products, which were amplified by 6 pairs of primers covering the whole coding region of *NDRG2* gene, were separated by electrophoresis on 12 g/L agarose gel to check the specificity of each PCR reaction (Figure 2). PCR products with only one specific band of right size in the gel can further be used for SSCP assay. Figure 3 shows representative results of SSCP silver staining of the PCR products amplified by 6 pairs of primers covering the whole coding region of *NDRG2*. By SSCP, all the PCR products from the cancer tissues of 27 patients of NDRG2 low-expression confirmed by RT-PCR, did not show any mutation.

**Figure 2** Agarose gel analysis of PCR products amplified by 6 pairs of primers covering the whole coding region of *NDRG2*. M: DNA molecular weight marker, PCR product size was 186 bp for A, 188 bp for B, 365 bp for C, 364 bp for D, 286 bp for E and 153 bp for F.

Figure 3 Representative results of SSCP silver staining of the PCR products (186 bp for A, 188 bp for B, 365 bp for C, 364 bp for D, 286 bp for E, and 153 bp for F) amplified by 6 pairs of primers covering the whole coding region of *NDRG2*. C: cancer tissue; N: normal tissue.

DISCUSSION

NDRG2, together with *NDRG1*, *NDRG3* and *NDRG4*, constitute *NDRG* gene family. The four members, which share 53-65% amino acid identity, belong to the alpha/beta hydrolase super family^[5]. Phylogenetic analysis of the family demonstrated that human *NDRG1* and *NDRG3* belong to a subfamily, and *NDRG2* and *NDRG4* to another. Expression of the fusion proteins showed that all of them were cytosolic proteins. Northern and dot blot analysis showed that *NDRG* gene family was evidently expressed in adult brain and almost not detected in some human cancer lines^[6-8]. In addition, *NDRG2* is highly expressed in adult skeletal muscle and brain, *NDRG3* remarkably expresses in brain and testis, and *NDRG4* evidently expresses in brain and heart, suggesting that they might display different specific functions in distinct tissues^[9,10]. Although *NDRG* gene family is believed to be involved in cell differentiation, the exact molecular and cellular function of members of this family is still unknown.

In 2000, our laboratory first discovered and successfully cloned human *NDRG2* cDNA from normal human whole brain cDNA library by subtractive hybridization. Our previous studies showed that the expression level of *NDRG2* mRNA was very high in brain, salivary gland, skeletal muscle and mammary gland, and low in bone marrow, testis, peripheral blood and placenta, and not detectable in leukocyte, colon and some tumor cell lines. Other studies have also shown similar result^[11,12], suggesting that *NDRG2* inactivation might play an important role in some cancer genesis or evolution, and *NDRG2* might be a new cancer suppressor gene candidate.

A recent study showed that over expression of *NDRG1* in tumor cells decreased the proliferation rate, enhanced differentiation, and suppressed metastasis potency of cancer cells. More interestingly, a nonsense mutation in *NDRG1* gene may be the cause of hereditary motor and sensory neuropathy-Lom (HMSNL)^[13].

The activation of oncogene and inactivation of cancer suppressor gene can lead to uncontrolled cell proliferation and occurrence of cancer. The inactivation of most cancer suppressor genes has been confirmed to relate to gene mutation such as *p53*, *p16* and *Rb* gene^[14]. To the authors' knowledge, we first investigated the expression patterns of *NDRG2* mRNA by RT-

PCR in 37 cases of human cancers including 29 liver cancers and 8 pancreatic cancers. The results showed that there was marked decrease in *NDRG2* mRNA expression in human liver cancer ($P < 0.05$) and pancreatic cancer ($P < 0.01$), compared with adjacent normal tissue. We speculated that different expression pattern of *NDRG2* might relate to gene mutation. The designed 6 pairs of primers covering the whole coding region of *NDRG2* gene to amplify the cancer tissue of 27 patients of *NDRG2* low-expression were confirmed by RT-PCR, but no mutation was found.

In conclusion, our results indicate that *NDRG2* gene expresses differently between normal tissues and cancer tissues, and it might play an important role in the development of pancreatic cancer and liver cancer. The low expression of *NDRG2* might be unrelated to mutation of the coding region of *NDRG2*. In addition, whether a mutation exists in the upstream sequence of transcription initial site of *NDRG2*, deserves further investigation.

ACKNOWLEDGEMENTS

We are grateful to Dai-Hua Yu, Bang-Yong Sun, Wei Lin, and Jiang-Wei Liu for the collection of tissue specimens and Jiang-Tian Yu, Li-Hu Wu, and Li-Feng Wang for digital photographs.

Abstract

AIM: To investigate the molecular mechanism of the influence of HBx protein on multidrug resistance associated genes: multidrug resistance 1 (MDR-1), multidrug related protein (MRP-1), lung resistance related protein (LRP) in hepatoma cells and the potential role of extracellular signal-regulated kinase/mitogen-activated protein kinase (ERK/MAPK) pathway in this process.

METHODS: A cell model stably expressing the HBx protein was established by liposome-mediated transfection of HBx gene into HepG2 cell line. The expression of multidrug resistance associated genes and proteins was detected by RT-PCR and Western blot. AnnexinV-FITC/PI assay was used to confirm the multidrug resistance (MDR) phenotype of transfected cells by fluorescence cytometry (FACS). The ERK/MAPK pathway activation was measured by Western blot through comparing the ratio of phosphorylation of ERK/MAPK to total ERK/MAPK protein. After treated with the ERK/MAPK pathway inhibitor U0126, the HBx-expressing cells were harvested. Then RT-PCR, Western blot and FACS were used to analyze the alterations in the expression of multidrug resistance associated genes and the MDR phenotype after exposure.

RESULTS: Compared with the control group, the transfected cells showed a higher expression of MDR associated genes and proteins. Marked elevations in MDR-1 (64.3%), MRP-1 (87.5%) and LRP (90.8%) were observed in the transfected cells ($P < 0.05$). RT-PCR revealed that the over-expression of MDR associated proteins was due to amplification of such genes (MDR1 2.9 fold, MRP1 1.67 fold, LRP1.95 fold). Furthermore, we found that the ERK/MAPK activity was remarkably high in the HBx-expressing cells. The activation of ERK/MAPK, as measured by the ratio of phosphorylated ERK bands normalized to the total ERK bands, was increased by 2.3-fold in HBx-transfected cells compared with cells transfected with the empty vector. After treated with the ERK/MAPK pathway inhibitor, the level of MDR associated genes and proteins in the transfected cells decreased to some extent. Compared with controls, a significant decrease in MDR-1 mRNA (53.3%), MRP-1 mRNA (59.7%) as well

as LRP mRNA (56.4%) was observed in the U0126 treated transfected cells after 12 h. Western blot also demonstrated that the protein expression of these MDR associated genes slightly reduced after treated with U0126 for 12 h (MDR-1 40.1%, MRP-1 29.4%, LRP35.7%). This change was accompanied with the rise of cell apoptosis ratio confirmed by Annexin V-PI detection. The apoptosis index of U0126-treated cells increased by 1.28 fold, compared with that of transfected cells. Obviously, the MDR phenotype of these cells was obviously related with increased activities of the ERK/MAPK pathway.

CONCLUSION: HBx protein might be one of the causes for the occurrence of MDR in HCC, and ERK/MAPK pathway might be involved in this change.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common cancers in China and approximately 90% of HCC cases in this region are associated with hepatitis B virus (HBV) infection^[1,2]. The mechanism underlying the development of HCC is still unclear. X gene, a unique open reading frame of HBV, codes for a 16.5 kd protein (X protein, HBx)^[3]. There is evidence that HBx is an essential viral protein with pleiotropic activity that might act directly or indirectly on development of hepatocellular carcinoma during chronic hepadnavirus infection^[4,5]. Over-expression of HBx induces transformation of some cell types^[6]. Additionally, it has been reported that HBx is involved in the arrest of cell cycle progression and the modulation of apoptosis^[7,8]. HBx protein also interacts with the tumor suppressor *p53*, resulting in a loss of its function^[9]. Due to its cytosolic localization, HBx has been shown to participate in a wide range of cellular signal transduction cascades, including Ras-Raf-mitogen-activated protein kinase, *c-Jun* N-terminal kinase, NF- κ B and Janus kinase (JAK) -signal transducer and activator transcription factor (STAT) pathway^[10-12]. It is well-known that tumor cells may avoid the death fate because apoptotic signals generated by the chemotherapeutic agents fail to activate the necessary pathways required to initiate apoptosis. Therefore, such survival signal pathways whose activation has been shown to play an anti-apoptotic role after treatment with various chemotherapeutic drugs have become the focus of recent researches. The mitogen-activated protein kinase (MAPK) family has emerged as one of such important membrane-to-nucleus signaling mechanisms of HBx, functioning as a mediator of cellular responses to a variety of cellular stimuli^[13]. The MAPK family has been classified into 3 distinct subfamilies: the extracellular signal-related protein

kinases (ERKs) including ERK1 and ERK2, the stress-activated *c-Jun* N-terminal protein kinase (JNKs) and *p38* kinase^[13]. Resistance to a broad spectrum of chemotherapeutic agents in cancer cells is called MDR^[15]. The MDR phenotype is associated with the increased drug efflux from cells that is mediated by an energy-dependent mechanism and the blockade of the apoptosis-inducing pathway, the latter is the highlight of research nowadays. The results of experiments aiming at exploring the role of HBx on apoptosis pathways, however, are controversial and thence disappointed^[15,16]. So we became more interested in determining whether these signal pathways were involved in the development of MDR, and investigated the potential role of MAPK pathways in multidrug resistance induced by HBx in hepatoma cells.

MATERIALS AND METHODS

Reagents

Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum (FBS), lipofectamine 2 000 and G418 were purchased from Invitrogen Inc. ERK/MAPK pathway inhibitor U0126, was purchased from Alexis Inc. Anti-phospho-ERK₁/ERK₂ rabbit polyclonal antibody was purchased from RD systems. Anti-ERK₁/ERK₂ rabbit polyclonal antibody was purchased from Biovision Inc. Polyclonal antibody to multidrug related protein (MRP-1), was from Alexis Inc. Lung resistance-related protein (LRP) mouse antibody, multidrug resistance 1 (MDR-1) mouse antibody and pan actin antibody-5 were provided by Neomarker Inc. Dimethyl sulfoxide (DMSO) was purchased from Sigma.

Cell lines and cell culture

Human hepatocellular carcinoma cell line, HepG2 (GDC024) was purchased from the China Center for Type Culture Collection (Wuhan University, Hubei). Cells were maintained in DMEM supplemented with 100 mL/L heat-inactivated FBS at 37 °C in a humid atmosphere containing 50 mL/L CO₂.

Plasmids and stable transfection

The expression vector pcDNA3-HBx (a kindly gift from Lian-Rui Zhao, PhD; Thomas Jefferson University, USA) was constructed by inserting HBx DNA fragments between the *Hind*III and *Kpn*I cloning sites of the pcDNA3 vector. After amplification in *DH-5α*, we used the EZNA plasmid maxiprep kit (OMEGA, USA) to purify the plasmids. HepG2 cells at 70-80% confluence were transfected with plasmids, using lipofectamine 2 000 (Life Technologies, Inc.). Plasmid transfections were performed according to protocols supplied with the reagents. At 48 h post-transfection, cells were split at a 10:1 ratio and cultured in the presence of 800 g/L G418. After 21 d in selective medium, individual G418-resistant colonies were isolated. Expression of HBx in various cell lines was verified by RT-PCR and Western Blot. The control cell line (HepG2/pcDNA) was generated from cells transfected with the vector alone and selected using G418. After isolation of resistant clones, the concentration of G418 was changed to 400 µg/mL.

Reverse transcriptase-PCR

Total cellular RNA of the stably transfected HepG2 cells was extracted with Trizol (Life Technologies, Grand Island, NY) according to the manufacturer's instructions and reverse transcribed into cDNA with 2 units of Moloney murine leukemia virus reverse transcriptase (MMLV-RT; MBI Fermentas Inc., Amherst, New York, USA), 4 µL of 10 mmol/L dNTPs (Fermentas, Inc.), 2 µL of oligo (dT), 10 µL of 5X reaction buffer (Fermentas Inc.), 2 µL of ribonuclease inhibitor and 26 µL of deionized water for 90 min at 37 °C. PCR was performed with 100 ng of cDNA in a 50 mL reaction volume containing 20 mmol/L Tris, pH 8.0, 50 mmol/L KCl, 2 mmol/L MgCl₂, 10 mmol/L of each dNTP, 20 pmol of each primer, and 1.25 units of *Taq* DNA

polymerase (Fermentas, Inc.). The profile was 94 °C for 5 min before 25 cycles at 94 °C for 45 s, at Ta for 45 s, at 72 °C for 55 s, and a final extension at 72 °C for 10 min. All amplification products were separated on agarose gels and visualized by ethidium bromide staining under *uv* transillumination.

The primers used for semi-quantitative PCR were: sense 5'-TCT CCG TCT GCC GTT CCA -3' and antisense 5'-TCG GTC GTT GAC ATT GCT G-3' for HBx; sense 5'-TGA AGG ACT TCG TGT CAG CC-3 and antisense 5'-GTCC CATGAT GGT GTT GAG CC-3' for MRP-1; sense 5'-CAT TGG TGT GGT GAG TCA GG-3' and antisense 5'-CTC TCT CTC CAA CCA GGG TG-3' for MDR-1; sense 5'-TAA GGG CTT CCA GCA CCA AC-3' and antisense 5'-GGA GTT CTC GCT TCT CGT CC -3' for LRP and sense 5'-GTG CGT GAC ATT AAG GAG-3' and antisense 5'-CTA AGT CAT AGT CCG CCT-3' for β-actin.

Protein preparation and Western blot analyses

Stably transfected HepG2 cells were rinsed with 0.01 mol/L PBS, and then lysed in a lysis buffer containing 50 mmol/L Tris-HCL (pH 8.5), 150 mmol/L NaCl, 0.2 g/L NaN₃, 0.1 g/L SDS, 100 µg/mL PMSF, 1 µg/mL aprotinin, 10 mL/L NP-40, 5 g/L sodium deoxycholate. The products were centrifuged at 14 000 g for 15 min to remove the cellular debris. Protein concentrations were determined by the Bradford methods. A total of 50-100 µg of protein was separated by electrophoresis using 60 g/L or 100 g/L sodium dodecyl sulfate-polyacrylamide gels (according to the molecular mass of target protein), transferred to a immunoblot NC membrane, blocked with degreased milk for 12 h and hybridized with polyclonal antibodies for MRP-1, LRP, MDR-1, p-ERK and ERK (each diluted to 1:1000) at 4 °C overnight. The membranes were then washed 4 times for 15 min incubation with TBST (10 mmol/L Tris-Cl, pH 7.4, 150 mmol/L NaCl, 10 mL/L Tween 20 and hybridized with peroxidase (HRP) -conjugated secondary antibodies corresponding to each primary antibody. Protein banding specifically to the antibodies was visualized by ECL-associated fluorography (Pierce Inc.).

Cell viability and apoptosis analysis by fluorescence cytometry (FACS)

Cells were plated and grown overnight until they reach 80% confluence, then the cells were treated with 20 µg/mL 5-Fu. Subsequently, detached cells in the medium were collected, and the remaining adherent cells were released by trypsinization. The cells were washed with phosphate-buffered saline (PBS) and resuspended in 250 µL binding buffer (annexinV-FITC kit; BD) containing 5 µL of annexin V-FITC stock and 10 µL of 20 µg/mL propidium iodide (PI) for the determination of phosphatidylserine (PS) exposure on the outer plasma membrane. After incubated for 10 min at room temperature in a light protected area, the samples were analyzed by a Becton Dickinson fluorescence cytometer using CellQuest software. We could discriminate intact cells (annexin⁻/PI⁻) from apoptotic cells (annexin⁺/PI⁺) and necrotic cells (annexin⁺/PI⁺) after treatment with 5-Fu.

Statistical analyses

The results were expressed as mean±SE. Student's *t* test was used to compare data. *P*<0.05 was considered statistically significant. All data were processed by SPSS10.0.

RESULTS

Isolation and identification of HBx-expressing cells

As shown in Figure 1, the restriction enzyme digestions demonstrated that the digestion products had exactly the expected size (about 500 bp). We also requested Shanghai Bioasia Biotechnology Inc to sequence the whole plasmid kindly gifted by Lian-Rui Zhao (Ph.D), and the result of sequencing was consistent with the sequence of V0866 in GeneBank.

After stable transfection, the cells of different groups were confirmed for the expression of HBx by using PCR and immunoprecipitation. The identification of the successful transfection at mRNA and protein levels is shown in Figure 2 and Figure 3, respectively. The expected bands could be seen in the HBx-expressing cells and the groups treated with ERK/MAPK signal pathway inhibitors. There was no detectable band in the control group. These results indicated that HBx was successfully transferred and expressed in HepG2 cells.

Figure 3 Western blot analysis of HBx protein in samples isolated from HepG2 cells with or without HBx transfection. Lane 1: the sample transfected with HBx; lane 2: the sample transfected with vector only.

Verification of MDR phenotype in HBx-expressing cells

To evaluate the effect of HBx introduction on the chemosensitivity of HepG2 cells, we initially used a FACS analysis of cells stained with PI and annexinV-FITC assay to compare the survival and apoptosis ratio of HepG2 cells transfected with empty pcDNA3.0 with HBx-transfected cells, i.e., HepG2/pcDNA and HepG2/pcDNA-HBx, after their exposure to 5-Fu (20 µg/mL) for 12 h and then cultured in normal medium for 6 h. Apoptosis index was quantified by a Becton Dickinson fluorescence cytometer. The apoptosis ratio in transfected cells (9.83±1.5%) analyzed by CellQuest software after administration of 5-Fu was significantly lower than that of the control (17.79±1.7%) (Figure 4). MTT assay also demonstrated that the inhibitory concentration 50% (IC₅₀) of adriamycin in the transfected cells was higher than that of the control (data not shown). The multidrug resistance transporter MDR-1, MRP-1, and LRP were associated with multidrug resistance. Western blot analysis was performed to examine whether the resistance to 5-Fu-induced apoptosis in HBx-expressing cells was due to the alterations of such proteins. Marked elevations in

MDR-1 protein (64.3%), MRP-1 (87.5%) and LRP (90.8%) proteins were observed in the transfected cells (Figure 5 and Tables 1-2), which were well correlated with the degree of resistance. Furthermore, semi-quantitative RT-PCR revealed that over-expression of MDR-associated proteins was due to amplification of such genes (1.9-fold MDR-1, 0.67-fold MRP-1, 0.95-fold LRP) (Figure 6). Taken together, these data suggested that reintroduction of HBx contributed to the development of MDR phenotype.

Table 1 Protein level of MDR associated genes (mean±SD)

Group	MDR-1	MRP-1	LRP
transfected	0.23±0.04	0.15±0.03	0.17±0.03
control	0.14±0.03	0.08±0.03	0.09±0.02
P	0.036	0.046	0.018

Table 2 mRNA level of MDR associated genes (mean±SD)

Group	MDR-1	MRP-1	LRP
Transfected	0.29±0.06	0.62±0.11	0.82±0.15
Control	0.10±0.03	0.37±0.09	0.42±0.07
P	0.038	0.012	0.014

ERK/MAPK pathway levels and activities in transfected cells

To assess the role of ERK/MAPK in HBx-induced activation of MDR1 expression, we measured the phosphorylation of ERK/MAPK in cells transfected with HBx. As shown in Figure 6, the phosphorylation of ERK/MAPK as measured by the ratio of the phosphorylated ERK bands (Figure 7A) normalized to the total ERK band (Figure 7B), was increased by 2.3-fold in HBx-transfected cells compared with control cells. These results suggested that the MDR phenotype induced by HBx was accompanied with the activation of ERK/MAPK pathways.

Effect of ERK/MAPK pathway inhibitors on MDR of HBx-expressing hepatoma cells

Based on the constitutive activation of ERK/MAPK, we determined whether U0126, a specific ERK inhibitor, could give rise to alterations in the expression of MDR associated genes and increase the transfected cell sensitivity to the cytotoxicity of 5-Fu. Treatment of transfected cells with U0126 decreased the levels of MDR-1 mRNA, as well as LRP and MRP-1 mRNA (Tables 3-4). Compared with controls, a significant decrease in MDR-1 mRNA (53.3%), MRP-1 mRNA (59.7%) as well as LRP mRNA (56.4%) was observed in U0126 treated transfected cells after 12 h. Western blot also demonstrated that the protein expression of these MDR associated genes was slightly reduced after treated with U0126 for 12 h (MDR-1 40.1%, MRP-1 29.4%, LRP 35.7%). The apoptosis index of U0126-treated cells increased by 1.28 fold, compared with that of transfected cells. All these observations proved that U0126 could impair the MDR phenotype induced by HBx and sensitize cells to the toxicity of 5-Fu.

Table 3 Changes of MDR related genes after treated with U0126 (mean±SD)

DISCUSSION

MDR was the leading cause of failure to comprehensive therapy of HCC^[17]. Although the detailed molecular mechanisms of MDR remain to be explored, the disorder of anti-apoptotic and pro-

apoptotic signal pathways and the over-expression of certain efflux proteins are generally believed to be due to MDR phenotype^[18]. HBV infection is known as one of the most important risk factors in HCC development. Among the proteins coded by HBV genome, HBx has been proved to play a central role in virus duplication and carcinogenesis^[2]. According to previous study, HBx could participate in several pathological processes of the generation and growth of HCC^[2,4]. Apart from interfering with the suppressing function of *p53*, HBx could act as a multi-functional transcriptional transactivator to stimulate some important signal pathways. The effects of HBx on such signal pathways as ERK/MAPK, JNK, NF- κ B and Src have been well-documented, especially in the aspect of apoptotic signals^[16,19]. However, the pathological implications of these complex interactions in the evolvement of HCC malignant phenotypes have not been fully understood.

Figure 8 RT-PCR analysis of the expression of MDR associated genes in HBx-expressing cells in response to treatment of U0126. Lane 1: HBx-expressing cells; lane 2: control cells; lane 3: transfected cells treated with U0126; lane M: marker. A: Specific primers to amplify MDR-1 gene; B: Specific primers to amplify MRP-1 gene; C: Specific primers to amplify LRP gene.

In this study, we investigated the influence of HBx protein on MDR associated proteins and the potential role of ERK/MAPK pathways in this process. Our data provided the evidence that HBx up-regulated the expression of MDR associated genes. Similar changes were witnessed in protein level. Our results indicated that HBx protein was a survival factor that could protect transfected cells from death induced by anti-tumor drugs in a constitutive expression system. Subsequent studies showed that HBx protein contributed to the MDR phenotype which was confirmed by apoptosis detection through FCAS. Furthermore, we demonstrated that the ERK/MAPK pathway worked as a downstream effector of HBx, mediating the MDR phenotype in the ERK/MAPK signal transduction pathway which was activated in HBx-expressing cells. To further confirm our previous hypothesis that the MAPK signal pathway played an important role in the MDR phenotype induced by HBx protein, we examined whether MAPK inhibited by U0126 (20 $\mu\text{mol/L}$, 12 h) could alter the phenotype of MDR. The experimental results showed that P-glycoprotein (product of the *MDR-1* gene) mediated MDR of transfected cells is reduced by the treatment of such inhibitors, which supports corroborated our presumption.

Among the myriads of intracellular signaling molecules regulated by HBx, ERK/MAPK plays an important role in regulating several cellular processes, such as proliferation and differentiation^[20]. Several studies suggested that ERK/MAPK was involved in the acquired resistance of cancer cells to cytostatic drugs^[22,23]. Kisucka *et al.* reported that the effect of PD98059 and U0126 on vincristine resistance of L1210/VCR cells, suggesting that both substances were reversing agents of P-glycoprotein-mediated MDR, and the role of ERK-mediated phosphorylation cascades in the occurrence of MDR should be considered. Dent *et al.*^[25] also demonstrated that the activation of the ERK/MAPK pathway played a critical role in leukemia cell survival after treatment with chemotherapeutic drugs and ionizing radiation. As shown in our experiment, the up-regulation of P-glycoprotein expression might be one of the mechanisms by which HBx induces the MDR phenotype. This result was consistent with the data reported by Chen *et al.*^[26], who pointed out in his recent paper that inhibitors of the ERK/MAPK signal pathway could remarkably inhibited the expression of MDR-1. Barancik *et al.*^[27] also suggested that SB203580, a specific inhibitor of the *p38*/MAPK pathway, could reverse the resistance of L1210/VCR cells mainly via P-glycoprotein dependent mechanisms. However, we could not exclude the possibility that ERK/MAPK activated by HBx could enhance the activity of P-glycoprotein (product of the *MDR-1* gene) by phosphorylation. P-glycoprotein is a phosphorylation substrate for a number of protein kinases including protein kinase C (PKC), MAPK, phospholipase C (PLC) *etc*^[28,29]. Therefore, phosphorylation of such MDR related proteins might be another function of ERK/MAPK pathway during MDR induced by

HBx protein. The influence of phosphorylation by such protein kinases as PKC or MAPK on the activity of MDR-1 protein and other MDR associated proteins is the target of our ensuing experiments in order to obtain a thorough understanding of the molecular mechanisms of interactions between HBx and MDR associated proteins.

In summary, MAPK pathway is involved in generation of MDR phenotype in hepatoma cells. The findings reported in this work might contribute to the understanding of pathogenic mechanisms involved in malignant phenotypes of HBV-associated hepatocellular carcinoma.

ACKNOWLEDGEMENTS

We thank Professor Lian-Rui Zhao (Ph.D, Thomas Jefferson University, USA) for his gift of plasmids and useful suggestions during the whole experiment. We are also grateful to Dr. Ji-Xiong Chen and Miss Shan-Shan Huang for their kind help and critical discussion.

Abstract

AIM: To study the effect of environmental hyperthermia on gastrin, somatostatin and motilin in rat ulcerated antral mucosa.

METHODS: Forty-two Wistar rats were equally divided into six groups, according to the room temperature (high and normal) and the treatment (acetic acid, normal saline and no treatment). Levels of gastrin, somatostatin and motilin in rat ulcerated antral mucosa were measured with a radioimmunoassay method.

RESULTS: The average temperature and humidity were 32.5 °C and 66.7% for the high temperature group, and 21.1 °C and 49.3% for the normal temperature group, respectively. Gastric ulcer model was successfully induced in rat injected with 0.05 mL acetic acid into the antrum. In rats with gastric ulcers, the levels of gastrin and motilin increased, whereas the somatostatin level declined in antral mucosa, compared with those in rats treated with normal saline and the controls. However, the change extent in the levels of gastrin, motilin and somatostatin in antral mucosa was less in the high temperature group than in the normal temperature group.

CONCLUSION: The levels of gastrin, somatostatin and motilin in rat ulcerated antral mucosal tissue remain relatively stable in a high temperature environment, which may relate to the equilibration of the dynamic system.

INTRODUCTION

The abnormal secretion of gastrointestinal hormones such as gastrin, somatostatin, motilin may affect the function of alimentary tract^[1,2]. In a high temperature living environment, body could develop adaptation reaction to hyperthermia, meanwhile induces a series of compensatory regulations in the central nervous system and endocrine system^[3-8], the content

of gastrointestinal hormones could be changed accordingly. Our experiment investigated the influence of ambient temperature on gastrin, somatostatin, motilin in rat ulcerated antral mucosa and their biological significance.

MATERIALS AND METHODS

Animals and preparation

We used healthy adult male Wistar rats weighing 200-260 g (purchased from Experimental Animal Center, Sun Yat-Sen University of Medical Sciences). The rats were raised in our Experimental Animal Center and fed with standard rat chow. The rats were randomly divided into six groups of seven rats each, respectively. They were high temperature ulcer group, normal temperature ulcer group, high temperature saline group, normal temperature saline group, high temperature control group, normal temperature control group. The room temperature of the hyperthermia group was not interfered, but that of the normal group was controlled by airconditioning.

Radioimmunoassay kits of gastrin and motilin were purchased from Tianjin Qianye Biotech Co. Ltd, and the kits of somatostatin from Department of Neurobiology of Second Military Medical University.

The temperature of the animal houses was measured by catathermometer (produced by Shanghai Medical Instrument Factory) at 8:00 and 20:00 everyday, the relative humidity was converted through the scale at the base of the catathermometer, and average values of dry bulb temperature and relative humidity were recorded. The dry bulb temperature (°C) in houses on the d 0, 1, 2, 3 after model-making and the day of rat sacrifice was 31.7, 32.5, 33.0, 32.8, 32.4 (average 32.5±0.5) for the high temperature group, and 21.2, 21.1, 21.0, 21.3, 21.1 (average 21.1±0.1) for the normal temperature group, respectively. The relative humidity (%) was 58.0, 65.5, 69.0, 76.0, 65.0 (average 66.7±6.6) for the high temperature group and 46.5, 48.0, 51.5, 53.0, 47.5 (average 49.3±2.8) for normal temperature group, respectively.

Establishment of rat model and measurement of gastrin, somatostatin and motilin

The rats of high temperature ulcer group and normal temperature ulcer group were anesthetized with 30 g/L sodium pentobarbital intraperitoneally. The abdomen was opened and 0.05 mL acetic acid was injected into the antral tissues. Omentum majus and antral tissue of the injection site were stitched. The peritoneum, parietal abdomen and ventral muscle, and skin were stitched continually. The rats of high temperature saline group and normal temperature saline group were injected with 0.05 mL saline instead of acetic acid at the same site. The rats of control group did not receive any treatment. After operation, the model-making rats were raised separately, and fasted overnight with free access to water one day before sacrifice. No treatment was given to normal control group. The rat stomach was separated and split from the greater curvature, and mucosa of gastric antrum was scraped about 0.1 g to be boiled after weighed on electronic analytical balance. The boiled tissue was homogenized into homogenates in a homogenizer with 1 mL of 1 mol/L acetic acid and neutralized

with 1 mL of 1 mol/L NaOH, the liquid of homogenates was centrifuged at 3 500 r/min for 15 min to obtain supernatant, and the samples were then stored at -70 °C until assay. Gastrin, somatostatin and motilin were measured by using radioimmunoassay (RIA) method, measurement procedures were performed according to the instructions attached to the kits. The unit of result was transformed to ng/g.

Statistical analysis

Data among the groups were analyzed with factorial analysis of variance by SPSS 10.0 software. The comparison between the two means of different groups was analyzed by Student-Newman-Keuls. $P < 0.05$ was considered statistically significant.

RESULTS

Observation of gross specimens

Gastric contents of the rats in high temperature and normal temperature ulcer groups obviously increased, the diameter of round shape ulcers on the frontal wall of gastric antrum was about 0.5-0.7 cm, the center of the ulcer was pale covered with offwhite membrane, the base was flat with clear verge, and the mucosa around the ulcer had hyperemia and edema. Gastric contents of the rats in the other groups were suitable, mucosa plica of gastric antrum was obvious, and its color was pale red without hyperemia and edema. There was no ulcer on the surface.

Level of gastrin in rat antral mucosa of each group

The difference of gastrin level in antral mucosa between ulcer group and nonulcer group was significant ($F = 9.500$, $P = 0.000$), gastrin levels in ulcer group (average 5.99 ng/g) were higher than those in control group (3.68 ng/g) and saline group (3.98 ng/g). But the differences in gastrin levels among the groups were insignificant in high and normal temperature groups ($F = 1.465$, $P = 0.234$). There was no mutual effect between the two treatment factors of ulcer and temperature ($F = 0.980$, $P = 0.385$). The gastrin level in ulcerated antral mucosa increased significantly ($P < 0.01$). But the level of gastrin in antral mucosa in the high temperature ulcer group increased less than that in the normal temperature ulcer group ($P < 0.05$) (Table1).

Table 1 Gastrin in rat antral mucosa ($n=7$, ng/g, mean \pm SD)

Group	Ulcer	Normal saline	Control
HT	5.24 \pm 1.65	3.91 \pm 1.31	3.64 \pm 1.15 ^b
NT	6.73 \pm 2.29 ^a	4.04 \pm 1.28	3.71 \pm 1.13

^a $P < 0.05$, vs high temperature ulcer group ^b $P < 0.01$ vs ulcer group.

Level of somatostatin in rat antral mucosa of each group

The difference of somatostatin level in antral mucosa between ulcer group and nonulcer group was significant ($F = 15.087$, $P = 0.000$), somatostatin levels in ulcer group (average 0.62 ng/g) were less than those in control group (1.37 ng/g) and saline group (1.24 ng/g). But the differences of somatostatin levels were insignificant in high and normal temperature groups ($F = 2.789$, $P = 0.104$). There was no mutual effect between the two treatment factors of ulcer and temperature ($F = 1.416$, $P = 0.256$). The level of somatostatin in gastric ulcerated antral mucosa declined significantly ($P < 0.01$). But the level of somatostatin in antral mucosa in the high temperature ulcer group declined less than that in the normal temperature ulcer group ($P < 0.05$) (Table2).

Level of motilin in rat antral mucosa of each group

The difference of motilin level in antral mucosa between ulcer group and nonulcer group was significant ($F = 18.178$, $P = 0.000$), motilin levels in ulcer group (average 8.04 ng/g) were higher than

those in control group (4.27 ng/g) and saline group (4.58 ng/g). But the differences of motilin levels were insignificant in high and normal temperature groups ($F = 3.632$, $P = 0.065$). There was no mutual effect between the two treatment factors of ulcer and temperature ($F = 2.611$, $P = 0.087$). The level of motilin in gastric ulcerated antral mucosa increased significantly ($P < 0.01$). But the level of motilin in antral mucosa in the high temperature ulcer group increased less than that in the normal temperature ulcer group ($P < 0.05$) (Table3).

Table 2 Somatostatin in rat antral mucosa ($n = 7$, ng/g, mean \pm SD)

Group	Ulcer	Normal saline	Control
HT	0.86 \pm 0.30	1.28 \pm 0.46	1.39 \pm 0.50 ^b
NT	0.37 \pm 0.15 ^a	1.19 \pm 0.41	1.36 \pm 0.41

^a $P < 0.05$, vs high temperature ulcer group ^b $P < 0.01$ vs ulcer group.

Table 3 Motilin in rat antral mucosa ($n = 7$, ng/g, mean \pm SD)

Group	Ulcer	Salt	Cont
HT	6.58 \pm 2.04	4.46 \pm 1.30	4.22 \pm 1.24 ^b
NT	9.50 \pm 2.98 ^a	4.70 \pm 1.43	4.31 \pm 1.40

^a $P < 0.05$, vs high temperature ulcer group ^b $P < 0.01$ vs ulcer group.

DISCUSSION

Our experiment established the model of rat gastric ulcer. Gastrin, somatostatin and motilin were measured with the RIA method. The result revealed that gastrin and motilin in antral mucosa tissue increased, and somatostatin declined when the rats had gastric ulcer. Compensative changes of gastrointestinal tract and other organs took place to accommodate hyperthermia. Our experiment detected the level of gastrin, somatostatin and motilin in antral mucosa tissue of gastric ulcer rats in high and normal temperature environments. We discovered that the level of gastrin and motilin in antral mucosa in the high temperature ulcer group increased less than that in the normal temperature ulcer group, the level of somatostatin in the high temperature ulcer group declined less than that in the normal temperature ulcer group.

Complex changes of many cytokines in body occurred in heat stress environment^[9-15]. Hyperthermia could change heat stress proteins (HSP), atrial natriuretic factor (ANF), angiotensin, nerve growth factor (NGF), cortisol and plasma protein, blood sugar, serum lipoprotein, microelement as well as body immune system correspondingly^[16-20]. The system of neuroendocrine, cytokine and heat stress constituted an organic network, in which a chain in dynamic action could make internal milieu stable^[21,22]. The result of this experiment indicates that the levels of gastrin, somatostatin and motilin in antral mucosa tissue remain relatively stable in a high temperature environment. This may relate to the equilibration of the dynamic system.

Abstract

AIM: To study the effect of selenium on peripheral blood mononuclear cell (PBMC) membrane fluidity and immune function in patients with chronic hepatitis.

METHODS: PBMCs were pretreated with selenium (1.156×10^{-7} mol/L) for 6 h *in vitro* or extracted directly from patients after administration of selenium-yeast continuously for 8-12 wk (200 µg/d), and then exposed to Con-A for 48 h. The membrane fluidity, interleukin-2 (IL-2) production and interleukin-2 receptor (IL-2R) expression in PBMCs and malondialdehyde (MDA) concentration in medium and lipid peroxide (LPO) in plasma were determined.

RESULTS: The PBMC membrane fluidity, IL-2 production and IL-2R expression in patients with chronic hepatitis were significantly lower than those in healthy blood donors (particle adhesive degree R, 0.17 ± 0.01 vs 0.14 ± 0.01 , $P < 0.01$; IL-2, 40.26 ± 9.55 vs 72.96 ± 11.36 , $P < 0.01$; IL-2R, 31.05 ± 5.09 vs 60.58 ± 10.56 , $P < 0.01$), and the MDA concentration in medium in patients with chronic hepatitis was significantly higher than that in healthy blood donors (1.44 ± 0.08 vs 0.93 ± 0.08 , $P < 0.01$). Both *in vitro* and *in vivo* administration of selenium could reverse the above parameters.

CONCLUSION: Supplement of selenium can suppress lipid peroxidation, and improve PBMC membrane fluidity and immune function in patients with chronic hepatitis.

INTRODUCTION

Hepatic viruses attack immune cells thus leading to cell immune functional disorders, which is one of the major mechanisms of chronic hepatitis^[1-4]. It is currently believed that the damage of immune cells caused by lack of the minor elements of selenium, proliferation of free particles and peroxidization of lipid are

probably associated with cell immune functional disorders in patients with chronic hepatitis^[5-9]. The use of anti-oxidants could contribute to improving the psychopathologic process of chronic hepatitis, suppress cell immune functional disorders and accelerate the recovery of liver functions^[10-11]. The minor elements of selenium have anti-oxidizing effects, and have been utilized in the immune regulation of many diseases, but the effect of selenium treatment on peripheral blood mononuclear cell (PBMC) functions in patients with chronic hepatitis is still unclear^[13-15]. We found during our early work that using selenium in the periphery could improve the interleukin-2 production of PBMCs and IL-2R expression in patients with chronic hepatitis^[16]. By examining the changes of PBMC membrane fluidity, interleukin-2 (IL-2) and its receptor system in patients with chronic hepatitis before and after using selenium, We further explored the effects and mechanism of selenium treatment on the cell immune functions in patients with chronic hepatitis.

MATERIALS AND METHODS

Patients

A total of 45 patients with chronic hepatitis were inpatients of our hospital from 1995 to 1997, among them 38 were males and 7 females, aged 21-52 years. The HBsAg of 30 patients with chronic hepatitis and 15 patients with cirrhosis was positive. The diagnosis was in accordance with the readjust standards of the National Academic Conference of Viral Hepatitis held in Shanghai in 1990. Besides, ten healthy blood donors were chosen as the control group.

Peripheral experiment

Elbow venous blood was taken from fasting healthy blood donors. Then PBMCs were routinely separated and floated in the RPMI-1640 culture medium. Then cell density was adjusted to 1×10^6 /L and 1 mL of cell suspension was added into each well of 24-well culture plates, and randomly divided into control group, tBHP damage inducing group, and selenium treatment group. In addition, PBMCs were taken and divided into 4 patient control group and 5 patient selenium group. NaSeO₂ (final density, 1.156×10^{-7} mol/L) was added into groups 3 and 5, each of the rest groups was added with the same amount of culture liquid followed by incubation for 6 h, and con A (5 mg/L) were added. Meanwhile, lipoperoxide inducing agents tBHP (20 µmol/L) were added into groups 2 and 3, and cultured at 37 °C for 48 h in a humidified atmosphere containing 50 mL/L CO₂.

Clinical treatment and survey

The patients were divided into two groups. The normal group was given bifendate pills and Fufangyiganling. Some individual patients were given compound ammonium glycyrrhetate injection and Qinkailing injection intravenously. Selenium treatment group, on the basis of the routine treatment, was given selenium yeast or selenium amylase (200-300 µg/d) orally for 8 to 12 wk. At the beginning of and after the treatment, blood was collected from the patients to separate PBMCs and to measure the blood plasma.

Measurement of induced IL-2 production and its activation

Each group of PBMCs was added with con-A (5 mg/L, Sigma) and cultured at 37 °C in a humidified atmosphere containing 50 mL/L CO₂. IL-2 activation expressed in 1×10^3 U/L was measured.

Measurement of IL-2R expression

The cells of each group, after induction and production of IL-2, were collected to measure IL-2R expression by indirect immune fluorescence and the positive rate was expressed as percentage of positive cells.

Measurement of lipid peroxidation

The supernatant from each group or patients' blood plasma was subjected to the measurement of MDA or LPO content by using microfluorescence technique.

Measurement of membrane fluidity

The cells of each group were suspended in the RPMI-1640 culture medium to a cell density of 1×10^6 /L. The same amount of 2×10^{-6} mol/L fluorescence probing agents DPH (sigma product) was added and cultured at 25 °C for 30 min. The polarization deviation degree (P) was measured under the condition of 432 nm (transmitting light)/362 nm (irritating light) on MPF-4 polarization meter and the particle adhesive degree (R) was calculated. The value of R and membrane fluidity were in inverse proportion.

Statistical analysis

All the data were expressed as mean \pm SD, and analyzed by *t*-test and ANOVA analysis. $P < 0.05$ was considered statistically significant.

RESULTS

Effects of selenium on IL-2 activation and IL-2R expression in human PBMCs

As shown in Table 1, after PBMCs in normal group were treated with tBHP, both IL-2R expression and IL-2 secreting activity were significantly declined, which was similar to those of the patient group. Six hours after addition of selenium, the above-mentioned changes in the cells of these two groups were obviously inhibited.

Table 1 Influence of selenium on IL-2 and IL-2R expression (mean \pm SD)

Groups	Cases	IL-2 activation (1×10^3 U/L)	IL-2R expression (%)
Normal control group	10	72.96 \pm 11.36	60.58 \pm 10.56
+tBHP	10	42.12 \pm 12.06 ^b	37.05 \pm 8.06 ^b
+Selenium+tBHP	10	53.26 \pm 18.15 ^a	52.12 \pm 9.68 ^a
Patient control group	22	40.26 \pm 9.55 ^b	31.05 \pm 5.09 ^b
Patients+selenium	23	60.32 \pm 15.24 ^c	54.06 \pm 5.22 ^c

^b $P < 0.01$ vs normal control group; ^a $P < 0.05$ vs tBHP inducing damage group; ^c $P < 0.05$ vs patient control group.

Influence of selenium on PBMC membrane fluidity

As shown in Table 2, after PBMCs in normal group were treated with tBHP, the amount of MDA increased and the membrane fluidity obviously lowered. The PBMC membrane fluidity of the patient group was also significantly lower than that of the normal control group. Six hours after addition of selenium, the above-mentioned changes could be obviously inhibited.

Changes in IL-2R expression and IL-2 secreting activity of PBMCs of patients before and after selenium treatment

As shown in Table 3, after treatment with selenium, both the

IL-2R expression and IL-2 secreting activity of PBMCs were significantly increased, while the content of MDA in the culture media was obviously decreased compared with the groups without selenium treatment ($P < 0.05$).

Table 2 Influence of selenium on PBMC membrane fluidity (mean \pm SD)

Groups	Cases	R	MDA (μ mol/L)
Normal control group	10	0.14 \pm 0.01	0.93 \pm 0.08
+tBHP	10	0.19 \pm 0.02 ^b	2.32 \pm 0.25 ^b
+Selenium+tBHP	10	0.16 \pm 0.02 ^a	1.36 \pm 0.09 ^a
Patient control group	22	0.17 \pm 0.01 ^b	1.44 \pm 0.08 ^b
Patients+selenium	23	0.15 \pm 0.01 ^c	1.21 \pm 0.09 ^c

^b $P < 0.01$ vs normal control group; ^a $P < 0.05$ vs tBHP inducing damage group; ^c $P < 0.05$ vs patient control group.

Table 3 IL-2 and IL-2R expression in PBMCs of patients before and after selenium treatment (mean \pm SD)

Groups	Cases	IL-2 activation (1×10^3 U/L)	IL-2R expression (%)
Before treatment			
Normal control group	22	43.22 \pm 9.25	31.24 \pm 5.20
Selenium treated group	23	42.26 \pm 9.55	31.05 \pm 5.09
After treatment			
Normal control group	18	49.45 \pm 15.25	35.12 \pm 6.49
Selenium treated group	17	60.32 \pm 13.28 ^a	46.05 \pm 4.46 ^b

^b $P < 0.01$ vs before treatment.

Changes in PBMC membrane fluidity of patients before and after selenium treatment

As shown in Table 4, the PBMC membrane fluidity recovered remarkably and the content of MDA in blood plasma decreased strikingly, whereas no significant changes were observed in the control group. The result was similar to that *in vitro* experiment.

Table 4 Effect on PBMC membrane fluidity of patients before and after selenium treatment (mean \pm SD)

Groups	Cases	R	Lipid peroxide (nmol/L)
Before treatment			
Normal control group	22	0.17 \pm 0.01	7.36 \pm 4.15
Selenium treated group	23	0.17 \pm 0.01	7.36 \pm 4.08
After treatment			
Normal control group	18	0.16 \pm 0.01	6.15 \pm 3.85
Selenium treated group	17	0.15 \pm 0.01 ^b	5.02 \pm 2.50 ^b

^b $P < 0.01$ vs before treatment.

DISCUSSION

Previous studies have shown that the activating oxidation or the organic peroxidation of the external chemical system could influence various functions of immune cells^[15,17-19]. Our previous study demonstrated that PBMCs from the patients with chronic hepatitis showed significantly increased production of IL-2 and expression of IL-2R after warmed with selenium for 6 h^[16]. In this experiment, our results showed that human PBMC producing IL-2 activation and IL-2R expression percentage obviously decreased after being induced by tertiary butyl peroxides. The content of lipoperoxide MDA in the culture liquid greatly increased, which was similar to the changes in PBMCs from chronic hepatitis B patients cultured *in vitro*. It was further reported that free particles and lipoperoxide receptor system probably associated with lipoperoxide reaction of

tertiary butyl peroxide could induce PBMC membranes, and thus resulting in changes of the normal structure and nature of PBMC membranes. Besides, some abnormal changes took place in receptors, enzymes and particle passages associated with the membranes, cell energy metabolism, signal transmission, proliferation, differentiation, *etc*, thereby finally leading to the organic disorder of PBMCs^[20,21].

Fluidity, one of the basic characteristics of the membranes, is the basic precondition of cells showing various functions. In many pathologic cases, excessive free particles and initiating lipoperoxide could affect membrane fluidity and lead to disorder of cell immune functions^[22-25]. Our results showed that PBMC membrane fluidity in normal group obviously decreased after treated with peroxide, and was accompanied by MDA increase in the culture supernatant. Moreover, PBMC membrane fluidity decreased and its IL-2-producing activity as well as IL-2R expression percentage changed unanimously, which was identical with the result of the cultured PBMCs from patients with chronic hepatitis. Abnormally strengthened lipoperoxide reactions could lead to decrease of PBMC membrane fluidity, which might be one of the causes of immune function disorder of patients with chronic hepatitis.

Studies shown that selenium influences immune cell functions through two ways^[13-16,26]. On the one hand, selenium can affect the mRNA expression of some immune cell surface receptors, such as IL-2R, iron transporter protein receptor (TfR). On the other hand, it is associated with the functions of selenium anti-oxidization. Free particles can directly damage lymphocyte membranes and destroy their completeness and fluidity, thus restraining the expressions of their surface markers and immune functions. Selenium and enzymes in combination with selenium can inhibit cell membrane peroxidization damage and defend membrane fluidity as well as functional expression. In our experiment, the degree of membrane fluidity, IL-2 secretion and IL-2R expression of PBMCs caused by selenium still remained high. Meanwhile, the content of MDA in the culture supernatant was greatly decreased, suggesting that selenium might defend human PBMC membrane fluidity and its normal functional expression through lipoperoxidation damage induced by anti-tertiary butyl peroxide.

PBMCs and IL-2 system play an essential role in cell immune system of patients with chronic hepatitis, maintaining PBMC functions and correcting IL-2 system disorder, which is of great significance in treatment of chronic hepatitis^[1-3]. It has been found that internal or external selenium can improve PBMC functions and increase IL-2 secretion and IL-2R expression percentage in patients with chronic hepatitis. It has been initially proved that selenium treatment is helpful to correct dysfunction of PBMCs in patients with chronic hepatitis, which is of great significance in the complete recovery of hepatic functions of patients.

Abstract

AIM: To assess the effectiveness of and complications associated with metallic stent placement for treatment of anastomotic colonic strictures.

METHODS: A 46-year-old man undergoing two procedures of surgery for perforation of descending colon due to a traffic accident presented with pain, abdominal distention, and inability to defecate. Single-contrast barium enema radiograph showed a severe stenosis in the region of surgical anastomosis and the patient was too weak to accept another laparotomy. Under fluoroscopic and endoscopic guidance, we placed two metallic stents in the stenosis site of the anastomosis of the patient with anastomotic colonic strictures.

RESULTS: In this case of postsurgical stenosis, the first stent relieved the symptoms of obstruction, but stent migration happened on the next day so an additional stent was required to deal with the stricture and relieve the symptoms.

CONCLUSION: This case confirms that metallic stenting may represent an effective treatment for anastomotic colonic strictures in the absence of other therapeutic alternatives.

INTRODUCTION

Self-expandable metallic stent treatment for colorectal diseases was falling behind that for other organs. Recently, however, there have been many reports on the use of self-expanding metallic stents in colorectal diseases, mainly from the West. Self-expanding metallic stent is generally used as a palliative treatment for malignant strictures of the colon and rectum and before bridge as a surgery for obstructing colorectal cancers^[1-3]. Some investigators have reported on the usefulness of self-expanding metallic stents for strictures of benign diseases^[4,5]. Management of narrow (<5-mm) colonic anastomotic stricture mainly is performed endoscopically by repeated balloon dilation, often ineffectively^[6]. The use of metallic self-

expanding stents in malignant and benign strictures of the large bowel has been suggested only recently, and is still being debated^[7,8]. In this report we proposed a single-stage procedure that we developed to manage narrow anastomotic colonic strictures.

CASE REPORT

A 46-year-old man undergoing two procedures of surgery for perforation of descending colon due to a traffic accident presented with pain, abdominal distention, and inability to defecate. Single-contrast barium enema radiograph showed a severe stenosis in the region of surgical anastomosis. The patient was too weak to accept another laparotomy. He reached us with a significant stricture of the descending colon anastomoses (smaller than 5 mm in diameter).

With the patient in supine position and two knee joints reflexing, a catheter was inserted over a hydrophilic guide-wire through the anus to the lesion targeted under fluoroscopic and endoscopic guidance. An 85-cm 6-F catheter (Cook) and a 180-cm 0.35-inch guide wire (Bard) were used. The guide wire was maneuvered passing the stricture and the catheter was advanced. This guide wire was then replaced with another guide wire (Amplatz super stiff Guide Wire) for stent delivery and insertion. The stent was then positioned precisely across the lesion and released. The symptoms were released immediately, but on the next day the patient manifested abdominal distention, and inability to defecate. Anteroposterior radiographs from a follow-up barium study showed the stent migrated and a second stent was needed. The second stent was deployed with the same stent placement techniques. Radiographs obtained after a water-soluble enema on the day after the second stent deployed showed that the stents expanded to provide an adequate lumen (Figures 1-4). The first coated stent (Nanjing MicroTech, China) was 12-cm in length, 32-mm in diameter. The second uncoated stent (Nanjing MicroTech, China) was 20-cm in length, 32-mm in diameter. At the time of this writing, ie, 18 mo of follow-up evaluation, the patient could defecate without any difficulty.

Figure 1 Stenosis at the segment of descending colon, less than 5 mm in diameter.

Figure 2 The first stent was appropriately positioned and deployed by withdrawing the enveloping membrane under fluoroscopic control to ensure that the lesion was adequately covered, thus relieving the obstruction.

Figure 3 Clinical symptoms of obstruction recurred the next day. Anteroposterior radiographs showed the stent migrated above the lesion and a second stent was needed. Second stent was deployed with the same stent placement techniques through the lumen of the first stent.

Figure 4 Radiograph obtained after a water-soluble enema on the day after the second stent was deployed shows that the stents expanded to provide an adequate lumen.

DISCUSSION

Benign postoperative anastomotic strictures are frequent^[9]. Several methods of treatment for benign anastomotic strictures after previous resection have been described, including microwave coagulation therapy, balloon and endoscopic bougie dilation, *etc*^[10-14]. Placement of self-expanding metallic stents across narrower anastomotic colonic strictures is a viable alternative to colostomy and, by avoiding emergent surgery, could potentially lower morbidity and mortality^[15-17]. The method of stent placement for treatment of benign colonic disorders is the same as that used in cases of malignant strictures, but few experiences with the placement of metallic stents for benign colonic disorders have been reported in the

literatures. The indications for stenting were failure to establish dilatation therapy and/or refusal of surgical treatment, in high-risk patients^[4-6].

In this case, the patient underwent two times of surgery and he was too weak to accept another surgery. Stenting might represent a therapeutic alternative, in cases of anastomotic strictures of esophageal carcinoma^[18,19]. Endoprotheses may have a more lasting dilating effectiveness than balloons or endoscopic bougies, and the ease of recovering the stent when it has fulfilled its purpose could make treatment of the stenosis last for months or years^[4-6].

Stent migration may be one of the most complications in treatment of anastomotic strictures. The stent tended to migrate once the stenosis was widened to a diameter at which it could no longer hold the prosthesis in place, and this phenomenon was followed by a recurrence of the clinical symptoms a few days later, which necessitated a series of interventions in these patients. The first stent migration happened and the second stent was needed to be placed in this case^[20-22].

We conclude that the application of self-expandable metallic stents in benign stenosis of the gastrointestinal tract may be a possible therapeutic tool in selected patients. Further trials with a greater number of patients dealing with the questions of duration of stay of self-expandable metallic stents and choice of stent type are needed.

Abstract

AIM: To determine the role of mucosal gene expression of cyclooxygenase 2 (COX-2), pS₂ (belongs to trefoil peptides), inducible nitric oxide synthase (iNOS) and transforming growth factor alpha (TGFα) in gastric adaptation to water immersion and restraint stress (WRS) in rats.

METHODS: Wistar rats were exposed to single or repeated WRS for 4 h every other day for up to 6 d. Gastric mucosal blood flow (GMBF) was measured by laser Doppler flowmeter-3. The extent of gastric mucosal lesions were evaluated grossly and histologically and expressions of COX-2, pS₂, iNOS and TGFα were determined by reverse transcriptase polymerase chain reaction (RT-PCR) and Western blot.

RESULTS: The damage to the surface of gastric epithelium with focal areas of deep haemorrhagic necrosis was induced by repeated WRS. The adaptive cytoprotection against stress was developed with activation of cell proliferation in the neck regions of gastric glands. The ulcer index (UI) in groups II, III and IV was markedly reduced as compared with group I (I: 47.23±1.20; IV: 10.39±1.18, $P<0.01$). GMBF significantly decreased after first exposure to WRS with an adaptive increasement of GMBF in experimental groups after repetitive challenges with WRS. After the 4th WRS, the value of GMBF almost restored to normal level (I: 321.87±8.85; IV: 455.95±11.81, $P<0.01$). First WRS significantly decreased the expression of pS₂ and significantly increased the expressions of COX-2, iNOS and TGFα. After repeated WRS, pS₂ and TGFα expressions gradually increased (pS₂: I: 0.37±0.02; IV: 0.77±0.01; TGFα: I: 0.86±0.01; IV: 0.93±0.03, $P<0.05$) with a decrease in the expressions of COX-2 and iNOS (COX-2: I: 0.45±0.02; IV: 0.22±0.01; iNOS: I: 0.93±0.01; IV: 0.56±0.01, $P<0.01$). Expressions of pS₂, COX-2, iNOS and TGFα showed regular changes with a good relationship among them.

CONCLUSION: Gastric adaptation to WRS injury involves enhanced cell proliferation, increased expression of pS₂ and TGFα, and reduced expression of COX-2 and iNOS. These changes play an important role in adaptation of gastric mucosa after repeated WRS.

INTRODUCTION

Gastric mucosa can enhance resistance to injury after exposure to repeated insults of noxious agents, such as aspirin, alcohol, stress or *H. pylori*-related gastrotoxins. This phenomenon is called gastric adaptation^[1]. It has been postulated that gastric adaptation involves enhancement of gastric blood flow and increased mucosal cell proliferation mediated by some growth factors, such as epidermal growth factor (EGF) or TGFα. The fact that the adaptation to stress is associated with increased cell proliferation let us to hypothesize that this process might be mediated by pS₂, COX-2, iNOS and TGFα.

It is now well established that trefoil peptides have cytoprotective functions in protecting the gastrointestinal tract against ongoing damage from agents as diverse as ethanol, non-steroidal anti-inflammatory drugs and restraint stress^[2]. The mechanism for this action is unclear. The pronounced and protracted increase in trefoil peptide expression in the inflamed and ulcerated stomach, intestine and colon implicates peptides in reparative processes of the injury gut. Studies reported that pS₂ took part in the protracted phase of glandular renewal (marked by proliferation, differentiation and migration)^[3]. TGFα, a 50 amino acid polypeptide produced in normal gastric mucosa, promotes cell proliferation, inhibits gastric acid secretion and exhibits gastroprotective activity against acute damage induced by topical irritants or stress^[4]. In addition, an increased TGFα mRNA expression has been detected during healing of chronic experimental ulcers and acute damage of gastric mucosa in rats, suggesting its important role in gastric mucosal repair. Previous studies showed that COX-2 was an inducible enzyme. Recently, studies have suggested that COX-2 is a constitutive enzyme expressed in gastrointestinal tract also, even plays a more important role than COX-1 for mucosal integrity^[5]. Gut epithelial COX-2 is rapidly induced by inflammatory stimuli, interleukin and TGFα. Suppression of COX-2 could result in exacerbation of inflammation-associated colonic injury, and impair the healing of gastric ulcer. It is generally accepted that nitric oxide (NO) plays an important role in gastric ulcer healing. NO production is highly increased by iNOS.

The aim of the present study was to determine the role of the expression of pS₂, COX-2, iNOS and TGFα, and the relationship among them in gastric adaptation to WRS in rats.

MATERIALS AND METHODS

Induction of gastric adaptation to WRS

Thirty male Wistar rats, weighing 210-250 g and fasted for 24 h with free access to water, were used. The animals were deprived of water 1 h before the experiment and divided into: normal control group ($n = 6$) and experimental control group ($n = 24$). After fasted for 24 h, the rats of normal control group were lightly anesthetized with ether and tied up on the rat board, the abdomen was opened, the stomach was exposed and GMBF

was measured in the oxyntic gland area, and then gastric mucosa was sampled. The rats of experimental control group were divided into four subgroups ($n = 6$ in each group) and exposed to repeated WRS^[3]. The rats of group I were lightly anesthetized with ether, tied up on the rat board and exposed to WRS for 4 h by placing in the water at 20-23 °C to the rat's xyphoid level at 10:00 am on the 1st d. Then the rats were anesthetized with pentobarbital (30 mg/kg ip), GMBF was measured and gastric mucosa was sampled. The rats of group II were treated similarly except that after WRS they were removed from the water, placed at room temperature, and refed with food and water until 10:00 am on the next day, at which time they were starved again for 24 h, and WRS was repeated. The rats of groups III and IV were exposed to the 3rd or 4th WRS as described above.

Measurement of GMBF

GMBF was measured by using laser Doppler flowmetry (LDF-3 flowmeter, Nankai University, Tianjin, China). In brief, the rats were anesthetized with pentobarbital (30 mg/kg ip), the abdomen was opened, the stomach was exposed and transected, and the gastric contents were gently evacuated to the exterior through the cut made in the stomach. Then, an optical probe was placed gently 0.5 mm above and perpendicular to the mucosal surface in the oxyntic gland area to monitor GMBF displayed in mV (value of Doppler signal voltage) on the digital panel of the flowmeter. After GMBF was stable, four points were selected for measurement (one point for 1 min) and the average value was calculated and expressed as U/mV .

Appreciation of UI

Mucosal lesions were evaluated by the score systems reported by Nie *et al.*^[3]. Briefly, after the measurement of GMBF, the stomach was dissected out and opened along the greater curvature, then examined with a 10× magnifier for the presence of erosions and scored as follows: 1 point for small round hemorrhagic erosions; 2 points when the length of hemorrhagic erosions was less than 1 mm; 3 points when the length was 1-2 mm; 4 points when the length was 2-3 mm; 5 points when the length was longer than 4 mm; and the score value multiplied 2 when the width of erosions was larger than 1 mm.

Detection of mRNA in pS2, COX-2, iNOS and TGF α by RT-PCR

The stomachs were removed from rats with intact gastric mucosa and from those exposed to a single stress or repeated stresses. Mucosal specimens (about 100 mg) were scraped off using a slide glass and immediately snap frozen in liquid nitrogen and stored at -80 °C until analysis. Total RNA was isolated from mucosal samples using a guanidium isothiocyanate/phenol chloroform single step extraction kit from Stratagene (Gibco BRL, USA). Following precipitation, the RNA was resuspended in RNase-free buffer and the concentration was estimated by absorbance at 260 nm wavelength. Furthermore, the quality of each RNA sample was determined by running the agarose formaldehyde electrophoresis. RNA samples were stored at -80 °C until analysis.

Single-stranded complementary DNA (cDNA) was generated from 5 μ g of total cellular RNA using StrataScript™ reverse transcriptase (Gibco BRL, USA) and oligo (dT) primers (Gibco BRL, USA). Briefly, 5 μ g of total RNA was used as the template to synthesize complementary DNA with 2.5 units of Maloney murine leukemia virus reverse transcriptase in 5 μ L of buffer containing 10 mmol/L Tris-HCl (pH 8.3), 50 mmol/L KCl, 5 mmol/L MgCl₂, 1 mmol/L of each deoxyribonuclease triphosphate, 2.5 mmol/L of oligo (dT) primers and 1.4 U/ μ L RNase blocker. Reverse-transcription was performed at room temperature for 20 min, then at 37 °C for 15 min, at 90 °C for 5 min and at

5 °C for min. The resulting cDNA was used as a template for subsequent PCR.

A 124-base pair (bp) fragment of pS2 was amplified from single-stranded DNA by PCR using two oligonucleotide primers to pS2 sequence: sense primer, 5'-CCATGGAGCACAAGGTGA CCTG-3' and antisense primer, 5'-GGGAAGCCACAATTTAT TCT-3'. A 230-base pair (bp) fragment of COX-2 was amplified from single-stranded DNA by PCR using two oligonucleotide primers to COX-2 sequence: sense primer, 5'-GCCACCTCTGCG ATGCTCTT-3' and antisense primer, 5'-GTGTTTGGGGTGGGC TTCAG-3'. A 576-base pair (bp) fragment of iNOS was amplified from single-stranded DNA by PCR using two oligonucleotide primers to iNOS sequence: sense primer, 5'-GTGTTCCACCAGG AGATGTTG-3' and antisense primer, 5'-CTCCTGCCCACTGA GTTCGTC-3'. A 246-base pair (bp) fragment of TGF α was amplified from single-stranded DNA by PCR using two oligonucleotide primers to TGF α sequence: sense primer, 5'-TCTGGGTACGTGGGTGTTTCG-3' and antisense primer, 5'-AGAGTGGCAGCAGGCAGTCC-3'. Concomitantly, amplification of the 521 bp fragment of rat β -actin was performed on the same RNA samples to assess RNA integrity using two oligonucleotide primers to β -actin sequence: sense primer, 5'-TGGGACGATATGGAGAAGAT-3' and antisense primer, 5'-ATTGCCGATAGTGATGACCT-3'. The nucleotide sequences of the primers for pS2, COX-2, iNOS and TGF α were based on the published cDNA sequences encoding pS2, COX-2, iNOS and TGF α ^[3,6,7]. The primers were synthesized by Bo-Ya Biotechnical Co. Ltd, Shanghai, China.

Reaction mixture for PCR contained cDNA template (2 μ L), 50 pmol of each primer, and 2.5 U of *Termus aquaticus* DNA (Promega) in 10 mmol/L Tris-HCl (pH 8.8), 50 mmol/L KCl, 1.5 mmol/L MgCl₂, 0.5 mmol/L dNTPs in a volume of 50 μ L. RT blanks (no RNA included) were incubated in each analysis. The mixture was overlaid with 25 μ L of mineral oil to prevent evaporation. Amplification was performed using a DNA thermal cycler for 35 cycles, each cycle consisting of denaturation for 2 min at 94 °C, annealing for 45 s at 55 °C (pS2), 52 °C (COX-2, iNOS) and 60 °C (TGF α), and extension for 1 min at 72 °C. The final cycle included an extension for 5 min at 72 °C to ensure a full extension of the product. The number of amplification cycles was previously determined to keep amplification in the linear to avoid the "plateau effect" associated with increased number of PCR cycles. Eight microliters of each PCR product was electrophoresed on 16 g/L agarose gel stained with ethidium bromide, and then visualized under *uv* light. Location of predicted PCR products was confirmed by using DNA digest phix 174/Hae III as a stained size marker. The gel was then photographed under *uv* transillumination. In addition to size analysis by agarose gel electrophoresis, specificity of the primer pairs for pS2, COX-2, iNOS and TGF α was assessed by sequencing PCR products. For quantification, we determined the intensity of PCR products on the negative film of gel photographs according to Morrissey *et al.*^[6]. Expression of the products was quantified using a video image analysis system (Tanon GIS-1000, Tanon Technical Co, Ltd, Shanghai, China). An index of mRNA expression was determined in each sample according to Konturek *et al.*^[8].

Western blot analysis of pS2, COX-2, iNOS and TGF α proteins

Gastric tissues for the analysis of protein expressions of pS2, COX-2, iNOS and TGF α were homogenized in a proteinase inhibitor buffer containing 50 mmol/L Tris HCl (pH 7.5), 150 mmol/L NaCl, 5 g/L β -cholate sodium, 1 g/L SDS, 2 mmol/L EDTA, 10 mL/L Triton X-100, 100 g/L glycerol, 1 mmol/L PMSF and aprotinin, and then centrifuged at 10 000 g for 15 min at 4 °C. The supernatant was collected and the protein content was determined with the dye-binding (Bio-Rad) method. Thirty micrograms of total protein was loaded onto SDS-polyacrylamide

gel and blotted onto hybrid C membranes (Amersham Life Science, Little Chalfont, Buckinghamshire, England) by electrophoresis. Pre-stained rainbow recombinant protein molecular mass markers (Amersham International plc, Little Chalfont, Buckinghamshire, England) were used for molecular mass determinations. Membranes were blocked with blocking buffer containing 50 g/L fat free milk powder, 10 mmol/L Tris-HCl (pH 7.5), 100 mmol/L NaCl and 1 mL/L Tween 20 for 1 h at room temperature. The blots were incubated overnight at 4 °C with 1:1 000 dilution of polyclonal antibodies against pS2 and TGF α (Stress-Gen, Victoria, Canada), monoclonal antibody against iNOS (Transduction Lab, Lexington, Kentucky, USA), polyclonal antibody against COX-2 (Santa Cruz Biotechnology INC, Santa Cruz, California, USA). After washed in washing buffer for 30 min, the membranes were treated with HRP conjugated secondary antibody (1:4 000 dilution) (Bio-Rad) for 1 h at room temperature, followed by another 30 min of washing. The ECL Western blotting system (Amersham Life Sciences) was used in accordance with the manufacturer's instructions for chemiluminescence of proteins, and the blots were then exposed to photographic films.

Statistical analysis

Results were expressed as mean \pm SD. Statistical comparisons were made by Student's *t* test. Linear correlation analysis was used to analyse the relationship between two variants. *P* values less than 0.05 were considered statistically significant.

RESULTS

Damage to the surface of gastric epithelium with focal areas of deep haemorrhagic necrosis was induced by repeated WRS. The adaptive cytoprotection against stress was developed

with activation of cell proliferation in the neck regions of gastric glands. The UI in groups II, III and IV was markedly reduced as compared with group I (I: 47.23 \pm 1.20; IV: 10.39 \pm 1.18, *P*<0.01). GMBF significantly decreased after the first exposure to WRS with a adaptive increasement of GMBF in experimental groups after repetitive challenges with WRS. After the 4th WRS, the value of GMBF almost restored to normal level (I: 321.87 \pm 8.85; IV: 455.95 \pm 11.81, *P*<0.01). The first WRS significantly decreased the expression of pS2 and significantly increased the expression of COX-2, iNOS and TGF α . After repeated WRS, pS2 and TGF α expressions gradually increased (pS2: I: 0.37 \pm 0.02; IV: 0.77 \pm 0.01; TGF α : I: 0.86 \pm 0.01; IV: 0.93 \pm 0.03, *P*<0.05) with a decrease in the expression of COX-2 and iNOS (COX-2: I: 0.45 \pm 0.02; IV: 0.22 \pm 0.01; iNOS: I: 0.93 \pm 0.01; IV: 0.56 \pm 0.01, *P*<0.01). The expressions of pS2, COX-2, iNOS and TGF α showed regular changes with a good relationship among them (decrease of COX-2 and iNOS was accompanied by an increased expression of pS2 and TGF α after 4 consecutive WRS). (Figure 1, Table 1).

DISCUSSION

The cytoprotective functions of pS2, COX-2, iNOS and TGF α in the gastrointestinal tract against ongoing damage may be accomplished in several ways, and there evidence is that these factors participate in both the early phase of epithelial repair known as restitution (marked by increased cell migration but no proliferation), and in the subsequent protracted phase of glandular renewal (marked by proliferation, differentiation and migration)^[9-11].

In this study, when WRS was applied once, it produced numerous gastric mucosal erosions, the adaptive cytoprotection against stress was developed after repeated stresses, and mucosal lesions were reduced markedly after the 2nd, 3rd and

Figure 1 Expression of pS2 mRNA and β -actin (A), COX-2 mRNA and β -actin (B), iNOS mRNA and β -actin (C), TGF α mRNA and β -actin (D) in gastric mucosa of rats after repeated exposure to WRS and in control intact rats. Lane M: PCR size marker; Lane 1: control group; Lane 2-5: groups I-IV.

4th WRS. The expressions of COX-2, iNOS and TGF α were all up-regulated, but that of pS2 was down-regulated after the first stress in rats with WRS-induced ulcers. But the major finding of this study was the gastric adaptation to WRS involving a gradually decrease of overexpression of COX-2 and iNOS, and a gradually increase of expression of pS2 and TGF α , and an increased rate of cell proliferation in the gastric mucosa.

Members of the trefoil peptide family, including pS2, share a common structural feature, which is a motif of six cysteine residues termed a trefoil or a P domain. There is increasing evidence that trefoil peptides are important in maintaining the integrity of gastric mucosae and involved in the repair of ulcerated areas in the gastrointestinal tract^[12-16]. This is supported by an observation that an increased expression of trefoil peptides was found in the ulcer-associated cell lineage (UACL), which is a glandular structure adjacent to the ulcerated mucosa^[17], and by the findings from *in vitro* studies showing that trefoil peptides exhibited a mitogenic effect on different cell lines^[18,19]. It has also been reported that the trefoil peptide family could contribute to gastric mucosal defence and repair by affecting cell proliferation^[1,20].

It has been found that NO produced from inflammatory cells by the inducible isoforms of NOS has antimicrobial, antitumor and cytotoxic effects, but an excessive amount may lead to peroxynitrite formation, protein tyrosine nitration, hydroxyl radical production and tissue damage^[21]. The present study also demonstrated that overexpression of iNOS on d 1 after the first stress was accompanied with the enlargement of ulcer crater. The expression of iNOS protein was declined when the ulcer began to heal. High expression and enzymatic activity of COX at the late ulcer healing stage were observed in stress. The changes of COX activity might be mainly due to the changes of protein level and activity of COX-2. Since tissue remodeling including reepithelization of gastric mucosa, maturation of granulation tissue, and reconstruction of extracellular matrix mainly occurs at the late ulcer healing stage, COX-2 plays an essential role in these remodeling processes^[5,22-31].

There may be interactions among pS2, COX-2, iNOS and TGF α . In the present study, after the 4th WRS, GMBF almost restored to normal level, and during the process of tolerant cytoprotection, GMBF, UI and expressions of pS2, COX-2, iNOS and TGF α showed regular changes and a good relationship among them. A dramatic decrease of COX-2 and iNOS was accompanied with an increase expression of pS2 and TGF α after the 4th stress. This inverse relationship between COX-2, iNOS and pS2, TGF α expressions support the existence of a close interaction among these factors.

Trefoil peptides are a new class of regulatory peptides involving mucosal protection and repair in the gastrointestinal tract. NO and epithelium-associated mucin have important roles in sustaining mucosal integrity in the gastrointestinal tract, and trefoil peptide modulate epithelial NO production via the iNOS pathway^[32-35].

Treatment with COX-2 inhibitors and COX-2 antisense oligonucleotides could suppress these responses induced by TGF α , suggesting the involvement of COX-2 in proliferation of gastric mucosal epithelium, and the synergistic stimulation of COX-2 expression by TGF α . Gut epithelial COX-2 could be rapidly induced by inflammatory stimuli, interleukin and TGF α ^[4,36-40].

We confirmed that WRS-adapted mucosae exhibited an augment action of GMBF, but it is not clear whether COX-2, iNOS and pS2 could directly or indirectly account for the mucosal adaptation, or what is the mechanism of this mucosal hyperemia in the stomach. TGF α has been shown to increase GMBF^[41], while trefoil peptides could promote synthesis of TGF α ^[42-48]. Hence, we believe that hyperaemia observed during the development of adaptation might be mediated by the release of COX-2, iNOS and pS2.

In summary, different expressions of pS2, COX-2, iNOS and TGF α occur during gastric ulceration and healing. COX-2 and iNOS may contribute to tissue inflammation during ulcer formation, while pS2 and TGF α may promote ulcer healing by proliferation, since their expressions are correlated with the protracted phase of glandular renewal of ulcer tissues.

Abstract

In the past decade, a variety of interventional procedures have been employed for local control of hepatocellular carcinoma (HCC). These include transcatheter arterial chemoembolization (TACE) and several tumour ablation techniques, such as percutaneous ethanol injection (PEI), radio-frequency ablation (RFA), or percutaneous microwave coagulation therapy (PMC), laser-induced interstitial thermotherapy (LITT), *etc.* For a definite assessment of the therapeutic efficacy of interventional procedures, histological examination using percutaneous needle biopsy may be the most definite assessment of the therapeutic efficacy of interventional therapy, however, it is invasive and the specimen retrieved does not always represent the entire lesion owing to sampling errors. Therefore, computed tomography (CT) and magnetic resonance imaging (MRI) play a crucial role in follow-up of HCC treated by interventional procedures, by which the local treatment efficacy, recurrent disease and some of therapy-induced complications are evaluated. Contrast enhanced axial imaging (CT or MR imaging) may be the most sensitive test for assessing the therapeutic efficacy. The goal of the review was to describe the value of CT and MRI in the evaluation of interventional treatments.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common cancers in the world^[1]. Its mortality is secondary to lung cancer in urban and gastric carcinoma in countryside in China^[2]. So far, surgical treatments including hepatic resection and liver transplantation are considered as the most effective treatment of HCC. However, less than 20% of HCC patients have been treated surgically, mainly because of multi-focal diseases, proximity of tumour to key vascular or biliary structures that precluded a margin-negative resection, potentially unfavorable biology with the presence of multiple liver metastases, or inadequate functional hepatic reserve related coexistent cirrhosis^[3]. Palliative treatment of patients with inoperable HCC, including transcatheter arterial chemoembolization (TACE)^[4], percutaneous ethanol injection (PEI)^[5], laser-induced interstitial thermotherapy (LITT)^[6,7], and local thermal ablation techniques

(such as percutaneous microwave coagulation therapy (PMC)^[8,9] and radio-frequency ablation (RFA)^[10]) have been tried. Despite initial remission of HCC, results of various therapeutic modalities in the treatment of HCC and the survival benefits of patients treated with them were not satisfactory because of frequent recurrences following the treatment. Therefore, to prevent recurrences following the initial excellent response may be crucial to improve the long-term outcomes of patients with HCC treated by these modalities^[11]. Early detection of a residual or locally recurrent tumour after interventional treatments is critical and can facilitate successful retreatment at early stage. Late diagnosis is associated with peripheral regrowth and makes retreatment difficult owing to unfavorable geometry^[12]. Histological examination using percutaneous needle biopsy may be the most definite assessment of the therapeutic efficacy of interventional therapy, however, it is invasive and the specimen retrieved does not always represent the entire lesion owing to sampling errors. Therefore, computed tomography (CT) and magnetic resonance imaging (MRI) play a crucial role in follow-up of HCC treated by interventional procedures.

MATERIALS AND METHODS

Resection or transplantation provides the potentially curative or survival-enhancing treatment. The aims of palliative treatment are to slow down tumour progression and provide palliation, and to improve survival. Which includes the use of TACE alone or in combination with other local treatments. Each treatment plan is tailored to the individual patients according to their tumour stage, symptomatology, age and overall health, needs and wishes^[13]. Most combined multimodal interventional therapies have enormous advantages as compared with any single therapeutic regimen alone, and play more important roles in treating unresectable HCC^[14]. Non-surgical palliative techniques include the following.

Radio-frequency ablation

Similar to other ablation techniques, RFA depends on several factors, such as clinical status, stage of liver cirrhosis and HCC of patients. RFA can be performed percutaneously, laparoscopically or after laparotomy^[15]. In comparison with PEI, RFA could achieve tumour necrosis in fewer sessions, and create large volumes of tumour necrosis in a shorter period of time than either laser or microwave therapy. RFA showed good control of tumors with necrosis in more than 90% of HCCs smaller than 5 cm in diameter^[16-19]. In HCCs larger than 5 cm in diameter, results were unsatisfactory with complete necrosis in less than 30%^[20].

The mechanism of RF is that a high-frequency alternating current (100 to 500 kHz), mostly 460 kHz, passes from an uninsulated electrode tip into the surrounding tissues and causes ionic vibrations as the ions attempt to follow the change in the direction of the rapidly alternating current. Such ionic vibrations cause frictional heating of the tissues surrounding the electrode, rather than the heat generated from the probe itself. The goal of RFA is to achieve local temperatures so that tissue destruction occurs. At the temperature above 60 °C, intracellular protein changes including collagen denaturation,

lipid bilayer melt and cell death are inevitable. Thermal coagulation begins at 70 °C and tissues desiccate at 100 °C, producing coagulation necrosis of tumor tissue and surrounding hepatic parenchyma. Tissue heating also drives extracellular and intracellular water out of the tissue and results in further destruction of the tissues due to coagulative necrosis^[21,22].

