Abstract

AIM: To investigate the role of mitochondria in cell apoptosis during hepatic ischemia-reperfusion injury and protective effect of ischemic postconditioning (IPC).

METHODS: A rat model of acute hepatic ischemia-reperfusion was established, 24 healthy male Wistar rats were randomly divided into sham-operated group, ischemia-reperfusion group (IR) and IPC group. IPC was achieved by several brief pre-reperfusion followed by a persistent reperfusion. Concentration of malondialdehyde (MDA) and activity of several antioxidant enzymes in hepatic tissue were measured respectively. Apoptotic cells were detected by TdT-mediated dUTP-biotin nick end labeling (TUNEL) and expression of Bcl-2 protein was measured by immunohistochemical techniques. Moreover, mitochondrial ultrastructure and parameters of morphology of the above groups were observed by electron microscope.

RESULTS: Compared with IR group, the concentration of MDA and the hepatocellular apoptotic index in IPC group was significantly reduced ($P < 0.05$), while the activity of antioxidant enzymes and OD value of Bcl-2 protein were markedly enhanced ($P < 0.05$). Moreover, the injury of mitochondrial ultrastructure in IPC group was also obviously relieved.

CONCLUSION: IPC can depress the synthesis of oxygen free radicals to protect the mitochondrial ultrastructure and increase the expression of Bcl-2 protein that lies across the mitochondrial membrane. Consequently, IPC can reduce hepatocellular apoptosis after reperfusion and has a protective effect on hepatic ischemia-reperfusion injury.

INTRODUCTION

Hepatic ischemia-reperfusion injury (IRI) is a common pathological process of traumatic surgical diseases in the liver, such as severe liver trauma, extensive hepatic lobus excision, liver transplantation, shock and infection. When hepatic IRI

happens, a series of metabolic and structural and functional disorder of hepatic tissue cells would occur, which directly influence the prognosis of patients^[1,2]. At present, the study about the mechanism and intervention method of hepatic IRI has been carried out extensively. It has been confirmed that apoptosis as a way of cell death is significant for maintaining normal cell development and stabilization, and is closely related to the initiation and development of many clinical diseases, and it also participates in IRI of tissues and organs^[3-6]. Mitochondria as one of the organelle of cells play an important role in providing energy, adjusting osmotic pressure, calcium balance, and pH value, and cell signaling. Mitochondria perform their function by production of ATP and reactive oxygen species (ROS) which are also known as signals regulating gene expression and triggering cell death^[7,8]. At present, mitochondria/ cytochrome C apoptotic pathway has attracted close attention of scholars. Many stimulators such as ROS, Ca^{2+} and cytokines could activate cysteine aspartate-specific proteases (Caspase) by inducing cytochrome C release^[9-12]. But the study on the changes of the structure and function of mitochondria in hepatic IRI and the adjusting function of mitochondria in hepatocellular apoptosis was rarely reported at home and abroad. We established a hepatic IRI model in liver of rats, and observed the influence of ischemic postconditioning (IPC) on cell apoptosis in hepatic IRI and the adjustment function of mitochondria. This experiment lays a theoretical foundation for adopting a more reasonable method to restore the blood flow after hepatic ischemia.

MATERIALS AND METHODS

Materials

Twenty-four healthy male Wistar rats, weighing 200-250 g, were supplied by the Experimental Animal Center of Wuhan University. Malondialdehyde (MDA), superoxide dismutase (SOD), catalase (CAT) and glutathione peroxidase (GSH-PX) assay kits were purchased from Nanjing Jiancheng Bioengineering Co.Ltd, China. Mouse anti-rat Bcl-2 monoclonal antibody and SP assay kit were provided by Beijing Zhongshan Biotechnology Co.Ltd, China. Terminal deoxynucleotidyl transferase (TdT) mediated dUTP nick end labeling (TUNEL) *in situ* cell death detection kit was the product of Boehringer Mannheim Co.Ltd, USA.

Animal model

The animals were fed standard laboratory chow. Before the day of experiment, the animals were fasted overnight, but allowed free access to water. They were anesthetized by sodium pentobarbital (30 mg/kg). Hepatoduodenal ligament was separated after entry into the belly, the first porta hepatis was exposed and a rat local hepatic IRI model was established with reference to the previous method^[13]. Blood flow of caudate and left lobe of the liver was blocked with non-trauma mini artery clamp, causing 70% liver ischemia. However, the blood flow of right lobe was not blocked to prevent blood clot in portal vein and gastrointestinal tract. Twenty-four rats were randomly divided into three groups (eight in each group) and

subjected to the following treatments. (1) Sham-operated group: only hepatoduodenal ligament was separated after entry into the belly, blood flow of porta hepatis was not blocked. (2) Ischemia-reperfusion group (IR): the livers were undergone ischemia for 60 min followed by reperfusion for 120 min. (3) Ischemic postconditioning group (IPC): the livers were subjected to porta hepatis occlusion for 60 min, then treated for 2 min, 3 min, 5 min, 7 min by brief reperfusion consecutively, each was separated with occlusion for 2 min, followed by a persistent reperfusion for 95 min, which made the total reperfusion time the same as the other two groups.

MDA and antioxidant enzyme measurement

Concentration of MDA and activity of SOD, CAT and GSH-PX in hepatic tissue were measured according to the commercial kit manual.

Immunohistochemical staining

Fresh hepatic tissues, cut from left lobe of the liver, were fixed in formalin for 12–24 h and then embedded in paraffin wax. A 4- μ m thick sections were cut and mounted onto slides. They were deparaffinized by passing through xylene and graded series of ethanol, followed by rinsing in tap water and 0.01 mmol/L phosphate buffered saline (PBS) respectively. Endogenous peroxidase activity was quenched by treating the sections with 30 mL/L hydrogen peroxide for 10 min. Nonspecific binding was blocked by incubating sections in PBS containing 10 g/L bovine albumin for 10 min. Then the sections were incubated for an hour in primary antibody (mouse anti-rat Bcl-2 monoclonal antibody). After rinsed in PBS, the sections were treated sequentially with biotin-conjugated second antibody for 10 min and then with streptavidin-peroxidase for another 10 min with PBS rinsing after each step. The sections were stained subsequently with freshly prepared DAB reagent for 3 min, terminated by rinsing in water, then immersed in hematoxylin for 3–5 min and 0.5 mmol/L HCl for 10 s. Finally, after passing through xylene and graded series of ethanol, the sections were covered with coverslips for light analysis. The sections were examined with HAIPS-2 000 image analysis and the Absorbency value was used to evaluate the content of Bcl-2 protein.

Hepatic TUNEL staining

In situ terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL) of fragmented DNA was performed on paraffin slices using the *in situ* cell death detection kit as described in the commercial kit manual. Positively labeled nuclei (brown color) were identified from negatively unstained nuclei (blue color). The number of positive nuclei was determined by counting (magnification \times 400) all the positively labeled nuclei present in five random visual fields under a microscope. The percentage of TUNEL positive nuclei to all nuclei counted was used as apoptotic index (AI). The

apoptotic cells had the following characteristics: single cells, no inflammation, curling of cell membrane, brown particulate or fragmented nuclei.

Morphopathological observation of ultrastructural organization

One mm³ fresh hepatic tissue, cut from left lobe of the liver, was pre-fixed with glutaraldehyde at the volume fraction of 2.5 % and post-fixed with 1 g/L osmic acid. Then the specimens were immersed in propylene oxide after dehydration with gradient ethanol, embedded with epoxy resin and made into ultrathin sections. The sections were stained subsequently with lead-uranium and the changes of ultrastructural organization were observed under H-600 transmission electron microscope. Finally, the sections were measured for cross-sectional area (A), cross-sectional perimeter (P) of mitochondria (using Image Pro Plus, USA), and computed specific surface of mitochondria following the formula: $\delta=4P/(\pi A)$.

Statistical analysis

All data were expressed as mean \pm SD. Comparisons between groups were analyzed with one-way ANOVA and Student-Newman-Keuls *q* test. *P* values less than 0.05 were considered statistically significant.

RESULTS

MDA concentration and antioxidant enzyme activity

The concentration of MDA in hepatic tissue was rapidly elevated after reperfusion in IR and IPC groups against sham group ($P<0.05$), while the activity of SOD, CAT and GSH-PX was significantly reduced ($P<0.05$). Compared with IR group, the concentration of MDA in IPC group was markedly reduced and activity of each antioxidant enzyme was significantly enhanced ($P<0.05$) (Table 1).

Table 1 Measurement of MDA concentration and antioxidant enzyme activity (mean \pm SD, *n*=8)

Group	MDA (nmol/mg)	SOD (U/mg prot)	CAT (U/mg prot)	GSH-PX (U/mg prot)
Sham	3.42 \pm 1.12	241.47 \pm 19.52	91.66 \pm 8.16	124.17 \pm 24.37
IR	17.56 \pm 4.80 ^a	132.99 \pm 22.11 ^a	40.24 \pm 7.73 ^a	51.75 \pm 16.43 ^a
IPC	10.18 \pm 3.56 ^{ab}	176.84 \pm 20.50 ^{ad}	64.81 \pm 7.19 ^{ad}	89.70 \pm 28.15 ^{ad}

^a $P<0.05$ vs sham, ^d $P<0.05$ vs IR.

Expression of Bcl-2 protein

The A value of Bcl-2 protein in IR group (0.067 \pm 0.011) was significantly lower than that in sham group (0.096 \pm 0.017) ($P<0.05$). After postconditioning, the expression of Bcl-2 protein was more eminent (A value 0.138 \pm 0.016) than that in IR group ($P<0.05$) (Figure 1A, B, C).

Figure 1 Bcl-2 expression in sham, IR and IPC groups (\times 200). A: Bcl-2 expression in sham group, B: Bcl-2 expression in IR group, C: Bcl-2 expression in IPC group.

Figure 2 TUNEL staining in sham, IR and IPC groups ($\times 200$). A: TUNEL staining in sham group, B: TUNEL staining in IR group, C: TUNEL staining in IPC group.

Effect of IPC on hepatocellular apoptosis

Under light microscope, TUNEL staining indicated that cell injury occurred primarily in the form of apoptosis at the early stage of reperfusion and apoptotic cells were mainly around the central vein (Figure 2A, B, C). Under electron microscope, the early manifestations of apoptosis, such as swelling and rounding of cells, cell exfoliation, and aggregation of chromatin in the edge, as well as the typical manifestations of apoptosis, such as the concentration of cytoplasm and nucleus, and formation of apoptotic body, could be seen (Figure 3). The apoptotic index in IR group (46.53 ± 3.47) was significantly higher than that in sham group (2.05 ± 0.83) ($P < 0.05$). After postconditioning, the apoptotic index (23.16 ± 2.67) was significantly reduced compared with IR group ($P < 0.05$).

Figure 3 Morphological change of hepatocellular apoptosis in IR group (TEM $\times 15\,000$).

Ultrastructural changes of mitochondria

In sham group, mitochondrial structure was normal. Mitochondria were orderly arranged in the form of round or ellipsoid without swelling. Mitochondrial membrane was intact and cristae were arranged in the form of concentric ring or vertical line,

congested and clear (Figure 4A). In IR group, mitochondria were swollen obviously. Mitochondrial membrane was vague or partly ruptured and cristae were obviously loose and dissolved, a lot of vacuoluses were formed (Figure 4B). In IPC group, mitochondrial structure was basically normal. Mitochondria were orderly arranged, mitochondrial membrane was basically intact, cristae were congested and there was no vacuolization (Figure 4C).

Quantitative analysis of mitochondrial morphology

The cross-sectional area and perimeter of mitochondria were markedly increased after reperfusion in IR and IPC groups against sham group ($P < 0.05$), while the specific surface of mitochondria was significantly reduced ($P < 0.05$). Compared with IR group, the cross-sectional area and perimeter of mitochondria in IPC group were markedly reduced and the specific surface was significantly increased ($P < 0.05$) (Table 2).

Table 2 Changes of parameters of mitochondrial morphology (mean \pm SD, $n=8$)

Group	Area (μm^2)	Perimeter (μm)	Surface (μm^{-1})
Sham	76.2 ± 8.1	22.7 ± 4.6	0.39 ± 0.04
IR	278.3 ± 22.2^a	60.9 ± 5.9^a	0.17 ± 0.05^a
IPC	150.9 ± 16.4^{ac}	42.1 ± 4.3^{ac}	0.26 ± 0.05^{ac}

^a $P < 0.05$ vs sham, ^c $P < 0.05$ vs IR.

DISCUSSION

Under the influence of many kinds of stress factors such as ROS, Ca^{2+} overloading, and toxin, mitochondrial ultrastructure and its function were easily damaged, then the active substance originally in mitochondria related to apoptosis including cytochrome C, was released into cytoplasm^[14-18]. Recent progress in studies on apoptosis has revealed that cytochrome

Figure 4 Mitochondrial ultrastructure in sham, IR and IPC groups (TEM $\times 15\,000$). A: Mitochondrial ultrastructure in sham group, B: Mitochondrial ultrastructure in IR group, C: Mitochondrial ultrastructure in IPC group.

C is a pro-apoptotic factor. It is released at early stage of apoptosis and, by combining with some cytosolic proteins, could activate conversion of the latent apoptosis-promoting protease to its active form^[19]. Once cytochrome C was released, cells would die through two ways. One was through quick apoptotic mechanism. Released cytochrome C and apoptotic protease activating factor-1 (Apaf-1) and Caspase-9 were combined, and then Cytc-Apaf-1-Caspase-9 compound was formed, which would lead to the activation of pro-Caspase-9, and subsequently, downstream Caspase-3 was activated, and apoptic cascade reaction was promoted. At the same time, part of the unreleased cytochrome C was steadily combined with cytochrome b-c1 and C oxidase, and adequate ATP was produced to provide energy for apoptosis^[20-23]. The other was through necrotic process. Permeability transition pore (PTP) opened, mitochondrial matrix was swollen and ruptured due to hyperosmotic effect, the transmembrane potential ($\Delta \Psi_m$) of the original mitochondrial membrane quickly collapsed, cytochrome C was released in great amount, electron transferring respiratory chain was blocked, ATP content was radically reduced, effective supply of energy could not be realized and cell necrosed. Consequently, mitochondria could determine the cells to go into apoptosis or necrosis^[24]. This experiment proved that early injury of cells after reperfusion occurred mainly in the form of apoptosis. The end product MDA of lipid peroxidation in liver tissue increased after reperfusion, while SOD, CAT and GSH-PX as the major antioxidant enzyme and free radical scavenger were obviously decreased, indicating their capacity of preventing cells from the injury caused by ROS. Excessive oxygen free radicals could directly react with unsaturated fatty acid on the surface of mitochondrial membrane, which led to the destruction of its structure and function. Cytochrome C and other apoptosis-promoting substances were released in great amount, which triggered the apoptosis of cells.

The quantitative analysis of the stereo-form of mitochondria indicated that the major morphological change of mitochondrial injury was swelling. It was considered previously that the apoptotic cells manifested condensed chromatin but intact mitochondria. Now much more evidence revealed that significant changes of mitochondria such as swelling, megamitochondria, mitochondrial pyknosis and disrupted outer-membrane could take place in many apoptotic models^[25,26]. Specific surface is the ratio of average area of granular membrane to its volume. It is the objective index to reflect the swelling degree of mitochondria. Our study found that, after reperfusion, the cross-sectional area and perimeter of mitochondria were obviously increased, but specific surface was markedly smaller. The swelling of mitochondria was obvious, and this was in accordance with the changing tendency of mitochondrial ultrastructural organization observed under electron microscope. After postconditioning, the degree of mitochondrial swelling injury was obviously relieved and hepatocellular apoptotic index was also decreased, indicating that the structural and functional changes of mitochondria in apoptotic cells were correlated with the initiation and development of cell apoptosis, suggesting that mitochondrial dysfunction might be the key event in the development of cell apoptosis. Moreover, IPC had a protective effect on the mitochondrial ultrastructure and function.

The exact mechanisms underlying this postconditioning-produced protection remain unclear. It is most likely, though still speculative, that the IPC scheme (reiterative brief pre-reperfusion followed by continuous reperfusion) adopted in this experiment to some extent equaled a controlled slow intermittent reoxygenation, which might reduce the burst production of oxygen free radicals at the early stage of reperfusion and stimulate the release of antioxidant enzymes and free radical scavengers, thus producing protective effects. Compared with IR group, in IPC group MDA in the liver tissue

was decreased and every antioxidant enzyme was increased conspicuously, which reduced the injury to mitochondrial membrane lipid peroxidation by toxic oxygen radicals, protected the integrity of the structure and function of mitochondria, and prevented the apoptosis of liver parenchyma cells. Cave *et al.*^[27] reported that, in an isolated perfused heart model, compared with sudden reperfusion (remove artery snare occluder abruptly), controllable and slow reperfusion could decrease the occurrence of ventricular fibrillation. The postconditioning treatment in the present study was essentially comparable in some senses to those controlled and slow reoxygenation.

In addition, in order to know the function of mitochondria in apoptotic regulatory pathway, we also measured the change of the content of Bcl-2 protein in liver tissue. Bcl-2 protein as the major representative of apoptotic restraining proteins in Bcl-2 family, functioned through signal-anchor sequence of carboxyl terminal stretching cross mitochondrial membrane^[28-31]. Bcl-2 protein could regulate the permeability of PTP on the surface of mitochondrial membrane, or itself could participate in the formation of the specific pathway directly. This could maintain the stability of transmembrane potential and inhibit the release of cytochrome C and other apoptosis-promotion substances, and consequently inhibit the activation of Caspase in cytoplasm and block apoptotic cascade reaction^[32-35]. Our experiment confirmed that after postconditioning, the A value of Bcl-2 protein was obviously higher than that of IR group, and apoptotic index was obviously decreased. This showed that IPC could decrease apoptosis in liver IRI by up-regulating trans-mitochondrial membrane Bcl-2 protein expression. But the detailed mechanism needs to be further studied.

To sum up, in hepatic IRI, various stress factors can activate the apoptotic pathway mediated by mitochondria, which leads to the increase of apoptosis, and the decrease of the total number of parenchyma cells, and thus the hepatic tissue and liver function are severely damaged. Mitochondrial apoptotic pathway participates in hepatic IRI, and is a ring-point in this complicated mechanism. IPC can protect the mitochondrial ultrastructural organization and function through the inhibition of synthesis of excessive oxygen free radicals after reperfusion and increase trans-mitochondrial membrane Bcl-2 protein expression. Consequently, IPC can inhibit cell apoptosis and reduce hepatic IRI. IPC should carry out after operation and before comprehensive blood perfusion. It is easy to perform and the time is adequate. Undoubtedly, it has direct clinical application value.

Abstract

AIM: To assess the value of computed tomography during arterial portography (CTAP) in portal vein-vena cava shunt, and analysis of the episode risk in encephalopathy.

METHODS: Twenty-nine patients with portal-systemic encephalopathy due to portal hypertension were classified by West Haven method into grade I(29 cases), grade II(16 cases), grade III(10 cases), grade IV(4 cases). All the patients were scanned by spiral-CT. Plane scans, artery phase and portal vein phase enhancement scans were performed, and the source images were thinly reconstructed to 1.25 mm. We reconstructed the celiac trunk, portal vein, inferior vena cava and their branches and subjected them to three-dimensional vessel analysis by volume rendering (VR) technique and multiplanar volume reconstruction (MPVR) technique. The blood vessel reconstruction technique was used to evaluate the scope and extent of portal vein-vena cava shunt, portal vein emboli and the fistula of hepatic artery- portal vein. The relationship between the episode risk of portal-systemic encephalopathy and the scope and extent of portal vein-vena cava shunt, portal vein emboli and fistula of hepatic artery- portal vein was studied.

RESULTS: The three-dimensional vessel reconstruction technique of spiral-CT could display celiac trunk, portal vein, inferior vena cava and their branches at any planes and angles and the scope and extent of portal vein-vena cava shunt, portal vein emboli and the fistula of hepatic artery- portal vein. In twenty-nine patients with portal-systemic encephalopathy, grade I accounted for 89.7% esophageal varices, 86.2% paragastric varices; grade II accounted for 68.75% cirsomphalos, 56.25% paraesophageal varices, 62.5% retroperitoneal varices and 81.25% dilated azygos vein; grade III accounted for 80% cirsomphalos, 60% paraesophageal varices, 70% retroperitoneal varices, 90% dilated azygos vein, and part of the patients in grades II and III had portal vein emboli and fistula of hepatic artery-portal vein; grade IV accounted for 75% dilated left renal vein, 50% paragallbladder varices, all the patients had fistula of hepatic artery- portal vein.

CONCLUSION: The three-dimensional vessel reconstruction technique of spiral-CT can clearly display celiac trunk, portal vein, inferior vena cava and their branches at any planes and angles and the scope and extent of portal vein-vena cava shunt. The technique is valuable for evaluating the episode risk in portal-systemic encephalopathy.

INTRODUCTION

Portal-systemic encephalopathy is a kind of syndrome caused by portal hypertension and the construction of lateral branches, leading to a series of metabolic disorders, and is related to many neuron conduction mechanisms^[1]. The main clinical manifestation is coma or the alteration of consciousness and behaviors. The syndrome has a close relationship with the construction of portal vein lateral branches. The three-dimensional vessel reconstruction technique of spiral-CT is the best method to display the vascular system^[2]. Using this technique, we detected the scope and degree of portal vein-vena cava shunt, analyzed the risk of portal-systemic encephalopathy, and the relationship between them. This is of importance for doctors to make appropriate therapy plan and predict the disease's prognosis.

MATERIALS AND METHODS

Selection of clinical portal-systemic encephalopathy patients

From April to October 2003, 480 patients were performed spiral-CT because of liver or portal vein diseases. Among them, 59 patients had portal-systemic encephalopathy, including 44 males and 15 females. They aged from 34 to 69 years, averaging 48.9 years. All the patients were diagnosed by clinical symptoms, laboratory examination and radiologic findings. They were classified by West Haven method into grade I (29 cases), grade II (16 cases), grade III (10 cases), grade IV (4 cases).

Based on West Haven method, encephalopathy was divided into 4 grades^[3]. Grade I had absence of normal consciousness, euphoria or anxious, shortening of attention time, and other damage manifestations. Grade II had somnolence or indifference, mild disorder of time or space, mild change of personality, unsuitable behaviors, damage of subtraction. Grade III had lethargy, even half coma, reactions to word stimulation, confusion, obvious orientation disorder. Grade IV had coma (The patient had no reaction to word stimulation or harmful stimulation).

Scan technique of spiral-CT

Lightspeed spiral-CT (GE Corporation, U.S.A) performed high-speed scan. The parameters^[4] were 120 KV, 250 mA, slice thickness 10 mm, pitch 1.375:1, and matrix 512×512. We

performed plane scan at first, and then enhancement scan. The dosage of Ultravist 300 (62.3 mg/mL) was 2 mL/kg, and the injection speed was 3.5 mL/s. The injection was executed by a hyperbaric injection syringe in elbow vein by bolus injection. We performed the artery phase and portal vein phase enhancement scans after the injection^[5].

Three-dimensional vessel reconstruction technique of spiral-CT

Double-phase enhancement 10-mm thick images were reconstructed in CT^[6], and the reconstructed slices were 1.25-mm thick. Then the images were pushed to the workstation. The three-dimensional blood vessel reconstruction was performed by ADW4.0 software. The reconstructed celiac trunk, portal vein, inferior vena cava and their branches were subjected to three-dimensional vessel analysis by volume rendering (VR) technique^[7,8] and multiplanar volume reconstruction (MPVR) technique^[9]. The VR technique could utilize any axis as basic axis and carry out 360-degree rotation so that we could observe the vessels in any degree^[10]. The MPVR technique could perform any slice cross-sectional analysis^[11]. We evaluated the scope and degree of portal vein-vena cava shunt, portal vein emboli and the fistula of hepatic artery- portal vein with the aid of source images and reconstructed images^[12], and analyzed the relationship between the above-mentioned changes and the risk of portal-systemic encephalopathy^[13,14].

RESULTS

Display effects of three-dimensional vessel reconstruction technique of spiral-CT for portal vein and its branches

Referring to Ishikawa vessel classification method and considering the patients' condition, we classified the portal vein-vena cava shunt into nine types, normally cirrhophalos, paragallbladder varices, lienorenal vein collateral branch opening, retroperitoneal varices, esophageal varices, paraesophageal varices, dilated azygos vein, paragastric varices and dilated left renal vein. At the same time, we observed whether there were portal vein emboli and fistula of hepatic artery- portal vein.

Assessment of hepatic artery- portal vein fistula

The VR technique could display the 3-dimensional vascular structures of celiac trunk, hepatic artery, superior mesenteric artery and their branches at any angle in artery phase. We could analyze the relationship between the arteries and portal vein. The VR technique could display artery- portal vein fistula very well. In the artery phase, the portal vein was visualized early, and the blood in portal vein was seen refluxed (Figure 1A). In portal vein phase, the portal vein was very slightly developed and portal vein-vena cava shunt emerged (Figure 1B).

Figure 1 Portal vein in artery phase and in portal vein phase. A: Portal vein in artery phase. VR technique could display artery-portal vein fistula clearly in artery phase, the portal vein was visualized early, even portal vein blood up the stream. The arrow points the fistula aperture between the right hepatic artery and right portal vein. B: Portal vein in portal vein phase. The portal vein was very slightly developed and portal vein-vena cava shunt emerged in the portal vein phase.

Detection of portal vein emboli

In the portal vein phase, the VR technique could show the 3-dimensional vascular structures of portal vein and its branches at any angle. The enlarged portal vein and a non-flow region in the trunk could be seen (Figure 2). An image of portal vein was reconstructed by MPVR, and the emboli's scope and size could be displayed at many angles (Figure 3).

Figure 2 Enlarged portal vein and a non-flow region in the trunk (arrow).

Figure 3 Image of portal vein reconstructed by MPVR. We could see the emboli's scopes and sizes at different planes (arrow).

Analysis of portal vein-vena cava shunt

The MPVR technique could perform any cross-section analysis. Combining the source images, we evaluated the scope and degree of portal vein-vena cava shunt, portal vein emboli and fistula of hepatic artery- portal vein on MPVR images (Figures 4A, B).

Figure 4 Portal vein-vena cava shunt, portal vein emboli and fistula of hepatic artery-portal vein on MPVR images. A: Paraesophageal varices and dilated azygos vein on MPVR image (arrow). B: Paragastric varices on MPVR image (arrow).

Assessment of portal vein-vena cava shunt in encephalopathy

Referring to Ishikawa vessel classification method, the patients were classified into 4 grades by West Haven method: grade I, 29 cases; grade II, 16 cases; grade III, 10 cases; grade IV, 4 cases. The main portal vein disorders are listed in Table 1.

Table 1 Assessment of portal vein-vena cava shunt in encephalopathy

	Grade I n(%)	Grade II n(%)	Grade III n(%)	Grade IV n(%)
Esophageal varices	26(89.7)	9(56.25)	8(80)	4 (100)
Paragastric varices	25(86.2)	11(68.75)	7(70)	3(75)
Cirsomphalos	12(41.3)	11(68.75)	8(80)	4(100)
Retroperitoneal varices	11(37.9)	9(56.25)	6(60)	4(100)
Paraesophageal varices	13(44.8)	10(62.5)	7(70)	3(75)
Dilated azygos vein	6(20.1)	13(81.25)	9(90)	2(50)
Dilated left renal vein	2(6.9)	1(6.25)	1(10)	3(75)
Paragallbladder varices	0(0)	1(6.25)	1(10)	2(50)
Hepatic artery- portal vein fistula	0(0)	3(18.75)	6(60)	4(100)
Portal vein emboli	2(6.9)	8(50)	7(70)	3(75)

As it shows in this table, esophageal varices and paragastric varices were common in grade I. Besides the varices in grade I patients, the patients in grades II and III had cirsomphalos, paraesophageal varices, retroperitoneal varices and dilated azygos vein, and some of them had portal vein emboli and hepatic artery- portal vein fistula. Among the patients in grade IV, dilated left renal vein and paragallbladder varices were usual, and all patients had hepatic artery- portal vein fistula.

DISCUSSION

Encephalopathy is a nervous system syndrome, originating from chronic liver disease and hepatic cirrhosis. It is associated with portal hypertension, hepatic artery- portal vein fistula, portal vein emboli, hyperammonemia and other metabolic disorders. It also has a close relationship with hypertension, portal vein-vena cava shunt and lateral branch formation. The three-dimensional vessel reconstruction technique of spiral-CT can display portal vein, its branches, the scope and degree of portal vein-vena cava shunt. The technique is valuable for evaluating the risk of encephalopathy.

Spiral-CT double-phase (artery phase, portal vein phase) scan and the reconstruction technique could display portal vein-vena cava shunt, hepatic artery- portal vein fistula and portal vein emboli^[15]. Computed tomography during arterial portography (CTAP) was one of the best ways to show portal vein disorders^[16]. Sixteen-slice spiral-CT had unique superiority for portal vein pictures^[17]. To evaluate hepatic artery- portal vein fistula, early visualization of portal vein, enlargement of portal vein and blood of portal vein reflux were the main characteristics^[18,19]. The double-phase images of volume rendering technique could not only display the position and size of fistulae, but also the diameter of portal vein and the extent of portal vein reflux. Reflux and fistulae would advance the portal hypertension, accelerate the portal vein-vena cava shunt, decrease the portal vein blood flow into the liver, and increase the opportunity for encephalopathy^[20]. There was no hepatic artery- portal vein fistula in grade I patients ($n=29$), only 18.75% patients had fistulae in grade II (Table 1). However, in grades III and IV patients, 60% and 100% patients had fistulae. We can draw a conclusion that hepatic artery- portal vein fistula increases the risk of encephalopathy, and fistulae would aggravate encephalopathy or indicate the risk of encephalopathy.

On the assessment of portal vein emboli, the VR images in portal vein phase could show the vein because the blood flow was hindered by emboli or the complete obstruction of the trunk. The portal vein embolus was possibly one of the markers that hint the deterioration of encephalopathy^[21,22]. Perhaps portal vein embolus could hinder blood flow into the liver^[23]. It was believed that encephalopathy would appear if the blood flow of portal vein was less than 692 mL/min^[24]. The portal vein embolus would accelerate portal hypertension and induce brain disorder at the same time.

Portal vein-vena cava shunts include^[25,26] esophageal varices, paragastric varices^[27], paraesophageal varices, cirsomphalos, paraumbilical veins^[28,29], retroperitoneal varices (Retzius venous plexus), dilated azygos vein, dilated spleno- renal vein and stomach- renal vein, even internal iliac vein communication^[30]. CT and barium meal had the same role in diagnosing esophageal varices and paragastric varices. But CT was more valuable than barium meal and esophagoscope in diagnosing other varices^[31,32]. Spiral-CT scan is a kind of volume scan, and its merits include high speed and short reconstruction time. An examination of a patient's liver can be finished in a breathholding. VR images could display large lateral branch circulation clearly, but the small branches unclearly. The multiplanar volume reconstruction (MPVR) technique could perform any slice cross-sectional analysis of the vessels and disclose their relationship with the surrounding tissues (Figures 2, 3), and esophageal varices, paragastric varices and azygos vein.

In a word, simple esophageal varices, paragastric varices and paraesophageal varices would not induce severe encephalopathy. However, the portal vein emboli, or hepatic artery- portal vein fistula, or wide portal vein-vena cava shunt, particularly the dilated left renal vein and paragallbladder varices, which may hint encephalopathy, would occur or deteriorate.

Not only would portal vein-vena cava shunt induce portal-systemic encephalopathy, but also the liver function of patients,

metabolic status^[33] and diseases outside the liver^[34] played a role. The relationship between them is still unclear. More work needs to be done. However, the three-dimensional vessel reconstruction technique of spiral-CT can display the celiac trunk, portal vein, inferior vena cava and their branches at any plane and from any angle, and show the scope and degree of portal vein-vena cava shunt. The technique is valuable for evaluating the episode risk in portal-systemic encephalopathy, and helpful for TIPSS.

Abstract

AIM: To investigate the role of curved planar reformations using multidetector spiral CT (MSCT) in diagnosis of pancreatic and peripancreatic diseases.

METHODS: From October 2001 to September 2003, 47 consecutive patients with pancreatic or peripancreatic diseases, which were confirmed by operation, endoscopic retrograde cholangiopancreatography and clinical follow-up, were enrolled in this study. CT scanning was performed at a MSCT with four rows of detector. A set of images with an effective thickness of 1.0-2.0 mm and a gap of 0.5-1.0 mm (50% overlap) were acquired in all patients for post-processing. Curved planar reformations were carried out by drawing a curved line on transverse source images, coronal or sagittal multiplanar reformations according to certain anatomic structures (such as cholangiopancreatic ducts or peripancreatic vessels) and the position of lesion.

RESULTS: With thin collimation, MSCT could acquire high-quality curved planar reformations to display the profile of the whole pancreas, to trace the cholangiopancreatic ducts and peripancreatic vessels, and to show the relationship of lesions with pancreas and peripancreatic anatomic structures in one curved plane, which facilitates diagnosis and rapid communication of diagnostic information with referring physicians.

CONCLUSION: MSCT with thin collimation could be used to create high-quality curved planar reformations in evaluating pancreatic and peripancreatic diseases with pertinent anatomic information and relative pathologic signs to facilitate the diagnosis and enhance communication with the referring physician. Curved planar reformations can serve as supplements for transverse images in diagnosis and management of pancreatic and peripancreatic diseases.

INTRODUCTION

Pancreas is located in the retroperitoneum with a tortuous

course, which is difficult for CT and MR to display the whole pancreas in one slice. There are abundant vessels around the pancreas. It is important to visualize these vessels and the cholangiopancreatic ducts for diagnosing and evaluating the local involvement of pancreatic and peripancreatic lesions. Curved planar reformations can delineate a curved path and display the whole course of pancreas in a single cross-section image according to a curved line drawn on the transverse source images, coronal or sagittal multiplanar reformations (MPR) from a three dimension (3-D) volumetric data set acquired by spiral CT^[1,2]. They have been widely used to display vessels and evaluate vascular abnormalities in conjunction with CT angiography^[1-7]. Recently the new techniques have been applied to evaluate the pancreas and bile duct system pathologically^[8-11]. This article focuses on the role of curved planar reformations using MSCT in the diagnosis of pancreatic and peripancreatic diseases.

MATERIALS AND METHODS

Patients

From October 2001 to September 2003, 47 consecutive patients (21 female and 26 male, age range: 13-72 years, mean age: 53 years) with pancreatic or peripancreatic diseases, which were confirmed by operation ($n=18$), endoscopic retrograde cholangiopancreatography (ERCP) ($n=6$) and clinical follow-up ($n=23$), were enrolled in this study. The diseases included pancreatic carcinoma ($n=9$), cystadenoma ($n=3$), neuroendocrine tumor ($n=4$), chronic pancreatitis with pseudocyst ($n=16$), real cyst of pancreas ($n=1$), choledochal cyst ($n=2$), ampullary carcinoma ($n=3$), choledocholithiasis ($n=5$), duodenal diverticulum ($n=1$), peripancreatic adenopathy ($n=3$) and splenic arterial aneurysm ($n=1$).

CT imaging

CT scans were performed with a MSCT scanner (Toshiba Aquilion, Tokyo, Japan). Seven patients underwent plain scanning, 38 patients underwent both plain and enhanced scanning, and the other two patients a drip infusion CT cholangiography. A scanning with parameters of 120 kVp, 300 mA, $4\times1-2$ mm collimation, rotation time of 0.5 s, and a pitch of 5.5 was included in all patients during a breathhold of 10-15 s. In patients who underwent both plain and enhanced scanning, this protocol was obtained at the pancreatic parenchyma phase (a delay of 40 s after the beginning of intravenous injection of nonionic contrast media with an iodine content of 300 mg/mL [Omnipaque, Nycomed-Amersham, Shanghai] at 3 mL/s using a power injector). The CT cholangiographic image was acquired 60 min after intravenous drip infusion of iodipamide methylglucamine. A set of images with an effective thickness of 1-2 mm and a gap of 0.5-1.0 mm (50% overlap) was reconstructed and transmitted to workstation for post-processing.

Curved planar reformations

Curved planar reformations were obtained using a cursor to draw a curved line along a special anatomic structure on a stack of axial, sagittal, coronal section at a SGI workstation

(Alatoview 1.21) by an experienced radiologist who was familiar with the pancreatic and peripancreatic anatomic structures and had carefully reviewed all transverse source images. The operator was asked to adjust the trace of the cursor interactively to create several curved planes to display essential anatomic structures, such as cholangiopancreatic ducts and peripancreatic vessels, and the relationship of the lesion with those structures according to diagnostic and clinical need (Figure 1). The section thickness of curved plane will never be larger than the effective section thickness or smaller than the transverse pixel dimensions.

Figure 1 Curve drawn on a transverse image along the pancreatic duct in a patient with pancreatic adenocarcinoma.

RESULTS

With thinner collimation and overlap image data sets, high quality curved planar reformations were obtained in all the 47 patients, displaying the whole pancreas and tracing cholangiopancreatic ducts or peripancreatic vessels in a single cross-section image without any misregistration and steps artifacts (Figures 2-12). For the 20 pancreatic local lesions (9 cases of pancreatic adenocarcinoma, 3 cystic adenomas, 4 neuroendocrine tumors, 3 intrapancreatic pseudocysts and 1 real cyst of pancreas), curved planar reformations demonstrated that the whole or major portions of the lesion was located in the pancreatic parenchyma clearly, which made it easier to determine lesion's location (Figures 2-5). Curved planar reformations, by tracing a certain vessel, such as the celiac artery, the superior mesenteric artery, the portal vein, could demonstrate changes in the caliber of the vessel and wall invasion, which was helpful for determining whether these vessels were involved and the length of involvement, as in the 9 patients with pancreatic adenocarcinoma and the 3 patients with ampullary carcinoma (Figures 6, 7). Combining with transverse images, curved planar reformations demonstrated 2 positivities and 1 false positivity in predicting respectability, 6 positivities in assessment of unresectability in 9 patients with pancreatic adenocarcinoma. The dilatation of cholangiopancreatic ducts in patients with chronic pancreatitis, pancreatic or ampullary carcinoma and peripancreas lymph nodes enlargement were well depicted on curved planar reformations (Figures 8,9). In 1 patient with pancreatic real cyst, the curved planar reformations after CT cholangiography revealed the beaded dilatation of pancreatic duct and the dilatation and stenosis of the common bile duct. The cyst lay beside the dilated common bile duct (Figure 4). In the 13 patients with pseudocyst beyond the pancreas and the 2 patients with choledochal cyst, curved planar reformations displayed the cystic lesion and the relationship of cysts with pancreas well. Stones' location and cholangiopancreatic ducts morphologic changes distal and proximal to obstruction were depicted on curved planar reformations in all patients with choledocholithiasis (Figure 10). The location and relationship with pancreas of peripancreatic

enlarged lymph nodes were easily identified on curved planar reformations, which made differential diagnosis from pancreatic mass more simple (Figure 11). In 1 case of splenic arterial aneurysm, the dilatation of the artery was detected on curved planar reformations but missed on transverse source images due to its small diameter and dilatation along the z axis of CT imaging (Figure 12).

Figure 2 Curve obtained from the curved line on Figure 1 displayed the hypoattenuation tumor at the head of pancreas and the distal dilated pancreatic duct (arrow).

Figure 3 Neuroendocrine tumor of pancreas. Curved planar reformations during pancreatic parenchyma phase demonstrated the enhanced mass located in the tail of pancreas.

Figure 4 Neuroendocrine tumor of pancreas and peripancreatic pseudocyst. Curved plane showed a non-enhanced hypoattenuation mass located in the pancreatic parenchyma (arrow) and a pseudocyst at the port of spleen during the pancreatic parenchyma phase. The normal pancreatic duct was also well depicted (long arrow).

Figure 5 Real cyst of pancreas. Curved planar reformations obtained after CT cholangiography showed the dilatation and obstruction of bile duct system, and the beaded-like dilatation of pancreatic duct. The cyst located beside the common bile duct. There was no contrast media entrancing into cyst.

Figure 6 A curved plane tracing superior mesenteric artery of the same patient with Figure 1 and Figure 2 demonstrated the vessel was not involved. The tumor was confirmed to be resectable at operation.

Figure 7 A curved plane tracing the celiac trunk and the splenic artery of a patient with pancreatic adenocarcinoma demonstrated the irregular stricture (arrow).

Figure 8 Ampullary carcinoma. Curved planar reformations depicted a low attenuation mass around the pancreatic head and the dilatation of both bile duct (arrow) and pancreatic duct (long arrow).

Figure 9 Gastric cancer with peripancreatic adenopathy. Curved planar reformations depicted the dilatation of the pancreatic duct.

Figure 10 Choledocholithiasis of common bile duct. Curved plane displayed the dilatation of the bile duct system and the pancreatic duct. The location of stones was depicted clearly.

Figure 11 Peripancreatic adenopathy. Curved planar reformations showed several enlarged lymph nodes located at the pancreatic head.

Figure 12 Splenic artery aneurysm. Curved planar reformations depicted the local dilatation of splenic artery (arrow).

DISCUSSION

Computed tomography (CT) is the most frequently used imaging modality for the evaluation of patients with suspected pancreatic and peripancreatic diseases, especially for diagnosing and staging pancreatic adenocarcinoma^[12-17]. In detection and staging of pancreatic ductal adenocarcinoma, CT had a sensitivity of more than 90% and a positive predictive value in the range of 96% to 100% for determining surgical unresectability^[9,12-14]. In determining resectability, the accuracy of CT remained low with positive predictive values ranging from 53% to 79% due to underestimation of vascular invasion and failure to detect small peritoneal and liver metastases^[9,12,14]. The introduction of MSCT and the development of three-dimensional (3D) imaging software have significantly improved the ability of CT to image the pancreas and evaluate a wide range of pancreatic and peripancreatic pathology^[8-11,17,18].