Andrea *et al.* reported that most frequent complications reported in literature were capsular necrosis, intraperitoneal hemorrhage (usually self-limiting), subcapsular hematoma, cholecystitis, hepatic abscesses. Needle track seeding after RFA was reported with a low incidence of complications (0.6-2.8%).

Frequency of major complications related to the procedure was low, ranging from 5% to 15%^[23,24]. Self-limiting intraperitoneal bleeding, liver abscess and right pleural effusions were the most frequently reported complications^[25]. Tumor seeding along the needle tract was also described, but its incidence from 0.6% to 12%, has been a matter of debate^[26-29]. Curley and Izzo^[30] suggested that RFA could be performed for unresectable hepatic malignancies less than 6.0 cm in diameter. In addition, equipments used for RFA were less expensive than either laser or microwave equipments. RFA could provide local control of advanced liver tumours with a low recurrence and an acceptable morbidity^[31].

Percutaneous ethanol injection

Livraghi *et al.* reported that in 746 HCCs with cirrhosis treated by PEI, the 5-year survival rate for a single HCC <5 cm was 47% for Child A, 29 % for Child B and 0 % for Child C, respectively^[32]. PEI was contraindicated in the presence of gross ascites, bleeding, or obstructive jaundice. PEI has been widely used with excellent results in patients with less than three HCCs^[33,34]. Ethanol in PEI acts by diffusing within the cells, which causes immediate dehydration of cytoplasmic proteins with consequent coagulation necrosis followed by fibrosis, and by entering the circulation, which induces necrosis of endothelial cells and platelet aggregation with consequent thrombosis of small vessels followed by ischemia of the neoplastic tissues. Advantages for using PEI include^[35,36]: no remarkable damage to the remaining parenchyma, relative safety, easy repetition when new lesions appear as in the majority of patients followed up for 5 years, application anywhere due to its low cost and easy operation, and fairly good long-term results.

Percutaneous microwave coagulation

It is well known that percutaneous microwave coagulation therapy (PMC) under local anesthesia is a palliative and effective therapy when carried out on a single occasion to treat HCC located near the liver surface, and it could be safely performed under direct visual guidance^[37]. MCT might be superior to PEI for the local control of moderately or poorly differentiated small HCC^[38], and for treating patients with HCC greater than or equal to 15 mm in diameter. In such patients with well-differentiated HCC, PEI was as effective as PMC^[39].

Laser-induced interstitial thermotherapy

Laser-induced interstitial thermotherapy (LITT) is another minimally invasive and attractive method for destroying relatively larger tumours within solid organs by causing carbonization and vaporization in tissues^[40]. MR-guided LITT is a local effective therapy with a low morbidity for malignant liver tumours with a maximum quantity of 5 and a size less than or equal to 5 cm in diameter^[41]. LITT may be also equivalent to limited hepatic resection and may influence the long-term survival comparable to that of segmentectomy, but local recurrence could occur even in small HCC, but infrequent^[42,45].

Transcatheter arterial chemoembolization

TACE uses combined agents to compromise the flow of hepatic

artery. The agents include gelatin (gelfoam), iodized oil (lipiodol), and a cytotoxic agent. Retreatment can be performed in 6-12 wk. The 5-year survival rate was reported to be 6-22%. TACE has been shown to reduce systemic toxicity and increase local effects thus improving the therapeutic results. However, its perceived benefit for survival has not been substantiated in randomized trials, presumably because its anticancer effect is offset by its adverse effects on liver functions. Its therapeutic effect is also limited due to lack of appropriate and reliable embolic agents and when the tumour is infiltrative in nature or is too large or too small.

LOCAL ABLATION THERAPY

Local ablation therapies fall into one or two categories: direct intratumoural injection of compounds such as absolute ethanol (PEI) or hot saline, and thermal ablation techniques such as laser-induced interstitial thermotherapy (LITT), percutaneous microwave coagulation therapy (PMC) and radiofrequency thermal ablation (RFA). These techniques produce coagulation necrosis of tumours with use of cytotoxic compounds or thermal energy. So the lesion should be avascular, if it has been treated successfully. For example, a typical RFA treatment producing a local tissue temperature over 100 °C could result in coagulative necrosis of the tumor tissue and surrounding hepatic parenchyma. The tissue microvasculature was completely destroyed, and thrombosis of hepatic arterial, portal venous or hepatic venous branches less than 3 mm in diameter occurred. For the assessment of therapeutic responses to these techniques, the same diagnostic criteria previously reported for lesions treated with TACE and PEI could be applied^[43-45]. The imaging appearances of the lesions after these treatments were very similar, regardless of which local ablation technique was used^[46].

IMAGING FOLLOW UP OF RADIO FREQUENCY ABLATION CT

Contrast-enhanced helical CT has been widely used in the evaluation of residual or recurrent tumours or of complications such as abscess, infarction, or hemorrhage in patients who have undergone percutaneous ablation therapy for a hepatic tumour^[47]. All successfully ablated lesions appeared as areas of low attenuation without contrast enhancements at follow up CT. This unenhanced low-attenuation area is believed to represent necrosis^[48,49]. Any focal enhancement in the treated region should be considered as an indicative of residual or recurrent lesions^[50].

All of the peripheral enhanced lesions at a short-term follow-up CT performed within 1 mo after treatment should not be regarded as a residual viable tumour^[51]. Reactive hyperemia surrounds the ablation lesions in tissue. It represents inflammatory reactions in the thermal injury frequently occurred during this period. Similar findings at CT have been reported in patients who underwent percutaneous ethanol injection therapy and microwave coagulation therapy^[52]. Peripheral rim enhancement resulting from reactive hyperemia was usually uniform in thickness and enveloped the ablated lesion, whereas a residual tumour showed focal and irregular peripheral enhancements. The other useful differentiating point between the two conditions was the peripheral rim enhancement, indicating that the reactive hyperemia had a high or isoattenuation during portal venous and equilibrium phases^[53]. The residual tumour usually became low in attenuation during the equilibrium phase. In addition to reactive hyperemia, nontumorous wedge like enhancement could occur at the periphery of the ablated lesion owing to iatrogenic arteriovenous shunt^[54,55].

It is well known that percutaneous needle biopsy and ethanol injection therapy could produce arteriovenous shunt along the needle tract^[56,57]. It was usually easy to differentiate residual

tumours from arteriovenous shunt at multiphase helical CT, because a residual tumour usually showed a high attenuation during the hepatic arterial phase and a low attenuation during the portal and equilibrium phases^[58]. If the finding of short-term follow-up CT was inconclusive, follow-up CT at 1-3-mo intervals could be helpful before invasive diagnostic procedures, such as percutaneous biopsy or retreatment were performed if the suspected lesion was small. Nontumourously enhanced lesions produced by reactive hyperemia and arteriovenous shunt were usually resolved by this time. During this period, even if one failed in detecting small residual tumours, they have seldom grown to a size for which successful retreatment was not feasible.

The absence of contrast enhancement in the ablated lesion at short-term follow-up CT within 3 mo after treatment could not always indicate successful treatment, as later follow up studies would demonstrate tumour regrowth at the periphery of the ablated lesion^[44,59]. Mitsuzaki *et al.*^[60] reported that 8 of 38 ablated lesions with the absence of contrast enhancement at 1-mo follow-up CT showed tumour recurrence at the margin of the treated lesions at subsequent follow-up CT performed 4-13 mo after treatment.

MRI

MR imaging may have an edge over CT in the early detection of local regrowth due to the high sensitivity of T2-weighted images. Two months after RF therapy, a uniform hypointensity on T2-weighted images, associated with lack of enhancement of RF-treated areas on contrast-enhanced T1-weighted images, always corresponded to complete efficient treatment^[61]. Most of the RF-treated areas were hyperintense on unenhanced T1-weighted images, which was probably due to hemorrhage or a proteinaceous material within the RF-treated area^[62]. Most of the RF-treated areas were hypointense on T2-weighted images, and this hypointensity could be explained by the dehydrating effect of RF-induced thermal damage resulting in coagulative necrosis. However, a marked hyperintensity on T2-weighted images, found in 14% of the successful treated areas, could signify bilomas or liquefactive necrosis, as an active tumour always displayed a less T2 signal intensity^[63].

The higher sensitivity of MR imaging over CT was mostly due to the T2 weighted images, which were the only imaging study capable of depicting tumours in two cases at two months^[64]. The superior sensitivity of T2-weighted images could be explained by an increase in contrast between the coagulated area, which had a low signal intensity and the viable residual tumour, which had high signal intensity. Moderately hyperintense areas on T2-weighted images corresponded to the presence of residual viable tumour in all cases. Therefore, T2-weighted imaging was demonstrated to be highly specific. Moreover, the moderately hyperintense areas on T2-weighted imaging associated with corresponding enhancement on contrast-enhanced T1-weighted imaging could offer an optimal specificity (100%) for residual viable tumours in all cases^[65].

Local regrowths were always depicted at the periphery of the treated area either as irregular thickening of one margin of the treated area or a new tumour nodule. These peripheral locations of treatment failures could be explained by lower energy deposition and reduced heating that was remote from the needle electrode^[66]. Furthermore, tissue perfusion could lower heat accumulation to cooling, and this phenomenon was even more marked in tissues in contact with large vessels. Indeed, regrowth close to large vessels arose in two of nine cases in their study and was described by others^[67].

Peripheral regrowth should not be diagnosed when a thin and regular (<1 mm) rim of progressive contrast enhancement was present at 2 mo in 32% of the entire RF-treated area and better seen at the later phase after contrast material administration.

It has been shown by comparison with histological findings that the thin ring is vascularized inflammatory reaction with granulation tissues surrounding the zone of coagulation necrosis^[68,69].

Similar findings were less frequently described in hepatocellular carcinoma treated with alcohol injection^[70] and in hepatic metastases treated with laser-induced thermotherapy^[71,72]. The peripheral rim disappeared with time and was present in only 8% of RF-treated areas at 4 mo^[73]. It could easily be differentiated from an active tumour whose area of contrast enhancement was thicker and irregular. Another RF-induced modification was the presence of wedge-shaped enhancement on arterial phase images in the liver parenchyma adjacent to the RF-treated area. This enhancement probably corresponded to peripheral arteriportal shunts caused by either needle punctures and/or thermal damage. These wedge-shaped areas should not be misinterpreted as tumour contrast material uptake^[74].

Although there are many similarities between the radiological aspect of RF-induced destruction and the necrosis induced by ethanol^[75], some differences need to be pointed out. First, T2-weighted MR imaging was demonstrated to be the best indicator of the efficacy of RF-treatment^[76]. In contrast, Sironi *et al.* and Fujita *et al.*^[75] described a limited value of T2-weighted signal intensity pattern of tumours injected with alcohol in ascertaining the viability of the tumour. This might be due either to differences in technical parameters (fast spin echo with respiratory monitoring versus standard spin echo with a higher rate of motion artifacts in their studies), or to histopathologic nature of the initial tumours, which was very different in their study from that of previous reports. Second, the area of RF-induced coagulation necrosis shrank more slowly than that of ethanol-induced necrosis. Indeed, in their study, 66% of the treated areas shrank, achieving a mean reduction of 15% at 6 mo, and 35% at 12 mo.

IMAGING FOLLOW UP OF TACE

Iodized oil is widely used with TACE. Because iodized oil shows a prolonged uptake in tumours and is readily identified with CT. The degree of uptake and the distribution within the tumour and the surrounding hepatic parenchyma could provide useful information on the degree of tumour necrosis and strategy for the subsequent TACE^[77]. Since it is difficult to completely kill the tumor cells once by TACE, the treatment efficacy of TACE is influenced by many factors, such as the size of tumors, blood supply and the ultra-selectivity of the catheter, *etc.* TACE is a liver-directed therapy that takes advantages of the relatively selective vascularization of hepatic arterial tumors. HCC could derive approximately 80% to 85% of their blood supply from the hepatic artery, whereas the portal vein as well as the hepatic artery supplied the normal hepatic parenchyma^[78]. Chemotherapeutic agents could thus be delivered angiographically with concomitant embolization to increase the local chemotherapeutic dwelling time and induce tumor ischemia. It is very important to objectively assess the viability and necrosis of the tumors after TACE in HCC, and to give further treatment to improve the general therapeutic effects and the survival rate.

After ablation therapy, contrast-enhanced CT is a reliable method for the assessment of therapeutic efficacy. On contrast-enhanced CT, necrotic tissues were unenhanced and viable tumours were enhanced. After TACE with iodized oil, however, retained iodized oil of high attenuation made it difficult to determine the presence of contrast enhanced within the tumour. It is generally agreed that the areas with retained iodized oil after a certain period (e.g. >4 wk) could be considered indicative of necrosis.

The complete disappearance of tumour was designated as complete remission, a 50% or more decrease in tumour as partial response, a less than 50% decrease or 25% increase in tumour as no response, and a 25% or more increase as progressive

disease. The focal defect in the mass with iodized oil or focal washout of iodized oil during follow-up suggested the presence of a viable tumour in the corresponding area, and further TACE was recommended. Sometimes, branches of hepatic arteries were totally obliterated and collateral vessels could feed the part of the tumour. Each collateral vessel supplies a specific area. The inferior phrenic artery supplies the right subphrenic location near the bare area, the internal mammary artery supplies the near falciform ligament, and the omental branches supply the anterolateral subcapsular location, *etc*^[74]. Focal washout of iodized oil from those areas suggests the presence of collateral vessels. Therefore, a careful search for the appropriate collateral vessel should be made during subsequent TACE.

Generally, the CT follow-up of patients treated with oily chemoembolization could be affected by artefacts produced by high concentrations of lipiodol, making it difficult to evaluate the characteristics of the lesion. On the other hand, the homogeneous and complete deposition of lipiodol within the lesions would indicate the high degree necrosis of the tumors, but it was difficult to judge the viability and necrosis of the tumors correctly due to the inhomogeneous deposition, because lipiodol negative areas could not actually represent the viability of the tumors^[79,80]. The necrosis within the lesions before TACE was also a lipiodol negative area.

Several authors considered that MR imaging was valuable in the evaluation of therapeutic efficiency of TACE, especially on spin echo (SE) T₂WI, most of viable tumors were hyperintense and the coagulative necrosis within the tumors considered as a positive response to TACE was hypointense^[81,82]. But a signal intensity of the tumors after TACE was variable on SE T₁WI and T₂WI, but all of viable tumors, hemorrhage, liquefied necrosis and inflammatory infiltration could also result in hyperintensity on the T₂WI. Therefore, it was difficult to assess the viable tumors of HCC after TACE by conventional SE imaging. However, it was reliable to judge coagulative necrosis on T₂WI, especially the changes during the process of intratumor hemorrhage after TACE presenting as a hyperintensity and then turned into coagulative necrosis presenting a hypointensity. It was significant to compare the signal intensity of HCC on T₂WI before and after TACE to evaluate the degree of coagulative necrosis. The original hyperintensity of HCC turned to hypointensity indicated the presence of coagulative necrosis after TACE.

Fast multiplanar spoiled gradient-recalled (FMPSGR) dynamic contrast scanning plays a very important role in the detection and characterization of HCC. It is possible to obtain high quality images of the whole liver during a single breath-hold with rapid acquisition. It could demonstrate accurately the blood supply of tumors and reveal the contrast enhancement patterns of HCC. HCC is hypervascular and enhanced rapidly and obviously at the dynamic early phase scanning and declined at the late phase^[83,84]. FMPSGR dynamic contrast scanning also has a great value in the evaluation of therapeutic efficacy of TACE. The residual viable tumors were shown as rapidly enhanced portions within the lesions, homogeneous or inhomogeneous, when necrotic portions had no enhancement at the contrast early phase scanning. At the late phase scanning, the enhancement of the most lesions became hypointense, and just a few lesions showed a persistent enhancement. Pathologically, both viable tumors and inflammatory infiltration could present such changes, so the contrast early phase scanning was more reliable in the evaluation of viable tumors combined with conventional SE sequence, and more accurate to assess the viability and necrosis of tumors and useful in the follow-up of HCC patients after TACE.

SUMMARY

In summary, CT and MRI have advantages and disadvantages

for evaluating the local treatment efficacy, recurrent disease and some of the therapy-induced complications. Surgeons and interventional radiologists have to choose the most suitable imaging means for patients who are treated by interventional procedures. Contrast enhanced CT or MR imaging may be the most sensitive test for assessing the therapeutic efficacy. For the later follow up, contrast-enhanced CT or MRI is then performed at 1 mo and every 3-mo thereafter. A short-term follow-up CT or MRI within 1 mo after treatment is not a reliable method for assessing the precise therapeutic effectiveness, because reactive hyperemia and/or arteriovenous shunt often make an accurate evaluation difficult. Knowledge of the serial changes at long-term follow-up CT and MRI is helpful in assessing the therapeutic response to HCC after interventional treatments.

Abstract

AIM: To explore the feasibility of performing minimally invasive surgery (MIS) on subsets of submucosal gastric cancers that are unlikely to have regional lymph node metastasis.

METHODS: A total of 105 patients underwent radical gastrectomy with lymph node dissection for submucosal gastric cancer at our hospital from January 1995 to December 1995. Besides investigating many clinicopathological features such as tumor size, gross appearance, and differentiation, we measured the depth of invasion into submucosa minutely and analyzed the clinicopathologic features of these patients regarding lymph node metastasis.

RESULTS: The rate of lymph node metastasis in cases where the depth of invasion was $<500\ \mu\text{m}$, $500\text{--}2\ 000\ \mu\text{m}$, or $>2\ 000\ \mu\text{m}$ was 9% (2/23), 19% (7/36), and 33% (15/46), respectively ($P<0.05$). In univariate analysis, no significant correlation was found between lymph node metastasis and clinicopathological characteristics such as age, sex, tumor location, gross appearance, tumor differentiation, Lauren's classification, and lymphatic invasion. In multivariate analysis, tumor size ($>4\ \text{cm}$ vs $\leq 2\ \text{cm}$, odds ratio = 4.80, $P=0.04$) and depth of invasion ($>2\ 000\ \mu\text{m}$ vs $\leq 500\ \mu\text{m}$, odds ratio = 6.81, $P=0.02$) were significantly correlated with lymph node metastasis. Combining the depth and size in cases where the depth of invasion was less than $500\ \mu\text{m}$, we found that lymph node metastasis occurred where the tumor size was greater than $4\ \text{cm}$. In cases where the tumor size was less than $2\ \text{cm}$, lymph node metastasis was found only where the depth of tumor invasion was more than $2\ 000\ \mu\text{m}$.

CONCLUSION: MIS can be applied to submucosal gastric cancer that is less than $2\ \text{cm}$ in size and $500\ \mu\text{m}$ in depth.

INTRODUCTION

Minimally invasive surgeries (MIS) such as endoscopic mucosal resection or laparoscopic surgery are performed as a treatment of early gastric cancer. This limited surgery should be conducted on strict indication in early gastric cancer which has a limited invasion in mucosa. Such a surgery can be attained without lymph node dissection. However, if the case is diagnosed as submucosal gastric cancer after MIS, the patient needs additional gastrectomy and lymph node dissection owing to the limitations of current diagnostic methods in assessing the depth of invasion and lymph node status.

Since the incidence of lymph node metastasis in submucosal gastric cancer is reported as less as about 20%, it can be expected that the chance of further operations will be reduced if we choose patients who have low risk of lymph node metastasis. Thus, we analyzed in our study the clinicopathological factors related to lymph node metastasis in submucosal gastric cancers retrospectively, in order to find out the subsets of submucosal gastric cancers to which MIS can be applied, and to establish the suitable treatment policy of submucosal gastric cancers.

MATERIALS AND METHODS

This study enrolled 105 submucosal gastric cancer cases that were pathologically proven after gastrectomy by lymph node dissection at Seoul National University Hospital from January 1995 to December 1995. The relationship between clinicopathological factors (sex, age, tumor location, gross appearance, tumor size, depth of invasion, tumor differentiation, Lauren's classification, and lymphatic invasion) and lymph node metastasis was investigated. Submucosal layer was divided into 3 layers (upper third = SM1, middle third = SM2, and lower third = SM3) and submucosal depth of invasion was directly measured from muscularis mucosae by a micrometer (Figure 1). χ^2 test and logistic regression analysis were used to evaluate risk factors for lymph node metastasis and $P<0.05$ was considered statistically significant.

Figure 1 Depth of submucosal invasion of gastric cancer (arrow) in hematoxylin and eosin staining in A ($\times 10$) and B ($\times 100$). M: mucosa, MM: muscularis mucosae, SM: submucosa, MP: muscularis propria. This case was classified as SM1 or less than $500\ \mu\text{m}$ from muscularis mucosae.

RESULTS

Patient characteristics

A total of 105 patients with submucosal gastric cancer were included in the study. Of them, 74 were males and 31 were females. Their mean age was 54.9 years (18-80 years). The rate of lymph node metastasis was 22.9% (24/105 cases).

Depth of invasion (Table 1)

According to the SM category, SM1, SM2, and SM3 lesions were 28 (27%), 47 (45%), and 30 (28%) respectively. The depth of invasion measured directly from muscularis mucosae was less than 500 μm in 68% of SM1 gastric cancers, more than 1 000 μm (1 mm) in 75% of SM2 gastric cancers, and more than 2 000 μm in 84% of SM3 gastric cancers.

Table 1 Depth of submucosal invasion as compared with three SM category measurements

Depth (μm)	SM1 (%)	SM2 (%)	SM3 (%)
≤ 500 ($n = 23$)	19 (68)	4 (8)	0 (0)

^aNumber of cases with lymph node metastasis; ^bNumber of total cases.

DISCUSSION

Gastric cancer is the most prevalent cancer in Korea, which accounted for 20.3% of the whole cancer cases^[1]. According to the report of Korea Gastric Cancer Association, the ratio of early gastric cancer was increased from 28.6% in 1995 to 32.8% in 1999^[2], while this tendency was more obvious in Japan, where the ratio of early gastric cancer in the last 20 years was increased from 18% to 57%^[3].

Lymph node metastasis was the most important prognostic factor in gastric cancer^[4,5]. Radical gastrectomy with D2 lymph node dissection, therefore, has been recognized as the standard surgical operation for early gastric cancer. But, as the five year survival rate of early gastric cancer patients has reached 93-98% recently, there arises more interest in preservation of body function and maintenance of quality of life rather than in radical treatment in order to reduce complications or sequelae, such as Dumping syndrome, reflux gastroesophagitis, nutritional deficit, and weight loss. Therefore, interest in MIS such as endoscopic mucosal resection and laparoscopic surgery or function-preserving surgery has been increased.

MIS with no or limited lymph node dissection should be applied to tumors that are unlikely to metastasize into lymph nodes. Endoscopic ultrasonography (EUS) has been introduced recently to diagnose the depth of invasion and lymph node status. An overall accuracy of EUS was reported over 80%^[6,7]. Yet, as the accuracy of EUS is not high enough to predict accurate lymph node status, it is important to know the prognostic factors related to lymph node metastasis. There have been already many reports on the prognostic factors associated with lymph node metastasis in early gastric cancer^[8-16], such as sex^[8], tumor size^[3,9,10,12], depth of invasion^[11], gross appearance of tumor^[8], tumor differentiation^[13] and lymphatic invasion^[14,15]. If we combine these prognostic factors successfully in the diagnosis of certain subtypes that have no lymph node metastasis, then they may become an indication of MIS. For example, the current indications of endoscopic mucosal resection of early gastric cancer are as follows, namely differentiated adenocarcinoma, mucosal cancer < 10 mm in diameter in IIb and IIc lesions without ulcer or ulcer scar, and mucosal cancer < 20 mm in diameter in IIa lesion^[17,18]. The reason why endoscopic mucosal resection can be applied to them is that these lesions are considered to have no lymph node metastasis.

When the depth of invasion reached mucosa in early gastric cancer, the rate of lymph node metastasis was reported as 1-3%, and submucosa as 11-20%^[19]. At present if endoscopic mucosal resection for early gastric cancer can detect the invasion of submucosal layer, additional gastrectomy and lymph node dissection are regarded necessary. However, as the incidence

of lymph node metastasis was about 20% in submucosal gastric cancer, lymph node dissection could be omitted if we chose cases with good selection of indications. In our study on submucosal gastric cancer, we found that sex, age, tumor location, tumor differentiation, Lauren's classification, gross appearance of tumor, were not associated with lymph node metastasis, but tumor size and depth of invasion were associated with lymph node metastasis. A recent study reported that there was a significant difference in the rate of lymph node metastasis according to submucosal depth of invasion, and the possibility of limited surgery for superficial submucosal gastric cancer was therefore suggested^[20]. We divided submucosal layer minutely into SM1, SM2, and SM3 on microscopic field and measured the depth of invasion by a micrometer directly from muscularis mucosae. Actually, because there was some difference between SM 1, 2, 3 categories and the directly measured depth associated with lymph node metastasis, it was considered more objective to use directly measured depth rather than SM category to describe submucosal tumor invasion. Ishigami *et al.*^[21] reported that patients with both slight invasion into submucosa and horizontal expansion that was < 5 mm were often negative in lymph node involvement. Kurihara *et al.*^[22] reported that when the pathological report revealed SM1 invasion after laparoscopic or endoscopic surgery, reoperation should be regarded unnecessary because SM1-carcinoma with its diameter less than 2 cm did not usually metastasize to lymph nodes. Moreover, Yasuda *et al.*^[23] showed that local resection could be applied when the depth of submucosal invasion was < 300 μm and tumor size was < 1 cm. Yamada *et al.*^[24] also showed that local resection might be possible when the depth of submucosal invasion was < 500 μm and tumor size was < 1.5 cm. Gotoda *et al.*^[25] proposed to expand the criteria for local treatment of submucosal gastric cancer by showing that none of the 145 differentiated adenocarcinomas, < 30 mm in diameter and without lymphatic or venous permeation, was associated with lymph node metastasis, provided the lesion invaded less than 500 μm into submucosa. In our study, the tumor size and depth of invasion as independent prognostic factors associated with lymph node metastasis were joined together. In cases where the depth of invasion was < 500 μm , lymph node metastasis was not found when the tumor size was < 4 cm. In cases where the tumor size was less than 2 cm, lymph node metastasis was not found when the depth of invasion was less than 2 000 μm . Therefore, the results suggest that additional operation is unnecessary when the depth of submucosal invasion is less than 500 μm and the tumor size is smaller than 2 cm after local excision. Moreover, in case that patients cannot endure general anesthesia because of old age or cardiopulmonary disability, in case that gastrectomy itself (with or without lymph node dissection) is considered to be dangerous to patients, or when patients refuse the operation, local excisions such as endoscopic mucosal resection, can be applied to submucosal gastric cancer.

In conclusion, the depth of invasion measured directly by a micrometer is more objective to describe cancer permeation into submucosal layer because it is associated more with lymph node metastasis than with SM category.

Our results suggest that additional operation is not necessary after MIS for submucosal gastric cancer when the depth of invasion is less than 500 μm and the tumor size is smaller than 2 cm.

Abstract

AIM: Aberrant DNA methylation of CpG site is among the earliest and most frequent alterations in cancer. Several studies suggest that aberrant methylation of the CpG sites of the tumor suppressor gene is closely associated with carcinogenesis. However, large-scale analysis of candidate genes has so far been hampered by the lack of high-throughput approach for analyzing DNA methylation. The aim of this study was to describe a microarray-based method for detecting changes of DNA methylation in cancer.

METHODS: This method used bisulfite-modified DNA as a template for PCR amplification, resulting in conversion of unmethylated cytosine, but not methylated cytosine, into thymine within CpG islands of interest. Therefore, the amplified product might contain a pool of DNA fragments with altered nucleotide sequences due to differential methylation status. Nine sets of oligonucleotide probes were designed to fabricate a DNA microarray to detect the methylation changes of p16 gene CpG islands in gastric carcinomas. The results were further validated by methylation-specific PCR (MSP).

RESULTS: The experimental results showed that the microarray assay could successfully detect methylation changes of p16 gene in 18 gastric tumor samples. Moreover, it could also potentially increase the frequency of detecting p16 methylation from tumor samples than MSP.

CONCLUSION: Microarray assay could be applied as a useful tool for mapping methylation changes in multiple CpG loci and for generating epigenetic profiles in cancer.

INTRODUCTION

The epigenetic event has been observed in GC-rich regions, called CpG islands, frequently located in the promoter and the

first exon regions of genes. CpG island hypermethylation is closely associated with transcriptional inactivation of tumor suppressor genes, which is a common feature in human carcinomas^[1]. Hypermethylated CpG islands therefore play a causal role in promoting tumor development and are useful molecular markers for cancer diagnosis and prognosis. p16, an inhibitor of the cyclin D-dependent protein kinases, is a classic tumor suppressor gene, and its inactivation is closely associated with carcinogenesis. Hypermethylation of the CpG islands of the p16 gene has been proposed as an alternative mechanism for the loss of p16 expression. p16 hypermethylation could be detected in each stage, which is consistent with the finding that aberrant methylation of p16 is a very early event in carcinogenesis^[2]. Detection of promoter hypermethylation of cancer-related genes may be useful for cancer diagnosis or the detection of recurrence^[3,4].

At present, several molecular biology methods are routinely used to determine the methylation status of a CpG island, such as Southern blot^[5], bisulfite genomic DNA sequencing^[6], restriction enzyme-PCR^[7], methylation-specific PCR (MSP)^[8], methylation-sensitive single nucleotide primer extension (MS-SNuPE)^[9], electrochemistry^[10], etc. Among these, bisulfite nucleotide sequencing is a standard technique for detailed mapping of methylated cytosine residues within a gene promoter. This meticulous method, developed by Frommer *et al.*^[6], relies on the ability of sodium bisulfite to deaminate cytosine residues into uracil in genomic DNA, whereas the methylated cytosine residues are resistant to this modification. The target DNA is then amplified by PCR with specific primers to yield fragments in which all uracil residues are converted to thymine, whereas methylated cytosine residues are amplified as cytosine. The PCR products are sequenced and the methylation status of individual CpG sites is then analyzed by comparing it with the unmodified sequences of a given promoter. Using this conventional method, many investigators have addressed the importance of promoter CpG hypermethylation in the regulation of specific gene transcription in cancer^[11-14]. The method, which requires cloning and sequencing of individual inserts, can be labor intensive and is restricted to the evaluation of DNA methylation on a gene-by-gene basis. Such an approach has given researchers a limited picture of complex epigenetic alterations in cancer. Clearly, it is of great importance to establish novel, reliable and high-throughput methods for the methylation detection of earlier cancer diagnosis.

For this purpose, considerable advances have been made in hybridization-based microarray technology for genome-wide analysis of gene mutations and single nucleotide polymorphisms^[15-17]. In this new approach, oligonucleotides are arrayed on solid supports known as probes, and the labeled complex DNA mixtures to be interrogated are known as targets^[18]. Recently, we developed an oligonucleotide microarray to analyze methylation patterns of several adjacent CpG sites^[19]. The DNA microarray can successfully map the methylation pattern of p16^{Ink4a} gene. However, it can not be used to quantify the methylation level of promoter region of gene. Gitan *et al.*^[20] have developed a methylation specific oligonucleotide (MSO) microarray to analyze methylation of human estrogen receptor (ER) α gene. The targets were derived from PCR products of bisulfite-modified DNA, whereas the probes used a series of

arrayed oligonucleotides that can discriminate between converted and unconverted nucleotides, that is, unmethylated and methylated cytosines, at CpG sites. The MSO microarray is a novel and powerful tool for determining the methylation level in multiple CpG island loci and for generating epigenetic profiles in cancer.

The aim of this study was to use oligonucleotides microarray method to analyze methylation changes of p16 gene CpG islands in gastric carcinomas. A 336 bp segment was selected in the 5' untranslated region and the first exon of the p16 gene, as the investigated target, which contain 32 CpG sites. Nine sets of oligonucleotide probes were designed to test 23 CpG sites within the island. Here, we described the oligonucleotide microarray procedure and its application for analyzing the methylation changes of p16 gene CpG islands in gastric tumor and corresponding normal tissues.

MATERIALS AND METHODS

Tissue samples

Eighteen gastric tumor and corresponding normal tissues were obtained from Gulou Hospital (Nanjing, China). Genomic DNA was isolated by standard methods using proteinase K digestion and phenol/chloroform extraction.

Bisulfite genomic sequencing

Bisulfite processing of DNA was performed as described by Frommer *et al.*^[6] and the modifications introduced by Clark *et al.*^[21]. Briefly, 1 µg of genomic DNA was digested by *Eco*R I and denatured in 0.35 mol/L NaOH at 37 °C for 20 min. Bisulfite reaction was carried out in 3.2 mol/L sodium bisulfite and 0.5 mmol/L hydroquinone (Sigma Chemical Co., USA) at 55 °C for 16-24 h. DNA was recovered by a desalting column (DNA Clean-Up System, Promega Inc., USA) and desulphonated in 0.2 mol/L NaOH at 37 °C for 15 min, neutralized by ammonium acetate, alcohol precipitated, dried and then dissolved in 30 µL of deionized water. After bisulfite processing, all unmethylated cytosine residues converted to uracil, whereas the methylated ones remained unchanged. For bisulfite genomic sequencing the sense strand of a 336 bp fragment of the p16 gene 5'-CpG island corresponding to nucleotides -128 to +208 relatively to the transcription start site^[22] was amplified with primers which did not contain cytosine in a CpG context and consequently annealed to the methylated status of the island. The sequence of forward primer is 5'-AAA GAG GAG GGG TTG GTT GGT TAT TA-3' and that of backward primer is 5'-TAC CTA ATT CCA ATT CCC CTA CAA ACT-3'. (Forward primer position 5-30 and reverse primer position 310-336 in GenBank accession number U12818). PCR-reaction was performed in a buffer containing 10 mmol/L Tris-HCl (pH 9.0), 50 mmol/L KCl, 1 g/L Triton X-100, 50 g/L DMSO, 1.75 mmol/L MgCl₂, 0.2 mmol/L of each dNTP and 1 µL bisulphite treated DNA. Amplification conditions were as follows: at 95 °C for 5 min; followed by 35 cycles, each at 95 °C for 1 min, at 62 °C for 1 min, and extension at 72 °C for 30 s, and ended with an extension at 72 °C for 7 min and quickly chilled to 4 °C on a PTC-225 thermocycler (MJ Research). PCR products were gel purified and cloned into the pMD18-T vector according to the manufacturer's instructions (TAKARA). Part of the same PCR products was fluorescently labeled later for MSO microarray analysis. Plasmid DNA from 30 positive recombinant clones was isolated, and inserts were sequenced on an automated sequence analyzer (ABI377A, Applied Biosystem Inc., USA).

Oligonucleotide microarray

Nine sets of paired oligonucleotides used in this study were designed to include two or three CpG sites of the p16 CpG island to be interrogated (Table 1). These oligonucleotides were specific to the bisulfite-modified sequence of portion of the p16 CpG island.

Each was synthesized with amino-linked C6 [NH₂(CH₂)₆] linker attached to its 5' end. These oligonucleotides were suspended in sodium carbonate buffer (0.1 mol/L, pH 9.0) to a final concentration of 80 µmol/L. Approximately, 1 nL (0.05-0.1 pmole) of each oligonucleotide was printed on the aldehyde-coated glass slides (DAKO) using a PixSys5500 microarrayer (Cartesian Technology Inc). After printed, the glass slides were incubated in a humid chamber at room temperature overnight, and then at 37 °C for 2 h. The slides were washed thoroughly in 1 g/L SDS to remove unbound oligonucleotides. After further treatment with a NaBH₄ solution for 15 min, the slides were ready for hybridization. For target labeling, PCR products of bisulfite-treated DNA were labeled with Cy3-dCTP (Amersham Pharmacia) by terminal transferase (TAKARA). The unincorporated dCTP was removed by passing the labeled target through a micro-Biospin column (Bio-Rad). The labeled products were resuspended in hybridization solution (1:3 dilution v/v). Then the mixture was denatured at 95 °C for 5 min, cooled to room temperature, and applied to the DNA microarray slides. Microarray hybridization was conducted in a moist hybridization chamber under a cover slip at 42 °C for 2 h. After hybridization, the slide was rinsed and washed at room temperature with 2×SSC-1 g/L SDS and 0.1×SSC-1 g/L SDS for a total of 15 min, respectively, and then dried by centrifugation at 600 rpm for 5 min.

Image scanning and data processing

DNA microarray slide was scanned with ScanArray Lite microarray analysis systems (A Packard BioScience Company, USA) after the above treatment. Images acquired by the scanner were analyzed with software Genepix Pro 3.0. Each spot was defined by the positioning of a grid of circles over the array image. For each fluorescent image, the average pixel intensity within each circle was determined and a local background using mean pixel intensity was computed for each spot. The net signal was determined by subtraction of this local background from the mean average intensity for each spot. The data generated by the software were exported in a spreadsheet format and processed using Microsoft Excel. Statistical analyses were conducted using Origin 5.0 software.

Methylation-specific PCR (MSP)

The 5'-CpG island regions of the p16 gene were amplified with primers for methylated and unmethylated DNA, respectively. Primer pairs described in Table 2^[8] were synthesized and purified by Shengyou Inc (Shanghai, China). PCR amplification was performed in a buffer containing 10 mmol/L Tris-HCl (pH 9.0), 50 mmol/L KCl, 1 g/L Triton X-100, 50 g/L DMSO, 1.75 mmol/L

MgCl₂, 0.2 mmol/L of each dNTP and 1 µL bisulfite treated DNA in a final volume of 30 µL. The amplification was carried out for 35 cycles (30 s at 95 °C, 30 s at the annealing temperature listed in Table 2, and 30 s at 72 °C), followed by a final 4-min extension at 72 °C and quickly chilled to 4 °C on a PTC-225 thermocycler (MJ Research). Products amplified with both types of primers were examined on 10 g/L agarose gel.

Table 2 MSP primers used for amplification of p16 gene CpG island. MS and US represent methylated and unmethylated sense primers, respectively. MA1 and MA2, UA1 and UA2 represent methylated and unmethylated antisense primers, respectively

RESULTS

Figure 1 outlines the MSO strategy for DNA methylation analysis. Test DNA samples were bisulfite-modified, PCR amplified products contained pools of DNA fragments with altered nucleotide sequences due to their differential methylation status. As shown, the unmethylated allele of a given DNA sequence was expected to have the unmethylated cytosine of the tested CpG sites converted to thymine, whereas these CpG sequences remained unchanged in the methylated allele. Target DNA was then hybridized to arrayed oligonucleotide probes specifically designed to discriminate between converted and unconverted nucleotides at these CpG sites.

A 336 bp segment was selected in the 5' untranslated region and the first exon of the p16 gene, as the investigated target, which contains 32 CpG sites (Figure 2). Nine sets of oligonucleotide probes were designed to test 23 CpG sites within the island, each set contained a pair of methylated and unmethylated oligonucleotides for interrogating 2 or 3 CpG sites in close proximity (Table 1). First, control DNA targets were used to test the accuracy and reproducibility of probes designed for microarray hybridization. We selected fully methylated and unmethylated ones as positive and negative controls from 36 positive recombinant clones. The positive control generated in this way remained 100% cytosine in the tested CpG sites, whereas the negative control had all cytosine residues converted into thymine in the tested CpG sites. Next, a series of microarray hybridization were performed with mixtures of Cy3 labeled positive and negative DNA targets at different proportions representing 0%, 25%, 50%, 75%, and 100% of DNA methylation

Figure 1 Schematic outline for analysis of DNA methylation based on oligonucleotide microarray^[20]. Genomic DNA was bisulfite treated and amplified by PCR for a specific CpG island region of interest. The amplified product was labeled with Cy3 fluorescence dye and hybridized to oligonucleotide probes attached to a glass surface. At left an oligonucleotide probe was designed to form a perfect match with a target DNA containing the unmethylated allele. At right a probe was designed to form a perfect match with the methylated DNA target.

to test the linearity of the protocol. An example of the microarray analysis for CpG#26-28 is shown in Figure 3A. The average intensity of hybridization signals from the four replicate spots for the methylated (M) and unmethylated (U) alleles was then derived and used to calculate the intensity ratio of M/(M+U). In this case, a linear relationship ($R_2 = 0.9882$) was established, showing that the increase in DNA methylation was proportional to the increase in intensity ratios in the control samples. The result suggested that this set of oligonucleotide probes was optimal for the detection of methylation changes at CpG#26-28. This approach was used to test other oligonucleotide probes and to generate a set of standards for the calibration of DNA methylation changes in the test samples (Figure 3B). We noticed that the regression line for CpG#24, 25 was much higher on the Y-axis than the rest of the CpG sites. Moreover, its slope was much lower than the others. This higher nonspecific hybridization was likely due to the lower melting temperature of the unmethylated probe. An oligonucleotide sequence such as this would result in the compression of the usable scale and make the assessment of methylation status a little more challenging.

Microarray assay was used to analyze the methylation status of 18 gastric tumor and corresponding normal tissues. Figure 4

B: A calibration curve for measuring methylation changes at the p16 gene CpG sites.

shows the representative examples of microarray results. By use of the standard curves derived from the aforementioned calibration controls, no methylation was detected in the normal tissues. Extensive methylation of the p16 CpG island was observed in 7 of 18 gastric tumor tissues (T1, T2, T3, T8, T9, T11, and T18), a modest degree of methylation was found in T10 and T15, whereas little or no methylation was seen in others (Figure 5).

To further validate the microarray findings in gastric tumors, methylation-specific PCR (MSP) was conducted in 18 tumor and corresponding normal tissues. The primers MA1 and MA2 for MSP included CpG#16-19 and CpG#26-28 sites, respectively. Therefore, CpG#15-17 and CpG#26-28 sites were used for this conformation. A representation of the MSP analysis is shown in Figure 6. By use of this approach, two normal tissues were completely unmethylated (N4 and N8). MSP results of the 18 gastric tumor tissues completely matched with microarray results. Interestingly, the MSP results indicated that the methylation

was not detected in T1 when the amplification was performed with primers MS and MA2, whereas the methylation could be found in T1 when the amplification was performed with primers MS and MA1 (Figure 6). A most possible reason was that some CpG sites were not methylated in the region of primer MA2. Figure 5 indicates that CpG#15-17 sites had no methylation in T1, whereas CpG#26-28 sites had 47% methylation in T1, which were consistent with the MSP results.

The above results indicated that microarray assay could potentially increase the frequency of detecting p16 methylation from tumor samples than MSP. MSP was a simple, sensitive, and specific method for determining the methylation status of virtually any CpG-rich region. However, methylation could not be detected when some CpG sites were not methylated in region of MSP primers. The issue could be easily overcome using microarray assay. Furthermore, microarray assay could estimate which CpG sites (or CpG-rich region) were easily methylated in certain tumors.

DISCUSSION

In this study, we have applied a microarray method to a comprehensive analysis of DNA methylation. The results indicated that the microarray was successfully used to map methylated CpG sites within the p16 gene CpG islands in clinical samples. The derived methylation information for gastric tumor and corresponding normal tissues was assessed quantitatively and independently validated by methylation-specific PCR.

This microarray-based analysis of DNA methylation is expected to provide new tools for research in this field. At present, most methylation assays have been limited to analyzing CpG islands of a few known genes and are restricted in throughput for a genome-wide analysis. Until recently, Gitan *et al.*^[20] have developed a novel technique called MSO microarray that combines bisulfite DNA assay and oligonucleotides microarray for analysis of DNA methylation. The MSO microarray potentially allows rapid screening of multiple CpG sites in many gene promoters. CpG island hypermethylation has been reported to be linked to the silencing of more than 100 cancer-related genes. A DNA microarray can be generated to contain hundreds of oligonucleotides designed to discriminate between methylated and unmethylated sequences in these gene promoters. Bisulfite-treated genomic DNA from each of these loci can be amplified from investigated samples in a 96-well format to generate multiple targets for oligonucleotides hybridization.

As with other oligonucleotide microarrays, cross-hybridization between imperfect-match probes and targets could be observed. In addition, some probes might inherently diminish hybridization signals, probably due to decreased duplex stability of targets and probes^[18]. Through careful data analysis, Gitan and his colleagues considered that cross-reactivity might also increase when oligonucleotide probes were designed to query methylation differences in one single CpG site. The issue is easily overcome by designing probes to include two or more CpG sites. This design consideration may limit the MSO assay's ability to detect methylation changes in single CpG sites. Adorjan *et al.*^[23] have developed a microarray-based assay that can analyze methylation changes of single CpG sites. Several hundred CpG sites were screened in 76 samples from four different human tumor types and corresponding healthy controls. The results demonstrated that the microarray could be applied as a powerful tool to the assessment of selected CpG dinucleotides and quantification of methylation at each site. As shown in this study, the use of a simple control system could test the accuracy and reproducibility of the probes designed for microarray hybridization. This control system can also be used to calibrate the levels of methylation changes detected in the investigated samples by microarray assay.

In summary, microarray assay can be readily used to high-throughput analysis of DNA methylation. It will contribute significant information to our understanding of CpG island methylation in cancer.

Abstract

AIM: To investigate *p53* mutation and *p21* expression in hepatocarcinogenesis induced by hepatitis B virus (HBV) and aflatoxin B₁ (AFB₁) in tree shrews, and to reveal the role of these genes in hepatocarcinogenesis.

METHODS: Tree shrews were divided into four groups: group A, those infected with HBV and fed with AFB₁ ($n = 39$); group B, those infected with HBV alone ($n = 28$); group C, those fed with AFB₁ alone ($n = 29$); and group D, normal controls ($n = 20$). The tree shrews underwent liver biopsies once every 15 wk. Expression of *p53* and *p21* proteins and genes in the biopsies and tumor tissues of the experimental tree shrews was detected, respectively, by immunohistochemistry, and by Southern blotting and reverse transcription-polymerase chain reaction and sequencing.

RESULTS: The incidence of hepatocellular carcinomas (HCC) was higher in group A (66.7%) than that in group B (3.57%) and C (30%). The time of HCC occurrence was also earlier in group A than that in group C (120.0 ± 16.6 wk vs 153.3 ± 5.8 wk, respectively, $P < 0.01$). *p53* protein was not detected by immunohistochemistry in all groups before the 75th wk of the experiment. At the 105th wk, the positive rates for *p53* were 78.6%, 60% and 71.4% in groups A, B and C, respectively, which were significantly higher than that in group D (10%) (all $P < 0.05$). An abnormal band of *p53* gene was observed in groups A and C. The mutation points of *p53* gene in tree shrews with HCC were at codons 275, 78 and 13. The nucleotide sequence and amino acid sequence of tree shrew's wild-type *p53* showed 91.7% and 93.4% homologies with those of human *p53*, respectively. The immunopositivity for *p21* was found before HCC development. The incidence of HCC was significantly higher in tree shrews that were positive for *p21* than those negative for *p21* (80.0% vs 11.0%, $P < 0.001$). The incidence of HCC in *p21* positive animals in group A was significantly higher than those positive for *p21* in group C ($P < 0.05$).

CONCLUSION: A remarkable synergistic effect on HCC

development exists between HBV and AFB₁. *p53* mutation promotes the development of HCC. HBV and AFB₁ may synergistically induce *p53* gene mutation, and stimulate *ras* gene expression. *ras* gene is activated at the earlier stage during hepatocarcinogenesis. *p21* protein may be an early marker, and the alterations of *p53* may be a late event in the development of HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the world's most common cancers and is predominant in Africa and South-east Asia^[1]. Epidemiological studies indicated that contamination of food with aflatoxin B₁ (AFB₁) and chronic infection with hepatitis B virus (HBV) are the major risk factors for human HCC^[2,3].

p53, a tumor suppressor gene located on the short arm of chromosome 17, normally regulates the activity of the cell cycle machinery. Mutation of the *p53* gene has been observed with a high prevalence in diverse types of human cancer and frequently occurs with point mutation. The frequencies of *p53* mutation in HCC from different studies were varied from 18% to 67%^[4,5]. Mutation of G to T transversion at the third base of codon 249 of *p53* gene has been found in human HCC associated with high exposures to AFB₁ in Africa and Qidong, China^[6,7]. Where this mutation is absent from HCC in the area with negligible exposure to AFB₁. The *ras* gene coding for *M_r* 21 000 protein (*p21*) binds guanine nucleotides and possesses GTPase activity. Through this mechanism, the *ras* *p21* participates in the control of cell proliferation, possibly as a signal transducer from cell surface receptors to the nucleus^[8]. *H-ras* oncogene could induce the metastatic phenotype of HCC cell *in vitro* to enhance its metastatic potential. The mutations of *ras* genes at codons 12, 13, and 61 leading to the increased expression of normal or mutant form of the *p21* protein have been observed in human HCC and several other tumors^[9]. However, some report that *ras* proto-oncogene can enhance or inhibit the malignant phenotype *in vivo* in different systems^[10]. In the present study, using tree shrew (*Tupaia belangeri chinensis*) as an animal model for studying the development of HCC induced by human HBV and/or AFB₁, we investigated the alterations of *p53* and *p21* during hepatocarcinogenesis in tree shrews.

MATERIALS AND METHODS

Animals

Tree shrews were obtained from Kunming Medical Biology Institute, Chinese Academy of Sciences. One hundred and sixteen adult tree shrews weighed 127 ± 14.5 g. Animals were raised in stainless steel cage individually at room temperature of 25 ± 1 °C and fed with basic diet supplemented with fruits, milk, and eggs. Drinking water was given *ad libitum*.

HBV sera for infection

Sera positive for HBV surface antigen (HBsAg), e antigen (HBeAg) and antibody against c antigen (anti-HBc) were obtained from several blood donors. The titres of HBsAg and HBeAg were more than 1:1 024. The sera were preserved in a refrigerator at -40 °C and pooled before inoculation.

AFB₁

AFB₁ was purchased from Sigma Chemical Co., USA. It was dissolved into dimethylsulphoxide (DMSO) and mixed with milk to be sipped by tree shrews.

Reagents

Rabbit polyclonal antibody against human p53 protein (CM1) and avidin-biotin peroxidase complex kit were purchased from Vector Laboratories Inc., USA. RNase mini-kit was purchased from Qiagen Inc., Germany. PCR kit was the product of Stratagene Inc., USA. Rat antibody against human p21 (pan-ras) was purchased from Biosource Inc., USA.

Methods

Blood sample 1 mL was drawn through the femoral veins of each tree shrew before the experiment started. Some tree shrews were inoculated with 0.5 mL of human HBV-infected serum via the femoral vein. Three days later, another 0.5 mL of the same serum was injected peritoneally. After a week, the sera of these animals were checked weekly for HBV infection markers by enzyme-linked immunosorbent assay (ELISA). HBV-infected tree shrews confirmed by ELISA were randomly divided into group A (39 animals) and group B (28 animals). The un-inoculated tree shrews were randomly divided into group C (29 animals) and group D (20 animals). The animals of groups A and C were given AFB₁, 200-400 µg/kg b.m. per day, while group D was used as control. Liver biopsies were performed in each group once every 15 wk. The samples of liver biopsy or HCC were cut into 2 pieces. One was fixed in 40 g/L buffered formaldehyde, and the other was kept at -80 °C after immersed in liquid nitrogen.

Southern blotting

Three samples of liver biopsy and 5 samples of HCC tissues stored at -80 °C were sent to Korea Research Institute of Bioscience and Biotechnology for Southern blotting to determine the p53 gene status.

Sequencing of p53

Total RNAs were extracted from 10 mg of frozen tumors or biopsied liver tissues. Exon 2-4 (415 bp) of the p53 gene was amplified using the forward primer CDF2: 5'-ATTGGCAGCCA GACTGCCTTCCGGG-3' and reverse primer CDR4: 5'-CGATT CTAGAGCAAAACATCTTGTGAGGG-3'. Exon 5-11 (974 bp) of the p53 gene was amplified using the forward primer CDF5: 5'-CGATGAATTCTTGCATTCTGGGACAGCCAA-3', and reverse primer CDR11: 5'-CGATAAGCTTCTGACGCACACCT ATTGCAA-3'. The reactions containing 0.5 µg total RNA, 5 mmol/L MgCl₂, 1 mmol/L dNTP, 20 pmol of each primer, 40 units of RNase inhibitor, 5 units of AMV reverse transcriptase, 5 units of AMV Tag DNA polymerase in a final volume of 50 µL in mRNA selective PCR buffer were used. The mixture of reactants was incubated at 42 °C for 30 min followed by PCR amplification with 25 cycles of at 85 °C for 30 s and at 72 °C for 1 min. PCR products were analyzed on 15 g/L agarose gel containing ethidium bromide. The PCR product of p53 was purified and sequenced by an automatic DNA sequencer.

Immunohistochemistry for p53 and p21

p53 and p21 proteins were detected by immunohistochemical staining using the avidin-biotin complex (ABC) method on the

sections of liver tissues and tumors. In brief, formalin-fixed, paraffin-embedded sections were deparaffinized in xylene and were passed through ethanol series. After the endogenous peroxidase activity was blocked, the sections were rinsed in 0.01 mol/L PBS. Non-specific binding was blocked by treatment with 5% normal horse or goat serum for 20 min. Primary antibody was applied to the sections and incubated in a moist chamber overnight at 4 °C. After the sections were washed in 0.01 mol/L PBS, biotinylated horse or goat anti-mouse or rabbit immunoglobulin G was applied and sections were incubated for 50 min at room temperature. After washed, the sections were incubated with avidin-biotin-peroxidase complex for 50 min and then washed again. The chromogen, 3,3'-diaminobenzidine (DAB) was added for 5 to 10 min. Finally, the sections were washed and mounted. The section without primary antibody served as negative control.

Statistical analysis

Differences of HCC incidence and percentages of immunopositivity for p53 and p21 were analyzed by the Chi-square (χ^2) test. The difference of the average time for appearance of HCC was analyzed by the Student's *t* test.

RESULTS

The first case of HCC appeared at the 83rd wk of the experiment in group B. At that time the number of living animals in groups A, B, C and D were 39, 28, 29 and 20, respectively. After feeding of AFB₁ for 105 wk, the amount of AFB₁ in groups A and C was 11.6-15.5 mg and 11.4-16.09 mg, respectively. The difference was not statistically significant. The experimental period was 160 wk.

Incidence of HCC

HCC occurred only in groups A, B and C, and the rates of HCC in those groups were 58.9% (23/39), 3.57% (1/28) and 20.68% (6/29), respectively. No HCC was observed in group D. One tree shrew died at the 120th wk in group B had two proliferating pale nodules with 0.5 cm in diameter. They were large proliferating nodules of liver cells under the microscope. Not only was the HCC incidence higher but also the average time for HCC appearance was significantly shorter in group A than that in group C (120±16.6 wk vs 153±5.8 wk, *t* = 3.336, *P* < 0.01).

p53 gene

No p53 protein was detected by immunohistochemistry in each group at the 75th wk. The percentages of immunopositivity for p53 in group A (78.6%), B (60%) and C (71.4%) were significantly higher than that in group D (10.0%) at the 105th wk. The positive rates for p53 in HCC samples were not significantly different between groups A and C (52.17%, 12/23 vs 50%, 3/6, *P* > 0.05). Immunopositive signal of p53 was located in nucleus of cell (Figure 1). At the 105th wk, the extra bands of p53 were detected in 2 of 3 liver biopsy tissues from group C but none from other groups by Southern blotting. One case from group C appeared a new band with a size of 12.8 kb and lost a normal band of 1.6 kb at the same time. This tree shrew developed HCC at the 120th wk. A new band of 3.4 kb was found in another case from group C. Before the experiment started and during the 15th to 75th wk of the experiment, totally 12 biopsy liver tissues from 2 animals in group C were detected by Southern blotting and a light extra band of 3.8 kb was found in the tissues of 45th wk. Two of 8 HCCs from group A also appeared an extra band of 4.8 kb. The point mutation of p53 gene from 3 of 8 tumors was found by sequencing. The mutations were at codons 275, 78 and 13 (changing proline to serine, T→C transversion at the first nucleotide of codon 275; changing cysteine to arginine, A→G transversion at the third position of codon 78; C→T transversion

Table 1 Status of *p53* gene from liver and tumor tissues of tree shrews

^b*P*<0.01 vs Group C; ^d*P*<0.001 vs Group B; ^f*P*<0.001, *p21*+ vs *p21*- in Group A; ^h*P*<0.01, *p21*+ vs *p21*- in Group C; ^a*P*<0.05 vs Group C in *p21*+; ⁱ*P*<0.01 vs Group B in *p21*-.

at the second position of codon 13; no amino acid change) (Table 1). The nucleotide sequence and amino acid sequence of tree shrew's wild-type *p53* showed 91.7% and 93.4% homologies with those of human *p53* sequence, and 77.2% and 73.4% homologies with mouse *p53* sequence, respectively^[11].

**Figure 1** Expression of *p53* protein located in nuclei of liver cancer cells (Original magnification: ×400).

p21 protein

p21 protein was located in plasma of liver cells (Figure 2) and overexpressed in totally 16 animals' liver tissues in group A during hepatocarcinogenesis. All those tree shrews developed HCC. However, only 7 of 23 tree shrews were *p21*-negative in liver tissues, and developed HCC in the same group at the end of experiment. The incidence of HCC was significantly higher in these *p21*-positive animals than in those negative ones. There were 2 animals positive for *p21* protein in the liver tissues in group B, one of them died at the 120th wk and had 2 proliferating nodules with 0.5 cm in diameter. They were large proliferating nodules of liver cells under microscope. At the end of the experiment, 4 of 7 tree shrews that were positive for *p21* developed HCC in Group C, whereas only 2 of 22 tree shrews that were negative for *p21* developed HCC in this group. *p21* overexpression was not found in group D (Table 2). Totally 25 animals were positive for *p21* in liver tissues in all groups and

20 of them developed HCC (80%), while only 10 of totally 91 animals which were negative for *p21* developed HCC (10.99%). Only 1 sample of HCC tissue was positive for *p21* in all 30 samples of HCC tissues (Table 3).

Table 3 Relationship between *p21* expression and HCC development

DISCUSSION

Animals in groups A and B were verified for infection with human HBV^[12]. In the present study, not only was the incidence of HCC significantly higher but also the average time for HCC development was shorter in the animals both infected with HBV and exposed to AFB₁ than those infected with HBV or exposed to AFB₁ alone. These results provided further support for the existence of the synergistic effect between HBV and AFB₁ in tree shrew's hepatocarcinogenesis^[13-15]. Even though

only one case of HCC developed in group B, which was infected with HBV alone, proliferation foci and/or nodules appeared quite early and frequently in this group. One tree shrew in group B which died at the 120th wk was found with 2 proliferating nodules with 0.5 cm in diameter in the liver. These results indicate that HBV has the capability of inducing liver cancer, but its capability is weak.

Wild type *p53* gene is the control gene at G₁ phase of cell cycle. It can inhibit DNA-damaged cell from entering G₁ phase and let the cell repair the damage^[16]. Mutated *p53* gene not only loses the functions that wild type *p53* has but also promotes malignant transformation of cells^[17]. All the liver tissues of tree shrews in all groups were negative for mutant *p53* protein by immunohistochemistry in early period of hepatocarcinogenesis. However, mutant *p53* proteins were detectable in the middle stage of hepatocarcinogenesis, before the appearance of HCC. This demonstrates that *p53* mutation occurs prior to the appearance of HCC. In the control group, no HCC developed and no mutant *p53* proteins and mutations of *p53* gene were detected, suggesting that the *p53* mutation is a crucial factor to initiate the malignant transformation of cell. The results of examining the status of *p53* gene by Southern blotting showed that 2 liver samples biopsied at the 45th wk in group C had an abnormal band of 3.8 kb. This indicates that the alteration of *p53* gene in the hepatocyte of tree shrew is dependent on a cumulative amount of AFB₁ and sufficient time, and also supports the finding that mutation of *p53* occurs before the appearance of HCC. The reason for loss expression of mutant *p53* in those 2 animals may be due to the low level of mutant *p53* protein. In the 8 samples sent to South Korea, *p53* mutation was not observed in 3 normal liver tissues, but 3 poorly-differentiated cases from the 5 HCC samples showed *p53* mutations. The rate of mutation was consistent with our previous report^[18]. It was also similar to the reports on human samples. The 3 tree shrews containing *p53* mutation gene were from group A treated by both HBV and AFB₁, implying that HBV and AFB₁ may play a synergistic role in *p53* mutation. This may be one of mechanisms that HBV synergies AFB₁ in hepatocarcinogenesis. *p53* mutations were located at codons 275, 78 and 13, respectively. No mutation was found at codon 249. It was differently from the mutation at codon 249 of the *p53* gene identified as a hotspot mutation in hepatocellular carcinomas occurring in populations exposed to AFB₁ and HBV^[14,5,19,20]. However, it was similar to the results of studies on non-human primate animal models^[21]. This discrepancy may be due to the different species, or too small amount of cases that were detected to find any mutation of *p53* at codon 249. Moreover, it also suggests that *p53* mutation, which is closely related to the development of HCC, does not merely occur at codon 249.

In HCC *ras* was first proved as one of the transforming genes, which belong to G-protein family gene. When it is converted to active oncogene by point mutation or gene amplification the signal transmission of cell membranes may change, which drives cell division, and results in abnormal differentiation and finally neoplasm formation. Oncogene *ras* directly takes part in human carcinogenesis, perhaps accounting for as many as 15-20% of all human tumors. It is well documented that the *ras* gene product, p21 protein, has GTPase activity and is involved in signal transduction. p21 is now well recognized for its essential function in transducing extracellular signals that regulate cell growth, survival, and differentiation. Overexpression and point mutations of *ras* gene were not only found in HCC^[22-23] but also found in liver cirrhosis and the correlation with liver cell dysplasia^[24]. We detected the p21 expression by immunohistochemistry in biopsied liver tissues of tree shrews at the 45th, 105th and 119th wk. The results showed that the accumulative total of positive rate for p21 in group A was 41.02%, which was significantly higher than that in group B (7.14%) and group C

(24.13%). This indicates that HBV and AFB₁ can synergistically activate *ras* gene in hepatocyte resulting in overexpression of p21^[25]. The p21 protein overexpression appeared before HCC development, indicating that the p21 protein overexpression is the early event during hepatocarcinogenesis and p21 protein may be an early marker in the development of HCC^[26]. In the present study, among the 25 animals that were positive for p21, 20 (80%) developed HCC whereas only 10 of 91 (10.99%) p21-negative animals developed HCC at the end of the experiment. This suggests that overexpression of p21 plays an important role in the development of HCC.

Comparison of the nucleotide and amino acid, sequences of human wild-type *p53* the structural homology was higher between tree shrews and human than between tree shrews and mouse^[11], indicating the tree shrew model is a useful animal model to study the etiology and pathogenesis of HCC in humans^[27].

Abstract

AIM: Dendritomas formed by fusing cancer cells to dendritic cells have already been applied to clinical treatment trial of several types of cancers. Dendritic cells for the fusion in most trials and experiments were from blood monocytes in standard 7-d protocol culture, which requires 5-7 d of culture with granulocyte-macrophage-colony-stimulating factor (GM-CSF) and interleukin-4 (IL-4), followed by 2-3 d of activation with a combination of proinflammatory mediators such as tumor necrosis factor α (TNF α), interleukin-1 β (IL-1 β), interleukin-6 (IL-6) and prostaglandin E₂ (PGE₂). One study showed that mature monocyte-derived dendritic cells could be obtained within 48 h of *in vitro* culture with the same protocol as standard 7-d culture and referred to as FastDCs. Here we aimed to fuse human hepatocellular carcinoma cell line HCCLM3 cells with mature monocyte-derived dendritic cells within 48 h of *in vitro* culture (FastDC).

METHODS: HCCLM3 cells were cultured in RPMI 1640 with 150 mL/L fetal calf serum (FCS). CD14+ monocytes from healthy human peripheral blood were purified with MACS CD14 isolation kit and cultured in six-well plates in fresh complete DC medium containing RPMI-1640, 20 mL/L heat inactivated human AB serum, 2 mmol/L L-glutamine, 100 μ g/mL gentamicin, 1 000 U/mL GM-CSF and 500 U/mL IL-4 for 24 h, then proinflammatory mediators such as TNF α (1 000 U/mL), IL-1 β (10 ng/mL), IL-6 (10 ng/mL) and PGE₂ (1 μ g/mL) were supplemented for another 24 h, and thus mature FastDCs were generated. HCCLM3 cells and FastDCs were labeled with red fluorescent dye PKH26-GL and green fluorescent dye PKH67-GL respectively. After the red fluorescent-stained HCCLM3 cells were irradiated with 50 Gy, FastDCs and irradiated HCCLM3 cells were fused in 500 mL/L polyethylene glycol(PEG)+100 mL/L dimethyl sulfoxide (DMSO) to generate novel dendritomas. The FastDCs

and novel dendritomas were immunostained with anti-CD80, anti-CD86, anti-CD83, anti-HLA-DR mAbs and analyzed by fluorescence-activated cell sorting (FACS). Novel dendritomas were nucleus-stained with Hoechst 33258 and analyzed by confocal laser scanning microscopy.

RESULTS: Mature FastDCs with highly expressed surface markers CD80, CD86, CD83 and HLA-DR were generated within 48 h *in vitro*. Novel dendritomas with dual red-green fluorescence were constructed fast and successfully, and FACS analysis showed that the fusion efficiency was 24.27% and the novel dendritomas expressed the same activation markers as FastDCs. Confocal laser scanning microscopy analysis showed representative images of dendritomas.

CONCLUSION: Dendritomas can be formed fast with mature FastDCs from healthy human peripheral blood monocytes (PBMC) by incubation with GM-CSF and IL-4 for 24 h and by activation with proinflammatory mediators for an additional period of 24 h. Owing to shorter time required for *in vitro* DCs development, the generation of these novel dendritomas reduced labor and cost. This rapid method for formation of dendritomas may represent a new strategy for immunotherapy of hepatocellular carcinoma.

INTRODUCTION

Dendritic cells (DCs) are professional antigen-presenting cells (APCs) and play key roles in initiating and managing specific primary immune responses, including the activation of tumor-reactive cytotoxic T cells (CTLs)^[1,2]. The fusion of DCs with tumor cells among various tumor vaccination strategies focusing on DCs has become a promising approach^[3,4]. At present, most experimental and clinical studies rely on the *in vitro* development of DCs from CD34⁺ progenitor cells or blood monocytes^[5-7]. Commonly, according to standard 7-d protocol, blood monocytes were cultured for 5-7 d with GM-CSF and IL-4 to develop immature DCs which were activated for another 2-3 d with monocyte-conditioned media (MCM) or a combination of proinflammatory mediators such as TNF α , IL-1 β , IL-6 and PGE₂ so that mature DCs with full T stimulatory capacity were obtained^[8]. It was reported that mature DCs in 48 h *in vitro* culture with the same combination of proinflammatory mediators as standard 7-d protocol's were obtained and referred to as FastDCs^[8]. The report indicated that FastDCs were as effective as monocyte-

derived DCs from standard 7-d protocol culture in stimulating primary antigen-specific Th1-type immune responses^[8]. Here we aimed to fuse human hepatocellular carcinoma cell line HCCLM3 cells with mature dendritic cells (FastDCs) within 48 h of *in vitro* culture.

MATERIALS AND METHODS

Materials

All reagents were obtained from the indicated sources. GM-CSF, TNF α , IL-1 β , IL-6 were purchased from R&D Systems (Minneapolis, USA), IL-4 from Promega (USA), PKH26-GL, PKH67-GL, 500 mL/L PEG+100 mL/L DMSO, gentamicin, Hoechst 33258 and PGE₂ from Sigma-Aldrich China Inc. (Shanghai, China), Fetal calf serum (FCS), RPMI-1640 medium, L-glutamine, penicillin and streptomycin from Invitrogen (USA). All mAbs (anti-HLA-DR, APC-conjugated; anti-CD80, Cy-Chrome-conjugated; anti-CD86, APC-conjugated; anti-CD83, APC-conjugated) were obtained from BD PharMingen (USA), and CD14 isolation kit from Miltenyi Biotec. (Bergisch-Gladbach, Germany), and Ficoll-Hypaque from Pharmacia (Sweden), Human AB serum from Chuanye Inc. (Tianjin, China). Human HCCLM3 cell line was a gift from Professor Zhao-You Tang in Liver Cancer Institute (Zhongshan Hospital, Fudan University).

Methods

Culture of hepatocellular carcinoma HCCLM3 cells Human HCCLM3 cells were grown in complete culture medium containing RPMI-1640, 150 mL/L heat-inactivated FCS, 2 mmol/L L-glutamine, 100 U/mL penicillin and 100 μ g/mL streptomycin.

Isolation and culture of CD14+ monocytes Peripheral blood mononuclear cells (PBMC) were isolated from peripheral blood of healthy donors by Ficoll-Hypaque (1.077 g) density gradient centrifugation. CD14+ cells of the PBMC were separated by performing positive selection with CD14+ micro magnetic beads according to the manufacturer's instructions and subsequently cultured in six-well plates (1×10^6 cells/mL) in fresh complete DC medium (RPMI-1640, 20 mL/L heat inactivated human AB serum, 2 mmol/L L-glutamine, 100 μ g/mL gentamicin, supplemented with 1000 U/mL GM-CSF and 500 U/mL IL-4) for 24 h, followed by incubation with a combination of proinflammatory mediators such as TNF- α (1 000 U/mL), IL-1 β (10 ng/mL), IL-6 (10 ng/mL) and PGE₂ (1 μ g/mL) for another 24 h to produce FastDCs.

Analysis of FastDCs by fluorescence-activated cell sorting FastDCs were immunostained with the following mAbs: anti-CD80, anti-CD86, anti-CD83, anti-HLA-DR. Surface marker analysis was performed by fluorescence-activated cell sorting (FACS).

Fluorescent labeling of dendritic cells and human HCCLM3 cells Commercial fluorescent cell linker kits PKH67-GL and PKH26-GL were used for membrane labeling of FastDCs and HCCLM3 cells. The FastDCs were labeled fluorescent green with PKH67-GL and HCCLM3 cells were labeled fluorescent red with PKH26-GL. The whole procedure was performed at 25 °C. The cells to be stained were washed with serum-free RPMI-1640. The cell suspension was centrifuged at 400 r/min for 5 min to produce a cell pellet. The supernatant was removed, leaving less than 25 μ L medium on the pellet. One milliliter of diluent C was added to resuspend the cells. Then 4×10^{-6} molar dyes ($\times 2$) were prepared with diluent C immediately before staining. The cells in diluent C were added rapidly to one milliliter of $2 \times$ dye. The cells and dye were mixed by gentle pipetting. The mixture was incubated at 25 °C for 5 min. The staining process was stopped by adding an equal volume of FCS and incubating for 1 min. The stained cells were diluted with an equal volume of complete culture medium and centrifuged at 400 r/min for 10 min and removed for at least three washes. Then the cells were

resuspended in fresh complete medium. The staining efficiency was monitored by fluorescent microscopy.

Fusion of dendritic cells and human HCCLM3 cells After the red fluorescent-stained HCCLM3 cells were irradiated with 50 Gy, the DCs and irradiated HCCLM3 cells were fused together by mixing two cell types at an 1:1 ratio in a 50 mL conical centrifugation tube. One milliliter of fusogen containing 500 mL/L PEG+ 100 mL/L DMSO was added to the mixture by dropping for 1-1.5 min. Nine milliliters of serum-free RPMI-1640 with 25 mmol/L Hepes was added to the mixture for over 5 min. Forty milliliters of serum-free RPMI-1640 was added to the cell mixture and the mixture was pelleted by centrifugation at 800 r/min for 10 min. After the supernatant was removed, the cells were resuspended in one milliliter of complete culture medium.

Sort and analysis of novel dendritomas The fused cells were resuspended in phosphate-buffered saline for detection of dual fluorescent dendritomas by FACS.

The novel dendritomas were sorted based on dual green and red fluorescence using a FACS caliber cell sorter (Becton Dickinson, USA). The cells were centrifuged at 800 r/min for 15 min. After the supernatant was removed, the cells were immunostained with the same mAbs as for FastDCs and activation markers were analyzed.

Analysis of novel dendritomas by confocal laser scanning microscopy The fused cells were resuspended in phosphate-buffered saline and centrifuged at 400 r/min for 10 min. After the supernatant was removed, Hoechst 33258 for nucleus staining was dropped in and the cells were resuspended in phosphate-buffered saline 5 min later and centrifuged at 400 r/min for 10 min again. After the cells were fixed with 10 g/L paraformaldehyde, nucleus-stained cells were resuspended in phosphate-buffered saline for analysis of dendritomas by confocal laser scanning microscopy.

RESULTS

Characteristics of DCs derived from human peripheral blood CD14+ monocytes within 48 h of *in vitro* culture

Monocytes were enriched from PBMC by CD14-positive selection with MACS and subsequently cultured with GM-CSF and IL-4 for 48 h. Proinflammatory mediators such as TNF α , IL-1 β , IL-6 and PGE₂ were added to accelerate DCs maturation after 24 h of culture with GM-CSF and IL-4. The cells displayed mature DC activation markers such as CD83⁺⁺, CD80⁺⁺, CD86⁺⁺ and HLA-DR⁺⁺ within 48 h (Figure 1A) and formed long cytoplasmic protrusions typical of mature DCs, while monocytes cultured with GM-CSF and IL-4 alone for 48 h displayed and maintained monocyte-like morphology. Using this two-step differentiation strategy, a large number of mature and viable DCs (about 30% of the initial population of monocytes) could be obtained.

Staining efficiency of dendritic cells and human HCCLM3 cells

After FastDCs and HCCLM3 cells were labeled with PKH67-GL and PKH26-GL respectively, the cells were examined under fluorescent microscopy and more than 95% of the cells were stained successfully.

Fusion efficiency indicated by FACS analysis

FastDCs were stained fluorescent green with PKH67-GL and HCCLM3 cells were stained fluorescent red with PKH26-GL. The stained two cell types were fused together by admixing them and dropping fusogen. The novel dendritomas would take on dual fluorescence. FACS analysis showed that the percentage of red and green dual fluorescent dendritomas in the fused cell mixture was 24.27%, which represented fusion efficiency (Figure 2) and the novel dendritomas expressed the same markers as FastDCs (Figure 1B).

Figure 1 FACS analysis of activation markers on FastDCs and novel dendritomas. A: Expression of DCs activation markers on FastDCs determined by FACS. B: DCs activation markers expressing on novel dendritomas determined by FACS.

Figure 2 Fusion efficiency analysis by FACS. A: Control group (mixture): 3.19% dual-fluorescent cells. B: Fusion group: 27.46% dual-fluorescent cells.

Representative images of dendritomas under confocal laser scanning microscopy

FastDCs and HCCLM3 cells were stained with PKH67-GL and PKH26-GL respectively. After FastDCs and HCCLM3 cells were fused, nuclear counterstaining was performed using Hoechst 33258. Under confocal laser scanning microscopy, FastDCs were detected as green cells and HCCLM3 cells were detected as red and the representative image of a dendritoma was a dual fluorescent cell with two blue nuclei (Figure 3).

Figure 3 Images of novel dendritomas and HCCLM3 cells under confocal laser scanning microscopy. A: Red tumor and dendritoma cells. B: Green dendritoma cells. C: One dendritoma cell with two blue nuclei and one tumor cell with one nucleus. D: One dendritoma cell (right) characteristic of a dual-fluorescent cell with two blue nuclei while one red fluorescent tumor cell (left) with one nucleus.

DISCUSSION

As highly specialized antigen-presenting cells, DCs constitute a unique system of cells that induce and control immune responses. Owing to their unique ability to capture and present antigens, thereby inducing and managing immune responses,

DCs have become attractive vectors and targets for immunological intervention in numerous diseases and represent optimal candidates, especially for cancer immunotherapy. So far, various tumor vaccination strategies have been developed based on the loading of DCs with tumor-associated antigens (TAAs)^[9,10], including defined peptides of known sequences^[11-13], undefined acid-eluted peptides from autologous tumors^[14], whole tumor lysates^[15], tumor cell-derived RNA *et al.*^[16] Another promising alternative is the fusion of DCs with tumor cells^[3,4]. This approach is based on the idea that multiple TAAs are endogenously processed and presented by MHC class I molecules, thereby stimulating tumor-specific CTLs^[17].

In 1997, Gong *et al.*^[3] reported that they fused breast carcinoma cells with DCs to produce dendritomas which were capable of presenting antigens effectively and inducing antitumor-specific CTLs. Afterwards, a number of experimental and clinical trials with significant effects on several types of cancers such as melanoma, leukemia, glioma, gastric carcinoma, myeloma, renal cell carcinoma and ovarian carcinoma were reported^[18-31].

At present, DCs, for experimental and clinical fusion trial, were obtained mainly from *in vitro* standard 7-d protocol culture. In fact, the kinetics of DCs differentiation from blood monocytes under physiologic conditions might not be reflected by current standard protocols for the *in vitro* development of DCs^[8]. One research showed that a subpopulation of blood monocytes differentiated into DCs within 48 h in a model simulating transendothelial migration into lymphatic vessels^[31]. Dauer *et al.*^[8] reported that they cultured blood monocytes within 48 h *in vitro* with the same combination of proinflammatory mediators as standard 7-d protocol and obtained mature DCs with their ability similar to standard protocol DCs in stimulating primary antigen-specific Th1-type immune responses, and inducing the production of IFN γ and activating autologous naïve T cells, and the DCs were referred to as FastDCs. We cultured and obtained FastDCs with activation markers using the same methods and successfully constructed dendritomas by fusing FastDCs with HCCLM3 cells. Our study showed that the fusion of the two cells was feasible and the novel dendritomas expressed the same surface markers as FastDCs. Compared with common standard protocol methods, this new strategy not only simplified the process and reduced labor, cost and time for the whole experiment procedure, but also may be less disrupted by microbial contamination.

In conclusion, our novel strategy may facilitate the use of dendritomas in clinical trials of cancer immunotherapy

Abstract

AIM: To study the difference in gene expression between solitary large hepatocellular carcinoma (SLHCC) and nodular hepatocellular carcinoma (NHCC).

METHODS: Polymerase chain reaction (PCR) products of 8464 human genes were spotted on a chip in array. DNAs were then fixed on a glass plate. Total RNA was isolated from freshly excised human SLHCC ($n = 7$) and NHCC ($n = 15$) tissues, and was reversely transcribed to cDNAs with the incorporation of fluorescent dUTP for preparation of hybridization probes. The mixed probes were then hybridized to the cDNA microarray. After highly stringent washing, cDNA microarray was scanned for the fluorescent signals to display the difference between the two kinds of HCC. In addition, the expression of *RhoC* and *protocadherin LKC* was also detected with the reverse transcriptase polymerase chain reaction (RT-PCR) method.

RESULTS: Among the 8 464 human genes, 668 (7.89%) genes were expressed differentially at the mRNA levels between SLHCC and NHCC. Three hundred and fifty five (4.19%) genes, including *protocadherin LKC*, were up-regulated, whereas 313 (3.70%) genes, including *RhoC*, were down-regulated. The mRNA expression levels of *RhoC* and *protocadherin LKC* were confirmed by RT-PCR. Analysis of differentially expressed genes confirmed that our molecular data obtained by cDNA microarray were consistent with the published biochemical and clinical observations of SLHCC and NHCC.

CONCLUSION: cDNA microarray is an effective technique in screening the difference in gene expression between SLHCC and NHCC. Many of these differentially expressed genes are involved in the invasion and metastasis of HCC. Further analysis of these genes will help to understand the different molecular mechanisms of SLHCC and NHCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) ranks one of the most common malignancies in the world. Although its morbidity and mortality have decreased recently in patients with surgically treated HCC, the long-term prognosis remains unsatisfactory because of the high recurrence and metastasis rate. It has been generally accepted that the invasive and metastatic potentials of HCC are mostly attributed to the individual clinical pathological and molecular biological characteristics. The diversity of biological characteristics determines the different invasive and metastatic potentials of HCC^[1]. In our institute, HCC was phenotypically divided into solitary large hepatocellular carcinoma (SLHCC, diameter >5 cm, and one node), nodular hepatocellular carcinoma (NHCC, node number ≥ 2) and small hepatocellular carcinoma (SHCC, diameter ≤ 5 cm). Our clinical observation implied different invasive and metastatic abilities between SLHCC and NHCC. To understand the mechanism of different invasive and metastatic potentials between SLHCC and NHCC, the changes in gene expression between SLHCC and NHCC need to be investigated.

Our previous investigations focused on the differentially expressed genes of integrin, matrix metalloproteinases-2 (MMP-2), vascular endothelial growth factor (VEGF), phosphatase and tensin homologue deleted on chromosome ten (PTEN), endoglin (CD105), survivin, which involved in invasion and metastasis, between SLHCC and NHCC^[2]. Given the complex molecular mechanisms of invasion and metastasis, however, it is not clear that expression of these specific genes alone can explain the diversity of molecular biological characteristics between SLHCC and NHCC. Therefore, a broad evaluation of difference in gene expression between SLHCC and NHCC is necessary.

cDNA microarray represents an important new tool to analyze human gene expression profiles. The technology enables investigators to measure the expression of several thousand mRNAs simultaneously in a biological specimen. It is technically possible to monitor almost the entire transcriptome, the collection of all mRNAs presented in a tumor specimen. cDNA microarray also enables us to study global gene profiles from various samples, thereby to speed up the identification of differentially expressed genes and the construction of different expression profiles. cDNA microarray analysis has become an increasingly popular tool to investigate the function of genes that are responsible for the phenotypes of diseases, to provide potential targets for treatment or prevention^[3-5].

Our study was designed to delineate the different expression gene profiles between SLHCC and NHCC from 22 patients to evaluate the difference in gene expression within the realm of 8 464 human genes for understanding the basement of the diversity of molecular biological characteristics between SLHCC and NHCC.

MATERIALS AND METHODS

Tissue specimens

The Ethics Committee of the Central South University approved the study protocol. Fresh surgical HCC was obtained from 22

(20 males and 2 females) patients, including 7 cases of SLHCC and 15 cases of NHCC with primary hepatocellular carcinoma who underwent hepatectomy at Xiangya Hospital of Central South University (CSU). The specimens were immediately freshly frozen in liquid nitrogen and stored at -80 °C for RNA isolation. The median age of the patients was 52 year (range, 27-73 years). All specimens obtained from surgery resection were confirmed by pathological examination.

RNA isolation

Total RNA was extracted from frozen tissue specimens (30-100 mg) using TRIZOL (GIBCO BRL, Gaithersburg, USA) reagent according to the instructions provided by the manufacturer. The quality was checked on 10 g/L agarose gels and the concentration was measured using an ultraviolet spectrophotometer (Biochrom Ltd, Cambridge, England). The *uv* wavelength was adjusted at 260 nm.

Construction of microarray

Microarray sequences included 8 464 full-length and partial complementary DNAs representing known, novel, and control genes were provided by United Gene Holdings, Ltd, Shanghai, China. The cDNA inserts were amplified by PCR using universal primers to plasmid vector sequences and then purified as described previously^[6]. The PCR products were then spotted onto silylated slides (CEL Associates, Houston, TX) using a Cartesian PixSys7500 motion control robot (Cartesian Technologies, Irvine, CA) fitted with Chipmaker micro-spotting technology (TeleChem International, Sunnyvale, CA). After spotting, the slide was exposed to ultraviolet light (65 mJ/cm) and processed at room temperature by soaking in 2 g/L sodium dodecyl sulfate (SDS) for 10 min, distilled H₂O for 10 min, and 2 g/L sodium borohydride (NaBH₄) for 10 min. The slide was dried again and ready for use.

Probes of expression profile preparation

Individual RNA specimens from the same group of HCC were mixed equally to obtain 60 µg total RNA. Fluorescent cDNA probes were prepared through reverse transcription and then purified. RNA samples extracted from NHCC were labeled with Cy3-dUTP and those from SLHCC with Cy5-dUTP. The two color probes were then mixed, precipitated with ethanol and dissolved in 20 µL of hybridization solution containing 5×SSC (0.75 mol/L NaCl and 0.075 mol/L sodium citrate), 4 g/L SDS, 500 g/L formamide and 5×Denhardt's solution (1 g/L Ficoll, 1 g/L polyvinylpyrrolidone and 1 g/L bovine serum albumin).

Hybridization and washing

Microarrays was prehybridized with hybridization solution containing 5 g/L denatured salmon sperm DNA at 42 °C for 6 h. Fluorescent probe mixtures were denatured at 95 °C for 5 min, and the denatured probe mixtures were applied onto the prehybridized chip under a cover glass. Chips was hybridized at 42 °C for 18 h. The hybridized chips was then washed at 60 °C for 10 min each in solutions of 2×SSC and 2 g/L SDS, 0.1×SSC and 2 g/L SDS, and 0.1×SSC, then dried at room temperature.

Detection and analysis

The chip was scanned with Scan Array 4000 standard biochip scanning system (Packard Biochip Technologies, Virginia, USA). ImaGene 3.0 software (Bio Discovery, Los Angeles, USA) was used to analyze the intensity of spots. The intensities of each spot at the two wavelengths represented the quantity of Cy3-dUTP and Cy5-dUTP, respectively, hybridized to each spot. The ratio of Cy5 to Cy3 was computed for each location. Overall intensities were normalized with a correction coefficient obtained using the ratios of the housekeeping genes. Genes were identified as differentially expressed if the absolute value of the natural logarithm of the ratio was >0.69. To minimize artifacts arising from low expression values, the genes with raw intensity values for Cy3 and Cy5 >800 counts were chosen for differential analysis.

RT-PCR

Total RNA (2 µg) was reversely transcribed in a final 25 µL reaction volume at 37 °C for 1 h by using 200 U M-MULV reverse transcriptase (Promega, Madison, USA). PCR amplification was performed in a final volume of 50 µL containing 5 µL of first strand cDNA solution, 2 U of Taq polymerase (Sangon, Shanghai, China), 5 µL of 10×PCR reaction buffer, 10 µmol/L of dNTP (Sangon, Shanghai, China) and 10 pmoL of each 3' and 5' sequence specific oligonucleotide primer (Sangon, Shanghai, China) for RhoC, protocadherin LKC and β₂-microglobulin gene (positive control). The amplification was performed on a DNA thermal cycler (Perkin Elmer, Shelton, USA). The primer sequences and the annealing temperature are shown in Table 1. PCR products were electrophoresed on 17 g/L agarose gels. The bands representing amplified products were visualized using ethidium bromide during the exposure to a UV transilluminator. The density of the bands on the gel was quantified by densitometry analysis. The expression of the genes was presented by the relative intensity of the PCR product bands from target sequences to that from the β₂-microglobulin gene^[7].

Statistical analysis

Statistical analysis was performed using the SPSS (version 11.0, Chicago, IL). The nonparametric Mann-Whitney test was performed to evaluate the differences in the expression of RhoC and protocadherin LKC between the groups. *P*<0.05 was considered statistically significant.

RESULTS

Quality and examination of total RNA

Ethidium bromide-stained total RNA agarose gel of SLHCC and NHCC was performed (Figure 1). None of our analyzed samples had detectable RNA degradation present at the leading edge of the gel, which is critical for reproducible gene expression data. The productive rate of RNA from SLHCC and NHCC was 0.42-1.64 mg/g and 0.34-1.85 mg/g, respectively. The rate of *A*₂₆₀/*A*₂₈₀ was 1.81-2.05. These results showed the high quality and purity of total RNA obtained.

Table 1 Primer sequences and annealing temperature for PCR

Gene		Primer sequences	Product size	Annealing temperature
RhoC	Up	5'-TCCTCATCGTCTTCAGCAAG-3'	183 bp	56 °C
	Down	5'-CTGCAATCCGAAAGAAGCTG-3'		
protocadherin LKC	Up	5'-GAAGCTTCAAGCTATGAAAA-3	256 bp	52 °C
	Down	5'-CCTTGATTTCCTGACTGTTC-3'		
β ₂ -MG	Up	5'-ACCCCACTGAAAAAGATGA-3'	120 bp	56 °C
	Down	5'-ATCTCAAACCTCCATGATG-3'		

Figure 1 Ethidium bromide-stained 1% agarose gel of four RNA samples. There were sharp ribosomal bands and minimal degradation that was critical for expression analysis. Lanes 1 and 2 represent total RNA derived from SLHCC. Lanes 3 and 4 represent total RNA from NHCC.

Identification of genes differentially expressed between SLHCC and NHCC

By applying the threshold value of 2 (up-regulation) and 0.5 (down-regulation) for intensity ratio of SLHCC vs NHCC, 668 genes (7.89%) were selected as differentially expressed genes, including 355 up-regulated (4.19%) and 313 down-regulated (3.69%) genes (Figure 2). Consistent with the precision of the assay, scatter plots comparing SLHCC with NHCC showed a wide distribution of the ratio in which red or green spots represented differently expressed genes, while yellow spots were related to similarly expressed genes (Figure 3).

The result revealed that the activated and repressed genes represented a different subset of cellular genes with biochemical activities consistent with the physiology and pathology between SLHCC and NHCC. Collectively, the genes provided a quantitative view of the changes in gene expression that occurred at the level of the human genome between SLHCC and NHCC. Based on the function discrepancy of encoding proteins, these variably expressed genes were mainly divided into 15 classes (Table 2).

Detection mRNA expression of RhoC and protocadherin LKC in SLHCC and NHCC by RT-PCR

Expression of RhoC and protocadherin LKC mRNA was detected in all SLHCC and NHCC. SLHCC tissues revealed significantly higher levels of protocadherin LKC mRNA than NHCC ($P = 0.026$), and showed significantly lower levels of RhoC mRNA than NHCC ($P = 0.031$) (Figure 4). The results were consistent with the results of cDNA microarray.

Table 2 Numbers of variably expressed genes in SLHCC and NHCC

Class	No. of up-regulated genes	No. of down-regulated genes
Oncogenes and antioncogenes	6	5
Genes encoding proteins related to ionic channel and protein transportation	7	7
Genes encoding cellular cycle modulator	3	9

Figure 2 cDNA microarray slide hybridized to SLHCC and NHCC shown before image analysis. The slide shown was spotted with 8 464 genes, hybridized to fluorescence-labeled cDNA, and exposed to scanArray 4000 for image capture. Red spots represent up-regulated genes, green spots represent down-regulated genes in SLHCC compared with NHCC. Yellow spots are related to genes of which gene expression was similar.

Figure 3 Scatter plot with ImaGene 3.0 software after hybridization of SLHCC (Cy5)/NHCC (Cy3) (8464 elements). Red spots represent similar expression genes. Yellow spots represent different expression genes.

Figure 4 Expression of RhoC and protocadherin LKC mRNA in SLHCC (lanes 1-3) and NHCC (lanes 4-6) SLHCC tissues revealed significantly higher levels of protocadherin LKC mRNA than NHCC and showed significantly lower levels of RhoC mRNA than NHCC.

DISCUSSION

Traditional viewpoint insists that the classification and prognosis of HCC are determined by the size of HCC, large HCC is always considered as terminal HCC and unexcisable HCC. However, UICC has changed this opinion in the 6th TNM classification for HCC. The number of nodes, but not the size of HCC, is the crucial factor for classification and prognosis of HCC^[8]. It is generally accepted that different HCCs have individual clinical pathological and molecular biological characteristics, which determined the different invasive and metastatic potentials of HCC^[1]. Our clinical observation implied different invasive and metastatic abilities between SLHCC and NHCC. As the genomewide expression profile of tumor is a representation of the biology of the tumor, and the diversity in gene expression profile reflects molecular biological diversity, thus, the further investigation of different gene expression profiles between SLHCC and NHCC is anticipated.

In this study, systematic investigation of gene expression patterns between SLHCC and NHCC was performed by using cDNA microarray to understand the mechanism of the diversity of molecular biological characteristics of HCC. A total of 668 genes (7.89%) showed significant change in their expression level between SLHCC and NHCC. It is not surprising that some differentially expressed genes were associated with the progression of HCC and most of them were related to the invasion and metastasis of tumor. These findings lend support to the presence of various molecular characteristics between SLHCC and NHCC. The gene expression profiles also provided a quantitative view of the changes in gene expression that occurred at the level of HCC genome between SLHCC and NHCC. These genes include matrix-degraded gene, cellular skeleton and motion gene, cellular signal and transferring gene, apoptosis-associated gene and so on. Some genes which were propitious to invasion and metastasis were up-regulated and made against these were down-regulated. We focused on matrix-degraded genes, cellular skeleton and motion genes, which were closely related to invasion and metastasis, and selected some of them for further study.

Both cell-cell interaction and cell-stroma interaction play an important role during the invasion and metastasis. Connections through cell-adhesion molecules, integrins, and cadherins stabilize tissue integrity, whereas loss or alteration of these cell surface proteins is associated with increased metastatic potential. The results of our study indicated that cathepsinL (CTSL), integrin α_6 , (ITGA $_6$) were down-regulated in SLHCC compared with NHCC. We also found that protocadherin LKC gene and H-cadherin gene were overexpressed in SLHCC vs NHCC. CTSL could promote migration of HCC cells through degrading ECM^[9,10]. ITGA $_6$ could promote invasion and metastasis of HCC cells through activating MMPs^[11]. Loss of H-cadherin expression in invasive cutaneous squamous cell carcinoma suggested it was a potential invasive and metastatic suppressive gene^[12]. Protocadherins are a major subfamily of the cadherin superfamily. This gene is predominantly expressed in liver, kidney and colon tissues, thus designating protocadherin LKC. The expression of protocadherin LKC is markedly reduced in cancers arising from these tissues at both transcriptional and protein levels. When protocadherin LKC was introduced into colon cancer cell line HCT116, which does not express this gene, a significant inhibition of cell proliferation could be observed. Recently, researcher identified the status of protocadherin LKC as an invasion and metastasis suppressor or gene which could increase the coagulation of tumor cells^[13-16]. Our study showed that protocadherin LKC mRNA was down-regulated in NHCC, suggesting a more disperse degree of NHCC cells compared with SLHCC cells.

We also found that many genes associated with cellular skeleton and movement were differentially expressed between

SLHCC and NHCC, for instance, RAB34 and RhoC. We focussed on RhoC because it was recently reported to play a crucial role in tumorigenesis. RhoC was found overexpressed in pancreatic ductal adenocarcinomas^[7], and its up-regulation was associated with tumor progression in ovarian carcinomas^[17]. Our previous study also showed a significant higher level of RhoC in extrahepatic metastasis of HCC compared with intrahepatic HCC and overexpression of RhoC gene was correlated with vein invasion, number of tumor nodes and extrahepatic metastasis^[18]. The expression level of RhoC could reflect the mobility of HCC cells^[19-22]. The results of our study that RhoC was down-regulated in SLHCC compared with NHCC suggested that SLHCC cells had a lower invasive and metastatic potential than NHCC.

Apoptosis is thought to play an important role in the regulation of proliferation of HCC cells. Apoptosis is modulated by a number of gene products which act through protein-protein interactions either as inducers or inhibitors. In our study, the genes of DAP, PHLDA, ATF $_2$, p21waf $_1$ /cip $_1$, and their products which could induce cellular apoptosis^[22-26], were obviously up-regulated in SLHCC compared with NHCC, whereas survivin, which inhibited cellular apoptosis^[27-31] was less in SLHCC than in NHCC. These data suggested that one of the mechanisms of SLHCC, which possesses a less invasive and metastatic potential than NHCC, might be a facility in apoptosis of HCC cells. Our study also showed many genes encoding proteins that were consistent with body growth and development were down-regulated in SLHCC compared with NHCC, for instance, SNRPN, NTRK3 and so on^[32,33]. These genes express usually in embryonic tissues and reflect the level of cell differentiation. These results suggested SLHCC cells has a better differentiation than NHCC cells.

In conclusion, the diversity of molecular biological characters between SLHCC and NHCC can be determined by differentially expressed gene profiles. SLHCC shares a better gene phenotype than NHCC, which is consistent with our previous clinical study.

Abstract

AIM: Attaining hepatitis B e antigen (HBeAg) seroconversion during lamivudine treatment is associated with fewer relapses in HBeAg-positive patients. In HBeAg-negative patients, predictors for post-treatment relapse remain largely unknown. We therefore studied whether end-of-treatment virologic response correlated with relapse after lamivudine treatment.

METHODS: We prospectively analyzed 12 HBeAg-negative patients and 14 HBeAg-positive patients with chronic hepatitis B, who received at least 9 mo of lamivudine treatment and were followed up for 12 mo post-treatment. Relapse of hepatitis B activity was defined by an elevation of serum ALT level above twice the upper limit of normal as well as reappearance of serum HBV DNA by the branched DNA assay or HBeAg during the follow-up period. The serum viral loads during and at the end of treatment were further determined by a quantitative real-time polymerase chain reaction assay.

RESULTS: Relapse occurred in 6 (50.0%) HBeAg-negative patients within 12 mo post-treatment. Two relapsers had end-of-treatment serum viral load <1 000 copies/mL, the proportion was not significantly different from that in the 6 non-relapsers (33.3% vs 16.7%; $P = 1.00$). Hepatitis B virus (HBV) DNA levels did not correlate with post-treatment relapse in HBeAg-positive patients either. However, genotype C patients tended to have a lower relapse rate than genotype B patients (14.3% vs 57.9%, $P = 0.08$).

CONCLUSION: Our results suggest that end-of-treatment virologic response cannot predict post-treatment relapse in patients with HBeAg-negative or -positive chronic hepatitis B. The impact of HBV genotype on the response to lamivudine treatment awaits further studies.

INTRODUCTION

Infection with hepatitis B virus (HBV) can cause a wide spectrum of liver diseases, such as fulminant or acute hepatitis, chronic hepatitis, liver cirrhosis, and hepatocellular carcinoma^[1]. About 350 million people throughout the world suffer from chronic HBV infection. Thus, active treatment of chronic hepatitis B to prevent progression into end-stage liver diseases is urgently needed.

Three drugs have been approved for the treatment of chronic hepatitis B: interferon (IFN) alpha, lamivudine and adefovir dipivoxil^[2-4]. IFN alpha is costly and has a narrow range of efficacy and tolerability. Adefovir is potent and has been approved for the treatment of chronic hepatitis B in the United States recently, but is nephrotoxic at doses higher than 10 mg per day and not available in other countries^[5]. Lamivudine is cheaper, better tolerated, and has been shown to be effective in patients with hepatitis B e antigen (HBeAg)-positive chronic hepatitis B^[6,7]. However, virologic response to lamivudine may not be as durable as that occurred spontaneously or induced by IFN treatment^[8,9]. Although Dienstag *et al.* reported that lamivudine-induced HBeAg seroconversion was durable after lamivudine treatment, conflicting data existed. It was reported that lamivudine-induced HBeAg seroconversion was not sustained and cumulative relapse rate within 12 mo was 38% in Korean patients^[9]. Thus, it is important to identify predictors for relapse after HBeAg seroconversion.

Lamivudine is also effective for HBeAg-negative chronic hepatitis B^[10-14]. The biochemical and virologic responses as well as the accumulated incidence of drug-resistant mutants were comparable to those in HBeAg-positive chronic hepatitis B^[11]. Nevertheless, in contrast to the HBeAg seroconversion as an unfavorable predictor for relapse in patients with HBeAg-positive chronic hepatitis B, predictors for post-treatment virologic response could be even more lacking in this special clinical setting, and thus the duration of lamivudine treatment is difficult to define^[2-4]. Recently, serum HBV DNA has been considered as a marker of efficacy during therapy for chronic HBV infection^[15]. The relationship between HBV DNA level and the post-treatment relapse in HBeAg-positive chronic hepatitis B has also been demonstrated^[16,17]. Whether similar situation holds true for patients with HBeAg-negative chronic hepatitis B remains to be clarified. In addition, HBV genotypes have been shown to correlate with the clinical outcomes of HBV infection, the response to IFN treatment, the rate of spontaneous HBeAg seroconversion, and the development of lamivudine resistance^[18-29]. It is therefore interesting to know the influence of HBV genotypes on the relapse after cessation of lamivudine treatment.

In this study, traditional polymerase chain reaction (PCR)-based assay was used to monitor and define the response to lamivudine treatment. In addition, we established a real-time PCR assay to quantify serum HBV DNA level in a wider dynamic

range, and compared the relapse rates between HBeAg-negative or -positive patients with detectable serum HBV DNA level and those with undetectable serum HBV DNA level at the end of lamivudine treatment. The impact of HBV genotype on the relapse rate was also analyzed.

MATERIALS AND METHODS

Patients

Between March 1998 and December 1999, 12 patients (10 men and 2 women, median age: 44 years, range: 19 to 61 years) with HBeAg-negative chronic hepatitis B (group I) and 14 patients (13 men and 1 woman, median age: 36 years, range: 20 to 55 years) with HBeAg-positive chronic hepatitis B (group II) who discontinued lamivudine treatment were prospectively enrolled for follow-up studies in the National Taiwan University Hospital. The diagnosis of HBeAg-negative chronic hepatitis B in group I patients was made upon elevated serum alanine aminotransferase (ALT) level at least twice the upper limit of normal (<40 IU/L) for more than 6 mo in the absence of HBeAg, but associated with active HBV replication as reflected by detectable serum HBV DNA by a commercial branched DNA assay (Bayer HBV DNA Assay, Bayer Corporation, Tarrytown, NY). All were positive for antibody to HBeAg (anti-HBe). The diagnosis of HBeAg-positive chronic hepatitis B in group II patients was made upon elevated serum alanine aminotransferase (ALT) level at least twice the upper limit of normal (<40 IU/L) for more than 6 mo in the presence of HBeAg and associated with active HBV replication. None had co-existing hepatitis C virus (HCV) or hepatitis delta virus infection. Other causes of hepatitis, such as alcoholic liver disease and autoimmune hepatitis were excluded. Patients with fulminant hepatitis accompanied with hepatic encephalopathy, concomitant human immunodeficiency virus infection, clinical evidence of pancreatitis, or in pregnancy were excluded.

All of the 12 group I patients received at least 9 mo of lamivudine treatment. During lamivudine therapy, liver biochemical tests were evaluated monthly. After the cessation of lamivudine treatment, liver biochemical tests were followed up monthly for 12 mo. Hepatitis B surface antigen (HBsAg), antibody to HBsAg (anti-HBs), HBeAg, and anti-HBe were examined every 3 mo. Relapse of hepatitis B activity was defined according to recommended criteria^[3,4,11], that was an elevation of serum ALT level above twice the upper limit of normal (<40 IU/L) as well as reappearance of serum HBV DNA by the bDNA assay or HBeAg during the follow-up period. Group II patients received the same regimen of lamivudine and follow-up schedule. In these patients, if HBeAg seroconversion (defined as loss of HBeAg and gain of anti-HBe) was attained, additional lamivudine treatment was given for at least 2 mo^[30]. For those not attaining HBeAg seroconversion after 9 mo of lamivudine treatment, to avoid the emergence of lamivudine-resistant mutants, the duration of therapy was determined arbitrarily by the attending physician^[30]. Again, post-treatment relapse of hepatitis B activity was defined according to recommended criteria^[3,4].

After written informed consent was obtained from each patient, serum samples were collected before treatment, at the 12th wk and at the end of lamivudine treatment, and at the time of relapse. Serum samples were stored at -70°C until virologic assays.

Hepatitis virus markers

HBsAg, anti-HBs, HBeAg, anti-HBe, and anti-delta were assayed with commercial kits (AxSYM System®, Abbott Laboratories, North Chicago, IL). Anti-HCV was tested by a second-generation enzyme-linked immunoassay (Abbott Laboratories).

Quantification of HBV DNA level

In this study, we basically used the traditional PCR-based

method to monitor and define the response to lamivudine treatment both in HBeAg-positive and -negative patients. Serum HBV DNA levels at baseline, the 12th wk of treatment, the end of treatment, and at the time of post-treatment relapse were determined by a branched DNA assay (Bayer Corporation) according to the manufacturer's instructions. The detection limit of this quantitative assay was 2.5 pg/mL (or 700 000 genome equivalents/mL). The serum HBV DNA levels at the 12th wk and at the end of lamivudine treatment were further determined by the real-time PCR.

Development of real-time PCR assay

To further clarify whether HBV DNA levels in the low range correlated with the response to lamivudine treatment, we developed another real-time PCR assay to detect HBV DNA levels below 2.5 pg/mL.

Extraction of serum HBV DNA

Serum DNA was extracted using a commercially available kit (QIAamp DNA Blood Mini Kit, QIAGEN Inc, Valencia, CA, USA).

Preparation of quantitative standards For preparation of an external standard of the real-time PCR detection assay, HBV DNA (3.2 kb) was cloned into vector pGEM-4Z (Promega, Madison, USA) and transformed into *Escherichia coli* DH5 α , and purified using a commercially available kit (GFX™ Micro Plasmid Prep Kit, Amersham Pharmacia Biotech Europe GmbH, Freiburg, Germany). The HBV copy number of the plasmid stock solution was determined by measuring the optical density at 260 nm. For each run, serial dilutions of the plasmid stock were prepared freshly from an aliquot stock solution.

Real-time PCR detection assay The real-time PCR assay including the design of primers and probes was performed as previously described^[31]. The number of HBV DNA copies was calculated relative to an HBV DNA plasmid 10-fold dilution series (1 pg/mL equals 280 000 copies/mL), which was included in each run. The input of this plasmid series ranged from 10^1 to 10^{10} copies per reaction mixture. Calibration curves were generated. The calculated r^2 was ≥ 0.99 in each run.

In our assay, less than 1 000 copies were not reliably detected by this assay, as judged by the varied detectable rate and the loss of linearity of the input copy number versus the cycle number at threshold crossing plot. For this reason, the lower limit for quantification was set at 1 000 copies/mL serum. In the range from 10^3 to 10^{10} template molecules per reaction, the curves showed good linearity and only minimal run-to-run deviations (data not shown). In 20 HBsAg- and anti-HBs-negative EDTA-plasma samples, none showed positive reactions in duplicate. The HBV DNA levels of the serum samples were then extrapolated using these calibration curves.

Determination of HBV genotype and drug-resistant mutants

HBV genotype was identified by using PCR-restriction fragment length polymorphism^[21]. The mutation on tyrosine-methionine-aspartate-aspartate (YMDD) motif of the HBV polymerase gene was identified by PCR and direct sequencing^[32].

Ethical considerations

The study protocol conformed to the ethical guidelines of the 1975 Declaration of Helsinki, and was approved by the Ethical Committee of the National Taiwan University Hospital. The sera were sampled after written or oral informed consent was obtained from the patients.

Statistic analysis

mean \pm SD or median (range) was used to describe the distribution of continuous variables. Baseline characteristics between relapsers and non-relapsers were compared by Student's *t* test

for continuous variables and by Chi-square test with Yates' correction for categorical variables. Statistical significance of differences in the relapse rate among different subgroups was estimated by using 2×2 contingency table according to serum HBV DNA level. All tests were two-sided and a *P* value <0.05 was considered statistically significant.

RESULTS

Characteristics of patients

The baseline characteristics of group I and group II patients are shown in Table 1. There was no significant difference with regard to clinical and virologic features. The mean duration of lamivudine treatment in group II patients was 2 mo longer than group I patients, but with no statistical significance.

Seven group II patients attained seroconversion of HBeAg after a median treatment period of 7 mo (range: 4 to 16 mo). Lamivudine was continued for an additional 2 to 12 mo (median: 4 mo in the 7 HBeAg seroconverters. The other 7 non-seroconverters discontinued lamivudine treatment after a median treatment period of 12 mo (range: 9 to 27 mo). The baseline characteristics of the 7 seroconverters and the 7 non-seroconverters were similar (data not shown).

Table 1 Baseline characteristics of HBeAg-negative and -positive patients

	HBeAg-negative	HBeAg-positive	<i>P</i> value
Case number	12	14	-
Male-number (%)	10 (83)	13 (93)	0.58
Age (yr)	45.2±15.3	35.3±11.2	0.08
ALT (IU/L)	227 (80-2410)	281 (84-1298)	0.92
Serum total bilirubin (mg/dL)	2.9 (0.9-18.6)	1.1 (0.6-11.7)	0.24
Serum HBV DNA level (pg/mL)	272 (3-3121)	863 (7-3376)	0.65
HBV genotype B/C-number (%)	9/3 (75/25)	10/4 (71/29)	1.00
Duration of lamivudine treatment-mo	12.3±1.9	14.2±4.9	0.23

Continuous values are expressed as mean±SD or median (range). HBV DNA levels were determined by a branched DNA assay (Bayer Corporation).

Characteristics of relapsers

At the end of lamivudine treatment, all group I and group II patients had normal serum ALT and undetectable serum HBV DNA by the bDNA assay. None developed biochemical or virologic breakthrough during the treatment period. After the

end of the treatment, 10 patients relapsed within 6 mo, including 5 group I and 5 group II patients. Another 2 patients relapsed between 6 and 12 mo, including 1 group I and 1 group II patients. There was no significant difference with regard to clinical and virologic features among relapsers and non-relapsers in HBeAg-negative or -positive patients (Table 2, 3). The duration of lamivudine treatment did not differ between them. Only one of the 7 genotype C patients relapsed after the discontinuation of lamivudine treatment, the incidence was lower compared with that in the 19 genotype B patients (14% vs 58%, *P* = 0.08).

Among 14 group II patients, the 7 seroconverters tended to have a lower rate of relapse than the 7 non-seroconverters (29% vs 57%, *P* = 0.30) (Table 3). The duration of additional lamivudine treatment after attaining HBeAg seroconversion did not correlate with clinical relapse (Table 3). Two relapsers already received an additional 4 and 12 mo of lamivudine treatment, respectively, after HBeAg seroconversion.

Table 2 Characteristics of relapsers and non-relapsers in 12 patients negative for HBeAg before lamivudine treatment

	Relapsers	Non-relapsers	<i>P</i> value
Case number	6	6	-
Male-number (%)	6 (100)	4 (66.7)	0.13
Age (yr)	50.7±10.1	39.7±18.5	0.24
ALT (IU/L)	227 (80-452)	320 (98-2410)	0.24
Serum total bilirubin (mg/dL)	1.2 (0.8-6.5)	2.9 (0.6-18.6)	0.21
Serum HBV DNA level (pg/mL)	287 (16-2489)	117 (3-3121)	0.41
Duration of lamivudine treatment (mo)	12.5±2.6	12.2±1.2	0.78
HBV genotype B/C-number (%)	6/0 (100/0)	3/3 (50/50)	0.18

Values are expressed as mean±SD or median (range). HBV DNA levels were determined by a branched DNA assay (Bayer Corporation).

Relation between virologic response at the 12th wk of lamivudine treatment and relapse

At the 12th wk of lamivudine treatment, none of the group I patients had serum HBV DNA level ≥10⁵ copies/mL. Of the 12 group I patients, 8 (67%) had serum HBV DNA level ≥1 000 copies/mL. Relapse of hepatitis B activity occurred in 6 (50%) after cessation of lamivudine treatment. All relapsers remained HBeAg-negative and anti-HBe-positive. Three relapsers had serum HBV DNA level <1 000 copies/mL and the other three had serum HBV DNA level ≥1 000 copies/mL. The distribution of post-treatment relapse was similar between patients with detectable and undetectable serum HBV DNA by the real-time PCR.

Table 3 Characteristics of relapsers and non-relapsers in 14 patients positive for HBeAg before lamivudine treatment

	Relapsers	Non-relapsers	<i>P</i> value
Case number	6	8	-
Male-number (%)	5 (83.3)	8 (100)	0.43
Age (yr)	32.5±12.6	37.4±10.4	0.44
ALT (IU/L)	281 (84-1 298)	306 (97-868)	0.34
Serum total bilirubin (mg/dL)	1.1 (0.7-11.1)	1.2 (0.7-3.3)	0.28
Serum HBV DNA level at baseline (pg/mL)	310 (7-1 590)	280 (20-3376)	0.34
Duration of lamivudine treatment (mo)	15.5±6.5	13.3±3.5	0.47
HBeAg seroconversion-number (%)	2 (33.3)	5 (62.5)	0.30
Duration of additional lamivudine treatment after HBeAg seroconversion (mo)	12.4	6.0±4.7	0.75
HBV genotype B/C-number (%)	5/1 (83.3/16.7)	5/3 (62.5/37.5)	0.58

Values are expressed as mean±SD or median (range). HBV DNA levels were determined by a branched DNA assay (Bayer Corporation).

Table 4 Relation between virologic response and relapse after cessation of lamivudine treatment

HBV DNA level (copies/mL)	Total (n = 26)		HBeAg-positive				HBeAg-negative	
			HBeAg seroconverters		HBeAg non-seroconverters			
	Relapser n = 12	Non-relapser n = 14	Relapser n = 2	Non-relapser n = 5	Relapser n = 4	Non-relapser n = 3	Relapser n=6	Non-relapser n=6
<1 000 copies/mL -number (%)	4 (67)	2 (33)	1 (50)	1 (50)	2 (67)	1 (33)	2 (67)	1 (33)
≥1 000 copies/mL -number (%)	8 (40)	12 (60)	1 (20)	4 (80)	2 (50)	2 (50)	4 (44)	5 (56)
	P ¹ = 0.37		P = 1.00		P = 1.00		P = 1.00	

Virologic response was determined at the end of lamivudine treatment. HBV DNA levels were determined by the real-time PCR assay. ¹Two-sided.

Relation between virologic response at the end of lamivudine treatment and relapse

Likewise, none of the group I patients had serum HBV DNA level $\geq 10^5$ copies/mL at the end of lamivudine treatment. Of the 12 group I patients, 9 (75%) had serum HBV DNA level ≥ 1 000 copies/mL and 3 had serum HBV DNA level <1 000 copies/mL. Two of the 6 relapsers had serum HBV DNA level <1 000 copies/mL and the other 4 had serum HBV DNA level ≥ 1 000 copies/mL. When compared with the non-relapsers, the proportion of relapsers with undetectable serum HBV DNA by the real-time PCR was similar ($P = 1.00$, Table 4).

Similar findings were noted in group II patients. Relapse of hepatitis B activity was detected in 6 (43%) of the 14 patients post-treatment. Three of the 6 relapsers had serum HBV DNA level <1 000 copies/mL and the other 3 had serum HBV DNA level ≥ 1 000 copies/mL. When compared with non-relapsers, the proportion of relapsers with undetectable serum HBV DNA by the real-time PCR was also similar (50% vs 75%, $P = 1.00$, Table 4). When in-treatment occurrence of HBeAg seroconversion was taken into consideration, serum viral loads in the low range (< 10^5 copies/mL) did not correlate with clinical relapse during follow-up, either (Table 3).

At the end of lamivudine treatment, YMDD motif of the HBV polymerase gene was amplified in all patients. PCR products were detectable in 11 and variation at this motif was found in 2 of them, including methionine-to-valine substitution in one (viral load: 32 400 copies/mL; serum ALT: 24 U/L) and methionine-to-isoleucine substitution in the other (viral load: 22 344 copies/mL; serum ALT: 30 U/L). Both developed relapse with wild-type YMDD HBV strain during the follow-up period.

DISCUSSION

In this study, we found that the relapse rate after lamivudine treatment was high and comparable between HBeAg-negative (50%) and -positive (43%) patients, which did not correlate with serum viral load at the end of treatment.

Because we only evaluated relapsers whose serum ALT levels were greater than twice the upper limit of normal, the rate of post-treatment virologic relapse could be even higher. The high relapse rate in our series indicated a poor durability of virologic response to lamivudine treatment in Asian countries when compared with that in Western countries^[6,8,9,17,33], and an urgency of identifying an effective means to predict the durability of post-treatment virologic response. Lamivudine possesses potent inhibitory effect on viral replication, and previous studies have shown that after the reduction of viral load by lamivudine, a T cell response over viral replication could be restored^[21]. Because serum viral load under anti-viral treatment reflected the control from both drugs and hosts over viral replication, we thus assumed that keeping viral load in the lower range might confer an adequate control over viral replication and therein have a lower relapse rate. Previous studies indeed revealed that

viral load at the 12th wk and at the end of lamivudine treatment correlated with a higher HBeAg seroconversion rate and a lower post-treatment relapse rate, respectively^[16,17]. In addition, serum HBV DNA level less than 10 000 genomes/mL within 12 wk of starting treatment might predict HBeAg seroconversion^[16], and serum HBV DNA level less than 4 700 genomes/mL at the time of HBeAg seroconversion might be associated with a lower relapse rate^[17]. However, our results showed that there was no correlation between serum viral load < 10^5 copies/mL at the end of lamivudine treatment and post-treatment relapse. Consistently, one recent study demonstrated that the end-of-treatment viremic status by a qualitative PCR assay did not correlate with post-treatment relapse in HBeAg-negative patients receiving lamivudine treatment^[34]. This fact suggested that serum viral load might represent the susceptibility of viruses to lamivudine but not reflect the status of host immune control. When suppression pressure from anti-virals was removed, residual viruses within the hepatocytes might actively replicate again and lead to relapse. However, whether an extremely low level of serum viral load can predict a durable anti-viral response post-treatment awaits ultrasensitive HBV quantitative assays. Actually, one recent study demonstrated that in patients with end-of-treatment serum HBV DNA levels of <200 copies/mL, the post-treatment relapse rate was significantly lower than in those with end-of-treatment serum HBV DNA levels of >1 000 copies/mL^[35]. This finding supported our speculation.

In HBeAg-positive patients, the serum viral loads at the end of lamivudine treatment were comparable between seroconverters and non-seroconverters. From another aspect, the virologic response was more durable in the seroconverters than in the non-seroconverters during follow-up. Again, this implied that appearance of anti-HBeAg rather than the viremic levels could reflect the ability of host immune control over viral replication. Extended therapy has been suggested to ensure the durability of virologic responses after HBeAg seroconversion was attained^[9]. However, whether longer duration of therapy can further enhance the host immunity against HBV needs future immunological assays.

Our results showed that the viremic level at the end of lamivudine treatment could not guarantee a durable post-treatment anti-viral response. Of particular note, HBV genotype C tended to have a lower relapse rate compared with genotype B. Although the molecular virologic mechanisms accounting for clinical outcomes or response to anti-viral treatments remain largely unknown, pathogenic and therapeutic differences do exist among HBV genotypes^[18-29,36]. However, in the individualized setting of HBeAg-positive and -negative patients, HBV genotype was not a factor associated with post-treatment relapse (Tables 2, 3). In addition, conflicting data existed in recent reports^[34,37]. Since our case number is small, whether HBV genotype serves as a predictor for durability of virologic response to lamivudine treatment remains to be examined.

The major limitation in this pilot study was the relatively small case number in each group. However, our findings highlighted

that virologic response at the end of lamivudine treatment could not predict post-treatment relapse. Further large studies by using more sensitive quantitative assays are needed to address this important issue. Other genetic determinants of the virus and host should be clarified in the future. Since the relapse rate was high in both HBeAg-negative and HBeAg-positive patients in HBV endemic areas and such events were usually preceded by an upsurge of serum viral load^[32], frequent monitoring of liver biochemical tests and serum viral loads could be considered to detect early relapse. With the advent of novel anti-viral agents, patients without durable virologic response to current therapy may hopefully benefit from further treatments.

Abstract

AIM: To study the application of artificial neural network (ANN) in forecasting the incidence of hepatitis A, which had an autoregression phenomenon.

METHODS: The data of the incidence of hepatitis A in Liaoning Province from 1981 to 2001 were obtained from Liaoning Disease Control and Prevention Center. We used the autoregressive integrated moving average (ARIMA) model of time series analysis to determine whether there was any autoregression phenomenon in the data. Then the data of the incidence were switched into $[0,1]$ intervals as the network theoretical output. The data from 1981 to 1997 were used as the training and verifying sets and the data from 1998 to 2001 were made up into the test set. STATISTICA neural network (ST NN) was used to construct, train and simulate the artificial neural network.

RESULTS: Twenty-four networks were tested and seven were retained. The best network we found had excellent performance, its regression ratio was 0.73, and its correlation was 0.69. There were 2 input variables in the network, one was AR(1), and the other was time. The number of units in hidden layer was 3. In ARIMA time series analysis results, the best model was first order autoregression without difference and smoothness. The total sum square error of the ANN model was 9 090.21, the sum square error of the training set and testing set was 8 377.52 and 712.69, respectively, they were all less than that of ARIMA model. The corresponding value of ARIMA was 12 291.79, 8 944.95 and 3 346.84, respectively. The correlation coefficient of nonlinear regression (R_{NL}) of ANN was 0.71, while the R_{NL} of ARIMA linear autoregression model was 0.66.

CONCLUSION: ANN is superior to conventional methods in forecasting the incidence of hepatitis A which has an autoregression phenomenon.

INTRODUCTION

Hepatitis A is an important infectious disease in the world^[1-4]. Guidelines of vaccination *versus* hepatitis A call for correct estimation of the incidence of hepatitis A^[5-9]. The occurrence of infectious diseases has its rules, affected by the speed of pathogen variation, susceptible accumulation and environmental changes. Early recognition of the epidemic rules is significantly important for the prevention and control of hepatitis. Among the available models, time series analysis^[10,11] and regression analysis^[12-14] are poorly suited for discovering the epidemic rules. The reason for this lies in the complexity of their relationship.

However, artificial neural networks (ANN) can recognize the rules to make right prediction and provide assistance for decision-making because they have the characteristics of self-organizing and self-learning processes^[15-18]. Artificial neural networks are computation systems that process information in parallel, using a large number of simple units, and that excel in tasks involving pattern recognition. These intrinsic properties of the neural networks have been translated into higher performance accuracy in outcome prediction compared with expert opinion or conventional statistical methods^[19-22].

Recently, backpropagation (BP) artificial neural network has been widely applied to a variety of problems in the field of medicine^[23-26]. It is also called the front forward network because it is the front forward error propagation network without feedback. There is no mutual connection among the neurons in the same layer.

In the present work, we applied several artificial neural networks to the forecast of the incidence of hepatitis A. We also represented the basic principles and how to train the neural networks.

MATERIALS AND METHODS

Materials

The data of the incidence of hepatitis A in Liaoning Province from 1981 to 2001 were obtained from Liaoning Disease Control and Prevention Center. The highest incidence of hepatitis A during this period was 160.07 per one hundred thousand, and then the incidence descended progressively from 1981-1986 and rose from 1986 to 1989 (Figure 1). The low incidence could be seen from 1996. To switch these data into $[0,1]$ intervals, we applied the following transformation: the network theoretical output was equal to the incidence of hepatitis A / 200 by using $1/10^5$ as the unit of measurement.

Construction, training and simulation of the network

Automatic network designer The automatic network designer determined a suitable architecture, using a combination of heuristics and sophisticated optimization strategies. It conducted a large number of tests, which were used to determine the best architecture. It could automatically compare linear, probabilistic neural network (PNN), generalized regression neural network (GRNN), radial basis function and multilayer perceptron networks (Figure 2), and automatically choose the smoothing factor for PNN or GRNN, the smoothing factor and the number of units for radial basis function networks, and the number of

units for multilayer perceptrons. We could control the length and rigor of search iteration to be performed, and bias the search towards smaller networks using a unit penalty factor.

Figure 1 Incidence of hepatitis A in Liaoning Province, China.

Figure 2 Topological structure of ANN.

Intelligent problem solver In ST NN, an intelligent problem solver was used to select the most excellent network. We chose the advanced version to customize the design process, the problem needed to be solved was a time series problem. Because many time series had a natural period, steps parameter equals to 1 was indicated here by ARIMA analysis. The output variables were transformed values of incidence of hepatitis A, and the input variables were time and AR (1) which meant former transforming values. The software could search for a useful subset of the specified variables. The cases in the data set were divided into three subsets, one for training the network, one for cross verification and the last one for testing. In practice, the data from 1981 to 1992 were used to train the network and the data from 1993 to 1997 were used as a verifying set. The performance of the network could be tested by estimating the data from 1998 to 2001.

Four types of networks, such as linear network, multilayer perceptron (3 layers), probability network or GRNN and radial basis function, needed to be considered. In the mean time, network complexity was determined automatically. A medium length of design procedure was selected, which conducted a fast search for an optimal network. The network saved would be one with balance performance against types and complexity. The best network found (taking account of diversity) was retained.

Choosing the number of hidden layers and units was the most critical problem. There were a few heuristics that could guide here. One hidden layer was sufficient for most problems when multilayer perceptrons were used. If the error could not be gotten down to an acceptable level even with a large number of hidden units, it might be worth trying two hidden layers.

A large number of hidden units could generally model a more complex problem, but required more training and were more prone to poor generalization. The changes in training and verification errors should be observed as the experiment was

being done. If the addition of more hidden units caused a decrease in both, then the network was probably too small. However, if the verification error was significantly larger than the training error and, in particular, if it deteriorated during iterative training, then the network was probably too large.

The number of weights and thresholds in the network should be less than or much less than the number of training cases. Ideally, there should be about two to five as many training cases as weights. If the number of training cases was small, the smaller networks should be used because of no enough data to model a complex function. If the cases were fewer than the product of the number of inputs and outputs, only a linear model should be used. Lack of sufficient data was one reason why it was sometimes good to remove input variables. Even if the variables had some genuine information, the reduction in network size consequent upon removing them might improve network performance.

Performance statistic index

One index to evaluate the performance of networks and ARIMA was sum square of error (SSE): $SSE = \sum (y_i - \hat{y}_i)^2$. The other was nonlinear determinant coefficient: $R_{NL} = 1 - \sqrt{\frac{\sum (y_i - \hat{y}_i)^2}{\sum y_i^2}}$, where y_i is the real value of case i and \hat{y}_i is the estimated value of case i .

RESULTS

Network structure and prediction

Finally 24 networks were tested, and 7 were retained. The best network we found was BP network, which had excellent performance, its regression ratio was 0.73, and its correlation was 0.69.

The structure of the network is shown in Figure 3. There were 2 input variables, one was AR(1), the other was time. The number of units in hidden layer was 3. The weight and threshold distribution of the best network is shown in Table 1.

Figure 3 Topological structure of the best network.

Table 1 Weight and threshold distribution of the best network

	Unit 1	Unit 2	Unit 3	Y

ARIMA model coefficient and its testing results

In ARIMA time series analysis results, the best model was first order autoregression without difference and smoothness. The coefficient of AR (1) and constant were 0.83 and 81.22, respectively (Table 2).

Table 2 ARIMA model coefficient and its testing results

Variables	Coefficient	SE of coefficient	t	P
AR (1)	0.83	0.12	6.88	5.27×10^{-6}
Constant	81.22	30.94	2.62	1.91

Comparison between BP network and ARIMA

The goal of training the network was to compare the performance with conventional methods by using inverse transforming predicted value obtained from the network. Predicted value and error are shown in Table 3, and its corresponding line graph is shown in Figure 4.

The total sum square error of the ANN model was 9 090.21, the sum square error of the training set and testing set was 8 377.52 and 712.69, respectively, while the corresponding value of ARIMA was 12 291.79, 8 944.95 and 3 346.84, respectively. The nonlinear determinant coefficient of ANN and the ARIMA linear autoregression model was 0.71 and 0.66, respectively.

Table 3 Comparison between BP network and ARIMA

Time (yr)	Incidence (1/100 000)	Predicted value from ANN	Error from ANN	Predicted value from ARIMA	Error from ARIMA
1981	160.07	-	-	-	-
1982	136.68	101.58	35.10	146.87	-10.19

DISCUSSION

From the above results, we can see that there was a first order autoregression phenomenon in the linear autoregression model. The nonlinear determinant coefficient of the ARIMA linear autoregression model was 0.66. The regression graph shows that there was an obvious linear tendency, but some values were still not perfectly fitted. Differences in the amount were great between values. The sum square error of the model was 12 291.79, the sum square error of the training set and testing set was 8 944.95 and 3 346.84, respectively. While in the model based on artificial neural networks, the nonlinear determinant

coefficient was 0.71, higher than that of linear autoregression model. The sum square error of the ANN model was 9 090.21, the sum square error of the training set and testing set was 8 377.52 and 712.69, respectively. In time series analysis, there was statistical significance in the test of coefficients, showing the existence of first order autoregression. Values from extrapolation forecasting based on ANN were mainly in concordance with the actual values, while values from ARIMA model forecasting were a little higher than the actual values of the incidence. These findings showed that ANN could recognize some rules by preliminary learning, but the effect of some special values over considering sum square error made the forecasting of low incidence inaccurate. Combined application of the traditional methods and artificial neural networks can make use of each other's merits and raise the right prediction level.

Forecasting the incidence of infectious diseases is very important for their prevention and control. Solving this problem calls for the ability to learn the unknown mapping or function only by the existing examples^[27,28]. However, after the mapping or a similar one is learned, artificial neural networks can be used to estimate the mapping when only several parts are known. Now artificial neural networks have been widely accepted as a potentially useful way in modeling complex nonlinear and dynamic systems^[29-31]. Neural networks could remove neither the need for knowledge nor prior information about the systems of interest^[32]. They just reduce the model's reliance on the prior information while totally removing the need for the model builders to correctly specify the precise functional forms of the relationship that the model seeks to represent^[33]. In addition, they offer real prospects for a cheaper, more flexible, less assumption-dependent and adaptive methodology.

Generally, there are two major ways to train the networks, one seeking high accuracy, and the other considering both the accuracy and performance. Through the former method, mapping was input from N-dimensional space and output to M-dimensional space. Thus, the phenomenon of overlearning occurred and the results of extrapolation were not perfect^[34]. In the present work, we divided the original data into three parts, one for training, one for verification, and one for extrapolation and prediction. Thus the problem of overlearning was solved effectively. Time series analysis showed that there was a first order autoregression phenomenon in the data without exponent smoothing. Autoregression phenomenon might often exist in the data of the incidence. Traditional method of solving this is time series analysis^[35]. However, it is difficult to practice because it requires to meet several conditions, such as white noise^[36]. There are no such limitations in artificial neural network, and the software could voluntarily choose appropriate order of autoregression to fit and predict. In addition, R_{NL} has shown that it is reasonable to employ artificial neural networks in modeling complex nonlinear data.

In conclusion, ANN is likely to be an effective tool in processing time series data. The construction and explanation of the model should be further explored.

Abstract

AIM: There are conflicting data about p53 function on cellular sensitivity to the cytotoxic action of 5-fluorouracil (5-FU). Therefore the objective of this study was to determine the combined effects of adenovirus-mediated wild-type (wt) p53 gene transfer and 5-FU chemotherapy on pancreatic cancer cells with different p53 gene status.

METHODS: Human pancreatic cancer cell lines Capan-1^{p53mut}, Capan-2^{p53wt}, FAMPAC^{p53mut}, PANC1^{p53mut}, and rat pancreatic cancer cell lines AS^{p53wt} and DSL6A^{p53null} were used for *in vitro* studies. Following infection with different ratios of Ad-p53-particles (MOI) in combination with 5-FU, proliferation of tumor cells and apoptosis were quantified by cell proliferation assay (WST-1) and FACS (PI-staining). In addition, DSL6A syngeneic pancreatic tumor cells were inoculated subcutaneously in to Lewis rats for *in vivo* studies. Tumor size, apoptosis (TUNEL) and survival were determined.

RESULTS: Ad-p53 gene transfer combined with 5-FU significantly inhibited tumor cell proliferation and substantially enhanced apoptosis in all four cell lines with an alteration in the p53 gene compared to those two cell lines containing wt-p53. *In vivo* experiments showed the most effective tumor regression in animals treated with Ad-p53 plus 5-FU. Both *in vitro* and *in vivo* analyses revealed that a sublethal dose of Ad-p53 augmented the apoptotic response induced by 5-FU.

CONCLUSION: Our results suggest that Ad-p53 may synergistically enhance 5-FU-chemosensitivity most strikingly in pancreatic cancer cells lacking p53 function. These findings illustrate that the anticancer efficacy of this combination treatment is dependent on the p53 gene status of the target tumor cells.

INTRODUCTION

Pancreatic cancer is a very aggressive tumor with a poor prognosis. Unfortunately, the majority of the patients are diagnosed at an advanced disease status and are not suitable for potentially curative resection. Intrinsic limitations of chemotherapy are the endogenous or acquired resistance of tumor cells to anti-cancer drugs and their toxicity to normal tissues, the latter being responsible for the occurrence of severe side effects. For these reasons, new approaches for the treatment of pancreatic cancer patients have to be developed.

The p53 tumor suppressor gene is functionally inactivated in about 50% of all human malignancies including up to 60% of pancreatic cancers^[1]. The tumor suppressor activity of p53 is mainly mediated through its ability to induce cell growth arrest or apoptosis in response to a variety of stress signals, whereas a lack of functional p53 usually leads to increased genomic instability, deregulated cell proliferation, accelerated tumor progression, and elevated cellular resistance to anticancer therapy^[2]. Expression of wt-p53 has been shown to be required for 5-FU-induced apoptosis and to greatly potentiate 5-FU-cytotoxicity^[3,4]. Several reports have suggested that the p53 status of the tumor cells may be an important response determinant to 5-FU-based chemotherapy^[5,6]. In contrast, other studies have failed to demonstrate any relationship between p53 expression and 5-FU chemotherapy^[7,8]. Gene therapy by adenovirus mediated introduction of the wild-type human p53 gene into tumors that are deficient in functional p53 has shown a significant tumor suppressing effect in preclinical studies and in clinical trials^[9-13]. Furthermore, these tumor suppressing activities of p53 reintroduction have been reported to be enhanced by combination with many chemotherapeutic drugs or ionizing radiation in various human tumors^[14,15]. However, the influence of the *de novo* expressed exogenous p53 on cellular sensitivity toward DNA-damaging agents is still not clear^[16-19].

The goal of the present study was to determine *in vitro* and *in vivo*, whether reintroduction of wt-p53 protein into pancreatic cancer cells could increase the sensitivity to 5-FU chemotherapy. Therefore, we tested pancreatic cancer cells with different p53 status. Our results demonstrate that wt-p53 gene transfer in pancreatic cancer cells with loss of p53 function has a significant impact on 5-FU-chemosensitivity leading to potential tumor regression both *in vitro* and in a pancreatic cancer model of immunocompetent rats.

MATERIALS AND METHODS

Cell lines and culture conditions

The human pancreatic cancer cell lines, Capan-1, Capan-2, PANC1 were provided by the Tumorbank, DKFZ, Heidelberg, Germany. FAMPAC was established in our laboratory from a 43 year old female with familial pancreatic cancer^[20]. The rodent pancreatic cancer cell lines, AS (BSp73AS) and DSL6A, were originally derived from a spontaneous pancreatic adenocarcinoma of a BDX rat^[21] and from a primary pancreatic carcinoma of an azaserine-treated Lewis rat^[22] respectively. All cells were grown

in Dulbecco's modified Eagle's medium (DMEM; Gibco BRL) supplemented with 100 mL/L heat inactivated fetal calf serum (FCS, Gibco BRL), 100 units/mL penicillin, 100 µg/mL streptomycin (Gibco BRL) and incubated at 37 °C in a humidified atmosphere with 50 mL/L CO₂.

Adenoviral vectors

The AdEasy system^[23] was used for construction and propagation of the human wt- p53 (Ad-p53) adenoviruses. The shuttle vector pAdTrack-CMV and the adenoviral backbone plasmid pAdEasy-1 were kindly provided by Bert Vogelstein (*Howard Hughes Medical Institute and Kimmel Cancer Center at Johns Hopkins University, Baltimore, MD 21 231*). The cDNA coding for human p53 was a gift from Martin Scheffner (*ATV, DKFZ, 69120 Heidelberg, Germany*). The control adenoviral vector expressing cytosine deaminase (Ad-CD) was kindly provided by Zhuangwu Li (*NIH/NCI Bldg. 10/Rm. 12N226, 9000 Rockville Pike, Bethesda, MD 20 892*) and the AdlacZ vector was a gift from Petra Klein-Bauerschmitt (*ATV, DKFZ, 69120 Heidelberg, Germany*). Recombinant adenoviruses were propagated in 293 cells, harvested, aliquoted and stored as described^[24]. Adenovirus titer in plaque-forming units (p.f.u.) was determined by plaque formation assays on 293 cells. The multiplicity of infection (MOI) was defined as the ratio of p.f.u. per total number of cancer cells to be infected. Adenoviruses were administered in phosphate buffer (20 mmol/L NaH₂PO₄, pH 8.0, 130 mmol/L NaCl, 2 mmol/L MgCl₂, 20 g/L sucrose).

β-galactosidase expression

Pancreatic cancer cells were infected with AdlacZ in a variety of MOI ranging from 1 to 100, in 1 mL of medium in 25-cm³ tissue culture flasks under routine conditions. After 24 h infected cells were fixed in 960 mL/L ethanol and stained with X-gal solution. The percentage of positively blue stained cells was determined by scoring five random high power fields per 25-cm³ flask.

Western blotting

The expression of p53 protein was assayed in all six pancreatic cancer cell lines before and after Ad-p53- infection. Cells were transduced with 10² MOI Ad-p53 and harvested at 24h. The protein lysates were separated by electrophoresis on a 100 g/L SDS/acrylamide gel and transferred to a PVDF membrane. The membrane was blocked in 200 mL TTBS, 50 g/L skimmed milk, 1 g/L Tween-20 for 1 h, incubated with primary p53 DO7 antibody (DAKO, Cambridgeshire, UK) for 1 h. After washing in TTBS the membrane was incubated with horseradish peroxidase (HRP) conjugated anti-mouse IgG for 45 min. Signals were detected using the enhanced chemiluminescence system (ECL, Amersham Life Science Ltd, Bucks, UK).

WST-1 cell viability assay

Cells were seeded at a concentration of 5-10×10³ cells/well in 100 µL culture medium into 96-well microtiter plates. After a 12 h incubation period, cells were infected either with Ad-p53 in a variety of MOIs (10⁻²-10²) or treated as controls with Ad-CD. After 24 h cells were washed with PBS and treatment with 5-fluorouracil (5-FU, Medac, Hamburg, Germany) at the concentration of 5 µL/mL was started for a period of 48 h. All dilutions were performed in culture medium. Cells were washed with PBS and 10 µL/well of the cell proliferation reagent WST-1 (Boehringer Mannheim, Germany) was added in 100 µL cell culture medium for 4 h. Absorbance of the samples was analysed using a bichromatic ELISA reader at 450 nm and 690 nm. Relative proliferation (A/Ao) was defined as the ratio of absorption measured in Ad-p53- infected and/or 5-FU treated cells or Ad-CD- infected cells (A) compared with the absorption measured in untreated control cells (Ao). All experiments were performed in triplicate.

FACS analysis

Cells were plated at a density of 10⁵ per 25-cm³ flask and infected with viral vectors at an MOI of 1 for 24 h. After 24 h cells were washed with PBS and treatment with 5-fluorouracil (5-FU, Medac, Hamburg, Germany) at the concentration of 5 µL/mL was started for a period of 48 h. The cells were harvested and washed with PBS. The apoptotic fraction of treated or untreated cells was determined by FACS analysis (FACSCalibur, Becton Dickinson) following permeabilisation and propidium iodide (PI) staining of the cells. Briefly, 250 µL of PI staining solution (1 g/L TritonX-100, 50 µg/mL PI in PBS, pH 7.4) was added to 5×10⁵ cells and analysed within 1 h using the CellQuest software. The proportion of apoptotic cells was calculated for each group: mock infected, Ad-CD, 5-FU, Ad-p53 and Ad-p53+ 5FU. Cell debris and fixation artefacts were excluded by appropriate gating. All experiments were performed in triplicate.

Animal experiments

Male Lewis rats, purchased from Charles River WIGA Laboratories (Sulzfeld, Germany), were kept in isolators and received food and water ad libitum. Animal experiments were performed under NIH and institutional guidelines established for the Animal Care Facility at the University of Heidelberg. A total of 10⁶ DSL6A tumor cells were injected in 100 µL of PBS/animal subcutaneously (sc.) into the abdominal wall of 4 wk-old rats. Eight weeks after tumor cell inoculation, when the tumor nodules had an average size of 8 mm×8 mm, the treatment as indicated was started and repeated twice a week for 1 mo. 5-FU (5 mg/kg bm) was given intraperitoneally (ip.) and Ad-p53 or Ad-CD infections (10⁸ infective units) were injected intratumorally (it.). The animals were separated by randomisation into 5 groups of 8 rats each namely mock infected, Ad-CD (1×10⁸ infectious particles it.), 5-fluorouracil (5 mg/kg bm ip.), Ad-p53 (1×10⁸ infectious particles it.) and Ad-p53+5-FU. Tumor size (mm²) was determined by measuring the largest and smallest diameter as tumor length (mm)×tumor width (mm). When the tumor size reached >600 mm², animals were sacrificed. Tumor size and survival rate were documented weekly.

TUNEL assay

Tumor tissues were fixed in 40 g/L neutral formaldehyde or snap frozen in liquid nitrogen and stored at -80 °C. Sections (5 µm) were stained with hematoxylin and eosin using standard procedures. At least 6 representative tumors of each group of treated or untreated animals were analysed for apoptosis. Immunohistochemical detection and quantification of apoptosis in formalin fixed tumor tissue sections were performed using the 'In situ cell death detection kit, AP' (Roche Diagnostics, Mannheim, Germany). The sections were stained and analysed microscopically according to the manufacturer's instructions.

Reverse transcriptase-PCR analysis

From snap frozen tumor tissue total RNA was extracted using RNazol (Cinna/Biotech, Friendswood, TX). cDNA was then generated using the cDNA cycle kit for RT-PCR (Invitrogen, San Diego, CA, USA). To assay expression of the p53 transgene from Ad-p53 in infected tumors, the following primers were generated to amplify a 294 bp product which is specific for Ad-p53: forward primer: 5' GGTGCATTGGAACGCGGA TT 3', reverse primer: 5' GGGGACAGAACGTTGTTTTC 3'. PCR was performed by an initial heating step at 95 °C for 5 min, followed by 35 cycles at 95 °C for 1 min, at 58 °C for 1 min and at 72 °C for 1 min and a final extension step at 72 °C for 5 min. The PCR products were separated on 1% agarose gels and visualized by ethidium bromide staining and UV light.

Statistical analysis

Statistical analysis was performed using SPSS software (Release 11.0.1, SPSS Inc.). The rate of cell viability and the rate of

apoptotic cells were expressed as mean \pm SE and 95% confidence interval. The 95% confidence intervals of the means were used to analyse the rate of cell viability and the rate of apoptotic cells between two groups of each cell line. Differences between means without overlap of the confidence intervals were described as statistically significant. Tumor size in rats was given as mean \pm SD. Normal distribution of tumor size in different groups was judged by the Shapiro-Wilk test. ANOVA was performed to analyse the therapeutic effects after 4 cycles and at study end between the groups with respect to tumor size. Two-sided *P*-values were reported and an effect was considered statistically significant at *P*<0.05.

RESULTS

Adenovirus mediated gene transfer efficacy in pancreatic cancer cells

The efficacy of Ad-p53 gene transfer into pancreatic cancer cell lines was assessed as the percentage of X-gal stained positive cells 24 h after infection with AdlacZ. There was a variation in transduction efficacy as summarised in Table 1. An MOI of 50 resulted in 73-95% of cells stained blue in the tested cell lines.

Table 1 p53 status, transduction efficacy and IC₅₀ value of 5-FU in pancreatic cancer cell lines; mean \pm SD

Cell line	p53 status	β -gal ¹ %	5-FU-IC ₅₀ value ¹ μ g/mL
Human			
Capan-1	159 GCC \rightarrow GTC	92 (4.5)	8.25 (0.45)
Capan-2	wild type	95 (7.2)	5.75 (0.55)
FAMPAC	175 CGC \rightarrow CAT	82 (7.8)	8.00 (0.45)
PANCL	273 CGT \rightarrow CAT	82 (7.8)	9.50 (0.75)
Murine rat			
AS	wild type	73 (5.3)	6.55 (0.45)
DSL6A	Null	83 (6.2)	7.75 (0.55)

¹ β -gal was the percentage of X-gal positive cells 24 h after AdlacZ infection at a multiplicity of infection of 50. ²IC₅₀ values were defined for each cell line as the 5-FU concentration leading to 50% growth inhibition. Results are expressed as mean \pm SD from three independent experiments.

p53 status and p53 protein expression after Ad-p53 infection in vitro

To determine the p53 status of the tested cell lines, we reviewed the literature (Capan-1²⁵, Capan-2²⁵, PANC1²⁶) or analysed cell samples (FAMPAC²⁷) for mutations in exons 5-8 of p53. For the rat pancreatic cancer cell lines, DSL6A and AS, the p53 status was determined by PCR-SSCP analysis followed by direct sequencing^[28]. Despite repeated attempts, the DSL6A cell line failed to give rise to amplified products for tested exons 5-8 of p53, suggesting a homozygous deletion of the loci. All exons could be amplified from normal control DNA of AS cells. The mutation status of the pancreatic cancer cell lines is outlined in Table 1.

The expression of p53 protein was confirmed by Western blot analysis. The antibody used reacted with both wild type and mutant p53. This was done to confirm the expression after Ad-p53 infection and to establish the baseline protein expression patterns. These *in vitro* experiments demonstrated for all cell lines detectable amounts of p53 protein 24 h after infection with Ad-p53 indicating an efficient translation. As indicated in Figure 1 the quantity of p53 was increased following infection with Adp53, with the exception of Capan-1 and FAMPAC cell lines showing a strong baseline overexpression of mutated p53.

Figure 1 Expression of p53 protein before (-) and after infection with Ad-p53 (+) in pancreatic cancer cell lines.

Effect of p53 gene transduction on in vitro pancreatic tumor cell proliferation

To establish defined conditions for the *in vitro* experiments, all six pancreatic cancer cell lines were transduced with different multiplicity of infection (MOI = p.f.u./cell) of the Ad-p53 vector in the range from 10⁻² to 10². To test the effect of the p53 recombinant adenoviruses on tumor cell growth, we assayed the cell viability using a colorimetric cell proliferation test. Infection with the control vector Ad-CD had no significant effect on cell growth (data not shown). In contrast, we observed that Ad-p53 infection dose dependently resulted in significantly decreased cell viability. A significant inhibitory effect on tumor cell growth was achieved at MOI ³ 1 in all tested cell lines with an alteration of p53, whereas lower levels of Ad-p53 virus particles had no effect. Capan-2 cells containing wt-p53, were less sensitive and a similar inhibitory effect was only achieved with a higher MOI of 10. The rat pancreatic cancer cell line, AS containing wt-p53, revealed only a small effect on tumor growth (Figure 2).

Figure 2 Decreased *in vitro* growth rate in pancreatic cancer cell lines 24 h after infection with Ad-p53. Data points represent means from 9 samples of viable cells in three independent experiments; bars, SD.

Efficacy of combined Ad-p53 and 5-FU therapy on tumor cell growth in vitro

To investigate whether the reintroduction of wt-p53 protein could enhance the tumor inhibitory effect of 5-FU treatment, all six pancreatic cancer cell lines were infected with Ad-p53 at MOI 1, which revealed an intrinsic antiproliferative activity by itself. 5-FU at the concentration of 5 μ g/mL was chosen for the combination experiments and was given 24 h after Ad-p53 infection. In preliminary dose escalation studies, the IC₅₀ values of each cell line were determined and listed in Table 1. Low dose FU (5 μ g/mL) given alone reduced cell viability most significantly to wt-p53 containing Capan-2 cells and AS cells compared to the other tested cell lines. The antiproliferative effects of the combination of Ad-p53 and 5-FU were next evaluated and non-functional p53 pancreatic cancer cell lines were most sensitive to the cytotoxic action of the combined treatment. This growth inhibitory effect was highly significant compared to either administration of p53 gene transduction or 5-FU treatment alone. For Capan-2 cells containing wt-p53, the combined antiproliferative effect of the two drugs was only 9%

Table 2 *In vitro* growth of different pancreatic cancer cell lines after indicated treatment ¹measured by WST-1 cell viability assay²; % mean (95% CI)

	Cell line	Control	Ad-CD-control	Ad-p53	5-FU	Ad-p53+5-FU
Human	Capan-1	97.8 (96.0-99.5)	91.9 (86.6-97.6)	55.0 (51.3-58.6)	72.9 (70.4-74.4)	30.7 (28.9-32.4)
	Capan-2	97.9 (95.7-100.0)	91.3 (88.2-94.5)	75.0 (71.3-78.6)	55.6 (53.1-58.0)	51.2 (48.0-54.4)
	FAMPAC	98.0 (95.9-100.1)	93.3 (90.5-96.2)	48.6 (44.7-52.4)	70.6 (68.0-73.1)	31.7 (29.6-33.8)
	PANCL	98.4 (97.1-99.8)	95.0 (92.2-97.8)	64.7 (59.8-69.5)	73.9 (71.6-76.2)	33.8 (31.5-36.0)
Murine rat	AS	99.0 (97.6-100.4)	97.9 (95.7-100.0)	92.3 (88.9-95.8)	56.8 (52.2-61.3)	53.1 (48.2-58.0)
	DSL6A	98.8 (97.5-100.0)	94.0 (90.8-97.2)	64.2 (60.5-67.9)	69.4 (66.0-72.9)	32.8 (29.3-36.2)

¹Cells were either infected with Ad-CD control or Ad-p53 (MOI 1) 24 h prior±5FU chemotherapy (5 µg/mL) given for 48 h. ²The data represents the ratio of the colorimetric values of viable cells treated as indicated (A) compared with the untreated control cells (Ao). Results are expressed as mean with 95% confidence interval (CI) from more than 9 samples in three independent experiments.

more than with 5-FU chemotherapy alone. In wt-p53 containing AS cells, Ad-p53 infection could not enhance the 5-FU antiproliferative action to a significant level (Table 2).

Effect of Ad-p53 gene transduction and 5-FU treatment on apoptotic cell death *in vitro*

To determine whether Ad-p53 mediated increase of 5-FU cytotoxic action was due to enhanced apoptosis, we analyzed DNA-fragmentation by fluorometric analysis of propidium iodide stained pancreatic cells. Cells treated with 5-FU (5 µg/mL) showed a percentage of dead cells between 8% and 16%, which was slightly above that of native cells or cells infected with the Ad-CD control vector. In cells transduced with the p53 gene (MOI 1), the percentage increased up to 25%. p53 gene transduction followed by 5-FU chemotherapy, caused a marked increase of apoptotic cell death. These findings were consistent showing the highest apoptotic rate for the pancreatic cancer cell lines with an altered p53 (47-58%), and the lowest apoptotic rate in wt-p53 containing cell lines (18-20%) as indicated in Figure 3.

**Figure 3** Percentage of apoptotic cells of human and rat pancreatic carcinoma cell lines either infected with Ad-CD control vector or Ad-p53 (MOI 1) 24 h prior±5-FU chemotherapy (5 µg/mL) given for 48 h. Points represent means from 9 samples in three independent experiments; bars, 95% CI.

In vivo effects of combined treatment on tumor growth in rat pancreatic cancer

Subcutaneous DSL6A tumors generated in 4-wk-old male Lewis rats were treated by intratumoral injection with adenoviral vectors and/or 5-FU chemotherapy given intraperitoneally twice a week for 1 mo. Details of the onset and cessation of treatment were indicated in the methods section. To determine if p53 recombinant adenoviruses could induce p53 mRNA expression, RT-PCR analysis was performed in the generated DSL6A tumors. Non-infected and Ad-p53 infected tumors were removed and p53 transgene expression was confirmed 24 h

after the last injection. As shown in Figure 4, a 294 bp band was detected only in Ad-p53 infected tumors.

Tumor growth was measured regularly during the 4 wk following treatment. Animals in both control groups showed an extensive tumor proliferation, and after 6 cycles of therapy tumor size was above 600 mm², so that treatment was stopped and animals were killed according to the protocol. During the first four cycles of treatment, in animals with 5-FU monotherapy tumor growth was significantly reduced compared to the controls (157±54 mm² vs 410±65 mm², $P<0.0001$). Ad-p53 treatment alone (72±19 mm², $P<0.0001$) or the combination Ad-p53 plus 5-FU (61±8 mm², $P<0.0001$) demonstrated local tumor growth control. However, within the following four cycles of therapy we observed an increasing tumor size in animals treated only with 5-FU (580±58 mm²) or Ad-p53 (347±52 mm²) alone compared to the combination of Ad-p53 plus 5-FU (67±14 mm², $P<0.0001$). As shown in Figure 5, the combination of Ad-p53 and 5-FU demonstrated the most potent inhibitory effect on tumor growth, but none out of the 8 animals was tumor free at the end of the treatment.

**Figure 4** Gel electrophoresis for PCR products from DSL6A tumors removed from Lewis rats 24 h following the last treatment. (P) positive control, vector DNA; (N) negative control (RT minus control); (C) Ad-CD control virus treated tumor (Ad-CD); (T) Ad-p53 infected tumor.**Figure 5** Efficacy of Ad-p53 infection and 5-FU as single agents vs the combination of both on tumor growth of Lewis rats challenged with DSL6A tumor cells. Arrowheads indicate treatment application. ¹All animals were killed after 6 cycles of therapy because the tumor size was above 600 mm².

Detection of apoptosis in tumor tissues after treatment

Since our *in vitro* data indicated that the tumor-inhibitory effects of the combined treatment of Ad-p53 plus 5-FU were significantly mediated by induction of apoptosis, we assessed the tumor tissue sections for DNA degradation using the TUNEL assay. Analyses of tumor sections of each group revealed a slight increase of apoptotic cells in rats treated with 5-FU compared to both control groups, mock or Ad-CD infected. Adenoviral p53 gene transduction significantly increased the number of apoptotic cells in comparison to single 5-FU chemotherapy. As shown in Figure 6, *in situ* quantification revealed the highest number of cells undergoing apoptosis in tumors treated with Ad-p53 plus 5-FU.

Figure 6 Ad-p53 mediated sensitisation of tumors to apoptosis in response to 5-FU *in vivo*. Formalin-fixed tissue sections were analyzed by TUNEL labelling. Original magnification $\times 200$.

DISCUSSION

A number of previous studies have shown that the restoration of wt-p53 may increase or decrease drug sensitivity, indicating that p53 status may influence the response of human cancers to chemotherapy in a cell- and drug specific manner^[3,16,17,29]. However, what is currently lacking is critical information on the cytotoxicity and target response to such a combined modality therapy. In this study we investigated a panel of human pancreatic cancer cell lines with well characterised defects in the p53 gene to identify differences following treatment with Ad-p53 vector and 5-FU chemotherapy. Because high concentrations of p53 were difficult to reach in patients by vectors available so far, and high doses of 5-FU could not be used *in vivo* due to their side effects, we evaluated the efficacy of low concentrations of p53 infection and low doses of 5-FU.

In our *in vitro* study infection with Ad-p53 alone produced tumor growth suppression in all pancreatic cancer cell lines ranging from highly significant to almost absent. The most prominent growth inhibitory effect was observed in the pancreatic cancer cell lines with an alteration of the p53 function. These findings may not only relate to the endogenous p53 status, but also to differences in transduction efficiency of cell lines to the expression of $\beta 3$ integrins and coxsackie virus and adenovirus receptors (CAR) on tumor cells^[30]. Ad-p53 infection at a low concentration (MOI 1) induced only a small number of apoptotic cells in the tested pancreatic cancer cell lines. These results are in agreement with those of other authors showing that levels of p53 expression that inhibited proliferation may

not be sufficient by themselves to induce cell death^[10,31-33]. The reduced cell proliferation observed after Ad-p53 infection might be rather attributed to a persistent S phase depletion and G0/G1 accumulation without induction of apoptosis.

However, the key question in our study was to correlate the exogenous p53 expression with the response to 5-FU based chemotherapy. Like a number of other studies the p53 replacement into tumor cell lines with altered p53, revealed the most effective tumor growth inhibition^[9-12]. Our data clearly support other *in vitro* studies, which have reported that loss of p53 function could reduce cellular sensitivity to 5-FU^[3,4,34]. These synergistic effects are less conclusive in cases of p53 transgene overexpression in wt-p53 tumors. Only a small, but not significant advantage of the combination regimen was achieved in the human Capan-2^{p53wt} cells, whereas the murine AS^{p53wt} cells failed to such a treatment. Since from the clinical point of view apoptotic death is the final outcome that can define the success of therapy, we screened for the induction of apoptosis in relation to the different treatment schedules. Our data demonstrated, that the combination regimen of Ad-p53 plus 5-FU was able to significantly increase the number of apoptotic cells in the pancreatic tumor cell lines with an altered p53 gene. Likewise to our findings some reports have shown, that high level expression of p53 could cause some cancer cells to undergo apoptosis, whereas others simply undergo prolonged cell cycle arrest^[10,31]. To overcome the resistance to p53 mediated apoptosis several reports have shown a significant advantage of Ad-p53 gene therapy in combination with DNA damaging agents^[10,14,15,32].