One major advantage of MSCT over single-detector spiral CT is substantial improvement in the speed of scan acquisition, which permits routine use of very thin collimation covering a large region during breath-hold to acquire volumetric data sets with high resolution along all three axes, especially along z axis, even with isotropic image^[9,10,18,19]. The improvement of resolution along the z axis is very helpful for generating high quality multiplanar reformations (MPR) and 3D images. Curved planar reformations are a special form of MPR; which depict the cross-section profile along any curved line the operator draws from the volumetric data sets to trace the course of an anatomic structure. The plane presents results in a 2D image that displays the entire course of the anatomic structure^[9]. Thus the techniques are very useful in displaying a complex anatomic structure with a tortuous course. They can delineate the curved vascular structure and display its whole course in one cross-section image. Therefore, curved planar reformations were used to display vessels and evaluate their abnormality^[2-7]. This provided a convenient and fast review method for radiologists and an effective format for communicating the pertinent findings to referring physicians. These techniques were especially useful in evaluating those vessels, such as the

carotid siphon, which has a tortuous course and is surrounded by complex bony structures and thus the maximal intensity projection (MIP) and 3D images were difficult to depict them^[5]. Recently, the application of curved planar reformations in the pancreatic and bile duct system showed that these techniques could provide helpful unique anatomic information, highlight critical anatomic and pathologic relationships, which were useful for surgical planning^[8-11]. The other advantage of curved planar reformations was that the referring physicians could review a few curved planes to acquire critical information instead of reviewing a large number of images in great detail, which enhanced rapid communication^[8].

In the present series, curved planar reformations using MSCT were performed in 47 patients with pancreatic and peripancreatic diseases. With thin collimation and overlap reconstruction, high quality curved planar reformations were obtained in all the patients displaying the whole tortuous pancreas in one cross-section image, tracing critical surrounding anatomic structures, such as cholangiopancreatic ducts and peripancreatic vessels, or highlighting relationships of the lesion with essential anatomic structures. All these were helpful for determining the lesion's location and evaluating its invasion to surrounding anatomic structures. The latter was important to determining the resectability of pancreatic ductal adenocarcinoma. In 9 patients with pancreatic carcinoma, curved planar reformations tracing critical peripancreatic vessels could not only demonstrate the vascular involvement of tumor, but also depict the length of the affected segment. Although one study showed that curved planar reformations were equivalent to transverse images in the detection of pancreatic tumors and determination of surgical resectability^[10], we did not assess the resectability according to curved planar reformations only due to their operator dependence, which would be discussed later. In this series, by combination of curved planar reformations with transverse images, 2 positivities and 1 false positivity in predicting resectability and 6 positivities in determining unresectability in 9 patients with pancreatic adenocarcinoma were obtained. Whether it would improve the accuracy of staging of pancreatic adenocarcinoma by combining curved planar reformation with transverse images was not carried out in this study due to the small sample size of pancreatic carcinoma, which was one limitation of this study. In one case of pancreatic real cyst, curved planar reformations after CT cholangiography demonstrated the beaded dilatation of pancreatic duct and the dilatation and obstruction of the bile duct system. The relationship of the cystic lesion with the pancreatic and bile duct system was depicted clearly. All these could provide guides for operation, although a correct diagnosis was not acquired before operation. For the peripancreatic lesions, such as peripancreatic adenopathy, ampullary carcinoma, duodenal diverticulum and pseudocysts, curved planar reformations depicted the changes of the bile duct system and pancreatic duct, and relationships of lesions with surrounding important anatomic structures, which were helpful for making diagnostic and treatment strategies. Direct display of morphologic changes of bile duct system and stones location in curved planar reformations would be very useful for surgical planning, especially for endoscopic management of choledocholithiasis. With their advantage in demonstrating vascular abnormality, curved planar reformations displayed the small splenic arterial aneurysm easily in this series although it was missed in transverse images. On the one hand, it needs the operator interactively to adjust the path of cursor and work intensively to generate proper curved planar reformations with highlight important diagnostic information. On the other hand, several curved planes may transfer the important information to referring physicians. This reduces

the referring physicians' burden to review all the transverse images for useful information.

One limitation of curved planar reformations is that they are exceedingly operator-dependent. Improper path of the cursor may generate spurious stenoses of cholangiopancreatic ducts and vessels, distort the anatomic structures or cause important lesion missed. Therefore, the operator should be familiar with the anatomy of pancreas and carefully review all transverse source images before beginning to draw the line. Although careful view of all transverse source images may be a time-consuming and tedious job, it is helpful to create proper curved planar reformations to highlight critical anatomic structures and pathologic signs. Due to this limitation, in this series a comparison with standard transverse images was not carried out. Curved planar reformations can serve as supplements in evaluating pancreatic and peripancreatic diseases while not a substitute. Recently, Raman *et al.*^[20] developed an automated method to generate curved planar reformations with reduced time and effort. With the development of post-processing software, a well-trained radiologic technologists may generate curved planar reformations routinely.

In summary, MSCT with thin collimation can be used to generate high quality curved planar reformations for evaluating pancreatic and peripancreatic diseases. Our preliminary study showed that curved planar reformations could clearly depict essential anatomic structures and highlight critical anatomic information and pathologic signs in several cross-section images, which enhanced the rapid communication with referring physicians. Curved planar reformations can serve as supplements for transverse images in diagnosis and management of pancreatic and peripancreatic diseases.

Abstract

AIM: To investigate the clinical value of miniature ultrasonic probes (MUPs) for the diagnosis and treatment of digestive tract diseases.

METHODS: Endoscopic ultrasonography (EUS) was performed for patients with its indications with 7.5-20 MHz MUPs and double-cavity electronic endoscope. According to the diagnosis of MUPs, patients who had indications of treatment received endoscopic resection or surgical excision. Postoperative histological results were compared with the preoperative diagnosis of MUPs. A few patients without endoscopic resection or surgical excision were periodically followed up with MUPs.

RESULTS: A total of 537 patients were examined by MUPs, of them, 256 were diagnosed with gastrointestinal submucosal lesions, 146 with pseudo-submucosal lesions, 50 with digestive tract cancers, 17 with peptic ulcer, 11 with cholecystolithiasis, 8 with chronic pancreatitis, and 2 with achalasia and 47 were diagnosed as normal. After MUPs examinations, 220 patients received endoscopic resection or surgical excision, and the postoperative histological results of 211 patients were completely consistent with the preoperative diagnosis of MUPs. The diagnostic accuracy of MUPs was 95.9%. The result of follow-up with MUPs indicated that gastrointestinal leiomyoma, lipoma, phlebangioma and cyst were unchanged within 1-2 years. The patients who received endoscopic resection or centesis did not have any complications.

CONCLUSION: MUPs are of value in diagnosing gastrointestinal submucosal lesions, staging of digestive tract cancers and biliary-pancreatic diseases. They play a very important role in making therapeutic plans.

INTRODUCTION

With the development of endoscopic ultrasonography (EUS) in clinical application, great progress has been made in diagnostic specificity and sensitivity of digestive tract diseases. EUS has usually been performed with a standard ultrasonic endoscope since the introduction of EUS with miniature ultrasonic probes (MUPs) in clinical diagnosis in the 1990s^[1]. In August 2000, MUPs series were adopted in the First Affiliated Hospital of Zhejiang University and since then EUS with MUPs have been performed in 537 patients with digestive tract diseases. In the present article, the clinical values of MUPs in the diagnosis of gastrointestinal submucosal lesions, digestive tract cancers, and biliary-pancreatic diseases were analyzed and reported.

MATERIALS AND METHODS

Patients

A total of 537 patients presenting EUS indications were examined by MUPs. Their mean age was 54 years, ranging from 16 to 89 years. There were 280 men and 257 women.

Instruments

Instruments of EUS with MUPs included Fujino EG-410D double-cavity electronic gastroscope, Olympus-100 electronic colonoscope and Fujino SP-70 high-frequency echoprobe system. The frequency spectrum of the probes is between 7.5-20 MHz.

Methods

The preparation before MUPs examinations was the same as that before gastroscopy and colonoscopy examinations. Intramuscular injection of atropine or scopolamine could also be made. According to the information of the location and size of the lesion in gastrointestinal gained by conventional endoscope examinations, microprobes of different frequencies were used. Patients who presented the indications of treatment accepted endoscopic resection or surgical excision according to the diagnosis by MUPs. Postoperative histological examination results of resected lesions were checked with the preoperative diagnosis by MUPs, and for patients with biliary-pancreatic diseases, diagnosis by MUPs was checked with that by ERCP and spiral CT examination. A few patients who did not receive endoscopic resection or surgical excision were periodically followed up with MUPs. The tolerance to EUS with MUPs and complications related to the examination in all these patients were investigated as well.

RESULTS

The results of MUPs examinations of the 537 suspected patients and the histopathologic diagnoses of some cases are summarized in Table 1. After examinations by MUPs, 256 patients were diagnosed with gastrointestinal submucosal lesions, 146 with pseudo-submucosal lesions, 50 with digestive tract cancer, with peptic ulcer, 11 with cholecystolithiasis, 8 with chronic pancreatitis, and 2 with achalasia and 47 were

diagnosed as normal. Among the 256 patients with gastrointestinal submucosal lesions, 162 (64.3%) were diagnosed with leiomyoma. Among the 162 patients with leiomyoma, 96 had esophageal leiomyoma. Of the 96 esophageal leiomyoma cases, 62 had lesions originating from muscularis mucosae and 34 had lesions originating from muscularis propria. Of the 57 gastric leiomyoma cases, 5 had lesions originating from muscularis mucosae and 52 had lesions originating from muscularis propria. Of the 5 duodenal leiomyoma cases, 1 was derived from muscularis mucosae and 4 from muscularis propria. All the 4 cases of colonic leiomyomas were derived from muscularis propria. After MUPs examinations, 122 patients with gastrointestinal true submucosal lesions accepted further treatment of endoscopic resection, surgical excision or puncture. The postoperative pathological diagnosis agreed with the preoperative MUPs diagnosis in 113 cases, thus the accuracy rate of the diagnosis by MUPs was 92.6%. Of the 162 patients with leiomyoma, 86 received either endoscopic resection or surgical excision. In 80 cases, the preoperative MUPs examination results were identical to the postoperative pathological diagnosis. However, the histological results of only 6 patients suffering from leiomyosarcoma (2 cases), gastric neurofibroma, esophageal tuberculosis granuloma, esophageal cyst gland retention, and colonic carcinoid were not consistent with the preoperative diagnoses by MUPs. The accuracy rate of the diagnosis by MUPs was 93%. Among the 146 patients with pseudo-submucosal lesions, 56 were diagnosed with polypus, 37 with inflammatory protruding and thickening of gastrointestinal mucosae, and 53 with extrinsic compression. The polypus and inflammatory protruding were confirmed by pathological biopsy, and the organs of extrinsic compression included spleen (15 cases), gallbladder (9 cases), aorta (8 cases), liver (6 cases), pancreas (4 cases), splenic vein (2 cases), lymph node (3 cases), thoracic vertebrae (2 cases) and mass with unknown nature (4 cases). Of the 11 patients with cholelithiasis, 7 were diagnosed with cholecystolithiasis, and 4 with choledocholith, which was not detected by surface type-B ultrasonography but was confirmed by surgical operation or ERCP. Among the 8 patients with chronic pancreatitis, 4 were diagnosed with pseudocyst of

pancreas, 1 with abscess of pancreas, 1 with distension of main pancreatic duct and 2 with pancreatic echo enhancement. Of the 8 patients, 4 were further confirmed by surgical operation or ERCP. The depth and healing of ulcer were verified by examination of EUS in 17 patients with peptic ulcer. According to the MUPs examination, 47 patients had normal stratification and structure of digestive tract. Of them, 5 patients were diagnosed with duodenal accessory papilla. In addition, some patients with gastrointestinal leiomyoma, lipoma, phlebotomy, cyst, inflammatory protruding or thickening were periodically followed up by MUPs, and the results of examinations showed no changes of these lesions in 1-2 years, but some lesions occurred such as inflammatory protruding, thickening and cyst shrank. All the patients could well tolerate this examination without serious complications such as bleeding, perforation and cardiac or pulmonary accident. No complications occurred in patients who received endoscopic resection or puncture.

DISCUSSION

The diameter of MUPs is small, so it can pass through the biopsy tube of a conventional endoscope and be placed anywhere inside the digestive tract to perform EUS. MUPs can reach or pass any small tubule or narrow space where the standard ultrasonic endoscope can not reach. MUPs do not cause compression on organ structures such as esophagus. MUPs can be easily operated. The frequency range of the probes was broad^[1]. The significance and experiences in using EUS with MUPs for the diagnosis and treatment of digestive tract diseases are as the following.

Value of MUPs in diagnosing gastrointestinal submucosal lesions

Studies have shown that EUS is the best diagnostic method of gastrointestinal submucosal lesions. EUS could not only confirm if the lesion is a true submucosal lesion, but also ascertain accurately the size, location, origin and nature of the lesion^[2-6]. We performed EUS with MUPs, and found 7.5-20 MHz MUPs was very important for the diagnosis of gastrointestinal true submucosal lesions. By this examination, we could

Table 1 MUPs diagnosis of 537 patients and histopathological diagnosis of 211 cases

Diseases	Esophagus	Stomach	Duodenum	Colon	Biliary tract	Pancreas	Total	Confirmation by pathological examination/operation
Leiomyoma	96	57	5	4			162	80/86

Total	173	242	24	26	11	14	537	211/220

determine the size, location, number and origin of the lesion. According to the ultrasonic characteristics of lesions, we could also distinguish the nature of different lesions^[7-11]. For example, scanned by MUPs, gastrointestinal leiomyoma presented homogeneous and hypoechoic lesions with a clear margin around the hyperechoic wrapping area, which was derived from muscularis mucosae or muscularis propria (Figure 1A). Gastrointestinal lipoma presented homogeneous and hyperechoic lesions with a distinct margin. The lesion often originated from submucosa (Figure 1B). Gastrointestinal cyst presented echoic lesions with a clear margin and enhancement behind. The lesion was often derived from submucosa (Figure 1C). Ectopic pancreas that often appeared in stomach or duodenum revealed non-homogeneous, middle-hyperechoic or patchy echoic lesions with a tubular structure and thickening of muscular layer. The lesions often originated from submucosa or muscularis propria (Figure 1D). Hemangioma and varicosis often appeared in gastric fundus and esophagus as echoic honeycomb-like lesions, and were easy to be deformed by compression. They mostly originated from mucosae or submucosae (Figure 1E). Our clinical research included not only these common submucosal lesions, but also leiomyosarcoma, lymphoma, carcinoid, neurofibroma, abscess, Brunner's adenoma and hematoma, etc. Leiomyoma was the most common benign tumor in gastrointestinal submucosal lesions, accounting for 64.3% of the total gastrointestinal submucosal lesions. According to our clinical and pathological study on gastrointestinal leiomyoma, leiomyoma mainly occurred in esophagus and stomach, and the incidence in small intestine and colon was much lower than that in esophagus and stomach. The size and layer of the origin of esophageal leiomyoma were obviously different from those of gastric leiomyoma. The majority of esophageal leiomyomas originated from muscularis mucosae, and the size was <1.0 cm. Whereas most of the gastric leiomyomas originated from muscularis propria, and the size was 1-2 cm. Almost all the patients with gastrointestinal leiomyoma only had a single lesion, which often progressed slowly or had no change^[12-14]. Among the 256 patients with gastrointestinal true submucosal lesions, 122 patients accepted further treatment of endoscopic resection, surgical excision, or puncture. The results showed that the size, layer, origin and number of the resected lesions were completely consistent with the diagnoses by MUPs. The nature of lesions was in agreement with preoperative diagnosis in 113 patients, and the diagnostic accuracy rate was 92.6%. Current studies with MUPs revealed its significant value in diagnosing gastrointestinal true submucosal lesions^[15-19]. In patients who were periodically followed, gastrointestinal leiomyoma, lipoma, ectopic pancreas, cyst and hemangioma remained unchanged within 1-2 years, and no obvious clinical symptoms were observed. This observation indicates that those who are old and can not or do not want to accept further treatment, with lesions located at unusual sites, should be regularly followed up.

Value of MUPs in diagnosing gastrointestinal pseudo-submucosal lesions

Scanning MUPs can display clearly the layer structure and adjacent organs of gastrointestinal tract, so that pseudo-submucosal or true submucosal protruding lesions could be accurately identified. According to our clinical experience, pseudo-submucosal lesions mainly included polypus, inflammatory protruding and pressure protruding lesions. Most gastrointestinal tract polypi and inflammatory protruding lesions could usually be diagnosed by conventional endoscopy. In a few patients, the color and structure of polypus or inflammatory prominence were similar to those of the surrounding normal mucosae, so we could not differentiate these lesions from submucosal lesions by conventional

endoscopy. By MUPs, according to the origin, layer structure, and changes of the lesion echoes, we could diagnose the lesions easily. As to some superficial and small lesions, we could not only locate them, but also show the layer structure and relationship of the lesions and gastrointestinal wall more clearly by changing probes with different frequencies. Gastrointestinal tract polypus and inflammatory prominences all originated from epithelia and mucosae. Polypus presented homogeneous or non-homogeneous, middle-hyperechoic lesions without envelope (Figure 1F). The latter manifested thickening or loss of epithelia and mucosae, but the layer, structure and echo of the lesions were all normal (Figure 1G). Our diagnostic accuracy rate of extrinsic compression by MUPs was 100%, the same as that reported by Cletti (1993) and Pfau (2002)^[20-21]. According to the complete layer and structure of gastrointestinal tract, the curved compression adventitia and the cross section images of surrounding tissues and structures, we could diagnose extrinsic compression easily by MUPs, just as by conventional ultrasonic endoscopy. At the same time, we could precisely distinguish most of the tissues and organs that caused the compression. Of the 537 patients, 53 were diagnosed with extrinsic compression, and the major organs that caused the compression were spleen (Figure 1H), gallbladder, aorta (Figure 1I), liver, pancreas, splenic vein, lymph node and thoracic vertebrae, etc. Furthermore, in most patients the compression was caused by the swelling and lesion of organs and tissues. So our clinical research confirmed the incomparable superiority of MUPs in diagnosing polypus, inflammatory protruding and extrinsic compression of gastrointestinal tract that are often difficult to be found out by conventional endoscopy.

Value of MUPs in diagnosing biliary-pancreatic diseases

When we performed EUS, we placed the ultrasonic probes in the gastrointestinal tract. Compared with surface ultrasonography, the probe closer to biliary tract and pancreas could avoid interference of duodenum and gas, so the images of biliary-pancreatic diseases (especially lesions of the lower middle part of common bile duct and ampulla) taken by EUS were clearer than those taken by surface ultrasonography. According to the literature, the diagnostic sensibility and specificity of EUS for choledocholith were 91% and 100% respectively, which were much higher than those of surface ultrasonography and common CT examination, and similar to those of ERCP, but the complications of EUS were much fewer than those of ERCP^[22,23]. In our study, 11 patients were diagnosed with cholelithiasis by a 7.5 MHz microprobe scan (Figure 1J, K). The calculi of the lower part of the common bile duct in 4 of the 11 patients were not detected by surface type B ultrasonography, but confirmed by ERCP or surgical operations. So MUPs are superior to surface ultrasonography and common CT for the diagnosis of calculus of the lower part of the common bile duct, and can greatly improve the diagnostic situations of common bile duct diseases. By MUPs, we could distinguish calculus from tumors in biliary tract by real-time observation and we could also observe the lesions of ampulla directly. Compared with surface ultrasonography, CT, and magnetic resonance cholangiopancreatography (MRCP), MUPs were much superior. Pancreas is deeply located, and its ultrasonic image may be influenced by abdominal gas, so ultrasonography has difficulty to examine it. By examinations with 7.5-12 MHz MUPs, 14 cases were diagnosed with pancreatic diseases. Of them, 8 cases had chronic pancreatitis, including 4 cases of pancreatic pseudocyst (Figure 1L), 1 case of abscess, 1 case of dilation of main pancreatic duct, and 2 cases of pancreatic echo enhancement. The results were consistent with those of spiral CT and ERCP. After examination by MUPs, 9 patients accepted surgical operations and the diagnoses were confirmed by pathologic examinations.

Figure 1 Lesions in digestive tract. A: Gastric leiomyoma, B: Gastric lipoma, C: Gastric cyst, D: Gastric ectopic pancreas, E: Gastric varicosis, F: Gastric polypi, G: Gastric inflammatory protruding, H: Gastric extrinsic compression (spleen), I: Esophageal extrinsic compression (aorta), J: Gallstone, K: Choledocholith, L: Pseudocyst of pancreas, M: Linitis plastica, N: Early gastric cancer, O: Pancreatic cancer.

On the basis of these results, we can make the conclusion that EUS with MUPs for pancreatic diseases is of diagnostic value. It can not only detect pancreatic duct, but also observe the changes of pancreatic parenchyma. Compared with ERCP, it was disadvantageous in displaying the full view of pancreatic duct, but it was advantageous in displaying the echo of pancreas, pancreatic calculus, and cyst. Furthermore, there were no ERCP-related complications in examinations by MUPs. So the diagnosis of pancreatic diseases by MUPs was effective, safe and convenient. Recently, there were reports about ultrasonography performed in biliary-pancreatic duct by MUPs^[1,24]. It can greatly improve the diagnostic situation of common bile duct and pancreatic parenchymal micro-lesions and has become the best diagnostic method for pancreatic endocrine tumors.

Value of MUPs in diagnosing and TNM staging of digestive tract cancer

TNM staging of digestive tract cancers by EUS is generally accepted. The sensitivity and specificity of EUS for TNM staging of digestive tract cancers were obviously higher than those of surface ultrasonography, conventional endoscopy, CT and MRI, etc, but EUS was inferior to CT and MRI in the diagnosis of stage M cancers^[25,26]. With 7.5-20 MHz microprobes, we researched the diagnosis, infiltrating depth and metastasis of surrounding lymph nodes in 50 patients with digestive tract cancers. The results showed the very important value of EUS with MUPs in diagnosing linitis plastica which could not be detected by conventional endoscopy. The growth pattern of this type of gastric cancer was unique. The cancer cells spread and infiltrated into submucosa. So it was hard to be detected by common biopsy. But it had special ultrasonic imaging changes which manifested obviously in diffuse thickening of gastric wall, loss of layer structure and hypoechoic lesion, etc. (Figure 1M). According to these ultrasonographic changes, 8 patients who were diagnosed with linitis plastica were confirmed by surgical operations. Investigations abroad have shown that the diagnostic accuracy rate of EUS for early stage gastrointestinal tract cancers was higher than that by any other examination^[24]. Our study also demonstrated that the depth of infiltration and surrounding lymph node metastasis in digestive tract cancers could be diagnosed by MUPs. 12-20 MHz microprobes could display the infiltrating depth of tumors in gastrointestinal wall clearly. A 7.5 MHz probe could show infiltrations in adjacent tissues, organs and lymph nodes, then we could judge whether the cancer lesion was in early stage (Figure 1N) or advanced stage (Figure 1O). The diagnoses by MUPs in 42 patients who received surgical operation or endoscopic resection were consistent with the pathological diagnoses. It is concluded that MUPs can be applied to TNM staging of digestive tract cancers. MUPs are superior to standard ultrasonic endoscopy because it can be inserted into the narrow gastrointestinal tract tumor infiltration or into other small tubules.

Value of MUPs in guiding treatment of digestive tract diseases

Our clinical research demonstrated that MUPs could not only diagnose digestive tract diseases, but also provide treatment plans for these diseases^[27-30]. MUPs had a very important diagnostic value in deciding the size, location, layer origin and nature of gastrointestinal submucosal lesions. By this examination, leiomyoma, lipoma and ectopic pancreas originating from above submucosae received endoscopic resection. Cysts derived from submucosa were treated by endoscopic puncture and aspiration. The procedure was effective, safe, economical and simple, and resulted in microtraumas only. Submucosal lesions originating from muscularis propria or adventitia were regarded as contraindications for endoscopic resection. The patients received

surgical operation or thoracoscopy or laparoscopy. Patients who did not undergo, or were unfavorable to undergo operations were followed up periodically; therefore, complications such as perforation were avoided. MUPs helped us in ascertaining the indications of endoscopic resection in patients with early stage gastrointestinal tract cancer. They also helped us in formulating scientific, reasonable treatment plans for patients with median or advanced stage of cancer. With the modality, hemangioma and varicosis in gastrointestinal tract were diagnosed, unnecessary biopsy and resection were avoided, and massive hemorrhage was prevented. The effective differentiation of inflammatory protruding from pressure protruding lesions helped formulate a correct treatment regimen and give up explorative operation. In addition, difficult biliary-pancreatic diseases could be diagnosed by MUPs; patients could be treated promptly and effectively. In conclusion, MUPs can greatly improve the accuracy rate of diagnosis and treatment of digestive tract diseases.

Abstract

AIM: Quality of life (QOL) is a concept that incorporates many aspects of life beyond "health". The chronic liver disease questionnaire (CLDQ) was developed to evaluate the impact of chronic liver diseases (CLD) on QOL. The objectives of this study were to translate and validate a liver specific questionnaire, the CLDQ.

METHODS: The CLDQ was formally translated from the original version to Thai language with permission. The translation process included forward translation, back translation, cross-cultural adaptation and a pretest. Reliability and validity of the translated version was examined in CLD patients. Enrolled subjects included CLD and normal subjects with age- and sex-matched. Collected data were demography, physical findings and biochemical tests. All subjects were asked to complete the translated versions of CLDQ and SF-36, which was previously validated. Cronbach's alpha and test-retest were performed for reliability analysis. One-way Anova or non-parametric method was used to determine discriminant validity. Spearman's rank correlation was used to assess convergent validity. P -value <0.05 was considered statistically significant.

RESULTS: A total of 200 subjects were recruited into the study, with 150 CLD and 50 normal subjects. Mean ages (SD) were 47.3(11.7) and 49.1(8.5) years, respectively. The number of chronic hepatitis: cirrhosis was 76:74, and the ratio of cirrhotic patients classified as Child A:B:C was 37 (50%): 26(35%): 11(15%). Cronbach's alpha of the overall CLDQ scores was 0.96 and of all domains were higher than 0.93. Item-total correlation was >0.45 . Test-retest reliability done at 1 to 4 wk apart was 0.88 for the average CLDQ score and from 0.68 to 0.90 for domain scores. The CLDQ was found to have discriminant validity. The highest scores of CLDQ domains were in the normal group, scores were lower in the compensated group and lowest in the decompensated group. The significant correlation between domains of the CLDQ and SF-36 was found. The average CLDQ score was strongly correlated with the general health domain of SF-36. ($P=0.69$; $P=0.01$).

CONCLUSION: The translated CLDQ is valid and applicable in Thais with CLD. CLDQ reveals that QOL in these patients

is lower than that in normal population. QOL is more impaired in advanced stage of CLD.

INTRODUCTION

The World Health Organization gave the definition of health as being not only the absence of disease and debility but also the presence of physical, mental and social well-being^[1]. Quality of life (QOL) is a concept that incorporates many aspects of an individual's experience, general well-being, satisfaction, social and physical function^[2]. By definition, QOL is subjective and multi-dimension. It can be influenced by socioeconomic factors, age, gender, presence of disease and treatment^[2]. QOL examines how patients experience and perceive. Its results provide a basis for holistic view of the patient and complements the organic outcomes. QOL has been evaluated in a large number of chronic medical and gastrointestinal conditions, such as dyspepsia, inflammatory bowel diseases, liver diseases, *etc.*^[3-7]. Well-developed and validated questionnaires have been used as instruments for QOL measurement. Generic and disease-specific instruments measure different aspects of QOL. It is encouraged to use both instruments in clinical research to gain substantial information^[5]. Since the development of the first liver-specific questionnaire, the chronic liver disease questionnaire (CLDQ)^[7], the QOL research in chronic liver diseases have been steadily reported^[6,8-12]. Previous studies in Western patients showed that chronic liver disease (CLD) had negative impact on QOL, and QOL worsened as the severity of disease increased^[8,9,12-14]. The study of QOL in gastrointestinal and liver diseases has hardly received attention in Asian population. Our study was aimed to translate and validate a disease specific questionnaire, the CLDQ, to be used in study of QOL in Thai population.

MATERIALS AND METHODS

Ethics

This study received ethics approval from the ethic committee of our hospital. All subjects provided written consent before participation.

Subjects

Between June 1 and September 31, 2003, 150 Thai patients with chronic liver diseases who attended gastroenterological clinic and 50 normal subjects were invited to participate in the study. Chronic liver diseases included chronic hepatitis and cirrhosis. Chronic hepatitis was defined by an elevation of serum transaminases above 1.5 times of upper normal limit for longer than 6 mo and cirrhosis by definition had biochemical and radiological findings consistent with cirrhosis^[15]. The staging of cirrhosis was categorized according to Child-Pugh classification: Child (class) A, B and C^[16]. Causes of chronic

liver disease were divided into viral hepatitis, alcohol, viral hepatitis combining with alcohol, non-alcoholic fatty liver (NAFLD) and others. Chronic liver disease due to alcohol was defined by the regular intake of alcohol (80 g/d in men, and 40 g/d in women)^[17]. History of other medical illness was taken from medical records. Exclusion criteria were concomitant presence of hepatic encephalopathy, other active medical diseases, malignancy, being treated with antiviral agents and those who refused to give consent.

QOL instruments

CLDQ The CLDQ is the first liver specific instrument developed by Younossi *et al.*^[7]. The CLDQ includes 29 items in the following domains: abdominal symptoms, fatigue, systemic symptoms, activity, emotional function and worry. The response of CLDQ results in 1 to 7 scales: ranging from “all of the time” to “none of the time”^[7]. The original CLDQ was shown to have constructed validity from the studies in chronic liver diseases^[7,12].

Translation of CLDQ After the translation permission was granted, the original version of CLDQ was translated into Thai according to the standardized guidelines proposed in 1993^[18]. Forward translation from the original English version was performed independently by two Thai native speakers. Reconciliation of both forward versions was done subsequently. A native English speaker living in Thailand who understood Thai language quite well and did not have knowledge about QOL carried out back translation. The semifinal version derived from reconciliation of the original, back translation and forward translation. A pretest in 10 patients with chronic liver diseases was performed. The final version was obtained after the step of cross-cultural adaptation.

Assessment of translated CLDQ The CLDQ and SF-36 questionnaires were administered in 150 patients with chronic liver diseases and in 50 normal subjects. The permission to use the SF-36, a generic questionnaire, in this study was granted from QualityMetric Inc. The study version of SF-36 was previously tested and validated in Thai population^[19]. CLDQ was repeated in 25 patients in 1-3 wk apart for test-retest analysis. Reliability was determined from Cronbach's alpha (reliability coefficient) and test-retest. One-way Anova or non-parametric method was used to determine discriminant validity of scores among different stages of liver diseases. Spearman's rank correlation was used to assess test-retest and convergent validity. A *P* value <0.05 was considered to be statistically significant.

RESULTS

Clinical and demographic data

One hundred and fifty patients with CLD and 50 normal subjects were enrolled into the study. Mean ages (SD) of CLD and controlled groups were 47.3(11.7) and 49.1(8.5) years (*P*=0.40). Of the 150 patients with CLD, 76(51%) had chronic

hepatitis and the remainder had cirrhosis. Summarized clinical and demographic data are shown in Table 1. Patients with cirrhosis were older, more unemployed and had lower education levels than those with chronic hepatitis. Viral hepatitis and regular alcohol drinking were the most common causes of CLD. Hepatitis B virus was the major cause of chronic viral hepatitis in this study (68.1%).

- Child C			11 (15)	

¹Incomplete data.

Reliability

Measurement of internal consistency Cronbach's alpha of overall scores was 0.96, which was above the acceptable level of 0.70 for comparison between groups^[20]. Cronbach's alpha of domains was higher than 0.93. Item-total correlation (omit that item) was above 0.45 (Table 2).

Test-retest Spearman's rank correlation of average CLDQ was 0.88 (*P*=0.00) and domains of CLDQ was higher than 0.67 (*P*=0.00).

Validity

Discriminant validity The various stages of liver diseases in this study were rearranged as normal, compensated (= chronic hepatitis + Child A cirrhosis) and decompensated (= Child B and Child C cirrhosis) groups. A comparison of domain scores in different groups was performed. All domain scores of CLDQ and SF-36 significantly decreased from normal group to

Table 2 Reliability of CLDQ

compensated and decompensated groups (Table 3). The CLDQ was found to have good discriminant validity.

Convergen validity Each domain of CLDQ correlated with all domains of SF-36 with correlation coefficient (r) >0.27: $P=0.01$ as shown in Table 4. The average CLDQ score was strongly correlated with the general health domain of SF-36 ($P=0.69$; $P=0.01$).

Influence of disease severity on HRQOL

The CLDQ scores in Thai patients with CLD deteriorated as severity of chronic liver disease increased similarly to previous reports in Western patients^[8,9,12-14]. However, we found that average CLDQ, emotional function and activity scores in chronic hepatitis were lower than those in Child A cirrhosis (5.2(1.1) vs 5.7(1.2), 5.0(1.1) vs 5.5(1.0) and 5.0(0.9) vs 5.4(0.9), respectively; P -values were 0.04, 0.02 and 0.03).

DISCUSSION

The original CLDQ is a well-developed and validated disease-specific questionnaire for measuring QOL in CLD^[7]. It consists of 29 items which are a suitable number for exploring QOL in patients who have a brief visit to a clinic^[7]. It has 7 linkert scale type of answers^[7]. To find a standardized disease-specific questionnaire for researches involving QOL in CLD, we translated the CLDQ from the original English to Thai versions by following the proposed guideline^[18]. Simple translation of questionnaire from one language to the other without concerning language difference, culture context and lifestyle, jeopardizes the sensibility of the original version. The translated CLDQ used the language which even poorly educated Thais were able

to understand the questionnaire meaning, and it was aimed for conceptual and semantic equivalences with the original concept. After the translation and cross-cultural adaptation, the reliability and validity of the translated version were proved to be maintained. Reliability of the CLDQ was confirmed from internal consistency and test-retest. Cronbach's alpha of overall CLDQ was higher than 0.70, indicating that the translated version had acceptable reliability^[20]. Chronic liver diseases greatly impacted QOL, which was confirmed by both generic and disease-specific questionnaires. We arranged chronic hepatitis and cirrhosis Child A into "compensated" group, and Child B and C cirrhosis into "decompensated" group according to the reserved function of the liver. The results from generic and disease-specific questionnaires were in agreement with the fact that a markedly decrease of QOL was seen in advanced stages of chronic liver diseases. On the other hand, it showed that the average CLDQ, activity and emotion function domains in chronic hepatitis were significantly lower than those in Child A cirrhosis. This finding may point out that chronic hepatitis had impairment in some parts of QOL more than Child A cirrhosis which may be a more stable condition. We could not compare the QOL between Child B and C cirrhosis due to the small sample size in both groups. The CLDQ domains correlated significantly with every domain of SF-36. The strongest correlation was seen in the relationship between the average CLDQ score and the general health domain of SF-36. The effect of other demographic and clinical factors on QOL of CLD was inconsistently reported. From a previous study, old age was inversely correlated with physical function of SF-36^[8]. However, a subsequent study revealed that younger patients showed more impairment in QOL^[9]. Several studies

revealed that chronic viral hepatitis, especially viral hepatitis C-related decreased QOL greater than cholestatic or alcoholic liver disease^[8,12]. Other socioeconomic factors, e.g. education, career and financial status may affect QOL as well. The validated CLDQ is found to be a satisfactory tool for future research of QOL in Thai population.

Abstract

AIM: To comparatively evaluate PCR and other diagnostic methods (the rapid urease test and / or culture) in order to determine which of the three PCR methods (*ureA*, *glmM* and 26-kDa, *SSA* gene) was most appropriate in the diagnosis of *Helicobacter pylori* (*H. pylori*) infection and also to evaluate the detection of a putative virulence marker of *H. pylori*, the *cagA* gene, by PCR in biopsy specimens.

METHODS: One hundred and eighty-nine biopsy specimens were collected from 63 patients (three biopsies each) undergoing upper gastroduodenal endoscopy for various dyspeptic symptoms. The PCR methods used to detect *H. pylori* DNA directly from biopsies were the *glmM*, 26-kDa, *ureA* and then *cagA* was used to compare the culture technique and CLO for urease with the culture technique being used as the gold standard.

RESULTS: Thirty-five percent of the biopsies were positive for *H. pylori* DNA using the 3 PCR methods, while 68% of these were positive for the *cagA* gene. Twenty-four percent of the biopsies were negative for *H. pylori* DNA in all PCR methods screened. The remaining 41% were either positive for *ureA* gene only, *glmM* only, 26-kDa only, or *ureA* + *glmM*, *ureA* + 26-kDa, *glmM* + 26-kDa. Out of the 35% positive biopsies, 41% and 82% were positive by culture and CLO respectively, while all negative biopsies were also negative by culture and *cagA*. *CagA* + infection was also predominantly found in *H. pylori* DNA of the biopsies irrespective of the clinical diagnosis.

CONCLUSION: This method is useful for correctly identifying infections caused by *H. pylori* and can be easily applied in our laboratory for diagnostic purposes.

INTRODUCTION

Culture has been for long the method of choice to detect infectious agents. However, for some organisms that are growing slowly like *Helicobacter pylori* (*H. pylori*), it may take several days to obtain a result. Furthermore, culture is very much dependent on infrastructure conditions and in developing countries may be jeopardized by shortage in electrical power supply.

Recently, assays based on PCR technology have been developed to detect the presence of microbial DNA, including *H. pylori* DNA, by using several gene targets directly from the biopsies^[1-3]. The targets of these PCR methods include the urease A (*ureA*) gene^[4], the 26-kDa species-specific antigen (*SSA*) gene^[5] and the phosphosamine mutase (*glmM*) gene^[3] to mention a few. It can be standardized to diagnose different agents. With such methods, all the experiments are not lost in case of shortage of power supply as they can be easily repeated. A similar approach has been applied in difficult environments such as in Russia.

The present study was therefore aimed (i) to comparatively evaluate PCR and other diagnostic methods (the rapid urease test and / or culture) in order to determine which of the three PCR methods was most appropriate in the diagnosis of *H. pylori* infection, and to evaluate the detection of a putative virulence marker of *H. pylori*, the *cagA* gene, by PCR in biopsy specimens.

MATERIALS AND METHODS

Patients

A total of 189 specimens from 63 patients (three biopsies each) undergoing upper gastroduodenal endoscopy for various dyspeptic symptoms were included in this study and 3 biopsies each were taken from the antrum of the patients for CLO test, culture and DNA, respectively.

The specimens were obtained from four centres in Nigeria: Lagos University Teaching Hospital (LUTH), Lagos; Mount Pleasant Medical and Endoscopy clinic, Ojuelegba, Lagos; University College Hospital, Ibadan; and Obafemi Awolowo Teaching Hospital Complex (OAUTHC), Ile-Ife.

Bacterial strains

Twelve *H. pylori* isolates were used in this study: one *cagA*-positive reference strain (26695), and 11 clinical isolates.

Other strains tested included local isolates of *Campylobacter jejuni* (4), *C. coli* (4) and *C. fetus* (3). The strains were tested by PCR to assess the specificity of the primers.

DNA extraction from biopsies was by the method of Marais *et al.*^[6]. Briefly, the biopsy samples were ground and centrifuged for 5 min at 10 000×g. The pellet was resuspended in 300 µL extraction buffer (20 mmol/L Tris-HCl, pH 8.0; 0.5% Tween 20) and proteinase K (0.5 mg/mL final concentration). The mixture was incubated at 56 °C for one hour after which

Table 1 Conditions for four different PCR methods

Target (reference), nucleotide (nt) positions amplified, and size of PCR products	Primer names and sequences	PCR conditions
26-kDa SSA gene (5), nt 474–776, 303 bp	Primer 3, 5' -TGGCGTGTCTATTGACAGCGAGC-3' Primer 4, 5' -CCTGCTGGGCATACTTCACCAG-3'	98 °C, 10 min (1cycle); 92 °C, 30 s; 68 °C, 1 min (37cycles); 92 °C, 30 s 68 °C, 1 min; 72 °C, 2 min (6 cycles)
Urease A gene (4), nt 304 – 714, 411 bp	HPU1, 5' -GCCAATGGTAAATTAGTT-3' HPU2, 5' -CTCCTTAATTGTTTTTAC-3'	94 °C, 1 min; 45 °C, 1 min 72 °C, 1 min (35 cycles)

the enzyme was inactivated by boiling for 10 min.

Five µL of DNA was used as the template for each PCR. Each sample was examined by four different PCRs. Primers used in this study were from, 26-kDa SSA gene (303 bp), urease A gene (411 bp), *glmM* gene (294 bp) and the *cagA* gene sequence (394 bp).

PCR reaction was carried out in a 50 µL volume in GeneAmp 9700 (Perkin Elmer). The primer sequences, conditions and sizes of these PCR methods are listed in Table 1.

Detection of amplified DNA products

A volume of seven µL of each PCR mixture was subjected to gel electrophoresis (1%) and ethidium -bromide staining for the detection of amplified DNA products.

RESULTS

Specificity of PCR assays with bacterial isolates

The specificity of PCR primers targeting *ureA*, *glmM*, 26-kDa and *cagA* gene was determined by testing 12 bacterial strains from related genus.

The 26-kDa PCR amplified the expected 303-bp fragment from the reference *H pylori* strain, while none from the other *Campylobacter* strains was amplified. Likewise, the *glmM* gene amplified the expected 294-bp fragment, *ureA*, 411-bp fragment and *cagA*, 394-bp fragment in *H pylori* reference and not in *Campylobacter* spp.

Detection of the three genes by PCR

Out of the 63 biopsies screened, 22(35%) were positive in all three PCR methods (26-kDa, *glmM*, *ureA*), 11 were positive for *ureA*, five for *glmM*, two for 26-kDa, two each for *ureA* and *glmM* and one each for *glmM*/ 26-kDa and *ureA* /26-kDa. Fifteen (24%) of the biopsies screened were negative for all three genes screened. Of these, 22 were positive for *H pylori* DNA, only nine (41%) were culture positive (Table 2). All negative biopsies from the 3 genes were negative by culture and CLO test. Two culture negative biopsies were positive in all three genes screened.

Detection of the *cagA* gene

Of the 22 biopsies that showed positive amplification in all three genes, 15(68%) were positive for the *cagA* gene. These comprised three biopsies from patients with cancer positive for the *cagA* gene. The patients with normal findings also had two out of three biopsies positive for the *cagA* gene. Out of the ten biopsies screened from patients with duodenitis or duodenal ulcer, only three (30%) were negative for the *cagA* gene (Table 3). All the biopsies that were positive for *cagA*

were also positive for their corresponding isolates. All negative biopsies were also negative for *cagA* gene.