A foremost concern with such a strategy is whether sufficient chemosensitisation can be accomplished with relatively few supplemental gene therapy treatments during 5-FU based chemotherapy. Experimental studies reported a rate of gene transduction between 5% and 15% using immunohistochemical analysis^[9]. Therefore we used a subcutaneous pancreatic tumor model to allow assessment of the efficacy of this approach. In immunocompetent Lewis rats, combination of intratumoral Ad-p53 infection of implanted pancreatic DSL6A^{p53null} tumors with additional systemic 5-FU chemotherapy resulted in a significant retardation of tumor growth. These combined effects clearly exceeded those achieved by administration of either agent alone. In contrast to all other treatment modalities, the combination regimen Ad-p53 plus 5-FU revealed no further *in vivo* tumor growth during the time of treatment. The reason for incomplete tumor regression may be related to the low p53 transduction rate and limited spread within the tumor. Our *in vivo* data point to an enhancement of 5-FU mediated apoptosis in DSL6A tumors as a result of adenoviral mediated p53 gene transfer. This is in line with our *in vitro* findings, which strongly suggest that the sensitisation is mediated by enhancing the apoptotic response of neoplastic cells to 5-FU treatment. Similar anticancer therapy approaches using combined administration of adenovirus mediated p53 gene therapy and chemotherapeutic drugs have been evaluated. In some tumors, inactivation of p53 correlated with an increased resistance to radiation and several antineoplastic drugs and transduction of the wt-p53 gene increased the sensitivity^[3,16,17,32]. In contrast, in other tumors the expression of exogenous wt-p53 reduced sensitivity, while the disruption of p53 function increased sensitivity^[35-37]. A number of clinical studies have found that p53 overexpression, a surrogate marker for p53 mutations, correlated with resistance to 5-FU^[5,6,38,39], but other studies found no correlation^[40,41]. Such conflicting findings might in part, be due to the wide variation in immunohistochemical protocols, and the use of different antibodies to detect p53. Other techniques, such as DNA sequencing, might provide a more objective assessment of the p53 status. At present, despite the *in vitro* evidence for p53 involvement in downstream signalling in response to 5-FU, the clinical value of p53 as a

predictive marker for 5-FU based chemotherapy remains a matter for debate.

In conclusion, our results confirm the feasibility of sensitising pancreatic cancer cells to 5-FU chemotherapy *in vivo* using adenovirus mediated p53 gene therapy. In tumors, where sustained expression of wt-p53 cannot be achieved or the levels of expression are insufficient to significantly induce apoptosis, wt-p53 can be used as a therapeutic agent in combination with conventional antineoplastic drugs. Our results have confirmed that this enhanced cytotoxicity is mostly provided by driving significant numbers of neoplastic cells into apoptosis. Therefore, the assessment of endogenous p53 status by DNA sequencing, which may correlate with the response to 5-FU chemotherapy may have an important role in defining patients who are most likely to benefit from 5-FU chemotherapy or combination treatment in the future^[42].

Abstract

AIM: Mitogenic and non-mitogenic activities of fibroblast growth factor (FGF) are coupled to a range of biological functions, from cell proliferation and differentiation to the onset of many diseases. Recent reports have shown that acidic fibroblast growth factor (aFGF) has a powerful anti-apoptosis function, which may have potentially therapeutical effect on gut ischemia and reperfusion injuries. However, whether this function depends on its mitogenic or non-mitogenic activity remains unclear. In this study, we identified the source of its anti-apoptosis function with a mutant, aFGF28-154 and observed its effect on reducing gut ischemia and reperfusion injury.

METHODS: aFGF28-154 was generated by amplification of appropriate DNA fragments followed by subcloning the products into pET-3c vectors, then they were expressed in BL21 (DE3) cells and purified on an M2 agarose affinity column. This mutant aFGF28-154 maintained its non-mitogenic activity and lost its mitogenic activity. With a dexamethasone (DEX)-induced mouse thymocyte apoptosis model *in vitro* and *in vivo*, we studied the anti-apoptotic function of aFGF28-154. Also, *in vivo* study was performed to further confirm whether aFGF28-154 could significantly reduce apoptosis in gut epithelium after gut ischemia-reperfusion injury in rats. Based on these studies, the possible signal transduction pathways involved were studied.

RESULTS: With a dexamethasone (DEX)-induced mouse thymocyte apoptosis model *in vitro* and *in vivo*, we found that the anti-apoptotic function of aFGF28-154 was significantly enhanced when compared with the wild type aFGF. *In vivo* study further confirmed that aFGF28-154 significantly reduced apoptosis in gut epithelium after gut ischemia-reperfusion injury in rats. The mechanisms of anti-apoptosis function of aFGF28-154 did not depend on its mitogenic activity and were mainly associated with its non-mitogenic activities, including the intracellular calcium ion balance protection, ERK1/2 activation sustaining and cell cycle balance.

CONCLUSION: These findings emphasize the importance of non-mitogenic effects of aFGF, and have implications for its therapeutic use in preventing apoptosis and other injuries in tissues and internal organs triggered by ischemia-reperfusion injury.

INTRODUCTION

Fibroblast growth factors (FGFs) are members of a family of polypeptides that are potent regulators of cell proliferation, differentiation, and function. They play very important roles in normal development, maintenance of tissues, wound healing and repair. They have also been implicated in a wide range of pathological conditions, including tumorigenesis and metastasis^[1-4]. Acidic and basic fibroblast growth factors (aFGF and bFGF), the important members of this family, were named for their different isoelectric points. They have similar molecular weights and spectra of biological activities, and show approximately 55% amino acid similarity. aFGF and bFGF stimulate the proliferation of all cells of mesodermal organ, and many cells of neuroectodermal, ectodermal, and endodermal origin. Also, both FGFs are chemotactic and mitogenic for endothelial cells *in vitro*, inducing production of many factors involved in regulation of many functions^[2-5]. Recent reports have shown that aFGF has a powerful anti-apoptotic function, which may have potentially therapeutical use in some diseases^[5-13]. However, whether this function depends on its mitogenic or non-mitogenic activity remains unclear, and clarification of this function may help to find its new mechanisms and active domains. In the present study, we modified the wild type of aFGF and acquired a mutant, aFGF28-154, which kept its non-mitogenic activity and lost its mitogenic activity. By using the dexamethasone (DEX)-induced apoptotic model, we found that the anti-apoptosis function of the modified aFGF28-154 was significantly enhanced when compared with the wild type of aFGF. The results indicated that the powerful anti-apoptosis function of aFGF28-154 was associated with the intracellular calcium ion balance protection and ERK1/2 activation sustaining, which did not depend on its mitogenic activity. Further studies showed that aFGF might have a surveillance function at the checkpoint of cell cycle, for determination of stagnation, division or apoptosis. Finally, *in vivo* study confirmed that aFGF28-154 could significantly reduce apoptosis in gut epithelium after gut ischemia-reperfusion injury in rats.

MATERIALS AND METHODS

Protein preparation

Plasmids encoding aFGF28-154 were generated by amplification of appropriate DNA fragments, followed by subcloning the

products into pET-3c vectors. aFGF28-154 protein was expressed in BL21 (DE3) cells and purified on an M2 agarose affinity column (Sigma). We carried out SDS-PAGE and Western blot analysis with aFGF monoclonal antibody (Sigma) to determine the accuracy of protein expression.

Mitogenic activity assay

MTT method was conducted to test the mitogenic activity of both aFGFs. NIH 3T3 fibroblasts and PC12 cell lines from Wuhan University were cultured in DMEM (Hyclone) with 150 mL/L fetal bovine serum (Gibico) plus 50 mL/L equine serum (Hyclone) for PC12 culture. These cells were stimulated with aFGF and aFGF28-154 at a final concentration of 0, 1, 2, 3, 4, 5, 6, 8, 10 ng/mL for 24 h before A value detection.

Apoptosis models in thymocytes and treatment methods in vitro

Twenty homogeneous Balb/c mice aged four weeks were randomised into 4 groups: control group (group 1); DEX group (group 2), DEX+aFGF (Biopharmaceutical R&D Centre) group (group 3) and DEX+aFGF28-154 (group 4). DEX, if applied, was taken at a final concentration of 1 μ mol/L. aFGF and aFGF28-154, if applied, were taken at a final concentration of 100 ng/mL. In order to explore the relationship between dosage and effects, different dosages of aFGF28-154 from 50 to 200 ng/mL were used in another experiment. After collected under sterile conditions, thymocytes were cultured in RPMI1640 medium (Hyclone) supplemented with 100 mL/L fetal bovine serum (Gibico) for 5 h.

In *in vivo* study, Group 1 was injected with saline, group 2 with DEX 10 mg/kg, group 3 with DEX 10 mg/kg and aFGF10 μ g/kg, and group 4 with DEX 10 mg/kg and aFGF28-154 10 μ g/kg. Animals were fed for 5 h before collection of thymocytes.

Flow cytometry

Flow cytometry was performed using an FACScaliber (Becton Dickinson). Phosphatidylserine (PS), a sign of early apoptosis, was stained with Annexin V-FITC (Baosai), while DNA fragments of the necrotic cells were evaluated with PI apoptosis.

Morphological observation and gel electrophoresis analysis of apoptosis

Transmission electron microscope was used to morphologically visualize apoptosis and agarose gel electrophoresis was performed to find the damage of nuclear chromatin DNA.

Analysis of intracellular Ca^{2+} concentration

Confocal microscope was used to analyse the changes of

intracellular Ca^{2+} concentration.

Apoptosis model in gut epithelium and treatment methods in vivo

Rat intestinal ischemia-reperfusion (I/R) injury was produced by clamping the superior mesenteric artery (SMA) for 45 min followed by reperfusion for 24 h. One hundred and fourteen Wistar rats were divided randomly into four groups, namely intestinal I/R plus saline treatment group (I/R+Saline), intestinal I/R plus wild type aFGF treatment group (I/R plus aFGF), intestinal I/R plus aFGF 28-154 group (I/R plus aFGF28-154) and normal control group (normal control). In groups 1, 2 and 3, SMA was separated and occluded for 45 min, then released for reperfusion for 24 h. At the onset of reperfusion, saline (0.5 mL) or aFGF (4 μ g/rat), or aFGF28-154 (4 μ g/rat) was injected through the jugular vein. In control group, SMA was separated without occlusion. After the animals were sacrificed, tissue biopsies were taken from the intestine at 30 min, 1, 2, 6, 12, and 24 h, respectively. Apoptosis in epithelium entericum was assayed with TUNEL technique and analyzed using light microscope. All animal experiments were carried out according to the Guidelines for Care and Use of Experimental Animals and approved by the internal ethical committees of the Trauma Centre of Postgraduate Medical College (Beijing).

Analysis of signal transduction in cells stimulated by DEX and both aFGFs in vitro

Cultured thymocytes were sampled to carry out Western blot analysis. Antibodies used were ERK1/2, p-ERK1/2, JNK1/2, p38 MAPK, c-Myc (Sigma), and Caspase-3 (Boster).

RESULTS

Protein preparation and mitogenic activation assay

Plasmids encoding aFGF28-154 were generated by amplification of appropriate DNA fragments, followed by subcloning the products into pET-3c vectors. aFGF28-154 protein was expressed in BL21 (DE3) cells and purified on an M2 agarose affinity column (Sigma). We carried out SDS-PAGE and Western blot analysis with aFGF monoclonal antibody (Sigma) to determine the accuracy of protein expression (Figure 1A, B). We tested both aFGF and aFGF28-154 for their effects on proliferation of NIH 3T3 fibroblasts and rat pheochromocytoma (PC12) cells. The results indicated that the latter significantly lost its mitogenic activity evidenced by MTT results (Figure 1C). Thus, we could perform a comparative research to clarify whether aFGF function depended on mitogenic activity.

Figure 1 Loss of mitogenic activity in aFGF after modification. A: Sequence comparison between modified aFGF (aFGF28-154) and the wild type. B: Western blot analysis of purified aFGF and aFGF28-154. C: MTT assay of the mitogenic activity of both aFGFs.

Assay of anti-apoptotic activation of both aFGFs

We examined the anti-apoptotic effects of both aFGFs by a DEX-induced thymocyte apoptosis model in mouse, which was considered as one of the best characterized apoptosis research systems^[14-16]. First, a number of typical apoptotic thymocytes with apoptotic bodies from the DEX-induced group were visualized by transmission electron microscope (Figure 2A, B). Second, agarose gel electrophoresis results of this group also indicated characteristic ladder bands of oligonucleosomal fragments (180-200 bp) produced by extracted chromatin DNA, while few were found in blank group and the DNA damage in DEX-induced group was much more serious than that in both aFGFs treated groups (Figure 2C). Third, Annexin V-FITC/PI staining was used to distinguish apoptotic and necrotic cells from normal ones by flow cytometry (Figure 2D). Our test

indicated that under the stimulation of DEX, thymocytes showed apoptosis both *in vivo* and *in vitro* (44.40% and 20.07%, respectively) after 5-h culture. With the protection of aFGF, when exposed to DEX, the apoptosis rate was lower both *in vivo* and *in vitro* (33.71% and 18.31%, respectively). Under the same condition, however, the apoptosis rate was significantly lower in aFGF28-154 group than in DEX and aFGF groups both *in vivo* and *in vitro* (23.95% and 13.80%, respectively) (Figure 2D). The quantitative analysis of anti-apoptosis results and the dose-effect relationship of aFGF28-154 are summarized in Table 1. Fourth, we studied the changes of concentration of intracellular calcium ion (Ca^{2+}) by confocal microscope to further confirm the anti-apoptotic effects of both aFGFs on mouse thymocytes. High concentration of intracellular Ca^{2+} caused by influx increase was involved in triggering protease and endonuclease

Figure 2 Comparative evaluation of the anti-apoptotic function of aFGF28-154 both *in vitro* and *in vivo*. A: TEM observation ($\times 20\,000$) of DEX-induced apoptosis in mouse thymocytes. activation and apoptosis. Hence, Ca^{2+} influx was considered as a sign of apoptosis occurrence^[17-19]. In this study, the intracellular Ca^{2+} concentration in thymocytes increased quickly when exposed to DEX. When administrated with aFGF, however, Ca^{2+} concentration decreased to a lower level (Figure 3A). However, the test for aFGF28-154 showed a marked reduction of Ca^{2+} influx (Figure 3B).

Table 1 *In vitro* quantitative analysis of anti-apoptotic effects and dose-effect relationship of aFGF28-154 on thymocytes induced by DEX (mean \pm SD)

Groups	Conc. (ng/mL)	Apoptosis (%)
Normal control		1.37 \pm 0.39
DEX only		18.99 \pm 0.52 ^a
DEX plus aFGF28-154	50	16.14 \pm 0.44 ^c
	100	12.35 \pm 0.36 ^b
	150	9.75 \pm 0.20 ^b
	200	11.23 \pm 0.71 ^b

^a $P < 0.05$ vs normal control; ^c $P < 0.05$, ^b $P < 0.01$ vs DEX only.

Gut epithelium apoptosis and treatment effects with both aFGFs *in vivo*

We investigated the therapeutic use of both aFGFs in gut ischemia-reperfusion injury in rats and found that the apoptosis rate of epithelium entericum was 5.83 \pm 1.47 in normal control rats, 46.16 \pm 4.06 in rats treated with saline, 39.66 \pm 3.56 in rats treated with wild type of aFGF and 40.66 \pm 2.73 in rats treated with aFGF28-154 2 h after ischemia-reperfusion injury (Table 2). The

Table 2 *In vivo* quantitative analysis of apoptosis in epithelium entericum in different groups (mean \pm SD)

Time	Normal control (n = 6)	I/R+Saline (n = 36)	I/R+aFGF (n = 36)	I/R+aFGF 28-154 (n = 36)
Before ischemia	5.83 \pm 1.47	5.83 \pm 1.47	5.83 \pm 1.47	5.83 \pm 1.47
I/R 30 min		29.83 \pm 3.43 ^b	23.83 \pm 2.78 ^c	25.50 \pm 1.87 ^c
I/R 60 min		39.33 \pm 4.32 ^b	30.33 \pm 3.07 ^c	33.44 \pm 5.60 ^c
I/R 2 h		46.16 \pm 4.60 ^b	39.66 \pm 3.56 ^c	40.66 \pm 2.73 ^c
I/R 6 h		31.33 \pm 3.72 ^b	25.5 \pm 2.16 ^c	26.00 \pm 2.61 ^c
I/R 12 h		62.5 \pm 3.08 ^b	48.50 \pm 2.74 ^c	50.16 \pm 3.71 ^c
I/R24 h		51.66 \pm 3.87 ^b	41.33 \pm 2.94 ^c	42.16 \pm 3.31 ^c

^b $P < 0.01$ vs normal control; ^c $P < 0.05$ vs I/R+Saline group. The percentage of positive apoptotic epithelium entericum was estimated after two hundred cells were counted in five different fields randomly chosen from preparation ($n = 5$). We did all analysis with SPSS. All data were presented as mean \pm SD. We used one-way analysis of variance and the t test where appropriate. Significance was defined as $P < 0.05$.

quantitative analysis of apoptosis in epithelium entericum in different groups of different time points is summarized in Table 2. The morphological examination with light microscope and immunohistochemical detection and quantification of apoptosis based on the labelling of DNA strand breaks confirmed that tissue edema, local necrosis (Figure 4A, C, E, G) and apoptosis in epithelium entericum were markedly reduced in both aFGFs treated rats (Figure 4B, D, F, H).

Analysis of possible signal transduction pathway

In *in vitro* study, we analysed the changes of ERK1/2, p-ERK1/2, JNK1/2, p38 MAPK, c-Myc and Caspase-3. The results showed that only ERK1/2 pathway was activated in all of the three pathways during aFGF anti-apoptosis course (Figure 5A, B, C, D) and no phosphorylated JNK1/2 and p38 MAPK could be detected. In normal control thymocytes, steady ERK1/2 activation was observed, and such an activation was almost completely blocked when cells exposed to DEX. But both aFGFs attenuated this DEX-induced blockage, maintaining ERK1/2 activation, which is required for normal thymocyte cycle at a certain level (Figure 5A). P38 expression in control group was steady with time lapse (Figure 5B) and decreased gradually when cells exposed to DEX (Figure 5C). However, the total p38 MAPK expression decreased at 30 min and then a peak expression appeared at 60 min when the DEX-induced cells were protected with aFGF or aFGF28-154 (Figure 5D, E). The expression of c-Myc and Caspase-3 in thymocytes in the control group was kept at a stable level following the time course (Figure 5B). When stimulated merely by DEX, c-Myc was highly expressed in the first 30 min and the activated Caspase-3 increased following c-Myc (Figure 5C). These results indicated that DEX-induced thymocyte cell cycle turned out to be c-Myc-induced apoptosis. In the aFGF group, however, c-Myc was expressed only at 0 min, and then showed no significant change at other time points (Figure 5D). In the aFGF28-154 group, c-Myc showed a peak expression at 30 min, and then held at a relatively steady level (Figure 5E).

DISCUSSION

Currently, the anti-apoptotic effects of aFGFs have been established from the results of DNA ladder electrophoresis, Annexin V-FITC/PI staining, examination of Ca^{2+} concentration with confocal microscope, and *in vivo* study on gut ischemia-reperfusion injury in rats. But the results were far beyond our expectation. aFGF, especially the modified non-mitogenic aFGF28-154 with a powerful ability to reduce the apoptosis rate, made us to explore whether there were some special mechanisms involved in such an action.

To further investigate the mechanisms of the anti-apoptotic function of aFGF, we studied three protein kinases, including

Figure 4 Morphological examination and immunohistochemical detection and quantification of apoptosis based on the labeling of DNA strand breaks (Roche Applied Science, Germany). A: Marked epithelial separation from the basement, subepithelial edema, haemorrhage, erosion. C: Necrosis in I/R plus saline control group. E and G: Tissue damage reduction in both aFGF and aFGF28-154 treated groups. B: Immunohistochemical detection and quantification of apoptosis in normal epithelium entericum. D: Increased number of apoptotic cells in epithelium entericum in rats treated with saline. F and H: Significant reduction of apoptotic cells in epithelium entericum in rats treated with both aFGF and aFGF28-154.

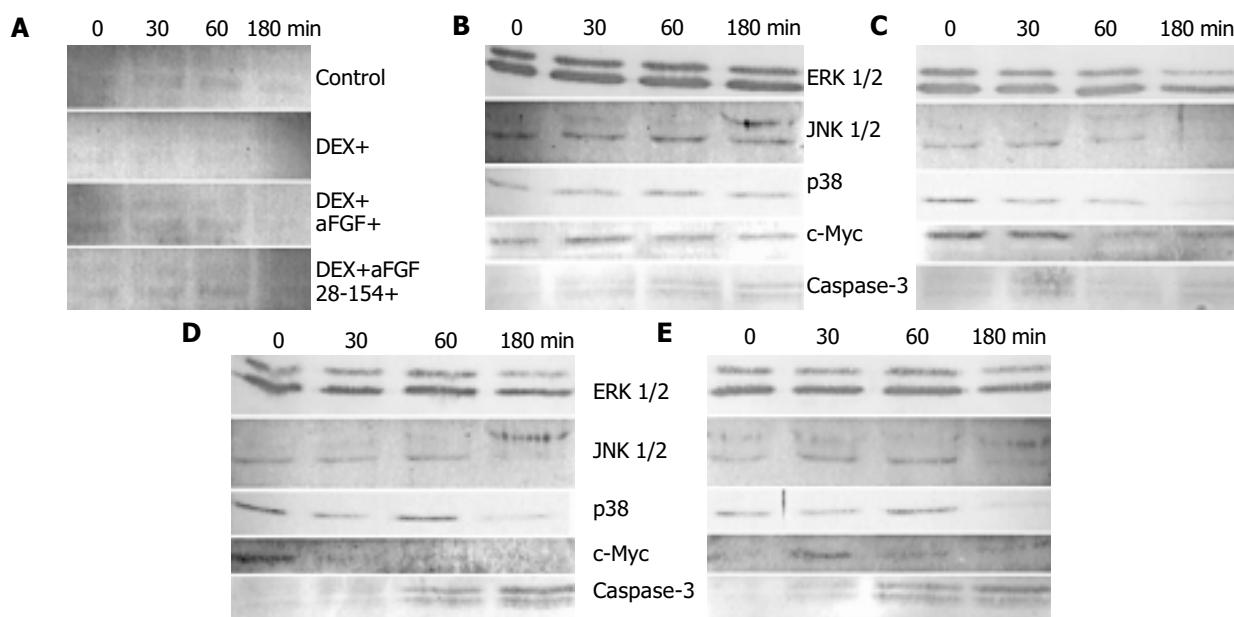

Figure 5 Function of aFGFs as a checker of cell cycle. A: Western blot analysis of the phosphorylation of ERK1/2. B: Western blot analysis of ERK1/2 MAPK, JNK1/2 and p38 MAPK, as well as c-Myc and Caspase-3 in control group. C: Analysis of thymocytes stimulated by DEX. D: Analysis of thymocytes under aFGF protection. E: Analysis of thymocytes under aFGF28-154 protection.

extracellular-signal-regulated kinase (ERK) 1/2, c-Jun-NH2-terminal kinase (JNK) 1/2, and p38 mitogen associated protein kinase (MAPK). According to the Western blot analysis on

phosphorylation, we found that only ERK1/2 pathway was activated in all of the three pathways during aFGF anti-apoptosis course (Figure 5A) and no phosphorylated JNK1/2 and p38

MAPK could be detected. In normal control thymocytes, the steady ERK1/2 activation was observed, and such an activation was almost completely blocked when cells exposed to DEX. But both aFGFs attenuated this DEX-induced blockage, maintaining ERK1/2 activation, which is required for normal thymocyte cycle at a certain level (Figure 5A). ERK1/2 activation was crucial for aFGF to exert protective effects on many cell types^[20,21]. DEX could induce mitochondrial membrane potential collapse and promote Ca^{2+} release from intracellular pool and the subsequent stimulation of a Ca^{2+} influx from extracellular environment, which contributes to apoptosis^[16]. However, an ERK1/2 activation could protect mitochondrial membrane potential by downstreaming Bcl-X activation^[22]. The fact that only ERK1/2 pathway was activated in all of the three pathways and Ca^{2+} influx reduction in both aFGF groups strongly suggested that the anti-apoptotic activity of aFGF involved in maintaining ERK1/2 activation and regulation of intracellular Ca^{2+} concentration.

A very interesting finding from the results of total p38 MAPK expression attracted our great attention. p38 expression in control group was steady with time lapse (Figure 5B) and decreased gradually when cells exposed to DEX (Figure 5C). However, the total p38 MAPK expression decreased at 30 min and then a peak expression appeared at 60 min when the DEX-induced cells were protected with aFGF or aFGF28-154 (Figures 5D, E). Normally, the activation of p38 MAPK often follows stress induction^[23]. Although p38 MAPK was not markedly activated in all groups in our study, we noticed that according to a previous study by Lasa *et al.*, dexamethasone could cause sustained expression of MAPK phosphatase 1 and phosphatase-mediated inhibition of p38 MAPK^[24]. We also found p38 MAPK was constantly decomposed by DEX induction (Figure 5C). Because the cells in control group were not stressed and the other 3 groups were all exposed to DEX, we speculated that the peak expression of p38 MAPK at 60 min in both aFGF groups might reflect an unveiled stress, which was lagged in both aFGFs groups compared with the DEX group.

To investigate the anti-apoptotic function of aFGFs at protein level, we further examined the changes of c-Myc and Caspase-3. Thymocytes in control group were kept at a stable c-Myc level following the time course (Figure 5B). When stimulated merely by DEX, c-Myc was highly expressed in the first 30 min and the activated Caspase-3 increased following c-Myc (Figure 5C). These results indicated that DEX-induced thymocyte cell cycle turned out to be c-Myc-induced apoptosis. In aFGF group, however, c-Myc was expressed only at 0 min, and then showed no significant change at other time points (Figure 5D). In aFGF28-154 group, c-Myc showed a peak expression at 30 min, and then held at a relatively steady level (Figure 5E). c-Myc, in association with its partner Max, could function as a transcription factor to drive apoptosis when low quantities of survival factors such as IGF-1 and aFGF were present^[25,26]. These results indicated that cell cycle was stagnated in aFGF group, and balanced in aFGF28-154 group. In both aFGF groups, Caspase-3 activation remained nearly null during first 30-60 min and was suddenly enhanced at 60 min and still kept at a high level until 180 min (Figure 5D, E). This activation is cohort with the p38 reaction during stress stimulation and especially with c-Myc expression in normal and both aFGF groups.

The above signal transduction analysis suggested that aFGF might serve as a “checker” for cell cycle while exerting anti-apoptotic function. These functions, including stagnation determination, cell division or apoptosis induction may be similar to those of p53, a typical checker of G1, S and G2/M phases of cell cycle, which contribute both to the cell cycle arrest and apoptotic functions by preventing replication of cells from DNA damage^[27-30]. Our results illustrated that when exposed to apoptosis inducers, aFGF would also induce cell cycle arrest.

This action was reflected by the stagnation of c-Myc expression in our study (Figures 5D, E). At the time interval of null c-Myc expression, thorough check up and repair might be conducted, thereby, new c-Myc would be expressed by aFGF induction. We regarded that this procedure as a “sentence procedure”, reflected by p38 implied second stress, might be carried out by the combined effects of c-Myc and Caspase-3. C-Myc is a typical two-face protein, which is necessary not only for DNA-cleavage in G2 phase of cell cycle, but also for cell proliferation, when cells are protected by trophy factors^[31]. If cells can pass through the examination and undergo a thorough “overhaul”, they would be kept in normal cell cycle; whereas other non-recoverable cells would be “sentenced to death” with high activation of intracellular procaspase-3 by newly expressed c-Myc. Caspase-3 may finally cleave the damaged DNA and execute apoptosis.

Here we conclude that the anti-apoptotic function of aFGFs was enhanced after cancelling of its mitogenic activity and the anti-apoptotic function did not depend on its mitogenic activity. The action is associated with the protection of intracellular Ca^{2+} concentration balance, ERK1/2 pathway sustaining, and cell cycle balance. During the process of anti-apoptosis, aFGF may play a role as a “checker” for cell cycle. Furthermore, we speculate that there are two possible reasons for the anti-apoptotic function enhancement after aFGF modification. First, aFGF28-154 loses the ability of nuclear translocation, a typical aFGF characteristic^[8], causing a longer interaction period with FGF receptors and higher efficiency for aFGF28-154 than the wild one. Second, the structural change of aFGF28-154 may be better exposed with its active domain, which contributes to some anti-apoptosis related activities.

FGF has been widely used in the fields of wound repair and regeneration and some other fields^[32,33]. Because of its extensive distribution and broad mitogenic functions, the side-effects or potential tumour induction is of great concern for doctors. In this study, we demonstrate a genetically engineered method to abolish the mitogenic activity and maintain the non-mitogenic activity of aFGF. This may be helpful to reduce people's worry about its tumour induction and to take as many preventive measures as possible clinically. In short, the powerful anti-apoptotic function of aFGF28-154 may play an important role in prophylaxis and treatment of some immune system diseases or as a protector in preventing apoptosis in tissues and organs triggered by ischemia and reperfusion injury.

ACKNOWLEDGEMENTS

Abstract

AIM: To detect the expression of p33^{ING1b} protein and the change of p33^{ING1b} gene in pancreatic carcinoma and to evaluate the significance of p33^{ING1b} in pancreatic cell carcinogenesis.

METHODS: Pathological specimens from pancreatic carcinoma and matched non-tumor pancreatic tissues were examined for p33^{ING1b} expression and mutation by immunohistochemistry, polymerase chain reaction single-strand conformation polymorphisms (PCR-SSCP) and loss of heterozygosity (LOH).

RESULTS: The rate of p33^{ING1b} protein expression was 85% (34/40). A single germline missense mutation was detected in 1 of 40 tumors located at codon 215:TGC-TCC (Cys-Ser). Fourteen (60.9%) of 23 tumor samples showed LOH in all of the informative markers tested, but no mutation was detected in these tumors and only two of the informative tumors lacked expressions of p33^{ING1b} protein.

CONCLUSION: Mutation and loss of expression are not the main reasons for the disfunction of p33^{ING1b} in pancreatic carcinoma, an abnormality at the level of chromosome and/or transcription may inhibit their normal functions, potentially contributing to pancreatic cell carcinogenesis.

INTRODUCTION

A candidate tumor suppressor gene, ING1, has recently been cloned and mapped on human chromosome 13q34, encoding p33^{ING1b} mainly, a nuclear protein which physically interacts with p53^[1,2] and cooperates with it in many ways^[3,4]. Forced overexpression of the ING1 gene could lead to cell arrest in the G1 phase of the cell cycle and induce apoptosis in several cell types^[5,6]. Conversely, inhibition of ING1 expression by antisense constructs could promote the transformation of mouse breast epithelial cells and increase the frequency of focus formation

with NIH3T3 cells and protect cells from apoptosis. Recently, p33^{ING1b} protein has been found to contain many specific structures, such as plant homeodomain (PHD)-like finger, nuclear localization sequence (NLS), nucleolar targeting sequence (NTS), proliferating cell nuclear antigen (PCNA) interacting protein (PIP) domain, Sin3-associated polypeptide (SAP30) interaction region and bromodomain which implicate that the p33^{ING1b} protein might play a critical role with other genes in oncogenesis, apoptosis, DNA repair and cell cycle regulation^[7-9].

High rates of 13q loss of heterozygosity (LOH) have been detected in cancer of the esophagus, ovary, breast and head and neck^[10]. And several gene mutations and reduced protein expression of p33^{ING1b} were found in head and neck, esophageal, lung, bladder, ovary, kidney, breast, and liver cell cancers^[7]. Major sequence features and biological effects and genetic alterations of p33^{ING1b} indicate that p33^{ING1b} may be a tumor suppressor and that functional loss of p33^{ING1b} might contribute to tumorigenesis. To the author's knowledge, only one study showed that p33^{ING1b} expression was increased in pancreatic adenocarcinoma cell line Mia PaCa-2 after incubation with COX-2 inhibitors for specific times^[11]. But little is known about its role and changes in pancreatic cancer. Accordingly, we examined whether genetic alterations, such as allelic imbalance or mutations of p33^{ING1b} gene, as well as altered protein expression of p33^{ING1b}, might be responsible for the emergence and progression of human pancreatic carcinoma using immunohistochemical study, LOH analysis, and PCR-SSCP.

MATERIALS AND METHODS

Materials

Fourty tumor and 23 matched normal tissues were obtained from 40 patients with pancreatic carcinoma undergoing surgical resection as primary therapy for their disease after informed consent was obtained. All patients were from the Department of Pathology, Changhai Hospital. Another four pancreatitis and 5 normal samples were also from the department. Histological studies were performed and all tumors were confirmed as exocrine pancreatic carcinoma. Among these patients whose age ranged from 31 to 86 years, 24 were males and 16 were females, and the average age was 60.5 years. Four types of tumor were involved namely, adenocarcinoma, adeno-squamous cell carcinoma, cystadenocarcinoma, and acinar cell carcinoma. The number of cases was 36, 2, 1, and 1, respectively. Thirteen cases of adenocarcinoma were well differentiated, and the other 23 cases were moderately or poorly differentiated.

DNA Extraction

Genomic DNAs were isolated from formalin-fixed paraffin-embedded sections and frozen by proteinase K treatment (method D)^[12], phenol-chloroform extraction, and ethanol precipitation following the manufacturer's instructions.

Immunohistochemistry

The expression of p33^{ING1b} protein in paraffin-embedded

histological sections was determined using the EnVision method. Histological sections (4 μ m thick) on 0.2 g/L poly-L-lysine-coated slides were deparaffinized and rehydrated, and the endogenous peroxidase activity was blocked by incubation with 20 mL/L H_2O_2 in phosphate buffer, followed by pre-treatment with proteinase K. Non-specific binding was blocked with normal goat serum, and sections were incubated with p33^{ING1b} antibody (supplied by Dr. Riabowol, Canada)^[1]. After washed with phosphate buffer, the sections were incubated with secondary antibody and enhanced labelled polymers for 3 h and washed with phosphate buffer, followed by incubation with DAB. Then the sections were washed and counterstained with methyl green. Sections of normal pancreas tissue were used as positive control for the expression of p33^{ING1b}, and the sections incubated with PBS instead of the corresponding primary antibody were used as negative controls. To quantitate the p33^{ING1b} expression in various samples, a scoring method was adopted^[13]. A mean percentage of positive tumor cells was determined in at least five areas at $\times 400$ magnification and assigned to one of the five following categories: 0, <5%; 1, 5-25%; 2, 25-50%; 3, 50-70%; and 4, >75%. The intensities of immunostaining were scored as follows: weak, 1+; moderate, 2+; and intense, 3+. For tumors showing heterogeneous staining, the predominant pattern was taken into account for scoring. The percentage of positive tumor cells and the staining intensity were multiplied to produce a weighted score for each case. Cases with weighted scores of less than 1 were defined as negative, otherwise as positive.

SSCP Analysis

The coding region of exon1 was amplified by PCR with primers on the flanking regions, primers S1 (5'-ATGTTGAGTCCTGCC AACGGGGA) and AS1 (5'-CTCTTGGTATTTCGCGTCGAT), 138 bp; exon2 was amplified as four: overlapping fragments with four primer sets: (a) S2 (5'-ATCCTGAAG GAGCTAGACG AGTGC) and AS2 (5'-CTTGCCGCTGTTGCCCGCTG), 246 bp; (b) S3 (5'-TTCGAGGCGAGCAGGAGCT) and AS3 (5'-CTTGGCCTTCTTCTCCTTGGG), 210 bp; (c) S4 (5'-CAGCAA CCACGACCACGACG) and AS4 (5'-TGAGCCCCACGCACGA GAAG), 240 bp; (d) S5 (5'-CCTCCCCATCGACCCCAACG) and AS5 (5'-CTACCTGTTGTAAGCCCTCTC), 235 bp. The PCR mixture contained 400 ng of DNA, 5 μ L of 25 mmol/L $MgCl_2$, 5 μ L of 10 \times PCR buffer, 5 μ L of 2.5 mmol/L each deoxynucleotide triphosphate, 25 pmol of each primer, and 1.25 unit of Taq DNA polymerase (Takara, Kyoto, Japan) in a 50- μ L volume. Initial denaturation at 94 $^{\circ}C$ for 4 min was followed by 35 amplification cycles, each consisting of a denaturation at 94 $^{\circ}C$ for 1 min, an annealing at 55 $^{\circ}C$ for 1 min, and an extension at 72 $^{\circ}C$ for 1 min. A final extension step at 72 $^{\circ}C$ for 10 min was carried out. Fifteen μ L of PCR products as mixed with 8 μ L of 3 \times loading dye (95% formamide, 20 mmol/L EDTA, 0.5 g/L bromphenol blue, and 0.5 g/L xylene cyanol), heat denatured, chilled on ice, applied onto an 400 g/L polyacrylamide gel with 50 g/L glycerol, and run at variable temperatures. The bands were detected by silver staining^[14]. Aberrantly migrating bands on the gels were excised, reamplified with the same sets of primers. Reproduction of the result was confirmed by sequencing the samples at least twice.

LOH analysis using a microsatellite marker on 13q

To study allelic deletion in pancreatic cancer, we examined DNA for LOH at D13S261, D13S1047, D13S1315 and DS42490^[15], which are located close to the ING1 locus. Primers sets were available through the Internet genome database. PCR was performed in 25- μ L reaction mixtures containing 200 ng of template genomic DNA, 5 pmol of each oligonucleotide primer, 0.75 unit of Taq DNA polymerase (Takara, Kyoto, Japan), 2.5 μ L

of 10 \times buffer, and 2.5 μ L of 2.5 mmol/L deoxynucleotide triphosphate. After predenaturation for 3 min at 94 $^{\circ}C$, PCR was carried out for 35 amplification cycles, each consisting of denaturation for 50 s at 94 $^{\circ}C$, annealing for 50 s at 55 $^{\circ}C$ (D13S261, D13S1047, D13S1315) or at 60 $^{\circ}C$ (DS42490), and extension for 1 min at 72 $^{\circ}C$. A final extension step at 72 $^{\circ}C$ for 10 min was performed. After amplification, 8 μ L of the reaction mixture was mixed with 8 μ L of 2 \times loading dye as described above, heat denatured, chilled on ice, and then electrophoresed on 80 g/L polyacrylamide gel containing 8 mol/L urea. DNA bands were visualized by silver staining. LOH was scored if one of the heterozygous alleles showed at least 50% reduced intensity in tumor DNA as compared with the corresponding normal DNA.

Statistical analysis

The SPSS 11.0 software package for Macintosh (SPSS Inc., Chicago, IL) was used for all statistical analyses. Variables associated with p33^{ING1b} expression were analyzed by χ^2 test. Differences in expression of p33^{ING1b} mRNA between groups were checked by independent *t* test. *P* < 0.05 was considered statistically significant.

RESULTS

p33^{ING1b} protein expression detected by IHC

p33^{ING1b} protein expression was examined in paraffin-embedded specimens from 40 pancreatic cancer patients (Figure 1). Normal and benign lesion sections were examined for p33^{ING1b} expression as controls. All of the non-tumor tissues were weak positive for p33^{ING1b}, and reduced p33^{ING1b} protein expression was noted only in 6 tumor samples (15%). The positive staining in cancer tissues was significantly stronger than that in matched normal tissues and other non-tumor samples (Figure 1). Statistical analysis showed no obvious correlation in p33^{ING1b} expression between tumor and non-tumor tissues, and also no correlation between expression of p33^{ING1b} protein and clinicopathological factors of all the patients.

Detection of p33^{ING1b} gene mutation

To investigate whether the p33^{ING1b} gene was the target of functional loss in tumors, we searched for mutations in the coding regions of the gene in all the 40 samples of pancreatic carcinoma. Only one possible mutation was identified by SSCP and DNA sequencing (Figure 2). The sample showed a substitution of cysteine (TGC) with serine (TCC) at codon 215, which located in plant homeodomain (PHD) finger. This change might affect the PHD finger and break the three-dimensional structure of ING1 protein, leading to the loss of function. But this sample still showed p33^{ING1b} protein expression, implicating that the protein expressed in tumor could not exert its normal function.

LOH analysis

We examined DNA from 23 pairs of matched pancreatic carcinomas and normal tissues for losses at four microsatellite markers (D13S261, D13S1047, D13S1315 and DS42490) on the chromosome 13q33-34 region. Figure 3 shows the summary and representative examples. Fourteen of 23 informative tumors (60.9%) showed LOH of at least one marker. The rates of LOH at D13S261, D13S1047, D13S1315, and DS42490 loci was 8.7%, 21.5%, 13.0% and 26.1%, respectively. The most frequent loss was seen at marker DS42490, which was located in the ING1 region. These markers were less than 3 cM. Only two of these 23 pancreatic carcinomas showed no p33^{ING1b} protein expression and none had a single mutation.

Figure 1 Representative examples of IHC staining for p33^{ING1b} (×200) on normal pancreatic tissues and cancer tissues. A: Weak positive pancreatic cells for p33^{ING1b}; B: No p33^{ING1b}; C and D: Extremely strong staining in pancreatic cancer samples.

Figure 2 SSCP analysis of p33^{ING1b} gene in genomic DNA from pancreatic carcinomas. N: normal DNA; T: tumor DNA. Arrow point indicates the altered band in tumor DNA as compared with the corresponding normal DNA. The amino acid substitution of p33^{ING1b} are shown to the right.

DISCUSSION

Several studies showed that reduced p33^{ING1} expression was found in esophageal squamous cell cancer (100%)^[16] and hepatocellular carcinoma (66.3%)^[17]. In our study, positive p33^{ING1b} staining was present in 85.0% of the pancreatic carcinoma tissues. No significant difference was found between cancer and non-cancer tissues, indicating that loss of p33^{ING1b} protein expression was not a major cause of the cancerization of pancreatic cells. But p33^{ING1b} protein was overexpressed in tumors compared with matched normal tissues in the patients with positive p33^{ING1b} stainings. Our results are in agreement with two previous studies^[18,19]. The functions and states of these overexpressed p33^{ING1b} proteins still need further study.

Limited analysis of ING1 gene demonstrated rearrangement of the gene in one neuroblastoma cell line and reduced expression in primary breast cancers and cell lines^[1]. Then the following experiments found several missense mutations and silent changes in cancers of esophagus^[16], head and neck^[20], esophagogastric junction^[21], gastrointestinal^[22], skin^[18,19] and breast^[23]. These mutations were all located in PHD finger and/or nuclear localization signal (NLS) in the COOH-terminal half of ING1. The PHD finger was found in several proteins, including transcription factors and proteins that could regulate chromatin structure. Mutations in PHD finger may lead to loss of the functions of ING1 through inhibiting the transcriptional activity of the gene. Mutations in NLS might interfere with the accumulation of ING1 protein in nuclei^[7]. But the rate of mutations was very low and no missense mutations were found in oral squamous cell carcinoma^[24], lymphoid malignancies^[25], colorectal carcinoma^[26], and haematological malignancies^[27]. We only detected one missense mutation at codon 215: TGC-TCC (Cys-Ser) on PHD finger among 40 samples of pancreatic carcinomas. All of these results suggested that mutations in certain types of tumor could lead to loss of the functions of p33^{ING1b}, but they were not the main reason.

Several studies have been reported that high rates of LOH were found in human chromosome 13q33-34 region^[10,16,20]. The rate of LOH in esophageal/head and neck squamous cell cancers was 58.9% (20/34) and 68% (23/34), respectively^[16,20]. Another study found that the rate of LOH in head and neck squamous cell cancers was 48% (21/44)^[10]. But the range between every two markers was more than 1 cm, far from ING1 locus, and these markers could not reflect the particular information about ING1. So we selected four markers, D13S261, D13S1047, D13S1315, and DS42490, to detect LOH in 23 cancer tissues. D13S261 and D13S1047 located on the upstream of ING1, D13S1315 on the downstream, while DS42490 in the ING1 locus. The results were described as above. As compared with the LOH (60.9%), the loss of p33^{ING1b} protein expression (8.7%) was very low in pancreatic carcinomas and no missense mutation of p33^{ING1} gene was found. The lack of mutations suggests that the ING1 gene is not the suppressor gene target of tumors in which frequent LOH was observed at 13q. The high frequency of LOH at ING1 locus and the vicinity may affect the function of p33^{ING1b} but not the expression of p33^{ING1} protein. The reason is very complex. An alternative target of inactivation may be involved in this tumor type which can affect the function of p33^{ING1b} protein. In addition, alterations at the transcriptional or post-transcriptional level may be another reason for the abnormal expression of p33^{ING1b} protein, for several experiments also detected reduced expression of p33^{ING1b} mRNA in primary breast cancers and cell lines^[23,28], human gastric cancer^[22], myeloid leukaemia^[29], head and neck squamous cell carcinoma^[20] and human diploid fibroblast^[30]. More detailed studies are needed to elucidate this possibility.

Abstract

AIM: Nucleocapsid (N) protein plays an important role in reproduction and pathological reaction of severe acute respiratory syndrome (SARS) coronavirus (SCoV), the antigenicity of the protein is better than spike (S) protein. This study was to find a highly specific and antigenic recombinant SCoV nucleocapsid (rSCoVN) protein, and to provide a basis for further researches on early diagnosis of SARS.

METHODS: Full length cDNA of SCoV nucleocapsid (SCoVN) protein was amplified through polymerase chain reaction (PCR) and cloned into yeast expression vector pPIC3.5K to construct plasmid of pPIC3.5K-SCoVN. The plasmid was linearized and then transformed into *Pichia pastoris* (*P.pastoris*) GS115 (*His Mut⁺*) by electroporation. *His⁺ Mut⁺* recombinant strains were identified by PCR and cultivated on MM/MD plates. The influence of different factors on biomass and rSCoVN protein production during induction phase, such as various induction media, dissolved oxygen (DO) and different final concentrations of methanol, was subsequently studied. The expression level and activation were detected by SDS-PAGE and Western-blot respectively.

RESULTS: All of the recombinants were *His⁺ Mut⁺* after transformation of *P.pastoris* with linearized plasmids. The BMMY medium was optimal for recombinant SCoV (rSCoVN) protein expression and growth of the recombinant strains. The final optimal concentration of methanol was 20 mL/L, the DO had a significant effect on rSCoVN protein expression and growth of recombinant strains. The rSCoVN protein expressed in recombinant strains was about 8% of the total cell protein, 520 mg/L of rSCoVN protein was achieved, and a maximum cell A at 600 nm of 62 was achieved in shake flask culture. The rSCoVN protein had a high specificity against mouse-anti-SARS-CoVN-mAb and SARS positive sera, but had no cross-reaction with normal human serum. The biological activity of rSCoVN expressed in *P.pastoris* was about 4-fold higher than that expressed in *E.coli* when the same rSCoVN protein quantity was used.

CONCLUSION: Active recombinant severe acute respiratory

INTRODUCTION

The etiologic agent of SARS has been recently identified as a novel coronavirus (SARS-CoV, SCoV) causing respiratory and enteric diseases in humans and other animals^[1-5]. The SCoV is a group of large, enveloped, positive single stranded RNA (ssRNA) viruses^[6]. Sequence analysis has revealed that the phylogeny of SCoV has most of the characteristic features of a coronavirus, but it belongs to a new group different from all known coronaviruses^[7]. The genome size is 29.725 kb in full-length, has 11 open reading frames (ORFs)^[8]. The SCoV is the largest virus found in any of the RNA viruses, encoding 23 putative proteins, including four major structural proteins, nucleocapsid (N), spike (S), membrane (M), and small envelope (E). The S, M, E and N mature proteins all contribute to generating the host immune response as seen in transmissible gastroenteritis coronavirus^[9], infectious bronchitis virus^[10,11], pig respiratory coronavirus^[12], and mouse hepatitis virus^[13].

SARS is an infectious disease with a high potential for transmission due to close contacts. The outbreak of SARS over 25 countries around the world, such as China, Singapore, Canada, threatened people's health throughout the world. Within a very short time, the disease became pandemic with new cases appearing in the rest of the world. However, it is not easy to differentiate SARS from other causes of pneumonia. Laboratory tests that can confirm a diagnosis of SCoV infection early in the course of the illness are therefore a critical clinical need^[14]. Serology is a sensitive and specific diagnostic approach in the early stage of the disease. N protein plays an important role in reproduction and pathology reaction of SCoV. Moreover, the antigenicity of N protein is better than S protein^[9,15,16]. To find an effective serologic diagnostic method, rSCoVN may be a perfect antigen.

Pichia pastoris (*P.pastoris*), a methylotrophic yeast, is an efficient host for recombinant protein production. The increasing popularity of this particular expression system can be attributed to several factors^[17-19], such as the simplicity of techniques needed for the molecular genetic manipulation of *P.pastoris*, the ability of *P.pastoris* to produce foreign proteins at high levels, many eukaryotic posttranslational modifications, and the commercially available expression system.

Up to now, rSCoVN has been expressed in *E.coli*. However, the biological activity of the rSCoVN protein expressed in *E.coli* is not perfectly understood. High-yield intracellular

expression in *P.pastoris* and activity analysis were investigated in this report. Western blot showed that the rSCoVN expressed in *P.pastoris* had a high specificity to mouse-anti-SCoVN-mAb and patient sera. The biological activity of rSCoVN expressed in *P.pastoris* was about 4-fold higher than that expressed in *E.coli* when the same rSCoVN protein quantity was used.

MATERIALS AND METHODS

Materials

E.coli strains used for cloning the gene were TOP10F⁺[proAB, lacI^q, lacZ Δ M15, Tn10 (Tet^R), and TG1 (supE hsd Δ 5 thi Δ (lac-proAB) F⁺[traD36 PROAB⁺ lacI^q, lacZ Δ M15]). These two strains were cultivated in LB medium (5 g/L yeast extract, 10 g/L peptone, 5 g/L NaCl). *P.pastoris* GS115 (*his*⁺*mut*⁺) used as expression host was purchased from Invitrogen (California, USA). The following media were employed in cultivation of *P.pichia* cells under different conditions: YEPD (10 g/L yeast extract, 20 g/L peptone, 20 g/L dextrose), BMGY and BMMY (10 g/L yeast extract, 20 g/L peptone, 100 mmol/L potassium phosphate, 13.4 g/L YNB, 4 \times 10⁻⁵ biotin, 10 g/L glycerol, pH 6.0), for BMMY, 5 mL/L filtersterilized methanol was added instead of 10 g/L glycerol. BMG and BMM (100 mmol/L potassium phosphate, 13.4 g/L YNB, 4 \times 10⁻⁵ biotin, 10 g/L glycerol, pH 6.0), for BMM, 5 mL/L filtersterilized methanol was added instead of 10 g/L glycerol. MGY and MM (13.4 g/L YNB, 4 \times 10⁻⁵ biotin, 10 g/L glycerol), for MM, 5 mL/L filtersterilized methanol was added instead of 10 g/L glycerol. MD and MM agar plates (13.4 g/L YNB, 4 \times 10⁻⁵ biotin, 20 g/L dextrose, 15 g/L agar), for MM, 5 mL/L filtersterilized methanol was added instead of 20 g/L dextrose. RDB and RDHB (20 g/L dextrose, 13.4 g/L YNB, 4 \times 10⁻⁵ biotin, 0.05 g/L each of filtersterilized L-glutamic acid, L-lysine, L-leucine, L-isoleucine, L-methionine), for RDBH, 0.05 g/L filtersterilized histidine was added. RDB-G418 agar plates (RDB agar plates, 0.5-3 g/L G418 was added). T-vector was purchased from Takara (Dalian city, China), plasmid pPIC3.5K was purchased from Invitrogen (California, USA).

Methods

Construction of pPIC3.5K-SCoVN expression plasmid The standard recombinant DNA technologies^[20] were used. The coding sequence of SCoVN protein was amplified from the T-SCoVN plasmid using the upstream primer (SCoVNFp: 5'-GGATCCACCATGTCTGATAATGGACCCC-3') containing a *Bam*H I site, in addition to a Kozak consensus sequence, and the reverse primer (SCoVNRp: 5'-GAATTCCTTATGCCTGAGTTGAATCAG-3') contained an *Eco*R I site immediately downstream of an inframe stop codon. The primers facilitated the subcloning of SCoVN protein coding sequence into pPIC3.5K expression vector. The conditions for PCR were as follow: template was initially denatured at 94 °C, cultivated for 4 min, followed by 19 cycles, (each at 94 °C for 50 s, at 57 °C for 50 s, at 72 °C for 80 s), finally, a cycle was performed at 72 °C for 10 min. The PCR products were ligated to T-vector, then cut off by *Bam*H I and *Eco*R I and the fragments were ligated into the same enzymes digested multiple cloning sites of pPIC3.5K expression vector. Finally, the clone was sequenced by 5' AOX primer and 3' AOX primer in the kit, and the fragments were confirmed to be inserted into the correct sites.

Transformation of *P.pastoris* and selection of *his*⁺*mut*⁺ transformants *P.pastoris* was transformed using electroporation protocol, competent cells were prepared as described^[21]. Transformed DNA was linearized using *Sac* I leading to targeting of recombinant plasmids to the chromosomal *his4* locus. Before transformation, the linearized DNA was desalted by gel extraction mini kit (Watson Biotechnologies, INC). Plasmid DNA (3-5 μ g) was mixed with 80 μ L of competent cells and stored on ice for 5 min. Cells transferred to an ice-cold 0.2 cm

electroporation cuvette. Transformation was performed using a BioRad GenePulser II. Parameters used were 7.5 KV/cm, 50 μ F and 400 Ω . After pushed, 1.0 mL of ice-cold RDB liquid media was immediately added to the cuvette, and then incubated at 29 °C for 60 min in a shaking incubator (250-300 rpm). Two aliquots of 400 μ L each were plated on RDB-geneticin agar plates, the plates were incubated at 29 °C for 3-4 d. Using sterile toothpicks, the *His*⁺ and geneticin resistant transformants were picked in a regular pattern on MM and MD plates and incubated at 29 °C for 2-3 d. The *His*⁺*Mut*⁺ (methanol utilization slow) transformants were differentiated from *his*⁺*Mut*⁺ (methanol utilization plus) via comparison of patch growth rate on MM and MD plates.

PCR analysis of *P.pastoris* recombinant transformants The primers used were as follows. 5' AOX1: 5'-GACTGGTTCCAAT TGACAAGC-3'; 3' AOX1: 5'-GCAAATGGCATTCTGACATCC-3'. The genomic DNA was isolated as described in multi-mopy *Pichia* expression kit. PCR amplification was performed as follows: initial denaturation at 95 °C for 4 min, followed by 34 cycles, (each at 94 °C for 60 s, at 55 °C for 60 s, at 72 °C for 150 s) and a final extension at 72 °C for 10 min. The genomic DNAs isolated from recombinant *P.pastoris* transformed with parent plasmid and *P.pastoris* GS115 were used as control for PCR^[21].

Shake-flask cultivation of *P.pastoris* and intracellular expression of rSCoVN The recombinant *P.pastoris* strains judged by PCR analysis were grown in 15 mL BMGY medium at 29 °C, until the final cell OD at 600 nm reached 2-6 (log-phase growth). The cells were harvested by centrifuging at 1 500 r/min for 6 min at room temperature, cell pellets were resuspended to a cell A at 600 nm of 1.5 in BMMY medium and induced at 29 °C in a shaking incubator (250-300 rpm). A 100 mL/L of methanol was added to a final concentration 5 mL/L every 24 h to maintain induction. Induced *P.pastoris* transformed with the parent vector was used as a control for background intracellular expression. At each time (about 12-24 h), samples were withdrawn to analyse expression level, activity and to detect A at 600 nm.

Optimization of culture and induction protocol in shake flasks The highly expressed recombinant strains judged by BMGY/BMMY media firstly were grown in different media, and then induced in relevant media. At last, the A and the final methanol concentration were optimized during induction phase. At each time during induction, samples were withdrawn to analyse expression level and the biomass of the recombinant strains.

Lysis of cells and detection of proteins Yeast cells induced to express rSCoVN protein were harvested, the cells were washed with sterile water, and then harvested and stored at -80 °C. Frozen yeast cells were removed from storage and thawed for approximately 3 h at room temperature, breaking buffer (25 mmol/L sodium phosphate, 150 mmol/L sodium chloride, 1 mmol/L EDTA, 1 mmol/L DTT) was added, the cells (6 mL breaking buffer/g wet cells) were resuspended and then stirred for 15 min, followed by approximately 18 h at 4 °C, then disrupted by four passes through a sanitized APV Gaulin 30 CD homogenizer at chamber pressures of 12 000 to 14 000 psi, resulting in 95% cell disruption. About 10 μ L breaking sample mixed with 10 μ L ddH₂O and 10 μ L SDS-PAGE sample buffer^[22] were boiled for 5-10 min, then centrifuged at 12 000 g for 10 min at room temperature, and 10 μ L of the supernate was applied to SDS-PAGE, and separated on 100 g/L polyacrylamide gels with 50 g/L stacking gel. For protein estimations, Coomassie-stained SDS-gels were analyzed by densitometry using UVI.

Western blot analysis of rSCoVN protein After equilibration of gels and nitrocellulose membranes in transfer buffer (25 mmol/L Tris-HCl, 192 mmol/L glycine, 3.5 mmol/L SDS, 200 mL/L methanol), the protein was electroblotted onto a membrane (Amersham Pharmacia Biotech Hoefer TE 70 Series Semiphor Semi-Dry transfer Units, 0.8 mA/cm² 30 min)^[23]. After the membrane (50 g/L fat free milk/TN buffer (10 mmol/L Tris-HCl, 150 mmol/L NaCl, pH 8.0) was blocked, it was probed with a

mouse-anti-SCoVN-mAb (dilution 1:1 000, 50 g/L fat free milk/TN buffer or human serum (dilution 1:100 in 5% fat free milk/TN buffer; 20-25 °C, 1 h), followed by a sheep-anti-mouse or sheep-anti-human IgG coupled to alkaline phosphatase (dilution: 1:10 000 in 50 g/L fat-free milk/TN buffer; 20-25 °C, 1 h). Bound antibodies were detected using 5-bromo-4-chloro-3-indolyl-phosphate (BCIP) and nitro-blue tetrazolium (NBT) in 100 mmol/L NaCl, 5 mmol/L MgCl₂, 100 mmol/L Tris. HCl buffer, pH 9.5^[7] as substrates.

Quantitative activity analysis of rSCoVN proteins expressed in *P.pastoris* and *E.coli* The biological activity of rSCoVN proteins expressed in *P.pastoris* and *E.coli* was compared using Western blot. The purified protein expressed in *P.pastoris* and *E.coli* was diluted by 4-fold gradient, and 12, 3, 0.75, 0.18 µg proteins were added to each well of SDS-PAGE respectively, then probed with a mouse-anti-SCoVN-mAb.

RESULTS

Construction of pPIC3.5K-SCoVN expression plasmid

The coding sequences for SCoV gene were amplified from T-SCoVN plasmid by PCR using primers (SCoVNFP and SCoVNRP) incorporating 5' *Bam*H I and 3' *Eco*R I, and subcloned into the *Bam*H I and *Eco*R I sites of the pPIC3.5K expression plasmid (Figure 1). Then the constructed expression plasmid was sequenced and proved to be correct. The SCoV protein coding sequence was under the control of the AOX1 promoter.

Figure 1 Construct of expression plasmid pPIC3.5K-SCoVN under the control of AOX1 promoter (5' AOX1: promoter fragment; 3' AOX1 (TT): transcription termination, HIS4 ORF: a select marker, SCoV was inserted between 5' AOX1 and 3' AOX1 (TT), Kanamycin: multi-copy select marker).

Screening of transformant phenotype

pPIC3.5K-SCoVN or pPIC3.5K was digested with *Sac* I to linearize the plasmids, and then electroporated into *P.pastoris* GS115 (*his⁺mut⁺*) respectively. Twenty geneticin-resistant colonies were cultivated on MD and MM plates. They were all *His⁺Mut⁺*, because they all had the same growth rate. The geneticin-resistant colonies were grown in YPED for 24 h, then the genomic DNA was purified, PCR amplification of SCoV gene was carried out with 5' AOX1 primer and 3' AOX1 primer. Twenty transformants each had the alcohol oxidase gene and SCoV gene. The result demonstrated that all geneticin-resistant colonies were *His⁺Mut⁺*, identical to the result identified on MD and MM plates. The SCoV protein coding sequence was correctly integrated into the *P.pastoris* genome in the positive recombinants via a single crossover (Figure 2: lanes 5 and 6).

Expression of rSCoVN protein in shake flasks and activity assay

A single recombinant colony (*His⁺Mut⁺*) was used for expression study in shake flask expression^[21]. After one day of cell growth on BMGY medium at 30 °C, 250 rpm, then the BMGY medium was changed to BMMY medium. The cells were fed with 100 mL/L methanol to 5 mL/L (final concentration) every day. The strains transformed by parent plasmid pPIC3.5K were taken as control.

Samples were withdrawn after 60 h. SDS-PAGE showed that heterologous rSCoVN protein was successfully expressed in *P.pastoris*, the rSCoVN protein expression level was about 6% of the total cell protein (Figure 3), a 45 ku protein band could be seen in the positive recombinant and there was no 45 ku protein band in control. To confirm the 45 ku protein was the SCoV protein, 45 ku protein was detected by Western blot with mouse-anti-SCoVN protein mAb, SARS positive serum and negative serum. The results showed that a single positive reaction band at about 45 ku (Figure 4) could be seen in the nitrocellulose membrane. The band of the same molecular mass could not be detected in the induced recombinant strain transformed pPIC3.5K vector by Western blot analysis. The results showed that the recombinant protein was successfully expressed and had a high-specificity and good-antigenicity against SCoV-Ab and SARS positive serum, but had no reaction with normal human serum.

Figure 2 Integration of SCoV gene into the *P.pastoris* GS115 confirmed by PCR using 5' AOX1 primer and 3' AOX1 primer (lane 1: DNA ladder, lane 2: PCR product of pPIC3.5K, lane 3: PCR product of pPIC3.5K-SCoVN, lane 4: PCR product of *P.pastoris* GS115 without transformation, lane 5: PCR product of control strains, lanes 6 and 7: PCR product of positive recombinants).

Comparison of biologic activity of rSCoVN in *P.pastoris* and *E.coli*

The biologic activities of rSCoVN protein expressed in *P.pastoris* and *E.coli* were compared using Western-blot. As shown in Figure 5, both rSCoV proteins were able to react with mouse-anti-SARSN-mAb. However, the rSCoVN protein expressed in *P.pastoris* appeared to have a more potent activity than that in *E.coli*. Dose-response studies demonstrated that the biological activity of rSCoVN expressed in *P.pastoris* was approximately 4-fold higher than that in *E.coli* when the same rSCoVN protein quantity was used. But the Western blot and SDS-PAGE demonstrated that there was no glycosylation in the rSCoVN protein expressed in *P.pastoris*, because the rSCoVN protein expressed in *P.pastoris* had the same molecular weight as in *E.coli*. So rSCoVN protein expressed in *P.pastoris* had more application potential as a diagnostic agent.

Figure 5 Determination of biological activity of rSCoVN protein expressed in *P.pastoris* and *E.coli*. SDS-PAGE (left) and Western blot (right). Lanes 1, 5: sample containing 12 µg rSCoVN, lanes 2, 6: sample containing 3 µg rSCoVN, lanes 3, 7: sample containing 0.75 µg rSCoVN, lanes 4, 8: sample containing 0.18 µg rSCoVN. Lanes 1, 2, 3, 4: sample expressed in *P.pastoris* and lanes 5, 6, 7, 8: sample expressed in *E.coli*.

Optimization of culture and expression condition

Comparison of the effect of various media on yeast growth and rSCoVN expression To investigate the effect of different media on rSCoVN expression level and the growth of recombinant strains, we compared the rSCoVN expression level and biomass in different induction media such as BMMY, BMM and MM

media in 20 mL scale. rSCoVN protein expression in *P.pastoris* was performed with a two-phase culture method: biomass production using glycerol as a solely carbon source and specific induction by methanol respectively in BMMY, BMM and MM media. Figure 6A, B show the biomass and rSCoVN protein expression level in each medium at different induction stages. The recombinant strains reached the stationary phase after 2 d of induction, and rSCoVN protein expression level also reached the maximum. A 2-fold difference in biomass and 3.5-fold difference in expression level were noticeable between BMMY and MM media. Difference in biomass and expression was also found between BMMY and BMM media. BMMY medium was optimal for induction expression.

Effect of DO on yeast growth and rSCoVN protein expression

The effect of DO in media on growth and rSCoVN protein expression of *P.pastoris* was also investigated. Different volume media (10, 20, 30, 40 and 50 mL) were loaded in 100 mL flasks. The different volume of the media loaded in flasks meant different DO. The more the medium was loaded, the less the DO was, and it should be noted that the shape was identical. Figure 6C, D show that the DO had an obvious effect on the yeast growth and expression of rSCoVN. The rSCoVN protein expression level was the same in the flask loaded 10 mL or 20 mL medium, because the DO was efficient for growth and rSCoVN protein expression of the recombinant strains in the flask, so the growth and rSCoVN expression level of the recombinant protein were very high, over 20% higher than others. When the volume of medium was increased (above 20 mL), the DO decreased, and the growth and expression level were decreased. So the DO was an important factor for the growth and rSCoV protein expression of the recombinants.

Effect of the final concentration of methanol during induction on yeast growth and rSCoVN protein expression

To find an optimum methanol feeding protocol, different volumes of 100% methanol were added to the media twice a day instead of once a day to decrease the resulting concentration shifts in the BMMY medium. Figure 6E, F show that when the

Figure 6 Effects of different media, DO (dissolved oxygen) and methanol amount on the growth and expression of rSCoVN. A, C, E: Growth curves during induction phase by different media, DO and methanol amount, B, D, F: rSCoVN expression and induction time by different media, DO and methanol amount.

methanol feeding was below 20 mL/L, and the concentration of methanol was increased, the biomass was also increased, while the rSCoVN protein expression level was the same at the methanol feeding of 10 mL/L and 20 mL/L, but was increased about 25% than that at the methanol feeding of 5 mL/L. Above the methanol feeding of 20 mL/L, the higher the methanol was fed, the lower the biomass and expression level were. So feeding with 20 mL/L methanol twice a day was considered an optimal feeding strategy.

Kinetics of biomass and rSCoVN protein expression of recombinant *P.pastoris*

After the optimal conditions for yeast growth and rSCoVN protein expression were found, the kinetics of the growth and expression were examined. The results are shown in Figure 7. The rSCoVN protein could be detected readily by SDS-PAGE after 12 h of induction (the inserted panel), rSCoVN protein expression was evident when cells entered the logarithmic growth state and peaked when cell growth reached a steady state and became more or less constant thereafter. The magnitude of expression level reached 526 mg/L. The rSCoVN protein expression was about 8% of the total cell protein, and the maximum cell OD at 600 nm of 62 was achieved. So the optimal harvesting time of cells was 48-60 h after induction. The insert in the panel showed the accumulation of rSCoVN protein by SDS-PAGE during the course of the 84 h experiment.

Figure 7 Kinetics of biomass and rSCoVN protein expression using SDS-PAGE over a span of 84 h. The insert shows rSCoVN protein expression level using SDS-PAGE during the course of experiment.

DISCUSSION

The *P.pastoris* expression system has gained acceptance as an important host organism for the production of foreign proteins as illustrated by the fact that a number of proteins synthesized in *P.pastoris* are tested for use as pharmaceuticals in clinic. IGF-1 as a treatment for amyotrophic lateral sclerosis and human serum albumin (HSA) in a serum replacement product have passed clinical trials. Another protein, hepatitis B surface antigen, has been currently available on the market as a subunit vaccine against hepatitis B virus^[24,25].

The etiologic agent of severe acute respiratory syndrome (SARS), has been recently identified as a novel coronavirus causing respiratory and enteric diseases in humans and other animals^[1-5]. SARS is an infectious disease with a high potential for transmission due to close contacts. So it is critical to find a perfect diagnostic agent. N protein plays an important role in reproduction and pathologic reaction of SCoV, and its antigenicity is better than spike protein. So N protein may be the perfect antigen.

In the present study, active rSCoVN was highly expressed in *P.pastoris*. Compared with various media, the BMMY medium

was optimal for rSCoVN expression. A 2-fold difference in biomass and 3.5-fold difference in expression level were noticeable between BMMY and MM media. Difference in biomass and expression was also presented between BMMY and BMM media. The result also revealed that peptone, yeast extracts and steady pH had prominent effects on the growth and expression of recombinant *P.pastoris*. The buffered medium could maintain a stable pH value, and benefit the absorption and use of the nutrients. Moreover, yeast extracts, peptone are rich in peptides, amino acids, vitamins and trace elements. These compounds could enhance the biomass and energy for foreign protein synthesis^[25].

The effect of DO on the growth and expression of rSCoVN revealed that DO was an important factor for yeast growth and expression of recombinant protein. While microorganisms growing on carbohydrates use molecular oxygen mainly for respiration. Oxygen availability could influence the production of proteins, both in prokaryotic cells^[26] and in yeast^[27]. Yeasts growing on methanol might also require a substantial amount of oxygen for the initial oxidation of methanol to formaldehyde^[28]. All methanol taken up by the cells is oxidized to formaldehyde in a coupled reaction involving alcohol oxidase (AOX) and catalase (CAT) in peroxisomes. These reactions use molecular oxygen as an ultimate electron acceptor. Foreign protein synthesis needs abundant energy, so it is important to maintain a relatively high DO for expressing foreign protein in *Pichia pastoris*.

For the expression of protein using AOX1 promoter, it is important to keep the methanol level within a relatively narrow range. In bioreactors it could be achieved by different methods^[29]. In shake flasks, a technique for online monitoring of methanol concentration was introduced^[30]. The ordinary methanol feeding protocol without any complicated devices, still has not been reported. So we established an empirically feeding protocol for our recombinant strains, which worked without any measuring devices. A methanol feeding of 20 mL/L, (final concentration) was optimal for yeast growth and expression of SCoV protein. Slightly reduced growth and expression while methanol feeding below or above 20 mL/L was probably due to the limited carbon or the toxic effect of accumulated methanol^[30].

Western blot demonstrated that rSCoVN protein had a high-specificity and good-antigenicity against SCoV-Ab and SARS positive serum, and no reaction with normal human serum. The biological activity of rSCoVN expressed in *P.pastoris* was about 4-fold higher than that expressed in *E.coli* when the same rSCoVN protein quantity was used. The preliminary results indicate that the conformation of rSCoVN protein expressed in *P.pastoris* is almost the same as the natural SCoV protein, and the rSCoVN protein produced may be suitable for the detection of anti-SCoV in diagnostic assay.

Abstract

AIM: To investigate the expression between γ -aminobutyric acid (GABA) and glutamate decarboxylase and its relation with differentiation and maturation of jejunal epithelial cells in rat jejunum.

METHODS: Immunohistochemical expression of GABA and glutamate decarboxylase (GAD, including two isoforms, GAD65 and GAD67) was investigated in rat jejunum. Meanwhile, double staining was performed with GAD65 immunohistochemistry, followed by lectin histochemistry of fluorescent wheat germ agglutinin. Furthermore, evaluation of cell kinetics in jejunum was conducted by ^3H -thymidine autoradiography and immunohistochemistry using a monoclonal antibody to proliferating cell nuclear antigen (PCNA).

RESULTS: The cells showing positive immunoreactivity GABA and GAD65 were mainly distributed in the villi in rat jejunum, while jejunal epithelial cells were negative for GAD67. Positive GABA or GAD65 staining was mainly located in the cytoplasm and along the brush border of epithelial cells in the middle and upper portions. In addition, a few GABA and GAD65 strongly positive cells were scattered in the upper two thirds of jejunal villi. Double staining showed that GAD65 immunoreactivity was not found in goblet cells. ^3H -thymidine-labeled nuclei were found in the lower and middle portions of jejunal crypts, which was consistent with PCNA staining. Therefore, GABA and GAD65 were expressed in a maturation or functional zone.

CONCLUSION: The characteristic expression of GABA and GAD suggests that GABA might be involved in regulation of differentiation and maturation of epithelial cells in rat jejunum.

INTRODUCTION

γ -aminobutyric acid (GABA), originally identified as the principal inhibitory neurotransmitter in the mammalian brain, has been demonstrated to be biologically active in different tissues throughout the body^[1-3]. In developing embryos, GABA was verified to play an important role in the morphogenesis and maturation of many tissues outside the nervous system^[4,5]. Our previous study indicated that GABA and glutamate decarboxylase (GAD, including two isoforms, GAD65 and GAD67) were expressed in chondrocytes on the epiphyseal growth plate of rats, and mainly localized in the maturation zone, rather than the reserve zone or proliferating zone^[6]. This suggests that GABA might play certain functional roles in the differentiation of chondrocytes during growth of the skeleton.

Recently, GABA and GAD have been proved to be increased in colorectal carcinoma tissues by both biochemical and immunohistochemical methods^[7,8]. However, the distribution patterns of GABA and GAD in growth zones of the intestinal epithelium have not been clarified. Therefore, the present study was designed to detect the expression of GABA and GAD in the growth zones of rat jejunum, with an attempt to elucidate the relationship between GABA expression and differentiation and maturation of intestinal epithelial cells.

MATERIALS AND METHODS

Reagents

Rabbit anti-GAD65 polyclonal antibody was purchased from Sigma (Sigma Co. St. Louis, MO, USA). Rabbit anti-GABA and anti-GAD67 polyclonal antibodies were acquired from Chemicon International Inc. (Temecula, CA, USA). Mouse anti-PCNA monoclonal antibody was obtained from Medical and Biological Laboratories Co. (Nagoya, Japan). Alexa FluorTM 488 goat anti-rabbit IgG (H+L) and Alexa FluorTM 594 wheat germ agglutinin (WGA) conjugates were acquired from Molecular Probes (Eugene, OR, USA). Biotin-conjugated anti-mouse immunoglobulin polyclonal antibody was purchased from Pharmingen International (San Diego, CA, USA). ^3H -thymidine was obtained from PerkinElmer Life Science Inc. ($[\text{6-}^3\text{H}]$ - thymidine, specific activity: 528 GBq/mmol, Boston, MA, USA).

Animals and tissue preparation

Male Wistar rats (4-6 wk, Nihon Clea, Osaka, Japan), weighing 80-100 g, were caged under controlled conditions of light (lights on 06:00-18:00 h) and temperature (23 °C). The rats were given food and water *ad libitum*. The Ethics Review Committee for Animal Experimentation of Osaka Medical College approved the experimental protocol.

The animals ($n = 5$) were deeply anesthetized with pentobarbital (50 mg/kg body weight), and then fixed by transcardial perfusion with 40 g/L paraformaldehyde in Ringer's solution. After whole body fixation, segments of jejunum (2 cm from Treitz's ligament) were excised and immersed in cold 40 g/L paraformaldehyde in phosphate buffered saline (PBS, pH 7.2)

at 4 °C overnight. For light microscopy study, tissues were soaked overnight in 300 g/L sucrose in PBS, and longitudinal cryostat 5 µm thick sections were cut on a freezing microtome (Leica CM 3050, Nusloch, Germany).

Immunohistochemistry for GABA, GAD65 and GAD67

Immunohistochemical study was performed with polyclonal antibodies against GABA, GAD65, and GAD67. The final dilution for these antibodies was 1:800, 1:1 000, and 1:1 000, respectively. With all antibodies, a two-step indirect immunohistochemical method was used. Cryostat sections were fixed with ice-cold acetone, incubated with 100 mL/L normal goat serum at room temperature for 60 min, and then incubated with primary antibodies overnight at 4 °C. Incubation with primary antisera was followed by Alexa Fluor 488-labeled goat anti-rabbit immunoglobulins. The secondary antibodies were diluted to 1:250 in PBS prior to use, incubated for 60 min at room temperature in darkness, and washed three times with 0.01 mol/L PBS. Sections were finally mounted with MO2 Crystal/Mount (Cosmo Bio, Tokyo, Japan) and preserved at 4 °C in a dark refrigerator. Primary antibodies were replaced by PBS for the negative controls. None of the controls revealed any specific signal.

Double staining and lectin histochemistry

Sections were first applied to immunohistochemical staining for GAD65 as aforementioned. After reaction with the second antibody and a brief wash in PBS, sections were further incubated with Alexa Fluor 594 WGA at room temperature for 60 min in darkness, and washed with 0.01 mol/L PBS three times and mounted with MO2 Crystal/Mount.

³H-thymidine autoradiography

Rats ($n = 2$) were injected intraperitoneally at 10:00 a.m. with 100 µCi (3.7 MBq) ³H-thymidine. After 90 min, the rats were anesthetized and fixed by intracardial perfusion with 25 g/L glutaraldehyde. Samples of jejunum were taken as aforementioned, and 5 µm thick paraffin sections were prepared regularly. Autoradiography^[9] was performed as follows: Tissue sections were deparaffinized and dipped into NR-M2 emulsion (Konica Co. Tokyo, Japan) that was diluted with an equal volume of distilled water containing 10 g/L glycerin. After 10 d of exposure in a dark refrigerator, the sections were developed at 20 °C for 8 min in Kodak D-19 diluted with an equal volume of distilled water, terminated in 10 g/L acetic acid for 1 min, and fixed in 300 g/L sodium thiosulphate solution at 20 °C for 8 min. Finally, the sections were lightly counterstained with hematoxylin.

PCNA immunostaining

After three washes with PBS, endogenous peroxides were blocked in 10 g/L hydrogen peroxide in methanol for 30 min at room temperature. For antigen retrieval, the sections were treated with 1 g/L pepsin in 0.01 mol/L HCl. Non-specific binding sites were blocked with 40 g/L bovine serum albumin. Subsequently, anti-PCNA was diluted to 1:100 and reacted with tissue specimens at 4 °C overnight. The sections were then washed three times with PBS, and incubated with biotinylated secondary antibody at room temperature for 60 min. Finally, immunohistochemical staining was performed using the avidin-biotin-peroxidase complex (Vectastain ABC kit, Burlingame, CA, USA). Diaminobenzidine was used as a chromogen, and the sections were counterstained with hematoxylin.

Microscopic observation

For the convenience of description, the crypts of jejunum were divided into the lower, middle and upper portions, while the villi as the basal, middle and top portions. PCNA immunostaining

was observed with a Nikon light microscope equipped with a digital camera (PDMC Ie, Polaroid Co., MA, USA). Fluorescence observation was performed using a confocal laser scanning microscopy (Radiance 2000, Bio-Rad Laboratories, CA, USA) equipped with an argon laser. The laser scanning differential interference contrast (DIC) and confocal mode with an argon laser at 488 nm and/or 590 nm were used. ³H-thymidine autoradiographs were observed with a confocal laser microscope (Carl Zeiss LS10, Germany)^[9]. ³H-thymidine labeling index or PCNA labeling index was calculated as the percentage of positive cells of the total cells by counting 10 different crypts^[10].

Statistical analysis

Welch's *t* test was used for the comparison of PCNA labeling index and ³H-thymidine labeling index.

RESULTS

³H-thymidine autoradiography

Radioactivity was located at the nuclei of cells at the lower and middle portions of the jejunal crypts, while the upper crypts and the whole villi were negative (Figure 1). The ³H-thymidine labeling index was 30±6%.