Table 2 Results of three PCR methods and *cagA* gene for the detection of *H pylori* from gastric biopsy

Negative predictive ²	44 (23/52)	56 (29/52)	67 (35/52)

¹Compared with 11 culture- positive samples, ²Compared with 52 culture- negative samples.

DISCUSSION

The *ureA* gene PCR had a very poor specificity in our study, as it amplified 29 of the 52 (npv=44%) culture negative biopsy specimens. This was contrary to the report by Lu *et al.*^[1], but they concluded that the sensitivity was unsatisfactory and could be due to sequence polymorphism in the loci.

However, the positive predictive value was 91%. The 26-kDa gene primer amplified all 100%(11/11) (ppv=100%) of *H pylori* culture positive biopsy samples and produced 17 false positive results on 52 culture negative specimens (npv=67%) (Table 2).

The *glmM* gene PCR amplified 10 out of the 11 culture positive biopsy specimens (ppv, 91%), with a low sensitivity, as 23 of 52 culture negative biopsy specimens (npv, 56%) were amplified.

Lage *et al.*^[2] however, reported in their study that there

were no false positive or negative biopsies amplified by the *glmM*. The reason for this is quite obvious as there are no problems of power outages in their environment and so it is easy to culture *H pylori* as a result of the steady power supply as opposed to our environment where constant power outages threaten the isolation of *H pylori*.

A comparison of the urease test using the CLO test kit (Delta West, Pty, Australia) showed that a total of 25 biopsies positive for urease test were negative by culture. This was possible as a result of the fact that the CLO test kit could detect the presence of *H pylori* even when they were very small, while when there was power outage the possibility of detecting the organism was small. In addition, occasionally the biopsy forcep could be contaminated during the passage of the endoscope in the stomach, resulting in growth of some other urease positive organisms from the biopsies^[7]. Another general explanation for the poor specificity of all tests compared to culture was as a result of incessant power outages in our country, thus decreasing the possibility of isolating *H pylori* (a fastidious organism) by culture.

Sixty-eight percent of the biopsies that were positive for all three PCR methods were positive for *cagA*. The presence of *cagA*, a virulence factor, was found to be common irrespective of the clinical diagnosis, similar to a previous study by Smith *et al.*^[8].

In conclusion, the 26-kDa gene, was found to be the most appropriate of the three different PCR methods for the detection of *H pylori* from biopsies. The study also showed that PCR had a potential value for studying *cagA* and possibly other virulent factors directly from biopsies, although it might not be important in rapidly detecting a patient that is at high risk of peptic ulcer since the frequency is similar to those of

non-ulcer dyspepsia and more importantly the method could be adapted for our environment, where there is constant power outage.

Abstract

AIM: To investigate the association between cytochrome P450 2C19 (CYP2C19) gene polymorphism and cancer susceptibility by genotyping of CYP2C19 poor metabolizers (PMs) in cancer patients.

METHODS: One hundred and thirty-five cases of esophagus cancer, 148 cases of stomach cancer, 212 cases of lung cancer, 112 cases of bladder cancer and 372 controls were genotyped by allele specific amplification-polymerase chain reaction (ASA-PCR) for CYP2C19 PMs. The frequencies of PMs in cancer groups and control group were compared.

RESULTS: The frequencies of PMs of CYP2C19 were 34.1% (46/135) in the group of esophagus cancer patients, 31.8% (47/148) in the stomach cancer patients, 34.4%(73/212) in the group of lung cancer patients, only 4.5%(5/112) in the bladder cancer patients and 14.0%(52/372) in control group. There were statistical differences between the cancer groups and control group (esophagus cancer, $\chi^2=25.65$, $P<0.005$, $OR=3.18$, 95% $CI=2.005-5.042$; stomach cancer, $\chi^2=21.70$, $P<0.005$, $OR=2.86$, 95% $CI=1.820-4.501$; lung cancer, $\chi^2=33.58$, $P<0.005$, $OR=3.23$, 95% $CI=1.503-6.906$; bladder cancer, $\chi^2=7.50$, $P<0.01$, $OR=0.288$, 95% $CI=0.112-0.740$).

CONCLUSION: CYP2C19 PMs have a high incidence of esophagus cancer, stomach cancer and lung cancer, conversely they have a low incidence of bladder cancer. It suggests that CYP2C19 may participate in the activation of procarcinogen of esophagus cancer, stomach cancer and lung cancer, but may involve in the detoxification of carcinogens of bladder cancer.

Shi WX, Chen SQ. Frequencies of poor metabolizers of cytochrome P450 2C19 in esophagus cancer, stomach cancer, lung cancer and bladder cancer in Chinese population. *World J Gastroenterol* 2004; 10(13): 1961-1963
<http://www.wjgnet.com/1007-9327/10/1961.asp>

INTRODUCTION

Individuals vary widely in their susceptibility to carcinogens.

One attractive genetic mechanism to account for this variability is the activity of polymorphically expressed cytochrome P450 enzymes that activate procarcinogens or conversely detoxify carcinogens. Cytochrome P450 2C19 (CYP2C19) is a clinically important metabolic enzyme responsible for the metabolism of a number of therapeutic drugs, such as S-mephenytoin, omeprazole, diazepam, proguanil, propranolol and certain antidepressants^[1]. Recently, there were several papers concerning the CYP2C19 polymorphism and cancer susceptibility. Wadelius *et al.*^[2] found no association between CYP2C19 polymorphism and prostate cancer. Roddam *et al.*^[3] reported an increased risk of CYP2C19 poor metabolizers (PMs) to develop adult acute leukaemia and Sachse *et al.*^[4] found CYP2C19*2 had an decreased risk of colorectal cancer. Normally, Oriental people had a higher incidence of CYP2C19 poor metabolizers, which was usually about 13-16%, but in Caucasian people it was only 1-3% as well. So, for the purpose of investigating association between CYP2C19 polymorphism and cancer susceptibility, it is more easy to draw a conclusion in Oriental population. The aim of this study was to evaluate the relationship between CYP2C19 polymorphism and susceptibility to different kind of cancer by means of CYP2C19 genotyping among Chinese subjects.

MATERIALS AND METHODS

Reagents

Taq DNA polymerase, dNTPs, PCR buffer and 25 mmol/L MgCl₂ were purchased from Promega USA, Primers (Sangon, Shanghai), Igepal CA-630 (Sigma, USA), DNA Ladder (Huamei, Shanghai), Agarose (Pharmacia, Sweden), *Sma*I and *Hma*HI were obtained from MBI, USA. Other chemicals were of analytical grade.

Equipments

PCR machine (Hybaid, USA), electrophoresis apparatus (Pharmacia, Sweden), gel imaging system (Stratagene, USA), high speed centrifuge (Hitachi, Japan) and electro-balance (Mettler, France) were used.

Subjects

Cancer patients were from No 1 and No 2 hospitals affiliated to Zhejiang University. Healthy controls were recruited randomly around the same area. This study was approved by the Medical Institutional Review Board of the University and all subjects were provided informed consent prior to their participation. All the subjects were Chinese Han Nationality.

Methods

DNA extraction and detection of CYP2C19*2 and CYP2C19*3 A 5 mL blood sample was collected from each subject and DNA was extracted from blood for CYP2C19 genotyping according to Lahiri *et al.*^[5]. For the detection of CYP2C19*2, paired PCR reactions were set, one containing CYP2C19*2 primers and the other containing wild-type

primers (Table 1). Each PCR reaction (50 μ L) containing 10 mmol/L Tris-HCl, pH 8.3, 50 mmol/L KCl, 2.0 mmol/L $MgCl_2$, 0.2 mmol/L of each dNTPs, 0.2 μ mol/L of each primers and 50-1 000 ng of DNA template, 1 unit of Taq DNA polymerase was amplified through 35 cycles, each cycle consisting of denaturation at 94 $^{\circ}C$ for 1 min, primer annealing at 61 $^{\circ}C$ for 1 min, and extension at 72 $^{\circ}C$ for 1.5 min. Finally, a further extension was carried out at 72 $^{\circ}C$ for 10 min. The amplicon was analyzed on 20 g/L agarose gel electrophoresis. For detection of CYP2C19*3, paired PCR reactions were set, one containing CYP2C19*3 primers and the other containing wild-type primers (Table 2). Each PCR reaction (50 μ L) containing 10 mmol/L Tris-HCl pH 8.3, 50 mmol/L KCl, 2.0 mmol/L $MgCl_2$, 0.2 mmol/L of each dNTPs, 0.2 μ mol/L of each primers and 50-1 000 ng of DNA template, 1 unit of Taq DNA polymerase was amplified through 35 cycles, each cycle consisting of denaturation at 94 $^{\circ}C$ for 1 min, primer annealing at 58 $^{\circ}C$ for 1 min and extension at 72 $^{\circ}C$ for 30 s. Finally, a further extension was performed at 72 $^{\circ}C$ for 10 min. The amplicon was analyzed on 20 g/L agarose gel electrophoresis.

Table 1 Primers designed for detection of CYP2C19*2

Genotype	Sequences		
Wild-type	Forward	5'-AATTAC AAC CAG AGA GCT TGG C-3'	
	Reverse	5'-GTA ATT TGT TAT GGG TTC CC-3'	
Mutant	Forward	5'-AAT TAC AAC CAG AGA GCT TGG C-3'	
	Reverse	5'-GTA ATT TGT TAT GGG TTC CT-3'	

Table 2 Primers designed for detection of CYP2C19*3

Genotype	Sequences		
Wild-type	Forward	5'-TAT TAT TAT CTG TTA ACT AAT ATG A-3'	
	Reverse	5'-AAC TTG GCC TTA CCT GGA TC-3'	
Mutant	Forward	5'-TAT TAT TAT CTG TTA ACT AAT ATG A-3'	
	Reverse	5'-AAC TTG GCC TTA CCT GGA TT-3'	

The genotypes were judged by shown up of goal fragments in the paired PCR amplifications. For CYP2C19*2 allele, the goal fragment (139 bp band) could be seen only in the lane of CYP2C19*2 PCR reaction means homozygous CYP2C19*2 allele (*2/*2), only in the lane of wild-type reaction means homozygous wild-type (*1/*1), and in both reaction means heterozygous CYP2C19*2 (*1/*2). For CYP2C19*3 allele, the goal fragment (253 bp band) could be seen only in the lane of CYP2C19*3 PCR reaction means homozygous CYP2C19*3 allele (*3/*3), only in the lane of wild-type reaction means homozygous wild-type (*1/*1), and in both reaction means heterozygous CYP2C19*3 (*1/*3). In the consideration of both alleles, the other genotype could be *2/*3.

Quality control checks of PCR procedures indicated DNA samples genotyped in a double-blinded fashion yielded the same alleles as found during previous genotyping of DNA. The genotypes were checked for reliability by comparing with PCR-RFLP procedure^[6,7].

RESULTS

Genotyping of CYP2C19

Four pairs of primers were designed according to CYP2C19 wild-type sequence and the mutations in CYP2C19*2 and CYP2C19*3 by the principle of allele-specific amplification. PCR amplification conditions were tested to find the optimum annealing temperature and $MgCl_2$ concentration. The method was proved to be quick, accurate and less contamination (Figures 1, 2).

Figure 1 Typical electrophoresis pattern in detection of CYP2C19*2. Goal fragment was 139 bp. Lanes 1 and 8: DNA ladder; Lanes 2, 4 and 6: wild-type primers; Lanes 3, 5 and 7: mutant primers; Sample 1: homozygous wild-type (lanes 2 and 3); Sample 2: heterozygote (lanes 4 and 5); Sample 3: homozygous mutant (lanes 6 and 7).

Figure 2 Typical electrophoresis pattern in detection of CYP2C19*3. Goal fragment was 253 bp. Lanes 1 and 6: DNA ladder; Lanes 2 and 4: mutant primers; Lanes 3 and 5: wild-type primers. Sample 1: heterozygote (lanes 2 and 3); Sample 2: homozygous wild-type (lanes 4 and 5); No homozygous mutant found in this study.

Frequency study of poor metabolizers in the cancer groups and the control group

The frequencies of poor metabolizers of CYP2C19 (genotypes of *2/*2 and *2/*3, no *3/*3 was found in this study) were of 34.1% (46/135) in the group of esophagus cancer patients, 31.8% (47/148) in the stomach cancer patients, 34.4% (73/212) in the group of lung cancer patients, only 4.5% (5/112) in the bladder cancer patients and 14.0% (52/372) in control group. There were statistical differences between cancer groups and control group (esophagus cancer, $\chi^2=25.65$, $P<0.005$, $OR=3.18$, 95% $CI=2.005-5.042$; stomach cancer, $\chi^2=21.70$, $P<0.005$, $OR=2.86$, 95% $CI=1.820-4.501$; lung cancer, $\chi^2=33.58$, $P<0.005$, $OR=3.23$, 95% $CI=1.503-6.906$; bladder cancer, $\chi^2=7.50$, $P<0.01$, $OR=0.288$, 95% $CI=0.112-0.740$). It was obviously that CYP2C19 PMs had a high incidence of esophagus cancer, stomach cancer and lung cancer, conversely CYP2C19 PMs had a low incidence of bladder cancer (Table 3).

Table 3 Frequencies of EMs and PMs in different cancer groups and control group

Group	Total cases	EMs (*1/*1, *1/*2, *1/*3)		PMs (*2/*2, *2/*3)	
		Cases	%	Cases	%
Esophagus cancer	135	89	65.9	46	34.1
Stomach cancer	148	101	68.2	47	31.8
Lung cancer	212	139	65.6	73	34.4
Bladder cancer	112	107	95.5	5	4.5
Control	372	320	86.0	52	14.0

Esophagus cancer, $\chi^2=25.65$, $P<0.005$, $OR=3.18$, 95% $CI=2.005-5.042$; Stomach cancer, $\chi^2=21.70$, $P<0.005$, $OR=2.86$, 95% $CI=1.820-4.501$; Lung cancer, $\chi^2=33.58$, $P<0.005$, $OR=3.23$, 95% $CI=1.503-6.906$; Bladder cancer, $\chi^2=7.50$, $P<0.01$, $OR=0.288$, 95% $CI=0.112-0.740$.

DISCUSSION

With the completion of the Human Genome Project, great opportunities exist to investigate the effects of genetic variation of the cancer susceptibility to environment exposure. It is known to all cigarette smoke can cause lung cancer, but the fact is not every smoker suffering from lung cancer. What is

the mechanism of which smoker is more susceptible to lung cancer, which smoker may not catch the disease. One of the answers may lie on the gene polymorphisms of drug metabolising enzymes. This rule may also apply to esophagus cancer, stomach cancer and bladder cancer.

Cytochrome P450s are the main drug metabolizing enzymes in human body, and are always found to participate in the metabolism of carcinogens or procarcinogens. Some are involved in the activation of procarcinogens, some may take part in the inactivation of carcinogens. That depends on what kind of carcinogens and what kind of cancers, and what kind of mechanism of carcinogenesis.

CYP2C19—one of the most important cytochrome P450s, is known as a key enzyme in the *in vivo* metabolism of a number of related hydantoins and barbiturates, as well as in the metabolism of structurally unrelated drugs such as omeprazole, lansoprazole, progulil, mephenytoin and citalopram^[1]. Individuals can be divided into two groups, poor metabolizers (PMs) and extensive metabolizers (EMs), depending on the hydroxylation ability of S-mephenytoin. There are two main enzyme deficient alleles called CYP2C19*2 (CYP2C19m1) and CYP2C19*3 (CYP2C19m2). CYP2C19*2 is a single base pair G₆₈₁→A mutation in exon 5 of CYP2C19 and accounts for 75% and 85% of Oriental and Caucasian mutant alleles, respectively^[6]. CYP2C19*3 is a single base pair G₆₃₆→A mutation in exon 4 of CYP2C19 which results in a premature stop codon^[7]. It accounts for 10–25% of Oriental mutant alleles and is rare in Caucasians. An individual who inherits two mutant CYP2C19 alleles, whatever same kind (*2/*2, *3/*3) or different kind (*2/*3), has a reduced capacity to metabolize CYP2C19 substrates and is a PM. Individuals who are homozygous (*1/*1) or heterozygous (*1/*2, *1/*3) for wild-type CYP2C19*1 have efficient enzyme to metabolize CYP2C19 substrates and are EMs. Although there are several other reports about rare enzyme defect alleles, it is recognized that the purpose of prediction of CYP2C19 phenotype can be achieved by genotyping CYP2C19 only with CYP2C19*2 and CYP2C19*3 in Chinese population^[8].

In this study, 135 esophagus cancer patients, 148 stomach cancer patients, 212 lung cancer patients, 112 bladder cancer patients and 372 controls were genotyped for CYP2C19. Among them, 34.1% of esophagus cancer patients, 31.8% of stomach cancer patients and 34.4% of lung cancer patients, but only 4.5% of bladder cancer patients and 14.0% of healthy controls were genotyped as CYP2C19 PMs. Statistical analysis of the frequencies of PMs in cancer groups and control group showed significant differences (Table 3). It means CYP2C19 PMs are more susceptible to esophagus cancer, stomach cancer and lung cancer, but it is unsuceptible to Bladder cancer.

Several studies on CYP2C19 polymorphism and its association with carcinogenesis have shown self-contradiction results^[2–4]. However, our data indicated that CYP2C19 polymorphism was associated with esophagus cancer, stomach cancer, lung cancer and bladder cancer. Furthermore, we found that CYP2C19 PMs had increased risk of esophagus cancer, stomach cancer and lung cancer, and a decreased risk of bladder cancer. However, Klose *et al.*^[9] reported that CYP2C19 was only expressed in liver and duodenum. How it functioned so differently in different organs remained a mystery. But from the organs listed above, it is deducible that CYP2C19 PMs are more susceptible to the cancers of upper or systemic organs, such as esophagus, stomach, lung and blood. And they are

unsusceptible to the cancers of lower organs, like bladder and colorectal cancers. Prostate cancer was another example which showed no relationship between CYP2C19 polymorphism and carcinogenesis. It implies that different type of cancers may have different oncological mechanisms.

The genetic background and living environment of an individual are most important factors for carcinogenesis^[10]. The relationship between genetic polymorphism of CYP genes^[11,12], ABO blood groups^[13] and well water pollution are widely recognized. But more efforts needed to elucidate the correlation of different types of cancer to so many different factors, the development of biochip technology may speed it up^[14].

Abstract

AIM: To investigate the association between loss of heterozygosity (LOH) on chromosome 18 and sporadic gastric cancer.

METHODS: Multiplex PCR was used to screen 14 highly polymorphic microsatellite markers on chromosome 18 in 45 cases of primary gastric cancer. PCR products were separated on polyacrylamide gels and the electrophoresis maps were analyzed with Genescan and Genotyper.

RESULTS: The LOH frequencies in gastric cancer at all 14 markers ranged from 10% to 58%. Eleven markers were found with over 20% LOH frequencies, in which 9 markers located in 18q, and 2 markers in 18p. Two overlapping deleted regions were identified: R1 between D18S61-D18S1161 at 18q22 (9cM) with 24% LOH frequency; R2 between D18S462-D18S70 at 18q22-23(6cM) with 32% LOH frequency.

CONCLUSION: LOH of chromosome 18 (18q and 18p) may be involved in gastric tumorigenesis. Two overlapping deleted fragments suggested that there might be unidentified tumor suppressor genes in those two regions.

INTRODUCTION

Inactivation of tumor suppressor genes (TSGs) has been considered to be one of the most important mechanisms during the human tumorigenesis^[1]. Earlier studies have shown that loss of heterozygosity (LOH) on specific chromosomal loci is related to the inactivation of TSGs. The Knudson "two-hit"

hypothesis has provided the rationale for identifying TSGs by mapping regions of LOH. Analysis of LOH has been developed and fully exploited for the detection of TSGs in a variety of tumors through comparison of copy number changes in tumor DNA with matched control DNA^[2]. Different chromosomal regions that are harboring putative TSGs can be found in tumors by searching for LOH markers. Furthermore, by identifying genetic distance between these markers and TSGs, the allelic loss regions can be narrowed step by step and the TSGs can be finally cloned.

Gastric cancer (GC) is one of the most frequent malignancies and remains a main cause of mortality in China^[3-5]. Many regions of LOH on different chromosomes have been found in GC^[6]. Allelic loss on the long arm of chromosome 18 (18q LOH) is highly related to GC^[7]. Little is known about allelic loss on the short arm of chromosome 18 (18pLOH) in GC, although a significant incidence of 18pLOH (specially 18q11) has been found in tumors of the lung, brain and breast^[8]. So in this paper, we chose fourteen highly polymorphic microsatellite markers spanning chromosome 18p and 18q and performed genome-wide allelotyping in 45 primary gastric cancers. We identified the chromosomal loci and overlapping regions that are frequently lost in GC for clarifying the roles of 18pLOH and 18qLOH in GC and providing evidences for finding new important TSGs.

MATERIALS AND METHODS

Sample collection and DNA extraction

Forty-five primary gastric tumors and corresponding non-tumorous tissue specimens were obtained at surgery from the First Hospital and the Second Hospital of Harbin Medical University. All the patients were confirmed by routine histologic examination and received no treatment before surgery. Each specimen was frozen immediately and stored at -80 °C until use. Genomic DNA was extracted using DNAzo1^R reagent-genomic DNA isolation reagent (Gibcol).

Fluorescent microsatellite analysis

Along chromosome 18, we chose 14 polymorphic microsatellite markers (5 markers at 18p, 9 markers at 18q) at a density of approximately one marker every 9 cM (<http://www.gdb.org>). The oligonucleotides were labeled with FAM, HEX and NED three different fluorescent dyes for allelotyping (primers were obtained from the ABI PRISM Linkage Mapping Set v. 2, Perkin-Elmer). Multiplex PCR was carried on in a Gene Amp^R PCR system 9600 (Perkin-Elmer) for amplifying matched pairs of normal and tumor DNAs. PCR reaction conditions were as follows: 5 µL final volume included 0.5 µL of 10×PCR buffer, 0.6 µL of 25 mmol/L MgCl₂, 0.1 µL of 10 mmol/L dNTP, 0.25 U of Hot-start tag polymerase, 0.04 µL of each primer and 50 ng of DNA. The following PCR run conditions were used: (a) an initial denaturation at 94 °C for 12 min; (b) 15 cycles each at 94 °C for 30 s, 63 °C for 1 min (0.5 °C decreased per cycle), 72 °C for 1 min 50 s; (c) 24 cycles each at 94 °C for 30 s, 56 °C for 1 min, 72 °C for 1 min 50 s; and (d) a final extension at 72 °C for 15 min. A portion of each PCR product (0.7 µL) was combined with 1 µL of the loading mix (ABI internal size standard and formamide loading buffer). After denaturation

at 95 °C for 5 min, products were electrophoresed on 4.5% polyacrylamide gels with 7 mol/L urea on ABI prism 377 DNA sequencer (Perkin-Elmer) for 2.5 h. The data were collected automatically and analyzed using ABI prism Genescan 3.1 and Genotyper 2.1 software. Two fragments amplified from normal DNA indicated heterozygote and alleles were defined as the two highest peaks within the expected size range of heterozygote. A ratio of $T_1:T_2/N_1:N_2$ (less than 0.67 or greater than 1.3) was scored as a LOH (Figure 1). A single fragment amplified from normal DNA (homozygote) and these PCR reactions in which fragments were not clearly amplified were scored as non-informative. The LOH frequency of a site was equal to the percentage of the number between allelic losses and informative cases.

RESULTS

LOH at various frequencies were found in GC patients, ranging

from 10% to 58%, with the highest rate at D18S70 (21/36, 58%). Of the 45 cases of GC studied, 36(80%) exhibited allelic losses at least at one site, 25 at over two sites. Figure 1 shows allelic losses in partial patients on several markers. Figure 2 shows LOH frequencies of 14 markers and cytogenetic locations. Eleven markers were found with over 20% LOH frequencies, including 2 markers at 18p and 9 markers at 18q. They were as follows: D18S59 (18p11.3, 28%), D18S452 (18p11.3, 24%), D18S478 (18q11.1-11.2, 37%), D18S1102 (18q12, 29%), D18S474 (18q21, 22%), D18S64 (18q21, 30%), D18S68 (18q21, 25%), D18S61 (18q22, 26%), D18S1161 (18q22, 21%), D18S462 (18q22-23, 29%) and D18S70 (18q23, 58%). Two overlapping deleted regions (Figure 2) were identified at 18q22 (between D18S61 and D18S1161, 9 cM or approximately 5 Mb DNA sequence, overlapping fragment LOH 24%) and 18q22-23 (between D18S462 and D18S70, 6 cM or approximately 3 Mb DNA sequence, overlapping fragment LOH 32%), respectively.

Figure 1 Representative LOH analysis of chromosome 18. The scales on the top and right side of each figure represent the size (bp) and the intensity, respectively; N: Nontumorous control; T: Tumor; Arrow: Informative case with allelic loss (a, b, c, d, e); f: An informative case without allelic loss (heterozygote); g: An non-informative case (homozygote).

Figure 2 Results of analysis for LOH on chromosome 18. Top: the number of GC patient with LOH; Left: An ideogram of chromosome 18 with the physical order of 14 microsatellite markers according to Genome Database; Right: Allelotyping results from 36 GC patients; ●: Loss of heterozygosity (informative, IN); ○: Retention of heterozygosity (informative, IN); ○: Homozygote (non-informative); -: Not available; Black frame: Overlapping deleted region.

DISCUSSION

Genetic instability is often observed in tumor cells^[9]. Losses of fragments in some chromosomes may lead to allelic losses of TSGs. In the present study, more extensive genome screening was conducted on chromosome 18 in 45 cases of primary GC using 14 microsatellite markers (5 markers at 18p, 9 markers at 18q). Thirty-six out of 45 GC patients (80%) exhibited allelic losses at least one marker, allelic losses of over two markers were seen in 25 cases of GC patients. We found that two markers (D18S59 and D18S452) with over 20% LOH frequencies on chromosome band 18p11.3. DAL-1 gene (18p11.32) localizes between the two markers, which undergoes allelic losses in lung tumors and a significant proportion of ductal carcinomas *in situ* of the breast. It has been revealed that the DAL-1 protein suppresses the growth of MCF-7 breast cancer cell lines in part through the induction of apoptosis and that expression of DAL-1 increases attachment of these cells to a variety of extracellular matrices^[10]. DAL-1 plays a critical role in the suppression of lung tumor formation and metastasis^[11]. Our results support the role of DAL-1 gene in gastric carcinogenesis. Future investigations need to be carried on to understand the biological importance of the two putative loci and their clinical relevance in the pathogenesis of GC.

18qLOH is a frequent event in tumors, especially head and neck, colon, lung and gastric cancers^[12-14]. All of our 9 markers on this chromosomal arm have shown allelic loss frequencies exceeding 20%. D18S70 was the highest rate of LOH (21/36, 58%) marker on which frequent allelic loss has been reported in head and neck cancers^[15] and serous ovarian carcinoma^[16]. On the chromosome 18q22-23, Takebayashi *et al.* have identified three loci (D18S39, D18S61 and D18S70) which are lost in 70-75% of head and neck primary tumor cell lines. Lassus *et al.* observed that 59% of serous carcinomas have shown allelic loss at one or more sites and have been associated with tumor grade and poor survival. Moreover, they have identified two minimal common regions of loss at D18S465-D18S61 (18q22, 3.9 cM) and D18S462-D18S70 (18q23, 5.8 cM). Our data, together with these findings of others, suggest that D18S70 is a new putative tumor suppressor site in GC and support the existence of at least one candidate TSG near the site. Significant LOH of the two overlapping lost fragments identified by us appears novel for GC and no candidate TSGs have been reported in the two overlapping deleted regions so far. LOH frequencies of the two overlapping fragments suggest the presence of as yet unidentified TSGs. Although TSGs harboured in the two overlapping lost fragments have not been defined yet, the two regions are useful candidates for further allelotyping with higher-density microsatellite markers and may help us narrow the sites of frequent allelic loss in order to search for new critical TSGs involved in the development of GC.

The molecular genetic mechanisms of GC remain unclear. Investigators have postulated that, like other tumors, the multistep processes with a variety of factors are involved in GC. Step-wise accumulation of DNA damage from "normal" to tumor tissue serves as the basis of the tumor progression models^[17]. Our findings have shown that allelic losses are widespread on chromosome 18 and gastric tumorigenesis may be involved in synthetic effect of multiple TSGs.

ACKNOWLEDGEMENTS

We are grateful to Dr. Shen Yan (Chinese National Human Genome Center, Beijing) for his helpful advice.

Abstract

AIM: To study the effects of *Radix Puerariae* flavones (RPF) on liver lipid metabolism in ovariectomized (OVX) rats.

METHODS: Forty adult female Wistar rats were randomly divided into four groups: OVX group; sham-OVX group; OVX+estrogen group and OVX+RPF group. One week after operation rats of the first two groups were treated with physiological saline, rats of OVX+estrogen group with estrogen (1 mg/kg·b.w.) and rats of OVX+RPF group with RPF (100 mg/kg·b.w.), respectively for 5 weeks. After the rats were killed, their body weight, the weight of the abdominal fat and uterus were measured, and the levels of total cholesterol (TC) and triglyceride (TG) in liver homogenate were determined.

RESULTS: Compared with the sham-OVX group, the body mass of the rats in OVX group was found increased significantly; more abdominal fat in store; TC and TG in liver increased and uterine became further atrophy. As a result, the RPF was found to have an inhibitive action on those changes of various degrees.

CONCLUSION: RPF has estrogen-like effect on lipid metabolism in liver and adipose tissue.

INTRODUCTION

Estrogen plays an important role not only in maintaining the reproductive function and the secondary sex characters of the female animals, but also in so-classical target tissues, such as the brain, bone, liver, kidney and the cardiovascular system^[1,2]. With the decreases of estrogen in postmenopausal women, the incidences of fracture in osteoporosis, cardiovascular and neurodegenerative diseases often increase^[3-5]. Estrogens replacement therapy is able to attenuate symptoms of menopausal syndrome and to reduce the incidence of above-mentioned diseases^[6-9].

Phytoestrogens are naturally occurring plant chemicals that

can produce an estrogen-like effect in the body, used as a natural alternative to hormone replacement therapy and to reduce menopausal symptoms. They are not chemically the same as the estrogens made in the body, but when digested and absorbed they can act somewhat as estrogen in the body^[10]. *Radix Puerariae* is the dried root of *Pueraria lobata* Ohwior *Pueraria thomsonii* Benth. Sweet in taste and neutral in nature, it can strengthen the spleen and stomach, invigorate the spleen and replenish *Qi*. Its main component is flavone. Recent research has found leguminous plants rich in flavone have a certain kind of estrogen-like effect^[11-13]. In this study extraction of *Radix Puerariae* was given to ovariectomized (OVX) rats and its estrogen-like effects were observed.

Previous studies in our laboratory have illustrated that when the female rats were OVX, the estrogen level in their body decreased, which might lead to the body weight gains, abdominal fat stores, increase of liver fat and atrophy of uterine^[12]. Therefore, the OVX rats can be used as models to reflect the pathologic changes in perimenopausal or postmenopausal women.

MATERIALS AND METHODS

Animals

All of the 40 female Wistar rats, 220±10 g in body mass, were purchased from the Experimental Animal Center of Chinese Academy of Medical Sciences. They were raised in an air-conditioned animal house at 25±1 °C with a light-dark cycle of 12 h, and fed with free forge and running water. The rats were randomly divided into four groups: OVX group; sham-OVX group; OVX+estrogen group and OVX+RPF group. After anesthetized with 15 g/L sodium pentobarbital intraperitoneally, the rats of OVX, OVX + estrogen and OVX+RPF groups were OVX. Rats from sham-OVX received only a squeeze in the connecting point between the ovary and the fallopian tube without having their ovary removed. Starting from the second week of the operation, the rats of OVX group and sham-OVX group were treated with saline, the rats of OVX+estrogen group were treated with estrogen (1 mg/kg·b.w.) and rats from OVX+RPF group were treated with RPF (100 mg/kg·b.w.) respectively for 5 wk. The average feed consumption and mass of the rats from various groups were measured once a week.

Drugs and reagents

The RPF, provided by Biochemistry Department of Beijing University of Chinese Medicine, was made into suspension of required concentration (10 g/L). The positive control drug was nilestriol (batch number: 20000403) provided by Beijing Four Rings Pharmaceutical Factory. TG and TC kit were provided by Beijing Zhong-Sheng High-Technology Bioengineering Company.

Instruments

The Semi-automatic Biochemistry Analyzer MD 100 was made in USA. The electronic analytical balance was produced by Shimadzu Co. in Japan and the high speed centrifuge TLLC

was manufactured by Beijing Sihuan Scientific Instrumental Company.

Collection and measurement methods of specimens

Five weeks after the operation, the animals were anesthetized with 15 g/L sodium pentobarbital and the liver, abdominal fat and uterus were taken weighed and frozen. Some liver specimens were collected after operation, fixed in 40 g/L formaldehyde, embedded in paraffin, sectioned and stained with hematoxylin and eosin for light microscopy. Some liver specimens were frozen stored at -20 °C. Liver triglyceride and total cholesterol concentration were measured with the TC kit and the TG kit on a MD100 Semi-automatic biochemistry analyzer respectively after lipid extraction.

Statistical analysis

Data were presented as mean±SD, and Student's *t* test was used to determine changes between different groups. *P*<0.05 was considered significant.

RESULTS

Effect of RPF on body weight of OVX rats

The mean body mass of the OVX group increased significantly after the operation, compared to the OVX group, RPF was found to have a long term effect on body weight gains (*P*<0.05). The mean body weight of the OVX group started to exceed that of the sham-OVX group significantly ever from the first week (*P*<0.05). The mean body mass of OVX+RPF group had a statistical difference from the mean body weight of OVX group after 3 wk (*P*<0.05). From the fifth week, the body mass of all rats began to drop, but the final data showed that RPF could control the weight gain caused by ovariectomy. During feeding, rats from the OVX+estrogen group were found with colporrhagia, magersucht, and anorexia, but no such symptoms found in the OVX+RPF group (Table 1).

Table 1 Effect of RPF on body mass of OVX rats

Group	<i>n</i>	Body mass after operation (g)	Body weight during recovery period (g)	Wk 1 (g)	Wk 2 (g)	Wk 3 (g)	Wk 4 (g)	Wk 5 (g)	Change rate
OVX	8	215±15	233±17	250±16	266±16 ^c	276±15 ^c	284±16 ^c	268±20 ^c	22.1%
Sham OVX	9	235±4.7	230±4	232±7	235±6	241±9	246±11	237±14	7.1%
OVX+estrogen	10	236±17	242.4±21	249±18	248±16 ^a	239±14 ^a	248±18 ^a	239±19 ^a	1.1%
OVX+RPF	10	216±15	233.3±16	243±17	251±20	249±16 ^a	246±19 ^a	245±17 ^a	5.6%

Results expressed as mean±SD. ^a*P*<0.05 vs OVX group, ^c*P*<0.05 vs sham-OVX.

Table 2 Effect of RPF on abdominal fat and fat factor of OVX rats

Group	<i>n</i>	Abdominal fat (g)	Compared with OVX (%)	Fat factor (%)	Compared with OVX (%)
OVX	8	13.2±2.1 ^c	—	5.1±0.4 ^c	—
Sham OVX	9	10.6±3.2	80.4	4.6±1.2	91.2
OVX+estrogen	10	6.8±3.6 ^a	52.1	3.1±1.6 ^a	60.1
OVX+RPF	10	8.5±2.5 ^a	64.4	3.7±1.2 ^a	72.1

Results expressed as mean±SD. ^a*P*<0.05 vs OVX group, ^c*P*<0.05 vs sham-OVX.

Table 3 Effect of RPF on liver lipid metabolism of OVX rats

Group	<i>n</i>	TC (mg/dL)	Compared with OVX (%)	TG (mg/dL)	Compared with OVX (%)
OVX	8	16.4±5.0 ^c	—	119±26 ^c	—
Sham-OVX	9	11.4±4.4	81±27	65±18	54±15
OVX+estrogen	10	10.2±1.7 ^a	62±10	54±31 ^a	45±26
OVX+RPF	10	10.2±2.0 ^a	76±15	46±24 ^a	39±20

Results expressed as mean±SD. ^a*P*<0.05 vs OVX group, ^c*P*<0.05 vs sham-OVX, OVX+estrogen and OVX+RPF group.

Effect of RPF on abdominal fat and fat factor of OVX rats

The mean weight of abdominal fat of the OVX group was obviously higher than that of the sham-OVX group (*P*<0.05). Both estrogen and RPF could inhibit the storing of abdominal fat caused by ovariectomy, the mean data was only 52.1% and 64.35% compared with OVX group, respectively (Table 2).

Effect of RPF on liver lipid metabolism of OVX rats

TC and TG in liver of the OVX group were 16.4±5.0 mg/dL and 119±26 mg/dL, respectively, which were significantly higher than other groups (*P*<0.05). In the sham-OVX group they were only 11.4±4.4 mg/dL and 65±18 mg/dL. The RPF was found to have a marked effect on controlling liver TC level, with TC 10.2±2.0 mg/dL and TG 46±24 mg/dL which were even lower than sham-OVX group and OVX+estrogen group (Table 3).

Effect of RPF on wet uterus weight of OVX rats

Six weeks after the operation, the uteri of the rats from the OVX group were found with severe atrophy with a quarter of the uterus weight of the sham OVX group. The uterus weight of the estrogen group was higher than the sham-OVX group (*P*<0.05). RPF has again been proved to have some effects on maintaining the uterus weight (*P*<0.05) in OVX group (Table 4).

Table 4 Effect of RPF on wet uterus weight of OVX rats

Group	<i>n</i>	Uterus (g)	Uterus factor (%)
OVX	8	0.11±0.02 ^c	0.40±0.10 ^c
Sham-OVX	9	0.39±0.14	1.70±0.60
OVX+estrogen	10	0.46±0.34 ^a	2.10±1.50 ^a
OVX+RPF	10	0.15±0.03 ^a	0.70±0.10 ^a

Results expressed as mean±SD. ^a*P*<0.05 vs OVX group, ^c*P*<0.05 vs sham-OVX.

DISCUSSION

Unlike the animal models that are often prepared by giving high fat diets for hyperlipemia study, the OVX rats were used in the present study. Results of the experiments showed that the animals with ovariectomy tended to have body weight gain, accumulated abdominal fat, increased TC and TG levels in liver and atrophied uterus, which are very similar to menopausal symptoms. Experience from our past studies has proved that animal models thus prepared are stable, which can be used in the study of lipid metabolic disturbance.

Current studies on phytoestrogen both at home and abroad are mainly focused on soy bean and its extracts, and there are very rare reports of *Radix Puerariae*, a plant from the leguminous family. In fact, the phytoestrogen content in *Radix Puerariae* is much higher than that in soy bean. The aim of the present research was to study the effects of extracts from *Radix Puerariae* on lipid metabolism in OVX rats, which mimicked the postmenopausal situation of the disorders of lipid metabolism. And we obtained a series of satisfactory results.

We found in the study that there was an obvious lipid metabolic disturbance in OVX rats. Five weeks after the operation, the TC concentration in liver in OVX group was found obviously higher than those in other groups. RPF could lower the TC concentration to the normal value. However, the mechanism for this change is not quite clear yet. The increased insulin concentration in OVX rats may accelerate the dephosphorylation effect of the hydroxymethylglutaryl CoA reductase (HMGCoA reductase), which is a rate-limiting enzyme of the composition of cholesterol. As a result, it accelerates the activity of the enzyme^[14-16]. Insulin could also induce the composition of the HMGCoA reductase directly to increase the composition of cholesterol^[17-19]. For the cholesterol metabolism *in vivo*, there are two transport pathways-the endogenous cholesterol transport and the reverse cholesterol transport. In the former, the cholesterol by exogenous absorption and synthesis in the liver is utilized when it, in the form of LDL-C, is combined with the receptors of the extra hepatic tissue, and the ligand combined with LDL receptors are mainly the apolipoprotein of apo B100 and apo E^[20-23]. In the latter, the extrahepatic cholesterol, in the form of HDL-C, is conveyed back to the liver and expelled out of the body after further metabolism^[24]. Some experiments have shown that estrogen can enhance the activity of the LDL receptors and promote the endogenous transport so as to lower the TC levels^[25]. In conclusion, the high insulin level in OVX rats may lead to a high level of cholesterol concentration, while, the low level of estrogen concentration may result in the low level of LDL-R concentration and activity, both of which can cause an accumulation of LDL. The increased production and decreased consumption together make a high level of cholesterol concentration in the body, followed by the hypercholeste and adiposis hepatica.

A high level of TG concentration was also found in the OVX rats. Extrinsic estrogen can be supplemented to reduce the TG accumulation in liver. It was found in our study that RPF had a similar effect. The histological sections revealed a great number of grease spots in the OVX group, while not so many in the estrogen treated group and RPF treated group. The mechanism may be as follows: First, glucose was promoted to change into TG by a high level of insulin concentration in OVX rats^[26]. Second, the high level of TC directly damaged the structure of hepatic sinusoid and chylomicrons that contained a high level of TG coming into the Disse's spaces without been treated. Therefore, the liver cell ingested a large amount of TG from the blood. Profound studies are still needed to further confirm its mechanisms.

We also noticed the side effects and risks of estrogen in this study. In clinic, the commonly encountered side effects of HRT are edema (fluid retention), nausea, breast tenderness,

and headache. Other side effects include rash, increased growth of facial hair, dizziness, and hypophrodisia. More serious potential health risks to consider of HRT are breast cancer, uterine cancer, blood clotting, and liver and gallbladder diseases^[27-29]. Today, selective estrogen receptor modulators (SERMs) have been used as an alternative approach to activate estrogen signaling pathways in a tissue-specific manner^[30,31]. Phytoestrogens have a similar chemical structure to estrogen, and could bind to the estrogen receptor (ER)-beta. Once they bind each other, the ER is occupied, and the real estrogen can not get in. Phytoestrogens then dispatch estrogen-like messages to the cells. Although it is a weak message, it is strong enough to produce some of the positive effects of estrogen but it is still too weak to stimulate the growth of cancer cells^[32,33]. When the estrogen levels are too high, this competition appears to reduce the effects of estrogen by replacing estrogen with the weaker phytoestrogen. When the estrogen levels are too low, it appears that phytoestrogen simulates the effects of estrogen and partially makes up for the deficiency^[34].