Figure 1 Autoradiograph of rat jejunum at 90 min after intraperitoneal injection of ³H-thymidine, observed by a confocal laser scanning microscope. A confocal image of reflectance from silver grains (red in color) was overlaid with the differential interference image (green in color). ×200.

PCNA immunostaining in rat jejunum

Strong PCNA staining was detected in the lower portion of the jejunal crypts, while epithelial cells in the villi were almost negative (Figure 2). PCNA labeling index was 57±8%, which was significantly higher than ³H-thymidine labeling index ($P < 0.01$, Welch's *t* test).

Figure 2 PCNA immunostaining in rat jejunum. ×100.

Expression of GABA in rat jejunum

GABA immunoreactive cells were distributed in the whole villi of rat jejunum. Strongly positive staining was mainly located in the cytoplasm and along the brush border of epithelial cells in the middle and upper portions (Figure 3).

Figure 3 Confocal laser microscopic image of GABA immunoreactivity in rat jejunum. Note the strongly positive staining cells distributed in the middle and upper portions of the villi. $\times 1\,000$.

Expression of GAD in rat jejunum

GAD65 immunopositive cells were distributed in the middle and upper portions of jejunal villi. Strongly positive staining of GAD65 was mainly localized along the brush border of enterocytes (Figure 4). In addition, a few strongly positive cells had no brush border, which were scattered in the middle or upper portion of jejunal villi. GAD67 was negative in jejunal epithelial cells.

The distribution of GABA and GAD65 immunopositive cells, in comparison with PCNA, is shown in Table 1. GABA and GAD65 were mainly localized in the place where PCNA was negative or weak positive. That is to say, GABA and GAD65 were distributed in the maturation zone and functional zone, rather than in the proliferating zone or stem cells of the jejunal epithelium.

Table 1 Immunoreactivity of GABA, GAD65 and PCNA in epithelium of rat jejunum

	Crypt			Villus		
	Lower	Middle	Upper	Basal	Middle	Top
PCNA	++	+++	±	±	±	-
GABA	±	-	+	+	++	++
GAD65	±	-	-	±	++	++

- negative, ± faint positive, + mild positive, ++ moderate positive, +++ strong positive.

Double staining of immunoreactive GAD65 and lectin histochemistry

Goblet cells were demonstrated by fluorescent WGA staining, while mature absorptive cells were characterized by a well-developed brush border that was positively stained for GAD65 in the jejunum. The GAD65 strongly positive cells in jejunal villi were negative for WGA (Figure 4). Pre-epithelial mucous layer was also stained by fluorescent WGA.

Figure 4 Double staining of immunofluorescent GAD65 (green in color) and fluorescent WGA (red in color) in rat jejunum. Arrow points to the GAD65 strongly positive cells showing WGA negative staining. Arrowhead indicates the strong line-like staining of GAD65 along the brush border, and the outer mucus layer stained by WGA. $\times 630$.

DISCUSSION

The replacement and cell kinetics in murine intestines have been established for decades. The proliferation sites are existed in the lower or middle portion of the small intestinal crypt and in the lower half crypt of the large intestine in rats^[11,12]. Bartkova *et al.*^[13] suggested that intestinal epithelium could be divided into four compartments, namely, stem cells at the base, proliferating zone, maturation zone, and functional zone near the luminal surface.

Cell kinetics has been examined traditionally by ^3H -thymidine as a marker for S phase cells. PCNA is an evolutionarily highly conserved acidic nuclear protein, which can function as an auxiliary protein for DNA polymerase δ ^[14]. It has been proved that PCNA expression is maximal during S phase of the cell cycle, and PCNA mRNA normally accumulates only in proliferating cells^[15]. Consequently, PCNA has been found to be a useful marker in immunohistochemical analysis of cell kinetics^[16].

In this study, the growth zones of jejunum were demonstrated by PCNA immunohistochemistry and ^3H -thymidine autoradiography. The proliferating zone was consisted of the lower and middle portions of the crypt in the jejunum. Our results also indicated that ^3H -thymidine autoradiography was more specific for marking S-phase cells than PCNA immunohistochemistry, as PCNA labeling index was significantly higher than ^3H -thymidine labeling index. Meanwhile, GABA and GAD65 immunoreactive cells were distributed in jejunal villi. In other words, GABA and GAD were found in maturation and function zones other than in proliferating zone in rat jejunum.

The characteristic distribution patterns of GABA and GAD in the intestinal epithelium remain unknown. Gilon *et al.*^[4] first reported their research about the possible role of GABA and cell differentiation. Their results documented the appearance of GABA in the developing pancreas and duodenum just prior to the termination of rapid growth and maturation of these tissues. These results are similar to the earlier findings in the developing brain^[17]. Our previous study also demonstrated that GABA and GAD were mainly localized in the hypertrophic zones rather than in the proliferating zone in rat epiphyseal growth plate chondrocytes^[6]. Recently, Kaita *et al.*^[18] reported that ciprofloxacin significantly increased the hepatic regenerative activity in animal models of alcohol-induced liver diseases. The results of PCNA staining showed an enhanced hepatic regeneration in the ciprofloxacin-treated group at 60 h (saline, $13.4 \pm 3.7\%$; ciprofloxacin, $47.4 \pm 7.3\%$; and putrescine, $8.4 \pm 2.8\%$ positively stained hepatocytes). Our results also showed that the intensity of immunoreactive GABA and GAD65 on well-differentiated cells was stronger than that on proliferating cells. Based on these results, we presume that GABA should be involved in the regulation of differentiation and maturation of epithelial cells. On the other hand, the characteristic distribution of GABA and GAD65 also indicates that GABA might have some inhibitory effects on epithelial proliferation in rat jejunum.

The intestine has been recognized as a "diffuse endocrine" system, where a variety of endocrine cells produce different peptide hormones. A number of studies have demonstrated that GABA exists in endocrine cells in the gastrointestinal tract^[19-21]. This study showed that there were some strong GABA and GAD65 immunoreactive cells in jejunal villi. It is well known that stem cells in intestinal epithelium give rise to four different kinds of cells: enterocytes (absorptive cells), goblet cells, enteroendocrine cells, and Paneth cells. Mature enterocytes are characterized by the presence of a brush border at their apical surface, while Paneth cells are localized in the lower crypts^[22]. Goblet cells in rat jejunum were clearly demonstrated by lectin histochemistry, because of the specific binding of WGA to sugar residues in mucin within the cells^[23]. Double staining showed that GAD65 strongly positive cells were neither goblet cells nor mature absorptive cells. We believe that these cells are enteroendocrine cells that can synthesize GABA from glutamic

acid. Therefore, it seems reasonable to assume that GABA might be related to the endocrine function of the small intestine.

GABA is known to be synthesized principally from glutamic acid via single enzymatic catalysis of GAD. Two isoforms of mammalian GAD with a predicted molecular weight of 65 300 (GAD65) and 66 600 (GAD67) are highly conserved, but derived from separated genes^[24]. The phylogenetic tree study indicated that the multiplicity of mammalian GAD in central nervous system might have developed some 500 million years before, when the widespread of gene duplications occurred in vertebrates^[25]. Though these isoforms could catalyze the same biochemical reaction, they have been proved to have a different distribution and may have different functions in peripheral as well as the nervous system^[26]. Our result showed that GAD65 was positive, while GAD67 was negative in rat jejunum. This difference further supported the multiplicity of GAD in mammal non-neural tissues^[27].

It should be noted that the distribution of GABA in rat jejunum was not exactly parallel to that of GAD65. In the basal third of jejunal villi, GABA was found to be moderately positive, while GAD65 was weakly positive. GABA in these cells might not be synthesized from glutamic acid via GAD. That is to say, GABA in some intestinal epithelial cells might have other synthetic routes. Putrescine route is a well-known alternative pathway of GABA synthesis in gastrointestinal tract^[28]. Apart from GABA formation, putrescine can be utilized for the biosynthesis of polyamines, such as spermidine and spermine, which have been proved to be involved in the control of cell proliferation^[29,30]. Further research is necessary to elucidate the metabolic routes and functional roles of GABA-polyamine system in epithelial cells of the intestine.

In conclusion, GABA and GAD65 are mainly expressed in the maturation or functional zone in jejunal epithelium of rats. This characteristic expression suggests that GABA may be involved in the regulation of differentiation and maturation of epithelial cells.

Abstract

AIM: To investigate the inhibitory effects of sodium orthovanadate on small-intestinal glucose and maltose absorption in rats and its mechanism.

METHODS: Normal Wistar rats were lavaged with sodium orthovanadate (16 mg/kg, 4 mg/kg and 1 mg/kg) for 6 d. Blood glucose values were measured after fasting and 0.5, 1, 1.5 and 2 h after glucose and maltose feeding with oxidation-enzyme method. α -glucosidase was abstracted from the upper small intestine, and its activity was examined. mRNA expression of α -glucosidase and glucose-transporter 2 (GLUT2) in epithelial cells of the small intestine was observed by *in situ* hybridization.

RESULTS: Sodium orthovanadate could delay the increase of plasma glucose concentration after glucose and maltose loading, area under curve (AUC) in these groups was lower than that in control group. Sodium orthovanadate at dosages of 10 $\mu\text{mol/L}$, 100 $\mu\text{mol/L}$ and 1000 $\mu\text{mol/L}$ could suppress the activity of α -glucosidase in the small intestine of normal rats, with an inhibition rate of 68.18%, 87.22% and 91.91%, respectively. Sodium orthovanadate reduced mRNA expression of α -glucosidase and GLUT2 in epithelial cells of small intestine.

CONCLUSION: Sodium orthovanadate can reduce and delay the absorption of glucose and maltose. The mechanism may be that it can inhibit the activity and mRNA expression of α -glucosidase, as well as mRNA expression of GLUT2 in small intestine.

INTRODUCTION

There is evidence that sodium orthovanadate could markedly

decrease the high blood sugar induced by alloxan and streptozotocin^[1,2]. Sodium orthovanadate acts on blood sugar by increasing the number of insulin-receptors and enhancing glucose transport via promoting the combination of insulin and insulin receptors^[3-7]. Besides, sodium orthovanadate can also inhibit glucose absorption from small intestines of rats by inhibiting the activity of Na^+/K^+ -ATPase and increasing contractility in the intestinal smooth muscles^[8,9]. Therefore we observed the effects of sodium orthovanadate on glucose and maltose absorption in the small intestine of Wistar rats and investigated the mechanisms in order to provide theoretical basis for its further development.

MATERIALS AND METHODS

Materials

Male and female Wistar rats weighing 180-220 g were obtained (Department of Animals, Harbin Medical University). Sodium orthovanadate was provided by Harbin Medical University. Acarbose was purchased from Bioer (Wuhan, China). Both α -amylase and p-nitrobenzene- α -D-malt pentose glycoside were supplied by Sigma (America). *In situ* hybridization kits of the small intestine GLUT2 and α -glucosidase were from BOSD Biotech (Wuhan, China).

Methods

Experimental schedule Normal Wistar rats were randomly divided into 5 groups (8 rats per group). Animals in group 1 were lavaged with saline, rats in groups 2-5 were lavaged with acarbose (30 mg/kg) and sodium orthovanadate (16 mg/kg, 4 mg/kg and 1 mg/kg) for 6 d at the dosage 1 mL/100 g. Blood glucose values 12 h after fasting and 0.5, 1, 1.5 and 2 h after feeding glucose (22 g/kg) were investigated using oxidation-enzyme method. The same method was used to determine the effects of sodium orthovanadate on maltose absorption. Small-intestine tissue was obtained after the blood glucose assay for *in situ* hybridization analysis.

α -glucosidase activity assay As described previously^[10,11], normal rats were killed 3 h after fasting. A 10 cm segment of the upper small intestine from the head of the dodecadactylon was washed twice with cool saline. Mucosae were homogenized after diluted at 1:10 in 0.5 mol/L NaCl-KCl buffer, then centrifuged at 2×10^4 g for 30 min (4 °C). Deposits were washed twice with cool saline, then 2×10^4 g centrifuged for 30 min (4 °C), diluted at 1:5 in saline again and 500 r/min centrifuged for 10 min (4 °C). Supernatant was collected and stored at -30 °C. After response architecture was dispensed, fluid samples were shaken and water-bathed for 10 min at 30 °C. Then samples were put into water bath at 85 °C to terminate the response. In the response architecture without enzymes and drugs, the control group was adjusted to zero absorption degree (A). In the response architecture without drugs, the standard group's enzyme activity was 100%. A was assayed at 405 nm wavelength. Then we calculated the percentage of inhibition of 10 $\mu\text{mol/L}$, 100 $\mu\text{mol/L}$ and 1 000 $\mu\text{mol/L}$ sodium orthovanadate on α -glucosidase activity.

***In situ* hybridization for α -glucosidase and GLUT2 expression**

A 2 cm segment of the upper small intestine was obtained from

the head of dodecadactylon. *In situ* hybridization was carried out according to the manual of BOSD Biotech. Two microliters thick specimens sectioned from a paraffin-embedded block were dewaxed in xylene and rehydrated in serially graded ethanol (100%, 95%). The activity of endogenous enzymes was deactivated by hydrogen peroxide solution (30%) for 1 min. Specimens were ingested with pepsin for 15 min at 20–22 °C, force-hybridized for 3 h at 38 °C and hybridized for 12 h at 38 °C. Finally, the slides were washed 4 times with PBS, each time for 5 min. After trickled with biotin-rat antibodies to digoxin at 37 °C for 60 min, then streptavidin-biotin-enzyme complex (SABC) was added at 37 °C for 20 min and biotin-peroxidase was added at 37 °C for 20 min. At last the slides were washed 4 times with PBS, each time for 5 min, and stained with DAB for 2–4 min. The positive expression of α -glucosidase showed brown staining signals in villi of small intestine and GLUT2 in incisures between two villi of small intestine.

Statistical analysis

Data was tested using Student's *t*-test. The measurement results were expressed as mean \pm SD.

RESULTS

Effects of sodium orthovanadate on glucose absorption

Sodium orthovanadate at the dosage of 10 μ mol/L, 100 μ mol/L, 1 000 μ mol/L delayed the increase of blood glucose concentration induced by lavaged glucose (22 g/kg) after 1.5–2 h (Figure 1A), and decreased the AUC in these groups to that in control [17.03 \pm 0.60 mmol/(L·h)] ($P<0.05$), which was [8.24 \pm 0.63 mmol/(L·h)] ($P<0.01$), [9.69 \pm 0.38 mmol/(L·h)] ($P<0.01$), [13.76 \pm 0.39 mmol/(L·h)] ($P<0.05$), respectively.

Effects of sodium orthovanadate on maltose absorption

Blood glucose concentration increase in rats after maltose feeding (22 g/kg) was delayed by both sodium orthovanadate and acarbose, the peak values were shown 2 h after maltose loading, and high and moderate dosages of sodium orthovanadate also inhibited the increase of the blood glucose concentration peak value ($P<0.05$) (Figure 1B). The AUC of blood glucose concentration in sodium orthovanadate groups at the 3 dosages was markedly lower than that in the control group [18.40 \pm 1.46 mmol/(L·h)]. AUC at high and moderate dosages was [8.97 \pm 1.56 mmol/(L·h)], and [6.19 \pm 0.47 mmol/(L·h)], both were lower than that in acarbose group with AUC [13.10 \pm 0.43 mmol/(L·h)] ($P<0.05$).

Effects of sodium orthovanadate on α -glucosidase activity in small intestine

Sodium orthovanadate at the dosages of 10 μ mol/L, 100 μ mol/L, 1000 μ mol/L, could inhibit α -glucosidase activity in small intestine, the percentage of inhibition was 68.18%, 87.22% and

91.91%, respectively. The inhibiting action of sodium orthovanadate (100 μ mol/L) was stronger than that of the same dosage of acarbose (70.37%) ($P<0.05$, Table 1).

Table 1 Inhibitory effect of sodium orthovanadate on α -glucosidase activity in small intestine (mean \pm SD, $n = 8$)

Group	Dosage (μ mol/L)	A	Percentage of inhibition (%)
Control	-	0	100.00
Standard	-	0.594	0.00
Acarbose	100	0.176 \pm 0.076	70.37 \pm 6.43
Na ₃ VO ₄	10	0.189 \pm 0.034	68.18 \pm 3.46
	100	0.076 \pm 0.019	87.22 \pm 2.00 ^a
	1000	0.048 \pm 0.012	91.91 \pm 4.23 ^b

^a $P<0.05$, ^b $P<0.01$ vs positive control group.

Effects of sodium orthovanadate on α -glucosidase and GLUT2 mRNA expression in small intestine

Sodium orthovanadate at the dosages of 1 mg/kg, 4 mg/kg and 16 mg/kg, could depress α -glucosidase mRNA expression in epithelial cells of small-intestine, the positive expression number of α -glucosidase particles in each villus was 38 \pm 5, 34 \pm 5 and 33 \pm 4. They were fewer than that in control group (45 \pm 6), ($P<0.05$) ($n = 16$) (Figures 2 A, B). The inhibiting action of sodium orthovanadate showed no marked difference between high and moderate dosages. GLUT2 mRNA was diffusely expressed in the incisures between two villi of small intestine. Sodium orthovanadate could inhibit GLUT2 mRNA expression in a dose-dependent manner. In the vision field of 100 cm², the expression area of GLUT2 mRNA was decreased to 0.5 \pm 0.12 cm², 0.77 \pm 0.15 cm², 1.02 \pm 0.24 cm² after sodium orthovanadate loading at the 3 dosages from 2.5 \pm 0.5 cm² in control group ($P<0.05$) ($n = 16$) (Figures 2 C, D).

DISCUSSION

First, in this study, we observed the effects of sodium orthovanadate on glucose and maltose absorption. The result proved that sodium orthovanadate could delay the increase of blood glucose concentration after glucose or maltose feeding and decrease AUC.

Generally, sugar is divided into monosaccharide, disaccharide and polysaccharide. The absorption of monosaccharide is an active transport process with energy consumption. Na⁺-dependent transporters exist in the brush border of epithelial cells in intestinal mucosae, which can transport Na⁺ along its concentration gradient and monosaccharide counter to its concentration gradient into cells from intestinal lumen via the brush border, then both Na⁺ and monosaccharide diffuse into blood. In this process, the exchange activity of Na⁺/K⁺-ATPase plays an important role in maintaining the Na⁺ concentration

Figure 1 Effects of sodium orthovanadate on glucose absorption (A) and maltose absorption (B) in small intestine ($n = 8$).

Figure 2 Effects of sodium orthovanadate on α -glucosidase and GLUT2 mRNA expression in small intestine A: Control group of α -glucosidase B: Sodium orthovanadate (4 mg/kg, 60 \times) on α -glucosidase C: Control group of GLUT2 D: Sodium orthovanadate (4 mg/kg, 60 \times) on GLUT2.

gradient. Decreased activity of Na^+/K^+ -ATPase can influence glucose transport and therefore decrease blood glucose concentration. In addition, GLUT2 existing in the epithelial cells of intestinal villi incisures can directly transport glucose into cells. Decreased expression and limited translocation process from cytoplasm to cell membranes of GLUT2 will decrease glucose absorption from the small intestine. In normal conditions, polysaccharides are the mainly existing pattern in foods, which can be absorbed into blood after degradation into oligosaccharides and disaccharides by amylase and further into monosaccharides by α -glucosidase existing in the brush border of epithelial cells in intestinal mucosae. So α -glucosidase is a very important factor, which can affect glucose absorption in small intestine. Acarbose, a kind of inhibitors of α -glucosidase used in clinic at present, can depress the absorption of polysaccharides by inhibiting α -glucosidase activity and effectively decrease postprandial blood glucose level of diabetes mellitus^[12,13], therefore Na^+/K^+ -ATPase, GLUT2 and α -glucosidase play the main role in increasing postprandial blood glucose concentration. Postprandial blood glucose concentration would change if any of them has dysfunction.

Sodium orthovanadate has antihyperglycemic actions by various means, such as increasing the protein expression of GLUT4 in skeletal muscles, accelerating hexose transport, increasing glycogen synthetase production by stimulating dextrose oxidan^[14,15], accelerating glycolysis and lipid synthesis, depressing Na^+ reabsorption via acting on $\text{Na}^+/\text{Ca}^{2+}$ exchanger^[16].

In the present study, we only investigated the effects of sodium orthovanadate on small-intestinal sugar absorption in rats. First, we observed the effects of sodium orthovanadate on glucose absorption. Glucose is a monosaccharide, which can be directly absorbed by the small-intestine without hydrolysis, so the function of both GLUT2 and Na^+/K^+ -ATPase can be reflected by its absorption state. The first body response after monosaccharide absorption is to induce insulin release by stimulating pancreatic islets to decrease blood glucose concentration. For this reason, blood sugar peak values show the tendency to elevate first and then decline, thus typical OGTT curve is formed. Studies have shown that acarbose, a kind of inhibitors of α -glucosidase, can inhibit the hydrolysis of disaccharides and polysaccharides, and then decrease postprandial blood glucose concentration and protect OGTT,

but it could not depress glucose absorption. Our results are similar to previous studies^[17-19]. In order to eliminate the lowering effect on blood sugar of insulin induced by pancreatic islets, sodium orthovanadate was orally administered into rats for 6 d to maintain a stabilizing effect on islet cells. Our results showed that sodium orthovanadate at all the 3 dosages could delay the absorption of glucose and blood sugar concentration peak value with decreased AUC in a dose-dependent manner. Compared with the control group, blood sugar concentration decrease at 0.5 h and 1 h after sodium orthovanadate feeding was due to decreased glucose absorption, but not due to insulin release, because AUC peak value was delayed but not extincted. The results imply that the activity and function of both Na^+/K^+ -ATP and GLUT2 may participate in this kind of actions of sodium orthovanadate. Studies have evidenced that sodium orthovanadate is a Na^+/K^+ -ATPase inhibitor, and has been used widely as a tool drug^[20]. So it is generally accepted that sodium orthovanadate can depress sugar absorption via inhibiting the activity of Na^+/K^+ -ATPase in the small intestine. The results in our study suggest that sodium orthovanadate can inhibit sugar absorption via affecting the function of GLUT2, because it could markedly inhibit the expression of GLUT2 mRNA in small-intestinal epithelia of normal rats.

But we still do not know if it is the whole mechanism of sodium orthovanadate underlying the inhibition of sugar absorption, and whether it also can affect the absorption of polysaccharides and disaccharides. Therefore we estimated the effect of sodium orthovanadate on maltose absorption.

Maltose is composed of two monosaccharides coupled with α -1,4 glycoside linkages, which can be absorbed only after it is hydrolyzed by α -glucosidase in the intestinal tract. The data reported here suggest that sodium orthovanadate can delay the absorption of maltose and the blood sugar concentration peak value in a dose-dependent manner. Moreover, the AUC of sodium orthovanadate in moderate and large dosage groups and acarbose group was definitely lower than that in the control group. The action of sodium orthovanadate was stronger than that of acarbose, because the AUC of sodium orthovanadate in moderate and high dosage groups was lower than that in the acarbose group. This phenomenon may be due to two reasons: One is the inhibition of sodium orthovanadate on the activity

of Na⁺/K⁺-ATPase and GLUT2 mRNA expression was stronger than that of acarbose on α -glucosidase, the other is that sodium orthovanadate might also inhibit the activity of α -glucosidase besides its action on Na⁺/K⁺-ATPase and GLUT2 mRNA expression. Its double action decreased blood sugar markedly. In order to further verify our tentative idea, we observed the influence of sodium orthovanadate on the activity of α -glucosidase; the results indicated that sodium orthovanadate could depress α -glucosidase activity in a dose-dependent manner.

There are two ways of sodium orthovanadate in decreasing the activity of α -glucosidase. One is that sodium orthovanadate could decrease α -glucosidase activity without enzyme protein content changes. The other is that it could reduce the expression of α -glucosidase. So we detected mRNA expression of α -glucosidase by *in situ* hybridization. The result demonstrated that sodium orthovanadate could depress the mRNA expression of α -glucosidase in a dose-dependent manner.

In conclusion, sodium orthovanadate has the ability to inhibit sugar absorption via versatile means which affect the function and activity of Na⁺/K⁺-ATPase, inhibit the activity and gene expression of α -glucosidase as well as depress gene expression of the glucose transporter.

Abstract

AIM: To investigate the gastroprotective effect and mechanism of amtolmetin guacyl (AMG, MED15) in mice.

METHODS: Male and female Kunming strain mice, weighing 18-22 g, were utilized in the experiment. Normal or ethanol-induced gastric mucosal damage models in mice were successfully established to investigate the gastroprotective effect and mechanism of AMG. In the experiment of gastric mucosal damage after repeated treatment with AMG, the mice were randomly divided into 5 groups: normal group, 3 AMG groups receiving (75, 150 and 300 mg/kg), and tolmetin group receiving 90 mg/kg. The mice were randomly divided into 6 groups as follows: normal group, model group, AMG groups with doses of 75, 150 and 300 mg/kg, respectively, and tolmetin group with a dose of 90 mg/kg in ethanol-induced gastric mucosal damage experiment. The severity of gastric mucosal lesions was scored from 0 to 5. Gastric tissue sections were stained with hematoxylin and eosin (HE) and examined under light microscopy. Also gastric tissue sections were stained with uranyl acetate and lead citrate, and examined under electron microscopy. In addition, nitric oxide (NO) and malondialdehyde (MDA) contents, and nitric oxide synthase (NOS) and superoxide dismutase (SOD) activities in the stomach tissue homogenates were measured by biochemical methods.

RESULTS: Repeated treatment with AMG (75, 150 and 300 mg/kg) for 7 d did not induce any appreciable mucosal damage, and the average score was not significantly different from that of normal mice. In contrast, tolmetin (90 mg/kg) produced significant gastric mucosal lesions compared with the normal group ($P < 0.01$). AMG (75, 150 and 300 mg/kg) significantly reduced the severity of gastric lesions induced by ethanol in a dose-dependent manner as compared with the model group ($P < 0.05$, AMG 75 and 150 mg/kg vs model; $P < 0.01$, AMG 300 mg/kg vs model). Light and electron microscopy revealed that AMG (150 and 300 mg/kg) induced minimal changes in the surface epithelium layer, without vascular congestion or leucocyte adherence. AMG (75, 150 and 300 mg/kg) demonstrated dose-dependent gastroprotective effects on mice in our

study. AMG (75, 150 and 300 mg/kg) could significantly increase NO content and NOS level in the stomach homogenates of mice compared with the model group ($P < 0.05$, AMG 75 mg/kg and 150 mg/kg groups vs model group; $P < 0.01$, AMG 300 mg/kg vs model group) respectively. Moreover, AMG (150 and 300 mg/kg) not only significantly increased SOD activities but also obviously decreased the MDA content in the stomach homogenates of mice.

CONCLUSION: AMG exerts significant gastroprotective actions on mice and the involved mechanisms may be its antioxidative effect and induction of NO production.

INTRODUCTION

Nonsteroidal anti-inflammatory drugs (NSAIDs) are the extensively utilized medicines worldwide with antipyretic, analgesic and anti-inflammatory properties. Besides the direct stimulation, NSAIDs have some other adverse reactions to the gastrointestinal system, such as nausea, vomit, bellyache and even ulcer, perforation. All these effects are considered to be associated with the inhibition of prostaglandin (PG) synthesis in gastrointestinal system, and thereby limiting the clinical application of NSAIDs^[1-7].

Amtolmetin guacyl (AMG) is a novel NSAID, and its chemical name is 2-methoxyphenyl-1-methyl-5-p-methylbenzoyl-pyrrol-2-acetamido acetate, whose metabolites are MED5 (chemical name: 1-methyl-5-p-methylbenzoyl-pyrrol-2-acetamido acetic acid) and tolmetin (TOL)^[8-12]. As a novel NSAID, it has been reported that AMG possesses antipyretic, analgesic and anti-inflammatory effects in previous studies^[13-20]. At the same time, it can also enhance the NOS activity of gastric mucosae, which facilitates the synthesis and release of NO so as to reduce the gastrointestinal system damage^[21-23].

In this study, normal and ethanol-induced gastric mucosal lesion models in mice were established to investigate the gastroprotective effect and associated mechanisms, which could guide the rational use of medicine in clinical practice.

MATERIALS AND METHODS

Materials

Male and female Kunming strain mice, weighing 18-22 g, were purchased from Animal Center of Anhui Medical University. They were housed in plastic boxes, 5 mice in each box. All mice were allowed to take food and tape water *ad libitum*. AMG and TOL were provided by Anhui Kelong Medicine Company. The assay kits of MDA, SOD, NOS and Coomassie brilliant blue reagents were obtained from Nanjing Jiancheng Bioengineering Institute (Nanjing, China). All experimental protocols described

in this study were approved by the Ethics Review Committee for Animal Experimentation of Anhui Medical University.

Gastric mucosal damage after repeated treatment with AMG^[21]

The mice were equally divided into 5 groups randomly: normal group, 3 AMG groups (3 different doses) and TOL group. The mice in AMG groups intragastrically received 75, 150 or 300 mg/kg of AMG a day through an 18-gauge stainless steel animal feeding needle for 7 d prior to the experiment. Similarly, the mice in TOL group intragastrically received 90 mg/kg of TOL a day. In normal group, the mice were only fed with the same volume (0.5 mL/mouse) of carboxymethylcellulose (CMC). On the seventh day, all the mice were sacrificed by cervical dislocation and the stomachs were removed, opened along the great curvature and examined for the macroscopic evaluation of gastric mucosae. The severity of gastric mucosal lesions was examined by an experienced histologist who was unaware of the treatment conditions.

Establishment of ethanol-induced gastric mucosal damage model and drug treatment^[21,24]

The mice were randomly divided into six groups as follows: normal group, model group, 3 AMG groups receiving 75, 150 and 300 mg/kg, respectively, and TOL group receiving 90 mg/kg, ten mice in each group. The 5 groups were intragastrically administered AMG, TOL and CMC (model group) once. One hour later, the animals received 500 mL/L ethanol (0.5 mL/mouse) intragastrically except normal group mice. One hour later, the animals were killed and the stomachs were removed. The severity of gastric mucosal lesions and histological assessments were made by an experienced histologist who was unaware of the treatment conditions.

Grading criteria of gastric mucosal damage^[21]

The animals were killed, the stomachs were removed, rinsed with 5 mL of saline and immersed in 100 mL/L formalin. They were later opened along the greater curvature, for the macroscopic evaluation of gastric mucosae^[21,24]. The severity of lesions was scored from 0 to 5: 0, normal; 0.5, light local reddening; 1, general reddening or small hemorrhage (<1 mm); 2, large hemorrhage (>1 mm); 3, small ulcer (<2 mm); 4, large ulcer (>2 mm); and 5, perforated ulcer. One score was assigned to each lesion. A researcher who was unaware of the treatment conditions gave the scores of gastric mucosal injury.

Microscopic assessment of gastric lesions^[21]

Light microscopy At the end of the experiment, the stomach was immediately exposed and a small strip was excised from the glandular portion, 3 mm below and parallel to the limiting ridge, so that the greater curvature was approximately located in the middle of the strip. The tissue samples were fixed in 100 mL/L formalin, 5-μm thick serial sections were taken from each block and stained with hematoxylin-eosin. The image of the sections to be examined was displayed on a color monitor by means of a videocamera attached to the microscope. An experienced histologist who was unaware of the treatment conditions made histological assessments.

Transmission electron microscopy After mice were killed, the stomachs were immediately removed, and a strip was excised in the same position as for light microscopy. Small specimens were fixed in 25 g/L glutaraldehyde liquid for 3 h at room temperature and post-fixed in 10 g/L OsO₄ in 0.1 mol/L phosphate buffer (pH 7.2) for 90 min at room temperature. After dehydration in a graded series of acetone and embedded in Araldite resin, semithin sections were cut for orientation. Thin sections (80 nm thick) were cut perpendicularly to the luminal

surface, stained with uranyl acetate and lead citrate, and examined with a Zeiss109 electron microscope. An experienced histologist who was unaware of the treatment conditions made histological assessments.

Tissue homogenization

Stomach tissue samples were weighed and homogenized in 9 g/L NaCl for the detection of SOD, MDA, NOS, NO₂⁻. Homogenates were centrifuged at 4 000 r/min for 10 min. Aliquots of the supernatants were used for studies. The assayed parameters were expressed as per mg protein, and the protein content of aliquots was determined by the method of Coomassie brilliant blue.

Measurement of MDA, SOD and NOS in stomach homogenates^[25]

SOD, MDA and NOS levels in stomach tissue homogenates were assayed by using assay kits (Nanjing Jiancheng Bioengineering Institute).

Examination of NO₂⁻

NO₂⁻ concentration in stomach tissue homogenates was measured as described by Prado *et al.*^[26].

Statistical analysis

The data were analyzed by SPSS 10.0 for windows. Results were expressed as mean±SD. Student's *t* test was used for statistical analysis. *P*<0.05 was considered statistically significant.

RESULTS

Repeated treatment with AMG on gastric mucosal damage in normal mice

Repeated treatment with AMG (75, 150 and 300 mg/kg) for 7 d did not induce any appreciable mucosal damage, and the average score was not significantly different from that of normal mice. In contrast, TOL, the prodrug of AMG, intragastrically administered at 90 mg/kg produced significant gastric mucosal lesions compared with the normal group (*P*<0.01) (Figure 1).

Figure 1 Repeated treatment with AMG on gastric mucosal damage in normal mice (*n* = 10). ^b*P*<0.01 vs TOL.

Effect of AMG on ethanol-induced gastric mucosal damage model

As showed in Figure 2, compared with that in the normal group, the average score of mice in the model group significantly increased (*P*<0.01). AMG (75, 150 and 300 mg/kg) significantly reduced the severity of gastric lesions induced by ethanol in a dose-dependent manner as compared with the model group (*P*<0.05, AMG 75 and 150 mg/kg vs model; *P*<0.01, AMG 300 mg/kg vs model). There was no obvious difference between TOL group and model group (Figure 2).

Figure 2 Effect of AMG on ethanol-induced gastric mucosal damage model ($n = 10$). ^a $P < 0.05$, ^b $P < 0.01$ vs model; ^c $P < 0.05$, AMG (300 mg/kg) vs TOL.

Microscopic assessment of AMG on ethanol-induced gastric lesion

Light microscopy As shown in Figure 3 for evaluation by light microscopy, the structure of gastric mucosae was normal in normal group. The cells were well stained by HE and there was no edema or exfoliation. In contrast, a visible hemorrhagic area was found in model group. In mice treated with AMG (300 mg/kg), the epithelial and parietal cells were slightly edematous with few epithelial cells exfoliated. In the group treated with AMG (150 mg/kg), severe edema was found with inflammatory cell infiltration. In the group administered AMG (75 mg/kg), edema was more severe in epithelial and parietal cells than that in AMG (300 mg/kg) group and many epithelial cells were deciduous. Conversely, in the TOL group, together with inflammatory cell infiltration, a hemorrhagic area was observed (Figure 3A).

Transmission electron microscopy As shown in Figure 4, gastric mucosal microvilli in normal group were well arranged with no defection and shorting, while those in the model and TOL groups were mostly deciduous, broken and defective. The microvilli were almost integrated and well arranged with no defection in mice treated with AMG (300 mg/kg). In mice administered AMG (150 mg/kg), the lesions were much smaller, while the microvilli were short and small and in a bad order with obvious defection in mice treated with AMG (75 mg/kg) (Figure 3B).

Effects of AMG on NOS level and NO content in ethanol-induced stomach homogenates

Compared with those in the normal group, the NO content and NOS level were significantly decreased in the model group ($P < 0.01$). AMG (75, 150 and 300 mg/kg) could significantly increase the decreased NO content and NOS level compared with the model group ($P < 0.05$, AMG 75 mg/kg and 150 mg/kg groups vs model group; $P < 0.01$, AMG 300 mg/kg vs model group) respectively. The NO content and NOS level in TOL group where not evidently different from those in the model group (Table 1).

Table 1 Influence of AMG on NO and NOS contents in stomach homogenates in ethanol-induced gastric mucosal damage models ($n = 10$, mean \pm SD)

Group	<i>n</i>	Dose (mg/kg)	NO ₂ ⁻ (μmol/mgprot)	NOS (U/mgprot)
Normal	10	-	60.57 \pm 22.11 ^b	4.22 \pm 0.92 ^b
Model	10	-	33.08 \pm 12.85	2.41 \pm 0.56

	10	150	58.65 \pm 17.11 ^a	4.12 \pm 1.02 ^a
	10	75	30.98 \pm 11.97	3.47 \pm 1.17 ^a

^a $P < 0.05$, ^b $P < 0.01$, vs Model.

Effects of AMG on SOD activity and MDA content in ethanol-induced stomach homogenates

Results are shown in Table 2. Compared with that in the normal group, the SOD activity in the model group was significantly lower, but the MDA content in the model group was increased ($P < 0.01$). However, compared with model group, AMG (150 and 300 mg/kg) could significantly increase the SOD activity while evidently reduce the MDA level in stomach homogenates ($P < 0.01$, Table 2).

Table 2 Influence of AMG on SOD, MDA contents in stomach homogenates in ethanol-induced gastric mucosal damage models ($n = 10$, mean \pm SD)

Group	<i>n</i>	Dose (mg/kg)	SOD (U/mgprot)	MDA (nmol/mgprot)
Normal	10	-	702.61 \pm 144.77 ^b	2.85 \pm 1.32 ^b
Model	10	-	551.94 \pm 125.94	4.18 \pm 1.19

^a $P < 0.05$, ^b $P < 0.01$, vs Model.

DISCUSSION

Gastrointestinal system lesions are resulted from the major adverse reaction of NSAIDs, which limits the wide clinical application of NSAIDs. Though the mechanism of the lesion remains unclear, some documents have proposed that these effects are related with the inhibition of PGs releasing from the mucosal epithelial cells^[1,3,27]. It is known that vascular damage is considered to be the earliest process of gastric mucosal ulcer. Vasodilators, such as PGs and NO, play an important role in gastroprotection. At present, NO, gastroprotective NSAIDs, specific cyclooxygenase-2 (COX-2) inhibitors as well as COX and 5-lipoxygenase (5-LOX) double inhibitors are used in reducing the adverse reactions of NSAIDs^[28,29].

It has been demonstrated that AMG has gastroprotective properties^[21-23]. Tubaro *et al.*^[30] found that repeated treatment with AMG did not induce gastric mucosa damage. Another animal experiment indicated that AMG (50-300 mg/kg ig) did not induce stomach lesions in rats, while its metabolite TOL (15-60 mg/kg ig) did in a dose-dependent manner^[21]. Light and electron microscopic assessment suggested that AMG only caused very slight epithelial cell changes without vascular congestion and WBC adherence.

In our study, the 7-d treatment with AMG (75, 150 and 300 mg/kg ig) did not induce any appreciable mucosal damage, and the score was not different from that of normal group, while TOL (90 mg/kg ig) produced severe gastric mucosal lesions compared with normal group. Compared to its metabolite TOL, AMG had obvious gastroprotective effects. In ethanol-induced gastric mucosal damage model, the scores of AMG (75, 150 and 300 mg/kg ig) obviously decreased in a dose-dependent fashion. Compared to that in TOL group, the scores in AMG (300 mg/kg) group were greatly decreased. Furthermore, the scores had no obvious difference between TOL and model groups. Microscopic assessment of ethanol-induced gastric lesions showed that the degree of gastric damages in AMG (300 mg/kg) group was smaller than that in TOL and model groups, indicating the effect of AMG on gastric mucosa. Ultrastructural studies suggested that the microvilli were almost integrated and well arranged with no defection in mice treated with AMG (300 mg/kg), but those in the model and TOL groups were mostly deciduous, broken and defective.

Figure 3 Light and electronic microscopy assessments of ethanol-induced gastric lesion. A: light microsocopy assessment of ethanol-induced gastric lesion (*100). A: normal group, B: model group, C: ToL group, D: AMG (300 mg/kg) group E: AMG (150 mg/kg) group, F: AMG (75 mg/kg) group. B: Electronic microscopy assessment of ethanol-induced gastric lesion (×6 000) G: normal group, H: model group, I: TOL group, J: AMG (300 mg/kg) group, K: AMG (150 mg/kg) group, L: AMG (75 mg/kg) group.

Tubaro *et al.*^[30] found that AMG could strongly inhibit the hydrochloric acid (HCl) excretion caused by histamine so as to exert gastroprotective effects. Compared with acetylsalicylic acid, AMG (50 mg/kg ig) caused no appreciable change in basal potential difference (PD) values in gastric mucosae. AMG (100 mg/kg ig) alleviated ethanol-induced damages, increased NOS activity and stimulated NO release, and thereby showing its gastric protective effect. A research showed that the nonspecific NOS inhibitor (L-NAME 10 mg/kg sc) could reverse the effect of AMG^[21]. Therefore, we concluded that the protective effect of AMG might be involved in NO release from gastric epithelial cells. In our study, AMG (75, 150 and 300 mg/kg) could significantly increase the NO content and NOS level in ethanol-induced gastric mucosal damage model group. These results suggested that the gastroprotective effect of AMG might be associated with promotion of NOS activity and induction of NO release, which is in agreement with previous reports^[21,31].

Moreover, it has been reported that ethanol is capable of generating oxygen radicals, inhibiting glutathione synthesis, producing glutathione loss from tissues, increasing MDA levels and impairing antioxidative defense systems in experimental animals. Our study also showed that AMG (150 and 300 mg/kg) could sharply decrease the increased MDA level while enhance the decreased SOD activity in the models of mice, suggesting that the gastroprotective effect of AMG could at least partly contribute to the antioxidative action, which has not been reported before.

In summary, AMG has significant gastroprotective effects in mice, and its mechanism may be associated with its antioxidative effect and promotion of NO release.

Abstract

AIM: To determine the dynamic changes in the expression of matrix metalloproteinases (MMPs) and the endogenous tissue inhibitors of MMPs inhibitors (TIMPs) during hepatic fibrosis induced by alcohol.

METHODS: Male Sprague-Dawley rats were randomly divided into normal, 4 d, 2 wk, 4 wk, 9 wk and 11 wk groups, and the model rats were fed with a mixture of alcohol by gastric infusion at the designed time, respectively, then decollated and their livers were harvested for the examination of MMP-2, MMP-3, MMP-9, MMP-13, TIMP-1 and TIMP-2 by immunohistochemistry, zymography and Western blotting, respectively.

RESULTS: Normal rats had moderate expression of MMP-2, which was decreased in the model rats except in the 11 wk group, where MMP-2 expression slightly increased. MMP-3 had the similar changing pattern to MMP-2 despite weaker expression. MMP-9 expression decreased in the 4 d and 2 wk groups, rose in the 4 wk group, decreased again in the 9 wk group and returned to normal levels in the 11 wk group. MMP-13 expression decreased in the 4 d and 2 wk groups, and returned to normal levels in the 4 wk, 9 wk and 11 wk groups. TIMP-1 expression decreased in the 4 d and 2 wk groups, but sharply increased in the 4 wk group and sustained at a high level even after modeling was stopped for 2 wk. In normal rats TIMP-2 expression was strong. However, it decreased as soon as modeling began, and then gradually rose, but remained to a level lower than that in normal rats even after modeling was stopped for 2 wk.

CONCLUSION: MMP-2 may not always expresses at a high level during hepatic fibrosis. MMP-13 and MMP-3 are acutely affected by TIMP-1. In this model TIMP-1 is the most powerful factor imposed on capillarization and peri-sinusoidal fibrosis. TIMP-2 is the most effective regulator on the metabolism of type IV collagen located in the basement of sinus.

INTRODUCTION

China's prosperity is accompanied with a dramatic rise in cases of alcoholic liver disease. Some scholars reported that hepatic pathological changes of alcoholic liver disease (ALD) included typical capillarization, peri-sinusoidal fibrosis, bridging fibrosis, and even cirrhosis which were often found in heavy drinkers who might have a drinking history over 10 to 20 years. In mild to moderate drinkers, however, the pathological changes which might be more popular at present were not thoroughly investigated. In order to probe into this field we improved a rat model of ALD induced by the gavage method, which is widely used among Chinese scholars to show the key mechanism of hepatic fibrosis. Liver fibrosis occurs as a consequence of net accumulation of matrix proteins (especially types I and III collagen) in response to liver injury. Liver fibrosis is underpinned by the activation of hepatic stellate cells (HSCs) to a myofibroblast like phenotype with a consequent increase in their synthesis of matrix proteins such as interstitial collagens that characterize fibrosis. The sinusoid and peri-sinusoidal space are the original site of fibrosis, which can badly affect the function of hepatocytes. The expression and ratio of matrix metalloproteinases/tissue inhibitor of matrix metalloproteinases (MMPs/TIMPs) are key factors to extra cellular matrix remodeling during hepatic fibrosis. The co-operation of urokinase and tissue plasminogen activator system is also very important. Considering that recent reports were almost all focused on MMPs/TIMPs, and that the dynamic changes of MMPs/TIMPs during ALD were not so clear, we decided to probe into such indexes. We have reported the early pathological changes of alcoholic liver disease located in sinusoid and peri-sinusoid (in another article), further elucidation of mechanism of such changes would depend on the investigation of the expression and ratio of MMPs/TIMPs during a dynamic course of fibrosis. So the dynamic changes of MMPs 2, 3, 9, 13, and TIMPs 1, 2 were worked out to show the mechanism of this new model.

MATERIALS AND METHODS

Materials

Male SD rats, weighing (150±5) g, were purchased from Beijing Vital River Company, corn oil from Carrefour Supermarket, xanthan gum and maltose from Beijing Chemical Agent Company, edible alcohol from Beijing General Alcohol Brewing Company, carbonyl iron and pirazole from Sigma, USA, First antibody to MMPs 2, 3, 9, 13 and TIMPs 1, 2 was purchased from Antibody Diagnostic Inc, ADI, USA with the help of its Chinese Dealer, Shanghai Long Island Antibody Company. PV-6 001 kits were from PowerVision, USA. ZLI-9 030 and ZLI9 001 were from Beijing Zhongshan Company.

Methods

Rats grouping: Normal (6), 4 d (8), 2 wk (8), 4 wk (10), 9 wk (12), 11 wk (12).

Modeling: The model of ALD was induced by intragastric infusion (gavage) of a mixture of alcohol (5 g/d·kg), pirazole (30 mg/d·kg), corn oil (3 mL/d·kg), and carbonyl iron (35 mg/d·kg, decreased to 15 mg after 4 wk), a little xanthan gum and maltose, one time a day for 5 d consecutively, with 2 d off per week, until

the end of the ninth wk, and all rats were maintained on a standard diet with water *ad libitum*.

Liver tissue management: The rats were executed at the end of 4 d, 2 wk, 4 wk, 9 wk and 11 wk, respectively. Harvested livers were split and fixed for electron microscopy, hematoxylin and eosin and Masson complex staining, and a portion was snap frozen for biochemical and molecular analysis. Further sections were cut from each liver, deparaffinized, HE and Masson staining. Histological analysis of each liver was undertaken, then the sections subjected to amylopin antigen retrieval before stained with the two-step method for antigen MMPs 2, 3, 9, 13 and TIMPs 1 and 2. The semi-quantitative computations were conducted on the image analyzing system MIS-2000 from 3Y Company, USA. The activity of MMP-2 and MMP-9, Western blotting of TIMPs 1 and 2 were undertaken with Bio-Rad Electrophoresis System, pictures were taken and analyzed with

Image master VDS from Pharmacia Biotech Company.

Statistical analysis

All values were expressed as mean \pm SD. ANOVA was used to determine the significance of differences among the six groups. $P<0.05$ was considered statistically significant.

RESULTS

The expression of MMP-2 in normal rats was at moderate level. However, during modeling it showed reducing curve changes and without recovery even after modeling was stopped for 2 wk. (Figure 1).

The expression of MMP-3 showed a similar pattern to that of MMP-2 but weaker, when modeling was stopped it recovered to normal level. (Figure 2).

Figure 1 Dynamic changes of MMP-2. A: Normal rat, $\times 400$ B: 4 d group, $\times 400$ C: 2 wk group, $\times 400$ D: 4 wk group, $\times 400$. E: 9 wk group, $\times 400$ F: 11 wk group, $\times 400$.

Figure 2 Dynamic changes of MMP-3. A: Normal rat, $\times 200$ B: 4 d group, $\times 200$ C: 2 wk group, $\times 200$ D: 4 wk group, $\times 200$. E: 9 wk group, $\times 200$ F: 11 wk group, $\times 200$.

Figure 3 Dynamic changes of MMP-9. A: Normal rat, $\times 400$ B: 4 d group, $\times 400$ C: 2 wk group, $\times 400$ D: 4 wk group, $\times 400$ E: 9 wk group, $\times 400$ F: 11 wk group, $\times 400$.

Figure 4 Dynamic changes of MMP-13. A: Normal rat, $\times 200$ B: 4 d group, $\times 200$ C: 2 wk group, $\times 200$ D: 4 wk group, $\times 200$ E: 9 wk group, $\times 200$ F: 11 wk group, $\times 200$.

The situation of MMP-9 was different from that of the two above. MMP-9 decreased in the 4 d and 2 wk groups, but in the 4 wk group and the following MMP-P showed higher expression than that of the normal rats with no significance. (Figure 3).

The expression of MMP-13 showed reduction in the 4 d and 2 wk groups, but recovered in the 4 wk group and then sustained, when modeling was stopped it showed higher expression than normal. (Figure 4).

The expression of TIMP-1 in the 4 d and 2 wk groups showed reduction, after then it gave distinct higher expression and did not recover to normal level even after modeling was stopped for 2 wk. (Figure 5).

The expression of TIMP-2 showed different type from that of TIMP-1. In normal rats it had a high level with some hepatocytes expressing, but as soon as modeling began it fell rapidly, then gradually ascended as modeling went on, but after modeling was stopped for 2 wk it was still lower than normal. (Figure 6).

We failed in this model to find any activities of MMP-2 and MMP-9 with zymography.

Western blotting tests showed that in the 4 wk and 9 wk groups there were strong expressions of TIMP-1, but in other groups there were not. As to TIMP-2 we did not find its expression. (Figures 7,8).

Figure 5 Dynamic changes of TIMP-1. A: Normal rat, $\times 400$ B: 4 d group, $\times 400$ C: 2 wk group, $\times 400$ D: 4 wk group, $\times 400$ E: 9 wk group, $\times 400$ F: 11 wk group, $\times 400$.

Figure 6 Dynamic changes of TIMP-2. A: Normal rat, $\times 200$ B: 4 d group, $\times 100$ C: 2 wk group, $\times 200$ D: 4 wk group, $\times 100$ E: 9 wk group, $\times 400$ F: 11 wk group, $\times 100$.

DISCUSSION

China's prosperity is accompanied with cases of alcoholic liver disease growing day by day. Alcohol can stimulate hepatic

stellate cells (HSCs) to proliferate and produce various fibrosis cytokines, which in turn result in hepatic fibrosis in the end. Abstinence itself can not reverse hepatic fibrosis, and more over, temperance is usually very difficult. So it is important to probe into the mechanism of hepatic fibrosis reversion in ALD research. Most of the recent reports^[1-11] reveal that the formation and prognosis of hepatic fibrosis were all related with MMPs/TIMPs, and this viewpoint has been accepted as a common sense. So we probed into the important factors among MMPs/TIMPs, and respective discussions were as follows.

Matrix Metalloproteinase-2 (MMP-2) is an important factor in the metabolism of type IV collagen in sinusoid basement. It has a peculiar activation course taking place on the membrane and forms a triple complex bridged with MT1-MMP by TIMP-2. Deactivation could be triggered by more competitive TIMP-2 to conjugate with MMP-2 to restrain the formation of triple complex. Because of local expression of TIMP-2 it is hypothesized

Figure 8 Dynamic changes of MMPs 2, 3, 9, 13 and TIMPs 1, 2. A: Dynamic changes of MMPs 2, 3, 9, 13. B: Dynamic changes of TIMPs 1, 2.

that MMP-2 could not be activated on a long trip, and it is only transient and local. Activated MMP-2 could decompose type IV collagen in the basement, resulting in broken micro circumstances of HSC and promoting HSC to activate, proliferate and migrate. Activated MMP-2 also could play an important role in reversion of hepatic fibrosis, metastasis of tumors, MOF induced by endotoxin, apoptosis of HSC, *etc*^[12-26]. MMP-2 is mainly composed and secreted by HSC in liver. Activation induced by various pathogens might need different time, and strong stimulation would result in rapid activation^[27]. It was reported that^[28] during reversion period activated MMP-2 was in favor of fibrosis reversion, so it was thought that MMP-2 played another role at this time because activated MMP-2 could activate HSC and promote fibrosis^[29,30].

The results of our experiment were different from those of others. MMP-2 showed moderate expression in SD rat liver slides along the sinus in normal, began to fall during modeling, instead of rising up as reported, meanwhile zymography tests did not show any activity of it. So we thought that it was peculiar that lowly expressed MMP-2 could also break down type IV collagen in sinus basement markedly. Capillarization of this model was not typical because of lower contents of type IV collagen than normal. This might imply lowly expressed MMP-2 not only decomposed parts of type IV collagen in sinus basement but also obstructed its accumulation, resulting in atypical capillarization in the end. It could not achieve success unless TIMP-2 markedly decreased its expression so as to alleviate MMP-2, and our experiment showed an authentic result just like this. This phenomenon may exclude the possibility that only high activity of MMP-2 could result in breakage of sinus basement and progression of fibrosis, and it also may imply that MMP-2 is not the most important factor imposed on the metabolism of type IV collagen in sinus basement. Our results also showed that the cooperation of MMP-2/TIMP-2 could make the contents of type IV collagen in sinus basement become normal after the modeling was stopped for 2 wk. This was not consistent with other scholar's report^[28] that apoptosis of HSC could decrease the expression of TIMP-2 and promote the activity of MMP-2. The differences between species, modeling, stages and types of pathology may be related with these diversities. The fast and accurate adjusting mechanism of MMP-2's function influenced heavily by TIMP-2, rather than TIMP-1, might be a commonfeature of different models.

MMP-3 also called stromelysin 1, originates from almost the same cells as MMP-1 but does not show synchronization in expression. MMP-3 has a wide range of substrates but important one may be laminin. it can also activate MMP-1, but there are not many reports about it. It has been reported that the measurement of serum MMP-3 was of little use for assessing fibrolysis in chronically diseased livers. However, because of the distinct pathological changes in sinusoid and peri-sinusoid in alcoholic

liver disease, the value of MMP-3 rose to some extent. We found that accumulation of laminin in basement was quite prominent during capillarization. It was evident that the sustained low expression during modeling of MMP-3 would be in favor of laminin's accumulation. The accumulated laminin in basement was still high after the modeling was stopped for 2 wk in spite of the normal expression of MMP-3, which might imply not only that the strong inhibiting effect of TIMP-1 on MMP-3 could result in delayed fashion of metabolism of laminin compared to that of type IV collagen, but also that sinusoid pathological changes were not entirely modulated by MMP-2/TIMP-2, and this is important.

MMP-9 is also called gelatinase B, the majority of which is secreted by kupffer cells in liver. MMP-9 could also decompose type IV collagen in basement, and this might happen a little earlier than that of MMP-2, implying MMP-9 might take part in the early events of fibrosis. In this model, however, MMP-9 had lower expression than MMP-2, and continued after the modeling began. It could be thought that MMP-9 did not play role in this model entirely. It was reported^[31] that widespread capillarization in cirrhosis suggested no MMP-2 activity but low MMP-9 activity, implying potent importance of MMP-9 in reversion of fibrosis. In this model in the 4 wk and 11 wk groups MMP-9 showed little higher expression than normal but still lower than that of MMP-2, actually it might not affect the accumulation of type IV collagen, so it was not an important factor. This result did not show any consistency with other reports^[29,30].

MMP-1, an interstitial collagenase (in rats it is MMP-13) is the most important enzyme secreted by kupffer cells and HSC in liver, and after secretion it is activated and the course may be related to plasminogen activator system. MMP-1/MMP-13 could be deactivated by forming a complex with TIMP-1 at a ratio 1:1. It was reported that kupffer cells in liver were one of the main originations of MMPs, including MMP-13. It was also reported recently that^[32] the rise of activity of MMP-13 would significantly improve cirrhosis, which could be realized by stimulating kupffer cells. This implied another way to reverse fibrosis. The activity of MMP-13 was also needed to ensure normal metabolism of hepatocytes^[33-35]. We found in our experiment that MMP-13 expressed themselves moderately mainly along sinusoid in normal rats which would support such a kind of viewpoints. MMP-13 decreased to some extent when the modeling began, in the 2 wk group some hepatocytes and kupffer cells showed active expression of MMP-13, then the expression along sinusoid again showed an ascending trend. In the 4 wk group when fibrosis was most severe the expression of MMP-13 was almost the same as normal, meaning that MMP-13 itself could not affect the course of peri-sinusoidal fibrosis. In the reversion phase the expression of MMP-13 was significantly higher than normal and the active stains implied that kupffer

cells might restart their expression, which would be helpful to fibrosis reversion, but the accumulation of type I collagen was not affected and became more severe with the modeling, evidently the inhibiting effect of TIMP-1 on MMP-13 should be the cause. The higher expression of MMP-13 in the reversion phase actually could not help reverse peri-sinusoidal fibrosis, demonstrating once more that TIMP-1 was the most important factor during hepatic fibrosis.

TIMP-1 is produced by kupffer cells, HSC and myofibroblasts in liver, but most of it is mainly produced by activated HSC. It could be induced by TGF beta, interferon or pentoxifylline. TIMP-1 could inhibit most of MMPs except MMP-14 and MMP-19 by integrating them at a ratio 1:1 to form a complex. Injured liver tissues showed more expression of TIMP-1, and in turn, this would help interstitial fibrils to accumulate^[33-36]. Serum TIMP-1 had a close relation to hepatic pathology, serum TIMP-1 could forecast hepatic pathological changes and prognosis, and could also be used as an index to evaluate the treatment. The transgenic model lacking TIMP-1 gene and anti-oligonucleotide treatment model aiming at TIMP-1 were established to find that without injury TIMP-1 itself could not result in fibrosis, but if there were injuries TIMP-1 would significantly accelerate the course in which fibrosis was formed. This might imply omni directional and all target treatment for hepatic fibrosis should be considered, nevertheless targeted and usual treatment still took TIMP-1 as a comprehensive index for evaluation^[37-41]. Overexpression of TIMP-1 could keep hepatic fibrosis by holding back the apoptosis of HSC, otherwise the down-regulation of TIMP-1 would promote MMPs to be activated, and in turn, fibrils decomposed, HSC apoptosis took place and fibrosis reversed. All this emphasized the importance of TIMP-1.

We found in this model that at the early phase TIMP-1 showed a relatively low expression, in the 4 wk and 9 wk groups TIMP-1 showed evident expression mainly along sinusoid, which might be attributed to the widely activated HSCs. The over-expression of TIMP-1 would inhibit MMP-13 and MMP-3, resulting in accumulation of type I collagen and laminin, which in turn would be in favor of the formation of capillarization and peri-fibrosis. This discovery supported the importance of TIMP-1. It was also underpinned by Western blotting tests which showed TIMP-1 expressed itself most evidently in the 4 wk and 9 wk groups. In this model after the stimulus was ceased for 2 wk TIMP-1 still showed high expression, which might imply that activated HSCs were difficult to start spontaneous apoptosis, and in turn, TIMP-1 would not cease its expression by itself, which again showed it was a key step to reduce the expression of TIMP-1 in order to reverse fibrosis. Our results demonstrated that even if MMP-13 expressed highly it still would be inhibited by TIMP-1 to result in accumulation of type I collagen. It was reasonable that normal-level MMP-3 was inhibited by over-expressed TIMP-1, resulting in high content of laminin in basement of sinusoid, and capillarization and peri-sinusoidal fibrosis were not drastically improved. So this should be attributed to the high expression of TIMP-1.

The ability of TIMP-2 to integrate MMP-2 is 7-9 fold higher than that of TIMP-1, so if it is true it is the most important factor imposed on the metabolism of type IV collagen in basement of sinus. MMP-2 itself could not affect the course of capillarization as found in this experiment. We also found in normal SD rat livers that TIMP-2 was highly expressed in hepatocytes and kupffer cells, but transformed to HSCs with few active stains along sinusoid as the modeling began, which might imply activated HSCs would be the main origin of TIMP-2. During the modeling decreased expression of TIMP-2 might weaken the inhibition on MMP-2 and result in the decomposition of type IV collagen in basement and could not accumulate to help form typical capillarization. This was a typical feature of our model. After the modeling was stopped for 2 wk, the expression

of TIMP-2 ascended but was little lower than normal, and the content of type IV collagen returned to normal level, which implied the gradually rising TIMP-2 could show its suppressing function on MMP-2, so that type IV collagen was protected and became normal. This demonstrated the significant effect of TIMP-2 and MMP-2 on the metabolism of type IV collagen in basement. However, TIMP-2 was apparently the more important.

In conclusion, the pathological changes of ALD model with fibrosis grades I-II can be controlled by TIMPs, especially the expression of TIMP-1 and TIMP-2 has significant effects on the prognosis of capillarization and peri-sinusoidal fibrosis, and MMPs are always dominated by TIMP-1 and TIMP-2. So the fatal step to reverse fibrosis might be to block or modulate the expression of TIMP-1 and TIMP-2.

ACKNOWLEDGEMENTS

The data of this article were obtained and analyzed with the help of Zhi-Gao Jin Professor and Ms. Hong Cai working in Academy of TCM. Many thanks to them!

Abstract

AIM: To evaluate the diagnostic sensitivity and accuracy and the cost-effectiveness of this technique in the detection of gastroenteropancreatic carcinoid tumors and their metastases in comparison with conventional imaging methods.

METHODS: Somatostatin receptor scintigraphy (SRS) was performed in 24 patients with confirmed carcinoids and 7 under investigation. The results were compared with those of conventional imaging methods (chest X-ray, upper abdominal ultrasound, chest CT, upper and lower abdominal CT). Also a cost-effectiveness analysis was performed comparing the cost in Euro of several combinations of SRS with conventional imaging modalities.

RESULTS: SRS visualized primary or metastatic sites in 71.0% of cases and 61.3% of conventional imagings. The diagnostic sensitivity of the method was higher in patients with suspected lesions (85.7% vs 57.1%). SRS was less sensitive in the detection of metastatic sites (78.9% vs 84.2%). The undetectable lesions by SRS metastatic sites were all in the liver. Between several imaging combinations, the combinations of chest X-ray/upper abdominal CT/SRS and chest CT/upper abdominal CT/SRS showed the highest sensitivity (88.75%) in terms of the number of detected lesions. The combinations of chest X-ray/upper abdominal US/SRS and chest CT/upper abdominal ultrasound /SRS yielded also a quite similar sensitivity (82%). Compared to the cost of the four sensitive combinations the combination of chest X-ray/upper abdominal ultrasound/SRS presented the lower cost, 1183.99 Euro vs 1251.75 Euro for chest CT/upper abdominal ultrasound/SRS, 1294.93 Euro for chest X-ray/upper abdominal CT/SRS and 1362.75 Euro for chest CT/upper abdominal CT/SRS.

CONCLUSION: SRS imaging is a very sensitive method for the detection of gastroenteropancreatic carcinoids but is

less sensitive than ultrasound and CT in the detection of liver metastases. Between several imaging combinations, the combination of chest X-ray/upper abdominal CT/SRS shows the highest sensitivity with a cost of 1294.93 Euro.

INTRODUCTION

The carcinoid tumor, argentaffinoma, is a member of a very exclusive neoplastic family known as neuroendocrine or amine precursor uptake and decarboxylation (APUD) tumors.

Carcinoid tumor has been found to arise from almost every organ and system derived from the primitive entoderm, but most frequently originated from the gastrointestinal (GI) tract, accounting for approximately half of all GI endocrine tumors^[1].

Over 95 per cent of all GI carcinoids are located in only three sites: the appendix, rectum and small intestine.

Irrespectively to their location, carcinoids are capable of producing one or more of the following substances: 5-hydroxy-tryptamine (serotonin), gastrin kinin-peptide, histamine, catecholamine and glucagon. Some of them induce systemic manifestations known as the carcinoid syndrome characterized by flushing, diarrhea, right-sided heart disease and wheezing^[2,3].

Carcinoid tumors are rare (incidence: about 2/100 000 people)^[4], malignancy -that is mainly liver metastases, may be encountered in 10-60% of cases depending on the site of the primary tumor^[5,6]. Metastases are observed in less than 2% of carcinoids 1 cm or less in size. In contrast, nearly all carcinoids 2 cm or greater show evidence of metastatic spread^[1].

Tumor localization is essential since surgery remains the optimal treatment for most patients without metastases^[7,8].

Curative surgery is difficult since primary tumors are frequently very small (<1 cm) and potentially undetectable by conventional imaging. When liver metastases occur, staging of these patients is essential for therapeutic manipulation.

Tumor localization for accurate staging and therapeutic management justifies the use of sophisticated imaging techniques such as somatostatin receptor scintigraphy (SRS)^[9,10].

Since the introduction of somatostatin receptor imaging in 1989^[9], many reports on the usefulness and limitation of this technique have been published.

It has been shown by autoradiography using ¹²⁵I-labeled octreotide that endocrine tumors of GI tract and especially carcinoids possess somatostatin receptors^[11-13]. When octreotide is labeled with radionuclides such as ¹²³I^[14,15] or ¹¹¹In, the specific receptor binding can be exploited for the scintigraphic *in vivo* demonstration of receptor-expressing tumors^[9,10,16].

The radiolabeled analogue ¹¹¹In-DTPA-octreotide also known as octreoscan is cleared by renal than hepatobiliary route, thus causing less artifacts on hepatic and mesenteric imaging^[17,18].

MATERIALS AND METHODS

Materials

A total of 31 patients (18 males, 13 females, age ranged 27-73 years) under SRS ^{111}In -pentatreotide were enrolled between April 1997 and October 2003 at "Agios Savvas" Cancer Hospital (Section of Nuclear Medicine), Athens, Greece. Their data are listed in Table 1.

Inclusion criteria required histological or cytological confirmation of a presently or previously operated abdominal carcinoid, or for patients with suspected tumors, a history of carcinoid syndrome-related signs and symptoms with an additional elevation of urinary 5-HIAA. All patients gave informed consent to participation in the study, which was approved by the ethics committee of our hospital.

Seven of the patients were under investigation for suspected

carcinoids in different sites (caecum, appendix, small intestine, pancreas) while the remaining 24 had histologically/cytologically confirmed tumors, in 10 of them the primary lesion was excised. All gastric carcinoids were type II or "mixed cellular composition" gastric carcinoid tumors.

Seven patients were treated by octreotide prior to SRS, in all but 3 of them therapy was withdrawn 36 h prior to somatostatin receptor imaging in order to lift the blockade of SRS. In the rest 3 patients the 3-d withdrawal period was clinically impossible. The administration dose of octreotide in these patients was 0.5 mg daily.

A low-residue diet was started 3 d prior to SRS and stopped at the end of the imaging procedure. Twelve hours before the injection of the tracer a mild laxative was administered to minimize the false positive results, because a small quantity of the

administrated dose underwent hepatobiliary excretion.

Patients were well hydrated prior to radioactive drug administration to increase renal clearance and to reduce radiation uptake to the thyroid, kidneys, bladder and other target organs. All individuals in our study had normal thyroid and renal function.

Methods

¹¹¹In-pentetreotide (Octreoscan, Mallinckrodt Medical BV, Petten, Holland) was supplied as two vial kits. The first contained ¹¹¹In as ¹¹¹InCl₃ diluted in 1.1 mL hydrochlorid acid and the other lyophilized pentetreotide. After reconstitution the pH of the final product was between 3.8 and 5. This product might be diluted with normal saline solution because the dilution would raise the pH slightly.

After an incubation period of 30 min at room temperature and before the administration, instant thin layer chromatography (ITLC) for quality control was performed. The dose for a planar investigation was 111 MBq (3.3 mCi) of octreoscan.

The radiolabeled somatostatin analogue was administered as an intravenous bolus and no side effects were observed after i.v. injection.

Imaging Whole body scanning and planar images were obtained with a large field of view gamma camera (Siemens) equipped with a medium-energy, parallel-hole collimator. The pulse-height analyser windows were centered over both ¹¹¹In peaks (172 keV and 245 keV) with a window width of 20%. Data from both windows were added to the acquisition frames. Images were obtained 24 and sometimes 48 h after tracer administration.

Scintigraphic results were compared with those obtained by other imaging methods such as chest X-ray performed, upper abdominal ultrasonography, chest CT scan performed, upper and lower abdominal CT scans.

Magnetic resonance imaging of the abdomen and digital abdominal angiography was performed in few cases, but because of the small number of patients these imaging techniques were not taken into account.

Statistical analysis

Statistical comparison between SRS and conventional imaging methods for the detection of primary and metastatic sites, globally and in each group of patients, was performed using McNemar's test based on discordant pairs. A *P* value ≤ 0.05 was considered statistically significant.

Cost analysis

A cost-effectiveness analysis was performed comparing the SRS with the conventional imaging methods (chest X-ray, upper abdominal ultrasonography, chest CT scan and upper and lower abdominal CT scan) in several combinations. The cost of each diagnostic procedure was calculated.

The personnel cost was calculated as the cost of a working hour for each person (physician, technician, nurse, assistant personnel).

The cost of materials was calculated including radiographs, injection systems, contrast liquids and kit material.

The equipment cost was calculated in working hours. A yearly payment on an annuity basis at 8% and a term of 5 and 8 years were used to calculate the cost of ultrasound equipment, scanners and gamma cameras. The prices of equipment were those of 2000. Maintenance cost was estimated at 8% of new value.

The housing and overhead costs based on the number of square meters required to investigate a patient, including the cost of furniture, cleaning, telephone and services of various overhead departments.

Costs were built up from a database of health care cost elements in Greece and from the currently applicable prices of octreoscan and contrast material.

RESULTS

SRS imaging visualized the primary tumor or metastatic sites in 22 (71.0%) out of 31 patients who had histologically-cytologically confirmed carcinoid tumors or were under investigation for highly suspected carcinoid (16/24-66.7% and 6/7-85.7% respectively) (Figure 1).

Figure 1 Carcinoid tumor of appendix (patient No 26).

Conventional imaging was positive in 19 (61.3%) patients (4/7- 57.1% with suspected carcinoids and 15/24-62.5% with known tumors). Thus, SRS provided additional detection sites compared with conventional imaging methods even if the global detection rate (71.0% vs 61.3%) was quite similar. Detection of primary sites was 33.3% higher with SRS than with conventional methods (71.4% vs 38.1% respectively, *P* = 0.039). The primary lesions were detected by SRS in 15 (71.4%) of 21 patients. Octreoscan scintigraphy failed to detect primary tumors in 6 patients (28.6%), 4 with known lesions (stomach, duodenum, appendix, caecum) and 2 under investigation (appendix, small intestine).

The 6 lesions (≤ 0.7 cm) that were not visualized after injection of ¹¹¹In-pentetreotide were detected by endoscopy (3) or surgery (3) and diagnosed by histology. Only 1 out of 6 lesions was visualized by conventional imaging methods (patient No 9). Further analysis of the results from each group of patients with residual primary tumors did not reveal any statistically significant difference between the two methods (*P* > 0.05).

The positive detection rate in metastatic sites was similar by SRS and conventional imaging methods, which was 48.4% and 51.6% respectively (*P* > 0.05).

In the 19 patients with metastatic disease, SRS detected metastatic lesions in 15 cases (78.9%) (Figures 2-5) and failed to visualize metastatic sites in 4 patients (21.1%), all in liver were subsequently detectable by ultrasonography and CT scans. On the other hand, conventional imaging visualized metastases in 16 (84.2%) patients with a detection rate of 5.3%, higher than that of SRS.

Figure 2 Increased accumulation of ¹¹¹In-octreotide in liver and abdominal lymph nodes (patient No 18).

Figure 3 Metastatic sites in the abdominal lymph nodes from a previously operated carcinoid.

Figure 4 Increased accumulation of ^{111}In -octreotide in supraclavicular lymph node. Metastases from a carcinoid tumor located in appendix (patient No 8).

Figure 5 Metastatic sites in axillary lymph nodes (patient No 6).

False negative results of SRS and conventional imaging methods for primary and metastatic tumor sites in patients with known and suspected carcinoids are shown in Table 2, 3.

Table 2 False-negative results of SRS and conventional imaging methods for primary sites

Method	Detection of carcinoids		Patient No	False-negative (%)
SRS	Known carcinoids	4/14 patients	1, 3, 7, 9	28.57
	Suspected carcinoids	2/7 patients	25, 27	28.57
Conventional imaging methods	Known carcinoids	10/14 patients	1-7, 10-12	71.42
	Suspected carcinoids	3/7 patients	25, 26, 27	42.85

Table 3 False-negative results of SRS and conventional imaging methods for metastatic sites

Method	Detection of carcinoids		Patient No	False-negative (%)
SRS	Known carcinoids	4/24 patients	16, 22-24	16.66
	Suspected carcinoids	0/7 patients	-	0
Conventional imaging methods	Known carcinoids	1/24 patients	6	4.16
	Suspected carcinoids	2/7 patients	27, 29	28.6

Comparison of 8 imaging combinations showed that the combinations of chest X-ray/upper abdominal CT scan/SRS and chest CT scan/upper abdominal CT scan/SRS achieved the highest sensitivity in the detection of primary and metastatic lesions (88.75% for each one).

The combinations of chest X-ray/upper abdominal ultrasonography/SRS and chest CT/upper abdominal ultrasonography/SRS yielded also a similar sensitivity (82% for each one in terms of the number of detected lesions).

Cost-effectiveness analysis

Eight combinations of imaging techniques were evaluated for their sensitivity and cost. The cost of each imaging technique in Euro is shown in Table 4.

Table 4 Cost in Euro of used techniques

Chest X-ray	3.29
Upper abdominal ultrasonography	8.22
Chest CT-scan	71.11
Upper abdominal CT-scan	71.11
48.11 • for the contrast liquid	
Lower abdominal CT-scan	71.11
SRS	1 172.42

In the four most sensitive combinations, the combination of chest X-ray/upper abdominal ultrasonography/SRS presented the lower cost, 1183.93 Euro vs 1251.75 Euro for chest CT/upper abdominal ultrasonography/SRS, 1294.93 Euro for chest X-ray/upper abdominal CT/SRS and 1362.75 Euro for chest CT/upper abdominal CT/SRS. The related sensitivity rate/cost for the combinations reported above is shown in Figure 6.

Figure 6 Relation between sensitivity rate and cost for combinations with the highest sensitivity.

DISCUSSION

Carcinoids were often indolent, asymptomatic, slow growing tumors and clinically silent for years^[3]. The vast majority would not cause symptoms until complications (e.g. intestinal obstruction) or symptoms and signs of the carcinoid syndrome occur. This syndrome occurred in less than 10% of cases and might be present in patients with midgut carcinoid tumors with liver metastases and also in some patients with foregut carcinoids. Patients with hindgut carcinoids did not exhibit the carcinoid syndrome.

The final diagnosis was not easy, unless bioptic material was examined for the secretory peptide chromogranin or the neuron-specific enolase^[19,20].

Due to their multiple localizations and their small size, images of carcinoid tumors were difficult to obtain even when the most sophisticated conventional imaging techniques were applied^[21-23]. MRI, CT scan and ultrasonography were very sensitive in the detection of liver metastases, but seemed to be less sensitive in the diagnosis of extrahepatic sites^[24-26].

It has been known that carcinoid tumors had a high expression of somatostatin receptors^[27,28]. More than 90% of patients with midgut carcinoids expressed somatostatin receptors detected by autoradiography with iodinated somatostatin analogues as ligands, while the somatostatin receptor expression in foregut carcinoid tumors was less frequent^[29].

Five different subtypes of somatostatin receptors have been cloned. Somatostatin receptor subtype 2 could bind to somatostatin analogues used in clinical practice with high affinity. Subtypes 3 and 5 had an intermediate affinity while subtypes 1 and 4 had low affinity for the available somatostatin analogues^[30].

SRS is a very sensitive method for the demonstration of receptor-positive tumors and their metastases and its diagnostic usefulness in patients with abdominal carcinoid tumors has already been reported^[31,32].

In our study SRS imaging visualized the primary or metastatic sites in 22 out of 31 patients with gastrointestinal and pancreatic carcinoid tumors (detection rate 71.0%) and the results were in concordance with other previously published reports^[31-33].

Conventional imaging was positive in 19 out of 31 patients (detection rate 61.3%).

Our results demonstrate that SRS, compared with conventional imaging, can provide major additional information.

More interestingly, SRS was positive in 71.4% of the primary tumor sites with a statistically significant difference ($P = 0.039$) compared with conventional imaging methods. Lebtahi *et al.* reported also similar results (75%) in a similar group of 38 patients^[34]. Conventional imaging modalities (ultrasonography and upper abdominal CT) are more sensitive in the detection of hepatic metastases. On the other hand SRS is more sensitive in the detection of extrahepatic metastatic sites and can provide additional information for previous unsuspected localizations. Schillaci *et al.*^[35] reported similar results in a group of 18 patients with abdominal carcinoid tumors.

Thus, it is clear that the combination of several conventional imaging techniques with SRS is the method of choice for a better evaluation of patients with carcinoid tumors. For individuals with carcinoid tumors of the digestive tract, gastrointestinal endoscopy is the first line diagnostic tool. Laparotomy can also provide useful information in some cases.

In our study, 2 (chest X-ray/upper abdominal CT scan/SRS and chest CT/upper abdominal CT scan/SRS) out of 8 combinations of imaging modalities yielded an overall sensitivity of 88.75% in the detection of primary and metastatic carcinoid sites. The cost was 1294.93 Euro for the combination of chest X-ray/upper abdominal CT scan/SRS and 1362.75 Euro for the combination of chest CT/upper abdominal CT scan/SRS. Thus, there was a benefit of 67.82 Euro using the first one.

In a similar cost-effectiveness analysis of patients with neuroendocrine tumors, Kwekkeboom *et al.* showed that the combi-

ination of SRS, chest radiography and upper abdominal ultrasound led to the detection of carcinoid lesions in all patients in whom carcinoid lesions could be demonstrated by any means, with a sensitivity of 100% in terms of the number of detected lesions, but the cost analysis was made between the proposed imaging strategy and the most sensitive combination of conventional imaging (chest and abdomen CT scans)^[36].

Abstract

AIM: H101, an E1B 55 kD gene deleted adenovirus, has been shown to possess oncolysis activity experimentally and proved to be safe in preliminary phase I study. The current study was designed to evaluate its anti-tumor activity and toxicity in combination with chemotherapy in patients with late stage cancers.

METHODS: H101 5.0×10^{11} virus particles were given by intra-tumor injection daily for five consecutive days at every three-week cycle, combined with routine chemotherapy, to one of the tumor lesions of 50 patients with different malignant tumors. Tumor lesions without H101 injection in the same individuals were used as controls. The efficacy and toxicity were recorded.

RESULTS: Forty-six patients were evaluable with a 30.4% response rate. H101 injection in combination with chemotherapy induced three complete response (CR) and 11 partial response (PR), giving an overall response rate of 28.0% (14/50) among intention-to-treat patients. The response rate for the control lesions was 13.0%, including one case with CR and five cases with PR, which was significantly lower than that for the injected lesions ($P < 0.05$). Main side effects were fever (30.2%) and pain at the injected sites (26.9%). Grade 1 hepatic dysfunction was found in four patients, grade 2 in one patient, and grade 4 in one patient. Hematological toxicity (grade 4) was found in four patients.

CONCLUSION: Intra-tumor injection of the genetically engineered adenovirus H101 exhibits potential anti-tumor activity to refractory malignant tumors in combination with chemotherapy. Low toxicity and good tolerance of patients to H101 were observed.

INTRODUCTION

The fights against tumors are far from being finished. Biotherapy seems to be a potential anticancer weapon, but still needs strengthening. Engineered virus against cancer is one of the most hopeful therapeutic approaches. There are two different methods: (1) to use replication incompetent viruses as delivery agents for therapeutic genes to access to tumors, and (2) to destroy tumor by using replication-selective oncolytic viruses as therapeutic agents themselves^[1,2]. Multiple gene dysfunctions taking part in tumor formation have been known, single gene correction or modification can hardly reverse the malignancy. Viruses engineered for the purpose to replicate only in tumor cells and destroy the cells do not depend on the gene function they take on and have been shown to have great efficacy in both experimental and clinical studies^[3-5].

H101 is a recombinant human type-5 adenovirus (Ad5), in which E1B-55 kDs gene has been totally deleted. The H101 virus produced by Shanghai Sunway Biotech, also contains a deletion of 78.3-85.8 μ m gene segment in the E3 region. The E1B-55kD gene product is responsible for p53-binding and inactivation^[6]. If deleted, the virus would be unable to inactivate p53 for efficient replication in normal cells. However, cancer cells lacking functional p53 would hypothetically be sensitive to viral replication and subsequent cytopathic effects. p53 mutation is the most common genetic abnormality identified in human cancer^[7]. This characteristic can be utilized for H101 to identify the target. *In vitro* and *in vivo* studies have shown that H101 has anticancer activity, and has been proved to be safe through a five dosage of 5.0×10^7 - 1.5×10^{12} virus particles (VP)/d within 5 consecutive days in a clinical trial^[8]. We carried out this clinical trial to evaluate anti-tumor activity of H101 and its toxicity in combination with chemotherapy in patients with late stage cancers.

MATERIALS AND METHODS

Enrollment criteria

Histologically confirmed late stage cancer patients with more than two measurable lesions (at least one could be injected with H101), who had recurrent disease after surgery and/or radiotherapy for the primary tumor, or had progressed at or within 8 wk after completion of chemotherapy and/or radiotherapy, were recruited. Patients had to be ≥ 18 years old, with performance status above grade 2 according to The Eastern Cooperative Oncology Group (ECOG) standard, and life expectancy of ≥ 3 mo. Normal hematological and renal functions were also required. An informed consent was obtained from each patient or from the patient's legal guardian prior to enrollment. The p53 gene status was not critical for enrollment, because there were factors that inhibited p53 protein function including expression of the human papilloma virus E6 protein or *mdm-2* gene amplification^[9]. Institutional Review Board approval of the protocol and consent form were granted. This study was also approved by the State Food and Drug Administration of China.

Baseline assessment

Baseline assessments were made prior to treatment, but these

results were not used as enrollment criteria. Baseline blood tests such as complete blood counts, neutralizing antibody titers, electrolytes, blood urea nitrogen, creatinine, and liver function tests were performed. In addition, plain chest radiography, electrocardiogram and type B ultrasonography of upper abdomen were performed.

H101

H101 was formulated as a sterile viral solution in PBS buffer and kept at -20°C . Each vial contained 0.5 mL of virus solution with 5×10^{11} VP and titered $<1:60 \text{ TCID}_{50}$. Sterile purified lots of virus were produced for human clinical use by Shanghai Sunway Biotech (Shanghai, China), and tested for the titer, sterility, and general safety by National Institute For the Control of Pharmaceutical and Biological Products (Beijing, China).

Treatment regimen

In each patient, the most symptomatic and/or largest tumor mass was injected with H101, and the patient was treated together with routine systemic chemotherapy simultaneously. The tumor for injection was mapped into five equally spaced sections. Local anesthesia was applied to the skin as needed. The tumor was injected with 5×10^{11} virus particles into one section per day for 5 consecutive days, and these injections were repeated every 3 wk as one treatment cycle. The suspension volume of saline used for H101 administration was normalized to 30% of the estimated volume of the tumor mass to be injected. Tumor volume was estimated as: $1/2 (\text{maximal transverse diameter} \times \text{maximal vertical diameter} \times \text{depth})$.

Tumor assessments and toxicity evaluation

Tumor masses were measured serially by either physical examination or radiographic scanning (computed tomography or magnetic resonance imaging), whichever the principal investigator deemed most accurate for the measurement of the injected tumor mass. In general, superficial lesions were measured by physical examination, and deep tumors were measured most accurately by radiographic scanning. The tumor mass injected with H101 (injected lesion) and non-injected lesion were evaluated independently. Tumor measurements were performed either every 3 wk (physical examination) while patients were on active study treatment. After treatment completion, patients' tumor (s) were assessed every 4 wk or sooner if signs/symptoms of progression became evident. Radiographic scanning was assessed by independent radiologists, who were not investigators on the study. The degree of response within injected tumors was categorized as follows: complete regression (CR), complete disappearance of measurable tumor; partial regression (PR), $\geq 50\%$ but $<100\%$ decrease in cross-sectional tumor area; minor response (MR), $<50\%$ but $\geq 25\%$ decrease in tumor area; stable disease (SD), $<25\%$ decrease or 25% increase in tumor area; and progressive disease (PD), $\geq 25\%$ increase in tumor area *versus* the baseline area. Toxicity was assessed using the National Cancer Institute Toxicity Criteria.

Additional follow-up after treatment initiation

Neutralizing antibody titers were repeated at the end of each cycle, and viral dissemination in blood was tested immediately after injection on d 5 and d 22 for each cycle. The routine blood tests were repeated every week. Fine-needle aspirate biopsies at the injected sites on day 22 of the first treatment cycle were optional, based on patients' consent because of ethical considerations. These biopsies were analyzed for type Ad5 coat protein by immunohistochemistry.

PCR detection of H101 viral genomes in plasma

The blood taken before and one day after injection were collected

for PCR detection of H101 genomes (the amplicon overlaps the E1B region deletion and does not detect wild-type adenovirus sequences). The left primer was $5'\text{ctggcgcagaagtattccat}3'$, at $\text{Tm } 60.24^{\circ}\text{C}$ and the right primer was $5'\text{gtcacatccagcatcacagg}3'$, at $\text{Tm } 60.12^{\circ}\text{C}$. Viral DNA was extracted from samples, using the Sangon DNA mini kit (Shanghai, China). The amplification procedure was: at 94°C for 10 min, then 94°C for 60 s, 55°C for 45 s, 72°C for 60 s for 35 cycles; then at 72°C , for 10 min. The products were analyzed by 10 g/L agarose electrophoresis. The lower limit of detection was 100 particles of H101 per microlitre plasma.

Detection of Ad-specific neutralizing antibodies by ELISA

Triplicate plasma (5 μL) taken before and on d 22 after injection were collected, and tested for Ad-specific antibodies according to the procedures provided by Jingmei Biotech (Shenzhen, China). The absorbance at 450 nm was read on a Bio-Rad Model 550 microplate reader. The positive results were those above or equal to the average of $A_{450\text{nm}}$ negative control plus 0.10. Otherwise, the samples were defined as negative.

Immunohistochemistry for Ad5

Injection site fine-needle aspiration biopsies were formalin-fixed, paraffin-embedded and cut into sections. Sections were then deparaffinized and hydrated. Slides were subjected to antigen retrieval at 120°C for 10 min in citrate buffer and incubated with an Ad5 monoclonal antibody (NeoMarker, America) for 90 min at room temperature. This was followed by incubation with a biotinylated goat anti-mouse secondary antibody, and the streptavidin/horseradish peroxidase conjugate, then mounted in DPX mounting medium (BDH Chemicals, America). The percentage of brown-stained cells (positive for Ad5) was determined by counting the cells under high-power magnification ($\times 40$) of microscope. The average percentage of three high-power field assessments was then calculated. Tumors that had greater than 10% of positively stained cells were considered to be Ad5 positive.

Statistical analysis

All patients enrolled were calculated under the ITT principle. The rates were compared by χ^2 test.

RESULTS

Patient characteristics

Totally, 50 patients were enrolled, including 18 with head and neck cancer, eight esophageal cancer, five gastric cancer, five lung cancer, three colorectal cancer, three breast cancer, three soft tissue sarcoma, two malignant melanoma, one ovarian cancer, one lymphoma and one chordoma. Most cancers were at end-stage. The head and neck cancer and esophageal cancer enrolled were all squamous carcinoma. Seventy percent of patients were males. The median age was 52 years. All patients had ECOG Performance Status of grade 0-2. Thirty-nine (78%) patients had received pretreatment before, and 31 (62%) had received more than two kinds of treatment. The tumor mass had a median cross-sectional area of 12.5 cm^2 (range, $1.43\text{--}360 \text{ cm}^2$) (Table 1).

Tumor response

Overall, 46 patients were evaluable. The response rate (CR+PR) among these patients was 30.4% (14/46), and the overall response rate according to ITT principle was 28.0%. For the control lesions, the response rate was 13.0%, which was significantly lower than the H101 treated lesions ($\chi^2 = 4.08$, $P < 0.05$) (Table 2). In the 14 cases with effective H101 injection, there were one CR, three PRs, two MRs, three SDs, and five PDs for

the control lesions, respectively. In these patients, combination of H101 injection with chemotherapy was more effective than chemotherapy alone ($\chi^2 = 15.6, P < 0.001$). The response rates to H101 injection combined with chemotherapy were different, no effect for gastric cancer was found in this study (Table 3). Figure 1 shows regression of the injected lesion in a patient with head and neck cancer.

Ovarian cancer	1	0

¹SCCHN, squamous cell carcinoma of head and neck.

Figure 1 A 51 yr-old male patient with neck metastasis of soft palate squamous carcinoma. About 3 mo before enrollment, he had been treated with radiotherapy and Docetaxel plus DDP, but the metastatic tumor did not show any reaction to the treatment. Before the enrollment the tumor was about 2.2×1.5 cm² (A, arrow), then the tumor was injected with H101 5×10¹¹VP per day for 5 consecutive days with systemic administration of 5-Fu and DDP, after one cycle treatment the tumor regressed (B, arrow).

Adverse reaction

The most frequent adverse reaction was fever (30.2%), injection site pain (26.9%), flu-like symptoms (26.4%), nausea and vomiting (34.0%), leucopenia (49.1%), liver dysfunction (5.7%), alopecia (13.2%) (Table 4). Fever was moderate, which appeared at about 12 h post H101 injection, persisted for 2-4 h, and then returned to normal without treatment. There was a significant difference in the regression rate between patients with fever (69.2%, 9/13) and those without fever (21.2%, 7/33) ($\chi^2 = 9.48, P < 0.005$).

Flu-like symptom	13	2	0	0	15 (28.3)
Alopecia	3	3	1	0	7 (13.2)

Humoral immune response and plasma H101 viral genome

Fourteen patients were tested for the Ad-specific neutralizing antibody. Three (21.4%) of them were positive at baseline. Another six turned to be positive on day 22. Two patients positive at the baseline and two negative patients experienced tumor regression, and thus there was no correlation between baseline neutralizing antibody titers and induction of tumor response. Sixteen patients were tested for plasma H101 viral genome before injection and 30 min after. Only six cases were positive after injection (Table 5). All these patients were positive for blood Ad-specific neutralizing antibody on d 22.

Table 5 Humoral immune response and plasma H101 viral genome test

	Before injection		After injection	
	Negative	Positive	Negative	Positive
Ad neutralizing titer	11	3	5	9
Plasma H101 PCR	11	0	7	4

H101 immunohistochemistry detection

Totally, three fine-needle aspiration biopsies of tumor were obtained at the end of treatment on d 22 or d 44, and detected for Ad5 coat protein by immunohistochemistry for adenovirus presence. Two of them were positive (Figure 2).

Figure 2 Immunohistochemical staining of Ad5 capsid from the fine-needle aspiration of the tumor tissue injected with H101 at the end of treatment cycle. The dark-brown stained granules (arrows in Figure A) represent a positive staining indicating adenovirus replication and package in the tumor cells. However negative staining was also obtained in one of the three samples (B).

DISCUSSION

Selective replication of E1B deleted adenovirus in the p53 dysfunctional human cancer for cancer therapy is one of promising treatment approaches. Its safety has been shown in a number of clinical trials^[5,10-12]. Although anticancer activity of the virus has been proved, the clinical efficacy is still not predominant. Therefore, the oncolytic ability needs to be enhanced. Current studies are focusing on arming these viruses with therapeutic genes to increase its potency.^[13-15]

But before that, the virus itself can be reinforced by augmentation or elimination of specific viral functions to enhance the anticancer efficacy. To enhance the virus-induced host anti-tumor immune response is one of the key points. However, the roles of the immune response to virotherapy are profound. Cutting down the functions of the virus to escape from immune surveillance can impede the spread of viral infection on the one hand, but augment tumor cell destruction through the recruitment of T cells “vaccinated” against tumor antigens on the other^[16]. The E3 region is related to the inhibition of host immunity, which enhances the virus replication and spread in tumor^[17]. But this is not necessary for intra-tumor injection of oncolytic viral. The virus replication and spread effect can be enhanced by

repeated injection. By sacrificing the spread ability, the virus may activate the host immune response to virus infected tumor cells and help the host immune system to recognize tumor cells themselves, and thus may benefit patients under such therapy. Metastasis is prevalent in malignant tumor patients, which is the main cause of treatment failure or even death. Moreover, patients may have more than one tumor lesion, and the lesion that cannot be injected could exist. Therefore, the ability of activating the host immune response seems crucial. So treatment with the E3 region deleted adenovirus, H101, may have additional benefit to patients.

The main purpose of this pilot study was to test the effect of H101 on a wide type of advanced cancers. Results showed that the total response rate was only 28.0% under the ITT principle, which was significantly higher than the lesions that received chemotherapy alone ($P < 0.05$). This indicates that H101 may have potential anticancer activity. The total regression rate observed is not salient for the treatment. This may be due to the late stage of the diseases, and most of the patients had been vigorously treated previously but failed at last. The other reason is the wide enrollment of the tumor types, some of which might not be sensitive to H101. For instance, gastric cancer showed no response.

However, some patients presented notable therapeutic efficacy without grievous adverse reactions. Moreover, in those who had fever during H101 injection, the efficacy was significantly higher than those who did not have fever ($P < 0.005$). Although there is not enough evidence to estimate the effect of H101 on host immunity to tumors, our results suggest that there is a relationship between the immune reaction to H101 and the efficacy, which was not well recognized in previous studies. In the beginning of last century, it was noticed that patients with various malignancies experienced spontaneous tumor regression after rabies vaccination, a viral illness or even bacterial infection^[18,19]. In these cases, virus infection may activate the host immune system, and elevated cell-mediated immunity may play a role in the tumor regression. But the mechanism is still unclear. On the basis of those results, immune modulation strategies should be further studied and developed.

Our study also shows that H101 intra-tumor injection is well tolerated. No severe toxicity was observed, and the main adverse reactions that related to H101 were injection site pain, nausea, fever and flu-like symptoms. Fever and flu-like symptoms were obviously caused by the virus injection and consequently transitory viraemia. H101 presence did not cause severe inflammation in peritumoral normal tissue, despite multiple directive injection. Thus, H101 may benefit the patient without adding severe affliction in clinical application.

Treatment for cancers with the recombinant oncolytic adenovirus is hopeful, but still immature. Experiences should be accumulated before it is applied in cancer therapy. Since patients enrolled in our clinical trial were in their end-stage of diseases, there were difficulties in patient selection and unifying the chemotherapy drugs due to ethical consideration, and immunosuppression was prevalent in those patients. The clinical benefit of intra-tumor injection with H101 should be further determined in randomized trials and, possibly, in earlier stage patients. The dosage, medication methods, treatment cycle and combined chemotherapy or immunotherapy should be explored in further studies as well. Genetically engineered and reinforced viruses may become a novel therapeutic platform for the treatment of cancers.

Abstract

AIM: To explain the role of Monocyte chemotactic protein-1 (MCP-1) and soluble adhesion molecules in chronic hepatitis C during the treatment of interferon alpha (IFN α) 2 b and ribavirin (RBV).

METHODS: Concentrations of MCP-1, soluble adhesion molecules intercellular adhesion molecule-1 (sICAM-1), sP-selectin, interleukin (IL) 6, and IL10 in serum were estimated in the group of 40 patients with chronic hepatitis C treated with IFN α 2 b and RBV in 0, 16, 32, 48 wk of the therapy.

RESULTS: In chronic hepatitis C, before and during the treatment, the serum levels of MCP-1 and sP-selectin in responders were similar to those of healthy subjects. In non-responders (NR), MCP-1 increased in the course of IFN α +RBV treatment, differences were statistically significant as compared to responders. MCP-1 correlated statistically with the activity of periportal inflammation ($r = 0.35$, $P < 0.05$) but not with staging of liver fibrosis. sICAM-1 positively correlated with inflammatory activity and fibrosis in NR. sP-selectin did not correlate with histological findings in the liver. The MCP-1 correlated with the soluble form of sP-selectin concentrations ($r = 6$, $P < 0.001$) and with IL-10 level in NR ($r = 0.4$, $P < 0.05$). There was no correlation observed between the concentration of MCP-1 and sICAM-1, IL-6 during the treatment.

CONCLUSION: MCP-1 concentration may be a prognostic marker of the efficacy of IFN+RBV therapy in patients with chronic hepatitis C.

INTRODUCTION

Alteration of the immune system in chronic hepatitis C patients may underlie their inadequate response to antiviral therapy. The factors responsible for the persistence of HCV infection and low response to interferon alpha treatment are poorly understood. Circulating monocytes/macrophages are important

for the host immune responses to HCV. HCV-RNA was detected in mononuclear cells of chronically infected patients^[1]. It seems that monocyte functioning impairment is a decisive factor of chronic HCV infection and lack of positive therapeutic response. Monocytes might be a reservoir of the virus and the source of re-infection after IFN treatment^[2]. In chronic hepatitis C, IFN-alpha mRNA was decreased in liver tissues and mononuclear cells significantly increased in peripheral blood. It might result in the inhibition of antiviral immune mechanisms in the liver and enable HCV infection persistence in monocytes^[3]. Some responders revealed, with negative HCV-RNA in blood serum, the presence of RNA virus in peripheral blood monocytes.

Hepatitis C virus chronic infection is associated with functional impairment of peripheral blood mononuclear cells. The application of IFN alpha could lead to HCV-RNA reduction in monocytes^[4]. Elimination of HCV in monocytes after 6-month treatment might be a coefficient of efficiency of the therapy^[5].

Chronic liver diseases are associated with increased hepatic and monocytic expression of monocyte chemotactic protein 1 (MCP-1). MCP-1 level was higher in hepatic veins than in peripheral blood and occurred in severe cases of liver diseases^[6]. Hepatic expression of MCP-1 is up-regulated during chronic HCV infection mainly in activated hepatic stellate cells (HSC). In chronic hepatitis C with advanced fibrosis and inflammation, hepatic MCP-1 mRNA levels were significantly higher^[7]. Peripheral blood monocytes and activated HSC are the source of MCP-1. Monocyte chemotactic protein-1 recruits monocytes and lymphocytes to damaged area in the liver tissue. Profibrogenic properties of MCP-1 could be reflected by the induction of HSC chemotaxis and its transformation to myofibroblasts^[8].

Adhesion molecules are proteins expressed on a variety of cells, which mediate the interaction between endothelial cells with lymphocytes, monocytes and leukocytes^[9,10]. Intracellular adhesion molecule-1 (ICAM-1), a member of the immunoglobulin superfamily participates in the immunological system, cell-to-cell communication and in inflammatory responses. Many of proinflammatory proteins (IL-1, TNF α , GM-CSF) generated by leukocytes, monocytes, macrophages could enhance the expression of adhesion molecules on cells and in soluble form in circulation^[10]. Activated blood platelets which constitute inflammatory cells are the source of P-selectin^[11]. Soluble ICAM-1 and sP-selectin, secreted from activated cells or expressed on the microparticles, transmit signals from inflammation sites to peripheral circulating monocytes, lymphocytes and others cells. In viral hepatitis, cell-mediated responses could lead to accumulation of activated immunocompetent cells into the hepatic parenchyma. This phenomenon could cause viral elimination and/or focal liver damage^[12,13].

The aim of the study was to estimate the monocyte chemotactic protein-1 in correlation with adhesion molecules, such as sICAM-1, sP-selectin and with cytokine Th2 (IL-6, IL-10) in chronic hepatitis C during IFN alpha and ribavirin treatment. Correlation of the factors and histological staging and grading in liver tissue was also analyzed. The factor concentrations in responders (R) and non-responders (NR) were analyzed as well.

MATERIALS AND METHODS

Examinations were performed in 40 patients with chronic hepatitis C (16 women, 24 men), aged 36 ± 12 years. Chronic hepatitis was confirmed by HCV infection persisting for longer than 6 mo (HCV-RNA positive) and increased ALT values. Blind liver biopsies were done by means of the Hepafix System (Braun, Melsungen, Germany) before the treatment. Histopathological inflammatory activity (grading, 0-4 scale) and fibrosis grade (staging, 0-4 scale) were evaluated in accordance with the classification of chronic viral hepatitis according to Scheuer classification^[14]. Patients were divided into responders (R) and non-responders (NR) according to their sustained response to a course of interferon alpha 2 b (3 MU three times weekly for 48 wk, Rebetrone, Schering-Plough Corporation, USA) with ribavirin (1.2 g/d for 48 wk, Rebetrone, Schering-Plough Corporation, USA) treatment.

The levels of monocyte chemotactic protein-1, soluble intracellular adhesion molecule-1, soluble form of P-selectin, and cytokines IL-6 and IL-10 were determined by ELISA method in blood serum in 0-16-32-48 wk of the therapy. Moreover, routine biochemical examinations concerning the grade of liver damage were performed. Ethical approval for research was obtained from local Ethics Committee in Medical University.

Statistical analysis

The results were presented as mean \pm SD. The statistical analysis was performed using Student's *t*-test for pairs, and the correlation by using parametric Spearman's test.

RESULTS

MCP-1 in chronic hepatitis C

MCP-1 concentrations before and during the treatment in non-responders were higher than those in responders and increased during the treatment (Table 1). MCP-1 concentrations in R were comparable to the values observed in the controls. The second half of the treatment showed the statistically significant increase in MCP-1 in R as compared to the control group. However, it diminished to normal values at the end of the treatment (statistically significant difference to NR, $P < 0.05$). There was no correlation between MCP-1 and ALT level, prothrombin index, leukocyte and platelet count. There was a positive

correlation between MCP-1 and periportal inflammatory activity in R (Table 2). However, no correlation was observed between MCP-1 and the grade of fibrosis and periportal inflammatory activity. A positive correlation was observed between MCP-1 and sP-selectin and IL-10 in NR in the second half of the therapy (examinations III and IV; $r = 0.6$, $P < 0.001$, Spearman test). A correlation between MCP-1 level and ICAM concentration and IL-6 in chronic hepatitis C during treatment was not observed.

sICAM-1 and sP-selectin in chronic hepatitis C

sICAM-1 concentrations were significantly higher in R than in NR and the controls. During IFNalpha+RBV treatment, sICAM-1 level decreased in both groups. Responders revealed its decrease, which was statistically significant ($P < 0.0001$) as compared to non-responders. However, there was a positive correlation between sICAM-1 concentrations and intralobular and periportal inflammatory activities and fibrosis in responders, which was not observed in non-responders. sICAM-1 and ALT levels, leukocytes, and platelet count showed a positive correlation.

Table 1 Levels of MCP-1, sICAM-1, sP-selectin, IL-6 and IL-10 in patients with chronic hepatitis C during IFN+RBV therapy in responders (R) and non-responders (NR)

		0-wk	16-wk	32-wk	48-wk	Control
sICAM-1 (pg/mL)	NR	434 \pm 104 ^{ab}	372 \pm 111 ^{ab}	404 \pm 87 ^b	389 \pm 77 ^b	230 \pm 29

a-statistically significant differences between responders (R) and non-reponders (NR), Student's *t* test, $^aP < 0.05$, *b*-statistically significant differences compared to healthy, Student's *t* test, $^bP < 0.01$.

The concentrations of sP-selectin were significantly higher in non-responders than in responders. During the treatment, sP-selectin concentrations decreased in both groups. Its concentrations in R were comparable to the control group and there was no correlation between histological changes in the liver and sP-selectin concentrations.

Serum Th2 interleukins (IL-6, IL-10) in chronic hepatitis C

The concentrations of IL-6 before and during the treatment were lower in R than in NR. Its levels in R were 8 times higher during the treatment while IL6 concentrations were significantly higher in NR than in R ($P < 0.02$) and during the treatment it increased twice. There was a positive statistical correlation between IL-6 concentrations and intralobular inflammatory activity in R, and fibrosis in NR. IL-6 level, leukocyte count, and prothrombin index showed a positive correlation.

IL-10 concentrations before the treatment were statistically higher in R than in NR ($P < 0.05$). Although IL-10 values increased during the therapy, there was a temporary decrease in IL-10 concentrations both in R and in NR during the second half of the treatment. There was no statistical correlation between IL-10 concentrations and histological changes in the liver.

DISCUSSION

The results confirmed that MCP-1 was a chemokine reflecting the inflammatory activity in the liver and might be a prognostic factor of the efficacy of the treatment with IFN α and RBV. Patients with a persisting long-lasting response to the treatment revealed MCP-1 concentrations statistically lower and during the treatment it did not undergo significant changes. Patients with negative effect of the therapy showed higher MCP-1 levels and increased significantly during IFN+RBV treatment.

Monocyte chemotactic protein-1 is a potent chemokine secreted by monocytes and activated hepatic stellate cells undergoing up-regulation during chronic HCV infection. In normal liver, MCP-1 protein and gene expression detected by immunohistochemistry and *in situ* hybridization showed a modest expression in peri-sinusoidal cells and in bile duct epithelial cells^[15]. In chronic hepatitis, MCP-1 expression was directly correlated with the degree of inflammatory infiltrate in the portal tract, activated stellate cells and monocyte/macrophages. In active cirrhosis, MCP-1 expression was present in the portal tract, epithelial cells of regenerating bile ducts, and the active septa surrounding regenerating nodules^[15]. There was a direct relationship between MCP-1 expression and monocyte infiltration after acute liver injury. Monocytes stimulated by lipopolysaccharide, T lymphocytes and by IL-2 become mature macrophages and place themselves in the liver tissue. Antioxidants significantly reduced MCP-1 expression and the number of infiltrating monocytes in toxic liver injury^[16].

Hepatic tissues are damaged by activated monocytes, which secrete MCP-1, a chemoattractant and activator for circulating monocytes and T lymphocytes. Soo *et al.* in experiment on cultured monocytes infected with HCV showed that secreted proteins could influence the progress and outcome of liver injury^[17]. It was shown that HCV NS5A proteins could lead to monocyte activation with MCP-1 secretion^[17].

We did not observe any dependence between MCP-1 and Th2 lymphocyte stimulation during the treatment. IL-6 and IL-10 concentrations were higher in chronic hepatitis C than in healthy subjects and their levels increased in the course of IFN+RBV treatment. We showed significant differences in IL-6 and IL-10 concentrations between R and NR before the therapy. Masaki *et al.* noted that non-responders revealed a significantly higher Th1 and Th1/Th2 ratio than responders^[18]. The prognostic factors for favorable long-term virological responses were non-1b genotype, low HCV viremia (HCV viral load less than

500 kilocopies/mL), and low Th1/Th2 ratio^[18]. In hepatitis C, the predominance of Th2 cytokine IL-10 was observed. Monocytes secreting cytokines could enable cellular immune responses to activate, which decided the outcome of HCV infection^[19]. IL-10 and IL-12 secreted by monocytes were higher in asymptomatic HCV carriers than in chronic hepatitis C ones. After IFN+RBV therapy was completed, increased IL-12 was noted in responders and decreased in non-responders^[1]. It seemed to confirm that damage of monocyte function could decide chronic HCV infection and lack of positive therapeutic response^[1]. The use of IFN α had no influence on the production of IFN γ and IL-10 by monocytes^[4].

We presented a significant correlation of MCP-1 in chronic hepatitis C and soluble P-selectin concentration. The main sources of sP-selectin are activated blood platelets. Our previous studies showed that there was a positive correlation between platelet activation and a degree of histological change intensity in the liver^[20]. We also noted the inhibition of activated blood platelets by interferon α 2 b in chronic hepatitis C (data in press). It may reflect the cooperation of monocytes and platelets in the process of inflammation and fibrosis in chronic hepatitis C. Soluble P-selectin level was significantly lower in responders than in non-responders and its concentration was sustained lower during IFN α +RBV therapy. However, we did not observe any correlation between sP-selectin with histological changes in liver. These results suggest lack of priority of sP-selectin in efficacy of antiviral therapy. It reflects the intensity of inflammation and mobilization of blood platelets in chronic hepatitis C. Activated platelets have been found to play a crucial role in HSC transformation to myofibroblasts and in liver fibrosis^[21].

Activated monocytes could also lead to endothelial cell damage^[22]. Our studies did not show any correlation between activation of endothelial cells and monocytes. On the other hand, sICAM-1 concentrations correlated positively with periportal and intralobular inflammatory activity as well as staging of liver fibrosis, mainly in non-responders. Decreased sICAM-1 level during the treatment was common in all patients with chronic hepatitis C especially in responders. Our observations were similar to those of researchers who suggested that sICAM-1 might be used as a prognostic marker of efficacy of antiviral therapy in chronic hepatitis C^[10,23,24]. Decreased sICAM-1 level could reflect diminished inflammatory processes in the liver due to HCV elimination.

Studies conducted so far have ascribed an important role to monocytes in chronic hepatitis C pathogenesis. However, ways for effective elimination of HCV infection are still to be discovered. Monocytes are the cells that are damaged by HCV and the non-specific immunologic barrier which prevents or removes the infection. Thus, the question why most HCV infected patients were not able to eliminate HCV by their immune system is still to be answered.

Abstract

AIM: Intestinal parasitic diseases are commonly accompanied with diarrhoeal symptoms and allergic reactions. Eosinophilia occurs as a result of IL-5 synthesized from Th2 cells during allergic reactions. IL-5 acts as a factor activating eosinophils. The aim of this study was to compare the IL-5 cytokine measurements in serum samples and cell cultures. And also to compare eosinophilia observed in helminth infections and protozoon infections accompanied with allergy.

METHODS: Twenty-three patients who presented with diarrhoeal symptoms and allergic complaints were tested positive for intestinal parasites, as well as 21 controls with allergic complaints who did not have any intestinal parasites were included in this study. IL-5 production in *in vitro* cell cultures prepared by using phytohemagglutinin (PHA) to stimulate peripheral blood mononuclear cells (PBMC) obtained from the blood samples taken from these patients were compared with the IL-5 level in serum. Furthermore, the IL-5 production in protozoon and helminth infections was also compared. Absolute eosinophil values in 1 mm³ of blood were calculated by means of peripheral smear in both groups within the scope of the study.

RESULTS: Parasites such as helminth detected in 15 (65.2%) and protozoon in 8 (34.8%) of the patients were included in this study. As regards the values of the sera in both patients with parasite infection and controls, the IL-5 production was found to be higher in the cell culture supernatant ($P < 0.001$ and $P < 0.05$). When the IL-5 level of the patients with helminth parasites was compared with that of those with protozoon, it was determined that the IL-5 level in serum was more significant in the patients with protozoon than in those with helminth ($P < 0.05$). In the study group, the patients were found to have parasites, the percentage of eosinophil was 7.0% compared to 6.5% in the control group. Thus, there was no significant difference between the eosinophil values ($P > 0.05$).

CONCLUSION: It was found that IL-5 cytokine levels in serum samples from the patients with helminth and protozoon displayed more measurable values as compared to the IL-5 levels after stimulation with mitogen. It is concluded that IL-5 acts as a triggering factor in the toxiallergic complaints

commonly seen in helminth and protozoon infections.

INTRODUCTION

Gastrointestinal (GI) parasites play an important role in the allergic and hypersensitive reactions. The prevalence of intestinal protozoans and helminths in stool samples of individuals with allergic symptoms was evaluated as a possible link between parasites and allergy^[1]. A wide variety of clinical findings related to the whole body are encountered in parasitic diseases. Hypersensitive reactions may start out in the host against the chemical substances excreted by the parasites. In addition, allergic reactions may occur^[2].

There has been an increase in the prevalence of allergic diseases in the past few decades. T helper 2 (Th2) responses associated with allergic diseases^[3]. Th2 cells elaborate cytokines such as IL-5 which works with toxic mediators of innate immune cells. Th2 cytokine involvement in allergy makes these cytokines attractive therapeutic targets, which protect against gastrointestinal worms^[4,5]. Immunological interventions could be designed to avoid induction of pathology while retaining protective responses^[6].

It has been shown that strong Th2 cytokine response occurs especially during the chronic phase of helminth infections. Allergic reactions triggered by this Th2 response are more commonly seen in helminth infections, and hypersensitive reactions against the chemical substances secreted by helminths may occur in some people^[7-9]. Long-lived parasites such as helminths, however, are more remarkable for their ability to downregulate host immunity, protecting themselves from elimination and minimizing severe pathology in the host^[10].

Allergic reactions may also be observed in protozoon diseases. Ameobiasis, giardiasis, Blastocystis were reported as the etiologic factors causing allergy in animals and human models in some publications^[11-11].

Eosinophilia is caused by the effect of IL-5 synthesized from the Th2 cells. IL-5 is the most important cytokine in the transformation and development of eosinophils, and acts as an "eosinophil activator". One of the significant causes of the increase in the amount of eosinophils in blood is parasitic diseases. Toxiallergic effects of certain parasites on the host's organism lead to an increase especially in eosinophil numbers. Eosinophils are effectors against parasitic targets. Both sets of diseases are associated with a polarized Th2-type immune response, typified by reactive cell types (eosinophils and mast cells)^[12,13].

It is suggested therefore that the function of IL-5 and eosinophils is to protect against repeated exposure to gastrointestinal parasites. On the other hand the eosinophilia observed may represent an immunopathological rather than a protective response and may merely be a consequence of the generalized inflammation induced by the Th2 response following infection with parasites. Th2 response is essential for the expulsion of GI helminths^[14].

Eosinophils are also responsible for considerable pathology

in mammals because they are inevitably present in large numbers in inflammatory lesions associated with helminth infections or allergic conditions^[15,16].

On the other hand current evidence shows a strong association between colonic infection and inflammation with development of inflammatory bowel disease (IBS)^[17]. It has been reported that mast cells and their inflammatory mediators are closely associated with a number of intestinal diseases including idiopathic IBD. Parasites induce mast cell degranulation, release histamine. Mast cells from healthy controls don't produce IL-5, but mast cells from patients with intestinal inflammatory disease could release a relatively large amount of IL-5^[18,19]. IL-5 induced by parasites may play a role in causing IBD.

The aim of this study was to compare the IL-5 cytokine measurements in the cell cultures of patients who presented with allergic complaints and diarrhea and were positive for parasites in stool examinations with the IL-5 syntheses determined in serum samples, and to investigate eosinophilia observed in helminth and protozoan infections accompanied with allergy and diarrhea.

MATERIALS AND METHODS

Twenty-three patients with intestinal parasites and 21 controls who had allergic complaints and not any intestinal parasite and diarrhea, were included in this study.

The study group included 12 females and 11 males, aged 18-45 and 25-53 years respectively. The control group included 9 females and 12 males, aged 20-45 and 28-50 years respectively.

IL-5 production in *in vitro* cell cultures prepared by using PHA to stimulate PBMC obtained from these patients was compared with the IL-5 level in serum. In addition, IL-5 production in protozoan and helminth infections was also compared.

Cells and sera

PBMC and serum samples separated from 5 mL of heparinized blood samples from the patients using the Ficoll hypaque density gradient centrifuge method were utilized in the study.

Mitogen and proliferation assay

PBMC ($83 \times 10^5/\text{mL}$) was incubated with PHA in RPMI 1640+10% HuS inside 96 well tissue culture plates containing 5 mL/L CO_2 for 48 h. Supernatants were taken at the end of 48 h and kept at -20°C until cytokine analysis was carried out^[20].

IL-5 measurement

IL-5 levels in the supernatant and serum samples were evaluated using the double sandwich ELISA as previously described by Geiger *et al.*^[21].

Eosinophil count

Absolute values in 1 mm^3 of blood were calculated by means of peripheral blood smear from the patients within the study as well as the controls.

Statistical analysis

Results were evaluated using the Student *t* test.

RESULTS

Helminths were detected in 15 (65.2%) and protozoans in 8 (34.8%) of the 23 patients (Table 1). All the patients had diarrheal symptoms.

A comparison between the sera of the treated group and the control group did not reveal any significant differences ($P>0.05$ and $P>0.05$). The nonspecific IL-5 synthesis determined after stimulation with PHA was higher as compared to the IL-5 values measured in the serum ($P<0.05$) (Figure 1).

It was also established that the IL-5 cytokine measurements were higher in the group with protozoans than in the group with

helminths. These values were also higher as compared to the cytokine measurements in the cell cultures ($P<0.05$) (Figure 2).

The eosinophil rate was 7.0% in the study group whereas the eosinophil rate was 6.5% in the control group. However, significant difference could not be found between these two groups ($P>0.05$) (Table 2).

Table 1 Parasites, IL-5 levels and eosinophil values in patients group

Parasites	Those with parasite infection	Mean serum IL-5 (pg/mL)	Mean PHA-IL-5 (ng/mL)	Eosinophil %
<i>E. vermicularis</i>	9	15.5	383.4	8
<i>A. lumbricoides</i>	1	9.98	750	9
<i>H. nana</i>	1	13.61	620	8
<i>T. saginata</i>	4	12.9	652.5	6
<i>E. coli</i>	3	21.15	415	2.4
<i>I. butschlii</i>	2	15.61	297	8
<i>B. hominis</i>	1	17.27	NA	4.4
<i>G. intestinalis</i>	2	22.35	872.5	3

(NA: Not Available).

Table 2 Serum IL-5, *in-vitro* IL-5 and eosinophil values in patients with parasite infection and controls

	Serum IL-5 (pg/mL)	<i>In-vitro</i> IL-5 (pg/mL)	Eosinophil %
Patients with parasite infection	16.2	634	7.0
Control	32.4	885.4	6.5

DISCUSSION

Th2 response is important in protection against and destroying the parasites. Especially in some tropical areas, helminths were the major immediate triggers of Th2 response^[22,23].

Pit *et al.* found that levels of IL-5 were induced by intestinal helminths^[24]. Protective immune responses to intestinal nematodes could be controlled by Th2 lymphocyte responses. Increased number of eosinophils in the GI mucosa and Th2 cell cytokine responsible for the generation of eosinophils, were prominent features of gastrointestinal nematode infections^[25]. Herrstom *et al.* found that *E. vermicularis* were more frequently found in children with allergic disease as defined by allergic symptoms^[26]. Sorci *et al.* suggested that there was an association between the pinworms (oxyuridae, nematoda) and eosinophil concentration^[27]. Varga *et al.* reported that patients infected with *A. lumbricoides*, had more severe allergic symptoms, and allergic symptoms were seen in patients infected with *G. intestinalis*^[28].

Previous studies, however, have shown that allergic complaints could precede other problems in protozoon infections. It was stated that allergic reactions also occurred in the disease caused by *G. intestinalis* that lives in the digestive tract. The relationship between allergy and giardiasis has been shown in various publications^[1-29]. In Moscow, during the clinical studies of children with *G. intestinalis* infection, allergic reactions were found in 15.7%^[30].

It was shown in some previous studies that IgG1, IgG3, IgM and IgA syntheses were important as resisting factors against the infection in intestinal protozoon infections such as giardiasis^[31]. The presence of anti-parasitic antibodies detected in the serum depended on the secretion of cytokines such as IL-4 which is also produced from Th2 cells. As high antibody levels triggered by IL-4 in the serum, high IL-5 levels coming from the same source of cells were found to be higher than those from, supernatants in patients with protozoon infection.

It was also reported that urticaria and eosinophilia were detected in people infected with *B. hominis*^[11]. Biedermann *et al.* reported that antigens from *B. hominis* caused urticaria^[32]. Hypersensitive (DTH) response to amebiosis delayed-type was evaluated in C3H/HeJ mice infected with *E. histolytica*^[33].

It is important to measure and assess IL-5 as a cytokine triggering eosinophilia in patients who present with allergic complaints and whose stool examinations reveal no parasites. It was established in this study that the IL-5 synthesis determined in the serum samples in the group with protozoa was more significant than that determined in the cell cultures in the group with helminths. Thus, eosinophilia was not only limited to helminth infection, but also in protozoon infection.

Eosinophils account was consisted of 2-3% of the total leukocytes in the blood and functioned as cytotoxic effector cells in allergic and parasitic disease, especially for the elimination of parasites^[34,35]. Eosinophilia occurred due to the IL-5 effect that reflects Th2 cell secretion^[36]. A number of studies have shown the presence of eosinophilia in parasitic infections. The blood eosinophils are associated with helminthic diseases. The primary function of the eosinophil is to protect against helminth parasites and eosinophils are responsible for a considerable amount of inflammatory pathology accompanying helminth infections^[16-37].

In the present study, the rate of eosinophilia was 7% in the study group and 6.5% in the control group. Because of the control group also had allergic complaints, no statistically significant difference could be found between the two groups ($P>0.05$).

It has also been shown that PBMC from healthy volunteers whose lymphocytes would not produce IL-5, failed to produce IL-5 after stimulation with PHA^[38]. Consistent with the results of Katial *et al.*^[38], IL-5 values obtained for 16 healthy volunteers

in the present study after stimulation with PHA were lower than those in the group with parasite infection and the control group.

Parasites induce IL-5 secretion. The effect of IL-5 on IBD should be investigated^[18]. Approximately 25% of patients with IBS had a history of infectious enteritis. Microbial agents including parasites could increase the number of mast cells within the colonic muscle wall, release pro-inflammatory substances, and increase the number of inflammatory cells that might cause IBS^[17].

Abstract

AIM: To analyze the experience within our hospital and to review the literature so as to establish the best means of diagnosis of abdominal tuberculosis.

METHODS: The records of 11 patients (4 males, 7 females, mean age 39 years, range 18-65 years) diagnosed with abdominal tuberculosis in Harran University Hospital between January 1996 and October 2003 were analyzed retrospectively and the literature was reviewed.

RESULTS: Ascites was present in all cases. Other common findings were weight loss (81%), weakness (81%), abdominal mass (72%), abdominal pain (72%), abdominal distension (63%), anorexia (45%) and night sweat (36%). The average hemoglobin was 8.2 g/dL and the average ESR was 50 mm/h (range 30-125). Elevated levels of cancer antigen CA-125 were determined in four patients. Abdominal ultrasound showed abnormalities in all cases: ascites in all, tuboovarian mass in five, omental thickening in 3, and enlarged lymph nodes (mesenteric, para-aortic) in 2. CT scans showed ascites in all, pelvic mass in 5, retroperitoneal lymphadenopathy in 4, mesenteric stranding in 4, omental stranding in 3, bowel wall thickening in 2 and mesenteric lymphadenopathy in 2. Only one patient had a chest radiograph suggestive of a new TB lesion. Two had a positive family history of pulmonary TB. None had acid-fast bacilli (AFB) in the sputum and the tuberculin test was positive in only two. Laparotomy was performed in 6 cases, laparoscopy in 4 and ultrasound-guided fine needle aspiration in 2. In those patients subjected to operation, the findings were multiple diffuse involvement of the visceral and parietal peritoneum, white 'miliary nodules' or plaques, enlarged lymph nodes, ascites, 'violin string' fibrinous strands, and omental thickening. Biopsy specimens showed granulomas, while ascitic fluid showed numerous lymphocytes. Both were negative for acid-fast bacilli by staining. PCR of ascitic fluid was positive for *Mycobacterium tuberculosis* (*M. tuberculosis*) in all cases.

CONCLUSION: Abdominal TB should be considered in all cases with ascites. Our experience suggests that PCR of ascitic fluid obtained by ultrasound-guided fine needle aspiration is a reliable method for its diagnosis and should at least be attempted before surgical intervention.

Uzunkoy A, Harma M, Harma M. Diagnosis of abdominal tuberculosis: Experience from 11 cases and review of the literature. *World J Gastroenterol* 2004; 10(24): 3647-3649 <http://www.wjgnet.com/1007-9327/10/3647.asp>

INTRODUCTION

Tuberculosis (TB) causes some 3 million deaths per year world wide and is increasing in incidence in developed, and developing countries. Abdominal TB, which may involve the gastrointestinal tract, peritoneum, lymph nodes or solid viscera, constitutes up to 12% of extrapulmonary TB and 1-3% of the total^[1,2]. The disease can mimic many conditions, including inflammatory bowel disease, malignancy and other infectious diseases^[3]. Diagnosis is therefore often delayed. This may not only result in mortality but also in unnecessary surgery. We therefore set out to establish the most useful diagnostic procedure(s) in the light of our experience and reports in the literature.

MATERIALS AND METHODS

A retrospective study of the files of patients admitted to Harran University Hospital from January 1996 to October 2003 was carried out. Cases of abdominal TB were identified and data on age, sex, clinical presentation, diagnostic investigations, treatment and outcome were abstracted.

RESULTS

Eleven patients, none of whom were immunocompromised, were diagnosed with abdominal TB during the period (Table 1). Nine cases had peritoneal TB, while the remaining two had TB of the colon. The median age was 39 years (range 18-65) and the ratio of males and females was 4:7.

The mean duration of symptoms was 14 wk (range 1-32 wk). Ascites was present in all cases, while 9 (81%) showed weight loss, 9 (81%) weakness, 8 (72%) abdominal mass, 8 (72%) abdominal pain, 7 (63%) abdominal distension, 5 (45%) anorexia and 4 (36%) night sweat.

The average hemoglobin was 8.2 g/dL and the average ESR was 50 mm/h (range 30-125). Levels of cancer antigen CA-125 were elevated in four patients.

Abdominal ultrasound (US) was carried out on all patients and abnormal findings were noted in all: ascites in all, tuboovarian mass in five, omental thickening in three, and enlarged lymph nodes (mesenteric, para-aortic) in two.

All patients also had computed tomography (CT) scans, with results consistent with US (Table 2).

At this stage, diagnoses of peritoneal carcinomatosis, colon cancer, Chron's disease and ovarian cancer were considered. Laparotomy was performed in the first six cases and the diagnosis of abdominal TB was made intraoperatively based on macroscopic findings, including multiple diffuse involvement of the visceral and parietal peritoneum, white 'miliary nodules' or plaques, enlarged lymph nodes, ascites, 'violin string' fibrinous strands and omental thickening, and confirmed by microscopic examination of biopsies of lymph nodes and peritoneal nodules and by positive polymerase chain reaction (PCR) for *Mycobacterium tuberculosis* (*M. tuberculosis*) on ascitic fluid taken during the procedure. Smears of ascitic fluid showed numerous lymphocytes but no acid-fast bacilli.

Laparoscopy was used in the examination of the next three cases. Biopsies were again taken and examined microscopically and confirmation of the diagnosis was made by PCR on ascitic fluid.

Table 1 Details of patients with abdominal tuberculosis

Case No.	Sex	Age (yr)	Clinical findings	Intervention	Diagnosis
1	M	38	Ascites, colonic obstruction, weight loss, weakness, abdominal distension, anorexia, retroperitoneal lymphadenopathy, bowel wall thickening	Laparotomy	Colon TB
2	F	26	Ascites, elevated CA-125 ($\times 4$), abdominal mass, weight loss, weakness, abdominal pain, anorexia	Laparotomy	Peritoneal TB
3	M	40	Ascites, abdominal mass, enlarged lymph nodes, weight loss, weakness, abdominal pain, abdominal distension, anorexia, bowel wall thickening	Laparotomy	Colon TB
4	F	54	Ascites, elevated CA-125 ($\times 3$), abdominal mass, weakness, abdominal pain, abdominal distension, night sweats	Laparotomy	Peritoneal TB
5	M	44	Ascites, omental thickening, enlarged lymph nodes, weakness, abdominal pain, anorexia	Laparotomy	Peritoneal TB
6	F	42	Ascites, tuboovarian mass, elevated CA-125 ($\times 4$), weight loss, weakness, abdominal pain, night sweats	Laparotomy	Peritoneal TB
7	M	65	Ascites, abdominal mass, weight loss, weakness, abdominal pain, abdominal distension	Laparoscopy	Peritoneal TB
8	F	51	Ascites, tuboovarian mass, positive family history of pulmonary TB, weight loss, weakness	Laparoscopy	Peritoneal TB
9	F	18	Ascites, elevated CA-125 ($\times 4$), tuboovarian mass, weight loss, weakness, abdominal distension	Laparoscopy	Peritoneal TB
10	F	20	Ascites, omental thickening, weight loss, abdominal pain, abdominal distension, anorexia, night sweats, retroperitoneal lymphadenopathy	Fine needle aspiration	Peritoneal TB
11	F	40	Ascites, abdominal mass, positive family history of pulmonary TB, omental thickening, weight loss, abdominal pain, abdominal distension, night sweats	Fine needle aspiration	Peritoneal TB

Table 2 CT scan characteristics of patients with abdominal tuberculosis

CT findings	No. of patients (%)
Ascites	11 (100)
Pelvic mass	5 (45)
Retroperitoneal lymphadenopathy	4 (36)
Mesenteric stranding	4 (36)
Omental stranding	3 (27)
Bowel wall thickening	2 (18)
Mesenteric lymphadenopathy	2 (18)

Because of this experience, the Radiology Department was alerted to the necessity of including abdominal TB in the differential diagnosis and the final two patients in the series were spared surgical intervention, the diagnosis was confirmed by PCR of ascitic fluid obtained by US-guided fine needle aspiration.

Only one patient had a chest radiograph suggestive of a new TB lesion. Two had a positive family history of pulmonary TB. None had acid-fast bacilli (AFB) in the sputum and the tuberculin test was positive in only two.

All patients were started on quadruple antituberculous therapy comprising rifampicin (10 mg/kg-d), isoniazid (5 mg/kg-d), ethambutol (15 mg/kg-d) and pyrazinamide (30 mg/kg-d) for two months and then maintained on rifampicin and isoniazid for 9-12 mo. Response was good in all patients. The mean follow-up time was 24 mo (range 19-38 mo).

DISCUSSION

In accord with other reports^[4,5], our 'typical' patient was a middle-aged female. Signs and symptoms observed were generally in line with those of other reports except that the percentage of our patients showing weight loss was the highest for any series. Fever was the most common finding (73%) in the series reported by Muneef *et al.*^[6], but our results agree with most other studies in reporting about half this incidence. The

most consistent finding, in our study and in the literature, was the presence of ascites, although Muneef *et al.*^[6] again differed in finding ascites present in only 61% of their patients.

Presence of TB at other sites or a patient with a family history of TB may be helpful in suggesting the diagnosis, but this occurs in somewhat less than 30% of patients. This may indicate that the majority of cases had primary lesions were acquired through the gastrointestinal tract. Given the preponderance of females affected, it may also be that some cases in females are acquired genitally (though not necessarily sexually). TB skin tests were positive in only about a quarter of patients in most reports but Demir *et al.*^[7] obtained a positive result in all their 26 patients.

Although US^[8] and CT scanning^[9] have been claimed to give definitive diagnoses, this was not the case in our series or in the other cases surveyed. Both US and CT were abnormal in all cases in most reports (though in only 80% of CT scans in the series reported by Muneef *et al.*^[6]) but findings were largely non-specific.

The great majority of reported cases were, like the first six cases in our series, diagnosed at laparotomy after they were initially misdiagnosed as tumors or carcinomas^[4-6,10-17]. In female patients, misdiagnosis was made even more likely by the raised levels of CA-125 that were apparently universally observed and the fact that an elevated level of CA-125 has been recognized as a marker of non-mucinous epithelial ovarian carcinomas^[13-17]. In the light of this finding, Thakur *et al.*^[13] went so far as to suggest that high serum CA-125 should always raise a suspicion of TB. However, the finding has not so far been validated in males.

Diagnosis at laparotomy was made largely by histology of frozen or paraffin-embedded sections, which typically revealed epithelioid granulomas with central caseous necrosis, although Muneef *et al.*^[6] reported 68% of peritoneal biopsies were positive by smear/culture. Zaidi and Conner^[12] performed PCR for *M. tuberculosis* on paraffin-embedded tissues.

With increasing experience, laparoscopy has become the diagnostic procedure of choice, both in our hospital and in the literature^[18-24]. Again, in most cases histology was the main confirmatory method, smear and culture were largely unhelpful.

PCR was used to confirm the diagnosis in two cases^[21,22].

Laparoscopy is, however, invasive and expensive, but was associated with an overall incidence of major complications in up to 5.7% of patients^[25]. Because of this, several investigators looked at abdominal paracentesis as a diagnostic method. Ascitic fluid in abdominal tuberculosis is exudative, usually containing 500 to 2000 cells. Lymphocytes typically predominate, although in some cases polymorphonuclear leukocytes were more abundant early in the process. Acid-fast stains were usually negative. Though culture might eventually be positive in up to a third of cases^[6], the time taken for growth (usually 6 wk) was too long to be useful in diagnosis.

The use of PCR to detect *M. tuberculosis* in abdominal tuberculosis was reported by Moatter *et al.*^[26]. In their study, as in most later ones^[12,21-23], DNA was extracted from tissues. They found that an IS6110 primer was detected in only 60% of specimens and another primer was necessary to detect the other 40%. Schwake *et al.*^[23] obtained a negative result in the two cases they tested, perhaps because they only used a single primer.

In all eleven patients presented here, PCR analyses for *M. tuberculosis* complex on ascitic fluid were positive. Protopapas *et al.*^[24] (single case) and Tzoanopoulos^[27] (3 patients) also successfully used PCR of ascitic fluid to obtain a diagnosis.

In the light of our accumulated experience, we would suggest that PCR of ascitic fluid obtained by US-guided fine needle aspiration is now the investigation of choice for patients with the described clinical and radiological presentations and should at least be attempted before surgical intervention. Our final two patients were diagnosed by this means. If the result was negative, diagnostic laparoscopy or, if this was not feasible, laparotomy should be performed.

Ascitic fluid adenosine deaminase (ADA) activity has been proposed as a useful diagnostic test for abdominal TB. In countries with a high incidence of TB and in high risk patients, measurement of ADA in ascitic fluid might be a useful screening test^[28]. However, in populations with a low prevalence of TB and a high prevalence of cirrhosis, ascitic fluid ADA activity has been good in accuracy but poor in sensitivity and imperfect in specificity^[29].

In the reports reviewed, there was only one recorded death due to TB in patients with abdominal tuberculosis receiving anti-TB therapy (most commonly, a four drug regimen for several mo) and that was in a patient with extensive involvement of other organs^[6]. The prognosis was therefore good if the condition was promptly diagnosed and treated, though the emergence of multi-resistant strains might alter this picture.

In conclusion, abdominal TB should be considered in the differential diagnosis of abdominopelvic masses, ascites or elevated CA-125. PCR for *M. tuberculosis* complex is a non-invasive method which can provide the diagnosis in most cases. If this test is negative and a high index of clinical suspicion remains, laparoscopy or, if this is not feasible, laparotomy should be performed.

Abstract

AIM: To estimate the amount of apoptosis among healthy HBsAg carriers, patients with chronic HBV infection treated with lamivudine and patients with chronic HCV infection treated with interferon alpha and ribavirin. Activity of apoptosis was evaluated by serum sFas/sFasL concentration measurement. Moreover dependence between apoptosis and HBV-DNA or HCV-RNA levels was studied.

METHODS: Eighty-six persons were included into study: 34 healthy HBsAg carriers, 33 patients with chronic HBV infection and 19 patients with chronic HCV infection. Serum levels of sFas/sFasL were measured by ELISA assay. HBV-DNA and HCV-RNA were measured by RT-PCR assay. Levels of sFas/sFasL were determined before and 2 and 12 wk after therapy in patients with chronic hepatitis B and C infection. HBV-DNA or HCV-RNA was detected before treatment and 6 mo after treatment.

RESULTS: Twenty-four (71%) healthy HBsAg carriers showed HBV-DNA over 10^5 /mL, which was comparable to the patients with chronic hepatitis B. Independently from HBV-DNA levels, the concentration of sFas among healthy HBsAg carriers was comparable to healthy persons. Among patients with chronic hepatitis B and C, the concentration of sFas was significantly higher in comparison to healthy HBsAg carriers and healthy persons. In chronic hepatitis B patients the concentration of sFas was decreased during lamivudine treatment. Among chronic hepatitis C patients the concentration of sFas was increased during IFN alpha and ribavirin treatment. sFasL was not detected in control group. Furthermore sFasL occurred more frequently in chronic hepatitis C patients in comparison to chronic hepatitis B patients.

CONCLUSION: There are no correlations between apoptosis and HBV-DNA levels. However there is an association between apoptosis and activity of inflammation in patients with chronic HBV infection. Apoptosis can be increased in patients with chronic hepatitis C by effective treatment which may be a result of apoptosis stimulation by IFN- α .

INTRODUCTION

Apoptosis is one of the factors prolonging inflammation in chronic hepatitis B and C. Impaired apoptosis activity or its hyperactivity may induce unfavourable course of HBV and HCV infection. Fas and FasL are proteins that regulate activity of apoptosis^[1]. Fas is dominantly localized on liver cells. Activation of Fas is an after-effect of fusion with FasL lymphocyte receptors. These particles are recognised defining coefficient state of stimulation apoptosis^[2,3]. The concentration of Fas/FasL in serum patients with chronic hepatitis B and C can define the success of therapy.

The aim of this study was to define the activity of apoptosis among healthy HBsAg carriers and patients with chronic hepatitis B and C. Apoptosis was defined by use of sFas and sFasL serum concentration measurements. Moreover the apoptosis activity was compared with HBV-DNA or HCV-RNA serum levels. sFas and sFasL levels were monitored during antiviral therapy and afterwards depending on treatment effectiveness.

MATERIALS AND METHODS

The study included 86 persons divided into three groups: HBsAg carriers ($n = 34$, 15 women and 19 men, aged 20-43 years), chronic hepatitis B patients ($n = 33$, 10 women and 23 men, aged 18-76 years), and chronic hepatitis C patients ($n = 19$, 6 women and 13 men, aged 18 - 76 years). Criteria for inclusion of HBsAg carriers group were: HBsAg presence for at least 1 year; ALT, AST activity, concentration of bilirubin, albumin and PT in normal range in one-year period of observation (triple investigation); no changes in USG investigation of liver; absence of drug or alcohol abuse, autoimmune disease, HIV, delta virus or hepatitis C coinfection, and neoplastic and other serious diseases which might alter apoptosis activity. Criteria for inclusion of chronic hepatitis B patients were: HBsAg, HBeAg and HBV-DNA in serum for 6 mo; ALT activity over 80 IU; inflammatory changes in histological evaluation of liver tissue. All chronic hepatitis B patients were treated with nucleic analogue - lamivudine (Zeffix[®], GlaxoSmithKline, Great Britain) in a dose of 100 mg/24 h for 12 mo.

Criteria for inclusion of chronic hepatitis C patients were: presence of anti-HCV and HCV-RNA in serum for 6 mo, ALT activity over 80 IU and inflammatory changes in histological evaluation of liver tissue.

Patients with chronic HCV infection were treated with Rebetron[®] (IFN- α 2 b and ribavirin, Schering-Plough, USA): IFN- α 2 b in 9 M IU/wk and ribavirin 1 000-1 200 mg /24 h for 12 mo.

The standard concentration of sFas and sFasL in serum was evaluated in 12 healthy persons, 8 women and 4 men, aged 26-46 years. Individuals in control group were HBs and anti-HCV negative and ALT activity in serum was within normal range during 6 mo observation.

Methods

HBsAg and HBeAg in serum were detected by MEIA test (ABBOTT, USA).

Extraction of HBV DNA from sera of patients

HBV-DNA was extracted from 200 μ L of patients' sera the gene

elute mammalian genomic DNA Miniprep kit (Sigma, USA) for DNA isolation. Part of HBV-DNA was amplified by PCR system with pair of complement primer to conservative part of genome (sense 5'-AG GGG AGG AGA TTA GGT TAA-3' antisense 5'-AGG AGT GCG AAT CCA CAC TC-3') in 20 µL reaction mixture containing 200 µmol/L dNTPs, 0.4 µmol/L all primers, 1.5 mmol/L MgCl₂, 1.0 U Taq polymerase (Sigma) and 4 µL DNA solution. Forty cycles of amplification were performed (at 96 °C for 30 s, at 57 °C for 60 s and at 72 °C for 60 s). The products of amplification were appointed in 20 g/L agar gel by electrophoresis, and stained by ethidium bromide. Electrophore was visualized in record system and computer analysis UVI-KS400i/Image PC (Syngen Biotech, USA). Part of solution from DNA was kept at temperature -20 °C for further stages of work.

In order to detect HBV-DNA sequences in sera of the patients, the conventional PCR method with primers to conserved pre-S/S region of the genome was used. Thermal cycling was performed using the following conditions: initial incubation at 96 °C for 120 s, and then 40 cycles at 94 °C for 30 s, at 50 °C for 30 s and at 72 °C for 60 s.

HBV-DNA concentration in sera was evaluated by real-time detection PCR based on TaqMan chemistry. Amplification was performed in 25 µL reaction mixture containing 2×TaqMan Universal Master Mix (Applied Biosystems, USA) with uracil N'-glycosylase, 30 pmol of forward primer, 30 pmol of reverse primer, 30 pmol TaqMan probe (5'-FAM) and 5 µL of isolated DNA. After incubation for 2 min at 50 °C, which enabled uracil N'-glycosylase to inactivate possible contaminating amplicons, incubation for 10 min at 95 °C allowed AmpliTaq Gold polymerase to activate and inactivate the uracil N'-glycosylase. Next cycles of PCR were moved. Number of copies was counted by interpolation from definite standard curve.

Presence of anti-HCV antibodies in serum was detected by MEIA (ABBOTT, USA). Test consisted of recombinant core proteins for HCr43, structural proteins for c 200 (NS3 and NS4) and unstructured proteins for c 100-3 (NS4) and NS5.

Extraction of HCV-RNA from blood of patients

HCV-RNA was isolated from 50 µL blood of patients. Parts of viral HCV-RNA were amplified in arrangement of RT nested PCR reaction with two peers nested primers, complementary to conservative part of genome virus (external primers: sense 5'-TCT AGC CAT GGC GTT AGT ATG AGT GT-3', antisense 5'-CACTCGCAAGCACCCATCAGGCA GT-3'; internal primers: sense 5'-GGC GAC ACT CCA CCA TAG AT-3', antisense 5'-GTG CAC GGT CTA CGA GAC CT-3'). Stages of reverse transcription as well as first PCR were executed in one test-glass in 20 µL reaction mixture containing 200 mmol/L dNTPs, 1 mmol/L from each steam external primer, 1.5 mmol/L MgCl₂, 0.75 mmol/L MnSO₄, 2.0 At Tth of polymerase (EPICENTRE®, USA) as well as 8 mL RNA. After 30 min of incubation at 60 °C for 40 cycles of amplification were executed (at 94 °C for 30 s, at 55 °C for 60 s, at 72 °C for 60 s). A 1 mL product of first PCR was amplified with par of internal primers in 20 mL reaction mixture containing 200 mmol/L dNTPs, 0.4 µmol/L from each primer, 1.5 mmol/L MgCl₂, 1.0 U Taq of polymerase (Sigma, USA). Afterwards, 40 cycle of amplification were performed (at 94 °C for 30 s, at 55 °C for 60 s, at 72 °C for 60 s). The products of amplification were evaluated in 20 g/L of agar gel by electrophoresis and stained by brom etydyne. The electrophore was visualized in VI-KS400i / Image of PC system (Syngen Biotech, USA).

The minimum detectable dose of HCV was 50 copies per mL of serum.

Concentration of sFas and sFasL

The sFas/sFasL concentration in serum was measured twice by quantitative sandwich enzyme immunoassay (ELISA) technique (Bender Med Systems, Austria).

Informed consent was obtained from each patient and the Bioethics Committee at the Medical University of Bia³ystok approved the study protocol.

Statistical analysis

Statistical analysis was performed by use of non-parametric Mann-Whitney U, Wilcoxon rank and Pearson tests. $P < 0.05$ was considered statistically significant.

RESULTS

Twenty-four (71%) of 34 healthy HBsAg carriers showed active HBV replication. The HBV-DNA levels exceeding 10⁵/mL were observed in 22 (65%) HBsAg carriers. According to National Institutes of Health, such persons should be considered for antiviral treatment as chronic hepatitis B patients^[4,5]. All individuals in chronic hepatitis B group presented HBV-DNA levels exceeding 10⁵/mL.

Independently from HBV-DNA levels, the concentration of sFas among HBsAg carriers and healthy persons was comparable ($x = 15.4$ ng/mL, $x = 18.4$ ng/mL, $P < 0.05$). Among patients with chronic HBV or HCV infection, the concentration of sFas was significantly elevated in comparison to healthy persons and healthy HBsAg carriers ($x = 29.0$ ng/mL, $x = 28.0$ ng/mL, $P < 0.05$), (Figure 1A). There were no statistical differences between chronic hepatitis B and C patients (Table 1).

Table 1 Serum sFas concentration and frequency occurrence and concentration of sFasL in serum of patients

	<i>n</i>	sFas-medium ng/mL	patients with sFasL (%)	sFasL-medium ng/mL
Healthy	12	18.4	0	0
Total healthy HBsAg carriers	34	15.4	56	0.9
Healthy HBsAg carriers				
HBV-DNA <10 ⁴ /mL or 0	12	13.6	58	0.6
Healthy HBsAg carriers				
HBV-DNA >10 ⁵ /mL	22	16.3	55	1.0
Chronic hepatitis B	33	29	32	0.18
Chronic hepatitis C	19	28	68	1.0

sFasL was not detected in control group. This protein was identified more frequently in chronic hepatitis C patients than in chronic hepatitis B patients.

ALT activity reached normal values during the first three months of lamivudine treatment in all chronic hepatitis B patients (114 IU before treatment vs 32 IU after 3 mo of therapy, $P < 0.001$). In the same period the concentration of sFas was decreased in all patients (before treatment $x = 29.0$ ng/mL, after 14 d of therapy $x = 25.0$ ng/mL, after 3 mo of therapy $x = 22.0$ mg/mL). FasL expression in chronic hepatitis B group was decreased 14 d after an antiretroviral treatment and then returned to initial values.

The normalization of ALT was observed 2 wk after therapy in patients with chronic hepatitis C (102 IU before treatment vs 30 IU after 14 d of therapy). All of the chronic hepatitis C patients included in our study had undetectable HCV-RNA after 6 mo of treatment. The highest concentration of sFas was observed in chronic hepatitis C patients with virological response to antiretroviral treatment. The concentration of this protein kept increas during therapy (all HCV infected patients: before treatment $x = 28.0$ ng/mL, after 14 d $x = 31.0$ ng/mL, after 3 mo of therapy $x = 30.0$ mg/mL patients with HCV infection had good response: before treatment $x = 35.0$ ng/mL, after 14 d $x = 39.0$ ng/mL, after 3 mo of therapy $x = 39.0$ mg/mL), (Figure 1B). The number of patients with sFasL occurrence in serum was the highest before and 3 mo after treatment (83%) among all patients who were effectively treated.

Figure 1 Concentration of sFas and sFasL in HBV infected patients and chronic hepatitis C patients. A: Concentration of sFas in HBV infected patients B: Concentration of sFasL in chronic hepatitis C patients.

DISCUSSION

Fas and FasL are “death domain”, proteins which regulate the process of apoptosis in patients with chronic inflammatory diseases, such as viral hepatitis^[6-9]. The Browicz-Kupffer cells participate in the process. It stimulates synthesis of cytokines regulating biosynthesis of Fas in hepatocytes. Recent studies indicated that it was dependent on the liver or serum sFas concentration and apoptosis activity as well as hepato-cytotoxic processes in viral chronic hepatitis patients^[10,11].

In this study we showed that the concentration of sFas in healthy persons and healthy HBsAg carriers was comparable and not dependant on the HBV-DNA levels. It was confirmed trough the lack of correlation between HBV-DNA levels and apoptosis. The concentration of sFas was significantly higher in patients with chronic hepatitis B infection than in healthy HBsAg carries, independent similar levels of HBV-DNA ($>10^5$ /mL).

Interestingly a large number of healthy HBsAg carriers presented sFasL in serum. The possible explanation of this fact is that HBV might stimulate expression of FasL on lymphocytes. The complex FasL and Fas could activate apoptosis and cytotoxic T lymphocytes. Activation of inflammation processes in the liver could influence FasL activity, associated with Fas and FasL complex formation. It could explain more uncommon occurrences of sFasL in patients with chronic hepatitis B than in healthy HBsAg carriers.

Hepatitis C virus core proteins could activate Fas particles expressed on hepatocytes through TNF-RI receptors stimulation. These receptors could enhance cysteine protease and subsequently interleukin-1 β -converting enzyme (ICE) and FADD like ICE (FLICE-Caspase 8) synthesis. Moreover ICE and FLICE could activate nuclear protein degradation, resulting in irreversible damage of cell DNA^[12-14].

However HCV could also inhibit apoptosis. HCV non-structural protein NS5A could suppress synthesis of Caspase 3, protein's kinase A and TNF- α stimulating polymerase^[15-17]. The protein's kinase A is known as an apoptosis initiating factor.

In patients with chronic hepatitis C, insufficient apoptosis activity could cause chronic inflammation^[18]. According to Di Martino *et al.*^[19] activity of apoptosis in chronic hepatitis C patients

was proportional to HCV-RNA levels. Ozaslan *et al.*^[20] suggested a positive dependence on chronic hepatitis C intensity and serum sFas concentration.

Our study showed a significant increase of sFas concentration in HCV infection patients compared to healthy persons, as well as a further raise in sFas serum levels during antiviral therapy. Moreover, we observed an association between high activity of apoptosis expressed as serum sFas concentration and sFasL occurrence, and antiviral treatment effectiveness.

Increased expression of FasL on peripheral blood mononuclear cells might be caused by IFN- α apoptosis stimulation^[21]. This fact is a probable explanation of the increased number of patients presenting sFasL during antiviral therapy. It may also confirm the beneficial influence of apoptosis in controlling chronic inflammation during HCV infection.

sFas serum concentration in chronic hepatitis B and C patients was comparable before treatment, but after antiviral therapy the concentration of this protein behaved in a different way. These differences underlined the diverse pathogenesis of an inflammation during chronic HBV and HCV infections. Our results indicated possible, new trends in antiviral therapy efficacy.

In conclusion, inflammation activity is associated with apoptosis in chronic hepatitis B, and there is no correlation between apoptosis and HBV-DNA concentrations. In HCV infection the effective therapy is accompanied with high activity of apoptosis, which can be a result of IFN- α activity.

Abstract

AIM: To investigate the effect of pyrrolidine dithiocarbamate (PDTC), a novel nuclear factor- κ B (NF- κ B) inhibitor, on expression of multiple inflammatory mediators and neutrophilic inflammation of cold preserved grafts after rat liver transplantation and its significance.

METHODS: Orthotopic liver transplantation (OLT) was performed after 24 h of cold storage using University of Wisconsin solution with varied concentrations of PDTC. We determined the time course of NF- κ B activation and expression of multiple inflammatory signals, such as tumor necrosis factor- α (TNF- α), cytokine-inducible neutrophil chemoattractant (CINC), and intercellular adhesion molecule-1 (ICAM-1) by ELISA methods. Serum alanine aminotransferase (ALT), intrahepatic myeloperoxidase (MPO)/WBC (a measure of neutrophil accumulation) and Mac-1 expression (a measure of circulating neutrophil activity) were also evaluated.

RESULTS: PDTC decreased NF- κ B activation induced by prolonged cold preservation in a dose dependent manner (from 20 mmol/L to 60 mmol/L), diminished TNF- α , CINC, ICAM-1 proteins in the grafts, and reduced the expression of increases in plasma TNF- α levels induced by prolonged cold preservation. Neutrophilic inflammation of the graft was significantly suppressed after preservation with PDTC ($P < 0.05$). The total neutrophil accumulation in PDTC (40 mmol/L) group (7.04 ± 0.97) was markedly reduced compared to control group (14.07 ± 1.31) ($P < 0.05$). Mac-1 expression was significantly reduced in PDTC (40 mmol/L) group ($181 \pm 11.3\%$) compared with the control group ($281 \pm 13.2\%$) ($P < 0.05$) at 6 h after reperfusion. Furthermore, PDTC inhibited the increased serum ALT levels after liver transplantation.

CONCLUSION: PDTC can inhibit NF- κ B activation and expression of the inflammatory mediators, which are associated with improved graft viability via inhibiting intrahepatic neutrophilic inflammation. Our study suggests that a therapeutic strategy directed at inhibition of NF- κ B activation in the transplanted liver might be effective in

reducing intrahepatic neutrophilic inflammation, and would be beneficial to cold preserved grafts.

INTRODUCTION

Poor graft viability is a frequent complication of liver transplantation, the incidence of primary graft nonfunction was reported to be 2-23%^[1]. Furukawa *et al.*^[2] reported that the primary nonfunction rate and retransplantation rate significantly rose as cold-ischemia time increased, especially beyond 20 h. It is currently accepted that sinusoidal endothelial cells (SECs) are the primary targets of cold ischemia-reperfusion injury^[3], however, parenchymal cell damage has direct effects on the deterioration of liver function. The functional impairment of the grafted liver, therefore, seems to be complex and multifactorial. Polymorphonuclear leukocytes (PMNs) have been implicated as a causal factor in the development of ischemia-reperfusion injury^[4,5]. In the previous study, we found the promoted neutrophil accumulation and activity in cold preserved grafts, and the evidence confirmed that cold preservation-reperfusion injury of liver allografts was a chain of cascades induced by activation of a variety of inflammatory mediators from early to late phase after reperfusion^[6]. Protective strategies were confused that inhibition of one mediator was always compensated by activation of other mediators from different pathways^[8]. Researchers are anxious to look for the core mediators that can trigger multiple proinflammatory genes. Recent studies have shown that transcription factor NF- κ B plays an essential role in regulation of these kinds of genes whose products take part in the pathogenesis of preservation-reperfusion injury in liver allografts^[6-11]. Hence, it is hypothesized that NF- κ B may be an appropriate target for treatment of reperfusion injury. NF- κ B appears to have both beneficial and harmful effects on liver transplantation^[12-16]. It was reported that NF- κ B could promote liver regeneration and prevent apoptosis^[14], and contribute to the inflammatory response of ischemia/reperfusion^[15]. In the present study, we determined the time course of NF- κ B activation after OLT in relation to the expression of tumor necrosis factor- α (TNF- α), intercellular adhesion molecule-1 (ICAM-1), and cytokine-induced neutrophil chemoattractant (CINC). The selectivity of pyrrolidine dithiocarbamate (PDTC) as an *in vivo* inhibitor of NF- κ B activation, the effects of PDTC on OLT-induced expression of these inflammatory gene products and the resultant hepatic neutrophilic inflammation, and the action of NF- κ B were studied.

MATERIALS AND METHODS

Reagents

Following reagent were purchased: Pyrrolidine dithiocarbamate (PDTC) from Sigma, nuclear extract kit and NF- κ B p65

Transcription factor assay kits from Active Motif, Pierce BCA protein assay reagent and MPO assay reagent from Jiancheng, Nanjing, ELISA assay kit for CINC, TNF- α and ICAM-1 from Amersham, Buckinghamshire, UK, FACS lysing solution from Becton Dickinson, San Jose, CA and FITC-labeled mouse anti-rat CD11b antibody from Camarillo, CA.

Animals

Male wistar rats, weighing 200 to 250 g, were purchased from Nanjing Medical Institute Animal Care Committee (Grade II, Certification No 2002-0017). Prior to the experiment, rats were fasted for 12 h and allowed free access to water.

Experimental protocol

Rats were allocated randomly into four groups (36 rats in each group): control group in which the grafts were harvested with injection of University of Wisconsin (UW) solution, PDTC20 group in which the grafts were harvested with the preservation solution added by 20 mmol/L PDTC, PDTC40 group in which the grafts were harvested with the preservation solution added by 40 mmol/L PDTC, and PDTC60 group in which the grafts were harvested with the preservation solution added by 60 mmol/L PDTC.

Liver harvesting and orthotopic transplantation were performed according to the methods described by Kamada and Calne^[17], with some minor modifications^[18], and the hepatic artery was not reconstructed. The graft liver was preserved with University of Wisconsin (UW) solution at 4 °C for 24 h. The portal vein clamping time in recipients varied from 18 to 20 min, implantation time was less than 50 min, all the procedures took about 60 min. No significant difference was seen in portal clamping time between groups. The recipients were sacrificed 0 h, 0.5 h, 1 h, 2 h, 4 h, and 6 h after reperfusion. Blood samples were collected from the hepatic vein draining the left lateral lobe as previously described to determine the serum levels of alanine aminotransferase (ALT) and neutrophil activity at indicated time points. The median lobe of the liver was carefully excised at the designated time point and stored at -80 °C for analysis.

Evaluation of NF- κ B activity

Preparation of nuclear extracts using a nuclear extract kit and determination of p65/relA subunits of NF- κ B using a TransAM NF- κ B p65 kit according to the manufacturer's instructions. The concentration of p65/relA subunits in liver tissue homogenates was standardized to the total nuclear protein content in each specimen as measured by the Pierce BCA protein assay reagent. NF- κ B activity was expressed as p65/relA subunits μ g/mg total nuclear protein.

Graft function test

Cellular function and damage were estimated by the peak serum ALT activity in six rats from each group at selected time points after reperfusion. Serum ALT was measured using the Opera clinical chemistry system.

Measurement of TNF- α , CINC and ICAM-1

Serum TNF- α and CINC were measured in duplicate by using the immunoassay kits according to the manufacturer's instructions.