In conclusion, our data suggest that as a natural estrogen replacement, the RPF could regulate the lipid metabolic disturbance in liver in the OVX rats. Furthermore, there may be a possible protective action against cardiovascular diseases and osteoporosis caused by deficiency of estrogen in menopausal women. However, our data was limited. More work is still needed to confirm its profound pharmacological effects.

Abstract

AIM: To observe the anti-cancer effects of COX-2 inhibitors and investigate the relationship between COX-2 inhibitors and angiogenesis, infiltration or metastasis in SGC7901 cancer xenografts.

METHODS: Thirty athymic mice xenograft models with human stomach cancer cell SGC7901 were established and divided randomly into 3 groups of 10 each. Sulindac, one non-specific COX inhibitor belonging to non-steroidal anti-inflammatory drugs (a series of COX inhibitors known as NSAIDs) and celecoxib, one selective COX-2 inhibitor (known as SCIs) were orally administered to mice of treatment groups. Immunohistochemistry was used to examine the expression of PCNA, CD44v6 and microvessel density (MVD). Apoptosis was detected by using TUNEL assay.

RESULTS: Tumors in sulindac and celecoxib groups were significantly smaller than those in control group from the second week after drug administration ($P < 0.01$). In treatment group, the cell proliferation index was lower ($P < 0.05$) and apoptosis index was higher ($P < 0.05$) than those in control groups. Compared with the controls, microvessel density was reduced ($P < 0.01$) and expression of CD44v6 on tumor cells was weakened ($P < 0.05$) in treatment groups.

CONCLUSION: COX-2 inhibitors have anticancer effects on gastric cancer. They play important roles in angiogenesis and infiltration or metastasis of stomach carcinoma. The anticancer effects of COX-2 inhibitors may include inducing apoptosis, suppressing proliferation, reducing angiogenesis and weakening invasiveness.

INTRODUCTION

Gastric cancer is one of the commonest malignancies of human beings. The incidence of gastric cancer is typically high in China and as a result, more than 170 000 people die of it each

year. It has important significance if certain drugs are found to lower its incidence or prevent it.

Chemoprevention of NSAIDs against colorectal cancer has been observed for long^[1]. Since cyclooxygenase-2 (COX-2), one of the isoenzymes catalyzing the production of prostaglandins, was discovered in early 1990s^[2], its gene construction, biochemical property and biological role have been understood step by step. The discovery of COX-2 has enlightened people to pay more attention to its relation with neoplasm. More and more selective COX-2 inhibitors (SCIs) have been found out, further facilitating the cognition to COX-2^[3]. Although the roles COX-2 inhibitors play in various cancers and their mechanisms are being widely studied recently, few people have gone deep into *in vivo* experiments^[4]. Based on *in vitro* cytologic experiments^[5-7], this study went further into *in vivo* experiments so as to clarify the anti-cancer mechanisms of COX-2 inhibitors.

MATERIALS AND METHODS

Cell line

Human moderately differentiated gastric cancer cell line SGC7901 was cultured in RPMI 1640 medium at 37 °C in a humidified box (Hareus) with 50 mL/L CO₂ in our laboratory. When cells were amplified to a certain amount, they were dissociated, collected and suspended in PBS at a density of 5×10^7 /mL.

Animals

Thirty male athymic mice (BALB/c nu/nu, 6 wk old, 17-20 g) were purchased from Shanghai Experimental Animal Center of Chinese Academy of Sciences. Mice were maintained under specific pathogen-free conditions (Micro-FLO positive air supply rodent cage system) and fed with sterilized food and autoclaved water. Experiments were started after 3 d of acclimatization.

Agents

Gum arabic (50 mg/kg) was dissolved in sterilized water at a concentration of 10 mg/mL. Sulindac (8 mg/kg; Sigma inc.) and celecoxib (10 mg/kg) were agitated and suspended with gum arabic (50 mg/kg) in water at a same concentration, respectively, by using a homogenizer.

Animal experiment procedure

Each mouse was inoculated with a subcutaneous injection of SGC7901 cells (5×10^6 in 0.1 mL PBS) into the right forelimb after weighed individually. Then these 30 mice were randomized into control, sulindac, and celecoxib groups. From the same day, the mice were orally administered different agents once daily (0.1 mL; according to mouse weight of 20 g): the controls with gum arabic, the sulindac group with sulindac, and the celecoxib group with celecoxib. Mice's diet, activity, stool, urine, and tumor growth were observed daily and shortest and longest diameters of xenografts were measured weekly. The tumor volume was deduced according to the formula^[8]: volume (mm^3) = (the shortest diameter)² × (the longest diameter) / 2. Both

body weight and tumor size of each mouse were measured again before they were killed by cervical dislocation on the 32 nd day. All tumors were dissected from the body and weighed, then divided along the longest diameter. Halves of the specimens were frozen in liquid nitrogen while the other halves were fixed in 40 g/L phosphate-buffered formaldehyde.

Immunohistochemical assays

The formalin-fixed tissues were embedded in paraffin, and sectioned at a thickness of 4 μ m. The sections were deparaffinized and hydrated gradually, and examined by histology of HE staining, immunohistochemistry, and TUNEL technique respectively. EnVision kits, the reagents of immunohistochemical assay, were purchased from GeneTech Co. Tests were performed according to the two step procedure. After incubated with 3% H_2O_2 for 10 min at room temperature and unmasked antigens by heat treatment, sections were covered with animal serum for 20 min. Specimens were then incubated with primary antibodies PCNA (PC10; 1/100; Santa Cruz), CD44v6 (ZM-0052; Beijing Zhongshan), or CD34 (BD) at 4 $^{\circ}$ C over night and further treated with EnVision kits for 30 min at room temperature. They were visualized by diaminobenzidin (DAB) and counter-stained by hematoxylin. TBS took the place of primary antibodies as a negative control. Sections were observed under microscope after mounted. The results of staining were analyzed and evaluated with American Image-Pro Plus software. The percentage of positive cells with PCNA staining in five 400 \times sights was counted as proliferation index (PI). The average of vessels with CD34 staining in three hot regions was calculated as MVD.

Apoptosis detection by TUNEL method

The reagent kit for apoptosis detection, TdT-FragEL DNA fragmentation detection kit was bought from ONCOGENE. Test procedures consisting of the following sections were provided in the brochure of the kit. The specimens were deparaffinized and hydrated gradually, and rinsed with 1 \times TBS, then incubated with proteinase K (20 μ g/mL in 10 mmol/L Tris-HCl) for 20 min. After immersed in 30 mL/L H_2O_2 at room temperature for 5 min and in TdT labeling reaction mixture at 37 $^{\circ}$ C for 1.5 h, specimens were covered with 1 \times conjugate for 30 min, visualized by DAB and counter-stained by hematoxylin afterwards. TBS took the place of primary antibodies as a negative control. After mounted, sections were observed under microscope. The results of staining were analyzed and evaluated with American Image-Pro Plus software. The percentage of positive cells with TUNEL staining in five 400 \times sights served as apoptosis index (AI).

Statistical analysis

Data were analyzed by software of SAS 6.12 and shown in a default form of mean \pm SD.

RESULTS

Animal experiments

During the experiment, the growth, diet, activity, *etc.* of mice were carefully observed, no hematuria and hematochezia were shown during experiment. Two mice died accidentally in the process however, which might be caused by the operation of enema clyster. The body weight among groups was not significantly different, nor did the weight change during the experiment. The growth of xenografts in treatment groups was significantly suppressed compared with the controls, but there was no difference between two treatment groups (Figure 1).

Difference of tumor growth in different groups was shown from the second week (Table 1).

Figure 1 Effects of sulindac and celecoxib on the growth of human gastric cancer xenografts in athymic mice.

Table 1 Tumor volume of three groups (mean \pm SD)

Group	Date (d)				
	7	14	21	28	32
Contro 1	45.2 \pm 35.5	609 \pm 289	1 779 \pm 366	2 920 \pm 776	2 984 \pm 589
Sulindac	78 \pm 137	351.5 \pm 227.0	723 \pm 514	1 370 \pm 832	1 590 \pm 1 009
Celecoxib	19.5 \pm 14.8	108 \pm 105	408 \pm 390	788 \pm 701	891 \pm 764
P	0.30	0.0002	0.0001	0.0001	0.0001

$F=27.95$, $P<0.01$ vs control group. No significant difference in volume was shown between sulindac group and celecoxib group.

In each group, five mice out of ten were picked out randomly and dissected with no obvious erosion, bleeding, or ulcer of stomach and no neoplasm metastasis.

Figure 2 Histology of tumors. A: *In vivo* appearance of xenografts; B: *In vitro* appearance of xenografts.

Tumor histology

Xenograft took on an appearance of big globular neoplasia or cluster of several small neoplastic nod (Figure 2). Necrosis could be seen comparatively common in cut of tumors, and the size of necrotic area seemed to be related to the volume of tumor. With regard to HE-stained sections, deeply stained tumor cells with big nuclei were arranged tightly with no cavum structure found under microscope, which coincided with the characteristics of tumor histology. Tumor cells among all groups showed no difference in morphology, while necrosis could be commonly seen under microscope.

Cell proliferation and apoptosis

PI of control group was significantly higher than that of sulindac group and celecoxib group ($P < 0.05$), but the difference was not notable between two treatment groups. AI in two treatment groups was higher than that in the control group ($P < 0.05$), while there was also no difference between the two groups. The AI/PI value was calculated and compared among all groups. Consequently, it was apparently larger in two treatment groups ($P < 0.01$), however no difference was shown between them.

Tumor angiogenesis

Immunohistochemical staining of CD34 revealed that celecoxib and sulindac could suppress angiogenesis of SGC7901 xenografts. MVD in sulindac and celecoxib groups was apparently lower than that in the control ($P < 0.01$). Although it was lower in celecoxib group, the difference is not notable.

Invasiveness of tumor cells

Membranes of tumor cells were stained brown by CD44v6 staining. By analysis of staining intensity and quantity of positive cells with Image-Pro Plus software, the expression of CD44v6 was markedly weakened by the treatment with sulindac and celecoxib ($P < 0.05$), but there was no apparent difference between sulindac and celecoxib groups.

DISCUSSION

COX-2 was successfully cloned and its structure has been clearly recognized more than ten years before^[9]. It is an inducible isoenzyme that catalyzes production of a series of prostaglandins. Participating in inflammatory reaction, COX-2 is expressed by a variety of tumor cells and correlated to tumorigenesis. Several researches have revealed the prophylactic effect of NSAIDs on colorectal carcinoma and their therapeutic effect on colon polyps^[10]. Here the mechanism of NSAIDs is considered as inhibiting COX-2. Non-specific COX inhibitors inhibit COX-1 at the same time, which may cause fatal side effects. As a result, they are not so ideal in long-term application for preventing tumorigenesis. Lately developed selective COX-2 inhibitors shed light on chemoprevention of neoplasms. Nevertheless a series of researches have to be carried out to confirm its effectiveness, reliability and virtues before extensive clinical application.

The expression of COX-2 also existed in gastric cancer while the positive rate might reach 61.4%^[11]. We have shown that human moderately differentiated gastric cancer cell SGC7901 can express COX-2. Its growth was suppressed *in vitro* after the treatment of sulindac, both proliferation and apoptosis were affected^[5]. This time we inoculated athymic mice with SGC7901 to observe the effects of sulindac and celecoxib, a clinically applied selective COX-2 inhibitor, on *in vivo* tumor by establishing animal models of gastric cancer. The results showed that both drugs had a notable inhibition on gastric cancer growth. Although the effect of celecoxib was better than of sulindac, no statistical difference was shown.

To explore the anticancer mechanisms of COX-2 inhibitors, we evaluated the influence of two drugs on tumor cell proliferation and apoptosis in xenografts by immunohistochemistry, which verified the results of *in vitro* researches. Administration of both sulindac and celecoxib increased apoptosis of cancer cells *in vivo*. The AI/PI, a value reflecting cytokinetics, showed a more significant difference.

The growth of tumor cells depends on nutrition supply, which largely relies on angiogenesis. Ischemia can induce tumor cell apoptosis, speeding up necrosis and cell extinction.

Many researches verified the relation between COX-2 and angiogenesis^[12] and the inhibition effects of NSAIDs on blood vessel endothelial cells^[13]. We observed that sulindac and celecoxib obviously decreased the blood vessel quantity of xenografts and reduced the MVD compared to that of the control group. COX-2 inhibitors realized their anti-cancer effects by repressing the expression of anti-apoptosis gene *Bcl-2*^[14] and reducing angiogenesis in stomach carcinoma, thereby impairing the nutrition supply of the tumor, further inhibiting proliferation and inducing apoptosis of gastric cancer cells. Our results were similar to those of Sawaoka *et al.*^[15].

Some studies suggested the expression of COX-2 was correlated to the clinicopathologic characteristics of gastric cancer, such as infiltration, lymphatic or hematogenous metastasis, prognosis, *etc*^[16]. As a cell surface adhesive molecule, CD44 was the receptor of hyaluronic acid and involved in cell-to-cell and cell-to-matrix interactions. Especially, the expression of its spliced variant 6 was closely correlated to cell movement, carcinogenesis, progress, incursion and metastasis of gastric carcinoma^[17]. In this study we evaluated COX-2 inhibitors' influence on the CD44v6 expression by using animal models, finding the positive cells of expressing CD44v6 (pigmented in membrane) often existed in the periphery of tumors with a tendency to surround blood vessels. The positivity of CD44v6 staining was strong in the control group and significantly weakened in two medication groups, which demonstrating that COX-2 inhibitors play a role in depressing invasiveness and reducing metastasis of gastric cancer, which could be one of their anti-cancer effects. No obvious metastasis was found by rough anatomy of mice in our study however. It requires improved experiment design.

In brief, the mechanisms of COX-2 inhibitors resisting the growth of gastric cancer might include suppressing cell proliferation, inducing apoptosis, reducing angiogenesis and weakening invasiveness. But selective COX-2 inhibitors were not observed obviously more effective than non-specific COX inhibitors. The former did not show any advantage in side effects either, such as gastrorrhagia, ulceration, and so on, which may be relevant to experiment animal model and short experiment duration. Further studies are required. This study also showed comparatively more necrosis of tumors, but its correlation to drug administration was unclear. In comparison, Japanese researchers discovered no relation between drug treatment of indomethacin or NS398 in MKN45 cell xenografts^[15].

This is the first part of a serial study, and we will verify the results afterwards using Western blotting, RT-PCR, *etc*.

Abstract

AIM: To analyze loss of heterozygosity (LOH) and homozygous deletion on *p53* gene (exon2-3, 4 and 11), chromosome 10q22-10q23 and 22q11.2-22q12.1 in human hepatocellular carcinoma (HCC).

METHODS: PCR and PCR-based microsatellite polymorphism analysis techniques were used.

RESULTS: LOH was observed at D10S579 (10q22-10q23) in 4 of 20 tumors (20%), at D22S421 (22q11.2-22q12.1) in 3 of 20(15%), at TP53.A (*p53* gene exon 2-3) in 4 of 20 (20%), at TP53.B (*p53* gene exon 4) in 6 of 20(30%), and at TP53.G (*p53* gene exon 11) in 0 of 20(0%). Homozygous deletion was detected at 10q22-10q23(8/20; 40%), 22q11.2-22q12.1(8/20; 40%), *p53* gene exon 2-3(0/20;0%), *p53* gene exon 4(6/20; 30%), and *p53* gene exon 11(2/20; 10%).

CONCLUSION: There might be unidentified tumor suppressor genes on chromosome 10q22-10q23 and 22q11.2-22q12.1 that contribute to the pathogenesis and development of HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a primary liver malignancy with high mortality. It is among the most common malignancies worldwide, especially in Asia, Africa and Southern Europe^[1]. It has been generally accepted that HCC is highly associated with chronic hepatitis B virus (HBV) or hepatitis C virus (HCV)

infection or alcohol intake which induces cirrhosis^[2]. High intake of aflatoxin B found in many kinds of food is also reported to be a risk factor for HCC^[3,4]. Like other solid tumors, It has been proposed that hepatocarcinogenesis and metastasis of HCC is a multi-step process requiring the accumulation of genetic alterations, but the precise molecular pathogenesis is far from clear.

Loss of heterozygosity (LOH) analysis has become an effective way to identify informative loci and candidate tumor suppressor genes (TSGs). Molecular chromosomal studies of tumors by using polymerase chain reaction (PCR) -based polymorphic markers can detect small loci of anomalies that may harbor TSGs. Search for novel TSGs is based largely on the identification of common regions of deletion on chromosomes. LOH has been found in many types of tumors, including HCC. LOH in HCC has been detected on chromosomal arms 1p, 2q, 4p, 4q, 5q, 6q, 8p, 8q, 9p, 9q, 11p, 13q, 16p, 16q and 17p^[5-11]. However, deletion of 10q22-10q23, and 22q11.2-22q12.1 and *p53* gene exon 2-3 and 11 in HCC has not been investigated.

In the present study, we detected LOH and homozygous deletion on chromosome 10q, and chromosome 22q near the NF2 gene locus, and *p53* gene locus in 20 cases of HCC.

MATERIALS AND METHODS

Specimens

Surgical specimens of HCC were collected from the First Affiliated Hospital of Anhui Medical University and the Affiliated Hospital of Bengbu Medical College. The patients were born and grew in different places of Anhui Province, China. Both tumor and corresponding non-tumor liver tissues were immediately put into liquid nitrogen after separation and then stored at -80 °C until DNA extraction. Diagnosis of HCC was confirmed by pathological examination.

DNA extraction

Genomic DNA was extracted from tissues with the standard proteinase K-phenol/chloroform method. To each of the samples, 500 µL of DNA extraction buffer containing 200 mmol/L NaCl, 10 g/L sodium dodecyl sulfate, 2 mmol/L EDTA, 0.1 mol/L Tris-HCl was added during the process of homogenization. After 0.2 mg/mL proteinase K was added, the sample was shaken for 12 h at 37 °C. After phenol-chloroform extraction, DNA was precipitated with cold ethanol overnight at -20 °C. After centrifugation, the pellet was dried and resuspended in 50 µL TE buffer (Tris-EDTA buffer). DNA was stored at -20 °C until polymerase chain reaction (PCR) amplification was performed.

Pcr amplification

PCR amplification primer pairs for *p53* gene, 10q22-10q23 and 22q11.2-22q12.1 are as follows (Table 1).

Polyacrylamide gel electrophoresis

PCR product (12 µL) was mixed with 3 µL 950 g/L deionized formamide and 3 µL DNA loading buffer containing 2.5 g/L

Table 1 PCR amplification primer pairs for p53 gene, 10q22-10q23 and 22q11.2-22q12.1

Markers name	Forward	Reverse	Annealing (T °C)	Size (bp)

CDK4 ¹	GGAGGTCGGTACCAGAGTG	CATGTAGACCAGGACAGG	60	364

¹The aim of PCR amplification of CDK4 gene was to confirm that genomic DNA had been truly extracted from all samples. These primer sequences were retrieved from the Genome Database (<http://gdbwww.gdb.org>). PCR amplification was performed in a 50 µL reaction volume containing 400 ng template DNA, 0.2 mmol/L of each deoxynucleotide triphosphate, 20 mmol/L of each primer, 1.5 mmol/L MgCl₂, 1× reaction buffer and 2 U Taq DNA polymerase. The reaction mixture was denatured for 5 min at 94 °C. DNA was subsequently amplified for 35 cycles with 94 °C for 30 s, 54-65 °C for 30 s, 72 °C for 40 s, and a final extension at 72 °C for 8 min. PCR product (8 µL) was electrophoresed in a 20 g/L agarose gel, visualized by staining with ethidium bromide and ultraviolet illumination, and documented by a computer-linked camera. The target DNA fragments were confirmed by comparing to a 100 bp DNA ladder.

LOH rate (%)				20	30	0	20	15
Homozygous deletion rate (%)				0	30	10	40	40

xylene cyanol FF, 2.5 g/L bromophenol blue, and 300 g/L glycerin. The mixture was denatured at 95 °C for 5 min, put onto ice for 10 min, loaded onto 80 g/L denaturing polyacrylamide gel containing 3.3 mol/L urea and then electrophoresed at 100 V for 2 h. The gel was silver-stained^[13]. LOH was determined by visual evaluation, which compared the allele bands from tumors and the corresponding non-tumor tissues. The complete loss of one polymorphic allele from those seen in the paired control DNA was scored as allelic loss by three independent observers. PCR reactions were performed twice to confirm LOH.

RESULTS

HCC tumor and corresponding non-tumor liver tissues of 20 patients were studied for LOH on 10q22-10q23 (D10S579), 22q11.2-22q12.1 (D22S421), and 17p13.1 by five microsatellite

markers, and the rate of LOH was 20%(4/20), 15%(3/20), 50%(10/20), respectively (Table 2). Homozygous deletion was observed in 8 of 20 cases (40%) for the marker D10S579, 8 of 20 cases (40%) for D22S421, 6 of 20 cases (30%) for TP53.B, 2 of 20 cases (10%) for TP53.G, and in 0 of 20 cases (0%) for the marker TP53.A.

Results of 20 g/L agarose gel electrophoresis are shown in Figure 1. LOH in tumor and corresponding non-tumor liver tissues are shown in Figure 2.

DISCUSSION

HCC is one of most malignant tumors. The mechanism of hepato-carcinogenesis is a multi-factor and multi-step process requiring the accumulation of genetic alterations, including chromosomal aberration, oncogene activation, inactivation of TSGs and abnormality of growth factors and growth factor

Figure 1 Agarose gel electrophoresis of PCR products of p53 gene exons 2-3, 4, 11, and chromosome 10q22-10q23 and 22q11.2-22q12. 1. A: PCR products of p53 exon 2-3. Lane 1, 100 bp DNA marker; Lanes 2-8, PCR products of p53 exon2-3 (A) and CDK4 gene (B, as a control) amplified from HCC genomic DNA. No homozygous deletion of p53 exon 2-3 was found in all HCC specimens. B: PCR products of p53 exon 4. Lane 1, 100 bp DNA marker; Lanes 2-8, PCR products of p53 exon4 (A) and CDK4 gene (B, as a control) amplified from HCC genomic DNA. Lines 4, 6-8, homozygous deletion. C: PCR products of p53 exon11. Line 1, 100 bp DNA ladder; Lanes 2-8, PCR products of p53 exon11 (A) and CDK4 gene (B, as a control) amplified from HCC genomic DNA. Lanes 5 and 7, homozygous deletion. D: PCR products of 10q22-10q23. Lane1, 100 bp DNA marker; Lanes 2-8, PCR products of 10q22-10q23 (A) and CDK4 gene (B, as a control) amplified from HCC genomic DNA. Lines 6 and 7, homozygous deletion. E: PCR products of 22q11.2-22q12.1. Lane 1, 100 bp DNA ladder; Lanes 2-8, PCR products of 22q11.2-22q12.1 (A) and CDK4 gene (B, as a control) amplified from HCC genomic DNA. Lanes 7 and 8, homozygous deletion.

Figure 2 Representative illustrations of LOH detected with the microsatellite markers TP53.A, TP53.B, TP53.G, D10S579, D22S421 in human hepatocellular carcinomas (C) as compared to non-tumor liver tissues (N). The arrows show the location of the missing alleles. A: TP53.A (case 4); B: TP53.B (case 17); C: TP53.G (case 19, no LOH); D: D10S579 (case 17); E: D22S421 (case 20).

receptors. Of these factors, inactivation of TSGs is a very important factor.

Allelic loss on chromosome 17p is among the most common genetic abnormalities in many human cancers. *p53* gene is thought to be the gene associated with the genesis of these cancer types, including HCC^[12]. *p53* is activated in response to DNA damage, inducing either cell cycle arrest to permit DNA repair or apoptosis. Loss of *p53* function occurs mainly through allelic deletions at chromosome 17p13, where *p53* gene is located. In human HCC, LOH at chromosome 17p13 has been reported in 25-60% of tumors, and the worldwide prevalence of *p53* mutation is around 28% with, however, important geographic variations. In this study, LOH was observed at exon 2 and 3 (TP53.A) and exon 4 (TP53.B), of the gene in 20% and 30% of HCC cases, respectively, but not detected at exon 11 (TP53.G). In addition, all but one (19/20) patients were positive with HBsAg. These data also support the idea that LOH at *p53* gene and HBV infection are highly associated with the pathogenesis and development of HCC.

LOH on D10S579 has been reported in renal cell carcinoma (RCC)^[13]. We investigated 20 HCCs in the present study, and found four cases had LOH and eight cases had homozygous deletion on 10q22-10q23 (D10S579). Our finding suggests that on 10q22-10q23, there might be unidentified TSG(s) that plays an important role in the pathogenesis of hepatocellular carcinoma.

22q11.2-22q12.1 (D22S421) is near the locus of *NF2* gene. *NF2* (neurofibromatosis 2) gene, which is located on

chromosome 22q12.2-22q12.2, is postulated to be a tumor suppressor gene. It encodes for a protein with 595 amino acids, designated as merlin or schwannomin which belongs to a family of cytoskeletal proteins. The majority of *NF2* gene mutations are deletions, insertions, and point mutations, all of which lead to a nonfunctional, truncated protein^[14].

LOH at the *NF2* locus has been observed in many tumors, including schwannoma^[15], meningioma^[16], malignant mesothelioma^[17], gastrointestinal stromal tumor^[18], colorectal carcinoma^[19]. However, Handel-Fernandez *et al.*^[20] found that there was no LOH at *NF2* gene in pancreatic adenocarcinoma, but 37% of the cases had deletions which were clustered into two separate areas of chromosome 22 - one proximal and one distal to *NF2* gene. In the present study, we detected LOH on 22q11.2-22q12.1 in three of 20 HCCs and homozygous deletion on 22q11.2-22q12.1 in eight of 20 HCCs. Our finding suggests that 22q11.2-22q12.1 likely contains an unidentified tumor suppressor gene that contributes to the pathogenesis and the development of HCC, that the region plays an important role of cis-acting element similar to *NF2* gene, or that it acts the part of trans-acting factor similar to other TSGs, such as *p53* gene.

In conclusion, we have obtained important new information on LOH and homozygous deletion in chromosome 10q, 22q and 17p, in a subset of HCC. Inactivation of *p53* gene and unidentified tumor suppressor gene(s), present in regions of 10q22-10q23 and 22q11.2-22q12.1, may play an important role in the pathogenesis of HCC.

Abstract

AIM: To observe the reversal effects of wide-type p53 gene on multi-drug resistance to 5-FU (LOVO/5-FU).

METHODS: After treatment with Ad-p53, LOVO/5-FU sensitivity to 5-Fu was investigated using tetrazolium dye assay. Multidrug resistance gene-1 (MDR1) gene expression was assayed by semi-quantitative reverse transcription-polymerase chain reaction and the expression of p53 protein was examined by Western blotting.

RESULTS: The reversal activity after treatment with wide-type p53 gene was increased up to 4.982 fold at 48 h. The expression of MDR1 gene decreased significantly after treatment with wide-type p53 gene, and the expression of p53 protein lasted for about 5 d, with a peak at 48 h, and began to decrease at 72 h.

CONCLUSION: Wide-type p53 gene has a remarkable reversal activity for the high expression of MDR1 gene in colorectal cancers. The reversal effects seem to be in a time dependent manner. It might have good prospects in clinical application.

INTRODUCTION

Resistance to cytotoxic agents is the major cause of failure of medical treatment of human cancer and it is known that tumor cells can become resistant to anticancer drugs by a variety of different mechanisms^[1]. MDR (multidrug-resistance) is a form

of drug resistance characterized by decreased cellular sensitivity to a broad range of chemotherapeutic agents and due significantly to the over expression of MDR1 mRNA and its product P-gp^[2,3]. As an integral membrane protein, the M_r 170 000 P-gp is thought to be an energy-dependent membrane pump involved in the excretion of toxins in normal cells^[4]. Elevated expression of P-gp in malignant cells results in increased efflux and therefore reduced intracellular accumulation of cytotoxic agents, such as 5-FU, anthracyclines, Vinca alkaloids, and epipodophyllotoxins, but is not cross-resistant to alkylating agents, antimetabolites, and cisplatin. This decrease is considered as the basic mechanism of the MDR phenomenon^[4-7]. While a number of pharmacological agents have been shown to partially reverse MDR *in vitro*^[8], there remains a need to identify more potent, more specific, and less toxic chemosensitizers for clinical use.

Inactivity of p53 gene by missense mutation or deletion is the most common genetic alteration in human cancers^[9]. The loss of p53 function has been reported to enhance cellular resistance to a variety of chemotherapeutic agents^[10-13]. Our preliminary experiments^[14] also showed that there was a strong relationship between the MDR1 gene expression and mutated p53 gene in colorectal cancers.

Thus, in light of the fact that MDR1 is over-expressed in colorectal cancer that often lacks a functional p53^[14], we ask whether p53 plays a role in the control of MDR1 gene. Therefore, we sought to determine whether the introduction of the wild - type p53 gene in LOVO/5-FU cells by an adenoviral vector could increase the sensitivity of cells to a DNA cross-linking agent 5-FU *in vitro* and *in vivo*.

MATERIALS AND METHODS

Cell culture

LoVo cells were derived from a human colon adenocarcinoma. 5-FU-resistant LoVo sub-line (LoVo/5-FU) was obtained from the LoVo cell line by selection with 5-FU^[15], and maintained in medium containing 5 ng/mL 5-FU as described previously. LoVo/5-FU cells were kindly provided by Dr. Xue-Qing Yao. Monolayer cultures of LoVo and LoVo/5-FU were maintained in RPMI 1640 medium supplemented with 150 g/L heat-inactivated fetal calf serum (Sigma Chemical Co), 10 mL/L of a 200 mmol/L glutamine solution, 100 U/mL penicillin, 100 µg/mL streptomycin, and 10 g/L vitamin solution for minimum essential Eagle's medium purchased from GIBCO-BRL (Gaithersburg, MD). Cell lines grown in the presence of agents were passed in drug-free medium 2 to 3 times prior to use. All cells were grown at 37 °C in a humidified atmosphere of 50 mL/L CO₂ and 950 mL/L air.

Adenovirus vectors

Construction and identification of Ad-p53 and Ad-LacZ were finished and kindly provide by Dr. Xin-Hua Yin. Briefly, recombinant p53 adenovirus, Ad5CMV-p53 containing cytomegalovirus promoter, wild-type p53 cDNA, and SV40

early lopyadenylation signal in a minigene cassette was inserted into the E1-deletion region of modified Ad5. p53 shuttle vector and recombinant plasmid pJM 17 were cotransfected into 293 cells (Ad-transformed human embryonic kidney cells) by a liposome-mediated technique. The culture supernatant of 293 cells showing the complete cytopathic effect was collected and used for subsequent infections. Control Ad-LacZ virus was generated in a similar manner. Viral titers were determined by plaque forming activity in 293 cells. Concentrated virus was dialyzed, aliquoted, and stored at -80 °C. Cells were harvested 36-40 h after infection, pelleted, resuspended in PBS, and lysed. Cell debris was removed by double cesium chloride gradient ultracentrifugation.

Transient transfections

Adherent cells were plated in the wells of a 12-well plate. After 24 h, Ad-LacZ was transfected into the cells in different diluting densities. Forty-eight transfection, the cells were washed twice with PBS and fixed for 2 h with 40 g/L formaldehyde solution at 4 °C, then washed twice again with PBS and stained with 1 g/L X-gal solution for about 8 h at 37 °C. Observed under the electron microscope, the cells with blue staining were positive cells with LacZ expression, and calculated to determine the transfection efficiency.

Drug sensitivity testing

Chemosensitizers in the various cell lines were determined by using the tetrazolium-based colorimetric assay (MTT [*i.e.*, 3-(4,5-dimethyl-2-thiazolyl)-2m 5-diphenyl-2H-tetrazolium bromide] assay). Cells (LoVo/5-FU/Ad-p53 cells, LoVo/5-FU cells, LoVo cells;) were seeded in a 96-well microtiter plate at a density of 1×10^5 cells/well and each well contained 200 μ L medium. Cells were exposed 24 h after plating to various concentrations of 5-FU for 4 h. After treatment, medium was removed and replaced with 200 μ L of drug-free medium. Plates were incubated for further 72 h. At this time, 15 μ L of MTT (4 mg/mL) solution was added to each well. After a 4-h incubation at 37 °C, the cellular supernatant was gently aspirated, and insoluble formazan crystals were dissolved by adding 180 μ L 1 000 g/L DMSO (dimethyl sulfoxide) to each well, then the plates were shaken for about 10 min. The absorbance of each well was determined by a spectrophotometry at the wavelength of 570 nm with a microculture plate reader. Inhibition of cell growth was determined as a percentage of absorbance of vehicle-treated control cultures. IC_{50} was the concentration of drugs that reduced staining (A_{570}) to 50% of vehicle-treated controls.

The effect of chemosensitizers on drug resistance was studied by exposing cells to a range of concentrations of cytotoxic drugs in the absence or presence of concentrations of chemosensitizers. Dose-response curves were corrected for the inhibition of cell growth caused by chemosensitizers alone, and the "fold reversal" of MDR for 5-FU plus chemosensitizer combination was calculated as follows:

$$\text{Fold reversal} = \frac{IC_{50} \text{ drug alone}}{IC_{50} \text{ drug +chemosensitizer}}$$

Western blot analysis of wild-type p53 expression

Cells infected with the indicated adenovirus and MOI were grown to about 80% confluence in 10-cm plates. After washed with PBS, cells were scraped from the plate, washed once with ice-cold PBS containing 1 mmol/L phenylmethylsulfonyl fluoride, and centrifuged at 1 000 r/min for 4 min. The cell pellet was resuspended in ice-cold radioimmunoprecipitation assay buffer (1% NP40, 0.5% sodium deoxycholate, and 1 g/L SDS, 10 μ g/mL aprotinin, 10 μ g/mL leupeptin and 1 μ g/mL pepstatin A)

and sonicated. After centrifugation at 12 000 g at 4 °C for 20 min, the resulting supernatant was harvested as the total cell lysate. The protein was aliquoted and stored at -70 °C until use. Protein samples were electrophoresed through a 125 g/L polyacrylamide gel containing 1 g/L SDS and the gel was run at 30 mA for 3 h. Separated proteins were transferred onto nitrocellulose paper by electroblotting. After blocked with 50 mL/L blocking reagent, the nitrocellulose membrane was probed with a monoclonal antibody against human wild-type p53 from Oncogene Science. Detection was accomplished using ECL western blotting detection reagents from Amersham Pharmacia Corp.

Determination of MDR1 mRNA expression by RT-PCR

Expression of the MDR1 gene was determined by measuring the mRNA level from total RNA by SUPERSRIPT™ first-strand synthesis system (GIBCO BRL, Gaithersburg, MD), using MDR1-specific primer pairs. Briefly, total RNA was extracted from established lines with TRIzol reagent (Life Technologies, Inc.). Equal amounts of RNA, as determined by absorbance at 260 nm, were denatured and size was fractionated by electrophoresis through a 12 g/L agarose gel containing formaldehyde and 2 μ g/dL ethidium bromide (Figure 1). Equal amounts (1 μ g) of total RNA from each tissue were treated with RNase-free DNase I to remove any contaminated DNA. DNase-treated RNA was then used to synthesize single-strand cDNAs by AMV reverse transcriptase in the presence of random primers, followed by PCR amplification. The primers used for PCR reaction were: MDR1-1, GTA CCC ATC ATT GCA ATA GC and MDR1-2, CAA ACT TCT GCT CCT GAG TC. These two MDR1 primers bracketed the COOH-terminal region of the MDR1 cDNA and gave a PCR product of 147 bp. PCR amplification was performed by pre-denaturing at 95 °C for 3 min, and then running 30 cycles in the following conditions: denaturation at 94 °C for 40 s, annealing for 40 s at 55 °C, and extension at 72 °C for 50 s. As internal control, RT-PCR for β -actin was carried out using 5' CGT GGG CCG CCC TAG GCA CCA 3' (forward primer) and 5' TTG GCC TTA GGG TTC AGG GGG 3' (reverse primer) in the same conditions as described for MDR1, and showed a PCR product of 243 bp. The PCR products were electrophoresed in a 20 g/L agarose gel with 0.5 μ g/mL ethidium bromide and visualized under UV light. Quantitation of relative band volume counts was performed using Molecular analyst for windows software. To estimate MDR1 expression levels, a MDR1 index was designated as a band volume count ratio of MDR1 to constitutively expressed β -actin, because β -actin mRNA was expressed constitutively in cells. The higher the MDR1 index, the higher the expression level of MDR1 mRNA in cells.

RESULTS

Sensitivity of LoVo and LoVo/5-FU to 5-fluorouracil

The sensitivity of LoVo and LoVo/5-FU cells to 5-fluorouracil was evaluated using the MTT assay as shown in Table 1. Previous studies utilizing MTT assays have shown that the LoVo/5-FU cell line is 8.988-fold more resistant to 5-fluorouracil than parental LoVo cells. We found the two cell lines showed differences in sensitivity to 5-fluorouracil, too. The concentration inducing 50% inhibition of cell proliferation for 5-Fluorouracil was 0.82 μ g/mL for the parental line and 7.37 μ g/mL for the LoVo/5-FU cells.

Effect of wtp53 gene on cell growth in LoVo/5-FU cells

Figure 1 showed the effect of wild-type p53 on the LoVo/5-FU cells. It suggested that the dose of Ad-p53 for experiment didn't affect the growth rate of LoVo/5-FU cells during the six days after transfection.

Figure 1 Effect of wild-type p53 on the growth rate of LoVo/5-FU cells.

Effect of wild-type p53 on LoVo/5-FU cells sensitivity to 5-fluorouracil

The effect of wild-type p53 on 5-fluorouracil sensitivity was examined using the MTT assay. A dose of 8.17×10^{10} pfu/mL Ad-p53 was chosen as the dose to modulate 5-fluorouracil sensitivity. For this study, cells were treated with wild-type p53 for 48 h, 5-fluorouracil was then added to the final concentration of 0.25 to 15 μ g/mL for 3 h, and then the medium was removed and replaced with a fresh medium without drugs and the incubation was continued. Cell growth was determined after an addition for 72 h. Treatment with wild-type p53 appeared to decrease the resistance of LoVo/5-FU cells to 5-fluorouracil (Table 1).

Table 1 Effect of wild-type p53 on LoVo/5-FU sensitivity to 5-fluorouracil

Cell lines	IC ₅₀ (μ g/mL)	Resistant time	Reverse time

Expression of wild-type p53 protein in cell lines

The X-gal staining suggested that the dilution of 1:20 for Ad-p53 could make about more than 80% cells infected successfully. LoVo/5-FU was transduced *in vitro* with the human wild-type p53 cDNA by exposing to Ad-p53 (1:20). To make sure that the constructed p53 expression vector, Ad-p53, efficiently expressed functional wild-type p53, we determined its protein expression and transactivating function. Western blot analysis showed a higher level of wild-type p53 protein expression as early as 48 h after infection with Ad-p53, and which lasted for 5 d, then decreased significantly on the sixth day. But no wild-type p53 was detected in parental (uninfected) cells or control cells infected with Ad-LacZ (data not shown), suggesting that the transfer and expression of p53 by Ad-p53 were highly efficient (Figure 2).

Figure 2 Western blot analysis of wild-type p53 in LoVo/5-FU cell line and LoVo/5-FU cells transiently transfected with p53 expression vector (Ad-p53). Lane 1: LoVo/5-FU cell line. Lanes 2, 3, 4, 5, 6: LoVo/5-FU cells transiently transfected with Ad-p53 for 2, 3, 4, 5, 6 d accordingly. Levels of wild-

type p53 protein (lanes 2-6) were determined by Western-blot analysis with an antibody which could detect wild-type forms of p53 protein.

Expression of wild-type p53 suppressed endogenous MDR1 gene expression

We asked whether wild-type p53 expression could indeed inhibit endogenous MDR1 gene expression in LoVo/5-FU cells. Successful generation of cell lines constantly expressing wild-type p53 was tested in human LoVo/5-FU cells transfected with Ad-p53 as above, and these cells constantly maintained wild-type p53 for about 6 d and provided a valuable reagent for studying drug sensitivity. As seen in Figure 2, vector-transfected LoVo/5-FU cells expressing wild-type p53, had a lower MDR1 mRNA expression than LoVo/5-FU cells without wild-type p53 expression, as determined by RT-PCR. There was a decrease in MDR1 transcripts compared with the empty vector-transfected cell line, suggesting that constitutive expression of p53 could inhibit endogenous MDR1 transcription in LoVo/5-FU cells, and this suppression showed a time-dependent mode Figure 3, 4 and Tables 2, 3.

Figure 3 Results of RT-PCR for expression of MDR1 mRNAs in p53-null and wild-type p53 expressing LoVo/5-FU cells. M: marker; Lanes 1 and 2: results of untransfected LoVo/5-FU cells; Lanes 3 and 4: results of transfected LoVo/5-FU cells.

DISCUSSION

Tumor cell resistance to chemotherapeutic drugs represents a major problem in clinical oncology; patients with colorectal

cancer are generally unresponsive to chemotherapy. The goal of our current cancer research was to find ways to improve the efficacy of gene replacement therapy for cancer by investigating interactions between the gene products and chemotherapeutic drugs.

Resistance to cytotoxic agents is the major cause of failure of medical treatment of human cancer and it is known that tumor cells could become resistant to anticancer drugs by a variety of mechanisms^[1]. In numerous *in vitro* models, this resistance has been shown to be mediated by MDR1 gene, whose product P-gp is thought to be an energy-dependent membrane pump involved in the excretion of toxins in normal cells. Elevated expression of P-gp in malignant cells could result in increased efflux and therefore reduced intracellular accumulation of cytotoxic agents. This decrease has been considered as the basic mechanism of the MDR phenomenon^[2-7].

LoVo/5-FU cells were selected from the LoVo parental cell line through culture in the presence of 5-fluorouracil and were resistant to 5-FU which was toxic to LoVo parental cells. LoVo/5-FU cells had cross-resistance to the drugs comprising the classical MDR phenotype^[15]. In this study, we found the resistance subline overexpressed MDR1 mRNA and no wild-type p53 protein was expressed.