Hepatic levels of TNF- α , CINC, and ICAM-1 were determined as previously described^[19]. In brief, the medial hepatic lobe was weighed and homogenized in 5 mL of 0.1 mol/L phosphate buffer (pH 7.4) containing 0.5 g/L of sodium azide at 4 °C. The homogenates were centrifuged at 2 000 r/min for 10 min to remove solid tissue debris. The supernatant was assayed using a rat ELISA system. The concentration of antigens in liver tissue

homogenates was standardized to the total protein content in each specimen as measured by the Pierce BCA protein assay reagent. The results were expressed as pictograms per gram of tissue (pg/g).

Intrahepatic neutrophil accumulation assessment

The activity of MPO, an enzyme in azurophilic granules of neutrophils, was used as a well-established marker to quantitate tissue neutrophil sequestration^[20]. Frozen livers were thawed and extracted for MPO, following the homogenization and sonication procedure as described in the manufacturer's protocol. One unit of MPO activity was defined as the amount of enzyme able to reduce 1 μ mol of peroxide/min. Results were expressed as units of MPO activity per gram of tissue. To control intravascular leukocytosis, we calculated the ratio of MPO activity in tissue to WBC count in peripheral blood, and expressed it as MPO/WBC.

Circulating neutrophil activity analysis

Blood samples collected from each animal at each time point were subjected to flow cytometric analysis^[21]. For CD11b and L-selectin determination, 50 μ L of samples were incubated with 10 μ L of PE-labeled mouse anti-rat L-selectin antibody and 10 μ L of FITC-labeled mouse anti-rat CD11b antibody for 15 min, then 1 mL of FACS lysing solution was added for 10 min, followed by centrifugation at 1 500 r/min for 5 min. Cell pellets were washed and then resuspended in 500 μ L of PBS. The cells were read on a Becton-Dickinson FACS calibur.

Statistical analysis

The data were expressed as mean \pm SE. Statistical analysis was performed using analysis of variance in SPSS software (version 11.0 for windows), followed by SNK multiple comparisons. *P* less than 0.05 were considered statistically significant.

RESULTS

PDTC inhibited NF- κ B activation in grafts of OLT rats

The time course of NF- κ B activity in liver tissue was established by evaluating p65/relA subunits in nuclear extracts from the whole liver obtained at various time points. In the control group, the activity of NF- κ B in preserved graft increased slightly 0.5 h after reperfusion, and markedly 1 h after reperfusion, peaked at 2 h of reperfusion and decreased 4 h after reperfusion (Figure 1). PDTC suppressed OLT-induced p65/relA subunit increase in a dose-dependent manner. PDTC administration did not affect the time course for maximal NF- κ B activation after OLT (Figure 1).

PDTC inhibited time course of expression of inflammatory mediators in grafts of OLT rats

We determined the time course of OLT-induced expression of TNF- α , CINC, and ICAM-1 in the same tissues as used for NF- κ B p65 transcription factor assay. We compared TNF- α , CINC, and ICAM-1 protein levels in tissue homogenates of livers treated by PDTC with those of livers untreated by PDTC. We observed different kinetics in the expression of inflammatory mediators. TNF- α expression was maximal 1 to 2 h after reperfusion, whereas CINC and ICAM-1 expression peaked 2 to 4 h after reperfusion (Figure 1). This was preceded by NF- κ B activation.

Pretreatment with 20, 40, and 60 mg/kg of PDTC suppressed the expression of these proteins, although the response was variable (Figure 1). Suppression by PDTC of OLT-induced expression of these proteins did not show a clear dose-dependency. Maximal inhibition of CINC and ICAM-1 expression was observed at a PDTC concentration of 40 mmol/L. Maximal inhibition of TNF- α expression was observed at a PDTC concentration of 60 mmol/L.

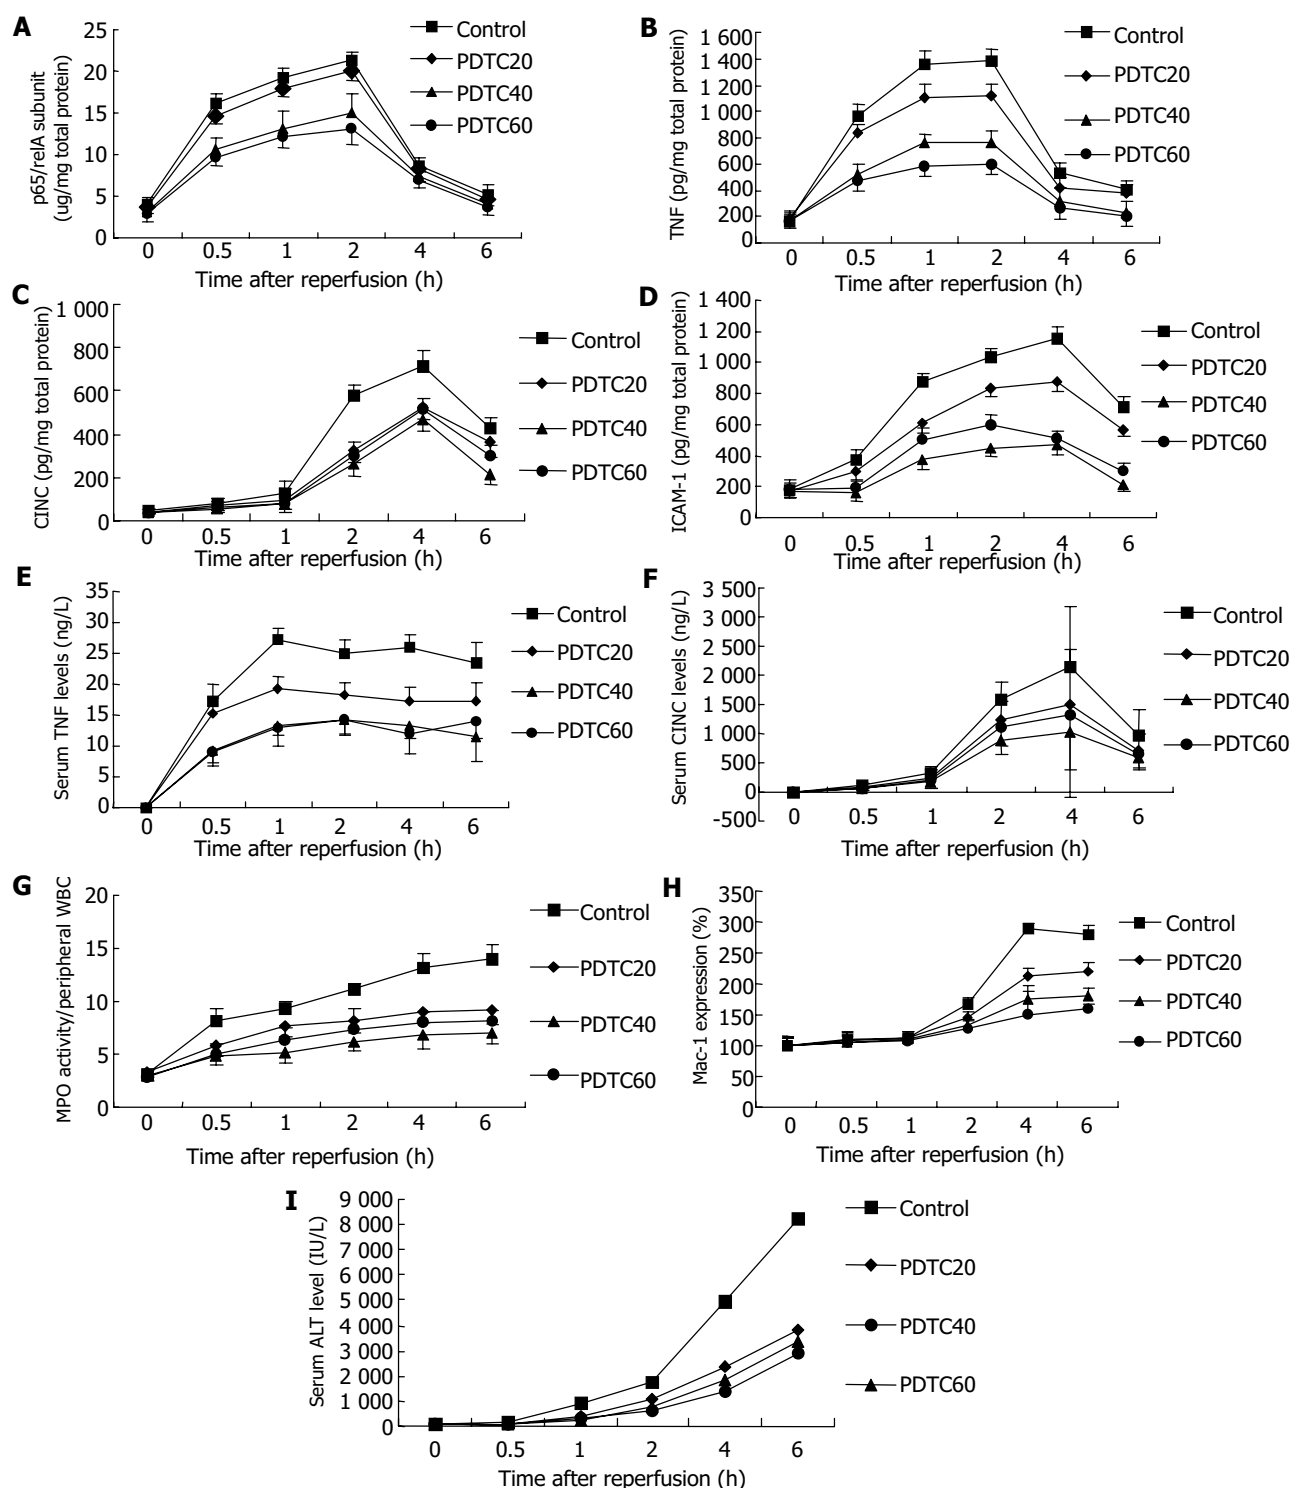

Figure 1 Effect of PDTC on NF- κ B (A), response of inflammatory mediators (B-D), systemic inflammatory recipients (E-F), intrahepatic neutrophil accumulation (G), Mac-1 expression (H), and serum ALT level (I) in OLT rats. Results are the mean \pm SD of six rats for each period in each group. A: Intrahepatic p65/reIA subunit levels were significantly inhibited in the PDTC cold-preserved group compared with the control group ($P<0.05$). P65/reIA subunit was significantly different in three preserved groups ($P<0.05$). Intrahepatic inflammatory mediator levels were significantly inhibited in the PDTC cold-preserved group compared with the control group ($P<0.05$). B: TNF- α was significantly different in three-preserved groups within 0.5 h of reperfusion ($P<0.05$), the maximal level reached at 1 h after reperfusion; C: CINC was significantly different in three preserved groups within 2 h after reperfusion ($P<0.05$), the maximal level reached at 4 h after reperfusion; D: ICAM-1 was significantly different in three-preserved groups within 0.5 h of reperfusion ($P<0.05$), the maximal level reached at 4 h after reperfusion. E: Serum TNF- α levels significantly inhibited in the PDTC cold-preserved group, compared with the control group since 0.5 h after reperfusion ($P<0.05$). There is no significantly different in PDTC 40 and PDTC 60 groups ($P<0.05$). F: Serum CINC levels significantly inhibited in the PDTC cold-preserved group, compared with the control group since 2 h after reperfusion ($P<0.05$). Serum CINC was significantly different in three-preserved groups ($P<0.05$). G: Intrahepatic neutrophil accumulation was significantly inhibited in the PDTC cold-preserved group, compared with the control group ($P<0.05$). Intrahepatic neutrophil accumulation was significantly different in three-preserved groups ($P<0.05$). H: Mac-1 expression in circulating neutrophil was significantly inhibited in the PDTC cold-preserved group, compared with the control group at 2 h after reperfusion ($P<0.05$). There was no great different between Mac-1 expression in PDTC40 and PDTC60 ($P<0.05$). I: Serum ALT was significantly inhibited in the PDTC cold-preserved group, compared with the control group ($P<0.05$); which was significantly different in three-preserved groups ($P<0.05$).

PDTC inhibited levels of systemic TNF- α and CINC response in OLT rats

The effects of PDTC on plasma TNF- α and CINC are shown in Figure 1. Pretreatment with PDTC at concentrations of 20, 40, and 60 mmol/L reduced the OLT-induced plasma TNF- α levels to 66%, 51%, 46% and plasma CINC levels to 70%, 48%, and 61% 4 h after reperfusion, respectively.

PDTC reduced neutrophil sequestration in grafts of OLT rats

We utilized the MPO biochemical assay to measure tissue neutrophil infiltration during the course of reperfusion. In control transplant livers, MPO/WBC was significantly elevated within 30 min of reperfusion than that in non-reperfusion liver tissue and remained significantly elevated throughout the 6 h of reperfusion. PDTC reduced the reperfusion-induced PMN accumulation (Figure 1). Maximal inhibition was observed at a PDTC concentration of 40 mmol/L that correlated with the inhibition of OLT-induced intrahepatic CINC and ICAM-1 expression.

PDTC inhibited circulating neutrophil activity in OLT rats

The CD11b content in circulating neutrophils was quantitatively evaluated by flow cytometric analysis at 0, 0.5, 1, 2, 4 and 6 h after the onset of reperfusion. In the control group, Mac-1 expression at the control time point (0 h) showed low levels of staining for CD11b [mean fluorescence intensity (MFI) = 76.75 ± 19.15], which reached 167% of baseline levels at 2 h, and 289% of baseline levels at 4 h, respectively, and remained constantly elevated at 6 h (281%) after reperfusion in control group (Figure 1).

PDTC inhibited Mac-1 expression in circulating neutrophils in a dose-dependent manner (Figure 1). Maximal inhibition was observed at a PDTC concentration of 60 mmol/L that correlated with the inhibition of OLT-induced systemic TNF- α response but not systemic CINC response, indicating that TNF- α was a much more strong inflammatory mediator for neutrophil activation.

PDTC ameliorated postransplant liver function

Serum ALT levels increased 0.5 h after reperfusion, remained greatly elevated throughout the 6 h reperfusion, and increased significantly in the 18 h and 24 h cold-preserved groups, compared with those in the 6 h group during the 6 h observation (Figure 1). PDTC ameliorated liver function after transplantation, the maximal increase was observed at a PDTC concentration of 40 mmol/L. PDTC administration did not affect the time course for maximal graft injury after OLT (Figure 1).

DISCUSSION

In this study, we extended our investigation on the pathogenesis of neutrophilic graft inflammation following rat orthotopic liver transplantation to assess the potential contribution of transcription factor after NF- κ B^[6]. Since transcription factors could determine cellular phenotypes by specifying protein production^[22], it is particularly interesting to relate changes in activation of transcription factors such as NF- κ B, to expression of a specific protein and evolution of biological relevant end points^[23-25]. We studied the expression of TNF- α , ICAM-1 and CINC because of their critical roles in the reperfusion-induced inflammatory responses. We demonstrated that reperfusion-induced NF- κ B activation *in vivo* preceded the expression of TNF- α , CINC and ICAM-1. In our rat model of orthotopic liver transplantation, we observed a link among NF- κ B activation, systemic and intrahepatic TNF- α and CINC responses, intrahepatic ICAM-1 expression, neutrophilic inflammation, and graft injury. In addition, we found that inhibition of NF- κ B activation with PDTC decrease local TNF- α ,

CINC and ICAM-1 expression, ameoliated neutrophilic inflammation, and improve graft function. These observations support the hypothesis that NF- κ B activation is critical for early graft injury in liver transplantation.

Dithiocarbamates, such as PDTC, represent a class of antioxidants reported to be potent inhibitors of NF- κ B and are capable of inhibiting the inflammatory process associated with the activation of NF- κ B^[26,27]. The most effective inhibitor of NF- κ B appears to be the pyrrolidine derivative of dithiocarbamate (PDTC) as a result of its ability to traverse the cell membrane and its prolonged stability in solution at physiological pH. PDTC, as well as other antioxidants, may inhibit NF- κ B by suppressing the production of intracellular reactive oxygen species^[26]. But it is well established that inhibition of NF- κ B is a major mechanism of the anti-inflammatory actions of PDTC^[27]. In our study, PDTC probably blocked neutrophilic inflammation in part by diminishing NF- κ B-dependent transcription of CINC and ICAM-1 expression. Blocking NF- κ B activation might also diminish the transcription of a variety of other genes involved in the production of inflammatory mediators.

It was interesting that PDTC at 60 mmol/L caused less inhibition of OLT-induced expression of CINC and ICAM-1 than PDTC at 40 mmol/L PDTC, although the higher concentration exerted greater inhibition of NF- κ B activation. This dissociation between inhibition of NF- κ B activation and ICAM-1, CINC expression might be explained by involvement of AP-1 in mediating the response^[14]. Thus, it is likely that 60 mmol/L PDTC inhibited the NF- κ B-mediated ICAM-1 and CINC expression, but augmented AP-1-mediated transcription of the ICAM-1 and CINC expression, the inhibitory effect of PDTC mediated through NF- κ B inhibition was consequently offset by the AP-1-mediated stimulatory effect, which needs further work to identify. In addition, PDTC at 60 mmol/L caused less neutrophil accumulation in the grafts, but the neutrophil activity correlated with less improvement of graft injury than 40 mmol/L PDTC, implying that local accumulation of activated neutrophils is the definitive factor of local neutrophilic inflammation.

The findings that PDTC administration ameoliated liver injury at 0.5 h and 1 h after reperfusion, as measured by serum ALT levels, were also noted to have some effects on neutrophil-independent phase of liver injury associated with OLT. In this study, neutrophil sequestration occurred quickly within 0.5 h after reperfusion, with no changes in Mac-1 and L-selectin expression at 0.5 h and 1 h time points. Previous studies demonstrated that increased expression of Mac-1^[28] and shedding of L-selectin^[29] were important to neutrophil-mediated injury. Hepatic injury at this time point was neutrophil-independent and was mediated by cytosolic xanthine oxidase and mitochondria in damaged hepatocytes^[30], the most relevant oxidant stress occurred initially in the vasculature and was produced by Kupffer cells^[31]. Our data suggested that there was a protective effect of PDTC in the liver at 0.5 h and 1 h after reperfusion, which might be mediated by antioxidants or Kupffer cells. In this study, the data showed that PDTC inhibited intrahepatic TNF- α expression in a dose-dependent manner. A study showed that TNF- α was probably from activated Kupffer cells in cold-preserved livers^[32], suggesting that the presence of primed Kupffer cells during extended cold preservation might result in overresponse and excessive production of TNF- α in the initial phase of reperfusion. The decreased expression of TNF- α in PDTC treatment group might in part reflect the inhibition of Kupffer cells.

In summary, the pathophysiological mechanisms of the protective effect of PDTC *in vivo*, appear to be pluripotent, comprising both antioxidative properties and inhibition of NF- κ B. Inhibiting early NF- κ B activity can protect against early graft injury in prolonged cold preservation after liver transplantation.

Abstract

AIM: To study the early diagnosis and management of familial adenomatous polyposis (FAP).

METHODS: Eight pedigrees of FAP were collected and their pedigree trees were protracted. Clinical characteristics and treatment outcomes of FAP patients in these kindreds were analysed.

RESULTS: A total of 157 members were investigated in eight kindreds and 25 patients with FAP were diagnosed. The ratio of male patients and female patients was 16:9 and the average age at onset was 38 years. Among them, six patients died of cancer with a mortality rate of 28%, and 36% (9/25) FAP patients were diagnosed as synchronous colorectal cancer on the basis of FAP. A proband was diagnosed as synchronous colorectal cancer with liver metastasis and died 11 mo later after partial colectomy and hepatic metastatic lesion biopsy. The other seven probands received total abdominal colectomy and rectal mucosectomy with ileal pouch-anal anastomosis (IPAA), and one of them was diagnosed as synchronous colon cancer on the basis of FAP and was still alive after 7.5 years follow-up. Among the other seven patients with synchronous colorectal cancer on the basis of FAP underwent total abdominal colectomy with ileorectal anastomosis (IRA), one underwent total remnant rectum resection and ileostomy for recurrent carcinoma in the retained rectum 2.5 years later after the IRA and was still alive, while the others all died of recurrence with a median survival time of 4.6 years. Through close follow-up and termly endoscopic surveillance, three FAP patients were detected before presenting symptoms at the age of 18, 20 and 23 years, respectively. Prophylactic IPAA was performed and results were satisfactory after the patients were followed-up for 6, 1, and 8 years, respectively.

CONCLUSION: Pedigree investigation, close follow-up and termly endoscopic surveillance are very important for early detection of FAP. Prophylactic IPAA can give satisfactory results to FAP patients.

INTRODUCTION

Familial adenomatous polyposis (FAP), which usually begins at a mean age of 16 years (range, 7-36 years), is an autosomal dominant hereditary colon cancer predisposition syndrome, in which hundreds to thousands of precancerous colonic polyps can develop. Without colectomy, colon cancer is inevitable. The mean age of developing colon cancer in untreated individuals is 39 years (range, 34-43 years)^[1]. Prophylactic colectomy has been considered to be the best treatment for familial adenomatous polyposis^[2]. In this paper, data of eight pedigrees of FAP were analysed retrospectively. The role of surveillance endoscopy and the effect of different surgical procedures were evaluated.

MATERIALS AND METHODS

We studied the patients with FAP and their families enrolled in our Familial Adenomatous Polyposis Registry from March 1991 to December 2003. Close follow-up and termly surveillance colonoscopy were performed and the results were analysed retrospectively. Pedigree trees were protracted according to their family history.

RESULTS

In our registry, eight probands had a family history. These eight pedigree trees were protracted (Figure 1). In these eight kindreds, a total of 157 members were investigated, among them 134 members were in the first to third generation with the age older than 14 years. As a result, 25 members (about 16%) were diagnosed as FAP with an average age of 38 years and the youngest patient was eighteen years old. The ratio of male patients and female patients was 16:9 and most of them were in the second and third generation. A total of 9 FAP patients (36%) were diagnosed as synchronous colorectal cancer, and six patients died of cancer with a mortality rate of 28%. Among 13 patients who had symptoms but no malignancy, 7 patients underwent total abdominal colectomy and rectal mucosectomy with ileal pouch-anal anastomosis (IPAA) and others received total abdominal colectomy with ileorectal anastomosis (IRA). All of them were still alive and no cancer was found after a median follow-up time of 4.2 years and 5.6 years, respectively.

In these eight kindreds, one proband was diagnosed as advanced colon cancer and died 11 mo later after partial colectomy and hepatic metastatic lesion biopsy, and the other probands underwent IPAA, among them one was diagnosed as synchronous colon cancer on the basis of FAP and was still alive after 7.5 years follow-up. Through endoscopic surveillance, three FAP patients were detected before presenting symptoms at the age of 18, 20 and 23 years, respectively. Prophylactic IPAA was performed and results were satisfactory after the patients were followed-up for 6, 1, and 8 years, respectively. Among the other seven patients with synchronous colorectal cancer on the basis of FAP, who received total abdominal colectomy with ileorectal anastomosis (IRA), one underwent total remnant rectum resection and ileostomy for recurrent carcinoma in the retained rectum 2.5 years later after the IRA and was still alive, while the others all died of cancer recurrence with a median survival time of 4.6 years. However, the other seven patients without colorectal cancer were still alive although one was given IPAA and the others received IRA.

DISCUSSION

FAP is an autosomal dominant hereditary disease. Approximately 80% of individuals with FAP had a family history^[3]. Offsprings of an affected individual had a 50% risk of the disease^[4]. The prevalence of FAP is 1 per 16 000 people to 1 per 8 000 people. Though FAP historically accounted for about 0.5% of all colorectal cancers, this figure has been declining as more family members at-risk underwent successful treatment following early polyp detection and prophylactic colectomy^[5-8]. In our study, the incidence rate of FAP in these eight kindreds was 16%, and most of the FAP patients were in the second and third generation without atavism. The average age of FAP patients was 38 years, and nine patients with FAP (36%) were in an advanced stage when they were diagnosed as colorectal cancer. Bulow^[5] reported that since the establishment of the Danish Polyposis Register, the prevalence of colorectal cancer had decreased considerably and the prognosis had improved substantially. They made a conclusion that the work of the Danish Polyposis Register was probably the main cause of this improvement. Other studies^[7-9] also showed that with pedigree investigation, close follow-up and termly endoscopic surveillance, more family members at-risk underwent successful treatment following early polyp detection and prophylactic colectomy, and the prevalence of colorectal cancer was considerably decreased and the prognosis was substantially improved. In our study, we established a FAP register in 1991, and then investigated all lineal and collateral relatives of FAP patients enrolled in our hospital and protracted their pedigree trees. Close follow-up and termly colonoscopy surveillance were performed to find early cases among the relatives at high risk. At the end, 3 FAP patients were detected before presenting symptoms at the age

18, 20 and 23 years, respectively. Prophylactic IPAA was performed and functional outcome and quality of life were satisfactory after the patients were followed-up for 6, 1 and 8 years, respectively. No patient was found with colorectal cancer or pouch adenoma or inflammation. Thus, we conclude that pedigree investigation, close follow-up and termly colonoscopy are feasible and effective methods for early diagnosis of FAP, although FAP has been found to be caused by mutations in adenomatous polyposis coli (APC) (chromosomal loci 5q21-q22) and molecular genetic testing and genetic counseling are clinically available in some developed countries^[6,10] while they are still in laboratories in China^[11].

For individuals with classic FAP, prophylactic colectomy is recommended when adenomas emerge. Colectomy includes total colectomy and rectal mucosectomy with IPAA and subtotal colectomy with IRA. Although IRA has fewer complications and comfortable defecation function, it is not generally accepted by patients because carcinoma may develop in 40% retained rectum^[12]. On the other hand, during IPAA all colorectal mucous membranes were removed to completely eliminate the risk of developing colonic carcinoma and a small reservoir was created to reduce the frequency of bowel movement. However, temporary ileostomy and creation of a reservoir might lead to more complications and increase the difficulty in operation^[2,8]. Parc *et al.*^[13] found that young patients had a good quality of life after IPAA, and suggested that this procedure was well suitable for the youth. In our study, three symptom-free patients underwent IPAA and all had satisfactory results. Among thirteen patients who had symptoms but no malignancy, although 7 patients underwent IPAA and 6 patients underwent IRA, no carcinoma developed after they were followed-up for 4.2 years and 5.6 years, respectively. But for those patients

with carcinoma, only one patient who underwent IPAA 7.5 years before was still alive, while the others who underwent IRA all died of cancer recurrence. Thus, we conclude that symptom-free patients should undergo prophylactic surgical procedure and IPAA should be preferred. Furthermore, IPAA should be the first choice for those patients with carcinoma.

Abstract

AIM: To investigate the effects of *c-myb* antisense RNA on cell proliferation and the expression of *c-myb*, TGF- β 1 and α 1-I collagen in cultured hepatic stellate cells (HSC) from rats.

METHODS: Recombinant retroviral vector of *c-myb* antisense gene (pDOR-myb) was constructed, and then transfected into retroviral package cell line PA317 by means of DOTAP. The pseudoviruses produced from the resistant PA317 cells were selected with G418 to infect HSCs isolated from rat livers. The cell proliferation was measured by 3-[4, 5-Dimethylthiazolyl]-2, 5-diphenyl tetrazo-dium bromide (MTT) method. The expression of *c-myb*, α 1-I collagen and TGF- β 1 mRNA, and *c-myb* protein in HSCs was detected with semi-quantitative reverse transcription-polymerase chain reaction (RT-PCR) and Western-blot respectively.

RESULTS: HSCs from rats were isolated successfully with the viability >98%. In the pDOR-myb infected HSCs, the *c-myb* protein expression, cell proliferation, and α 1-I collagen and TGF- β 1 mRNA expression were repressed significantly compared with their corresponding control groups ($P < 0.01$).

CONCLUSION: *c-myb* plays a key role in activation and proliferation of HSC. *c-myb* antisense RNA can inhibit cell proliferation, α 1-I collagen and TGF- β 1 mRNA expression, suggesting that inhibition of *c-myb* gene expression might be a potential way for the treatment of liver fibrosis.

Ma HH, Yao JL, Li G, Yao CL, Chen XJ, Yang SJ. Effects of *c-myb* antisense RNA on TGF- β 1 and α 1-I collagen expression in cultured hepatic stellate cells. *World J Gastroenterol* 2004; 10(24): 3662-3665

<http://www.wjgnet.com/1007-9327/10/3662.asp>

INTRODUCTION

The activation and proliferation of hepatic stellate cells (HSC) have been regarded as the critical events in early hepatic fibrosis irrespective of the underlying etiology^[1-6]. *c-myb* oncogene encodes nuclear protein that functions as a transcriptional transactivator that regulates expression of genes critical for cell differentiation and proliferation^[7,8]. Several studies have indicated that *c-myb* expression is critical for HSC activation

and proliferation in rat and human livers affected by chronic viral hepatitis, and that the level of *c-myb* expression reflects the severity of disease activity^[9,10]. However, little information is available concerning the effects of *c-myb* expression on the pathogenesis of liver fibrosis.

It has been shown that α 1-I collagen is the main extracellular matrix (ECM) protein produced by HSCs during the pathogenesis of liver fibrosis, while TGF- β 1 has been identified as a potent cytokine in the regulation of the production, degradation and accumulation of ECM. In this study, retrovirus-mediated antisense *c-myb* RNA was transferred into cultured HSCs from rats to investigate its anti-proliferative and antifibrotic effects.

MATERIALS AND METHODS

Materials

PA317 and NIH3T3 cells were cultured in our laboratory. Anti-desmin and anti- α -SMA antibodies were purchased from DAKO Corporation, anti-*c-myb* antibody from Santa Cruz Biotechnology Corporation. G418, DMEM, and fetal bovine serum were from GibcoTM Invitrogen Corporation. Pronase E and collagenase IV were from Sigma-Aldrich Corporation. The retroviral vector pDOR was provided by Dr. Lin Yang (Department of Infectious Diseases, the 3rd Affiliated Hospital, Sun-Yat Sen University).

Cell isolation, culture and identification

Primary rat HSCs were isolated from 200-300 g male Sprague-Dawley rats by a two-step pronase-collagenase perfusion method^[11]. All cells were cultured in DMEM supplemented with 100-200 mL/L fetal bovine serum, 2 mmol/L glutamine and 1% antibiotic solution at 37 °C in a humidified atmosphere containing 50 mL/L CO₂. HSCs were identified by immunohistochemical staining for desmin and α -SMA with monoclonal mouse anti-desmin and anti- α -SMA antibodies, respectively.

Packaging of *c-myb* recombinant retroviral vector and its transfection into HSCs

The segment of *c-myb* gene amplified by RT-PCR from the spleen of a rat was cloned into pUC19 with TA cloning method, and then subcloned into retroviral vector pDOR after sequencing. The recombinant retroviral vector, named pDOR-myb, was transfected into retroviral package cell line PA317 by means of DOTAP. Stable retroviral vector-produced lines were generated by expanding the G418-resistant (600 μ g/mL) colonies. The supernatants containing the packaged retroviruses were harvested, filtered and titrated 9.0×10^4 - 2.2×10^5 CFU/mL determined in NIH3T3 cells^[12]. The fourth generation of HSCs was infected with the recombinant *c-myb* retrovirus (pDOR-myb) and controlled retrovirus (pDOR), while the untreated HSCs from the same generation were used as the control group. Infection was performed in suspension by a 30 min incubation of HSCs with 10 mL of virus supernatants, supplemented with 4 μ g/mL polybrene. The cultured medium was changed with DMEM containing G418 after 48 h, and repeated every 2-3 d.

Proliferation assay of infected HSCs

The cell proliferation was measured by 3-[4, 5-Dimethylthiazolyl]-2, 5-diphenyl tetrazo-dium bromide (MTT) method. HSCs of three

groups (pDOR-myb, pDOR and control groups) were seeded into 96-well plates (5×10^3 cells/well), respectively and incubated in a final volume of 200 μ L medium for 48 h. Fifty microliter of MTT (5 g/L) was subsequently added to each well. After the incubation was continued for 4 h, suspension was abandoned, and dimethyl sulphoxide (DMSO) 200 μ L was added to each well. Then absorbance at 570 nm ($A_{570\text{nm}}$) was measured using an automatic enzyme-linked immunosorbent assay plate reader.

Semi-quantitative reverse transcription-polymerase chain reaction (RT-PCR)

For reverse transcription PCR analysis, total RNA was extracted from cultured cells using a RNeasy Mini kit (QIAGEN). Complementary DNAs were prepared from 1 μ g of total RNA using a RT kit (MBI) with oligo (dt) primer according to the manufacturer's instructions. The resulting complementary DNA was amplified with the following sets of primers: GAPDH (420 bp), 5'ATGACTCTACCCACGGCAAG3' (forward) and 5'CCACAGTCTTCTGAGTGGCA3' (reverse); TGF- β 1 (143 bp), 5'GACCTGCTGGCAATAGCTTC3' (forward) and 5'GTTGAGGGAGAAA GCAGCAG3' (reverse); α_1 -collagen (269 bp), 5'GCGAGGACATGAGGAGTAGC3' (forward) and 5'CCTGTGACCAGGGATGTTCTT3' (reverse); *c-myb* (350 bp), 5'TCCTTCTCCTCCTCCTC CTC3' (forward) and 5'GTTCCACCAGCTTCTTAGC3' (reverse). *c-myb*, TGF- β 1 and α_1 -I collagen mRNA levels were determined by semi-quantitative RT-PCR followed by densitometry scanning. GAPDH served as an internal control. The following PCR program was performed for TGF- β 1 and α_1 -I collagen: at 94 °C for 2 min (initial denaturation), at 94 °C for 30 s, at 62 °C for 30 s, at 72 °C for 1 min, 35 cycles. For *c-myb*, except the primer annealing temperature was 65.5 °C, all other conditions were the same as above.

Western-blotting

c-myb proteins of the pDOR-myb group, pDOR group and control group were detected with Western-blotting. HSCs of the three groups were washed 2 times with PBS, and then 1 \times SDS loading buffer was added. After boiled for 5-10 min, 10 μ g of protein was electrophoresed on 100 g/L SDS-polyacrylamide gel. The protein was transferred to PVDF membrane, which was then blocked overnight at 4 °C with PBST (PBS containing 4 mL/L Tween 20)-30 g/LBSA. The blots were incubated with the primary polyclonal antibody against *c-myb* (1:100) at 4 °C overnight, and subsequently with HRP-labeled secondary antibody (1:100) at room temperature for 1 h. At last, the protein bands were visualized with 4-Cl-1-Naphenol- H_2O_2 .

Statistical analysis

Data were presented as mean \pm SE. The Student's *t* test was to

analyze the changes in different groups with SPSS10.0 software, and $P < 0.05$ was considered statistically significant.

RESULTS

HSCs identification

The number of isolated cells was 1.3×10^7 from a rat with the viability $> 98\%$. Immunohistochemical staining with desmin and α -SMA showed a selective cytoplasmic pattern with about 95% positive cells.

c-myb expression

Semi-quantitative RT-PCR and Western-blot were performed to determine *c-myb* expression in the recombinant *c-myb* virus infected HSCs. RT-PCR showed a 420 bp band corresponding to GAPDH in each sample. As expected, a 350 bp band of *c-myb* was detected in the pDOR group and the control group, but not in the pDOR-myb group, and the results of densitometry scanning showed that *c-myb* mRNA expression value in the pDOR-myb group was 4.63 ± 0.66 , significantly lower than that in the control (44.48 ± 2.79) and pDOR groups (46.91 ± 3.57) ($P < 0.01$). Western blot analysis demonstrated that *c-myb* protein was markedly reduced in the pDOR-myb group compared with the control group. (Figure 1).

HSC proliferation

Proliferation assay showed that $A_{570\text{nm}}$ values of the pDOR-myb group, pDOR group and control group were 0.40 ± 0.12 , 0.58 ± 0.10 and 0.59 ± 0.09 , respectively, indicating a marked decrease in the pDOR-myb group compared with the control groups ($P < 0.01$), but no difference between two control groups (Figure 2).

Figure 2 Measurements of cell proliferation with MTT method in three groups of HSCs. The results were expressed as mean \pm SE ($n = 6$). ^b $P < 0.01$ vs pDOR and control.

Figure 1 Expression of *c-myb* mRNA, internal control and *c-myb* protein by RT-PCR, density and Western blot. A: *c-myb* mRNA expression assayed by semi-quantitative RT-PCR analysis of total RNA. Co-amplification of GAPDH in all samples served as an internal standard. Lane 1: control HSC; Lane 2: pDOR treated HSC; Lane 3: pDOR-myb treated HSC; Lane M: 100 bp ladder. B: Relative expression levels are shown as percent of the internal control by densitometry scanning. The results were expressed as mean \pm SE ($n = 3$). ^b $P < 0.01$ vs pDOR and control. C: Western-blotting of *c-myb* protein expression. Fifty μ g of extracted cellular protein was loaded in each lane. Lane1: control HSC; Lane2: pDOR treated HSC; Lane3: pDOR-myb treated HSC.

TGF- β_1 and α_1 -I collagen mRNA expression

Semi-quantitative RT-PCR was used to analyze TGF- β_1 and α_1 -I collagen mRNA expression. The mRNA levels of α_1 -I collagen and TGF- β_1 were markedly reduced in the pDOR-myb group compared with the two control groups ($P < 0.01$). The results of densitometry scanning showed that α_1 -I collagen and TGF- β_1 mRNA expression values in the pDOR-myb group were 6.94 ± 1.58 and 10.09 ± 2.26 , respectively, which were markedly reduced compared with the control (44.10 ± 5.63 and 13.01 ± 0.94 , respectively) and pDOR groups (44.59 ± 2.54 and 12.47 ± 0.48 , respectively) ($P < 0.01$). But there was no difference between the two control groups (Figure 3).

Figure 3 Expression of TGF- β_1 and α_1 -I collagen mRNA. A: α_1 -I collagen mRNA expression assayed by semi-quantitative RT-PCR analysis. Lane 1: pDOR-myb treated HSC; Lane 2: control HSC; Lane 3: pDOR treated HSC. B: TGF- β_1 mRNA expression assayed by semi-quantitative RT-PCR analysis. Lane 1: pDOR treated HSC; Lane 2: control HSC; Lane 3: pDOR-myb treated HSC. The relative expression levels were shown as percent of the internal control by densitometry scanning. The results were expressed as mean \pm SE ($n = 3$), ^b $P < 0.01$ vs pDOR and control. Co-amplification of GAPDH in all samples served as an internal standard.

DISCUSSION

HSC is regarded as one of the key cell types involved in progression of liver fibrosis, and as a therapeutic target for treatment of hepatic fibrosis^[1-6]. Several findings have implied that HSC activation status could be directly manipulated through controlled expression of *c-myb*. *c-myb* was reported to be involved in transcriptional regulation and cell proliferation, since high levels of *c-myb* DNA-binding activity were found in activated HSCs but not in quiescent HSCs^[13,14]. Transfection of *c-myb* stimulated α -SMA expression in quiescent HSCs, and transfection of *c-myb* antisense RNA inhibited the expression of α -SMA and the activation of HSCs^[14].

In this study, we found that the *c-myb* expression in HSCs could be successfully inhibited by *c-myb* antisense RNA transfection and this antisense *c-myb* RNA could dramatically inhibit HSC proliferation detected by MTT, suggesting that blockade of *c-myb* transcriptional signals in HSC might lead to the inhibition of HSC proliferation. However, little is known about how *c-myb* expression can influence HSC activation and proliferation. It has been reported that *c-myb* is an important

transcriptional factor that can regulate cell cycles and control plasma membrane Ca^{2+} -ATPase^[15,16], which may be involved in HSC proliferation.

TGF- β_1 is the most potent fibrogenic stimulant to HSCs. The activated HSCs respond to it by increasing production of collagen and decreasing its breakdown. Modifying the secretion or activity of TGF- β_1 could attenuate fibrosis, and recent studies of experimental liver fibrosis have shown the potential of this approach^[17-22]. Our study showed that TGF- β_1 mRNA expression was repressed significantly in the pDOR-*c-myb* infected group compared with their corresponding control groups. The mechanism might be partly related to the fact that *c-myb* antisense RNA could inhibit HSC proliferation and block TGF- β_1 autocrine loop. It is necessary to investigate HSC activation and its relationship with *c-myb* expression and TGF- β_1 secretion, since *c-myb* also plays an important role in HSCs activation^[1,14].

Hepatic fibrosis is characterized by accumulation of extracellular matrix (ECM), and collagen I is the main component of ECM while fibrosis occurs^[23-26]. Activated HSCs are known to be the major source of this fibrillar collagen. On the other hand, collagen I could further enhance HSC activation^[1]. Clearly, this feedback loop plays an important role in the progression of liver fibrosis. In our study, α_1 -I collagen mRNA expression in HSCs was inhibited significantly by transfection of *c-myb* antisense RNA. Considering *c-myb* antisense RNA could also inhibit HSC proliferation, which might influence α_1 -I collagen mRNA expression levels, the number of HSCs in each group was adjusted to the same count. Our results indicated that *c-myb* could influence α_1 -I collagen expression through some direct but yet unclear ways.

Liver fibrosis and its end stage, cirrhosis, represent worldwide healthcare problems. Current treatments for fibrosis and cirrhosis are limited to removing the underlying injurious stimuli, eradicating viruses using interferon, ribavirin, and lamivudine in viral hepatitis, and liver transplantation. To date, various new drugs have been attempted to prevent the progression of hepatic fibrosis, such as hepatocyte growth factor^[26,27], TGF- β_1 antagonist or truncated TGF- β_1 type II receptor^[21,28,29] and tissue inhibitors of metalloproteinases^[30]. Now that HSC activation and proliferation have been shown to be the critical events, and also to contribute to portal hypertension. Hence, the strategies to design some specific agents to inhibit HSC activation and proliferation are appealing. In conclusion, *c-myb* antisense RNA can inhibit *c-myb* gene expression, cell proliferation, α_1 -I collagen and TGF- β_1 mRNA expression in HSCs, suggesting that inhibition of *c-myb* gene expression might be a potential way for the treatment of liver fibrosis.

Abstract

AIM: The role of intravenous pantoprazole in treatment of patients with high-risk bleeding peptic ulcers following endoscopic hemostasis remains uncertain. We therefore conducted the pilot prospective randomized study to assess whether intravenous pantoprazole could improve the efficacy of H₂-antagonist as an adjunct treatment following endoscopic injection therapy for bleeding ulcers.

METHODS: Patients with active bleeding ulcers or ulcers with major signs of recent bleeding were treated with distilled water injection. After hemostasis was achieved, they were randomly assigned to receive intravenous pantoprazole or ranitidine.

RESULTS: One hundred and two patients were enrolled in this prospective trial. Bleeding recurred in 2 patients (4%) in the pantoprazole group ($n = 52$), as compared with 8 (16%) in the ranitidine group ($n = 50$). The rebleeding rate was significantly lower in the pantoprazole group ($P = 0.04$). There were no statistically significant differences between the groups with regard to the need for emergency surgery (0% vs 2%), transfusion requirements (4.9 ± 5.9 vs 5.7 ± 6.8 units), hospital days (5.9 ± 3.2 vs 7.5 ± 5.0 d) or mortality (2% vs 2%).

CONCLUSION: Pantoprazole is superior to ranitidine as an adjunct treatment to endoscopic injection therapy in high-risk bleeding ulcers.

INTRODUCTION

Bleeding is a common and potential life threatening complication of peptic ulcer diseases. Recently, endoscopic hemostasis has been the treatment of first choice for bleeding peptic ulcer, providing better outcomes compared with both medical and surgical therapies^[1-4]. However, acute recurrent bleeding after initial hemostasis by therapeutic endoscopy has been reported to occur in 4% to 30% of cases, and the mortality rate in these patients is high^[5-10].

In vitro studies have shown that clotting proceeds more efficiently and the dissolution of clots by proteolytic enzymes occurs more slowly at high pH levels^[11-14]. Pepsin can digest blood clots overlying ulcer craters, and its activity is pH-related^[13]. Additionally, the function of platelets is severely impaired at low pH *in vitro*^[14]. A profound reduction of gastric acidity, therefore, could stabilize the clots over an ulcer and stop bleeding or prevent recurrent hemorrhage.

However, evidence of the effectiveness of H₂-receptor antagonists in bleeding peptic ulcers is conflicting. Collins *et al.*^[15] conducted a meta-analysis of 27 randomized studies and concluded that H₂-receptor antagonists reduced the rate of continued bleeding, the need for surgery, and the mortality rate among patients with gastric ulcers. Nonetheless, a subsequent large trial of 1 005 patients with bleeding peptic ulcers demonstrated that intravenous famotidine treatment did not affect the rebleeding rate, the operative rate, and the mortality^[16].

In vivo studies have shown that a regimen including a high dose of a proton pump inhibitor (PPI) can maintain intragastric pH at a nearly neutral level and inhibit acid production more effectively than does an infusion of an H₂-receptor antagonist^[17,18]. Thus, a high-dose PPI is theoretically better than an H₂-receptor antagonist as a treatment to prevent rebleeding of peptic ulcers. A recent meta-analysis^[19] disclosed that intravenous omeprazole was more effective than an H₂-antagonist in preventing persistent recurrent bleeding from peptic ulcer, but this advantage seemed to be restricted to those patients who did not have adjunct sclerotherapy. Nonetheless, the authors emphasized that the data were too scarce and heterogeneous to draw definitive conclusions, and further comparative trials were clearly warranted.

Currently, intravenous omeprazole is available in Europe and other countries, but it is not available in the United States of America. Although pantoprazole was the first intravenous PPI marketed in the United States of America, it does not have an indication for treatment of upper gastrointestinal bleeding, mainly due to the lack of published clinically relevant outcome data. We therefore conducted this pilot, prospective, randomized study to compare the efficacy of intravenous pantoprazole and ranitidine for prevention of rebleeding of peptic ulcers following initial endoscopic hemostasis.

MATERIALS AND METHODS

Patients

From October 2002 to September 2003, all patients with hematemesis, melena, or both, had emergent upper endoscopy

performed within 24 h of admission to the emergency units of Kaohsiung Veterans General Hospital. Patients with active bleeding ulcers or ulcers with major signs of recent bleeding were treated with distilled water injection. Patients with successful initial hemostasis and who gave their consents were enrolled in this study. Criteria for exclusion included: the presence of other possible bleeding sites (for example, esophageal varices, gastric cancer), coexistence of an acute significant illness (for example, sepsis, stroke, acute myocardial infarction, acute respiratory failure, acute surgical abdomen), the presence of a systemic bleeding tendency (for example, platelets $<50\,000/\text{mm}^3$, prolonged prothrombin time >3 s, or use of an anticoagulant).

Therapeutic endoscopy

Upper gastrointestinal endoscopy was performed within 24 h of hospital admission. The equipments used were the Olympus GIF XV10, GIF XQ 200, and GIF 1T20 (Olympus Corp., Tokyo, Japan). To improve the visual field, gastric lavage was carried out before endoscopy. Ulcers with stigmata were cleaned by water irrigation through the biopsy channel. We divided the ulcer lesions into six categories according to our previous study^[10]: clean base, red or black spot, adherent clot, nonbleeding visible vessel (NBVV), oozing visible vessel, and spurting visible vessel. An NBVV was defined as a raised red or bluish-red hemispheric lesion protruding from the ulcer base, without active bleeding. An adherent clot was defined as an overlying clot that was resistant to washing. If an adherent clot, NBVV or bleeding visible vessel was noted during the first examination, endoscopic local injection with distilled water was performed for hemostasis. Distilled water was injected in aliquots of 0.5–2 mL over and around the bleeding area, up to a total of 5.0–20.0 mL^[6,8]. Once hemostasis was achieved, the bleeding site was observed for at least 5 min. Initial hemostasis was defined as no endoscopic evidence of bleeding during 5 min of observation after therapy.

We did not check *H. pylori* status for our patients during acute bleeding episodes since several studies^[20,21] disclosed that biopsy-based tests had decreased sensitivities for the detection of *H. pylori* in bleeding peptic ulcers. Besides, it would increase operating time to take gastric specimens in critical patients who required therapeutic endoscopies.

Randomization

Patients with successful initial hemostasis were randomly assigned to two groups. Randomization of eligible patients was carried out by a neutral individual who opened sealed envelopes containing the treatment assignments, derived from a table of random numbers. One group was treated with intravenous pantoprazole, with an initial dose of 40 mg and subsequently with 40 mg every twelve hours during the first three days, followed by 40 mg a day orally. The other group was treated with intravenous ranitidine, with an initial dose of 50 mg and subsequently every eight hours during the first three days, followed by 150 mg of oral ranitidine every 12 h. We chose the dose of intravenous ranitidine because it was commonly used in clinical practice. Previous studies^[22] revealed that this dose of intravenous ranitidine could suppress gastric acid secretion by 83%. The study protocol was approved by the Medical Committee of Kaohsiung Veterans General Hospital.

Follow-up

During the stay in the hospital, patients received partial parenteral nutrition for 2 d. After a 48-h observation, patients were given soft diet for 48 h, and then a regular diet. The hemoglobin level was checked every day for 3 d, and a blood transfusion was given if the hemoglobin concentration fell below 8 gm/dL or if vital signs deteriorated.

A clinician independent of the endoscopist observed the patients for evidence of rebleeding. The definition of rebleeding

was recurrent hemorrhage during an 8-wk observation period. Evidence of rebleeding included fresh hematemesis, aspiration of fresh blood from NG tube, or continuous melena with a pulse rate greater than 100 beats/min, a fall in systolic blood pressure exceeding 30 mmHg, or a decrease in hemoglobin of at least 0.2 g/L. When rebleeding was suspected, a second therapeutic endoscopy was performed immediately. If hemostasis could not be achieved, surgical intervention of uncontrolled rebleeding was performed.

After discharge, patients assigned to the pantoprazole group were treated with pantoprazole 40 mg daily for up to 8 wk, and those in the ranitidine group were treated with ranitidine 150 mg twice daily. All patients were requested to return to the outpatient clinic 14 d, 4 wk and 8 wk after initial hemostasis.

Statistical analysis

The sample size was calculated according to previous experiences^[6–8,18,19]. The rebleeding rates following distilled water injection were 13% of patients treated with PPI^[7,18,19] and 29% of patients treated with H_2 receptor antagonist^[6,8]. A sample size of 46 was thus required for each group to achieve a statistical power of 80% at 10% type I error. The chi-square test with or without Yate's correction for continuity and Fisher's exact test were used when appropriate to compare the rates of rebleeding, emergency operation and mortality between groups. A *P* value less than 0.05 was considered statistically significant.

RESULTS

During the study period, 236 patients were admitted due to bleeding peptic ulcers. Endoscopic treatment was not required in 136 patients who had ulcers with clean bases or flat pigments. Nineteen patients were excluded from this study for the presence of other possible bleeding sites ($n = 5$), coexistence of an acute significant illness ($n = 9$), association with a systemic bleeding tendency ($n = 6$). One hundred and nine patients with high-risk bleeding ulcers received endoscopic injection therapy. Initial hemostasis was not achieved in 7 patients who had profuse bleeding, and they underwent surgical treatment or further endoscopic hemostasis with thermocoagulation or hemoclippling.

The other 102 patients with successful endoscopic hemostasis were randomly assigned to either pantoprazole ($n = 52$) or ranitidine ($n = 50$) therapies. Data regarding the clinical characteristics of patients at entry are summarized in Table 1. The two groups had comparable clinical features, site and size of ulcers, and bleeding severity. At index endoscopy, 40% of randomized patients had bleeding visible vessels (spurting: 6%; oozing: 34%), 38% had NBVVs and 22% had adherent clots in the ulcer craters.

All patients were followed up through the eight-week period after initial endoscopy. Treatment results are shown in Table 2. Rebleeding developed in 2 patients in the pantoprazole group. One of the rebleeding patients underwent a second endoscopy, and hemostasis was controlled by local injection of diluted epinephrine. The other died of profuse rebleeding. Neither second endoscopic therapy nor surgical intervention was performed for him because of rapid deterioration of clinical course. In the ranitidine group, 8 patients developed rebleeding. In 7 of the 8 treatment failure patients, endoscopic retreatment by local injection ($n = 5$), heater probe ($n = 1$) and hemoclippling ($n = 1$) stopped the bleeding. The other one patient underwent immediate surgery to control rebleeding after failure of second therapeutic endoscopy. None of the patients died of uncontrolled rebleeding, but one female patient died of heart attack.

The rebleeding rate of the pantoprazole group was significantly lower than that of the ranitidine group (3.8% vs 16.0%, $P = 0.04$). There were no statistically significant differences between the groups with regard to the need for emergency surgery (0% vs

2.0%), transfusion requirements (4.9 ± 5.8 vs 5.7 ± 6.8 units), the length of hospital stay (5.9 ± 3.2 vs 7.5 ± 5.0 d) or mortality (1.9% vs 2.0%).

DISCUSSION

The use of PPIs in patients with bleeding peptic ulcers has been evaluated in several studies. In a meta-analysis of 11 randomized trials^[19], Gisbert *et al.* showed that PPIs were more effective than H₂-receptor antagonists in preventing persistent or recurrent bleeding from peptic ulcers. However, meta-analysis had several limitations. For example, there was a marked variability between studies with respect to doses of PPIs and H₂-receptor antagonists, schemes of administration of the drugs, Forrest classification of bleeding ulcers and concomitant endoscopic therapies. The authors thus concluded that the data were too scarce and heterogeneous to draw definite conclusions. In addition, it is important to point out that all the trials^[23-26] analyzed by Gisbert *et al.* used omeprazole or lansoprazole as the test drug of PPIs.

To date, there are limited clinical outcome data on intravenous pantoprazole for the prevention of peptic ulcer rebleeding^[27]. Furthermore, all the published data concerning the effects of intravenous pantoprazole on bleeding peptic ulcers were in abstract form^[28], which has limited the ability to completely evaluate and generalize the suggested outcomes. We therefore designed the prospective randomized study to investigate the effects of intravenous pantoprazole on recurrent bleeding after endoscopic treatment of bleeding peptic ulcers. The rebleeding

rate of the pantoprazole and ranitidine groups in this study was 4% and 16%, respectively. The data suggest that pantoprazole is more effective than ranitidine for preventing rebleeding in high-risk bleeding ulcer patients.

However, it is important to note that continuous infusion of ranitidine was more effective to elevate intragastric pH than intermittent bolus injection^[22]. Additionally, the percentage of intragastric pH value equal to or above 7.0 was significantly greater during high dose ranitidine infusion (300-mg/24 h) compared with conventional dose infusion (150-mg/24 h)^[22]. Fired *et al.*^[28] revealed that the efficacy of infusion of high dose ranitidine to prevent recurrent ulcer bleeding was similar to that of pantoprazole infusion.

Data from *in vitro* studies suggest that both acid and pepsin can alter coagulation by interfering with the coagulation system, fibrinogen polymerization, and platelet aggregation^[12,13]. Therefore, profound acid suppression may improve the microenvironment at the bleeding point by keeping the gastric pH above the proteolytic range for pepsin to prevent clot lysis, and thus benefiting patients with bleeding peptic ulcers. Traditionally, pharmacological treatment for bleeding peptic ulcers has included H₂-receptor antagonists, but these drugs have shown no effect at all when compared with placebo^[16,29]. The lack of a clear beneficial effect of H₂-receptor antagonists could be due to the limited control of gastric pH. This is because at the conventional recommended doses of these drugs, gastric pH could not be maintained higher than 4.0 for a long period in patients with a bleeding peptic ulcer^[30]. On the other hand, intravenous PPIs could produce consistently high gastric pH values in patients with bleeding peptic ulcers^[25,31]. Pharmacokinetic studies with PPIs have shown that a bolus of 80 mg pantoprazole or omeprazole followed by immediate continuous infusion of 8 mg per hour could result in an intragastric pH of 7 within 20 min^[32]. Pisegna *et al.*^[33] also demonstrated that a single intravenous dose of pantoprazole 80 mg suppressed pentagastrin-induced acid output by 99% for approximately 24 h and had an onset of action in less than 1 h. Its acid inhibition effect was much stronger than that of intravenous famotidine. The loss of effectiveness of famotidine might be due to tolerance (tachyphylaxis), which is known to occur in response to repetitive doses of H₂-receptor antagonists^[34,35], but has never been found with PPIs. Therefore, parenteral PPIs seem to be more effective than H₂-antagonists in keeping the intragastric pH above the proteolytic range for pepsin to stabilize the clotting process.

In this study, there were no significant differences between the pantoprazole and ranitidine groups with regard to the need for emergency surgery, transfusion requirements, hospital stay or mortality. Several previous studies^[18,19] also reported that PPIs were not more effective than H₂-receptor antagonists for reducing surgery or mortality rates. However, the lack of differences in these parameters between study and control groups might be due to beta error since the numbers of cases in these studies were too small to draw definite conclusions to these parameters. In a large-scaled study of Lau *et al.*^[7], a high-dose infusion of omeprazole was reported to decrease the hospital stay of patients following endoscopic treatment of bleeding ulcers.

Recently, the combinations of injection and thermal coagulation therapies have been applied in the treatment of high-risk bleeding peptic ulcers^[36,37]. A meta-analysis by Calvet *et al.*^[37] demonstrated that combined therapies were superior to injection therapies alone. It merits further studies to investigate whether combined therapies for high-risk bleeding ulcers will effectively control bleeding ulcers and change the results in the current study.

In conclusion, after endoscopic injection treatment of bleeding peptic ulcers, intravenous pantoprazole is more effective than ranitidine for the prevention of rebleeding.

ACKNOWLEDGEMENTS

The authors express their deep appreciation to Dr. Lung-Chih Cheng, Chao-Ming Wu, Hsien-Chung Yu and Miss Yu-Shan Chen for their generous support.

Abstract

AIM: To study the inhibitory effect of transfected PTEN on LoVo cells.

METHODS: Human PTEN cDNA was transferred into LoVo cells via lipofectin and PTEN mRNA levels and its expression were analyzed by Western blot and flow cytometry. Before or after transfection, the effects of 5-Fu on inhibiting cell proliferation and inducing apoptosis were measured by flow cytometry, DNA bands and MTT.

RESULTS: PTEN transfection significantly up-regulated PTEN expression in LoVo cells. 5-Fu inhibited cell proliferation and induced apoptosis in transfected LoVo cells.

CONCLUSION: Transfected PTEN can remarkably up-regulate PTEN expression in LoVo cells and promote the apoptosis. PTEN transfection is associated with 5-Fu treatment effect and has a cooperatively cytotoxic effect.

INTRODUCTION

Apoptosis and abnormal proliferation play a critical role in the development of carcinoma^[1-8]. 5-Fu is one of the most popular drugs in colon cancer treatment. *In vivo* 5-Fu converts into fluorouracil deoxynucleotide and inhibits thymidylate synthetase and consequently, hinders deoxyuridylic acid into deoxythymidylate catalyzed by the enzyme thus blocking DNA synthesis and inducing apoptosis in cancer cells. The effect of phosphatase and tensin homologue deleted on chromosome 10 (PTEN)^[9-21] transfection associated with 5-Fu on LoVo cells in human colon cancer was studied.

MATERIALS AND METHODS

Materials

Human LoVo cells and PTEN plasmid pcDNA-PTEN-WT, wild type-WT, plasmid DNA extraction kit were purchased from Hangzhou Weitejie BioTech Co. The samples of normal human tissue and highly malignant colon cancer tissues were obtained from 461 Hospital of PLA and immediately stored in liquid nitrogen. Plasmid pcDNA3.1 (+) of eukaryonal expression

vectors was from Invitrogen. *E. coli* DH5 α , LoVo were stored in our laboratory. Diethyl pyrocarbonate (DEPC) was from Sigma. Total RNA was extracted by Trizol (Gibco). Oligo dT, TaKaRa RNA PCR Kit (AMV) pMD 18-T, Ex TaqTM enzyme (including dNTPs and Mg²⁺), DNA Ligase Kit Ver.2, DNA marker were from TaKaRa. LipofectamineTM 2 000 transfection reagent was from Invitrogen. DNA sequence kit was ABI BigDye terminator kit. DNA fragment extraction and purification kit was from Beijing Dingguo Bio Corp. Rabbit-anti-human PTEN polyclonal antibody (rabbit anti-PTEN) was from Beijing Zhongshan Bio Corp. Horseradish enzyme labeled goat-anti-rabbit IgG (H+L) was obtained from Beijing Zhongshan Biotechnology Co., LTD. **Reagents and enzymes** Restriction enzymes *Bam* HI and *Hind* III, basic proteolytic enzyme, DNA kit, Lipofectin, G418 were used. **Primers** The primers were designed according to human PTEN sequence published in GenBank using Primer Premier 5.0 software. The upper stream primer was 5' AAG CTT ATG ACA GCC ATC ATC AAA GAG AT 3' with *Hind* III digestion site. The down stream primer was 5' -GGA TCC GGA ATA AAA CGG GAA AGT GCC-3' with *Bam* HI digestion site. The primers were synthesized by Beijing Baisheng Bio Corp.

Methods

RNA extraction One hundred milligrams of the samples in liquid nitrogen were taken. Total RNA was extracted by the protocol of Trizol.

RT-PCR amplification of PTEN gene It was carried out by TaKaRa RNA PCR kit. The reaction mixture was 20 μ L. Reaction condition was at 30 °C for 10 min, 45 °C for 40 min, 95 °C for 2 min, 5 °C for 5 min. The primer was designed as above. Amplification condition was at 94 °C for 5 min, 94 °C for 30 s, 53 °C for 30 s, 72 °C for 1 min, 72 °C for 10 min. After the reaction 5 μ L was taken for agarose gel electrophoresis.

PTEN clone and identification Fifty microliters of PCR product were used for 1% agarose gel electrophoresis to extract cDNA fragment and after extraction it was identified by agarose gel electrophoresis. cDNA fragment was inserted into pMD18-T vectors and ligated at 16 °C overnight to construct the recombinant plasmids pMD-PTEN-WT (wild type) and pMD-PTEN-MT (mutant type). The recombinant plasmids transfected competent DH5 α cells by CaCl₂. The transfected cells were cultivated in 50 mg/L ampicillin (Amp) LB agar plates at 37 °C for 14-16 h. Single colonies were inoculated in LB liquid medium with Amp at 37 °C overnight. The plasmids were extracted from cell culture. The positive clones were selected and doubly digested by *Hind* III and *Bam* HI at 37 °C for 1 h. After digestion it was identified by electrophoresis and the sequences were verified by ABI 3 100 and the results were analysed by DNAsis software.

Construction and identification of eukaryonal expression vectors Recombinant plasmids with correct sequences were doubly digested by *Hind* III and *Bam* HI. The product was used for agarose gel electrophoresis to extract 1.4 kb PTEN fragments. pcDNA3.1 (+) was also doubly digested by *Hind* III and *Bam* HI and extracted. The linear vector fragments and extracted PTEN fragments were ligated by T4 DNA ligase at 16 °C overnight and the product was transferred into competent DH5 α cells. Single colonies were randomly selected and cultivated at 37 °C overnight. Plasmids were extracted and amplified by PCR and identified by digestion.

Transfection According to Lipofectamine™ 2000 transfection kit, pcDNA3.1 (+) vacant vector and none-transfected LoVo cells served as controls. After transfection the cells were grown at 37 °C with 50 mL/L CO₂ for 4-6 h and 2 mL of medium supplemented with 10% calf serum was changed and cultivated for 48 h. Four to ten cells were transferred and incubated. When the cells were 80% in confluence, 600 µg/mL G418 was added to select the positive clones.

Cell growth The cells were digested by 0.25% trypsin to get monocyte suspension and inoculated into 6 well plates at 1×10^4 /well. Seven wells were for each kind of cells. The medium was changed after 2 d. Cells were counted every day. The cell growth was observed for 7 d and cell growth curve was obtained.

Detection of PTEN gene expression Total RNA extracted was used as template for reverse transcription. The reaction system and condition were described as above. Western assay was performed according to the reports^[22-24], horseradish peroxidase-labeled rabbit-anti-human IgG was used as the second antibody.

Gene preparation Total RNA was extracted from tumor and normal tissues. PCR product was collected and ligated into pMD 18-T vectors and then transformed. The constructs were verified by DNA sequencing.

Cell culture Frozen cells were taken out of liquid nitrogen and rapidly melted at 37-40 °C for 1 min in water bath. The tube of cells stored was opened and the cell suspension was transferred into the culture plate. After the medium was added the cells were grown at 37 °C. The medium was changed after cell growing on the wall (around 4 h). After the cells were cultivated into a single layer, the next generation was grown. The restored cells were transferred onto the 35 mm plate and cultivated at 37 °C with 50 mL/L CO₂ for 18 h. The cells were digested by 0.25% pancreatin and cultured in 2 mL of DMEM supplemented with 10% fetal calf serum to stop digestion. The cells were cultured for 12 h. When the cells were in 30-50% confluence, they were transfected by plasmid DNA.

Western blot Total RNA was extracted with Trizol from transfected LoVo cells or non-transfected cells. Five microliters of samples were separated by electrophoresis, transblotted, prohybridized, hybridized and stained.

PTEN protein expression Before or after transfection PTEN protein expression was assayed by flow cytometry. The cells were resuspended in PBS, PTEN monoclonal IgG1 antibody was labeled and incubated at room temperature for 30 min and analyzed by flow cytometry.

DNA ladder bands assay 5-Fu at 20 µL/mL was added into PTEN cells transfected or non-transfected and incubated for 48 h and centrifuged. DNA was extracted from the cells and electrophoresis was performed in 2% agar gel in 0.5× TBS for 2 h. Photos were taken under UV light.

Inhibitory rates of 5-Fu on LoVo cells before or after transfection by MTT assay One hundred microliters of LoVo cells at 1×10^6 /mL was inoculated into 96 well plates and 100 µL of 5-Fu was added so the concentrations were 10, 20, 40, 100, 200, 400 µg/mL. After incubation for 48 h, 100 µL of dimethylsulfoxide was added. After 20 min, the absorbance in each well was measured by enzyme-labelled meter and the inhibition rate was calculated.

The inhibition rate = $[1 - (\text{the value of Abs in experiment} / \text{the value of Abs in the control})] \times 100\%$.

Flow cytometry The apoptosis of LoVo cells induced by 5-Fu was analyzed by flow cytometry. 5-Fu 10 µg/mL was added into LoVo cells transfected or non-transfected and incubated for 48 h, then centrifuged, and 20 µL of propidium iodide (PI) was added for half an hour in the dark and analyzed by flow cytometry.

Statistics analysis

The differences between groups were analyzed by *t* test.

RESULTS

The digested plasmid PTEN-pMD18-T is shown in Figure 1. After plasmid PTEN-pMD18-T was digested, two fragments were 5.3 kb and 1.4 kb, which were consistent with dl 2 000 marker.

Four cell growth curves are shown pcDNA-PTEN-WT cell growth was slower than other cells (Figure 2).

PTEN mRNA expression in LoVo cells was assayed by Western blot. The PTEN mRNA expression level was higher after transfection (Figure 3).

LoVo cells transfected with PTEN-WT gene were assayed by flow cytometry and it was mainly found in cell cycle blockage period G₀-G₁ (58.21%) (Figure 4).

The results of DNA-ladder bands showed that in transfected LoVo cells treated by 5-Fu there were typical DNA ladder bands, but in non-transfected LoVo cells there was no DNA ladder band.

After 5-Fu 10 µL/mL was added for 48 h, the apoptotic LoVo cells reached 71.75% and only 18.84% in the control (Figure 5).

The effect of same concentration of 5-Fu on PTEN transfected and non-transfected LoVo cells was detected using MTT. The inhibition rate on cell proliferation was higher in the former than that in the later, and there was a significant difference between them ($P < 0.01$).

DISCUSSION

Tumor formation is a process of multi-factors and multi-stages. The activation of cancer genes and inactivation and abnormality of anticancer genes are considered as important molecular mechanisms. Recently PTEN was found to be an anticancer gene^[25-28]. PTEN deletion and mutation were found in many malignant tumors including glioma, squamous carcinoma, prostate cancer, kidney cancer, endometrium cancer, breast cancer, colon cancer, etc.^[29-35]. The gene is on 10q23 chromosome in human and there are 9 exons at 5' terminal end and 804 nucleotides. The open reading frame is 1 209 bp encoding 403 amino acid residues of PTEN protein with a molecular weight 47.1 kD. Chromosome allele gene deletions mainly occurred in highly malignant tumors such as glioblastoma multiform (GBM) and malignant meningioma. PTEN mutation also occurred in GBM and was seldom found in low degree malignant glioma. Davies^[36] analyzed the DNA sequences in 46 glioma samples and found that PTEN mutation rate in an atlastic astrocytoma was 23% (3/13) and 36% (5/14) in GBM, but it was not found in 19 subjects with low degree malignant glioma. Such results indicated that PTEN might be related to the progress of glioma. Steck *et al.*^[37] discovered that 10q23 PTEN gene domain was frequently lost in GBM but was conserved in most low malignant tumors. The gene deletion was in 12q25-q26 domain and then PTEN gene loss appeared in the process of GBM. Dicuonzo *et al.*^[23] found that in colon cancer PTEN mutation, deletion and loss or replacement were all on chromosome 10 and the more malignant it was, the more evident the mutation and deletion were.

PTEN mutation rates in glioma cell lines and GBM were 41-63% and 17-44%, respectively. The literatures in Medline were reviewed for 674 malignant gliomas, the mutation rate of PTEN was 24%, including frame shift mutation, missense mutation, nonsense mutation and PTEN deletion. The point mutation rate was 41% and most of mutations were in core phosphorylase

domain of 5 exons. Davies *et al.*^[38] used adenovirus as vector and PTEN gene was transfected into glioma cell lines U251, pkb/akt, phosphorylation level was decreased and its activities were inhibited. The apoptosis rate was significantly higher than that in the control. It was reported that tumor cell growth was inhibited (60-70%) by transfected wild type PTEN with reverse transcription and PTEN mutation with U87MG and U178MG of glioma cell lines and cell growth stopped at G₁ stage by flow cytometry.

In our study, after transfection PTEN mRNA expression level in LoVo cells was higher than that before PTEN was transfected. After transfection PTEN protein expression level was higher by flow cytometry and the positive rate was increased from 21% to 47%, which indicated that PTEN gene was transferred into LoVo via lipofectin. Typical DNA ladder bands were found by 5-Fu in transfected LoVo cells and DNA ladder bands were not remarkable in non-transfected LoVo cells. The apoptosis rate was 71.75% after incubation of 5-Fu 10 μ L/mL in LoVo cells for 48 h and in the control it was only 18.84%. The effect of same concentration of 5-Fu on PTEN transfected LoVo cells and non-transfected LoVo cells was measured. The inhibition rate of cell proliferation was higher in the former than in the later and there was a significant difference between them, which demonstrated that PTEN gene expression promoted signaling in DNA damage by 5-Fu and induced apoptosis and inhibited cell proliferation in tumor.

PTEN protein is in cytoplasm of cells and homologous to tensin which is important in cell framework and in local adhesion. PTEN not only acts on the nuclei but also on membranes. PTEN protein could down-regulate the interaction of tumor cells and extracellular matrix (ECM) by inhibiting activities of focal adhesion kinase. (fak)^[39]. Malignant cells proliferate without local adhesion. Fak is an important signal mediated by integrin and its inhibition could induce apoptosis and its activation could induce non-dependent growth and tumor formation^[40]. Fak is over-expressed in many high degree malignant tumors. PTEN inhibits non-dependent cell growth by reducing Fak activities.

It was shown that apoptosis reached 71.75% when transfected LoVo cells were incubated with 5-Fu 10 μ L/mL for 48 h and it was 18.84% in the control. Maybe 5-Fu up-regulated the new protein synthesis on the surface of cells and promoted signaling in PTEN system in the cells or 5-Fu blocked some protective protein synthesis. The mechanism of cooperative effect of 5-Fu and PTEN gene transfection may be due to PTEN protein expression on the surface of cells and 5-Fu transmembrane transportation. 5-Fu can accumulate in cells and produce cytotoxin and induce cell apoptosis.

Abstract

AIM: To approach the relationship between alveolar echinococcosis (AE) pathology and level of sIL-2R, TNF- α and IFN- γ in sera and the significance of cytokines in development of AE.

METHODS: After 23 patients with AE were confirmed by ELISA and ultrasound, their sera were collected and the concentrations of sIL-2R, TNF- α and IFN- γ were detected by double antibody sandwich. Twelve healthy adults served as controls. According to the status of livers of AE patients by ultrasound scanning, they were divided into 4 groups: P₂, P₃, P₄ groups and C group (control). Average of concentrations of sIL-2R, TNF- α and IFN- γ in homologous group was statistically analyzed by both ANOV and Newman-Keuls, respectively.

RESULTS: The mean of sIL-2R in P₂ group was 97 ± 29 , P₃: 226 ± 80 , P₄: 194 ± 23 and control group $(111 \pm 30) \times 10^3$ u/L ($P < 0.01$). The mean of TNF- α in P₂ group was 1.12 ± 0.20 , P₃: 3.67 ± 1.96 , P₄: 1.30 ± 0.25 and control group 0.40 ± 0.19 μ g/L ($P < 0.01$). The mean of IFN- γ in P₂ group was 360 ± 20 , P₃: 486 ± 15 , P₄: 259 ± 19 and control group: 16 ± 2 ng/L ($P < 0.01$). Judged by ANOV and Newman-Keuls, the mean concentrations of sIL-2R, TNF- α and IFN- γ had a significant difference among groups. Except for P₂ group, the mean sIL-2R between other groups of AE patients had a significant difference ($P < 0.05$). The mean of TNF- α concentration in P₃ group was the highest ($P < 0.01$). The mean of IFN- γ concentration in all patients was higher than that in control group ($P < 0.01$), but there was no difference between AE groups ($P > 0.05$).

CONCLUSION: Low sIL-2R level indicates an early stage of AE or stable status, per contra, a progression stage. Higher level of TNF- α might be related to the lesion of liver. The role of single IFN- γ is limited in immunological defense against AE and it can not fully block pathological progression.

INTRODUCTION

Alveolar echinococcosis (AE) is a rare and potentially fatal

parasitic disease^[1,2]. B ultrasound and immunological tests are the most useful diagnostic methods for AE. In keeping with the popularity of B-ultrasound in diagnosis and epidemiological survey of AE, it is of important clinical and theoretical significance to understand the relationship between AE clinical types or pathological process and cytokines from patients with AE. B ultrasound has the characteristics of rapidity, accurate location and direct viewing for AE diagnosis and could reflect the pathological process of AE.

Since the early 1990 s, the study on cell mediated immunity of AE has rapidly progressed^[3,4], but studies on AE clinical types coupled cytokines are rare. During the epidemiological survey in Gansu Province, China, cytokines in patients with AE were detected. According to the pathological lesions obtained by B-ultrasound, the patients were divided into different stages, and the relationship between clinical types and cytokines in sera was discussed.

MATERIALS AND METHODS

Twenty-three cases of AE were confirmed by ELISA and ultrasound and their sera were collected. Absorbency values of sIL-2R, TNF- α and IFN- γ were detected by double antibody sandwich. Twelve healthy adults served as controls. The standard curve was drawn and the concentrations of above cytokines were measured respectively. In reference to the standardization of TNM classification system for hepatocellular carcinomas, all subjects were divided into 4 groups: P₂, P₃, P₄ groups and C group (control group). The average of concentrations of sIL-2R, TNF- α and IFN- γ was statistically analyzed by both ANOV^[5] and Newman-Keuls^[6] respectively.

RESULTS

A total of 23 patients with AE were divided into P₂ group: 7 cases, P₃ group: 9 cases, P₄ group: 7 cases. The mean of sIL-2R in P₂ group was 97 ± 29 , 226 ± 80 in P₃ group, 194 ± 23 in P₄ group and $(111 \pm 30) \times 10^3$ u/L in control group (F: 9.19; $P < 0.01$). The mean of TNF- α in P₂ group was 1.12 ± 0.2 , 3.67 ± 1.96 in P₃ group, 1.30 ± 0.25 in P₄ group and (0.40 ± 0.19) μ g/L in control group (F: 13.56; $P < 0.01$). The mean of IFN- γ was 360 ± 20 in P₂ group, 486 ± 15 in P₃ group, 259 ± 19 in P₄ group and (16 ± 2) ng/L in control group (F: 17.25, $P < 0.01$). This indicated that the mean concentrations of sIL-2R, TNF- α and IFN- γ had a significant difference between different groups ($P < 0.01$). Except in P₂ group, the mean concentration of sIL-2R between other groups of AE patients and controls had a significant difference ($P < 0.05$), so was between P₂ and other 2 groups of AE. The mean concentration of TNF- α in P₃ group was the highest and had a significant difference from the other 3 groups ($P < 0.01$). The mean concentration of IFN- γ in all patients was higher than that in control group ($P < 0.01$), but there was no difference between AE groups ($P > 0.05$). Table 1 summaries the comparison of the Q value of mean sIL-2R, TNF- α , IFN- γ between each two groups.