An adenovirus system has potential advantages for gene delivery *in vivo*, such as easy production of high titer virus, high infection efficiency, and infectivity for many types of cells^[16-18]. The stability and duration of the expression of introduced gene are still controversial. For chemo-gene therapy, the expression levels and high infectivity may be more significant than the duration of expression because drugs can kill infected cells within several days. In our model, the expression of wild-type p53 gene was driven independently by the cytomegalovirus promoter contained in an Ad-p53 vector. The expression of wild-type p53 protein by Ad-p53 peaked after 48 h and decreased to a low level by the sixth day. This suggests that a transiently high level of wild-type p53 expression is sufficient to initiate the cytotoxic program in cancer cells.

We found that pretreatment of LoVo/5-FU cells with Ad-p53 was capable of restoring cell sensitivity to 5-fluorouracil. In the parental cell line, however, Ad-p53 did not potentiate 5-fluorouracil toxicity. The functional reversal of MDR by Ad-p53 in LoVo/5-FU cells appeared to be mediated by changes of the MDR1 gene expression.

Several agents have been described to affect MDR1 gene expression or the MDR phenotype in human or rodent cells, such as the Ca²⁺ channel blocker, verapamil, calmodulin inhibitor, trifluoperazine, which have been shown to reverse the MDR phenotype *in vitro* through direct competition with drugs for P-gp binding in the absence of changes in P-gp expression. Treatment with these agents could result in increased intracellular concentrations of cytotoxic drugs, which are thus a final common pathway in the reversal of the multidrug-resistant phenotype. They are presently used in clinical trials to patients with drug refractory tumors. However, they could induce significant cardiotoxicity, thus which limiting their clinical usefulness^[19,20]. The Ad-p53 concentrations reported here are active *in vivo* in the absence of significant toxicity.

Wild-type p53, a M_r 53 000 nuclear phosphoprotein involved in the control of cell growth and apoptosis is the most commonly altered gene in human tumors^[21]. Its role as a tumor suppressor has been well documented as its inactivation was strongly correlated with human cancer^[21-23]. p53 protein had different domains for DNA binding, transactivation, and tetramerization functions^[24,25]. After binding to consensus for DNA sequences, p53 could positively regulate the expression of downstream effector genes, including Gadd45, p21(WAF1/CIP1)^[26], and mouse muscle creatin kinase^[27]. In addition,

wild-type p53 could also negatively regulate a variety of genes that lack a p53 consensus binding site, including DNA topoisomerase II^[28], MDR1^[29-32], c-fos^[33], and other viral and cellular promoters. It has been suggested that transcriptional repression by p53 could result from its direct interactions with transcription factors, such as TATA-binding protein^[34,35], Sp1^[36,37] and CCAAT-binding factor^[28]. Taken together, these observations strongly imply that p53 acts directly with the transcription machinery to modulate MDR1 transcription.

Many tumors have no functional p53, and others express high levels of MDR1. Whether there is a direct connection has remained to be determined^[38]. However, our results suggested that restoration of wild-type p53 in tumor cells could overcome the uncontrolled up-regulation of MDR1 gene expression, and could add to the beneficial effect of wild-type p53 gene therapy that would restore cell growth inhibition and apoptosis pathway to facilitate drug-induced cell killing.

A variety of treatment protocols, including surgery, chemotherapy, and radiotherapy, have been tried for human colorectal cancer, but the long-term survival rate remains unsatisfactory. The combination therapy we present here might be effective as an adjuvant treatment to prevent local recurrence following primary tumor resection or as a treatment that could be given by intralesional injections in drug-resistant primary, metastatic, or locally recurrent colorectal cancer. Protocols are being developed to explore these clinical applications.

Abstract

AIM: To evaluate the role of survivin and caspase-3 in apoptosis of gastric carcinoma, as well as in prognosis of patients with gastric carcinoma.

METHODS: Expressions of survivin and caspase-3 were investigated immunohistochemically in 80 gastric carcinoma patients without a history of chemo-radiation therapy. Tumor cell apoptosis was examined by TUNEL method.

RESULTS: Immunohistochemical analysis showed that survivin expression was positive in 61 of 80 patients (76%) with gastric carcinoma. In contrast, no expression of survivin in adjacent normal tissues was detected. Expression level of caspase-3 was higher in normal tissues than in carcinoma. Patients with higher expression of survivin had worse histological grades and pathological stages. Expression of caspase-3 was significantly associated with histological stages, but not with the pathological stages. Although survivin expression in carcinoma was not inversely related to caspase-3, patients with survivin (-) and caspase-3(+) had the maximum apoptosis index.

CONCLUSION: Expression level of survivin was associated with histological grades and pathological stages of the tumor, indicating that survivin may be a poor prognosis factor for gastric carcinoma. Unlike caspase-3, survivin (an apoptosis inhibitor) can markedly inhibit the apoptosis of tumor cells.

INTRODUCTION

Abnormalities in cell death control are implicated as a cause or contributing factor in a range of diseases, including cancer,

autoimmunity, and degenerative disorders^[1]. This control involves several proteins that promote or inhibit apoptosis and an evolutionarily conserved multistep cascade^[2]. A number of proteins, such as Bcl-2, Fas and Bax affect upstream of the cascade^[3,4]. Survivin, a recently discovered inhibitor of apoptosis, may prolong cell survival by targeting the terminal effector caspase-3^[5,6]. Located at the end of cascade, caspase-3 acts as both initiators and executors in the apoptotic process. So survivin and caspase-3 have been the focus of debate regarding apoptosis.

In the last decade, molecular abnormalities of tumor cells have emerged as important prognostic indicators of gastric carcinoma. As a candidate molecule to influence the apoptosis balance, survivin has unique properties such as undetectable in normal adults tissues and overexpression in a variety of human cancers *in vivo*^[7]. Although studies indicated that survivin was a prognostic tumor marker^[8-13], little is known about its potential role in gastric carcinoma. In this study we sought to investigate the expression of survivin and caspase-3 in gastric carcinoma and to dissect their potential prognostic value, and discuss the relationship between survivin, caspase-3 and tumor cell apoptosis.

MATERIALS AND METHODS

Patients and samples

A total of 80 patients with gastric adenocarcinoma did not receive any treatment prior to surgery. Of them 56 were males and 24 were females, with a mean age of 60 years. Surgically resected specimens were fixed in 10% neutral formalin, embedded in paraffin, and stained by haematoxylin-eosin. Histological grades and pathological stages were conformed to the criteria of UICC (Figure 1). The subjects consisted of 17 cases in stage I, 34 cases in stage II, and 29 cases in stage III. Tumor tissues and normal tissues from every patient were detected.

Immunohistochemical staining for survivin and caspase-3

A pilot study using the anti-survivin antibody and anti-caspase-3 antibody was conducted on various neoplasms, including gastric carcinoma, lung cancer, breast cancer and non-Hodgkin's lymphoma to determine an appropriate dilution. The immunostaining was performed, and negative control slides processed without primary antibody were incubated for each staining. Paraffin-embedded slides were deparaffinized and put in 400 mL EDTA solution (0.001 mol/L, pH 6.0). Then the solution was heated in a pressure cooker and boiled for 2 min while maintaining the pressure. After cooling the slides were incubated with the primary antibody (mouse anti-human survivin or caspase-3 monoclonal antibody purchased from NEO MAEKERS) overnight at 4 °C and rinsed by PBS (0.01 mol/L, pH 7.4) three times. Then the slides were incubated with an anti-mouse conjugate containing horseradish peroxidase at 37 °C for 30 min and rinsed by PBS three times. Finally 3,3'-diaminobenzidine was used for color development and hematoxylin was used for counterstaining. The mean percentage of positive tumor cells was determined in at least five areas at 400-fold magnification and assigned to one of the following five categories^[14]: -, <5%; +, 5-25%; ++, 26-50%; +++, 51-75%; +++, >75%.

Figure 1 HE staining of gastric carcinoma. A: well differentiated gastric carcinoma; B: Moderately differentiated gastric carcinoma; C: Poorly differentiated gastric carcinoma (Original magnification: $\times 200$).

Figure 2 Survivin expression in gastric carcinoma. A: well differentiated gastric carcinoma; B: Moderately differentiated gastric carcinoma; C: Poorly differentiated gastric carcinoma; D: Substitution for antibody with PBS as negative control (Original magnification: $\times 200$).

Histochemical detection of apoptosis

All cases received detection of apoptosis except those with both survivin and caspase-3 negativities. Apoptotic cells and apoptotic bodies were detected by *in situ* labeling using a TUNEL kit purchased from Borriman Company. In brief, deparaffinized and rehydrated sections were digested with proteinase K for 20 min at room temperature and washed. After quenching in 30 mL/L hydrogen peroxide for 10 min and washing with PBS, terminal deoxynucleotidyl transferase enzyme was pipetted onto the sections, which were then incubated at 37 °C for 1 h. After stopping the reaction by putting sections in PBS and washing, anti-digoxin-peroxidase was added to the slides. Finally slides were washed with PBS, stained with 3,3-diaminobenzidine, and counterstained with hematoxylin. Substitution for terminal deoxynucleotidyl transferase with distilled water was used as negative control. Positive cells were determined according to the method described previously^[15]. In brief, positive cells had dark or dark brown nuclei and some morphological characteristics, including chromatin condensation, nuclear disintegration, and formation of crescent caps of condensed chromatin at the nuclear periphery. Counting method was the same as described previously.

Statistical analysis

Differences of positivity rates between different groups were assessed by *t*-test. Kruskal-Wallis' rank sum test was used to assess the differences between ranked data. Linear correlation

hypothesis test was used to evaluate the extent of correlation between two groups. All of the statistical analyses were performed with SAS statistical package.

RESULTS

Immunohistochemical staining revealed that anti-survivin mAb 8E2 specifically reacted with gastric carcinoma cells, with positive staining in cytoplasm and near the Golgi apparatus, whereas no expression of survivin was observed in adjacent normal tissues. A total of 61 cases of gastric carcinoma in this series were defined as positive staining (76%, Figure 2), with the mean percentage of 29.83%.

Of the 80 cases of gastric carcinomas, 75 cases (94%) of the adjacent normal tissues were positive for caspase-3, while 68 cases (85%) of the tumors were caspase-3 positive (Figure 3). Student's *t*-test showed that caspase-3 expressed higher in normal tissue than in carcinoma. Survivin and caspase-3 were not positive at the same position in cancer cells. Expression of survivin in carcinomas showed a negative but not linear correlation with that of caspase-3 ($r=-0.18$, $P>0.05$).

Through Kruskal-Wallis' rank sum test, we found that the expression of both survivin and caspase-3 had significant differences between tissues with different histological grades (Tables 1, 3). The expression of survivin was significantly associated with pathological stages, but caspase-3 was not (Tables 2, 4).

<i>n</i>	25	36	7	68	

$H_c=11.7$, $P<0.005$ between poorly, moderately and well differentiated gastric carcinomas.

Table 4 Correlation between pathological stages and expression of caspase-3

Positive degree	Stage I	Stage II	Stage III	Sum	Mean ranks
+	1	5	2	8	4.5
++	7	7	11	25	21
+++	5	14	10	29	48
++++	3	2	1	6	65.5
<i>n</i>	16	28	24	68	

$H_c=0.54$, $P>0.75$ between stages I, II and III.

Apoptotic cells and apoptotic bodies were observed in gastric carcinoma by using *in situ* labeling (Figure 4). The mean apoptotic index (AI) of the 80 cases was 0.84%. The mean AI in survivin-positive tumors was 0.59%, which was significantly lower than the mean AI of 1.26% observed in survivin-negative tumors ($P < 0.005$). The mean AI in caspase-3-positive tumors (0.97%) was significantly higher than that in caspase-3-negative tumors (0.56%, $P < 0.05$). Tumors with survivin(-) and caspase-3 (+) had the highest AI of 1.58%.

DISCUSSION

Recently, several inhibitors of apoptosis (IAP) related to the baculovirus IAP gene have been identified in humans, mice, and *Drosophila*^[4]. Recombinant expressions of IAP proteins counteract various forms of apoptosis *in vivo*^[16] and *in vitro*^[17]. These molecules are thought to block an evolutionarily conserved step in apoptosis. At least in the case of X-linked IAP, this may involve direct inhibition of the terminal effectors caspase-3 and caspase-7 through a BIR-dependent recognition^[18]. Among the recently described IAP family, survivin is characterized by a unique structure with a single BIR and no-zinc-binding domain known as the RING finger^[19,20], and by the selective distribution in common human cancers^[4,7]. In this study, specific staining for survivin was detected in 61 cases (76%), with a variable proportion of positive tumor cells (10-85%). In contrast, the adjacent normal tissues or the infiltrating lymphocytes did not express survivin, consistent with similar studies^[13]. As the histological differentiation decreased and pathological stage increased, positivity rate and expression level of survivin were elevated. So survivin expression has prognostic value in human gastric carcinoma.

Alessandra^[21] reported that survivin was expressed in G₂-M phase of the cell cycle in a cell cycle-regulated manner and associated with mitotic spindle microtubules. In this study, survivin-positive patients had lower AI as compared with survivin-negative patients, suggesting that the overexpression of survivin in cancer might obliterate the checkpoint of the cell cycle and allow aberrant progression through the G₂-M phase checkpoint in gastric carcinoma.

In normal gastric tissues, caspase-3 was mainly expressed in gastric surface mucous cells, being in accord with the gastric cell turnover. Caspase-3 expression was increased in well differentiated tumors and apoptotic cells were increased in tumors with caspase-3 positivity, indicating that the expression of caspase-3 promoted apoptosis of tumor cells. It is well known that a number of genetic alterations are required for malignant transformation. Therefore we can speculate that abnormal differentiation leads to decreased expression of caspase-3 in tumor cells.

As a key effector molecule of apoptosis, caspase-3 can inactivate number proteins, which are associated with the structure and cycle of normal cells. Survivin showed an inversed function compared with caspase-3, which can be illustrated by the results that cases with survivin (-) and caspase-3 (+) had higher AI than cases with survivin (+) and caspase-3 (-). Then what we wanted to know was, if survivin inhibited directly the expression or function of caspase-3. Although our results indicated that expression of survivin was inversely associated with that of caspase-3, statistic analysis showed no linear correlation. So we think survivin did not inhibit the function of caspase-3 by directly inhibiting its expression. One of the relevant points to this issue was that survivin induced caspase-9 deactivation first^[22,23], and then caspase-3 could not be activated at the end of the cascade. Some other reports suggested that survivin inhibited caspase pathway of apoptosis, and controlled apoptosis and mitotic spindle checkpoint^[19,24]. We speculate that survivin mainly oppresses caspase-3

activation or possesses effect on the upstream promoter activity, but not its expression. Further studies are needed to confirm the process of how survivin inhibits caspase-3.

As long as survivin affects terminal effector of apoptosis and exists in tumor cells, it would be an ideal target of apoptosis-based therapy. One of the roles of chemotherapy is inducing apoptosis, and caspase-3 has been proved to participate in this process^[25], so acting on this target might also enhance sensitivity to chemotherapy or reduce the effect of drug-resistance. A recent *in vitro* study demonstrated that anti-survivin RNA down-regulated the expression of endogenous survivin in transformed cells and induced apoptotic cell death^[26]. Targeted antagonists of survivin may offer a new therapeutic method for gastric carcinoma. A homeland study^[27] revealed that antisense oligonucleotide targeting survivin induced decrease of survivin expression, increase of cell apoptosis, inhibition of cell proliferation in hepG2 cells. It also has been reported^[28] that survivin-based plasmids could induce apoptosis in gastric cancer cells and sensitize gastric cancer cells to chemotherapeutic agents. Gene therapy targeting survivin gene expression may offer a new approach to cancer therapy.

Abstract

AIM: To investigate the antitumor activity of adriamycin (ADR) encapsulated in nanoparticles (NADR) and injected into the hepatic artery of hepatoma-bearing rats.

METHODS: NADR was prepared by the interfacial polymerization method. Walker-256 carcinosarcomas were surgically implanted into the left liver lobes of 60 male Wistar rats, which were divided into 4 groups at random (15 rats per group). On the 7th day after implantation, normal saline (NS), free ADR (FADR), NADR, or ADR mixed with unloaded nanoparticles (ADR+NP) was respectively injected via the hepatic artery (i.a.) of rats in different groups. The dose of ADR in each formulation was 2.0 mg/kg body weight and the concentration was 1.0 mg/mL. Survival time, tumor enlargement ratio, and tumor necrosis degree were compared between each group.

RESULTS: Compared with the rats that received NS i.a., the rats that received FADR or ADR+NP acquired apparent inhibition on tumor growth, as well as prolonged their life span. Further significant anticancer efficacy was observed in rats that received i.a. administration of NADR. Statistics indicated that NADR brought on a more significant tumor inhibition and more extensive tumor necrosis, as compared to FADR or ADR+NP. The mean tumor enlargement ratio on the 7th day after NADR i.a. was 1.106. The mean tumor-bearing survival time was 39.50 days. Prolonged life span ratio was 109.22% as compared with rats that accepted NS.

CONCLUSION: Therapeutic effect of ADR on liver malignancy can be significantly enhanced by its nanoparticle formulation and administration via hepatic artery.

INTRODUCTION

Transhepatic arterial chemotherapy (TAC) is recognized as an efficient therapy for liver primary and metastatic tumors by increasing the drug concentration in tumor and improving the therapeutic effect subsequently. It was reported that administration of ADR via the hepatic artery (i.a.) was able to increase the drug concentration in tumor by 3-fold as compared to intravenous administration^[1]. In patients with cancers, the i.a. administration of ADR reduced the plasma AUC by about 30%^[2].

During recent years, nanoparticles have been extensively applied as carriers of antitumor drugs. *In vivo* studies have demonstrated that nanoparticles are specifically concentrated to the reticuloendothelial system (RES), especially to liver and spleen, after administered into body^[3]. On the basis of these experiences, we hypothesized that a further significant therapeutic effect could be expected by TAC in combination with nanoparticle techniques. We carried out a randomized control study to test it.

MATERIALS AND METHODS

NADR preparation and characterization

NADR was prepared by the interfacial polymerization method^[4]. α -polybutylcyanoacrylate (PBCA) was used as polymeric materials. The final product had an appearance of reddish, colloidal, semi-transparent solution. Under transmission electron microscopy (TEM), NADR showed a global, regular contour with a homogenous size and distribution. The diameter of particles ranged from 22 to 130 nm (mean, 93.1 nm). The drug-embedding ratio was 82.6%, the drug-loading ratio was 40.9%, and the effusion rate was less than 3% three months later.

Animals and anesthetic

Sixty male Wistar rats weighing 230-270 g (mean, 250 g) were provided by Laboratory Animal Center of our university and randomly divided into 4 groups, with 15 in each. Sumianxin (Changchun Agricultural Pastoral University) was used as anesthetic.

Establishment of hepatoma model

One mL of suspension containing 10⁷ Walker-256 (W256) carcinosarcoma cells (Shanghai Medical Industrial Institution) was injected into the thigh muscle of a carrier rat (not included in experimental rats). One week after inoculation, a palpable tumor generated at the injected site. Viable tumor tissue was excised under sterile conditions and soaked in 20 mL of Hanks balanced salt solution. Tissue was diced into approximately 1 mm×1 mm×1 mm fragments. Experimental rats were anesthetized with intramuscular injection of Sumianxin at 0.2 mL/kg. Median incision beneath the metasternum was made and the liver was exposed. The tumor fragment was implanted into the left liver lobe.

Administration i.a.

On the 7th day after tumor implantation, all animals received laparotomy again. The longest (a) and shortest (b) diameters of

the tumor were measured. The tumor volume was calculated as

$$\frac{a \times b^2}{2}$$

By cannulation method described previously^[5], normal saline (NS), free ADR (FADR), NADR, or ADR mixed with unloaded nanoparticles (ADR+NP) was injected into the hepatic artery of rats in groups 1-4 respectively. The dose of ADR in each formulation was 2.0 mg/kg body weight. The concentration of ADR was 1.0 mg/mL.

Assessment of therapeutic effect

Tumor growth inhibition Seven days later, all animals received the third laparotomy. The longest (a) and shortest (b) diameters of the tumor were measured again and the tumor volume after administration was calculated. The tumor volume ratio (TVR) was calculated as

$$\text{TVR} = \frac{\text{Tumor volume after administration}}{\text{Tumor volume before administration}}$$

Tumor necrosis degree Seven random rats in each group were killed and anatomized. Hepatoma was removed completely and fixed in 40 g/L formaldehyde. Three 5-μm thick sections in each tumor were cut on the maximal transverse plane and mounted on glass slides overnight at room temperature. After HE staining, the sections were examined under microscope. According to the percentage of necrosis area, tumors were graded on the following criteria: I, 0-30%; II, 30-70%; III, 70-100%.

Increased life span Survival time of the remaining 8 rats in each group was recorded. The mean survival time of NS group was reckoned as control. Increased life span (%ILS) was calculated as

$$\% \text{ILS} = \left(\frac{\text{Mean survival of treated group}}{\text{Mean survival of control group}} - 1 \right) \times 100\%$$

Statistical analysis

SPSS 10.0 for windows was used for statistical analysis. Statistical significance was tested by ANOVA and Dunnett test for tumor growth inhibition, log rank test for survival time. $P < 0.05$ was considered statistically significant.

RESULTS

Tumor growth inhibition

No difference in tumor volume was found among groups before treatment ($P > 0.05$, Table 1). After treatment, the tumor grew rapidly in rats that received NS. The mean tumor volume was 31.55 times greater than that before treatment. Metastases were observed in about half of these rats. In contrast, the speed of tumor growth lowered apparently in rats that received FADR or ADR+NP ($P < 0.01$). No difference between FADR and ADR+NP was observed ($P > 0.05$). The slowest tumor growth was found in rats that received i.a. administration of NADR. Statistics indicated that NADR brought on a further significant tumor inhibition, as compared with FADR or ADR+NP ($P < 0.01$). In addition, no metastasis was found in rats that received NADR.

Tumor necrosis degree

Under microscope, W256 tumor cells in rats that received NS appeared active proliferation and extensive mitoses. Small areas of necroses were observed in the center of tumor tissue and accompanied with a few inflammatory cells (Table 2). Moderate to severe necroses were found in tumors of rats that

received FADR or ADR+NP. Grade III of tumor necroses was found in 5 of 7 tumors after administration of NADR, including 2 cases of complete tumor necrosis.

Increased life span

Compared with the survival time (18.88 d) in saline controls, the tumor-bearing survival time was greatly prolonged in animals that received NADR (mean, 39.50 d), or FADR (mean, 27.75 d), or ADR+NP (mean, 26.13 d) (Table 3). NADR prolonged the life span by 109.22%, which was longer than FADR (46.98%) and ADR+NP (38.40%) ($P < 0.05$).

Table 1 Tumor volume (V) and tumor volume ratio (TVR) after treatment (mean±SD)

Group	V (cm ³)		TVR
	Before treatment	After treatment	
NS	0.086±0.049	2.521±0.840	31.550±7.975
FADR	0.083±0.035	0.149±0.072	1.883±0.708 ^b
ADR+NP	0.079±0.036	0.161±0.105	1.896±0.565 ^b
NADR	0.079±0.033	0.087±0.038	1.106±0.275 ^d

^b $P < 0.01$, vs NS; ^d $P < 0.01$, vs FADR, ADR+NP.

Table 2 Tumor necrosis degree after treatment

Grade	NS	FADR	ADR+NP	NADR
I	6	2	1	0
II	1	3	5	2
III	0	2	1	5 ¹

¹Complete necrosis in 2 cases.

Table 3 Mean survival time and increased life span (%ILS) after treatment (mean±SD)

Group	Mean survival time (d)	%ILS
NS	18.88±2.80	-
FADR	27.75±6.34	46.98 ^b
ADR+NP	26.13±5.75	38.40 ^b
NADR	39.50±8.97	109.22 ^a

^a $P < 0.05$, vs FADR, ADR+NP; ^b $P < 0.01$, vs NS.

DISCUSSION

We did not include intravenous administration (i.v.) in the present experiment because the i.a. route was much more efficient than i.v. in the treatment of liver malignancies. Different from the liver parenchyma, which receives more than 70% of its blood supply from the portal vein and the rest from the hepatic artery, hepatoma receives approximately 90% of its blood supply from the hepatic artery. The speciality of liver blood supply determines the great difference between the two routes of administration. The difference did not warrant repeat comparison in our study.

The results of our experiments demonstrated that the antitumor activity of ADR could be markedly enhanced when the drug was encapsulated in nanoparticles and administered into the hepatic artery. Equivalent or similar effects could not be acquired using FADR or ADR+NP. Compared with FADR or ADR+NP, NADR produced a more significant tumor inhibition and more extensive tumor necrosis. The average tumor volume on the 7th day after treated with NADR was 0.087 cm³, nearly the half of 0.161 cm³ of the volume after treated with ADR+NP. The survival time of rats that received NADR was evidently increased. Compared with saline

controls, NADR prolonged the life span by 109.22%.

The likely explanations for the improved therapeutic activity in four aspects are as follows. First, it has been testified that the cytotoxic effect of ADR depends on the concentration and duration of exposure^[6]. Increasing ADR concentration in tumor cells or slowing its elimination could certainly enhance its antitumor efficacy. Secondly, encapsulating the drug into nanoparticles might modify its distribution pattern in tissues. After administered into body, nanoparticles were taken up selectively by RES, such as the liver, spleen, and bone marrow. Accumulation of biodegradable nanoparticles with associated drugs in Kupffer cells would create a gradient of drug concentration for a massive and prolonged diffusion of the free drug towards neoplastic tissues^[3]. Thirdly, *in vitro* studies reported that compared to FADR, NADR exhibited a 3-fold enhancement of cytotoxicity, as determined by cell growth inhibition and DNA synthesis, after continuous exposure to 0.02 and 0.04 µg/mL^[7]. Further studies showed that nanoparticulate pharmaceuticals were able to enter specifically certain types of tumor tissues or tumor cells^[8]. Fourthly, the tiny size of nanoparticle could increase its contact areas significantly, which would result in an apparent improvement in its bioavailability. A recent study compared carbendazim, a novel anticancer drug, with its nanoparticles. The result confirmed that nanoparticle formulation improved the drug bioavailability by 166%^[9].

Our experiments support the hypothesis that the therapeutic effect could be dramatically enhanced by TAC in combination with nanotechnology. We conclude that nanoparticles can be used as a promising drug carrier in TAC for the treatment of liver primary and metastatic tumors.

Abstract

AIM: To study the effects of glutamine (Gln) on the change of intestinal permeability and its relationship to systemic inflammatory response in early abdominal postoperative patients.

METHODS: A prospective, randomized, double-blind and controlled trial was taken. Twenty patients undergoing abdominal surgery were randomized into Gln group (oral administration of glutamine, 30 g/d, for 7 d, $n=10$) and placebo group (oral administration of placebo, 30 g/d, for 7 d, $n=10$). Temperatures and heart rates of all patients were daily recorded. White blood cell counts (WBC) and biochemical variables were measured before operation and 4 and 7 d after drug administration. Serum concentrations of glutamine, endotoxin, diamine oxidase and malondialdehyde and urine lactulose/mannito (L/M) ratio were measured before and 7 d after drug administration.

RESULTS: The patients in the 2 groups were comparable prior to drug administration. Serum Gln concentration was significantly decreased in the placebo group and increased in the Gln group 7 d after drug administration. Urine L/M ratio was significantly increased in the placebo group and decreased in the Gln group. The serum concentration of endotoxin, diamine oxidase and malondialdehyde was significantly decreased in the Gln group compared with those in the placebo group. Temperatures, heart rates and WBC counts were significantly lower in the Gln group than those in the placebo group.

CONCLUSION: Gut is one of the sources of systemic inflammatory response in abdominal postoperative patients and glutamine can decrease intestinal permeability, maintain intestinal barrier and attenuate systemic inflammatory response in early postoperative patients.

Quan ZF, Yang C, Li N, Li JS. Effect of glutamine on change in early postoperative intestinal permeability and its relation to systemic inflammatory response. *World J Gastroenterol* 2004; 10(13): 1992-1994

<http://www.wjgnet.com/1007-9327/10/1992.asp>

INTRODUCTION

Gut has been considered as one of the central organs responding to stresses in surgical patients^[1]. In the last few years, animal experiments and clinical researches have proved that the

intestinal permeability increases during stresses, such as severe trauma, operation. Glutamine as a semi-essential amino acid is a special nutrient to intestinal mucosal cells. It can reduce the permeability of gut, but becomes increasingly exhausted after severe trauma or operation. In this research we studied the effects of glutamine on the change of intestinal permeability and its relationship to systemic inflammatory response in abdominal postoperative patients.

MATERIALS AND METHODS

Patient grouping

A prospective, randomized, double-blind and controlled trial was taken. Twenty abdominal surgical patients aged 18-65 years and without any severe disease in liver, kidney, cardiovascular system and hematopoietic system, were randomized into Gln group (oral administration of glutamine, 30 g/d, for 7 d, $n=10$) and placebo group (oral administration of placebo, 30 g/d, for 7 d, $n=10$). Their sex, age, body mass and operation type were similar (Tables 1, 2).

Table 1 General data of two groups

	Placebo group	Glutamine group
Age (yr)	48.3±12.2	48.3±10.8
Male/Female	7/3	6/4
Weight (kg)	54.2±11.1	56.7±12.1

Drug dose and administration

Glutamine was dissolved in warm water (1 g in 10 mL) and orally taken or by gastric tube (10 g one time, and 3 times per day) after operation for 7 d. Placebo was administered as glutamine.

Measurement

Temperature and heart rate of all patients were daily recorded from the day before operation to the end of drug administration.

Peripheral blood was sampled on the morning of the day before operation, the day before drug administration, 4 and 7 after drug administration. Liver and kidney functions were measured.

Peripheral blood was sampled on the morning of the day before and 7 d after drug administration for the measurement of the concentration of the serum glutamine (Gln)^[2], diamine oxidase (DAO)^[3] and malondialdehyde (MDA)^[4].

Peripheral blood was sampled before and 7 d after drug administration for the measurement of the concentration of serum endotoxin with an endotoxin detection kit (Shanghai Yihua Clinical Technology Company).

On the morning before and the 7th day after administration, 6 h's urine was collected after 50 mL lactulose/mannito (L/M) solution (lactulose 10 g and mannito 5 g) was taken for the measurement of the levels of lactulose and mannito with method of enzyme^[5,6] and calculation of the ratio of L/M.

Statistic method

Results were expressed as mean±SD and analyzed with Student *t*-test. $P<0.05$ was considered statistically significant.

Table 2 Detailed clinical data of patients in two groups

Group	Case(n)	Sex	Age(yr)	Diagnosis	Operation type
Gln group	1	Male	55	Cardiac orifice cancer	Total gastrectomy
	2	Male	30	Acute suppurative cholangitis	Cholecystectomy choledochostomy
	3	Female	40	Rectal cancer	Anterior resection of rectum
	4	Male	47	Sigmoid cancer	Sigmoidectomy
	5	Male	62	Cardiac orifice cancer	Proximal subtotal gastrectomy
	6	Female	28	Rectal cancer	Anterior resection of rectum
	7	Female	52	Cholecystolithiasis	Cholecystectomy
	8	Male	49	Gastric cancer	Subtotal gastrectomy
	9	Male	60	Gastric cancer	Subtotal gastrectomy
	10	Male	60	Cardiac orifice cancer	Proximal subtotal gastrectomy
Placebo group	1	Male	50	Pancreas pseudocyst	Cyst-jejunal Roux-en-y anastomosis
	2	Female	56	Ascending colon cancer	Right semi-colectomy
	3	Female	60	Rectal cancer	Anterior resection of rectum
	4	Female	54	Sigmoid cancer	Sigmoidectomy
	5	Male	48	Cardiac orifice cancer	Proximal subtotal gastrectomy
	6	Male	43	Ascending colon cancer	Right semi-colectomy

	8	Female	29	Gastric cancer	Proximal subtotal gastrectomy
	9	Male	43	Sigmoid cancer	Sigmoidectomy
	10	Male	36	Acute biliary pancreatitis	Selective cholecystectomy

RESULTS

General condition

During the research, there were no complication and death in both Gln group and placebo group.

Temperature

The highest, average and lowest temperatures increased after operation. The highest and average temperatures from d 3 to 6 and the lowest temperatures from d 2 to 6 in the Gln group were significantly lower than those in the placebo group.

Heart rate

The highest, average and lowest heart rates increased after operation in patients of both groups. The highest and average heart rates on d 2, 3 and 5 and the lowest heart rates from d 2 to 5 were significantly lower in the Gln group than in the placebo group.

WBC count

WBC counts increased from the first day after operation in both groups with the maximum being above $12.0 \times 10^9/L$. WBC counts decreased to normal level 4 d later in the Gln group, but 7 d later in the placebo group.

Serum concentration of Gln

In the placebo group, the serum concentration of Gln decreased from $432.17 \pm 142.68 \mu\text{mol/L}$ to $250.78 \pm 77.10 \mu\text{mol/L}$ ($P < 0.05$), whereas in the Gln group the serum concentration of Gln increased from $361.17 \pm 161.25 \mu\text{mol/L}$ to $583.22 \pm 171.52 \mu\text{mol/L}$ ($P < 0.05$). The serum concentration of Gln in the Gln group was significantly higher than that in the placebo group ($P < 0.01$) (Table 3).

Table 3 Serum levels of Gln in two groups ($\mu\text{mol/L}$)

Group	Before drug administration	7 d after drug administration
Placebo group	432.17 ± 142.68	250.78 ± 77.10^b
Gln group	361.17 ± 161.25	583.22 ± 171.52^{ad}

^a $P < 0.05$, ^b $P < 0.01$, vs before drug administration; ^d $P < 0.01$, vs placebo group.

Serum DAO concentration

Serum DAO concentrations were not significantly different in the 2 groups before drug administration. Seven days after drug administration, serum DAO concentrations increased in the

placebo group and decreased in the Gln group ($P < 0.01$). The difference in serum DAO concentrations was very significant ($P < 0.01$) between the two groups (Table 4).

Table 4 Serum DAO levels in two groups (U/mL)

Group	Before drug administration	7 d after drug administration
Placebo group	2.06 ± 0.48	3.18 ± 1.13
Gln group	2.26 ± 0.63	1.25 ± 0.65^{bd}

^b $P < 0.01$ vs before administration; ^d $P < 0.01$ vs placebo group.

Serum MDA concentration

Serum MDA concentrations were not significantly different in the 2 groups before drug administration. Seven days after drug administration, they increased in the placebo group and decreased in the Gln group ($P < 0.01$). The serum MDA concentrations were significantly different between the two groups ($P < 0.01$) after drug administration (Table 5).

Table 5 Serum MDA levels in two groups (nmol/mL)

Groups	Before drug administration	7 d after drug administration
Placebo group	3.94 ± 0.56	4.85 ± 0.63^b
Gln group	4.46 ± 0.67	3.53 ± 0.59^{bd}

^b $P < 0.01$ vs before drug administration; ^d $P < 0.01$ vs placebo group.

Table 6 Levels of serum endotoxin in two groups (EU/mL)

Group	Before drug administration	7 d after drug administration
Placebo group	0.21 ± 0.07	0.25 ± 0.08
Gln group	0.23 ± 0.05	0.18 ± 0.06^{ab}

^a $P < 0.05$ vs before drug administration; ^b $P < 0.01$ vs placebo group.

Serum endotoxin concentration

Levels of serum endotoxin in the 2 groups were not significantly different before drug administration. After 7 d, the serum endotoxin concentrations increased in the placebo group significantly and decreased in the Gln group ($P < 0.05$) with a very significant difference between the two groups ($P < 0.01$, Table 6).

Ratio of urine L/M

The ratio of L/M was not significantly different in the 2 groups initially, which was 134.00 ± 18.48 in the placebo group and 146.102 ± 20.21 in the Gln group. After 7 d, the ratio of L/M significantly increased in the placebo group ($P < 0.01$), and significantly decreased in the Gln group ($P < 0.05$). Then, the ratio of L/M was significantly lower in the Gln group than in the placebo group ($P < 0.01$, Table 7).

Table 7 Changes of urine L/M ratio in two groups

Group	Before drug administration	7 d after drug administration
Placebo group	134.00 ± 18.48	194.83 ± 45.31^b
Gln group	146.10 ± 20.21	117.47 ± 25.68^{ad}

^a $P < 0.05$, ^b $P < 0.01$, vs before drug administration; ^d $P < 0.01$ vs placebo group.

DISCUSSION

Normally, besides digestion and absorption, the gut functions as a mucosal barrier to bacteria, endotoxin and some other toxins. Whether the mucosal barrier works well or not is closely related to intestinal permeability. To measure it, some material with large molecular weight was used as a probe. Lactulose/mannitol was most often used^[7]. During the period of severe trauma or operation, the intestinal mucosal barrier was damaged, and therefore the intestinal permeability increased from which bacteria and endotoxin can easily transfer through the intestinal mucosa and invade tissue and blood, which is called bacterial translocation. Then the bacteria and endotoxin in blood would inversely affect the intestinal mucosal barrier and get it further damaged, thus forming a vicious circle. The more critical condition was that systemic inflammatory response syndrome (SIRS) and multiple organ dysfunction syndrome (MODS) could even occur^[8]. Therefore, how to maintain the function of intestinal mucosal barrier in severe trauma or postoperative patients and how to decrease the permeability and bacterial translocation to avoid the occurrence of SIRS and MODS have become a very important problem.

Brooks *et al.*^[9] took L/M as a molecular probe to measure the intestinal permeability in 25 cases of gastrointestinal tumor. The ratio of L/M was greatly increased in the placebo group. Li *et al.*^[10] measured 24 hours' urine ^{99m}T-DTPA taken orally in 8 cases of postoperative patients 7 d after operation. The excretory rate of ^{99m}T-DTPA was $13.71 \pm 4.85\%$, which almost doubly increased to that before operation ($6.64 \pm 3.95\%$). In this research, serum Gln concentration decreased by 41.97%, and increased by 61.48% in the Gln group after administration of Gln for 7 d, when compared with the level before administration. It was significantly higher in the Gln group than in the placebo group. The ratio of L/M was not significantly different in the two groups initially. After 7 d, the ratio of L/M significantly increased in the control group and significantly decreased in the Gln group. The ratio of L/M was significantly lower in the Gln group than in the placebo group. This result showed that supplement of ectogenetic Gln could significantly decrease the intestinal permeability. Jiang *et al.*^[11,12] also proved this in surgical patients. Supplement of alanyl-glutamine could increase serum Gln level and decrease urine L/M ratio.

Li *et al.*^[13-16] studied that measurement of serum DAO was helpful to determine the degree of intestinal mucous damage. In their research after administration of Gln, serum DAO level significantly increased in the placebo group and significantly

decreased in the Gln group compared with the level before drug administration. The change in serum endotoxin level was similar in the 2 groups. This change of serum endotoxin level was related to the fact that high serum Gln level could enhance the function of intestinal mucosal barrier. Low serum endotoxin level was helpful to reduce SIRS in patients. Some researches showed that endotoxin in early trauma could lead to the increase of production and release of cytokines such as TNF- α , IL-6, IL-8, which could take part in the generation of SIRS^[17].

Haga *et al.*^[18] studied the postoperative conditions of 292 gastrointestinal patients. The result was that 245 patients had SIRS early after operation, which was 83.9%. The possibility of postoperative complication and MODS in these patients was much higher than that in those without SIRS. The results in our study indicate that SIRS can be reduced in early postoperative patients.

Abstract

AIM: To evaluate the impact of advanced age on outcome after hepatectomy, gastrectomy and pancreatoduodenectomy.

METHODS: Two hundreds and eleven patients undergone hepatectomy, gastrectomy and pancreatoduodenectomy from January 1998 to September 2002 were analyzed retrospectively. Clinicopathologic features and operative outcome of 83 patients aged 65 years or more were compared with that in 128 younger patients aged less than 65 years.

RESULTS: The nutritional state, such as pre-operation level of serum albumin and hemoglobin in the older patients was poorer than that in the younger patients. The older patients had higher comorbidities than the younger patients (48.2% vs 15.6%). No significant difference was observed in perioperative mortality, and complication rate between the older and younger patients (2.4% vs 1.6% and 22.9% vs 20.3%, respectively). Multivariate analysis demonstrated that pancreatoduodenectomy, hepatectomy with resection of more than 2 segments and comorbidities were independent predictors of postoperative complication, whereas age was not ($P=0.3172$).

CONCLUSION: It is safe for patients aged 65 years or more to undergo hepatic, pancreatic and gastric resection if great care is taken during perioperative period.

INTRODUCTION

The number and proportion of the elderly in our population have increased progressively as a result of increased life expectancy. The population over the age of 65 years is growing at the fastest rate than any other age groups^[1]. But surgery for potentially curable disease frequently leaves elderly patients numerically de-represented^[2]. Worrying about surgical risks and morbidity may be one reason accounting for this phenomenon. There are different opinions about whether elderly surgical patients have poor outcome. Some studies suggested that elderly surgical patients had high morbidity and mortality^[3,4]. Other reports showed that there was no significant difference in the rate of complications and death between the

older and the younger surgical patients^[5,6]. Two hundreds and eleven patients undergone major abdominal operations, including hepatectomy, gastrectomy and pancreatoduodenectomy in recent 5 years were analyzed retrospectively to see whether the older patients face more risks than younger patients.

MATERIALS AND METHODS

Two hundreds and eleven patients who underwent hepatectomy, gastrectomy or pancreatoduodenectomy in our hospital from January 1998 to September 2002 were studied retrospectively. The patients were divided into two groups: older group (age ≥ 65 years) and younger group (age < 65 years). The patients' age and sex, diagnosis, comorbidities, preoperative laboratory values, type of operation, clinical and pathologic characteristics of local lesion, postoperative complications and death, operative blood loss and transfusion, relaparotomy, length of hospital stay were obtained from the operative records and medical notes. The primary carcinoma was divided into different stages according to TNM staging system defined by Union Internationale Contre le Cancer (UICC, 1997). The patients were considered to have comorbidity when treatment was required in additional organ systems. Complications were defined by the classification proposed by Clavien *et al.*^[7]. Because grade I complications (minor and were likely to resolve spontaneously) were difficult to collect due to retrospective audits, only grade IIa complications (requiring drug for treatment), grade IIb complications (requiring reoperation or invasive procedure), grade III complications (events with residual or lasting disability including organ resection), grade IV complications (death as a result of any complication) were included in this study. Mortality was defined as death from any cause within 30 days of the operation.