DISCUSSION

Ninety-five percent of primary foci of AE locate in the liver. They proliferate through exogenous budding and metastasize from the primary location to distant sites. At the early stage of AE,

Table 1 Comparison of Q value of mean sIL-2R, TNF- α , IFN- γ between each two groups

	P ₂ and P ₃	P ₂ and P ₄	P ₃ and P ₄	P ₂ and C	P ₃ and C	P ₄ and C
sIL-2R	6.19 ^b	4.64 ^a	1.56	0.64	5.56 ^b	4.00 ^a
TNF- α	5.99 ^b	0.41	5.58 ^b	1.7	7.69 ^b	2.11
IFN- γ	0.28	1.72	2	7.98 ^b	8.26 ^b	6.26 ^b

^a $P < 0.05$, P₂ vs P₄, P₄ vs C for sIL-2R; ^b $P < 0.01$, P₂ vs P₃, P₃ vs C for sIL-2R; P₂ vs P₃, P₃ vs P₄, P₃ vs C for TNF- α ; P₂ vs C, P₃ vs C, P₄ vs C, for IFN- γ .

the main pathologic manifestation was limited to vesicles with a few millimeters in diameter, while hepatic ultrasound scanning showed limited nodes. Next AE lesions infiltrated, without well-defined limits, and tended to extend to a large area of the liver. The infiltration, which is similar to some malignant hepatic neoplasms, could bring about stenoses of intrahepatic bile ducts, the hepatic veins and portal branches. Following parasite reproduction, necrosis would occur and gave rise to a large central cavity containing gelatinous effusion with debris, bile and sometimes pus. Although TNM-system has some defect for the classification of liver cancers^[7], it is still considered authoritative, because it could reflect the size of tumor, growing pattern, encapsulation of tumor, daughter nodules (including microscopic nodules), vascular invasion, or biliary involvement and metastases^[8]. AE is similar to a malignant hepatic tumor in growth and pathologic process, however there has been no standard classification of AE by now. In reference to the standardization of liver cancer in the present study, AE was divided into 3 types, namely parasite location in the liver (type P), involvement of adjacent organs (type I), and metastasis (type M). Type P was further divided into 5 stages: P₀: no detectable tumor in the liver; P₁: single lesion involving <2 segments without intra-hepatic vascular or biliary involvement; P₂: single lesion involving 2 segments with intra-hepatic vascular or biliary involvement or single lesion involving 3 or 4 segments without intra-hepatic vascular or biliary involvement; P₃: single lesion involving 3 to 5 segments with intra-hepatic vascular or biliary involvement or multiple lesions without intra-hepatic vascular or biliary involvement; P₄: single lesion involving 6 to 8 segments or multiple lesions with intra-hepatic vascular or biliary involvement. Type I was also divided into 3 stages: I₀: no regional involvement; I₁: regional involvement of only one contiguous organ or tissue; I₂: regional involvement of several organs or tissues (> 1). There were a single lesion involving 2 segments in P₂ and P₁ groups with ultrasound image locating multiple nodule lesions, a single lesion involving 3-5 segments with heterogeneous hyper-reflective image in P₃ group; there were multiple lesions involving 3-5 segments and intra-hepatic vascular or biliary involvement with pseudocystic sonogram of central necrosis in P₄ group. Besides involvement of portal vein and gallbladder, the pathological process of liver involved 3-5 segments with pseudocystic sonogram of central necrosis in type I, which belonged to mid- and late stages of the disease. Since the late 1970 s, ultrasound has been used for detecting pathological lesions due to a number of parasitic infections including cystic echinococcosis. The manifestations of B ultrasound of AE were local multiple echogenic nodules in early stage and large non-heterogeneous hyperreflective lesion or pseudo-cystic image in mid- or late stage. B ultrasound could also reflect the pathological process of AE^[9].

In the early 1990 s, it was found that Th₁ cytokines had a role against AE infection and a relation with the slow growth stage of tumor or parasites. IL-2 secreted by CD₄⁺ T lymphocytes induced and activated by its antigens, reinforced host immunity and had anti-tumor activities or restrained growth of parasites^[10]. Its activity is dependent on expression of mIL-2R (membrane

interleukin-2 receptor), which can block IL-2. Due to the action of protein lyase at special sites, mIL-2R is partly incised and chopped off in blood, forming the so-called sIL-2R. It also has activity of blocking IL-2R and plays a negative regulation role in immune response of tumor and parasites, thus promoting the growth of tumor and parasites. Therefore sIL-2R level could also act as an index of tumor stage^[11]. As shown in Table 1 except for P₂ group, the mean of sIL-2R between other 2 groups of AE and controls had a significant difference ($P < 0.05$), so was the difference between P₂ and other 2 groups of AE ($P < 0.05$, $P < 0.01$). It could be rationally explained that IL-2 played a role in inhibiting worms in early stage or in stable status of AE, while low level of sIL-2R occurred in blood. Per contra, high-level of sIL-2R in blood means AE in progression stage.

TNF is secreted by macrophages and B lymphocytes and the former is called TNF- α and the latter TNF- β . Both have similar structures and functions, and act on the same acceptor. They could strengthen phagocytic ability of neutrophils. TNF could inhibit reproduction of some protozoa and decrease their density in blood. It could activate phagocytes, depending on nitric oxide that acts on parasites. However, the pathological process of brain tissue of patients with encephalic-malaria, omphalos lesion and vascular hemorrhagic necrosis, was related to the high level of TNF in blood^[12]. The mean concentration of TNF- α in P₃ group was the highest ($P < 0.01$) and had a significant difference from other 3 groups ($P < 0.01$). P₃ stage was the key time of AE from early stage to mid and late stages and the tissues appeared severe damage at this stage. It is obvious that TNF could participate in and exacerbate the pathological process of AE. But accompanying serious tissue necrosis, serum TNF concentration was also decreased in cases of P₄ group. This seems to be related with TNF location, in other words, it depends more on TNF concentration in local tissue. It was reported that TNF-mRNA was expressed in cells of the periparasitic granuloma in AE patients, and this particular expression was observed only in those patients with severe fertile lesions and associated with centro-granulomatous necrosis. No cytokine mRNA expression was observed in patients with an abortive disease^[13]. It was proved that TNF- α could inhibit growth of alveolar echinococcosis in experimental mice. In fact, TNF- α plays a complex role in patients with AE. But in cases of P₄ group, accompanying serious tissue necrosis, TNF value was also decreased and its mechanism still remains to be elucidated.

IFN- γ is induced by antigen and it could inhibit Th₂ cells to secrete in defence against parasites. It could fortify phagocytic function of macrophages and restrict multiplication of metacestodes in mice. In this study, the mean concentration of IFN- γ in any group of AE patients was higher than that in control group ($P < 0.01$), but there was no difference between AE groups ($P > 0.05$). This indicated the efficacy of IFN- γ was limited on inhibiting AE growth in humans. Even though IFN- γ inhibited metacestode growth in mice with AE at a low dose^[14], when it was used in combination with mebendazole or nitric oxide which plays a role in host defense mechanisms in human hydatidosis, it was effective for patients with AE^[15,16]. So IFN- γ depends on the synergism of chemical medicines or other factors to produce curative effects on AE.

Abstract

AIM: To study the effect of arsenic trioxide (As_2O_3) on human
hepatoma cell line BEL-7402 *in vivo*.

METHODS: Human hepatoma cell line BEL-7402 cultured
in vitro was inoculated into nude mice and arsenic trioxide,
5-Fu and saline were injected into abdominal cavity of the
nude mice respectively. The volumes of tumor and general
conditions of the nude mice and structural changes of the
liver and kidney were observed. Morphologic changes were
studied under electron microscope. Expression of AFP was
investigated by immunohistochemical method.

RESULTS: As_2O_3 could inhibit the growth of tumor. The tumor
growth inhibitory rate in mice treated with 2.5 mg/kg As_2O_3
was 53.42% on the tenth day. The tumor growth inhibitory
rate in mice treated with 5 mg/kg As_2O_3 was 79.28% on the
fifth day and 96.58% on the tenth day respectively. As_2O_3 did
not damage the liver and kidney of nude mice, or affect the
blood system. Typical apoptotic morphological changes
were found under electron microscope, and the change of
mitochondria was obvious. The expression rate of AFP
declined after treatment.

CONCLUSION: Arsenic trioxide can induce apoptosis of
human hepatoma cells, and inhibit proliferation of tumor
with no obvious side effects on liver and kidney.

INTRODUCTION

Liver cancer is one of the most aggressive malignancies and
the fourth leading cause of cancer death in China, and the vast
majority of patients die within the first year after diagnosis. There
is still no effective therapeutic modalities. Surgical resection is
the only potentially curative option, but it is not feasible in most
patients because of early spread of the disease. Since arsenic
trioxide (As_2O_3) has recently been recognized as an effective
treatment for patients suffering from acute promyelocytic
leukemia (APL)^[1-5], it has also been hypothesized to be effective
on some solid tumors^[6,7]. As_2O_3 has been shown to have dual
effects on human hepatocellular carcinoma (HCC) cell lines
in vitro^[8], including induction of apoptosis and inhibition of

proliferation^[9,10]. However it is not clear whether As_2O_3 has the
same effect *in vivo*. We established an HCC nude mice model to
evaluate anti-tumor effect of As_2O_3 *in vivo*, which might provide
an experimental basis for its clinical application to the treatment
of patients with HCC.

MATERIALS AND METHODS

Chemicals and reagents

As_2O_3 was purchased from Harbin Yida Medical Co (Harbin, China).
Murine monoclonal antibody and antimouse rabbit polyclonal
antibody were purchased from Maixin Co., Fuzhou, China.

Cell line and preparation

Human hepatoma BEL-7402 cells were purchased from the Cell
Institute of Chinese Academy of Sciences and maintained in
our laboratory. All media were supplemented with 100 mL/L
heat inactivated fetal bovine serum, penicillin G (100 IU/mL), and
streptomycin (100 µg/mL). The cells were incubated at 37 °C in a
humidified atmosphere with 50 mL/L CO₂ and grown as monolayers
in RPMI 1640 medium supplemented with 80 mL/L calf serum.

Animals

Five-week-old male nude mice weighing 17-20 g were used for
subcutaneous implantation. All animals were housed in semisterile
microisolator cages with autoclaved bedding, maintained on a
12-h light/dark cycle and given food and water. The experimental
protocol was approved by the Experimental Animal Center of
Chinese Academy of Sciences (identification No. Scfk11-6A-
0006) in accordance with the national guidelines for animal care
and use of laboratory animals.

Tumor induction in nude mice

Human hepatoma BEL-7402 tumor cells were grown in
monolayer culture. The exponentially growing BEL-7402 cells
in culture flasks were harvested, and adjusted to the concentration
of 1×10^7 /mL. For subcutaneous tumor formation, 200 µL of cells
was injected subcutaneously into the flanks of the animals
(donor mice). These mice were randomly divided into four
groups: negative control group (saline), and groups of As_2O_3
(2.5 mg/kg, 5 mg/kg), 5-Fu (2.5 g/L). Each group was injected
with the same volume of saline, As_2O_3 (2.5 mg/kg, 5 mg/kg), and
5-Fu (2.5 mg/mL) respectively, once a day for 10 d.

Tumor assessment

The tumor was measured with a caliper in all three perpendicular
dimensions on the 1st, 5th and 10th d of treatment, and tumor
volume was calculated using the following formula: volume =
length×width×depth/2. All animals were killed and underwent
complete examination of abdominal cavity after ten days. The
liver and kidney were resected and examined under microscope.
The tumor mass was isolated and weighed. The inhibitory rate
of tumor was evaluated using the following formula: inhibitory
rate of tumor (%) = (1-mean tumor weight in experiments / mean
tumor weight in controls) × 100%.

Morphologic observation

Tumor specimens were fixed with 4 g/L formaldehyde and
wrapped with wax, then stained with HE.

Transmission electron microscopy

The samples were prefixed in 25 g/L glutaraldehyde, then in 10 g/L OsO₄, dehydrated in ethanol series, and replaced in propene oxide. The samples were examined with a JEM-1220 transmission electron microscope.

Immunohistochemistry

AFP protein was detected with SABC method. Tumor specimens were incubated with 3 mL/L hydrogen peroxide in methanol for 30 min to block endogenous peroxidase activity, then washed in PBS and incubated in 100 mL/L normal goat serum for 20 min to reduce nonspecific antibody binding. Specimens were then incubated with a 1:50 dilution of murine monoclonal antibody against human AFP oncoprotein overnight at 4 °C, followed by three washes with PBS, then incubated with biotinylated rabbit antimouse polyclonal antibody at a dilution of 1:100 for 30 min followed by 3 washes. Slides were then treated with streptavidin-peroxidase reagent for 30 min at a dilution of 1:100 and washed with PBS 3 times. Finally, slides were incubated in phosphate-buffered saline containing diaminobenzidine and 10 mL/L hydrogen peroxide for 10 min, counterstained with hematine, and mounted.

Blood routine test

Venous blood was taken from the orbital venous plexus of the mouse before the animal was killed. The blood routine test was done.

Statistical analysis

Data were presented as mean±SD, the differences between the rates of different groups were analyzed by χ^2 test.

RESULTS

General condition

The tumor node of the saline group was larger on the 5th and tenth days than on the first day. The appetite of mice was normal, as well as the body mass. The stool was normal. The tumor had no obvious increase after five days in 5-Fu group. The mice did not eat or drink, had a low spirit. The color of the skin turned red, and more weight was lost. The mice died gradually. The mice in As₂O₃ group was in better spirit and just the color turned red. Only two mice had diarrhea (Table 1).

Morphologic changes

The morphologic changes were observed by microscopy. Large areas of necrosis were seen under microscope. In saline group of mice BEL-7402 cells in areas of non-necrosis proliferated rapidly. The mitotic nuclei were more frequently seen. Large areas of necrosis could also be seen in the 5-Fu group, and also in the higher concentration As₂O₃ group. Nuclei appeared condensation. The liver system and kidney were normal in the low As₂O₃ group. A few vacuolar degeneration were found in the liver of the higher As₂O₃ group, but the kidney was normal. The nucleocytoplasmic ratio increased and microvilli were identified on the surface of cells in saline group. The distortion of the nuclei was frequent.

There were many endoplasmic reticula and mitochondria. In As₂O₃ group, the cell nuclei became round and smaller. The aberrant cells were fewer. The microvilli were much decreased. The intact cell membrane, nuclear condensation and apoptotic body formation were seen. The changes were more obvious in the high concentration As₂O₃ group.

Effect on blood system

White blood cells, hemoglobin, and blood platelets had no significant difference between saline group and As₂O₃ group (Table 2).

Table 2 Routine blood examination results (mean±SD)

Groups	Number	WBC ($\times 10^{10}/L$)	Hgb (g/L)	PLT) ($\times 10^9/L$)
Saline	10	1.05±0.12	140.24±13.21	221.65±70.34
As ₂ O ₃ (2.5 mg/kg)	10	1.13±0.16	138.67±13.17	231.75±68.48
As ₂ O ₃ (5 mg/kg)	10	1.21±0.16	142.58±15.29	246.38±60.45

Expression of AFP protein

The expression of AFP was significantly lower in As₂O₃ group than in saline group ($P<0.01$, Table 3).

Table 3 Expression of AFP protein (mean±SD)

Group	Number	AFP (%)
Saline	10	48.32±4.56
As ₂ O ₃ (2.5 mg/kg)	10	29.78±3.10 ^b
As ₂ O ₃ (5 mg/kg)	10	22.26±2.31 ^b

^b $P<0.01$ vs saline group.

DISCUSSION

Recent clinical studies in China have shown that arsenic trioxide is an effective and relatively safe drug in the treatment of acute promyelocytic leukemia^[1,2,11,12]. Chen^[8] found that arsenic trioxide could trigger apoptosis of APL cell line NB4 cells, associated with downregulation of Bcl-2 gene expressions and modulation of PML-RAR alpha chimeric protein.

Experimental studies on antitumor effect were carried out in solid tumor, cancers of the lung, esophagus, stomach, colon, pancreas, breast, cervix^[13,14]. It has been demonstrated that As₂O₃ could inhibit the proliferation of HCC cells and induce apoptosis of HCC *in vitro*^[8,15]. Antitumor function of As₂O₃ *in vivo* was limited. We studied the action and mechanism of As₂O₃ in human hepatocarcinoma of nude mice. Our results showed that tumor mass in As₂O₃ group was smaller than that in saline group after 5 d, but there was no significant difference between the two groups ($P>0.05$), the growth in As₂O₃ group became slower from the 6th d. The inhibitory rate of tumor was 53.42%. The tumor node of mice treated with 5 mg/kg As₂O₃ became smaller than that of saline group. There were obvious differences between the two groups. The inhibitory rate of

Table 1 Inhibitory action of arsenic trioxide on tumor mass (mean±SD)

Groups	Number	Volume d 1	Volume d 5	Volume d 10	Mouse mass (g)	Inhibitory rate (%) 5 th d	Inhibitory rate (%) 10 th d
Saline	10	0.123±0.052	0.234±0.072	0.415±0.084	23.07±3.14		
5-Fu	10	0.113±0.060	0.134±0.040	14.07±2.29		86.85	
As ₂ O ₃ (2.5 mg/kg)	10	0.102±0.041	0.218±0.099	0.238±0.043 ^b	20.50±1.95		53.42
As ₂ O ₃ (5 mg/kg)	10	0.098±0.030	0.121±0.038	0.103±0.042 ^b	20.28±1.63	79.28	96.58

^b $P<0.01$ vs saline group.

tumor was 79.28% on the 5th d and 96.58% on the 10th d. Our concern was the toxicity of As₂O₃. It has been proved that it was not so poisonous in experiments and clinic. The toxicity depended on its dosage and the time of its use. As₂O₃ could damage normal cells when treating APL or others^[2] at 0.1-0.2 μmol/L. Experiments showed that they had no effect on stem cells at this concentration. At 3.0 μmol/L As₂O₃ had teratogenic effect on mouse embryo. The results showed it had no effect on embryo growth, development and differentiation. Our study also showed that the mice were normal in higher As₂O₃ group. The weight of mice had no significant difference between As₂O₃ group and saline group. The number of WBC, RBC, PLT was not obviously different between the two groups. There was a higher inhibitory rate of tumor in 5-Fu group (86.8%), but the weight of nude mice was reduced. The mice died gradually in 5-Fu group. Although the inhibitory rate of tumor was higher in 5-Fu group, the mice did not eat or drink. The weight was lost, and dystrophy could inhibit the growth of tumor.

AFP is a specific marker of liver cancer. BEL-7402 cells could secrete AFP. The expression rate of AFP was decreased after treatment. It showed that the level of tumor cell differentiation could be raised and the number of tumor cells was reduced after treatment. The divisions of tumor cells were decreased and apoptotic cells could be found in the lower As₂O₃ group. Large areas of necrosis could be seen in 5-Fu group, but survival tumor cells grew vigorously. It showed that 5-Fu could inhibit tumor growth due to its cytotoxic function. As₂O₃ could induce apoptosis of tumor cells.

We observed the morphologic changes of apoptosis by TEM in As₂O₃ group, the nucleocytoplasmic ratio became smaller, nuclei appeared round, mitochondria became distended, cells wrinkled, nuclear condensation and apoptotic body formation occurred. Early and obvious changes occurred in mitochondria, suggesting that As₂O₃ is toxic to mitochondria. The change of mitochondria could induce apoptosis. Further studies on the mechanism of mitochondria denaturation in order to prove that As₂O₃ could treat HCC are needed.

In conclusion, arsenic trioxide can induce apoptosis of human hepatocarcinoma cells and inhibit their proliferation. It has no side effects on the liver, kidney and blood system.

Abstract

AIM: To analyze the clinical manifestations, pathological features and treatment of primary small cell carcinoma (SCC) of the esophagus and to review the literature on this entity.

METHODS: The records of 9 patients with primary esophageal small cell carcinoma were examined and the demographic data, presenting symptoms, methods of tumor diagnosis, and types of treatment given, response to treatment, pathologic findings, and clinical outcome were reviewed. Features of mixed patterns of histological differentiation and lymph node metastases were specifically sought.

RESULTS: All the patients reported dysphagia, weight loss and chest pain as the initial symptoms. In 5 cases the tumors were located in the mid-esophagus, 3 cases in the lower third of the esophagus and 1 case in the upper third. The average length of esophageal involvement was 5 cm. They underwent radical resection, regional lymph node clearance and esophageal-stomach anastomosis in thorax or at neck. Two patients had a stage IIa disease, five had a stage IIb disease, and the other two had a stage III disease of International Union Contrele Cancer (UICC). All of them were histologically and immunohistochemically confirmed SCC of esophagus. Immunohistochemical staining for neuron-specific enolase (NSE), synaptophysin (Syn) and chromogranin A exhibited strong immunoreactivity in all specimens. Three of the nine resected specimens showed foci of squamous cell carcinoma *in situ*. Metastasis was present in 7 of 9 adjacent lymph nodes. All the patients survived the operations and made an uneventful postoperative recovery. They received adjuvant systemic chemotherapy and local radiation therapy after discharge. During follow-up, three patients developed multiple liver, brain, lung and bone metastases and died between 5 and 18 mo after the diagnosis. Three patients developed widespread metastasis disease and died between 18 and 37 mo after the diagnosis. There was no local tumor recurrence in these 6 patients. The other three patients were lost during follow-up.

CONCLUSION: Primary small cell carcinoma of the esophagus is a rare but very malignant tumor. Radical resection combined with chemotherapy and radiotherapy is helpful in limited stage cases.

INTRODUCTION

Primary small cell carcinoma (SCC) of the esophagus is a rare tumor characterized by early dissemination and poor prognosis if untreated^[1]. To our knowledge the standard of treatment for esophageal SCC has not been defined yet due to the paucity of cases. Treatments such as operation alone^[2], local radiotherapy^[3], chemotherapy alone^[4], or operation with adjuvant therapy^[5] have been reported. Here we described the clinical manifestations, pathological feature and treatment of 9 patients with primary esophageal SCC treated at our institution between January 1985 and December 2000 and reviewed the available literature on this entity.

MATERIALS AND METHODS

Patients with a diagnosis of SCC of the esophagus were identified from clinical and pathologic records from a 16-year period. The clinical, radiographic, and pathologic findings were reviewed and all patients in which esophageal invasion by a primary bronchial SCC could not be ruled out were excluded from the study. A total of 9 patients identified from the records were considered to have a primary esophageal SCC.

The demographic data, presenting symptoms, methods of tumor diagnosis, staging procedures done, types of treatment given, response to treatment, pathologic findings, and clinical outcome were recorded. Histological sections were reviewed to confirm the diagnosis of SCC. Features of associated carcinoma, mixed patterns of histological differentiation, and lymph node metastases were specifically sought. Immunohistochemical staining was done in differential diagnosis.

RESULTS

The study group consisted of 9 consecutive patients. There were 6 men and 3 women, with a mean age of 56 years (range from 45 to 66). All the patients reported dysphagia, weight loss and chest pain as the initial symptoms. Barium swallow, flexible esophagoscopy and biopsy established their diagnosis. Preoperative work-up excluded distant metastasis diseases in all the patients. There was no evidence of a primary bronchogenic small-cell tumor on chest radiograph. Liver ultrasonography was done before resection to exclude liver metastases. Calcium, phosphate, and alkaline phosphatase levels were measured in an attempt to exclude occult bone metastases. In 5 cases the tumors were located in the midesophagus, 3 cases in the lower third of the esophagus, and 1 case in the upper third. The average length of esophageal involvement was 5 cm (range, 3 to 7 cm).

These patients underwent radical resection, regional lymph node clearance and esophageal-stomach anastomosis in thorax or at neck. During the curative operations, all the tumors were

Figure 1 Immunohistochemical staining in SCC of esophagus (LSAB×145). A: NSE staining; B: Syn staining; C: chromogranin A staining.

confirmed to be confined to the esophagus, and the adjacent lymph nodes were either uninvolved or less than 2 cm in the greatest dimension, discrete, and within the vicinity of the primary tumor. Based on the intraoperative findings and pathological assessment, two patients had a stage IIa disease, five had a stage IIb disease, and the other two had a stage III disease of UICC. All the patients were histologically and immunohistochemically confirmed to have a SCC of esophagus. The histological criteria for small cell lung carcinoma (SCLC) proposed by the World Health Organization were used. Immunohistochemical staining for neuron-specific enolase (NSE)^[6], synaptophysin (Syn)^[7] and chromogranin A^[8] exhibited strong immunoreactivity in the specimens, which indicated that neurosecretory granules were positive in the tumor cells (Figure 1). Three of the nine resected specimens showed foci of squamous carcinoma *in situ*. All the mucosal margins were negative for tumors. Metastasis was present in 7 of 9 adjacent lymph nodes.

All the patients survived the operation and made an uneventful postoperative recovery. They received adjuvant systemic chemotherapy and local radiation therapy after discharge. The regimen of the multi-drug chemotherapy was combined with cisplatin (DDP), fluorouracil (5-Fu) and bleomycin (BLM) of 4 cycles, alternating every 3 wk. They also received radiation of the tumor bed and regional lymph nodes with the doses of 5 000 cGy at a rate of 1 000 cGy/wk. During the follow-up, three patients developed multiple liver, brain, lung and bone metastases and died between 5 and 18 mo after the diagnosis. Three patients developed widespread metastasis diseases and died between 18 and 37 mo after the diagnosis. There was no local tumor recurrence in these 6 patients. The other three patients were lost during follow-up.

DISCUSSION

Undifferentiated SCC is an aggressive tumor most frequently described in the bronchial tree, which makes up approximately 15% of all lung cancers^[9]. The most common extrapulmonary sites of SCC are the salivary glands, pharynx and larynx, esophagus, stomach, pancreas, colon, rectum, skin and cervix^[4]. To our knowledge, more than 200 cases of esophageal SCC have been described in the medical literature^[10]. The incidence of esophageal SCC ranges between 0.4–7.6% of all esophageal malignancies in different regions^[11]. In our institution, these 9 patients represented about 1% of all patients with esophageal tumors between January 1985 and December 2000.

The cellular origins of esophageal SCC have been the subject of intense speculation and debate. Esophageal SCC was initially thought to arise from argyrophilic Kulchitsky cells in esophageal mucosa^[12]. These cells have the ability to synthesize and store amines and to decarboxylate some amino acids: a feat that gave rise to the term amine precursor uptake, decarboxylation

(APUD) cells. It would now appear that esophageal SCC is of endodermal origin derived from pluripotential basal epithelial cells served as the common precursor for adenocarcinoma, squamous cell carcinoma and SCC^[13]. The small cells retain their potential for further differentiation into either mucin-producing or keratin-forming cells. This explains the coexistence of small cells, squamous and glandular elements in the same lesion. The surgical resection specimens in our group showed mixed histologic types in three out of the nine cases, all of the mixed squamous and small cell carcinomas, showed this multiple differentiation. Our findings of a high incidence of histologic heterogeneity in esophageal SCC in association with squamous carcinoma *in situ* strongly support this unified hypothesis.

Esophageal SCC may show a variety of genetic changes, including mutation of tumor-suppressor gene and loss of heterogeneity involving the genetic loci for various tumor-suppressor genes. Recent studies have shown that microsatellite instability (MSI) may be more frequent in SCC of the esophagus than in squamous-cell carcinoma of the esophagus in the development of esophageal cancer^[14]. In a previous study, we used polymerase chain reaction-polyacrylamide gel-silver stain method to investigate the presence of MSI in 3 of the 9 cases in this series and MSI was observed in 3 out of 3 cases (100%), significantly higher than squamous cell carcinoma (40.3%)^[15]. This observation suggests that the incidence of MSI and DNA replication errors may play an important role in esophageal SCC and may be an early event in esophageal SCC carcinogenesis.

Grossly, esophageal SCC was not distinguishable from esophageal squamous carcinoma. Esophageal SCC might present as an ulcerating hard tumor mass on the mucosal surface of the esophagus or as a polypoid infiltrative process growing in the submucosal layer without obvious ulceration of the mucosal surface. Microscopically, in all of the cases, the tumor was described as having a histological appearance of SCLC, consisting of round to spindle-shaped cells with scanty cytoplasm, granular nuclei, inconspicuous nucleoli, and ultrastructural and immunohistochemical evidence of neuroendocrine differentiation^[16]. The cells might be argyrophil positive with neurosecretory granules seen on electron microscopy. Immunohistologically, these cells were immunoreactive with low-molecular-weight cytokeratins and epithelial membrane antigen. Although neurosecretory granules could be identified within esophageal SCC, and they could be stained immunohistochemically for various hormones, clinical manifestations of paraneoplastic syndromes were, however, infrequent, with only scattered reports. We have not encountered paraneoplastic syndromes in the current patients.

The mean age of patients with esophageal SCC at the time of presentation, the location of esophageal SCC and presenting symptoms of esophageal SCC are similar to those of esophageal squamous cell carcinomas. But esophageal SCC is a more aggressive tumor and associated with rapid growth, and

patients usually present with widespread metastasis disease. In our series, metastasis tumor was present in 7 of 9 (78%) adjacent lymph nodes. But preoperative work-up excluded distant metastasis diseases in all the patients and all the tumors were confined to the esophagus. The resectability of these 9 cases was significantly higher than that reported by other investigators. This might be due to the advance to the advantage of early diagnosis and treatment of esophageal carcinomas.

Prospective randomized trials of therapy for esophageal SCC were unlikely given the rarity of the disease. The management of primary esophageal SCC remains controversial. Yachida *et al.*^[17], described a patient with esophageal SCC with extensive lymph node metastases. Treatment comprised a subtotal esophagectomy and extended lymph node dissection, but no chemotherapy or radiation therapy. He has survived for more than 7 years with no evidence of recurrent disease. A recent work by Casas *et al.*^[18] suggests that multimodality therapy might improve resectability and overall outcome. To allow for the evaluation of prognostic factors that influenced survival, esophageal SCC patients were grouped according to limited stage (LS), which was defined as a disease confined to the esophagus, or extensive stage (ES), which was defined as a disease that had spread beyond locoregional boundaries. There was a significant difference in survival between patients with LS and those with ES ($P < 0.0001$)^[18]. The median survival time was 8 mo for patients with LS and 3 mo for those with ES. In LS, favorable prognostic factors were the tumor size (≤ 5 cm) and the association of chemotherapy with local treatment. The best prognostic factor for ES was the feasibility of any kind of active treatment. The longest survival in our series of esophageal SCC with multimodality was 37 mo. We conclude that patients with operable diseases should be offered resection with curative intent in combination with adjuvant chemotherapy and radiation therapy.

Abstract

AIM: To study the effect of integration of tandem *aroG-pheA* genes into the *tyrA* locus of *Corynebacterium glutamicum* (*C. glutamicum*) on the production of L-phenylalanine.

METHODS: By nitrosoguanidine mutagenesis, five *p*-fluorophenylalanine (FP)-resistant mutants of *C. glutamicum* FP were selected. The *tyrA* gene encoding prephenate dehydrogenase (PDH) of *C. glutamicum* was amplified by polymerase chain reaction (PCR) and cloned on the plasmid pPR. Kanamycin resistance gene (Km) and the P_{BF} -*aroG-pheA*-T (GA) fragment of pGA were inserted into *tyrA* gene to form targeting vectors pTK and pTGAK, respectively. Then, they were transformed into *C. glutamicum* FP respectively by electroporation. Cultures were screened by a medium containing kanamycin and detected by PCR and phenotype analysis. The transformed strains were used for L-phenylalanine fermentation and enzyme assays.

RESULTS: Engineering strains of *C. glutamicum* (Tyr⁻) were obtained. Compared with the original strain, the transformed strain *C. glutamicum* GAK was observed to have the highest elevation of L-phenylalanine production by a 1.71-fold, and 2.9-, 3.36-, and 3.0-fold in enzyme activities of chorismate mutase, prephenate dehydratase and 3-deoxy-D-arabinoheptulosonate-7-phosphate synthase, respectively.

CONCLUSION: Integration of tandem *aroG-pheA* genes into *tyrA* locus of *C. glutamicum* chromosome can disrupt *tyrA* gene and increase the yield of L-phenylalanine production.

INTRODUCTION

L-phenylalanine is one of the essential amino acids for humans. Its applications range from feed to food, and pharmaceutical products. such as *p*-fluorophenylalanine are used as anti-tumour drugs. At present, L-phenylalanine biosynthesis genes have been well characterized and the enzymology of L-

phenylalanine biosynthesis has been extensively investigated^[1-10]. In bacteria, the biosynthesis of aromatic amino acids starts from condensation reaction of central carbon intermediates such as phosphoenol pyruvate (PEP) and erythrose-4-phosphate (E4P) to form 3-deoxy-D-arabino-heptulosonate-7-phosphate (DAHP), which is catalyzed by DAHP synthase (DS). DAHP is then converted to chorismate, the branch point of aromatic amino acid biosynthesis. L-phenylalanine is synthesized from chorismate by three continuous steps catalyzed by chorismate mutase (CM), prephenate dehydratase (PD) and aromatic-amino-acid transaminase (AT). *aroG*^[1-5] and *pheA*^[6-10] are two key genes in L-phenylalanine biosynthesis. In *E. coli*, they encode the 3-deoxy-D-arabinoheptulosonate-7-phosphate synthase (DS) and chorismate mutase/prephenate dehydratase (CM/PD), respectively. However, in *Corynebacterium glutamicum* (*C. glutamicum*), CM and PD are encoded by two different genes *pheB* and *pheA*^[10]. The over-expression of *aroG* and *pheA* can increase the yield of L-phenylalanine biosynthesis in *E. coli* or in *Corynebacteria* by shuttle vectors^[11-17]. *tyrA* encoding prephenate dehydrogenase (PDH) is a key gene in L-tyrosine biosynthesis branch pathway^[18]. DS and CM of *C. glutamicum* can be synergistically inhibited by L-tyrosine and L-phenylalanine. Every step from DAHP to chorismate is repressed weakly by L-tyrosine. In addition, PD is strongly inhibited by L-phenylalanine and L-tryptophan, L-tyrosine stimulates PD activity and restores the enzyme activity inhibition by L-phenylalanine and L-tryptophan^[19]. These regulations seem to result in balanced synthesis of L-tyrosine and L-phenylalanine (Figure 1). Therefore, elimination of feedback inhibition of L-phenylalanine on the key enzymes and deletion of *tyrA* gene can improve the yield of L-phenylalanine biosynthesis. There are successful examples by using homologous recombination technology to introduce genes into chromosome^[20-23].

Figure 1 Pathway and primary regulations of phenylalanine biosynthesis in *C. glutamicum* ----- indicates feedback inhibition, - - - ➔ indicates activation.

In this study, we used nitrosoguanidine (NTG) to treat *C. glutamicum*. Mutants resistant to FP were isolated in a

minimal medium plate with FP and named *C. glutamicum* FP. The tandem *aroG-pheA*^[15] genes obtained from *E. coli* resistant to FP were inserted into the chromosome of *C. glutamicum* FP by a double-exchange homologous recombination between the fragments of *tyrA* gene on targeting vectors and the *tyrA* gene on the chromosome of *C. glutamicum* FP. Enzyme activities and L-phenylalanine biosynthesis in the engineered strains of *C. glutamicum* KM and *C. glutamicum* GAK were analyzed.

MATERIALS AND METHODS

Bacterial strains, media, and culture conditions

The bacterial strains and plasmids used in this study are listed in Table 1. Minimal medium^[15] (MM) and NB (LB added with 10 g/L beef extract) were used for culture *C. glutamicum*. The medium for *C. glutamicum* fermentation was reported previously^[16]. LB was used for growth of *E. coli*. When required, appropriate antibiotics were added to the suitable concentrations. Solid media were made by the addition of agar at the concentration of 15 g/L.

Chemicals

T₄ DNA ligase, restriction enzymes, gel extract kit and DNA blunting kit were obtained from Takara Co. NTG and the reagents used in the enzyme assays were purchased from Sigma Co. They were used according to the instructions of their manufacturers.

Isolation of L-phenylalanine analogue resistant mutants

C. glutamicum cells were grown in NB supplemented with 20 mg/L nalidixic acid until log phase, and collected by centrifugation, followed by two washes with phosphate buffered saline (pH6.0). The cells were then resuspended in 500 µL of 9 g/L NaCl containing 5 mg of NTG and kept on shaking at 30 °C for another 30 min. The cells were collected by centrifugation followed by two washes before suspension in 9 g/L NaCl. Appropriate aliquots of the suspension were spread on the minimal agar plate containing different concentrations of *p*-fluorophenylalanine (*p*-FP) for mutant screening.

Preparation and manipulation of DNA

Chromosomal DNA of *C. glutamicum* was extracted as described previously^[10]. Manipulation of plasmid DNA was performed as described by Sambrook *et al.*^[24].

Construction of recombinant plasmids

Primers of *tyrA* and Km were designed according to the sequences in GenBank (NC_003450 and AF012346). Primer P1: 5'-G GCTGCAGCAGGCCATCCTCTTCAGTGTTC-3' and

primer P2: 5'-CCCAAGCTTCGAGGGTTTCAGCGTGGATG-3' were designed for amplifying *tyrA* gene carrying *Pst*I and *Hind*III restriction enzyme sites, respectively. Primer P3: 5'-GCGGAAT TCACCGGAATTGCCAGCTG-3' and primer P4: 5'-GCGGAAT TCTGCAGTTATCAGAAGAAGCTCGTCAAG-3' were designed for amplifying Km gene carrying *Eco*RI and *Pst*I sites, respectively. The primer P5 for PCR detection was 5'-CCCA AGCTTAGG AATCGCCTGAGAATCATCA-3'. Construction of recombinant plasmids was performed as shown in Figure 2.

Electroporation of linear DNA into C. glutamicum

Targeting vectors were digested by *Hind* III and the linear DNA was obtained by gel extraction. Then, they were denatured by 1 mol/L NaOH at 37 °C for 10 min, quickly placed on ice before the same volume of 1 mol/L HCl was added to neutralize the alkali. The method of Molenaar^[25] was used to introduce denatured targeting vectors into *C. glutamicum* FP.

Selection and identification of the recombinant strain

After electroporation, *C. glutamicum* was incubated in 1 mL NB medium containing 0.5 mol/L sucrose at 30 °C by shaking (100 r/min) for 1 h, then the culture was plated on selective NB medium containing 0.5 mol/L sucrose, 10 µg/mL nalidixic acid and 15 µg/mL kanamycin for 96 h. The strains on resistant plates were singled out and inoculated on NB with 100 µg/mL ampicillin, 15 µg/mL kanamycin and NB with 15 µg/mL kanamycin, respectively; Clones (Ap^r Km^r) were detected by PCR using primers pair P3 and P5. PCR products were sequenced.

Detection of Tyr phenotype

The strain cultures were washed three times with sterile physiological saline and plated on MM plates containing 2 g/L glucose and 1 mol/L L-tyrosine or other amino acids to detect the Tyr⁻ auxotroph.

Enzymatic activities assay

Crude cell lysates used for enzymatic activity assays were prepared as described previously^[15]. Total protein level was determined according to the method of Bradford^[26]. DS activity was assayed as described previously^[15]. CM activity was determined as described by Xia *et al.*^[27]. PD activity was assayed as previously described^[28].

Fermentation and analysis of phenylalanine

Transformants of *C. glutamicum* were obtained by PCR and phenotype analysis. L-phenylalanine fermentation of them was carried out in the shaking flask and the yields of L-phenylalanine biosynthesis were determined as described by Zeng *et al.*^[15].

Table 1 Strains and plasmids

Strains or plasmids	Relevant characteristics	Sources or references
<i>E. coli</i> JM110	Strain for vectors construction	Our laboratory
<i>C. glutamicum</i>	Nx ^r , original strain mutagenesis	ATCC
<i>C. glutamicum</i> FP	FP ^r , from <i>C. glutamicum</i> ATCC13032	This work
<i>C. glutamicum</i> KM	<i>C. glutamicum</i> FP inserted with Km gene	This work
<i>C. glutamicum</i> GAK	<i>C. glutamicum</i> FP inserted with GAK	This work
pBluscript SK (pSK)	Ap ^r , vector for gene cloning	Our laboratory
pPR	Ap ^r , pBR322 derivative, suicidal vector	Our laboratory
pGA	Km ^r , carrying P _{BF} - <i>aroG-pheA</i> -T fragment	Ref.15
pT	pPR carrying <i>tyrA</i> gene	This work
pTK	pT carrying Km gene(<i>tyrA</i> ::Km)	This work
pSKGAK	pSK carrying GAK fragment	This work
pTGAK	pT carrying GAK fragment (<i>tyrA</i> ::GAK)	This work

FP^r: resistance to *p*-fluorophenylalanine; Nx^r: resistance to nalidixic acid; Ap^r: resistance to ampicillin; Km^r: resistance to kanamycin; ATCC: American Type Culture Collection. P_{BF}: promoter from *C. glutamicum*; T: terminator of gene32 in T₄ phage. GAK: P_{BF}-*aroG-pheA*-T-Km fragment.

RESULTS

Isolation of *L*-phenylalanine analogue resistant mutants

Five mutants resistant to *p*-FP up to 3 mg/mL were picked out on MM plates after NTG mutagenesis. In those mutants, the feedback inhibition on the key enzymes in biosynthesis pathways was released from phenylalanine. The mutant with the highest yield of phenylalanine was named *C. glutamicum* FP and used as the recipient strain for electroporation (unpublished data). *C. glutamicum* FP was detected by PCR with primers P1 and P2. The sequence of PCR products was consistent with *tyrA* of *C. glutamicum* ATCC 13032.

Construction of recombinant plasmids

Km (950 bp) and *tyrA* (1067 bp) genes were amplified by PCR and they were verified by sequencing. pPR vector and *tyrA* gene were digested with *Pst*I and *Hind*III and ligated to form pT. pT was digested with *Bst*EII, and then blunted. Km gene and P_{BF}-*aroG*-*pheA*-T fragment from pGA plasmids were subcloned into pSK vector, then digested with *Pst*I and *Hind*III to get GAK fragment (P_{BF}-*aroG*-*pheA*-T-Km). This resulting fragment and the Km gene were inserted into the pT to form targeting vectors pTGAK and pTK, respectively. The detailed process refers to Figure 2.

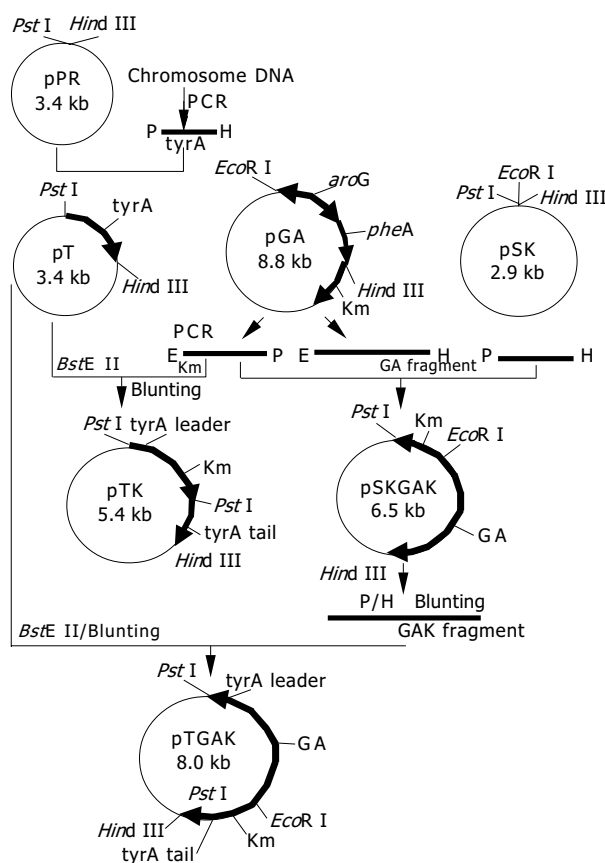

Figure 2 Construction of recombinant plasmids. E: *Eco*RI; P: *Pst*I; H: *Hind*III; GA: P_{BF}-*aroG*-*pheA*-T fragment; GAK: P_{BF}-*aroG*-*pheA*-T-Km fragment.

Identification of transformants

Because primer P5 was located at the end of *tyrA* gene, it only existed on the chromosome of *C. glutamicum*, but not on the targeting vector. Only when the Km gene was inserted into the chromosome of *C. glutamicum*, could the product be obtained by PCR using the primer pair P3 and P5 (Figure 3). The expected PCR products of 1570 bp are shown in Lane 3 and Lane 5 of Figure 4. Since a *Pst*I restriction site was introduced into Km

gene in fore side (Figure 2), the obtained PCR products could be digested by *Pst*I to produce two fragments whose sizes (950 bp and 620 bp) accorded to the sizes of Km gene and an expanded *tyrA* tail as shown in Lane 2 and Lane 4 of Figure 4. Sequencing of the 1570 bp fragment demonstrated it consisted of Km gene and a 620 bp fragment including *tyrA* tail (unpublished data). The strains obtained by PCR detection were named *C. glutamicum* KM (inserted with Km) and *C. glutamicum* GAK (inserted with GAK).

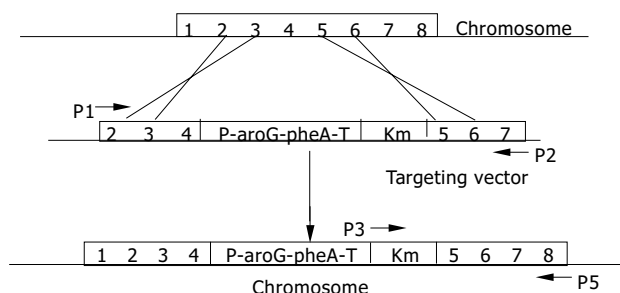

Figure 3 Insertion of P_{BF}-*aroG*-*pheA*-T-Km fragment of pTGAK into chromosome *tyrA* locus of *C. glutamicum* by double-exchange homologous recombination and detection of ligated DNA fragment Km-*tyrA* tail on chromosome by PCR amplification with P3 and P5.

Figure 4 DNA detection of transformants by PCR amplification and *Pst*I digested PCR products. Lane 1: control for PCR; lane 2: *Pst*I digesting product of lane 3; lane 3: PCR detection of *C. glutamicum* KM; lane 4: *Pst*I digesting product of lane 5; lane 5: PCR detection of *C. glutamicum* GAK; lane 6: Markers, *Eco*RI/*Hind*III digesting λ phage DNA.

Detection of *Tyr* auxotroph

As shown in Figure 5, *C. glutamicum* GAK, in which *tyrA* was disrupted by inserting a GAK fragment, only grew on the MM with L-tyrosine, but not on MM and MM with L-tryptophan or L-phenylalanine plates. This result indicated that *C. glutamicum* GAK was an auxotroph requiring L-tyrosine for growth. Here, we demonstrated that the pathway of tyrosine biosynthesis at steps from prephenate to 4-hydroxyphenylpyruvate was disrupted, and the function of prephenate dehydrogenase was inactivated successfully.

Figure 5 Auxanogram detection of *C. glutamicum* (Tyr). MM: *C. glutamicum* GAK on MM; Tyr: *C. glutamicum* GAK on MM+Tyr; Phe: *C. glutamicum* GAK on MM+Phe; Trp: *C. glutamicum* GAK on MM+Trp.

Enzyme assay

As shown in Figure 1, in the pathway of L-phenylalanine biosynthesis, there were three key enzymes, PD, CM and DS, encoded by *pheA*, *pheB* and *aroG*, respectively in *C. glutamicum*. The results of enzyme activity in *C. glutamicum* are listed in Table 2. The activity of the original strain was used as the control. Compared to the original strain, the relative activities of three enzymes (CM, PD and DS) in *C. glutamicum* FP were 1.73-, 2.37- and 1.93-fold higher and in *C. glutamicum* GAK were 2.9-, 3.36- and 3.0-fold higher respectively. The relative activities of these enzymes in *C. glutamicum* KM (Km^r FP^r) were similar to those in *C. glutamicum* FP (FP^r) respectively. The results indicated that the enzyme activities were increased differently by inhibiting the release of L-phenylalanine feedback using FP^r selection and the integration of tandem genes *aroG-pheA* into chromosome of *C. glutamicum*. At the same time, it also proved that the homologous recombination was successful.

Table 2 Relative activities of CM, PD and DS compared with the original strains

Strains	Enzymes		
	CM	PD	DS
<i>C. glutamicum</i>	1.0	1.0	1.0
<i>C. glutamicum</i> FP	1.73	2.37	1.93
<i>C. glutamicum</i> KM	1.74	2.30	1.95
<i>C. glutamicum</i> GAK	2.90	3.36	3.00

The enzyme activity of *C. glutamicum* was used as the standard, i.e. the relative activity of 1. CM: chorismate mutase; PD: prephenate dehydratase; DS: 3-deoxy-D-arabinoheptulosonate-7-phosphate synthase.

Measurement of phenylalanine yields

Recombinant strains were shaken in 25 mL of fermentation medium with 0.5 mol/L L-tyrosine in 250 mL flask at 30 °C for 72 h. The average yield of three measurements is shown in Table 3. From these data, we could find inhibition of the release of feedback contributed to increase the yield of L-phenylalanine obviously, the yield was increased 42%. On the other hand, interruption of the L-tyrosine branch pathway also increased 9% of the yield. Integration of the tandem genes *aroG-pheA* made 20% improvement. The total yield was increased 71%. The highest yield was added up to 3.97 g/L.

Table 3 Yields of L-phenylalanine biosynthesis in flask fermentation (mean±SD)

Strains	<i>C. glutamicum</i>	<i>C. glutamicum</i> FP	<i>C. glutamicum</i> KM	<i>C. glutamicum</i> GAK
Yields (g/L)	2.20±0.15	3.12±0.17	3.32±0.12	3.76±0.21
Relative yields	1	1.42	1.51	1.71

The phenylalanine yield of the original stain was used as the standard, i.e. the relative yield of 1.

DISCUSSION

The results of this study showed that interruption of the branch pathway of L-tyrosine biosynthesis could accumulate intermediates for L-phenylalanine synthesis and integration of the tandem *aroG-pheA* encoding DS, CM and PD from *E. coli* into the *C. glutamicum* chromosome was also favorable to L-phenylalanine synthesis due to the improvement of key enzyme activities in biosynthesis pathways. These two factors contributed to the increase of 30% yield in L-phenylalanine

biosynthesis. By increasing the precursors for phenylalanine synthesis, interruption of the tyrosine branch pathway could decrease L-tyrosine synthesis, and inhibit L-phenylalanine synthesis because L-tyrosine could stimulate prephenate dehydratase activity and restore the enzyme activity inhibited by L-phenylalanine and L-tryptophan. Ours results also indicated that mutagenesis by NTG was still an effective method for screening phenylalanine-producing strains. This method could effectively to improve the amino acid production in this study. The strains integrated with Km gene kept their resistance to kanamycin after cultured in medium without antibiotics for 96 h (unpublished data). Compared to the strains carrying plasmids^[15-17], strains integrated with heterologous genes had lower yields of L-phenylalanine but a higher stability. Further mutagenesis and application of strong promoters may be useful to increase the yield of L-phenylalanine of engineering strains. Further investigations are necessary to understand the mechanism of aromatic amino acid biosynthesis.

ACKNOWLEDGEMENTS

We thank professor Jiang Zhong, associate professor Han-Ying Yuan and De-Qiang Xu from Fudan University for their helps on this work.

Abstract

AIM: To determine the accuracy of p53 gene mutations predicted by overexpression of p53 protein immunohistochemically, and to investigate the co-mutation of p53 and *K-ras* genes in rectal cancer and its effect on promoting malignant biologic behaviors of tumors.

METHODS: Ninety-seven specimens of rectal cancer were surgically resected in our hospital from August 1996 to October 1997. The hot mutation areas of p53 gene (in exons 5-8) and *K-ras* gene (in codon 5/12 and 13) were detected with polymerase chain reaction-single strand conformation polymorphism (PCR-SSCP), and overexpression of p53 protein was detected with immunohistochemistry (IHC) in the 97 specimens of rectal cancer. Correlation between gene mutations and tumor clinicopathologic factors was studied, and survival analysis was performed as well.

RESULTS: There were 36 cases of p53 gene mutations in 61 p53 protein positive cases, and 21 cases of p53 gene non-mutation in 36 p53 protein negative cases respectively. The coincidence rate of p53 gene mutation by IHC method with PCR-SSCP method was 58.8% (57/97). The mutation rate of p53 gene was 52.6% (51/97), while *K-ras* gene mutation was observed in codons 12 and 13 in 61 cases with a mutation rate of 62.9% (61/97). Single gene mutation of p53 or *K-ras* was found in 32 cases. Both p53 and *K-ras* gene mutation were found in 48 cases. Statistical analysis showed that p53 and *K-ras* gene mutations were not related to the clinicopathologic factors, including tumor size, gross tumor type, histological classification, differentiation, invasion to intestinal veins, lymphatics and nerves, invasive depth to wall, lymph node metastasis, and Dukes' stages ($P>0.05$). The survival in patients with no gene mutation, single gene mutation and both gene mutations were similar ($P>0.05$).

CONCLUSION: IHC has a certain false positive and false negative rate in detecting p53 gene mutations. Malignant biological behaviours of rectal cancer are not enhanced by p53 and *K-ras* gene mutations. Co-mutation of p53 and *K-ras* gene has neither synergic carcinogenesis-promoting effect, nor prognostic effect on rectal cancer.

INTRODUCTION

Carcinogenesis and development of colorectal cancer are a process with multiple steps, in which epithelial cells of colorectum go through small adenoma, large adenoma, and finally become adenocarcinoma^[1]. The changes of several genes involve this process, including the activation of *K-ras* oncogene and the mutation and deletion of p53 anti-oncogene^[2]. To date, the clinical significance of the change of these genes is still disputed. Some studies reported that simultaneous mutations of p53 and *K-ras* could promote the development of colorectal cancer directly or indirectly, and were related to lymphatic metastasis, and a poor prognosis, but others had opposite results^[3]. It is still unclear which one is the prognostic factor, the p53 cDNA mutation or the alteration of p53 protein expression or both^[4]. Moreover, 90% dot mutations of p53 happen in exons 5-8, the individual incident rate of p53 mutations in these exons is not known^[5]. Therefore, to explore the effect of simultaneous mutations of p53, *K-ras* gene on the promotion of malignant biologic behaviors of rectal cancer and its clinical significance, the mutation patterns of exons 5-8 of p53 gene and codons 12 and 13 of *K-ras* gene in rectal cancer were detected by PCR-SSCP.

MATERIALS AND METHODS

Patients

From August 1996 to October 1997, 97 patients with rectal cancer underwent surgical resection in our hospital, including 54 males and 43 females, aged from 21 to 84 years with an average age of 53 years. Gross classification of tumors consisted of 27 cases of protruding type, 63 cases of ulcerating type, and 7 cases of infiltrating type. Histological classification included 3 cases of adenoma with cancer, 17 cases of papillary adenocarcinoma, 69 cases of tubular adenocarcinoma, 1 case of mucinous adenocarcinoma, 7 cases of signet-ring cell carcinoma, with 20 cases of well differentiated, 51 moderately and 26 poorly differentiated. According to Dukes classification, patients were categorized into four stages: stage A ($n = 27$), stage B ($n = 22$), stage C ($n = 36$) and stage D ($n = 12$).

Methods

Serial paraffin sections were used for HE staining, anti-p53 immunohistological staining, and detection of p53 and *K-ras* gene mutation by PCR-SSCP.

Immunohistochemistry

The Labeling-streptavidin-biotin peroxidase complex (LSAB) method was used for IHC staining. The colorectal tissue positive for p53 was taken as positive control, normal tissue as negative control, PBS instead of first antibody as blank control. Background of IHC staining was clear.

Positive standards for IHC staining were the same as previously described. Cells with pale brown granules in nuclei were judged as positive. The sections with 10-25% positive cells were defined as +, 26-50% as ++, 51-70% as +++, more than 70% as +++++, less than 10% as -.

PCR-SSCP

DNA was abstracted from tissues of 5 μ m paraffin sections

with routine method, and then stored at -20 °C. Exons 5,6,7,8 of p53 gene and codons 12, 13 of K-ras gene were amplified by polymerase chain reaction (PCR, PCR amplifier produced by American PE Company) respectively. The primers were synthesized and provided by Genetics Department of Sun Yat-Sen University. The sequences of primers are shown in Table 1. The single DNA chain from denatured PCR products was treated by normal vertical plane electrophoresis and stained with silver. Increased, and decreased numbers and translocation of electrophoresis bands in tumor specimens compared with normal tissues suggested the existence of gene mutations.

Statistical analysis

Data were analyzed with SPSS statistical software (Version 8.0). The relationship between mutations of p53, *K-ras* genes and clinicopathological factors was analyzed by χ^2 test. Survival rates were calculated with life table and Wilcoxon-Gehan test.

RESULTS

Expression of p53 protein

p53 protein was detected in 61 cases (62.9%, 61/97) according to IHC staining, strong positive (++++), moderately positive (+++), (++) , weak positive (+) were found in 26/61, 22/61, 10/61, and 30/61, respectively.

Sensitivity of p53 IHC method to p53 gene mutation detection

p53 gene mutations (in exons 5-8, hot mutation area) were found in 51 cases of rectal cancer by PCR-SSCP, with a mutation rate of 52.6% (51/97). Among the cases with p53 positive IHC staining, 36 cases were positive for p53 gene mutations by PCR-SSCP, while no p53 gene mutation was found by PCR-SSCP in 21 cases negative for p53 IHC staining (Table 2). The accuracy of IHC method to detect p53 gene mutations was 58.8% (57/97), the sensitivity was 70.6% (36/51), and the specificity was 45.7% (21/46).

Table 2 Sensitivity of IHC to detect p53 gene mutation

p53 gene (PCR-SSCP)	p53 IHC staining (%)	
	Negative	Positive
No mutation	21(45.7)	25(54.3)
Mutation	15(29.4)	36(70.6)

Mutation of p53 and K-ras genes

In the present study, p53 gene mutations were located in exons 5,6 in one case, in exon 7 in 48 cases, in exons 5,6 and 7 in 2 cases, and no mutation was found in exon 8. The mutation rate of p53 gene was 52.6% (51/97). *K-ras* gene mutations were located in codons 12 and 13 in 61 cases with a rate of 62.9% (61/97). p53 or *K-ras* gene mutations were found in 32 cases, both p53 and *K-ras* gene co-mutations were found in 48 cases.

Correlation of gene mutation and clinicopathological factors

The differences between p53 and *K-ras* gene mutations and clinicopathological factors had no statistical significance ($P>0.05$), including tumor size, gross tumor type, histological classification and differentiation, invasion to intestinal veins, lymphatics and nerves, invasive depth to intestinal wall, lymph node metastasis, and Dukes' stages.

Correlation of gene mutation and prognosis

All cases were followed up to December 2002, ranging from 14 d to 2058 d with an average of 1107 d. One case died of cardiopulmonary disease 14 d after operation, 28 cases died of tumor metastasis or recurrence, 3 cases were lost for follow-up, 2 cases died of other diseases rather than tumor. Life table was used to assess survival rates. Results indicated that p53 and *K-ras* gene mutations had no effects on prognosis ($P>0.05$, Table 3).

DISCUSSION

The methods normally used to detect p53 gene mutations include immunohistochemistry (IHC), PCR-SSCP, denaturing gradient gel electrophoresis (DGGE), and sequencing. According to literatures, the sensitivity of IHC was 75%, and its positive predictive value for detecting p53 gene mutations was 63%. More than 85% p53 gene mutations in exons 5-8 could be detected by PCR-SSCP with a sensitivity of 80-90%^[6,7]. In the present study, p53 gene mutations in rectal cancer were detected by IHC and PCR-SSCP respectively. The positive rate of IHC was 62.9% (61/97), while that of PCR-SSCP was 52.6% (51/97). The accuracy of IHC was 58.8%, and the sensitivity was 70.6%. However, its specificity was only 45.7%, implying that IHC had a rather high false positive and false negative rate in detecting p53 gene mutations.

It was reported that wild type p53 proteins could combine with viral oncoproteins or cellular oncoproteins to enhance their stability and prolong their half-life, leading to p53 protein accumulation in cells. In such cells, IHC staining was still positive even without p53 gene mutations, furthermore, about 10% p53 gene mutations could take place out side of exons 5-8. Therefore the positive rate of PCR-SSCP targeting only exons 5-8 was usually lower than that of IHC^[8-11]. The present study also had similar results. The variance in p53 gene mutations and p53 protein accumulation indicated that dysfunction of p53 gene might be caused by mechanisms other than mutations.

It is known that the oncogenesis and development of most colorectal cancers abide by the rule from normal epithelia to adenoma then to adenocarcinoma, and finally to metastasis. This complicated process has been found to involve several oncogene changes in a certain order, that is, from APC to *K-ras* to p53 to DCC^[12].

p53 and *ras* gene mutations could be observed in both adenoma and carcinoma of large intestine^[13]. Extent of p53 expression varies during different phases of tumor oncogenesis. p53 expression can be found extensively in villous adenoma, early stage of adenocarcinoma and well differentiated adenocarcinoma. The above lines of evidence support that p53 and *K-ras* gene mutation might happen before canceration and may be an early event in colorectal carcinogenesis and development. Participatin in the process from adenoma to adenocarcinoma, p53 and *ras* gene mutations may be used as the markers for early detection and diagnosis of colorectal cancer arising from adenoma.

Many studies indicated that the point mutation of p53 gene was related to lymph node metastasis in rectal cancer ($P < 0.001$), while the cross deletion was related to distal metastasis ($P = 0.0001$). The 5-year survival of colorectal cancer patients with chromosome 17p deletion was much poorer. p53 gene mutation was an important prognostic factor for colorectal cancer^[14]. On the contrary, some studies showed that intensity, distribution area and positive rate of p53 IHC staining were independent of the biological factors, such as tumor grade, histological type, tumor site, size, invasive depth to wall, invasion of local lymphatics and veins, lymph node metastasis, peritoneal seeding, and liver metastasis^[15]. Therefore, the clinical significance of p53 is still controversial.

In the present study, detected by PCR-SSCP, the p53 gene mutation rate in exons 5-8 was 52.6%. Most mutations (in 50 cases) took place in exon 7, 3 in exons 5-6, 2 in exon 7. No mutation was found in exon 8. The mutation rate of codons 12 and 13 of *K-ras* gene was 62.9%. Statistically p53 and *K-ras* gene mutations were independent of clinicopathological factors of rectal cancer, including tumor size, gross classification, histological type, differentiation, invasion of veins, lymphatics

and nerves, invasive depth to wall, lymph node metastasis and Dukes' stages. Co-mutation of *K-ras* and p53 gene had no correlation to clinicopathological factors or prognosis.

In conclusion, p53 and *K-ras* gene mutations have no effect on biological behaviours of tumor cells. The co-mutation of both genes has neither carcinogenesis-promoting effect, nor any effect on prognosis. Carcinogenesis and development of colorectal cancer involve changes of several genes, such as APC, *myc*, *K-ras*, MMC and p53. The accumulative effects of such genes may play a more important role during carcinogenesis than the order of change in these genes^[12,16]. So, genetic therapy for colorectal cancer should target multiple genes involved in the process of carcinogenesis.

Abstract

We present two diagnostically challenging cases of acute pancreatitis with hypertriglyceridemia accompanied with chylomicronemia caused with a deficiency of lipoprotein lipase and with the presence of type V hyperlipidemia. Both cases suffered from acute abdomen following the ingestion of fatty food and revealed the increase in parameters of inflammation without significant elevation of serum amylase levels. The imaging examination of ultrasonography could not detect significant findings of acute pancreatitis and a computer tomography scan eventually confirmed the findings of acute pancreatitis. Both cases responded to a low fat diet and administration of a cholecystokinin receptor antagonist, exhibiting a relief of abdominal symptoms. As in the present cases with acute abdomen following the ingestion of fatty food, the identification of serum hypertriglyceridemia and an abdominal computer tomography scan might be useful in establishing the diagnosis of acute pancreatitis and in developing the therapeutic regimen, when hypertriglyceridemia interferes with the evaluation of pancreatic enzyme activities and ultrasound examination provides poor pancreatic visualization.

INTRODUCTION

Secondary pancreatitis is caused by severe hypertriglyceridemia accompanied with chylomicronemia, and marked hypertriglyceridemia has been found in 12 to 22 percent of patients admitted to a hospital for acute pancreatitis^[1]. The diagnosis of acute pancreatitis is sometimes complicated, since the presence of hypertriglyceridemia may often produce multiple spurious laboratory data including serum and urinary amylase and serum lipase levels^[1-5]. Therefore, hypertriglyceridemia sometimes is underrecognized by admitting physicians as a possible cause of acute pancreatitis^[6]. Moreover, although the imaging examination of ultrasonogram is a relatively sensitive noninvasive test for the diagnosis of acute pancreatitis and can be performed rapidly and at the patient bedside, pancreatic visualization is limited by

intestinal gas or adipose tissue in 30-40% of patients^[7]. In this report, we present two cases suffering from acute abdomen following the ingestion of fatty food in which the identification of hypertriglyceridemia proved to be useful in diagnosing acute pancreatitis.

CASE REPORT

Case 1

A 61-year-old Japanese woman was admitted to the emergency department of a local hospital for repeated episodes of vomiting and epigastric discomfort following the ingestion of fatty food. The white blood cell (WBC) count and serum amylase level were both mildly elevated. Although echosonogram could not detect pancreatic disorders such as hypoechoic change or fluid collections, the treatment with gabexate mesylate, an inhibitor of pancreatic serine proteinases, was initiated with a suspected diagnosis of acute pancreatitis and her epigastric discomfort and nausea improved. She was transferred next day for purposes of further examination of acute abdomen. She had midepigastric discomfort and tenderness that migrated to the back. Bowel sounds were normal to auscultation, and there was no hepatomegaly or splenomegaly. Arcus corneae, cutaneous eruptive xanthomas and the xanthomas of Achilles tendon were absent. A chest radiogram was normal. X-rays of the abdomen revealed no abnormal gas patterns, calcifications, or ascites.

Table 1 illustrates the laboratory data on admission. We observed an elevated WBC count and erythrocyte sedimentation rate (ESR) and a positive C-reactive protein (CRP), with moderate normocytic anemia. Although an elevated serum pancreatic secretory trypsin inhibitor (PSTI) level was revealed in the pancreatic enzymes, other pancreatic enzymes including serum and urinary amylase levels were normal. Marked hypertriglyceridemia and a low level of high density lipoprotein-cholesterol (HDL-C) were apparent. A layer of chylomicrons could be seen at the top of the plasma stored for 24 h in a refrigerator. Although an abdominal ultrasonogram showed no pancreas abnormality and no evidence of cholelithiasis or choledocholithiasis, a computer tomography (CT) scan of the abdomen could detect pancreatic edematous changes and enlargement with a score of 3 according to CT severity index by Balthazar^[8]. These findings were confirmed as an initial change of acute pancreatitis by two established radiologists and indicated a diagnosis of secondary pancreatitis with hypertriglyceridemia.

Figure 1 illustrates the patient's clinical course. Her epigastric discomfort improved after administration of loxiglumide, a cholecystokinin receptor antagonist 300 mg/d, and flomoxef, an antibiotic 2 g/d, and they disappeared after two days. The serum PSTI level returned to normal and there were no major changes in other serum pancreatic enzymes. The patient was started on a low fat diet on the third hospital day. We conducted a diagnostic investigation to exclude possible secondary causes for acute pancreatitis other than hypertriglyceridemia. Endoscopic retrograde cholangiopancreatography (ERCP) performed on the seventh hospital day revealed no apparent structural alterations in the common bile duct or pancreatic duct such as pancreas divisum. Despite the administration of a low fat diet for two weeks, hypertriglyceridemia and low serum

level of HDL-C failed to improve dramatically. The serum CRP level returned to normal on the eleventh hospital day.

Focusing on the hypertriglyceridemia, we evaluated the patient's glucose metabolism. The serum HbA1C level was 4.8 and 75 g oral glucose tolerance test (OGTT) performed on the twenty-third hospital day demonstrated an impaired glucose tolerance pattern, not that of diabetes mellitus (DM) as a cause of hypertriglyceridemia (Table 2). Excessive alcohol intake, and administration of estrogen, diuretics, and β -adrenergic blockers could be excluded as possible causes of hypertriglyceridemia according to her episode.

In terms of lipid metabolism, we observed high serum levels of apolipoprotein (Apo) B, CII, CIII and E, indicating the increase in triglyceride-rich lipoprotein (Table 2). Polyacrylamide gel electrophoresis (PAGE) demonstrated the presence of chylomicron fraction at base line and a decreased pre- β , β and α fraction, indicating the presence of chylomicron and low levels of very low density lipoprotein (VLDL), low density lipoprotein (LDL) and HDL, respectively (Figure 2a). The post-heparin plasma lipoprotein lipase (LPL) activity, which was obtained 15 min after 50 U/kg body weight intravenous injection of heparin, was markedly low and the immunoreactive LPL mass was below the level of detection (less than 20 ng/mL), confirming the diagnosis of LPL deficiency. These findings suggested that the fatty food ingestion led to acute pancreatitis in the patient with severe hypertriglyceridemia due to the LPL deficiency.

Figure 1 Clinical course of case 1. Normal range is shown in []. TG: triglycerides, TC: total cholesterol, HDL-C: high density lipoprotein-cholesterol, S-Amy: salivary amylase, P-Amy: pancreatic amylase, PSTI: pancreatic secretory trypsin inhibitor, WBC: white blood cell, CRP: C-reactive protein.

Figure 2 Polyacrylamide gel electrophoresis using the fasting plasma of (a) case 1, (b) case 2 and (c) control. The presence of chylomicrons is demonstrated at the base line indicated by arrows (↑).

Case 2

This 30-year-old Japanese man was admitted with severe left hypochondralgia following the ingestion of fatty food. He had a history of moderate alcohol intake (more than 80 g/d) since the age of 20 and a history of repeated hospitalizations for acute abdomen following the ingestion of fatty food but the definite cause of acute abdomen was not determined. He was

obese, being 169 cm tall and weighing 78 kg, with a body mass index of 27.3 kg/m². He complained of abdominal pain that radiated to the left back. Abdominal auscultation revealed a decrease in bowel sounds. We observed eruptive xanthomas; small, yellow, papular, cutaneous lesions, localized over the buttocks, the femoral region and the extensor surface of the arms that had been present for the past two months. Chest X-rays showed no abnormalities. No abnormal gas patterns, calcifications, or ascites were noted on abdominal X-rays. An abdominal ultrasonogram provided poor pancreatic visualization due to the obesity. An abdominal CT scan revealed fatty changes in the liver and the presence of edematous and enlarged changes in the pancreas, suggesting acute pancreatitis, with a score of 3 according to CT severity index^[8]. These findings were confirmed as initial findings of acute pancreatitis by two established radiologists.

Laboratory data on admission (Table 1) revealed an elevated WBC count and ESR, positive CRP, elevated hemoglobin level and a low concentration of serum sodium. High serum levels of cholesterol and marked high triglyceride level of more than 10 000 mg/dL, compatible with type V hyperlipidemia according to the classification of Frederickson^[9], and a low serum level of HDL-C were present. Only an elevated serum PSTI level was revealed in pancreatic enzymes.

The patient's clinical course is illustrated in Figure 3. His pain in the left hypochondrium improved on fasting and administration of loxiglumide, 300 mg/d, and latamoxef, an antibiotic 2 g/d, and disappeared on the tenth hospital day. A low fat diet with 1 800 kcal/d was started on the tenth hospital day. Although there was no significant alteration in serum HDL-C levels after the diet was initiated, the markedly elevated serum triglyceride levels fell dramatically and serum cholesterol levels also decreased markedly, returning to normal limits. The WBC count, serum CRP level and serum PSTI level improved significantly. ERCP on the twenty seventh hospital day demonstrated no structural alterations and no stones in the pancreatobiliary ductal system.

Figure 3 Clinical course of case 2. Normal range is shown in []. TG: triglycerides, TC: total cholesterol, HDL-C: high density lipoprotein-cholesterol, S-Amy: salivary amylase, P-Amy: pancreatic amylase, PSTI: pancreatic secretory trypsin inhibitor, WBC: white blood cell, CRP: C-reactive protein.

In terms of the lipid metabolism, the presence of chylomicrons was identified from the development of a chylomicrons layer at the top of the patient's plasma taken on admission and placed overnight at 4 °C in a refrigerator. In addition, PAGE revealed the presence of chylomicrons fraction at base line and an increase in pre-β fraction, indicating an increase in VLDL (Figure 2b). On the thirty fourth hospital day after initiating a low fat diet, we performed a further investigation of the lipid metabolism and 75 g OGTT (Table 2). The 75 g OGTT demonstrated a pattern typical of DM and serum HbA1C was 9.0. Although the serum cholesterol level returned to normal and the serum triglyceride level fell to 251 mg/dL, we observed high serum levels of VLDL-triglyceride, Apo B and Apo CIII, indicating an increase in the hepatic VLDL-triglyceride synthesis. Post-heparin plasma LPL activity was within normal ranges. These findings suggested that ingestion of fatty food could lead to type V hyperlipidemia characterized by the presence of chylomicrons and an increase in VLDL. A low fat diet proved effective in managing this case of massive hypertriglyceridemia.

Table 2 75 g OGTT and serum lipid profile

		Case 1	Case 2	[Normal range]
75 g OGTT				
BS (mg/dL)	Before	82	113	<110
	30 min	148	198	<160
	60 min	176	274	<160
	120 min	159	262	<120
Insulin (μU/mL)	Before	20.3	9.3	<20
	30 min	67.5	15.7	
	60 min	86.9	27.5	
	120 min	67.5	31.1	
Cholesterol fraction				
Total	(mg/dL)	161	199	[150-220]
VLDL	(mg/dL)		79.1	<38
LDL	(mg/dL)		97.5	[56-160]
HDL	(mg/dL)	15	22.4	[35-70]
Triglycerides fraction				
Total	(mg/dL)	571	382	[50-150]
VLDL	(mg/dL)		280.6	[6-84]
LDL	(mg/dL)		71.1	[10-35]
HDL	(mg/dL)		30.3	[11-28]
Apolipoproteins				
Apolipoprotein AI	(mg/dL)	71	78.9	[119-155]
Apolipoprotein AII	(mg/dL)	20	29.8	[25.9-35.7]
Apolipoprotein B	(mg/dL)	154	136.6	[73-109]
Apolipoprotein CII	(mg/dL)	11.1	7.0	[1.8-4.6]
Apolipoprotein CIII	(mg/dL)	22.4	21.9	[5.8-10.0]
Apolipoprotein E	(mg/dL)	20.6	6.4	[2.7-4.3]
Post-heparin plasma enzyme activities				
LPL activity (μmol FFA/mL/min)		0.048	0.181	[0.119-0.195]
LPL mass (ng/mL)		<20		[136-321]

OGTT: oral glucose tolerance test, BS: blood sugar, VLDL: very low density lipoprotein, LDL: low density lipoprotein, HDL: high density lipoprotein, LPL: lipoprotein lipase, FFA: free fatty acid, HTGL: hepatic triglyceride lipase, LCAT: lecithin cholesterol acyl transferase.

DISCUSSION

Hypertriglyceridemia accompanied with chylomicronemia is clinically important because an elevated serum triglyceride level predisposes to the development of pancreatitis, occasionally

leading to total pancreatic necrosis and death^[1,10,11]. Both cases suffered from acute abdomen following the ingestion of fatty food and revealed high levels of inflammation parameters accompanied with hypertriglyceridemia. In pancreas enzymes, only serum PSTI revealed high levels and no elevation of serum and urinary amylase could be detected. On the imaging examination, an abdominal ultrasonogram could not detect pathological findings of acute pancreatitis and a CT scan eventually confirmed the findings of acute pancreatitis. Their symptoms improved after administration of a pancreatic serine proteinase inhibitor and fasting. The clinical courses supported the diagnostic evidence for acute pancreatitis with hypertriglyceridemia triggered by the ingestion of fatty food.

In the differential diagnosis of acute pancreatitis, the imaging examination detected no structural causes of acute pancreatitis such as gallstones, microlithiasis, pancreas divisum and sphincter of Oddi disease in both cases. Other etiologies of acute pancreatitis such as drug-induced pancreatitis, viral and bacterial infection could be deniable according to their clinical episodes.

Hypertriglyceridemia in case 1 was caused by a deficiency of LPL, a rate-limiting lipolytic enzyme that hydrolyzes triglyceride-rich lipoproteins in plasma. Brunzell *et al.* demonstrated that the appearance of chylomicrons was a marker for severely impaired triglyceride metabolism showing massive accumulation of triglyceride-rich lipoprotein in the serum^[1,12]. In case 1, the presence of chylomicrons might result from a severe reduction in the clearance of triglyceride-rich lipoproteins due to the LPL deficiency.

Marked hypertriglyceridemia has also been reported in other forms of impaired triglyceride metabolism besides LPL deficiency^[1,8,13,14]. Secondary causes of hypertriglyceridemia, such as a high fat diet or excessive alcohol intake, can lead to massive hypertriglyceridemia in patients with type IV hypertriglyceridemia. When an overproduction of VLDL-triglyceride was induced by secondary causes, extreme elevation of serum triglyceride levels, e.g. more than 10 000 mg/dL in case 2, might occur, since the LPL-related triglyceride removal system approached saturation at triglyceride concentrations of 700 to 1 000 mg/dL^[15]. In case 2, dietary fat restriction with a calorie control and alcohol prohibition had beneficial effects on serum lipids, and serum triglyceride level decreased dramatically.

Although the exact pathogenesis of pancreatitis caused by hypertriglyceridemia remains uncertain, hyperlipidemic pancreatitis is believed to result from chemical irritation to the pancreas from toxic fatty acids and lysolecithin^[16-19]. These compounds are liberated by pancreatic lipases from the core and surface of chylomicrons circulating at high concentrations in the capillaries of the exocrine pancreas. Moreover, there are some other hypotheses of the pathogenesis by which hypertriglyceridemia causes acute pancreatitis. Trypsinogen could be activated by acidosis due to the presence of free fatty acids, which may disturb the microcirculation of the pancreas by damaging the endothelium^[19,20]. Chylomicrons seem to be also involved in calcium-dependent agglutination by CRP, suggesting that non-traumatic fat embolism may be caused by agglutination of chylomicrons due to high levels of plasma CRP^[21]. Although hypertriglyceridemia with chylomicrons plays an important role in the occurrence of pancreatitis, hypertriglyceridemia sometimes was underrecognized in patients with acute pancreatitis^[6]. The measurement of serum triglyceride level or the identification of chylomicrons on the earliest available serum specimens may be important to increase the diagnostic yield and help prevent further occurrences of pancreatitis.

While pancreatitis is a major complication of hypertriglyceridemia, it is difficult to identify the onset of acute pancreatitis exactly from the clinical symptoms and laboratory data, since hypertriglyceridemia may often produce multiple spurious

laboratory results^[1-5]. Upon examination of patients with pain or discomfort in the abdomen of unknown origin, one should conduct tests to determine the lipid profile as well as the profile of pancreatic enzymes and imaging examination of the abdomen. If patients showed hypertriglyceridemia, it might be practical to measure serum amylase levels using diluted serum or plasma samples^[2]. Eruptive xanthomas, shown in case 2, caused by the phagocytosis of chylomicrons by macrophages in the skin^[22] may indicate the presence of chronic chylomicronemia. One of the simplest tests to detect plasma chylomicrons is the observation of a layer of chylomicrons at the top of the plasma stored overnight at 4 °C in a refrigerator, the so-called refrigerator test^[17]. However, this test can give false-negative results even in the presence of massive hypertriglyceridemia. PAGE remains one of the most useful methods for detecting and evaluating chylomicronemia, as demonstrated in this report (Figure 2). Measurement of serum remnant like particle-cholesterol levels^[23], a parameter of impaired triglyceride metabolism, could be useful to speculate on the presence of chylomicrons.

In conclusion, determination of serum triglyceride levels and identification of chylomicrons as well as measurement of pancreatic enzymes might be important in developing the therapeutic regimen. As in the present cases with acute abdomen following the fatty food ingestion, the identification of hypertriglyceridemia as well as an abdominal CT scan might be useful in establishing the diagnosis of acute pancreatitis and in preventing further progression of pancreatitis, when hypertriglyceridemia interferes with the evaluation of pancreatic enzyme activities and ultrasound examination provides poor pancreatic visualization.