Data were analyzed with the SAS 8.0 statistical software. Differences were analyzed with the Chi-square test or Fisher's exact test for group contingency analysis and the Student's *t* test and Mann-Whitney non-parametric test for continuous variables. Using logistic regression, the influence of different variables on the complication was studied. Length of hospital stay of the two groups was compared with a nonparametric product-limit method analogous to a Kaplan-Meier survival analysis. $P < 0.05$ was considered statistically significant.

RESULTS

Of the 211 patients, 150 cases were men and 61 cases were women. The median age was 60 years (range, 18 to 88).

The older group consisted of 83 patients, including 51 cases (≥ 65 years), 21 cases (> 70 years), 6 cases (> 75 years), and 5 cases (> 80 years). Diagnosis included primary hepatic carcinoma (31 cases), hepatic adenoma (1 case), hepatic chronic granuloma (1 case), metastatic cancer in liver (5 cases), gastric carcinoma (30 cases), gastric carcinoid (1 case), pancreatic carcinoma (4 cases), periampullary cancer (8 cases), and chronic pancreatitis (2 cases).

The younger group consisted of 128 patients. Diagnosis included primary hepatic carcinoma (45 cases), hepatic malignant stroma (1 case), focal nodular hyperplasia of liver

(1 case), metastatic cancer in liver (1 case), gastric carcinoma (37 cases), gastric ulcer (1 case), gastric malignant stoma (1 case), pancreatic carcinoma (15 cases), periampullary cancer (23 cases), chronic pancreatitis (2 cases), and benign biliary stricture (1 case).

No difference in stage of primary cancer was seen between the older group and younger group, but the levels of serum albumin and hemoglobin in older group were lower than those in younger group (Table 1). A 48.2% of total patients in older group had one or more comorbidities, which was significantly higher than that in younger group (15.6%). There was no difference in the constitution of operative procedure in the older and younger group. Median operative blood loss and transfusion were similar in both groups (500 mL vs 500 mL and 2 units vs 2 units, Table 1).

Table 1 Comparison of clinicopathologic features between the two age groups

Clinicopathologic Features	Younger group (<65 yr)	Older group (≥65 yr)	P value

¹Chi-square test; ²Fisher's exact test; ³Mann-Whitney non-parametric test; ⁴Kaplan-Meier method.

There was no apparent difference in complication rates between the older and younger group (22.9% vs 20.3%, Table 2). The most common complications were wound infection. Other complications included pneumonia, bile leak, pancreatic fistula, delayed gastric emptying, gastrointestinal fistula, cerebrovascular accident, abdominal bleeding, gastric bleeding, DIC, hepatic encephalopathy, pleural effusion, and renal failure. Two patients (2.4%) were re-operated because of gastric bleeding and bile leak in older group. Three patients (2.3%) were re-operated because of intestinal fistula, abdominal bleeding and bile leak in younger group. There was no significant difference in the rate of the re-operation between the two groups (Table 2). In older group, one patient died of DIC and severe metabolic acidosis 4 d after operation, another patient died of pneumonia 24 d after operation. In younger group, two patients died of abdominal hemorrhage and hepatic encephalopathy 13 and 27 d, respectively, after operation. The older patients had almost same perioperative mortality rate as the younger patients (2.4% and 1.6%, respectively). The median hospital stay was 24 d (range, 8 to 147 d) in the older group, which was significantly longer than that in the younger group (median, 21 d, and range, 4 to 128 d) (Figure 1).

Figure 1 Length of hospital stay of the two age groups. Kaplan-Meier curves showed that the hospital stay in older group was significantly longer than that in younger group ($P=0.024$).

Table 3 Multivariate analysis of factors influencing major post-operative complications

Variables	Odds ratio	95% confidence interval	P value
Pancreatoduodenectomy	3.7736	1.7699-8.0145	0.0006
Hepatectomy >2 segments	1.0858	1.0060-1.1834	0.0334
Comorbidity	3.2787	1.5361-6.9930	0.0021
Age (as continuous variable)	1.0173	0.9833-1.0537	0.3172

Logistic regression analysis showed pancreatoduodenectomy and hepatectomy with resection of more than 2 segments and comorbidities were independent factors for complications, whereas age was not.

The multivariate analysis by a stepwise logistic regression model identified three independent significant variables for postoperative complications in the both groups: pancreatoduodenectomy, hepatectomy with resection of more than 2 segments and comorbidities. Sex, reasons of operations, serum albumin, hemoglobin did not influence the morbidity as an independent factor. Calendaric age (in years) was not an independent predictor of complication ($P=0.3172$) (Table 3).

DISCUSSION

Our study suggests that there is no difference between the older patients and the younger patients in postoperative morbidities and mortalities. Similar results have been reported by others. Hodul *et al.*^[6] studied in 122 patients with pancreatoduodenectomy, including 48 patients aged over 70 years, and reported no significant difference between older group and younger group comparing the rate of complications, such as wound infection, abdominal abscess, pancreatic leak, and so on. A retrospective study carried out on 97 patients with a gastric tumor measuring 10 cm or more in diameter showed age was not the influencing factor of frequency of complications^[5]. Furthermore, analysis of extended hepatectomy (more than four liver segments) demonstrated age was not a contributor to in-hospital mortality^[8].

The improvement in perioperative management was a vital reason for reducing the morbidity and mortality^[9]. Developed guidelines for perioperative care may contribute the safety of operation for the elderly, for example, less use of nasogastric tubes can decrease the pulmonary complications, routine drainage being avoided in most cases or limited to a short period can facilitate early mobilization^[10]. Preoperative assessment of elderly and formulation of an effective anesthetic plan according the "individual principle" can decrease the risks of anesthesia^[11]. The surgeon's skill was enhanced due to specialization and made the major abdominal operation become safety. Special team including surgeons, physicians, anesthetists and nurses for unstable elderly patients can decrease the morbidity and mortality^[12]. The environment of operation room^[13] was improved, the operative instruments were updated, which could attenuate the stress of an operation. Positive and effective treatment in surgical intensive care unit (SICU) helps elderly patients live through the crisis after operation.

Older patients need more perioperative care. First, older patients have more comorbidities require to manage than younger patients. Blair *et al.*^[14] reported older cases had more comorbidities than the younger (49% vs 25%) in a series of 179 patients undergone gastrectomy and pancreatectomy. In our study, nearly half of older patients had one or more comorbidities, which were significantly higher than that in younger patients. Second, the nutrition of older patients is poorer than younger patients. Our study showed the level of serum albumin and hemoglobin in older group was lower than younger group. More comorbidities and poorer nutrition mean the older patients need more waiting time for operation and more time for postoperative management, which lead more length of hospital stay in the older cases. Thus, the median hospital stay was longer significantly in older group longer than that in younger group in our study.

In this study, the level of serum albumin and hemoglobin were not the independent predictors for complications, suggesting that short-term nutritional support before operation could improve the nutritional status and reduce the risks of the surgery and anesthesia^[15]. Comorbidity was an independent factor for complication in our study because the comorbidity

could not be controlled in short-term. Comorbidity must be treated during perioperative period, which is a positive measure to reduce perioperative morbidity and mortality.

The patients with complex major operation should receive more perioperative care. Pancreatoduodenectomy and hepatectomy with resection of more than 2 segments were independent predictors of complication in our study. The result was supported by more recent reports. Jarnagin *et al.*^[16] studied in 1803 consecutive cases with hepatic resection over the past decade, and reported that the number of hepatic segments resected and operative blood loss were the independent predictors of both perioperative morbidity and mortality. So, the authors figured out that the major operation has more complications than minor operation^[16].

In conclusion, the present data suggest that advanced age does not predict high morbidity and mortality after major abdominal operations. Surgeons should not advise against an operation just because the patient is old.

Abstract

AIM: To discuss the clinical significance of postoperative gastrointestinal decompression in operation on lower digestive tract.

METHODS: Three hundred and sixty-eight patients with excision and anastomosis of lower digestive tract were divided into two groups, i.e. the group with postoperative gastrointestinal decompression and the group without postoperative gastrointestinal decompression. Clinical therapeutic outcome and incidence of complication were compared between two groups. Furthermore, an investigation on application of gastrointestinal decompression was carried out among 200 general surgeons.

RESULTS: The volume of gastric juice in decompression group was about 200 mL every day after operation. Both groups had a lower girth before operation than every day after operation. No difference in length of the first passage of gas by anus and defecation after operation was found between two groups. The overall incidence of complications was obviously higher in decompression group than in non-decompression group (28% vs 8.2%, $P < 0.001$). The incidence of pharyngolaryngitis was up to 23.1%. There was also no difference between two groups regarding the length of hospitalization after operation. The majority (97.5%) of general surgeons held that gastrointestinal decompression should be placed till passage of gas by anus, and only 2.5% of surgeons thought that gastrointestinal decompression should be placed for 2-3 d before passage of gas by anus. Nobody (0%) deemed it unnecessary for placing gastrointestinal compression after operation.

CONCLUSION: Application of gastrointestinal decompression after excision and anastomosis of lower digestive tract cannot effectively reduce gastrointestinal tract pressure and has no obvious effect on preventing postoperative complications. On the contrary, it may increase the incidence of pharyngolaryngitis and other complications. Therefore, it is more beneficial to the recovery of patients without undergoing gastrointestinal decompression.

INTRODUCTION

At present, gastrointestinal decompression after excision and anastomosis of lower digestive tract is still widely used in clinic. Although some researches regarding the application of gastrointestinal decompression after digestive tract operation were made, few researches related to the value of decompression after lower digestive tract have been carried out. Therefore, we performed a prospective randomized controlled study on 368 patients undergoing excision and anastomosis of lower digestive tract in West China Hospital, Sichuan University between July 2002 and October 2003. We also made an investigation in the application of gastrointestinal decompression among 200 general surgeons in China.

MATERIALS AND METHODS

Cases selection

Three hundred and sixty-eight cases underwent excision and anastomosis of lower digestive tract were divided into two groups. One group underwent gastrointestinal decompression after operation and the other group did not.

Clinical data

Of one hundred and eighty-six cases underwent postoperative gastrointestinal decompression, 109 were males and 77 were females, aged between 21-82 years with an average age of 56.8 years. Of the 182 cases in the group who did not undergo postoperative gastrointestinal decompression, 112 were males and 70 were females, aged between 23-84 years with a mean age of 57.2 years. In decompression group, there were 4 cases of small intestinal tumor, 6 cases of benign colon disease, 31 cases of carcinoma of colon and 145 cases of rectal cancer. In non-decompression group, there were 5 cases of small intestinal tumor, 8 cases of benign colon disease, 28 cases of carcinoma of colon and 141 cases of rectal cancer. Partial excision of small intestine was performed for small intestinal tumors. Patients with benign colon disease and colon carcinoma underwent partial or subtotal excision of colon, and those with rectal cancer received anterior resection.

Methods

A nasogastric tube was placed in all patients during operation. The tube was removed in the group with gastrointestinal decompression after passage of gas by intestines with continuous vacuum aspiration. The nasogastric tubes in the group without gastrointestinal decompression were immediately removed after operation. Then, the following procedures were carried out. The gastric juice of patients was collected and measured after operation, the postoperative girth was measured by circling umbilical region in the morning as a comparison value with preoperative one, the time for passage of gas by intestines and defecation, the length of hospitalization after operation and the incidence of complications and prognosis were observed and recorded. Those suffering from anastomotic leaks were subjected to treatments such as anti-infective treatment, nutrition support or colostomy. Correspondingly, acute dilatation of stomach was subjected

to gastrointestinal decompression and vacuum aspiration, pulmonary infection to anti-infective therapy, wound infection to local drainage, and cough and throat pain to oral nursing and fog inhalation therapy.

Clinical investigation

An investigation was carried out among 200 general surgeons from 18 hospitals by way of communication. The contents of investigation included the length of placing gastrointestinal decompression after excision and anastomosis of lower digestive tract by these surgeons and their cognition of the significance of placing gastrointestinal decompression.

Statistical analysis

SPSS 10.0 software was used to conduct statistical analysis.

RESULTS

General data

There were no significant differences between two groups in terms of sex ($P>0.05$), age ($P>0.05$). No statistical difference was found between two groups in case distributions ($P=0.892$).

Table 1 Girth of 368 cases before and after operation on lower digestive tract (mean \pm SD)

Girth	Decompression group (n=186)	Non-decompression group (n=182)	P value
Before operation (cm)	76.3 \pm 17.6 ^b	75.1 \pm 16.2 ^d	0.051
After operation (cm)			
Day 1	82.4 \pm 21.5	81.5 \pm 20.7	0.562
Day 2	82.8 \pm 19.8	83.6 \pm 21.8	0.367
Day 3	82.2 \pm 21.5	84.7 \pm 21.2	0.551

^b $P<0.001$, ^d $P<0.001$ vs the three initial days after operation.

Clinical observation

None of the 368 cases died due to operation. The volume of gastric juice in the group with gastrointestinal decompression was 10-520 mL every day after operation (146.5 \pm 87.4 mL on the 1st day, 204.9 \pm 92.5 mL on the 2nd day, and 205.3 \pm 107.1 mL on the 3rd day, respectively). The volume of gastric juice on the 1st day was lower than that on the 2nd and 3rd days ($P<0.001$). However, there was no statistical difference between the volumes on the 2nd and 3rd days ($P>0.05$). There was no significant difference between two groups in terms of girth before and after operation ($P>0.05$). However, the preoperative girth of two groups was less in comparison with the postoperative one ($P<0.001$) (Table 1). The time for passage of gas by anus was 3.2 \pm 1.1 d in the group with gastrointestinal decompression and 3.2 \pm 1.3 d in the group without gastrointestinal decompression ($P<0.05$). The time for the first defecation of the group with gastrointestinal decompression and the group without gastrointestinal decompression was 4.5 \pm 1.4 and 4.6 \pm 1.6 d, respectively ($P>0.05$). The time of hospitalization after operation was 9.0 \pm 4.5 d for the group with gastrointestinal decompression and 8.6 \pm 4.0 d for the group without gastrointestinal decompression ($P>0.05$). All patients

were completely recovered from such illnesses and discharged from hospital.

Incidence of complications

Table 2 shows the incidence of complications after operation. Symptoms as fever and leakage of intestinal contents were diagnosed as anastomotic leakage. There were 5 cases suffering from the lesion in the two groups. All the leakages occurred during excision and anastomosis of lower or ultra-lower rectal tumor and healed after clinical therapy. Those who suffered from abdominal distension, emesis and succussion splash of stomach were diagnosed with acute dilatation of stomach and then subjected to gastrointestinal decompression. Four cases of pulmonary infection were found in two groups by chest X-ray and cured through anti-inflammatory therapy. Any symptom with throat upset or pain was diagnosed as pharyngolaryngitis, 23.1% of patients suffered from pharyngolaryngitis in decompression group and only 4.4% in non-decompression group. Through statistical analysis, the incidence rate of pharyngolaryngitis in decompression group was obviously higher than that in non-decompression group ($P<0.001$). No statistical difference was found in terms of other complications ($P>0.05$). Compared with non-decompression group, the total incidence of complications in decompression group was evidently higher ($P<0.001$).

Investigation results

We conducted an investigation among 200 general surgeons in China, 97.5% (195/200) of surgeons routinely placed nasogastric tube for the passage of gas by anus after excision and anastomosis of lower digestive tract, while 2.5% (5/200) of surgeons discarded gastrointestinal decompression 2-3 d after operation before the passage of gas by anus. All patients of these surgeons underwent gastrointestinal decompression after operation and this kind of management was assumed as a matter of course by the surgeons investigated. Ninety-five percent of the surgeons (190/200) held that gastrointestinal decompression should be maintained till the passage of gas by anus, 4.5% (9/200) of surgeons thought it unnecessary for placing gastrointestinal decompression till passage of gas by anus.

DISCUSSION

Present status of application of gastrointestinal decompression after excision and anastomosis of lower digestive tract

At present, it is still generally believed that gastrointestinal decompression should be performed after operation on abdominal region. The monographs on operation pointed out that gastrointestinal decompression should be conducted for the passage of gas by anus^[1]. A randomized study on general surgeons showed that 72% of them performed routine gastrointestinal decompression after excision of small intestine and 49% of them performed routine gastrointestinal decompression after excision and anastomosis of large intestine^[2]. The present study revealed that 97.5% of surgeons thought gastrointestinal decompression should be performed for the passage of gas by anus after excision and anastomosis of lower digestive tract, suggesting that it has become a routine

Table 2 Complications of 368 cases after operation on lower digestive tract

Patient group	Anastomotic leakage (n, %)	Acute dilation of stomach (n, %)	Pulmonary infection (n, %)	Pharyngolaryngitis (n, %)	Wound infection (n, %)
Decompression group (n=186)	3(1.6)	1(0.5)	3(1.6)	43(23.1) ^b	2(1.1)

procedure after excision and anastomosis of lower digestive tract.

Effects of gastrointestinal decompression

Paralysis of intestine is a natural and transient physiological process after operation on abdominal region. Some researches^[3,4] regarding the relationship between such a phenomenon and gastrointestinal decompression have been made. However, there were few reports focusing on the theoretical basis of this field. It is well-known that the volume of secreted digestive juices was about 5 300-9 500 mL, and the gas secreted by deglutition and intestines was about 30-300 mL^[5]. Nevertheless, the volume extracted by gastrointestinal decompression every day was less than 10% of digestive juices. This study showed the volume extracted by gastrointestinal decompression every day was 200 mL. It is thus evident that gastrointestinal decompression could not effectively extract digestive juices. After operations on abdominal region, gastrointestinal motor function was reduced and the function of intestinal absorption was not greatly influenced. This research showed that the postoperative girth was increased as compared with preoperative girth, demonstrating that there exists paralysis of intestines after operation and paralysis of intestines is a normal and brief process. Clevers *et al.*^[3] reported that paralysis of intestine could not be alleviated by gastrointestinal decompression. The present study demonstrated that there were no significant differences between two groups in terms of passage of gas by anus and the length of defecation. The findings made it clear that gastrointestinal decompression could not get rid of paralysis of intestine or shorten the length of paralysis of intestine. There was no statistical difference between two groups in the increase of girth after operation, demonstrating that with the aid of gastrointestinal decompression, the liquid and gas were difficult to be extracted from intestines and there was no obvious effect upon postoperative abdominal distension. The above research results showed that gastrointestinal tract pressure could not be effectively reduced by means of gastrointestinal decompression.

Influence of gastrointestinal decompression upon postoperative complication

It is undoubtedly that the risk of incidence of anastomotic leakage would increase with the increased tract pressure after anastomosis. One of the purposes of gastrointestinal decompression was to reduce the inner pressure of gastrointestinal tract and the incidence rate of anastomotic leakage. This study revealed that there was no significant difference between two groups in the development of anastomotic leakage, which might be correlated with the fact that gastrointestinal decompression could not effectively reduce stoma pressure of gastrointestinal tract, and especially that gastrointestinal decompression played a small role in reducing the pressure of stoma of lower digestive tract. In the two groups, 3 cases suffered from acute dilation of stomach and no statistical difference was found between two groups. Of the 3 cases of acute dilation of stomach, 1 was from the non-decompression group and cured by the gastrointestinal decompression for 28 d. Although there was an increased probability of acute dilation of stomach without gastrointestinal decompression, its incident rate was lower and easily treated when it happened. In the two groups, there were 4 cases of pulmonary infection. Although gastrointestinal decompression was not the immediate cause for pulmonary infection, it could lead to cough and expectoration, and indirectly induce pulmonary infection. Owing to a low incidence rate of pulmonary infection, further researches for more cases need to be conducted. According to the report by Huerta *et al.*^[6], the incidence rate of pulmonary infection in those with gastrointestinal decompression after operation on

abdominal region was 10 times higher than that in those without gastrointestinal decompression. In addition, this report deemed that it was improper to perform gastrointestinal decompression as a routine procedure and that gastrointestinal decompression could be only used for the treatment of paralysis and dilation of stomach. Pharyngolaryngitis could be immediately induced by long-term irritation and compression of throat by gastrointestinal decompression tubes. Nathan *et al.*^[2] reported that the incidence rate of throat pain was greatly increased in gastrointestinal decompression group. This study revealed that the incidence rate of pharyngolaryngitis in decompression group was up to 23.1%, 5 times as high as in non-decompression group, showing that pharyngolaryngitis was related to nasogastric tubes. This kind of pharyngolaryngitis could be easily dealt with through treatments as fog inhalation therapy and oral nursing after removal of the tube. Michowitz *et al.*^[7] revealed that the incidence rate of complications was obviously increased in the group with gastrointestinal decompression after operations on abdominal region, and that postoperative hyperpyrexia and atelectasis were markedly enhanced. Another randomized research report showed that 70% of severe upsets were caused by gastrointestinal decompression^[8]. This study demonstrated that gastrointestinal decompression could not effectively prevent severe postoperative complications such as anastomotic leakage and instead, resulted in an increased incidence rate of pharyngolaryngitis.

Influence of gastrointestinal decompression upon prognosis

According to some research reports^[9,10], there were no increase in incidence rate of complications and no obvious influence upon prognosis by fluid feeding from the 1st day after operation on gastrointestinal tract without gastrointestinal decompression. Researches showed that it was unnecessary for gastrointestinal decompression after operation on abdominal region, which could reduce the incidence rate of pneumonia and recover the tract functions as early as possible^[11-16]. The present study showed that there was no obvious difference between two groups in terms of passage of gas by anus and length of defecation time, implying that there was no adverse influence upon recovery of intestinal functions without gastrointestinal decompression. Despite of no significant difference in the time of postoperative hospitalization, the total incidence rate of complications in decompression group was obviously higher than that in non-decompression group, demonstrating that it was more beneficial to the recovery of patients without gastrointestinal decompression.

In conclusion, gastrointestinal decompression following excision and anastomosis of lower digestive tract cannot reduce the pressure of gastrointestinal tract and has no obvious effects upon preventing of postoperative complications. Contrary to expectations, it may increase the incidence rate of pharyngolaryngitis and other complications. Therefore, it is more beneficial to the patients' recovery without gastrointestinal decompression.

Abstract

Despite medical treatment, the lethality of severe acute pancreatitis is still high (20-30%). Therefore, it is very important to find good animal models to characterise the events of this severe disease. In 1984, Mizunuma *et al.* developed a new type of experimental necrotizing pancreatitis by intraperitoneal administration of a high dose of L-arginine in rats. This non-invasive model is highly reproducible and produces selective, dose-dependent acinar cell necrosis. Not only is this a good model to study the pathomechanisms of acute necrotizing pancreatitis, but it is also excellent to observe and influence the time course changes of the disease. By writing this review we illuminate some new aspects of cell physiology and pathology of acute necrotizing pancreatitis. Unfortunately, the reviews about acute experimental pancreatitis usually did not discuss this model. Therefore, the aim of this manuscript was to summarise the observations and address some challenges for the future in L-arginine-induced pancreatitis.

Hegyi P, Rakonczay Jr Z, Sári R, Góg C, Lonovics J, Takács T, Czakó L. L-arginine-induced experimental pancreatitis. *World J Gastroenterol* 2004; 10(14): 2003-2009

<http://www.wjgnet.com/1007-9327/10/2003.asp>

EFFECT OF EXCESSIVE DOSES OF L-ARGININE ON DIFFERENT TISSUES

Mizunuma *et al.* were the first who studied the effect of an excessive dose of L-arginine (Arg) on different tissues in rats^[1]. After a single intraperitoneal (ip.) injection of 500 mg/100 g body mass (bm) Arg, the liver cells showed slight vacuolar degeneration. The kidney contained eosinophilic compositions in some proximal convoluted tubules, but showed no degenerative changes. Adipose tissues around the pancreas showed fat necrosis. There were no changes in the weight of different organs (liver, kidney, spleen, thymus), except for the pancreas. Due to the effect of pancreatitis the weight of the pancreas nearly doubled by the end of the first 24 h. No evidence of pathophysiological lesions was observed in the lung, heart, intestine, testis, spleen and thymus^[1]. After the first observation Kishino *et al.* examined the pancreas by electron microscopy^[2]. They found that degeneration started with disorganization of the rough endoplasmic reticulum. The main changes in acinar cells after 24 h were partial distension of the endoplasmic

reticulum. At this time large sequestered areas in the cytoplasm contained disarranged rough endoplasmic reticulum and degraded zymogen granules. Forty-eight hours after Arg-injection, dissociation and necrosis of acinar cells were noted. Subsequently, the necrotic cells were replaced by interstitial tissue composed of leucocytes and fibroblasts. The early morphological changes of the acinar cells may be related to metabolic alterations associated with the endoplasmic reticulum. The final conclusion was that an excessive dose of arginine was toxic to the rat pancreas when injected intraperitoneally^[2]. Tani *et al.* continued this work by observing the effect of Arg on the pancreas^[3]. They clearly proved that excessive doses of Arg could cause a severe acute necrotizing pancreatitis. On the other hand, Delaney and Weaver showed that long term administration of Arg caused pancreatic atrophy with insufficiency, therefore high doses of Arg were also suitable for the induction of chronic pancreatitis^[4,5].

INDUCTION OF PANCREATITIS

Mizunuma *et al.* induced acute necrotizing pancreatitis by a high dose of Arg ip. (500 mg/100 g bm), which evoked selective pancreatic acinar cell damages without any morphological change in the Langerhans islets^[1]. After this first observation, researchers investigating Arg-induced pancreatitis usually modified the method of pancreatitis induction. Tani *et al.* tried to use higher doses of Arg, but found that Arg at the dose of more than 500 mg/100 g bm killed most of the treated rats within a few hours^[3]. When a single dose of 500 mg/100 g bm of Arg was injected, 70-80% of the pancreatic acinar cells were necrotized within 3 d^[3]. When rats were given additional 3 injections of 250 mg/100 g bm over 10 d, there was up to 90% acinar destruction^[4]. The longest treatment of Arg was performed by Weaver *et al.* Daily administration of 350 mg/100 g bm of Arg for 30 d resulted in severe pancreatic necrosis by wk 4, only isolated single acinar cells remained within a fibrous connective tissue matrix^[5]. Most of the authors, who studied the pathomechanisms of this pancreatitis used 250 mg/100 g bm of Arg twice at an interval of one hour^[6-8]. On the other hand, when the regenerative processes were studied after pancreatitis, a smaller dose of Arg (200 mg/100 g bm of Arg ip. twice at an interval of 1 h) was used^[9,10].

All in all, the dose- and time-dependency of the effects of Arg gives an excellent opportunity to study the different phases of pancreatitis. A higher dose of Arg is suggested to study the pathomechanism of acute pancreatitis, while a smaller dose of Arg seems more suitable to characterize the regenerative processes. Long-term administration of Arg is suggested to study chronic pancreatitis (Table 1).

PATHOMECHANISM OF L-ARGININE INDUCED PANCREATITIS

The mechanism by which Arg causes pancreatitis is not fully known. Accumulating evidence suggests that oxygen free radicals^[7,8,11-13], nitric oxide (NO)^[14], inflammatory mediators^[6,12,15,16] all have a key role in the development of the disease.

Changes in cytokine levels

We found that both serum tumor necrosis factor- α (TNF- α) and interleukin (IL)-6 level were already significantly increased

Pancreatic iNOS	2x250 mg	↑	Takács <i>et al.</i> , 2002
CCK	2x250 mg	↑	Czakó <i>et al.</i> , 2000

↓ : decreased activity, ↑ : increased activity, Arg: L-arginine, MDA: malondialdehyde, NSG: nonprotein sulfhydryl group, SOD: superoxide dismutase, TNF: tumor necrosis factor, IL: interleukin, CCK: cholecystokinin-octapeptide.

at 12 h after administration of 2×250 mg/100 g bw Arg, and remained elevated at 48 h in Arg-treated animals *vs* controls (Table 2)^[6,12]. Increased serum TNF-α, IL-6 and IL-1 levels were demonstrated at 24 h after the induction of pancreatitis with 2×230 mg/100 g bw Arg^[15] (Table 2).

Later on, we showed that the pancreatic IL-1β level significantly decreased at 1 h after ip. administration of 300 or 400 g/100 g bw Arg^[15]. The IL-1β levels increased significantly at 12 h after Arg injection, peaked at 24 h and decreased thereafter (Table 2). The pancreatic TNF-α content increased significantly at 6 h, peaked at 18 h, and then remained elevated at a relatively constant level during pancreatitis (Table 2). Pretreatment with antioxidant pyrrolidine dithiocarbamate (PDTC) or methylprednisolone (MP) significantly decreased the pancreatic levels of these proinflammatory cytokines, ameliorated pancreatic oedema and exerted a beneficial effect on pancreatic morphological damage^[15]. It can be proposed that these cytokines are involved in the pathogenesis of Arg-induced acute pancreatitis.

Oxidative stress changes

In 1998, we demonstrated that the pancreatic malondialdehyde (MDA) level was significantly elevated at 24 h, and peaked at

48 h after administration of 2×250 mg/100 g bw Arg^[8]. Among the endogenous scavengers Mn-superoxide dismutase (SOD) and catalase activities decreased significantly throughout the entire study *vs* the control. Cu, Zn-SOD activity decreased only at 12 h, while the glutathione peroxidase activity decreased at 6 and 12 h after Arg injection (Table 2). Pretreatment with the xanthine oxidase inhibitor allopurinol (100 and 200 mg/kg) prevented the generation of reactive oxygen metabolites and ameliorated the severity of Arg-induced pancreatitis.

We also showed that 300 mg/100 g bw Arg significantly increased the pancreatic non-protein sulfhydryl group content, malondialdehyde and the protein carbonyl levels *vs* the control (Table 2)^[15]. Pretreatment with PDTC or MP significantly ameliorated these changes and reduced the severity of the disease.

These results suggest that generation of free radicals is an early and perhaps pivotal mechanism in the pathogenesis of Arg-induced acute pancreatitis.

Role of nitric oxide

NO, a highly reactive free radical, is generated from Arg by an enzymatic pathway (NO synthase: NOS) originally demonstrated in vascular endothelial cells^[17]. Under physiologic conditions,

constitutive NO synthase (cNOS) results in a low level of NO, while in different inflammatory processes inducible NO synthase (iNOS) produces larger quantities of NO in various cell types. The activity of NOS is specifically inhibited by structural analogues of L-arginine such as N^G-nitro-L-arginine methyl ester (L-NAME)^[17].

It was demonstrated that the cNOS activity was depleted at 6 h after onset of Arg-induced pancreatitis, it then gradually increased to a level significantly higher than that in controls and decreased thereafter at 48 h^[13]. The iNOS activity was significantly increased at 24 and 48 h *vs* control (Table 2). Treatment with L-NAME significantly reduced the amylase activity, pancreatic oedema, pancreatic vascular permeability and cNOS activity in the pancreas at 24 h after the onset of pancreatitis as compared with those in the control. L-NAME treatment reduced the iNOS activity, but not significantly, and did not exert any beneficial effect on the histological score^[14]. It can be concluded that both cNOS and iNOS play an important role in the development of Arg-induced acute pancreatitis in rats.

Endogenous cholecystokinin

Endogenous cholecystokinin (CCK) and CCK-A receptors have been suspected to play a role in the development of acute pancreatitis in rats^[18,19]. No significant differences in plasma CCK bioactivity were found between the pancreatic animals and the control group during the course of Arg-induced pancreatitis (Table 2). KSG-054, a CCK receptor antagonist did not exert any beneficial effect on the laboratory and morphologic changes observed in Arg-induced pancreatitis^[12]. These results suggest that endogenous CCK is not involved in the pathogenesis of Arg-induced pancreatitis.

Effect of nuclear factor-kappa B activation

Recent studies have established the critical role played by inflammatory mediators in acute pancreatitis^[14,20]. One of the most important transcription factors that control proinflammatory gene expression is nuclear factor kappa B (NF- κ B)^[21]. Therefore, we set out to investigate NF- κ B activation and proinflammatory cytokine synthesis in the pancreas during Arg-induced acute pancreatitis in rats^[15]. The dose-response (300 or 400 mg/100 g bm) and time-effect (0.5-96 h) curves related to the action of Arg on the pancreatic NF- κ B activation and IL-1 β , TNF- α , heat shock the protein (HSP) 60 and HSP72 synthesis were evaluated. Also we wanted to establish whether PDTC or MP pretreatment could block the activation of pancreatic NF- κ B and their effects on the severity of Arg-induced acute pancreatitis. Our results showed that pancreatic NF- κ B and proinflammatory cytokine expressions were activated dose-dependently during Arg-induced acute pancreatitis in rats, although at a later stage as compared with other models. We have established that PDTC and MP pretreatment specifically and dose-dependently can block this NF- κ B activation in the pancreas. Furthermore, the inhibition of NF- κ B activation and proinflammatory cytokine synthesis has been found to be clearly associated with a protective effect against pancreatic damage^[15].

Apoptosis and gene expression of pancreatitis-associated protein

Pancreatitis-associated protein (PAP) is an acute phase secretory protein known to be overexpressed in acute pancreatitis^[22]. Motoo *et al.* examined the effects of arginine (1.25, 2.5, 5 or 10 mg/mL) on cellular morphology, PAP expression and apoptosis in rat pancreatic acinar AR4-2J cells^[23]. This *in vitro* experimental design allowed the study of acinar cells without the confounding effects of other cell types involved in acute pancreatitis (e.g. inflammatory cells). The growth of AR4-2J

cells was inhibited by Arg in a dose-dependent manner. This inhibition was due to Arg-induced apoptosis of cells which was shown by fluorescence staining, and DNA fragmentation assay. The DNA fragmentation was most prominent at 24 h when the PAP mRNA level was low, whereas it was not seen when the level was high. The expression of PAP mRNA was detected at 2 h and peaked at 6 h, it was highest at a dose of 2.5 mg/mL Arg. Motoo *et al.* speculated that PAP might inhibit the induction of apoptosis^[23].

Role of transforming growth factor beta 1

Mild acute pancreatitis is often followed by full recovery of pancreatic tissue structure and function once the primary cause is eliminated^[24]. Transforming growth factor beta (TGF- β) and the extracellular matrix are believed to play an important part in this process^[20]. TGF- β promotes regeneration in wounded tissues by attracting monocytes and leukocytes and inducing angiogenesis and fibroblast recruitment. Kihara *et al.* induced acute necrotizing pancreatitis by intraperitoneal injection of 500 mg/100 g bm Arg, and examined the expression of TGF- β 1, extracellular matrix proteins and metalloproteinases (degrading a variety of extracellular matrix components). TGF- β , procollagen types I, III, IV, and fibronectin mRNA expression reached a peak value on d 2.5-3 and gradually decreased thereafter to reach control levels on d 7. Matrix metalloproteinase-2 mRNA levels peaked on d 5, whereas the immunoreactivity was maximal on d 7. TGF- β immunoreactivity was detected in disrupted acinar cells on d 3 and 5. Immunoreactivity for fibronectin was detected around disrupted acinar cells and interstitial spaces on d 3 and maximally on d 5. The authors believe that the results suggest an important role of TGF- β in extracellular matrix production during the early phase of acute pancreatitis^[20].

Effect of endotoxaemia in Arg-induced pancreatitis

Systemic endotoxaemia is a common feature of severe acute pancreatitis^[25]. The effect of *E. coli* endotoxin was investigated by Pozsár *et al.* on the mortality rates and pancreatic histology of Arg-induced (250 mg/100 g bm) acute pancreatitis in rats^[26]. The mortality rates of rats treated with 5 and 10 mg/kg endotoxin were 10 % and 30%, respectively (no death was observed in the group with only Arg-induced pancreatitis). The extent of acinar cell necrosis, hemorrhage, oedema and leukocyte infiltration was significantly greater in the endotoxin-treated groups *vs* the control groups. The authors speculated that systemic endotoxemia might exert its effect by stimulating pro-inflammatory cytokine synthesis in granulocytes. The animal experiments were closely related to similar observations made in humans. It was found that high serum endotoxin levels showed a positive correlation with disease severity^[26].

Expression of nerve growth factor

Nerve growth factor (NGF) is a known mediator of the inflammatory response^[27]. It is believed to play an important role in the pathogenesis of pain. NGF expression was investigated after injection of 250 mg/100 g bm Arg twice intraperitoneally^[28]. No significant differences in NGF mRNA levels were found between the Arg-injected and control rats before 3 d. However, NGF mRNA levels significantly increased On days 3 (10-18 fold) and 5 (3.2-6 fold). NGF protein levels were 2-fold higher than control levels on day 3, but this did not reach statistical significance. On d 5 there was a 4-fold increase in NGF protein levels. The cellular sites of increased NGF production were investigated by immunohistochemistry. In control rats NGF-immunoreactivity was localized to the islets of Langerhans. In Arg-induced pancreatitis, NGF was detected in the cytoplasm of exocrine pancreatic tissues, including acinar

and ductal cells at 2 and 6 h. On d of NGF was predominantly found in ductal cells. It was possible that this change in staining pattern represented a release of stored NGF from the islets to the parenchyma^[28].

Effect of Arg-induced pancreatitis on the cytoskeleton

Disruption of the cytoskeleton seems to be a common prominent early feature in acute pancreatitis. Actin cytoskeleton was investigated using rhodamin phalloidin and epifluorescence microscopy combined with Normanski images^[29]. In control tissue actin was primarily localised as an intense fluorescent band beneath the luminal membrane. Arg administration (200-500 mg/100 g bm) resulted in changes of the actin cytoskeleton, including reduced actin staining underneath the luminal and basolateral membranes and increased cytoplasmic staining in pancreatic acinar cells. Interestingly, the total actin content of cells was increased twofold at 24 h. The intermediate filaments were investigated by confocal microscopy. A single large dose arginine also induced the disruption of intermediate cytokeratin filaments, which were replaced by a few focal deposits or small aggregates. Sub-basolateral staining appeared with a lower intensity whereas cytoplasmic staining was not present^[29].

Role of heat shock proteins

Heat shock proteins (HSPs) are highly conserved cytoprotective proteins that are present in all species and have essential functions in protein folding, transport, translocation, assembly and degradation. HSP families have been categorized by their molecular mass. HSPs can be induced by a wide variety of conditions. Interestingly, cerulein pancreatitis has been reported to increase^[30-32] or decrease^[33-35] the synthesis of pancreatic HSP60 and HSP72. Arg-induced pancreatitis was accompanied with large increases in HSP27 and HSP70 levels, peaking at 24 h and localized to acinar cells^[36]. Moreover, HSP27 shifted to the phosphorylated forms during pancreatitis. There were smaller increases in HSP60 and HSP90, and no effect on GRP78. Interestingly, a lower dose of Arg induced less pancreatitis, but larger increases in HSP27 and HSP70 expression and phosphorylation of HSP27. The results of Tashiro *et al.* are in accordance with our findings^[36]. The smaller increases in the quantity of HSPs following 400 mg/100 g bm Arg were probably due to tissue necrosis, protein degradation and decreased gene activation. We believe that the increased levels of HSPs most probably act to limit the severity of the disease. In a recent study, Tashiro *et al.* have shown that hyperthermia and possibly HSPs confer significant protection against Arg-induced (400 mg/100 g bm) pancreatitis^[36]. More specifically, the degradation and disorganization of the actin cytoskeleton were prevented. These previous findings are in contrast with ours^[16]. We could only demonstrate decreases in the serum proinflammatory cytokine (TNF- α , IL-1, IL-6) levels after hot-water (and also cold-water) immersion pretreatment of rats with Arg-induced pancreatitis (2 \times 250 mg/100 g bm), but the biochemical and morphological parameters of the pancreas were not significantly different. The explanation of the discrepancies between the results of the two studies may lie in the different types of pretreatment and the differences in the dose of Arg and the strains of rats used.

Role of vacuole membrane protein 1

In vitro expression of vacuole membrane protein 1 (VMP1) promoted formation of cytoplasmic vacuoles which was followed by cell death^[37]. In order to test if VMP1 expression was related to the cytoplasmic vacuolization of acinar cells during acute pancreatitis, Vaccaro *et al.* studied the *in vivo* expression of the VMP1 gene during Arg-induced (500 mg/100 g

acute pancreatitis^[38]. Northern blot analysis showed that the maximal induction of VMP1 after 24 h remained high after 48 h of arginine administration. Significant increases in the number of apoptotic cells were found during those periods. Twenty-four and 48 h after arginine administration, light micrographs from thin plastic toluidine blue sections revealed numerous vacuoles in the cytoplasm of acinar cells. *In situ* hybridization studies showed a high expression of VMP1 in acinar cells with cytoplasmic vacuolization. VMP1 mRNA highly and significantly correlated with vacuole formation. The results suggest that VMP1 expression might be involved in the cytoplasmic vacuolization of acinar cells during the early stage of acute pancreatitis^[38].

EXTRAPANCREATIC MANIFESTATIONS OF L-ARGININE INDUCED PANCREATITIS

Whereas the mortality of interstitial pancreatitis was close to zero, patients with necrotizing pancreatitis had a considerable mortality. The extrapancreatic manifestations, such as circulatory, pulmonary, renal and hepatic failure (multi-organ failure) contributed significantly to the morbidity and mortality of this disease^[39-41]. This model seems to be an appropriate tool to study the extrapancreatic organ damage and its pathomechanisms.

We found that oxidative stress developed not only in the pancreas but also in remote organs during acute pancreatitis induced by 2 \times 250 mg/100 g bm Arg^[11]. The MDA concentration was significantly increased at 6 h after Arg treatment in the liver and at 24 h in the kidney. Among the endogenous scavengers, Mn-, and Cu, Zn-SOD and glutathione peroxidase were significantly reduced both in the liver and in the kidney during the course of Arg-induced pancreatitis. The catalase activity was significantly increased in the liver, whereas it was significantly decreased in the kidney. The prophylactic application of 200 mg/kg allopurinol significantly restrained the generation of free radicals in the liver. Histologic examination revealed vacuolar degeneration within hepatic cells and eosinophilic components in proximal convoluted tubules in the kidney.

Hypertonic saline (HTS) could restore the circulating volume in haemorrhagic shock by improving cardiac contractility and peripheral tissue perfusion^[42]. The aim of Shields^[43,44] was to investigate the effect of HTS resuscitation on the development of end-organ damage in Arg-induced pancreatitis. They demonstrated increased pulmonary endothelial permeability and increased myeloperoxidase activity at 72 h after pancreatitis induction by a single 500 mg/100 g bm Arg injection. Histological examination of the lung revealed marked interstitial congestion and hemorrhage. HTS injections (75 g/L NaCl, 2 mL/kg) were applied at 24 and 48 h after the administration of Arg. Pulmonary oedema, endothelial leak, enhanced neutrophil activity were all attenuated and the pancreatic and pulmonary histological scores were improved in animals treated with HTS.

REGENERATIVE PROCESS AFTER L-ARGININE-INDUCED PANCREATITIS

Time course changes

In the early phase of acute pancreatitis evoked by 200 mg/100 g bm Arg (d 1-3), the laboratory signs of acute pancreatic inflammation predominated in the Arg-treated rats^[9]. Pancreatitis revealed an intercellular edema with the infiltration of leukocytes, dilatation of the capillaries, and microfocal necroses in the parenchyma on d 1 after pancreatitis induction. Interestingly, acinar cells surrounding the Langerhans islets remained intact (Figure 1). Following the early acinar cell necrosis, histological examinations revealed a marked adipose tissue deposition at the end of the first week. Accumulation of adipose tissue was a sign of atrophy. The rest of the pancreas (not involved in Arg-induced cell

destruction) could be the site of pancreatic hypertrophy and hyperplasia. The pancreatic content of enzymes (amylase, trypsinogen and lipase) was decreased by d 7 as a sign of pancreatic acinar cell damage. After the first week regenerative processes dominated. Furthermore, by the end of the fourth week the pancreatic content of enzymes was significantly elevated^[9].

The mortality of this type of pancreatitis was 2.5%. The rats died between days 1-5 after pancreatitis induction. No mortality was found in the control group.

Figure 1 Histologic alterations in the pancreas following Arg-induced pancreatitis on d 3. The signs of acute inflammation and tubular complexes are visible. Segmental fibroses with blue stained fibroblast are observed. Intact pancreatic acinar cells are presented mainly around the Langerhans islets (Chrossmonn's trichrome staining $\times 100$).

Effect of exogenous CCK on the regenerative process

In the early phase of pancreatitis, administration of low doses of CCK-8 further deteriorated the laboratory and histologic parameters of acute pancreatitis^[9]. The mortality rate (15%) also demonstrated the harmful effect of CCK-8 in the early phase of this pancreatitis. Histologic sections demonstrated a more intense mitotic activity due to the effect of CCK-8 on d 7. Moreover, histologic examination revealed that the bulk of hypertrophized pancreatic acinar cells were found surrounding the enlarged Langerhans islets following CCK-8 administration. It appears that the closeness of the Langerhans islets protects acinar cells and accelerates the regenerative process during Arg-evoked pancreatic tissue damage. The reason for this might be the complex interaction of acinar and islet cells. The laboratory changes (such as pancreatic DNA and enzymes content) also proved the positive effect of CCK-8 during the recovery phase^[9].

Secretory changes

Experimental studies have revealed that, suggesting that pancreatic enzyme secretion is reduced after the induction of acute pancreatitis^[45-47]. We characterized the secretory changes in Arg-induced pancreatitis on d 1, 3, 7 and 14 following pancreatitis induction, when the rats were surgically prepared with pancreatic duct and femoral vein cannulae under urethane anesthesia^[48].

In pancreatitic rats, both the basal and the maximal pancreatic volumes were significantly increased *vs* controls on d 1 following the induction of pancreatitis. The basal output was still significantly higher *vs* controls on d 3 and 7, but the maximal output was significantly decreased *vs* the controls on d 7. No change in basal pancreatic fluid secretion was observed in pancreatitic rats, but the maximal output was significantly decreased on d 14. These results proved that there was a conversion from the acute inflammatory phase to the late regenerative phase on d 7. As far as the pancreatic protein secretion was concerned, in pancreatitis-group the basal secretory protein level was significantly diminished throughout

the experiment. The maximal pancreatic protein secretion was significantly decreased in a progressive manner on d 3, 7 and 14. In the pancreatitic rats, both the basal and the maximal pancreatic amylase secretion were significantly increased on d 1. The maximal output was significantly decreased only on d 14. Taken together, the pancreatic secretion in the early phase of Arg-induced pancreatitis is characterized by increases in the secretory volume and amylase level, with a simultaneous decrease in protein output. A progressive decrease in pancreatic secretory capacity was then detected confirming the acinar cell damage.

Effect of diabetes on Arg-induced pancreatitis

The interesting finding that periinsular acini remained intact during Arg-induced-pancreatitis prompted us to continue studies on the effects of diabetes in the process of pancreatic remodeling^[9]. An insulo-acinar correlation was also indicated by the morphological evidence. Acinar cells around the islets could be distinguished from teleinsular acini by their staining characteristics. These periinsular cells were larger, contained larger nuclei and nucleoli, and had more abundant zymogen granules^[49,50]. To achieve our aims, we used streptozotocin (STZ) to evoke diabetes^[51]. STZ was specifically toxic to the β -cells of the islets of Langerhans, which was irreversible and dose-dependent^[52]. When pancreatitis was induced in diabetic rats, the periinsular acini did not remain intact during Arg-induced-pancreatitis. We also found that in diabetic rats, the pancreatic regenerative processes (mitotic activity of acinar cells) in response to low doses of CCK-8 were markedly diminished. The lack of regenerative effect of CCK-8 may be due to the low insulin level. Furthermore, histological sections indicated no difference between the peri- and teleinsular acinar cell damage in diabetic rats. This is a morphological confirmation of the pivotal role of insulin in the regulation of the exocrine pancreatic structure. However, other islet cell hormones might also be involved in this process.

When Arg-induced pancreatitis was evoked in STZ-diabetic rats, the significant elevation in serum amylase level was not so obvious as that observed in pancreatitic rats. The explanation of this phenomenon is that a diabetic state (in rats without pancreatitis) appeared to shift the normal pancreatic enzyme content (decreased amylase and increased trypsinogen). These data are in accordance with those of Sofrankova *et al.*, who demonstrated a similar pancreatic enzyme pattern in a secretory study^[53].

Early increases were observed in the basal pancreatic fluid and amylase secretion in Arg-STZ-treated rats. However, no CCK-8-stimulated fluid secretory peak following pancreatitis induction was detected in diabetic animals, in contrast with the situation in non-diabetic rats, suggesting that diabetes could moderate the CCK-8-stimulated secretory changes in both the early and late phases of Arg-induced pancreatitis.

In order to clearly prove the effect of β -cells during the process of pancreatitis, we replaced the endogenous insulin with mixed exogenous insulin (2 IU s.c. twice daily, 30% short-acting and 70% intermediate-duration insulin), and found that simultaneous administration of exogenous insulin replaced the hypertrophic effect of low-doses of CCK-8^[54].

Late recovery in normal and diabetic rats

Six months after Arg-induced pancreatitis without diabetes, a major restitution of the pancreatic enzyme content was found^[55]. The lipase and trypsinogen contents of the pancreas were recovered, but amylase was significantly decreased *vs* the controls. In spite of this large-scale restitution of the pancreatic enzyme compositions, marked histologic alterations, periductal fibroses, adipose tissue and tubular complexes, were detected 6 mo following pancreatitis induction. No mitotic activity and centroacinar hyperplasia were observed at this time. When

pancreatitis was induced in STZ-diabetic rats, a very considerable recovery of the enzyme content was noted 6 mo following pancreatitis induction. Even at this time, however, the amylase content remained significantly decreased. This may be due to the combined effect of STZ-evoked decrease on amylase biosynthesis and the toxic damage caused by Arg to pancreatic acinar cells^[56]. So far as the pancreatic histologic structure was concerned, the morphologic changes were similar to those seen in Arg-induced pancreatic non-diabetic rats.

Effect of fibroblast growth factor-7 and fibroblast growth factor-10, and role of keratinocyte growth factor receptor

Keratinocyte growth factor (KGF) is a member of the rapidly growing fibroblast growth factor (FGF) family of mitogens^[57]. FGF-7 and FGF-10 show high structural homology and similar biological characteristics. Both are mainly synthesized by mesenchymal cells and stimulate epithelial cells via KGF receptor (KGFR) which is a splice variant of FGF receptor-2^[58].

In normal pancreas, FGF-7 is localized in alpha islet cells, but FGF-10 is not detected. KGFR is also localized in islet cells, ductal cells, and centroacinar cells in the normal pancreas. In the pancreatic tissues of rats with Arg-induced pancreatitis, FGF-7 was localized in alpha cells, whereas FGF-10 was expressed in vascular smooth muscle cells (VSMCs). KGFR was not expressed in centroacinar cells after Arg treatment. These findings suggest that FGF-7 and FGF-10 contribute to the regeneration and differentiation of acinar cells and angiogenesis in acute pancreatitis through KGFR^[58].

Expression of lumican proteins

Lumican is a member of a small leucine-rich proteoglycan family^[59]. It has been reported that lumican mRNA and its protein were ectopically and highly expressed in acinar cells in chronic pancreatitis (CP)-like lesions close to pancreatic cancer cells^[60]. CP-like lesions are characterized by acinar and ductal-ductular cell proliferation with expanding fibrosis. Immunohistochemically, the lumican proteins are localized in ductules and a few centroacinar cells in normal pancreas.

After administration of an excessive dose of Arg, an immature fibrosis with fragmented and loose collagen fibers was observed on d 4 after pancreatitis induction. Moreover, lumican immunoreactivity was also detected in the collagen fibers on d 4. Lumican mRNA was barely detected in islet cells in the normal pancreas, but it was strongly expressed in acinar and islet cells on d 1 following the induction of pancreatitis. Lumican mRNA was expressed in many proliferating fibroblasts on d 4. These findings indicate that lumican is transiently synthesized by acinar cells and fibroblasts during Arg-induced acute pancreatitis. Lumican proteins may contribute to immature and transient fibrosis of acute pancreatitis.

CONCLUSIONS AND PERSPECTIVES

We are just starting to understand the pathophysiology of acute necrotizing pancreatitis. By this review we tried to illuminate new aspects of cell physiology and pathology of acute necrotizing pancreatitis. Firstly, we explored the effects of high doses of Arg on different tissues. Then, we concentrated on the pancreas showing that Arg could cause a necrotizing acute pancreatitis. Finally we characterized the early and late phases of this model of acute experimental pancreatitis.

We believe that this review confirms the value of Arg-induced pancreatitis. In the past plenty of excellent observations were published on this necrotizing pancreatitis model. Many questions were answered concerning acute necrotizing pancreatitis using high doses of Arg. On the other hand, authors usually left the endocrine status of the pancreas unexamined. Using this model, we could highlight the importance of the insulo-acinar axis.

Despite our current knowledge, many hypotheses and questions remain unanswered concerning the effects of Arg. Therefore, it seems to be well worthwhile to continue to explore the pathomechanism of Arg-induced pancreatitis.

Abstract

AIM: To evaluate the effect of aclacinomycin A-loaded magnetic polybutylcyanoacrylate nanoparticles on gastric tumor growth *in vivo* and *in vitro*.

METHODS: Magnetic polybutylcyanoacrylate (PBCA) nanospheres encapsulated with aclacinomycin A (MPNS-ACM) were prepared by interfacial polymerization. Particle size, shape and drug content were examined. Female BABL/c nude mice were implanted with MKN-45 gastric carcinoma tissues subcutaneously to establish human gastric carcinoma model. The mice were randomly divided into 5 groups of 6 each: ACM group (8 mg/kg bm); group of high dosage of MPNS-ACM (8 mg/kg bm); group of low dosage of MPNS-ACM (1.6 mg/kg bm); group of magnetic PBCA nanosphere (MPNS) and control group (normal saline). Magnets (2.5 T) were implanted into the tumor masses in all of the mice one day before the therapy. Above-mentioned drugs were administered intravenously to the mice of every group on the first day and sixth day. When the mice were sacrificed, tumor weight was measured, and the assay of granulocyte-macrophage colony forming-unit (CFU-GM) was performed on semi-solid culture. White blood cell, alanine aminotransferase and creatine were examined. 3-[4-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) was used to examine the viability of MKN-45 cells after incubation with different concentrations of ACM, MPNS and MPNS-ACM suspension respectively for 48 h.

RESULTS: Content of ACM in MPNS-ACM was 12.0% and the average diameter of the particles was 210 nm. The inhibitory rates of ACM (8 mg/kg bm), high dosage of MPNS-ACM (8 mg/kg bm), low dosage of MPNS-ACM (1.6 mg/kg bm) and MPNS on human gastric carcinoma in nude mice were 22.63%, 52.55%, 30.66% and 10.22%, respectively. There was a significant decrease in the number of CFU-GM of bone marrow in ACM group compared with control group, whereas no obvious change was observed in that of the nanosphere groups. The values of 50% inhibition concentration (IC₅₀) of ACM, MPNS and MPNS-ACM were 0.09, 97.78 and 1.07 µg/mL, respectively.

CONCLUSION: The tumor inhibitory rate of MPNS-ACM was much higher than that of ACM under magnetic field and the inhibition on bone marrow was alleviated significantly compared with ACM group.

INTRODUCTION

Cytotoxic medicine has extensively been employed in cancer chemotherapy. However, the usage of these drugs has been limited by the non-targeting towards cancer and serious toxicity to normal cells in the body. To enhance the therapeutic efficacy of anticancer drugs and reduce the toxicity to normal tissue of the body, targeted drug delivery systems at solid tumors have been developed.

Magnetic targeted drugs are the fourth generation of targeted reagents. The advantage of the magnetic targeted drug delivery systems over other drug targeting techniques is their ability to minimize the uptake by reticuloendothelial system (RES)^[1]. Some investigators have reported successful tumor remission in animal experiments upon the use of magnetically responsive anticancer drug carriers under magnetic fields, but in previous studies the majority of magnetically responsive drug carriers, which included magnetic albumin microspheres and magnetic liposomes had been administered intra-arterially to obtain highly efficient localized targeting during the first circulation passing through a strong magnetic field^[2,3]. However intra-arterial administration of these carriers is not considered to be suitable for the treatment of multiple systemic lesions and is inconvenient to apply. Accordingly, the treatment of solid tumors requires the development of magnetically responsive carriers that can be effectively delivered to any systemic site via intravenous administration. Yet the therapeutic efficacy of intravenously administered magnetically responsive carriers has not been established maturely to date.

Polyalkylcyanoacrylates (PACAs) were not employed as polymers until the early 1980s. However the corresponding monomers, alkylcyanoacrylates, have been extensively used as tissue adhesives for the closure of skin wounds^[4]. More recently, one application of the polymers is the use of PACAs as nanoparticulate drug carriers^[5-9]. This very exciting area of research has gained increasing interest in therapeutics, especially for cancer treatments. Other molecules of interest, including poorly stable compounds such as peptides and nucleic acids, have been combined with PACAs nanoparticles for targeting purposes^[10]. Today, PACAs nanoparticles are considered the most promising polymer colloidal for drug delivery system and are already in clinical development for cancer therapy^[11-15]. The main attraction of PACAs nanoparticles is their ability of tissue targeting and enhancing intracellular penetration of drugs^[16]. Among the species, polybutylcyanoacrylate (PBCA), as a polymer with medium-

length alkyl side chain, is of lower toxicity, proper degradation time. PBCA carrying drugs could increase the antibacterial efficacy^[17], elevate the anti-cancer effect^[18], enhance the relative bioavailability of insulin^[19] *etc.* So PBCA has recently been regarded as a kind of widely used, biocompatible, degradable, low-toxic drug carrier.

Employing supermagnetic iron oxide as the ferromagnetic material, aclacinomycin A (ACM) as the targeted fat soluble model drug and PBCA as the carrier, a kind of magnetically targeted polymer encapsulated with an anticancer drug, magnetic PBCA nanospheres encapsulated with ACM were designed and successfully prepared. The anticancer efficacy of the magnetically targeted system was investigated on gastric cancer *in vivo* and *in vitro*.

MATERIALS AND METHODS

Materials

Butylcyanoacrylate was supplied by Zhejiang Golden Roc. Chemicals Co. Inc. ACM was obtained from Shenzhen Main Luck Pharmaceuticals Inc. Human gastric cancer MKN-45 cell line and BALB/c nude mice (SPF, female) were kindly supplied by Shanghai Cancer Institute. Column NdFeB permanent magnets (surface field strength 2.5 T, diameter 1 mm, length 10 mm) were supplied by Shanghai Jiuling Magnetic & Device Co. Ltd. Semi-solid methylcellulose M3545 and Iscove's Modified Dulbecco's Medium (IMDM) were purchased from Stemcell Company, Canada.

Methods

Synthesis of magnetic colloidal nanoparticles Magnetic colloidal iron oxide nanoparticles were prepared with the method of coprecipitation as described before^[20]. Briefly, 10 mol/L sodium hydroxide was added into the mixture of solution of FeCl₂ and FeCl₃ (Fe²⁺/Fe³⁺ molar ratio 1/2) in a nitrogen atmosphere. The solution was stirred for 1 h at 20 °C, and heated at 90 °C for 1 h. The obtained iron oxide suspension was then stirred for 30 min at 90 °C with the addition of 100 mL trisodium citrate solution (0.3 mol/L). Subsequently, the iron oxide dispersion was cooled down to room temperature with continuous stir. The magnetic particles were washed with double distilled deionized water and collected with the help of a magnet. Finally, the ultrafine magnetic particles were redispersed in water and the suspensions were adjusted to 2.0% (w/w) for further use.

Preparation of ACM encapsulated magnetic PBCA nanoparticles (MPNS-ACM) Interfacial polymerization was applied to synthesize MPNS-ACM based on the methods used before^[21,22]. Briefly, 20 mg ACM dispersed in diluted hydrochloric acid and 2 mL magnetic fluid were mingled, then the mixture was added to 100 g hexane including 2 g Span 80 and 0.6 g polysorbate 80 which was stirred at 600 r/min. The fluid was stirred for 0.5-1 h to make it uniform and emulsive. Then 2 mL butylcyanoacrylate was added dropwise with constant stir at room temperature. After 6 h polymerization the particles were separated with the help of a magnet and washed with methanol for several times. Then the particles were washed with deionized water for several times. The particles were lyophilized and ⁶⁰Co irradiation (15 kGy) was performed to sterilize them. The preparation of magnetic PBCA nanoparticles (MPNS) is similar to the synthesis of MPNS-ACM except no ACM in HCl solution.

Characterization and measurements Transmission electron microscopy (TEM) was performed for MPNS (Hitachi HU-11B). Scanning electron microscopy (SEM, Philips XL30) was used to determine the size and morphology of MPNS. Dynamic light scattering (DLS, Malvern 4700) was used to measure the

hydrodynamic diameter of nanoparticles. The particles were treated with ammonia and then ACM was extracted with ethyl acetate. ACM concentration was determined with UV spectrophotometer at 259 nm. And then drug contents were calculated.

Human gastric carcinoma model of nude mice Human gastric carcinoma MKN-45 cells during exponential growth phase were adjusted to 5×10⁷/mL with RPMI 1640. Then 0.2 mL suspension of MKN-45 cells was inoculated subcutaneously near right forefoot in female BALB/c nude mice. Two weeks later, the solid tumors were taken out from the mice in which the tumors were well growing without necrosis. Tumor masses were cut into small pieces with the diameter of about 2 mm. One tiny piece was implanted into one mouse subcutaneously near right forefoot with a needle. The models were successfully produced after about 2 wk when the tumor grew up to 1 cm in diameter.

Tumor inhibition rate *in vivo* Thirty nude mice models were randomly divided into 5 groups of six each: ACM group (8 mg/kg bm), high dose of MPNS-ACM group (equivalent to ACM 8 mg/kg bm), low dose of MPNS-ACM group (equivalent to ACM 1.6 mg/kg bm), MPNS carrier group (equivalent to MPNS-ACM loaded with ACM 8 mg/kg bm) and control group (normal saline). Magnets (with surfacial field strength 2.5 T) were implanted into the center of the tumors one day before the administration. Above-mentioned agents were administrated intravenously on the first day and sixth day. The largest diameter (LD) and its vertical diameter (VD) of the tumors were measured with calipers every two days after the beginning of administration. The volume of tumor was equal to LD×VD²/2. The mice were sacrificed on the eleventh day after treatment. The tumors were taken out, weighed and the tumor inhibition rate (TIR) was calculated with the following formula: TIR(%)=(1-average tumor weight of experimental group/average tumor weight of control group)×100%.

Stem cells colony-forming unit assay of bone marrow was performed. White blood cell, serum alanine aminotransferase (ALT) and creatine of the mice were examined.

Assay of granulocyte-macrophage colony-forming unit (CFU-GM) of bone marrow The assay of CFU-GM was performed with semi-solid methylcellulose culture. The femoras of the mice were taken out under sterile condition. Both extremities of them were cut and the bones were immersed into Iscove's modified Dulbecco's medium (IMDM). The bone marrow was washed out and the concentration of the cells with nuclei was adjusted with IMDM to 2×10⁵/mL. Cell suspension 0.2 mL was added to 2 mL M3534 semi-solid culture. The mixture was added to a 12-well cell culture plate. The cells were cultured for 7 d at 37 °C with 50 mL/L CO₂ in air and >95% humidity. The number of colonies (>30 cells) were counted under inverted microscope^[23].

Anticarcinoma effect on gastric cancer cell line *in vitro* Gastric cancer cell line MKN-45 cells were trypsinized and suspended in RPMI 1640 with the concentration of 2×10⁵/mL. The cells were seeded onto 96-well culture plates with 190 µL per well and then were cultured at 37 °C with 50 mL/L CO₂ in air and >95% humidity for 24 h. Different concentrations of ACM, MPNS and MPNS-ACM in RPMI 1640 were added to the wells and the final concentrations were 0.001, 0.01, 0.1, 1.0, 10 and 100 µg/mL, respectively. The cells were cultured for another 48 h. Then, 10 µL of 5 mg/mL 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenylterazolium bromide (MTT) was added to each well and the cells were cultured for 4 h at 37 °C. Then the culture medium was discarded, and 150 µL dimethylsulfoxide was added to each well and the absorbance at 570 nm (A₅₇₀) was measured with microplate reader.

Inhibition rate=(1-A₅₇₀ in treatment group/A₅₇₀ in control group)×100%.

Statistical analysis

The data were presented as mean±SD. One-Way ANOVA analysis was used to perform single factor multiple comparison in animal tests. The level of significance was set at $P<0.05$. Logistic regression was applied to analyze the inhibition rate of ACM, MPNS and MPNS-ACM in the *in vitro* study.

RESULTS

Characteristics of MPNS-ACM

The average particle size was 210 nm and the size distribution range was 100–400 nm with the most frequent size around 210 nm (Figure 1). A typical core-shell structure is shown under TEM (Figure 2), it indicated black Fe_3O_4 was surrounded by white polymer. SEM photograph shows uniform sphere. The drug content of MPNS-ACM was 12.0%.

Figure 1 Size distribution of MPNS-ACM.

Figure 2 TEM photograph of MPNS-ACM.

Antitumor effect on human gastric carcinoma model of nude mice

The tumor mass and volume were significantly decreased in both ACM group and MPNS-ACM group than control group at the end of the therapy ($P<0.05$). The anti-tumor activity of high dosage of MPNS-ACM was higher than those of the other agents (Table 1).

Table 2 White blood cells, marrow CFU-GM, serum ALT and creatine ($n=6$, mean±SD)

Group	White blood cells ($\times 10^9/\text{L}$)	CFU-GM number ($/10^4$)	ALT (U/L)	Creatine ($\mu\text{mol/L}$)
ACM	76.67±17.32	74.75±21.91 ^b	30.67±16.51	12.17±1.17
High dosage of MPNS-ACM	70.00±8.74	107.83±14.75	29.17±14.36	12.50±1.05
Low dosage of MPNS-ACM	74.67±9.71	115.25±12.53	23.83±3.55	13.00±2.19
MPNS	79.00±11.23	117.50±12.75	20.83±4.71	12.00±1.55
Control	74.83±6.08	117.00±12.48	37.83±35.13	12.67±1.51

^b $P<0.001$ vs control group.

Table 1 Tumor mass on the 11th day and TIR of the five groups ($n=6$, mean±SD)

Group	Tumor mass (g)	TIR (%)
ACM	1.06±0.27 ^a	22.63
High dosage of MPNS-ACM	0.65±0.26 ^{a,c,g}	52.55
Low dosage of MPNS-ACM	0.95±0.15 ^{a,g}	30.66
MPNS	1.23±0.25	10.22
Control	1.37±0.21	//

^a $P<0.05$ vs control group; ^c $P<0.05$ vs ACM group; ^e $P<0.05$ vs group of low dosage MPNS-ACM; ^g $P<0.05$ vs MPNS group.

The TIR of ACM was 22.63%. The tumor mass of ACM group on the eleventh day (1.06±0.27 g) was much lower than that of control group (1.37±0.21 g) ($P<0.05$).

The TIR of high dosage of MPNS-ACM was 52.55%. The tumor mass on the eleventh day (0.65±0.26 g) was much lower than those of the same dosage of ACM group, low dosage of MPNS-ACM group (0.95±0.15 g), MPNS carrier group (1.23±0.25 g) and control group.

The TIR of low dosage of MPNS-ACM (1.6 mg/kg bm) group was 30.66%, which was higher than that of ACM group (8 mg/kg bm), but there was no statistical difference as to the tumor mass between the two groups ($P>0.05$). The tumor weight of low dosage of MPNS-ACM group was lower than those of MPNS group, and control group ($P<0.05$).

The TIR of MPNS carrier was 10.22%. The tumor weight (1.23±0.25 g) was similar to that of control group (1.37±0.21, $P>0.05$).

Side effects of the agents

The white blood cell counts, serum ALT and creatine of the mice in all the groups were similar ($P<0.05$) (Table 2). The number of CFU-GM of ACM group was much lower than those of the other four groups ($P<0.001$). The white blood cell counts in ACM group was lower than that in control group, yet the ones in MPNS carrier and MPNS-ACM groups were similar to that in control group ($P>0.05$, Table 2).

Anti-tumor effect on gastric cancer cell line in vitro

The IC₅₀ of ACM, MPNS and MPNS-ACM was 0.09, 97.78 and 1.07 (Table 3).

Table 3 Inhibition concentration of the drugs ($\mu\text{g/mL}$)

Group	IC ₁₀	IC ₅₀	IC ₉₀
ACM	0.006	0.09	1.53
MPNS	10.34	97.8	925

DISCUSSION

Selective targeting agents are the trend of antineoplastic chemotherapy. However the production of the biodegradable agents of proper size, high targeting ability and good

bioconsistency is an ongoing challenge. Small-sized magnetic particles (<400 nm) can be extravasated into the tumor interstitium and retained there, owing to the enhanced permeability and retention effect of the tumor^[24]. Polymer carriers encapsulated with magnetite are difficult to prepare because of the different solubility of magnetite and polymers. Here, a kind of modified superparamagnetic iron oxide particles was introduced to prepare the magnetic targeting agents and the particle size could be controlled to 210 nm also, which was very important for the tolerance and efficacy of the agents.

There were two steps for preparation of MPNS-ACM: the preparation and modification of superparamagnetic iron oxide nanoparticles and the synthesis of magnetic polymer loaded with drug. Chemical coprecipitation was applied to synthesize the iron oxide nanoparticles. After modification with acid, well-suspended and stable magnetite fluid was successfully made. It can be stored as suspension for over one year at room temperature. The magnetite can be localized under magnetic field and redispersed when the magnetic force disappears. Interfacial polymerization was applied to the second step where the biodegradable macromolecular material butylcyanoacrylate reacted at the interface between oil and water. Magnetic nanoparticles and fat soluble ACM were encapsulated during the polymerization. The encapsulated ACM was more stable than the one by attachment. The lyophilization agent can be stored long-term at room temperature. After complete ultrasonication, the nanoparticles intravenously administered could locate at the tumor by magnetic force. ACM was slowly released to produce high efficacy and low toxicity with the degradation of polymer.

The results showed that the anti-tumor effect of MPNS-ACM *in vitro* without magnetic field was similar to that of MPNS carrier group (considering the drug content was 12% approximately), yet the anti-tumor test *in vivo* showed higher inhibitory efficacy of the magnetic carrier encapsulated with ACM on the gastric cancer model under magnetic field, which was based on the high targeting capacity of the system. TIR of targeted agent was higher than that of five-fold dosage of non-targeted drug. On the other hand, no toxicity to marrow, liver function and kidney function was found from targeted agents. The results show the high therapeutic efficacy on the tumor and the low toxicity to other organs of the magnetic targeted drug delivery system. It is a kind of safe chemotherapeutic agent.

Due to the difference between fat soluble drugs and water soluble drugs, different methods have been applied to encapsulate the drugs to the biopolymer carrier system with or without magnetite. The attempt to load ACM in to the carrier benefits the studies on other drugs including fat soluble drugs and water soluble drugs.

In conclusion, the magnetic targeted chemotherapy using MPNS-ACM has better tumor targeting, therapeutic efficacy and lower toxicity.

ACKNOWLEDGEMENT

We are grateful to Ming Yao and Shi-Ming Fan of Shanghai Cancer Institute for their kind help with the animal experiments.

Abstract

AIM: To evaluate the correlation between serum vascular cellular adhesion molecule-1 (VCAM-1) levels and clinicopathological features in patients with hepatocellular carcinoma (HCC).

METHODS: Ninety-six patients who underwent HCC resection were recruited in the study. Preoperative serum levels of soluble VCAM-1 were measured by enzyme-linked immunosorbent assay.

RESULTS: Serum VCAM-1 level in HCC patients was inversely correlated with platelet count ($r=-0.431$, $P<0.001$) and serum albumin level ($r=-0.279$, $P<0.001$), and positively correlated with serum bilirubin level ($r=0.379$, $P<0.001$). Serum VCAM-1 level was not associated with tumor characteristics such as tumor size, venous invasion, presence of microsatellite nodules, tumor grade and tumor stage. Serum VCAM-1 level was significantly higher in HCC patients with cirrhosis compared with those without cirrhosis (median 704 vs 546 ng/mL, $P<0.001$). Furthermore, a significantly better disease-free survival was observed in HCC patients with low VCAM-1 level ($P=0.019$).

CONCLUSION: Serum VCAM-1 level appears to reflect the severity of underlying chronic liver disease rather than the tumor status in HCC patients, and low preoperative serum VCAM-1 level is predictive of better disease-free survival after surgery.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a tumor characterized by a rich vasculature. The formation of rich vasculature depends on angiogenesis, which is a process that plays an important role in tumor progression, growth, and metastasis. Many angiogenic factors and mediators are involved in the control of angiogenesis.

Vascular cell adhesion molecule-1 (VCAM-1) is one of the adhesion molecules that have been implicated as a mediator of angiogenesis^[1]. As one of the cell adhesion molecules in the immunoglobulin superfamily, human VCAM-1 is M_r 100 000-110 000, type 1 transmembrane glycoprotein^[2-4]. VCAM-1 is transiently expressed on activated vascular endothelial cells in response to vascular endothelial growth factor (VEGF) and other cytokines, such as tumor necrosis factor α , interleukin 1 β , and interferon γ ^[2,5-7]. Functionally, its expression plays a major role in adhesion of leukocytes to the endothelium in inflamed tissue and in the tumor site^[2]. It also plays an important role in providing attachment to the developing endothelium during angiogenesis^[8-10]. Furthermore, it may also exert its function as an adhesion molecule to facilitate metastasis^[2]. A previous study showed that VCAM-1 expression was associated with the metastasis of melanoma^[11].

VCAM-1 is a soluble molecule that can be detected in the circulation. Although the exact mechanism by which VCAM-1 is shredded into the bloodstream is unknown, it may involve both proteolytic processing and alternative splicing^[12,13]. Because VCAM-1 can be identified in bloodstream, it is potentially useful as a non-invasive biomarker for the monitoring of disease progression in cancer and other diseases^[14-16]. It has been reported that VCAM-1 is over-expressed in various diseases and cancers. Recent studies have demonstrated high serum levels of VCAM-1 in patients with colorectal cancer and gastric cancer^[16-17]. One study demonstrated that a high serum VCAM-1 level was significantly associated with advanced disease stage and the presence of distant metastasis in gastric cancer^[17]. A high serum VCAM-1 level has been shown to be associated with angiogenesis and poor prognosis in breast cancer^[18]. A study has also found that serum VCAM-1 was an independent prognostic marker in patients with Hodgkin's lymphoma^[19].

Up-regulated VCAM-1 expression in chronic liver disease has also been reported, suggesting that VCAM-1 may play a role in the pathogenesis of chronic hepatitis or cirrhosis^[20-26]. Serum VCAM-1 levels higher than normal have been consistently reported in several studies of chronic liver disease of various etiologies^[19-27]. However, the clinical significance of serum VCAM-1 in HCC patients has not yet been reported before. The majority of HCC patients have associated chronic hepatitis or cirrhosis. It is of interest to study serum VCAM-1 in HCC patients because VCAM-1 may be involved in the progression of both the tumor and the underlying chronic liver disease.

The objective of this study was to evaluate the levels of serum soluble VCAM-1 in HCC patients compared with cirrhotic patients without HCC and normal controls, and to analyze the correlation of serum VCAM-1 level with clinicopathological features in HCC patients.

MATERIALS AND METHODS

Patients

Ninety-six patients (71 men and 25 women; median age 55.5 years, range 16-79 years) who underwent resection of HCC in the Department of Surgery of the University of Hong Kong at Queen

Mary Hospital were studied. In the majority of cases (81%, $n=78$), HCC was related to hepatitis B viral infection. None of the 96 patients had received any preoperative treatment. The study was approved by the Ethics Committee of our institution and informed consent was obtained from the patients.

Preoperative serum was collected from the patients. Venous blood samples were drawn into a serum separator tube and centrifuged at 3 000 r/min for 10 min, then stored at -80°C until VCAM-1 levels were determined. Serum samples were also obtained from 19 healthy controls without evidence of any active disease and 23 patients with cirrhosis but no evidence of HCC on ultrasonography and alpha fetoprotein (AFP) surveillance. The majority of the 23 cirrhotic patients (74%, $n=17$) had cirrhosis related to hepatitis B viral infection.

Measurement of serum VCAM-1 level

Serum VCAM-1 levels were quantified using an enzyme-linked immunosorbent assay kit designed to quantitatively measure human soluble VCAM-1 concentration in serum (Human sVCAM-1 Immunoassay; R&D systems, Minneapolis, MN). This assay contains recombinant human VCAM-1 and antibodies against the recombinant factor. The assay can recognize both recombinant and natural human VCAM-1. Briefly, 100 μL of diluted VCAM-1 conjugate (antibody to recombinant VCAM-1 conjugated to horse-radish peroxidase) was added to each well that was pre-coated with monoclonal antibody specific for VCAM-1, after which, 100 μL of serially diluted recombinant VCAM-1 standards and serum samples were added to the wells and incubated at room temperature for 1.5 h. After the wells were washed with wash buffer 6 times to clear any unbound substances, tetramethylbenzidine was added to the wells for color development. The intensity of the developed color was measured by reading absorbance at 450 nm. Each measurement was made in duplicate and the serum VCAM-1 level was determined by extrapolation from a standard curve generated for each set of samples assayed. The sensitivity of the assay was 2 ng/mL, and the coefficients of variation of intraassay and interassay determination were in the range given by the manufacturer (4.3–5.9% and 8.5–10.2%, respectively).

Clinicopathologic and follow-up data

All clinicopathologic and follow-up data were prospectively collected and entered into a computerized database. Detailed preoperative blood tests such as complete blood count, coagulation profile, liver biochemistry, indocyanine green retention at 15 min (ICG_{15}), serum AFP level, and hepatitis viral serology were assessed for all patients. Histopathologic data including Edmonson grade^[28] (1–2 or 3–4), any venous invasion, tumor capsule, microsatellite lesion and pTNM stage^[29] (I/II or III/IVA) were collected. All patients had a computed tomography (CT) scan 1 mo after the hepatic resection to detect any tumor, which was considered a residual disease. Patients who had a positive margin or residual tumors in the 1-month CT scan were considered having a palliative resection.

Postoperative follow-up included monitoring for tumor recurrence by monthly serum AFP level and chest X-ray detection together with ultrasonography or computed tomography (CT) scan every 3 mo. Recurrence of disease was diagnosed by the detection of any intrahepatic or extrahepatic tumor with a typical enhancement pattern of HCC in contrast CT scan and elevation of serum AFP level on serial measurements. Percutaneous fine-needle aspiration cytology was performed to confirm the diagnosis of recurrence in uncertain cases. Disease-free survival was calculated from the date of hepatic resection to the date when recurrence was diagnosed or, in the absence of detectable recurrence, to the date of death or last follow-up.

Statistical analysis

Continuous data were expressed as median with range in parenthesis. For comparison between groups, Mann-Whitney U test was used for analysis of continuous variables, and Chi-square test (or the Fisher's exact test, where appropriate) was used for analysis of discrete variables. Correlation analysis was performed using the Spearman rank correlation test. Cumulative disease-free survival was computed using the Kaplan-Meier method and compared between groups by the log-rank test. Serum VCAM level was entered into a multivariate Cox regression analysis together with 7 other variables that were demonstrated to be of prognostic importance in previous studies from our center and others, namely, serum AFP level, tumor size, presence of venous invasion, presence of microsatellite nodules, presence of underlying cirrhosis and pTNM stage^[30,31]. All statistical analyses were performed using the SPSS statistical software (SPSS/PC+, SPSS Inc., Chicago, Illinois). $P<0.05$ was considered statistically significant.

RESULTS

Serum VCAM-1 levels

Figure 1 shows the distribution of serum VCAM levels in normal controls ($n=19$), patients with cirrhosis only ($n=23$) and HCC patients ($n=96$). The median serum VCAM-1 level in healthy individuals, patients with cirrhosis only, and patients with HCC was 631 ng/mL (449–1 103), 780 ng/mL (509–4 120), and 621 ng/mL (179–3 199), respectively. There was no significant difference in serum VCAM-1 levels between HCC patients and normal individuals ($P=0.447$). However, there were significant differences in serum VCAM-1 levels between cirrhotic patients without HCC and normal individuals ($P=0.010$), and between cirrhotic patients with and without HCC ($P<0.001$).

Figure 1 Scatter plot to illustrate the distribution of serum VCAM-1 level (ng/mL) in healthy control subjects ($n=19$), cirrhosis subjects without HCC ($n=23$), and HCC patients ($n=96$).

Correlation between serum VCAM-1 levels and clinicopathological features in HCC patients

Preoperative serum levels of VCAM-1 in the 96 patients with HCC were analyzed to identify any relationship with the clinicopathological parameters. When analyzed in relation to preoperative clinical parameters categorized as binary variables (Table 1), serum VCAM-1 level had no significant relationship with patients' sex, age, hepatitis B surface antigen status, serum AFP level or serum albumin level. However, serum VCAM-1 levels were significantly higher in patients with high ICG_{15} ($>10\%$), which signifies impaired liver function, and in patients with thrombocytopenia, which signifies the presence of significant hypersplenism. When correlated as continuous variables, serum VCAM-1 levels were positively correlated with serum bilirubin level ($r=0.379$, $P<0.001$) and negatively correlated with white cell count ($r=-0.226$, $P=0.027$), platelet count ($r=-0.431$, $P<0.001$) and serum albumin level ($r=-0.279$, $P<0.001$).

Table 1 Preoperative serum VCAM-1 levels categorized by clinical and laboratory variables

Variables	Median serum VCAM-1 (ng/mL)	<i>P</i> ¹

pTNM: Pathological tumor-node-metastasis. ¹By Mann-Whitney *U* test; ²Compared with normal nontumorous liver; ^b*P*<0.001 compared with both normal liver and chronic hepatitis.

Table 2 shows the relationship of serum VCAM-1 levels and histopathologic features of the resected HCC. There was no significant relationship with the tumor size (*P*=0.185), the presence of microsatellite tumor nodules (*P*=0.359) or venous invasion (*P*=0.248). Significantly higher serum VCAM-1 levels were observed with the presence of tumor capsule (*P*=0.015) and the presence of cirrhosis in adjacent non-tumor liver tissues (*P*<0.001). When categorized according to tumor pTNM staging or Edmonson grading, no significant differences in serum VCAM-1 levels were observed between different tumor stages or grades.

Serum VCAM-1 levels in HCC patients with or without cirrhosis

Fifty out of the 96 HCC patients had cirrhotic liver adjacent to the resected tumor. The median level of serum VCAM-1 in these cases of HCC with cirrhosis was 704 ng/mL (179-3 199), which was significantly higher than that in the HCC cases without cirrhosis (median 546 ng/mL, range 207-1 248, *P*<0.001), but it was significantly lower than that in the 23 patients with cirrhosis only (*P*=0.034). All patients with HCC and cirrhosis had Child's A liver function status, whereas among the 23 patients with cirrhosis only, 8 patients were Child's A, 7 patients were Child's B and 8 patients were Child's C. When compared with the healthy individuals, although the median level of serum VCAM-1 in HCC patients with cirrhosis was higher, the difference was not statistically different (*P*=0.271). In contrast, HCC patients without cirrhosis (*n*=46) had a significantly lower level of VCAM-1 when compared with healthy individuals (*P*=0.008). HCC patients with chronic hepatitis (*n*=39) had a higher serum VCAM-1 level than HCC patients with normal liver, but the difference was not statistically significant (*P*=0.084).

**Figure 2** Disease-free survival analysis of HCC patients segregated into low (≤467 ng/mL, *n*=21) and high (>467 ng/mL, *n*=67) preoperative serum VCAM-1 levels (*P*=0.019).

Prognostic value of serum VCAM-1 levels on disease-free survival

Excluding 8 patients with hospital mortality or palliative resection, 88 patients were available for survival analysis to determine the prognostic influence of serum VCAM-1 levels. The median follow-up of the patients was 33 mo (range 15-52 mo). Because of the skewed distribution of serum VCAM-1 levels among the 88 patients, the 25 th percentile of VCAM-1 levels (467 ng/mL) was used as a cut-off point of high and low values of serum VCAM-1 levels in these patients^[32]. At the time of analysis, 52 of the 88 HCC patients had postoperative recurrence. The disease-free survival was compared between two groups of patients who were segregated in low (*n*=21) and high (*n*=67) serum VCAM-1 levels. Patients with low levels of VCAM-1 had significantly better disease-free survival than those with high levels of VCAM-1 (3-year disease-free survival 66.7% vs 32.8%, *P*=0.019, Figure 2). The overall survival was also better in the group with low serum VCAM-1 levels than in the group with high levels, but the difference was not statistically significant (3-year overall survival 75.0% vs 54.2%, *P*=0.406).

Serum VCAM-1 was entered into a Cox regression analysis of disease-free survival together with serum AFP ($>$ or ≤ 20 ng/mL), tumor size ($>$ or ≤ 5 cm), presence of venous invasion, presence of microsatellite lesions, presence of cirrhosis and tumor pTNM stage. Only pTNM stage (risk ratio 1.409, 95% confidence interval 1.080-1.840, $P=0.012$) and serum VCAM-1 (risk ratio 2.329, 95% confidence interval 1.045-5.191, $P=0.039$) were significant prognostic factors for disease-free survival.

DISCUSSION

Evaluation of angiogenic factors has shown important clinical implications in many types of cancer. In particular, the measurement of various circulating angiogenic factors might provide important prognostic values independent of conventional pathological factors in cancer patients^[33]. HCC is a highly vascularized malignancy, and angiogenesis has been known to be important for its development and metastasis^[34]. Hence, it is of great interest to evaluate the clinical significance of circulating angiogenesis-related markers in HCC patients. Serum VCAM-1 appears to be a promising circulating marker that might have a prognostic value in several types of cancer^[16-19]. To our knowledge, this is the first study that evaluated the clinical significance of serum VCAM-1 levels in HCC patients.

Although the median level of VCAM-1 in HCC patients appeared to be similar to that in normal subjects, within the group of HCC patients, those with underlying cirrhosis had a significantly higher VCAM-1 level than those with chronic hepatitis or normal nontumorous liver. Furthermore, high serum VCAM-1 levels in HCC patients correlated positively with serum bilirubin level and inversely with serum albumin level and platelet count. These findings suggested that high serum VCAM-1 levels were related to the severity of underlying chronic liver diseases. In contrast, there was no significant relationship between serum VCAM-1 levels and tumor size, pathological features of invasiveness or tumor stage. This finding in HCC patients was contrary to the findings of higher serum VCAM-1 levels associated with more advanced stage tumors in other cancers^[16-19]. Analysis of serum VCAM-1 levels in HCC patients is complicated by the fact that most cases of HCC are associated with chronic liver disease, which could also contribute to the serum VCAM-1 levels. The source of VCAM-1 in the circulation of HCC patients could come from activated endothelial cells in both the tumor and chronic hepatitis or cirrhosis in the nontumorous liver. Our study suggested that serum VCAM-1 level in HCC patients could reflect the severity of underlying chronic liver disease rather than the tumor status. Unlike the case of some other cancers, VCAM-1 may play a less important role as a mediator of angiogenesis or related pathological processes in HCC. One of the main functions of endothelial adhesion molecules in tumor is to facilitate the adhesion of leukocytes into tumor endothelium, which in turn could promote angiogenesis^[35]. Yoong *et al.*^[36] demonstrated that vascular adhesion protein-1 and intercellular adhesion molecule-1, rather than VCAM-1, supported adhesion of tumor infiltrating lymphocytes to tumor endothelium in HCC. In fact, the serum VCAM-1 levels of the 46 patients with HCC and noncirrhotic liver were significantly lower than those of normal controls, suggesting that VCAM-1 expression may be down-regulated in HCC patients. While most studies in other types of cancer reported the expression of serum VCAM-1 levels was up-regulated, down-regulation of VCAM-1 has also been reported in node positive breast cancer patients^[37].

The serum VCAM-1 levels in the 96 HCC patients in this study were significantly lower than those of 23 patients with cirrhosis only. Even when the 50 patients with HCC and background cirrhosis were separately analyzed, their serum

VCAM-1 levels were still significantly lower than those of the 23 patients with cirrhosis only. This is probably attributable to the fact that all cirrhotic patients with HCC who underwent hepatic resection had Child's A cirrhosis, whereas the majority of patients in the group with cirrhosis only had Child's B or C cirrhosis. Several previous studies have demonstrated that serum VCAM-1 levels were elevated in cirrhotic patients compared with normal controls, and that serum VCAM-1 level was higher with more severe impairment of liver function or more severe portal hypertension^[22,23,26,27]. Two studies demonstrated that serum VCAM-1 levels reflected the degree of fibrosis in hepatitis C related cirrhotic patients^[24,25]. Our study suggested a similar relationship between serum VCAM-1 level and severity of cirrhosis in a group of patients with predominantly hepatitis B virus related cirrhosis. VCAM-1 appears to play an important role in liver inflammation and fibrosis, probably by mediating interaction between lymphocytes and endothelium. Further studies to clarify the role of VCAM-1 in chronic liver disease may lead to a better understanding of the pathogenesis of cirrhosis and may provide a novel target of intervention to prevent progression of cirrhosis.

Although serum VCAM-1 level was not related to tumor invasiveness or stage, we observed a significantly better disease-free survival in HCC patients with low level of serum VCAM-1. Our study demonstrated that preoperative circulating level of VCAM-1 had a prognostic value in patients undergoing resection of HCC independent of conventional prognostic factors. The exact mechanism underlying the survival differences between patients with low and high serum VCAM-1 levels is unclear. In view of the relationship between serum VCAM-1 levels and the severity of underlying chronic liver disease or cirrhosis found in this study and other studies^[22-27], we speculate that the unfavorable prognostic influence of high serum VCAM-1 level is likely to be related to the underlying cirrhotic or fibrotic condition. The presence of cirrhosis or a higher degree of liver fibrosis has been shown to predispose to multicentric hepatocarcinogenesis and hence postoperative recurrence of HCC^[30,31]. An alternative possibility is that HCC with significantly down-regulated VCAM-1 expression may be associated with more favorable prognosis after resection. However, the exact mechanism for the reduction in serum VCAM-1 level in the presence of HCC observed in some patients is far from clear, and such a possibility seems less likely in view of the lack of association between serum VCAM-1 and tumor characteristics. Further studies that correlate serum VCAM-1 level with the expression of VCAM-1 in HCC tumor tissues and adjacent nontumorous liver may help clarify the mechanism underlying the prognostic significance of serum VCAM-1 levels in HCC patients. Irrespective of the underlying mechanism, the predictive value of serum VCAM-1 level might have potential clinical application in selecting patients with a higher risk of postoperative recurrence for some adjuvant therapy to reduce recurrence.

In conclusion, our data demonstrated that serum VCAM-1 levels in HCC patients correlated with the impairment of liver function and the presence of cirrhosis but not tumor size or features of tumor invasiveness. Hence, serum VCAM-1 levels appear to reflect the severity of underlying liver disease rather than the tumor status in HCC patients. A low serum VCAM-1 level predicts better disease-free survival after tumor resection in HCC patients. Further studies are merited to investigate the exact mechanisms involved in these observations and to explore the potential use of serum VCAM-1 level as a novel prognostic marker in HCC patients.

Abstract

AIM: To study the effects of sense and antisense KAI1 genes on the growth and invasion of human hepatocellular carcinoma (HCC) cell line MHCC97-H.

METHODS: KAI1 sense and antisense eukaryotic expression plasmids were constructed using subclone technique and transfected into MHCC97-H cells respectively by DOTAP liposome. After successful transfection was confirmed, *in vitro* growth curve, cell cycles, plate clone formation efficiency, invasive ability in Boyden Chamber assay and ultrastructural morphology were studied.

RESULTS: KAI1 sense and antisense genes had no significant effects on the cell growth curve and cell cycles. After transfection with sense KAI1 gene, decreased invasive ability in Boyden Chamber assay and decreased amount of mitochondria, but no significant changes of plate clone formation efficiency were observed in MHCC97-H-S cells. The plate clone formation efficiency and invasive ability in Boyden Chamber assay were significantly increased in MHCC97-H-AS cells, after transfection with antisense KAI1 gene. Furthermore, increased amount of mitochondria, rough endoplasmic reticulum, Golgi apparatus and expanded endoplasmic reticulum were also noted in MHCC97-H-AS cells.

CONCLUSION: Changes of KAI1 expression in HCC cells may alter their invasive and metastasis ability of the tumor.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignant tumors in China. Metastasis and recurrence are the most principal factors for the prognosis of patients with the tumor^[1]. KAI1 gene, isolated from human metastatic prostate tumor in 1995, was regarded as a new metastasis suppressor gene. Up to now, many researches on the relationship between

KAI1 gene and invasion, metastasis of malignant tumors have been reported, but most of them were made by histopathological and molecular pathological methods^[2-16]. In the present research, we studied the effects of KAI1 gene on the growth and invasion of human hepatocellular carcinoma (HCC) by subclone, gene transfection and antisense technology.

MATERIALS AND METHODS

Plasmid and vector

Plasmid pCMV-KAI1, with a full length of 8.2 kb, containing human a full-length of KAI1 structural cDNA gene, was a generous gift from Professor J. Carl Barrett and Dr. Dong of National Institute of Health of USA^[2]. Eukaryotic expression plasmid vector pCI-neo, with a full length of 4.7 kb, was purchased from Promega Corporation.

Gene recombination and identification

Sense and antisense KAI1 eukaryotic expression plasmids constructed by subclone technique, were confirmed and identified by restriction endonuclease *Sal* I and *Xba* I analysis.

Cell line and culture

MHCC97-H, a hepatocellular carcinoma cell line with highly metastatic potential^[17], purchased from Liver Cancer Institute, Zhongshan Hospital, Shanghai Fudan University, was used as target cells of gene transfection in the present study. The cell line was cultured in Dulbecco minimum essential medium (Hyclone, USA) containing 100 mL/L fetal calf serum (Hyclone, USA), 100 kU/L penicillin and 100 kU/L streptomycin at 37 °C in a 50 mL/L CO₂ incubator.

Gene transfection

Sense and antisense KAI1 eukaryotic expression plasmids were transfected into MHCC97-H cells respectively by DOTAP (Roche, USA) liposome transfection system similar to our previous report^[18]. Forty-eight hours after transfection, the cells were transfer-selection-cultured for two weeks under the pressure of 800 mg/L G418 (Pierces, USA) in the culture medium. Then the positive cell clones were mixed and the resistance cells were expanded to be cultured under the pressure of 250-600 mg/L G418. Enhanced culture, passaging and storage were performed until few cells were killed by G418.

Integration and expression of transfected genes

Gene integration was identified with amplification of neo genes^[19] by polymerase chain reaction (PCR). The primers, designed to amplify the neo genes in vector pCI-neo: forward (P1): 5' -CAA GAT GGA TTG CAC GCA GG-3', reverse (P2): 5' -CCC GCT CAG AAG AAC TCG TC-3', were synthesized by Shanghai Bioengineering Company, China. Theoretical length of PCR product was 790 bp. Western blot and immunocytochemistry were also performed to understand whether transfection was successful and the effects of transfected genes on KAI1 expression in MHCC97-H cells.

Ultrastructural morphology

Ultrastructural changes of the cells transfected with sense or antisense KAI1 gene were observed with transmission electron microscope.

Cell growth curve

Cells in exponential growth phase were trypsinized to develop single-cell suspension. Four $\times 10^4$ viable cells in 1 mL of medium were added to each well of the 24-well culture plates, which were incubated at 37 °C with 50 mL/L CO₂. Cell numbers in 4 wells were counted and averaged with blood counting chamber every 24 h for 10 consecutive days, and cell growth curve was plotted based on these results.

Cell cycles

Cell cycle analyses were performed by flow cytometry, and each group was examined for 3 times.

Plate clone formation test

Cells cultured (2×10^3) for 48 h were added to each well containing 1 mL of culture medium of a 6-well culture plate, each cell group contained 4 wells. Then the culture plate was gently swayed to disperse cells. The cells were incubated at 37 °C with 50 mL/L CO₂ for 12 d. Then the cells were washed twice with warm PBS, and stained with Giemsa solution. The number of colonies containing 50 cells or more was counted under a microscope.

In vitro invasion assay

In vitro invasive ability was tested by Boyden Chamber assay^[20,21] according to the kit directions. Invasion Chamber inserts (BD Biosciences, USA) with 8 μ m-pores in their PET membrane had been coated by matrigel. Before invasion assay, the invasion chambers were rehydrated with DMEM (serum-free) for 2 h in a humidified tissue culture incubator at 37 °C with 50 mL/L CO₂ atmosphere. DMEM with 100 mL/L fetal bovine serum was added to the lower compartment, and 1.5×10^5 tumor cells in serum-free DMEM were added to the upper compartment of the chamber. Each cell group was plated in 3 duplicate wells. After 48 h incubation, the matrigel was removed, and the filter was washed, cells were fixed and stained in Giemsa solution. Then the cells having migrated to the lower sides of the PET membrane in 5 random visual fields (200 \times) were counted under a light microscope.

Statistical analysis

Statistical analysis software package SPSS (V10.0) was used for data processing, and $P < 0.05$ was considered statistically significant.

RESULTS

KAI1 gene recombination and identification

Two fragments of 3 kb and 5.2 kb appeared after pCMV-KAI1 was digested by *Xba* I. According to the plasmid pCMV-KAI1 map, the 3 kb fragment containing human full-length structural KAI1 cDNA gene was extracted. The cleaved vector pCI-neo after digestion by *Xba* I and dephosphorylation by CIP was linked up with the 3 kb fragment. Two recombinant plasmids were extracted and digested by *Sal* I, the plasmid appearing 2 fragments of 2.25 kb and 6.22 kb after digestion was consistent with the expected sense KAI1 expression plasmid, and the other appearing two fragments of 0.75 kb and 7.72 kb was consistent with the expected antisense KAI1 expression plasmid (Figure 1A). Then the 2 recombinants were digested by *Xba* I to further confirm the insertion of target fragment into the vector. The results showed the two recombinants were respectively cleaved into the same two fragments 3 kb, 5.4 kb (Figure 1B),

and suggested subclone reconstruction was successfully performed.

Figure 1 Identification of KAI1 recombinant plasmids digested by *Sal* I and *Xba* I. M: λ DNA/*Hind* III marker (23.13, 9.42, 6.56, 4.36, 2.32 and 2.02 kb), 1, 2: pCI-KAI1, 3, 4: pCI-anti-KAI1.

KAI1 gene transfection and identification

The recombinants containing sense or antisense KAI1 cDNA were respectively transfected into MHCC97-H cells by DOTAP liposome system. After stable cell clones were screened by G418, the cells transfected with sense KAI1 gene were renamed as MHCC97-H-S, the cells transfected with antisense KAI1 gene were renamed as MHCC97-H-AS, and the cells transfected with vector pCI-neo (vacant vector) were renamed as MHCC97-H-pCI. With amplification of the neo genes by PCR, a specific fragment with a length of 790 bp could be produced from MHCC97-H-S, MHCC97-H-AS and MHCC97-H-pCI cells, but none from MHCC97-H cells (Figure 2). It suggested that the recombinant genes were integrated into genomes of the target cells respectively.

Figure 2 Identifications of gene integration by neo gene amplification. M: Ladder marker (1.0, 0.9, 0.8, 0.7, 0.6, 0.5, 0.4 and 0.3 kb), 1: MHCC97-H-S (790 bp), 2: MHCC97-H-AS (790 bp), 3: MHCC97-H-pCI (790 bp), 4: MHCC97-H.

Western blot and immunocytochemistry staining showed KAI1 protein expression was enhanced in MHCC97-H-S, but decreased in MHCC97-H-AS, and no obvious difference in MHCC97-H-pCI as compared with MHCC97-H cells (Figures 3, 4).

Figure 3 KAI1 protein expressions in different cells revealed by Western blot. 1: MHCC97-H, 2: MHCC97-H-pCI, 3: MHCC97-H-S, 4: MHCC97-H-AS.

Ultrastructural changes in transfected cells

Under electron microscope, the amount of mitochondria was decreased in MHCC97-H-S cells, but increased in MHCC97-H-AS cells. Furthermore, increased amount of rough endoplasmic reticulum (RER), Golgi apparatus, expanded endoplasmic reticulum and myelin-sheath-like changes of mitochondria were also noted in MHCC97-H-AS cells (Figure 5). However, there were no obvious differences in cell shape, superficial microvilli, karyotype and karyokinesis among MHCC97-H-S, MHCC97-H-AS and MHCC97-H cells.

Table 1 Cell cycle distribution of different cells revealed by flow cytometer (%)

Cell	G ₀ /G ₁	S	G ₂ /M
MHCC97-H-S	69.8±6.7	19.7±6.4	10.5±0.9
MHCC97-H-AS	72.1±7.2	19.0±6.3	8.9±0.9
MHCC97-H	73.1±2.0	16.4±1.4	10.5±1.5

Figure 6 Growth curves of different cells.

Growth curve and cell cycles

No significant differences in growth curve and cell cycles were observed among MHCC97-H-S, MHCC97-H-AS, and MHCC97-H cells in 10 consecutive days (Figure 6, Table 1). The results demonstrated that KAI1 gene had no obvious effect on cell proliferation ability.

Figure 4 KAI1 protein expression in different cells revealed by immunocytochemistry (SP×400). A: MHCC97-H-S, B: MHCC97-H, C: MHCC97-H-AS.

Figure 5 Ultrastructural changes in transfected cells. ×6 200. A: MHCC97-H-S cells, fewer RER and mitochondria, B: MHCC97-H-AS cells, more mitochondria, expanded endoplasmic reticulum, C: MHCC97-H-AS cells, myelin-sheath-like changes of mitochondria.

Figure 7 Penetrated cells (blue) in Boyden Chamber test. Giemsa×400. A: MHCC97-S, B: MHCC97-H, C: MHCC97-H-AS.

Plate clone formation efficiency

After two weeks of culture, the results of plate clone formation test showed no statistical difference in clone formation number between MHCC97-H-S (36.2 ± 3.3) and MHCC97-H (38.5 ± 1.9) ($P > 0.05$). However, MHCC97-H-AS (132.5 ± 2.9) showed more clone formation number ($P < 0.01$).

Cell invasive ability

Boyden Chamber assay showed that the cells penetrated the artificial basement membrane in MHCC97-H-S (59.7 ± 3.5) were fewer than in MHCC97-H (92.7 ± 1.5) ($P < 0.01$). However, more penetrated cells in MHCC97-H-AS (188.00 ± 4.5) were noted as compared with those in MHCC97-H ($P < 0.01$). These results suggested that sense KAI1 gene could decrease the invasive ability of MHCC97-H, while, antisense KAI1 gene could increase the invasive ability of MHCC97-H (Figure 7).

DISCUSSION

KAI1 is a newly discovered metastasis suppressor gene in human prostate cancer, which was mapped to chromosome 11p11.2 by Dr. Dong *et al.*^[2] of National Institute of Health, USA in 1995. KAI1 specifies a leukocyte surface glycoprotein of 267 amino acids with molecular mass of 29 610 u. KAI1 protein has been recognized as a structurally distinct family of membrane glycoproteins, transmembrane 4 superfamily^[22]. Recent researches showed the expression of KAI1 was down-regulated not only in human prostate cancer but also in a variety of human malignant tumors^[3,16], and these suggested KAI1 might be a broad-spectrum metastasis suppressor gene for human tumors.

Previous studies on the relationship between KAI1 gene and tumor invasion, metastasis were mostly based on the detection of KAI1 protein, DNA or RNA in tissue samples from surgical resections with immunopathological and molecular pathological methods in combination with analysis of clinical data. In the present study, we transfected full-length structural sense and antisense KAI1 genes from subclone recombinants into hepatocellular carcinoma MHCC97-H cell line with highly metastatic potential respectively. By observation of the changes of cell growth, invasion and ultrastructures of MHCC97-H before and after KAI1 transfection, we hoped to understand the effects of KAI1 gene on the capability of growth and invasion of hepatocellular carcinoma and to provide experimental evidences for the prevention and treatment of invasion and metastasis of this malignant tumor.

Restriction endonuclease analysis showed KAI1 full-length cDNA was respectively inserted into plasmid vector pCI-neo by two different directions, indicating that sense and antisense KAI1 genes eukaryon expression plasmids were successfully reconstructed. After KAI1 gene transfected into MHCC97-H by DOTAP liposome system, amplification of the neo gene in transfected cells was performed by PCR to confirm whether KAI1 gene was integrated into genomes of target MHCC97-H cells. Neo is a screening marker gene in the vector pCI-neo, and no sequence of this gene exists in the genomes of mammal cells, but it could stably exist in the genomes of mammal cells after transfection. Therefore, if the sequence could be amplified from the genomes of transfected cells by PCR, it could confirm the exogenous genes were integrated into genomes of MHCC97-H cells. PCR results showed sense and antisense KAI1 genes eukaryon expression plasmids were successfully integrated into genomes of MHCC97-H. Western blot and immunocytochemical staining were made to determine if the recombinant plasmids could expectantly express in the transfected cells. The results showed that sense KAI1 could up regulate the expression of KAI1 protein in MHCC97-H as compared with the control parental cells, but antisense KAI1 could down regulate the

expression of KAI1 protein, and no obvious difference between the cells transfected with pCI-neo and the control parental cells was noted. These results showed the transfected genes could produce expected effects, and vector pCI-neo itself had no obvious effects on the expression of KAI1. These suggested that the above cells transfected with genes could be used to explore the effects of KAI1 on the biological behaviors of HCC cells.

In the present study, our data indicated that KAI1 gene had no obvious effects on the *in vitro* cell growth and proliferation of hepatocellular carcinoma MHCC97-H cell line. These results were consistent with the studies in prostatic cancer, colon cancer cells by Dong and Takaoka *et al.*^[2,23]. In contrast with MHCC97-H control parent cells, the plate clone formation ability had no obvious reduction in MHCC97-H-S, but had obvious enhancement in MHCC97-H-AS cells. These data suggested down regulated expression of KAI1 could enhance motricity and aggregative abilities of MHCC97-H. Though the cells transfected with sense KAI1 expressed more KAI1 protein revealed by Western blot and immunocytochemical staining, their plate clone formation ability had no obvious reduction. This may be attributed to the small amount of KAI1 protein expression in MHCC97-H cells.

Invasion has been found to be one of the important and necessary properties for tumor metastasis formation^[24-29]. Boyden chamber assay, which imitates the invasion process of *in vivo* tumor cells, has also been found to be an ideal method for evaluating the invasive and metastatic abilities of tumor cells^[20,22]. Our data suggested that the invasive ability of HCC cells transfected with antisense KAI1 gene was increased, but the invasive ability of HCC cells transfected with sense KAI1 gene was partly inhibited. These indicated that different levels of KAI1 protein expression in HCC cells could affect their invasive and metastatic ability and that it might be an effective route to up regulate KAI1 expression for inhibiting the metastasis of HCC.

Under transmission electron microscope, we found that though KAI1 gene had no obvious effects on cell shape, superficial microvillus, karyotype and karyokinesis of MHCC97-H, sense KAI1 gene transfected into MHCC97-H resulted in reduction of the amount of mitochondria, however antisense KAI1 gene transfection resulted in increase of the amount of mitochondria, RER and Golgi apparatus with expanded endoplasmic reticulum and myelin-sheath-like changes of mitochondria. The biological function of these changes was unknown. It is still necessary to further study whether increased expression of KAI1 can inhibit invasion and metastasis of tumor cells by decreasing products of some organelles.

Though present researches have suggested KAI1 gene is important in preventing the development of metastases in a wide variety of human tumors, the mechanism of KAI1-mediated metastasis suppression remains unclear. The molecular structure of KAI1 protein indicates KAI1 functions in cell-cell interactions and cell-extracellular matrix interactions. These suggest that KAI1 may affect cell-cell adhesion and cell-extracellular matrix adhesion through some signaling pathways to inhibit tumor metastasis^[30,31].

Abstract

AIM: To evaluate the effects of tanshinone II-A on inducing growth inhibition and apoptosis of human hepatocellular carcinoma (HCC) cells.

METHODS: The human hepatocellular carcinoma cell line SMMC-7721 was used for the study. The cells were treated with tanshinone II-A at different doses and different times. Cell growth and proliferation were measured by MTT assay, cell count and colony-forming assay. Apoptosis induction was detected by microscopy, DNA ladder electrophoresis and flow cytometry.

RESULTS: In MTT assay, the inhibitory effect became gradually stronger with the passage of time, 24, 48, 72 and 96 h after treatment with tanshinone II-A, and the most significant effect was observed at 72 h. On the other hand, the increase of doses (0.125, 0.25, 0.5, 1.0 mg/L tanshinone II-A) resulted in enhanced inhibitory effect. The growth and proliferation of SMMC-7721 cells were obviously suppressed in a dose- and time-dependent manner. The results of cell count were similar to that of MTT assay. In colony-forming assay, the colony-forming rates were obviously inhibited by tanshinone II-A. In tanshinone II-A group, the morphology of cellular growth inhibition and characteristics of apoptosis such as chromatin condensation, crescent formation, margination and apoptotic body were observed under light and transmission electron microscopes. DNA ladder of cells was presented in electrophoresis. The apoptosis index (AI) was 16.9% (the control group was 4.6%) in flow cytometry. The cells were arrested in G₀/G₁ phase, and the expressions of apoptosis-related genes *bcl-2* and *c-myc* were down-regulated and *fas*, *bax*, *p53* up-regulated.

CONCLUSION: Tanshinone II-A could inhibit the growth and proliferation of HCC cell effectively *in vitro* by apoptosis induction, which was associated with up-regulation of *fas*, *p53*, *bax*, expression and down-regulation of *bcl-2* and *c-myc*.

INTRODUCTION

Hepatocarcinoma is one of the most common causes of malignancy-related death in China. Its therapy in clinic is a big challenge. New remedial method would possibly depend on advances in basic research^[1]. Recent evidence suggests that apoptosis of cell is closely related to occurrence, progress and metastasis of tumor^[2]. Study on induced apoptosis of tumor cells is an important field of tumor therapy and tumor molecular biology at present. Inducing apoptosis is a new therapeutic target of cancer research. New and promising anticancer drugs could be discovered by studies on apoptosis induction^[3-5]. Tanshinone II-A is an alcohol-extracted product from the root of the traditional Chinese medicine-*Salvia miltiorrhiza* Bunge, which is known to have anti-inflammatory, anti-oxidative and cytotoxic activities^[6-9]. Traditional Chinese medicines considered as potential drug in cancer treatment. Previous studies confirmed that tanshinone II-A could induce differentiation of human cervical carcinoma cell line (ME180) and leukemia cells (NB4, HL60 and K562), reverse malignant phenotype of human hepatocarcinoma cell line (SMMC-7721)^[10-16]. However, there were no studies about growth inhibition and apoptosis induction of tanshinone II-A in hepatocarcinoma cell. In this *in vitro* study, human hepatocarcinoma cell line SMMC-7721 was used. The growth inhibition and apoptosis induction of tanshinone II-A on SMMC-7721 cell were obviously exhibited. We conclude that the effect of growth inhibition of tanshinone II-A on hepatocarcinoma might be related to induction of cellular apoptosis through regulation of apoptosis-associated genes.

MATERIALS AND METHODS

Cell line culture and reagents

Human hepatocellular carcinoma SMMC-7721 cell line was provided by Shanghai Institute of Cancer Research^[17]. The cells were grown in RPMI 1640 (Gibco) supplemented with 100 ml/L fetal bovine serum (Huamei, Chengdu, China), penicillin (100 mg/L) and streptomycin (100 mg/L) in a humidified atmosphere of 50 mg/L CO₂ at 37 °C. Anti-*p53*, *fas*, *c-myc*, *bax* and *bcl-2* antibodies were obtained from Sigma. Other special chemicals were purchased from Sigma (St Louis, MO, USA).

Drugs and treatment

Tanshinone II-A (Tan II-A) was provided by Institute of Traditional Chinese Medicine (concentration 96%). It was dissolved in DMSO (final concentration 0.2 mL/L). The solution was filtered through a 0.22 µm micropore filter and stored at 4 °C.

SMMC-7721 cells were seeded in flasks or dishes. The Tan II-A group was treated with Tan II-A of different doses (0.125, 0.25, 0.5, 1.0 mg/L) for 24, 48, 72 and 96 h, respectively. The control group was added with equal concentration of DMSO

for negative control. The cells were measured after successive 96-h treatment.

MTT assay

SMMC-7721 cells were seeded in 96-well microtitre plates with 1×10^3 per well and incubated for 24 h in 100 μ L culture media. Then the cells were treated with 0.125, 0.25, 0.5, 1.0 mg/L of Tan II-A in the experimental group for 24, 48, 72, and 96 h respectively. MTT 100 μ L (5 g/L) was added to the cells and cultivated for another 4 h. After the supernatant fluid was removed, DMSO 100 μ L per well was added to the cells and shaken for 15 min. The absorbance at 570 nm was measured by an ELISA reader. At the same time, the SMMC-7721 cells without treatment were served as control. Each assay was repeated three times.

Cell count

SMMC-7721 cells were treated with Tan II-A (0.125, 0.25, 0.5, 1.0 mg/L) for 96 h, respectively, then condition of the cell growth was observed under an inverse and light microscope. Number and viability of the cells were assessed by trypan blue exclusion.

Cell colony-forming assay

Cells were seeded in a 6-well plate with 300 cells per well. After 24 h, the cells were treated with Tan II-A (0.125, 0.25, 0.5, 1.0 mg/L), and cultured in routine medium for 10 days continually. Then the cells were fixed by methanol, Giemsa staining. Finally, the sum of colony per group was counted. The inhibiting rate of colony-formation was calculated.

Light and transmission electron microscopy

SMMC-7721 cells were treated with DMSO (control group) or 0.5, 1.0 mg/L Tan II-A for 48 h. The cells were gently washed with serum-free medium, and observed by inverse and light microscopy after Giemsa staining. On the other hand, some other cells were fixed with 25 g/L glutaraldehyde in 0.1 mol/L of sodium cacodylate buffer, osmicated with 10 g/L osmium tetroxide, then cell block was stained, dehydrated in graded ethanol, infiltrated with propylene oxide, and embedded overnight and incubated in a 60 °C oven for 48 h. Silver sections were cut with an Ultracut E microtome, collected on a formvar and carbon-coated grid, stained with uranyl acetate and Reynold's lead citrate, and examined under a transmission electron microscope to identify the morphological changes of apoptosis.

DNA ladder detection

After induction of apoptosis, the cells (1×10^6 /group, both attached and detached cells) were washed by PBS, and fixed in ice-cold 700 mg/L ethanol for 24 h. After the ethanol was removed, the cells were rinsed in 0.2 mol/L Na_2HPO_4 and 0.1 mol/L citric acid (192:8, pH 7.8) for 60 min at room temperature. After being centrifuged (10 000 g), the supernatant was collected in Eppendorf tubes, 2.5 g/L NP-40 and 10 g/L RNase A were added at 37 °C for 30 min, then Protein K (1 g/L, Promega) was added at 50 °C for 30 min. Equal quantity of DNA was electrophoresed in 15 g/L agarose gels and stained with ethidium bromide (5 mL/L) for 2 h at 80 V. Ladder formation of oligonucleosomal DNA fragmentation was detected under ultraviolet light.

Flow cytometry measurement

The sample preparation and measurement followed the method described in reference^[15]. The cells were harvested, counted and fixed. The cell concentration was adjusted to 10^6 /mL. According to the routine method, cell frequency distribution of each phase in cell cycle was measured. Cellular *fas*, *p53*, *bax*, *bcl-2* and *myc* gene expressions were detected by immunohistochemical method on FACS-420 FCM. The results were shown with scanning figure and date.

Statistical analysis

Data were presented as the mean \pm SD error of the mean. Student's *t* test was used for comparison among different groups. A *P* value of less than 0.05 is considered statistically significant.

RESULTS

Cell growth and proliferation

Tan II-A exhibited a statistically significant dose-dependent growth-inhibitory effect on SMMC-7721 cell evaluated by MTT assay. The inhibiting rates of cell growth were 12.2%, 30.6%, 52.4% and 82.5%, respectively when treated with Tan II-A of different doses (0.125, 0.25, 0.5, 1.0 mg/L) for 96 h (Figure 1A). Moreover, the growth-inhibitory effect of Tan II-A on the cells was found to be time-dependent. The inhibiting rates were 12.5%, 38.2%, 47.6% and 58.7%, respectively when treated separately for 24, 48, 72 and 96 h with 0.5 mg/L of Tan II-A (Figure 2B). The inhibitory effect became gradually stronger with the passage of time after treatment, and the most significant effect was observed at 72 h. The cell growth and proliferation were obviously inhibited in a dose- and time-dependent manner. The same inhibitory effect was found by cell count. In colony-forming assay, the colony-forming rates of SMMC-7721 cell were 11.6%, 22.5%, 38.5%, 42.2% in Tan II-A group and 68.2% in control group, respectively, suggesting the obviously inhibiting effect of Tan II-A on cell proliferation.

Figure 1 Growth-inhibitory effect of Tan II-A on SMMC-7721 cells detected by MTT. A: In a dose-dependent manner detected by MTT; B: In a time-dependent manner detected by MTT.

Morphological changes of apoptosis

As shown in Figure 2, Tan II-A-induced morphological changes were evident by 72 h of treatment in SMMC-7721 cell. Roundish, large and serried cells (in control group, Figure 2A) became polygonal, small, detached or sparse, membranous frothed and wizened (Tan II-A group, Figure 2B) in the dishes under light microscope. The ultrastructural characteristics of apoptosis such as chromatin condensation, crescent formation, margination and apoptotic bodies were observed by electron microscopy in the Tan II-A group (Figure 3), which were more obvious in the given experimental period than that in the control group.

DNA fragments

Agarose gel electrophoresis exhibited DNA ladder formation in SMMC-7721 cell after exposed to different concentration of Tan II-A for 96 h. Compared with control, the DNA ladder was

Figure 2 Morphological characteristics of SMMC-7721 cells before and after Tan II-A treatment. A: Roundish, large and serried SMMC-7721cells (in control group); B: Polygonal, small, detached or sparse, membranous frothed and wizened SMMC-7721cells (in Tan II A group).

more clearly observed by treatment with 0.5, 1.0 and 2.0 mg/L Tan II-A, while the DNA fragment induced by 0.125, 0.25 mg/L Tan II-A was not clear (Figure 4).

Figure 3 Ultrastructural changes of SMMC-7721 cells with 1.0 mg/L Tan II-A treatment for 96 h under TEM ($\times 10\,000$). The chromatin condensation, original margination were observed.

Figure 4 DNA agarose gel electrophoresis of SMMC-7721 cells with Tan II-A treatment for 96 h. Lane 1: Marker, Lane 2: Control, Lane 3: 2.0 mg.L⁻¹, Lane 4: 1.0 mg.L⁻¹, Lane 5: 0.5 mg.L⁻¹.

Figure 5 Flow cytometry analysis of apoptosis in SMMC-7721 cells treated with Tan II-A (A) and DMSO (B).

Cell cycle effect

In order to determine the effect of Tan II-A on proliferation and apoptosis in SMMC-7721 cell, the cells were exposed to 0.5 mg/L Tan II-A for 96 h. Cell cycle distribution, cell proliferation and apoptotic damage of DNA were determined on a flow cytometer. The result showed the accumulation of cells in G₀/G₁ and a corresponding reduction in percentages of cells in S and G₂/M phase, and decreased proliferation index (PI). The cells in sub-G₁ phase were increased. An apoptotic peak was detected (Table 1, Figure 5)

Table 1 Effect of Tan II-A on cell cycle distribution and apoptosis in SMMC-7721

Group	Cell cycle distribution (%)			PI %	AI %
	G ₀ /G ₁	S	G ₂ /M		
Control	71.3±2.3	9.8±0.6	18.9±1.6	28.7±2.6	4.9±0.4

χ^2 test, ^b $P < 0.01$ vs control group.

Apoptosis-associated genes expression

The expressions of apoptosis associated genes *fas*, *bax*, *p53* were up-regulated. The expressions of *bcl-2* and *c-myc* were

down-regulated (Table 2). The tabulated percentages were an average calculated on the results of three separate experiments. The values were presented as mean \pm SE ($n=3$).

DISCUSSION

Cellular proliferation and apoptosis in normal tissue maintain a balance. Unlimited growth and proliferation, but blocked apoptosis are main characteristics of malignant tumor cell. So inhibiting proliferation by apoptosis induction of cancer cell is a new method for cancer control and therapy^[18-20].

On the basis of previous studies, we chose different concentrations of non-cytotoxic Tan II-A to study Tan II-A induced-apoptosis *in vitro*. MTT, cell count assay and colony-forming assay showed that 0.25, 0.5, 1.0 mg/L Tan II-A obviously inhibited the growth and proliferation of SMMC-7721, and the inhibiting effect was in a dose- and time-dependent manner. The most significant effect was observed at 72 h by 1.0 mg/L Tan II-A. Flow cytometer showed that Tan II-A produced significant cell cycle arrest in G₀/G₁, decreased proliferation index (PI) as evidence of an antiproliferation effect. The cellular growth and inhibition could be observed by morphology. The morphological characteristics of cellular growth inhibition were also observed under light microscope. Our results demonstrated that Tan II-A inhibited growth and proliferation of SMMC-7721 cells^[21,22].

Apoptosis, or programmed cell death, has an essential role in controlling cell number in many developmental and physiological settings and in chemotherapy-induced tumour-cell killing. The execution of apoptosis may be initiated by many different signals, either from within or outside the cell involving ligand-receptor interactions, as has been shown for Fas/Fas-ligand, or potentially by more unspecific signals such as DNA damage. During the modulation phase of apoptosis many different genes such as *p53*, *c-myc* or *Bcl-2/Bax* have been shown to be able to shift the balance either to cellular proliferation or death. Cellular growth and proliferation are closely related to apoptosis^[23-25].

The detection of apoptotic cell by microscopy is based on several well-established morphological features. These features include condensation of chromatin and cytoplasm as well as fragmentation of the cells that lead to the appearance of membrane bound apoptotic bodies^[26]. Those ultrastructural characteristics apoptosis, the DNA ladder and increased cells in sub-G₁ phase were observed in SMMC-7721 cells treated with 0.5, 1.0 mg/L Tan II-A.

Apoptosis-associated genes play a major role in apoptosis, participating in the initiation and progress of programmed cell death. *Bcl-2* has been identified as an apoptosis inhibitor, and shown to cooperate with *c-myc* in immortalizing cells. Under certain conditions, constitutive expression of *c-myc* induces apoptosis and can be suppressed by *bcl-2*. It appears that the *c-myc* cooperating oncogenic activity of *bcl-2* is related to its inhibition of apoptotic pathways^[26]. Bax protein inhibits the function of *bcl-2* leading to increased apoptosis.

The tumor suppressor gene *p53*, a transcription factor, has been identified as a participant in the cellular DNA damage response. Upon DNA damage, *p53* up-regulation causes G₁ arrest. The apoptosis promoting capacity of *p53* is presumably due to its ability to activate *bax*, a gene that encodes an inhibitor of *bcl-2*. Fas (CD95/APO-1) is a death-promoting receptor that belongs to the tumor necrosis factor (TNF) receptor family, and induces apoptosis through different ways^[27].

In the present study, we observed down-regulation of *bcl-2* and *c-myc* expression, which is in keeping with the role of *bcl-2* in blocking apoptosis and *c-myc* in promoting proliferation. At the same time, the expressions of apoptosis

associated genes *fes*, *bax*, *p53* were up-regulated. These suggested that *Bcl-2*, *c-myc*, *fes*, *bax* and *p53* were involved in apoptosis of hepatocarcinoma cells induced by Tan II-A. Parts of these mechanisms were related to inhibition of cell growth. Some results of our study on inducing apoptosis in human hepatocellular carcinoma cell are consistent with other researches^[28].

Tan II-A inhibits growth and proliferation of hepatocarcinoma cells by inducing apoptosis. Tan II-A might have different mechanisms in inducing apoptosis and inhibiting proliferation of cancer cells. Other possible mechanisms of the action of Tan II-A need to be further investigated. We consider that Tan II-A could be a new prospective, highly effective and low toxic anticancer drug.

Abstract

AIM: To express chimeric Fd (cFd) and chimeric light chain (cL) in *E.coli* respectively and refold them into chimeric Fab (cFab) antibody.

METHODS: cFd and cL genes were respectively inserted into the prokaryotic expression vector pET32a to construct recombinant vectors pET32a/cFd and pET32a/cL. Then, the competent *E.coli* cells were transformed by the recombinant vectors and induced by IPTG. Moreover, a large quantity of cFd and cL expression products were prepared and mixed with equal molar to refold into cFab by gradient dialysis. The refolded products were identified and analyzed by sodium SDS-PAGE, Western blotting, ELISA and HPLC.

RESULTS: High efficient prokaryotic expressions of both cFd and cL in the form of non-fusion protein were obtained with the expression levels of 28.3% and 32.3% of total bacteria proteins, respectively. Their relative molecular masses were all 24 ku or so, and both of them mainly existed in the form of inclusion bodies. In addition, cFd and cL were successfully refolded into cFab by gradient dialysis, with about 59.45% of recovery when the starting total protein concentration was 100 µg/mL. The renatured cFab could specifically bind to related antigen with high affinity.

CONCLUSION: The cFab antibody against human hepatoma was highly and efficiently expressed and refolded, which laid a solid foundation for studying its application in the treatment of hepatoma.

INTRODUCTION

The advent of monoclonal antibody (mAb) greatly promotes

application of antibodies in various fields^[1]. However, due to immunogenicity and comparatively high molecular mass, mouse derived complete antibody was more or less limited in the application of disease diagnosis and treatment^[2]. The cFab antibody is about 50 ku, only 1/3 of full-length IgG. Because of good penetrating ability, better characteristics of pharmaceutical kinetics and good antigen-binding activity, cFab antibody has been used more and more widely^[3-5]. Compared with complete antibody, the cFab has no Fc fragment so that non-specific binding is decreased greatly. In addition, the cFab could not produce antibody-dependent cellular cytotoxicity (ADCC) and complement-dependent cytotoxicity (CDC), so it was mostly used as the carrier for targeted delivery of drugs^[6]. It could also be further reconstructed into engineering cF(ab)₂ antibody^[7]. In this paper, based on cloned V_H and V_L genes of mAb HAb18 against human hepatoma^[8], we expressed cFd and cL in *E.coli* in the form of non-fusion protein and refolded them into cFab antibody. It was expected that a practical protocol could be established for the preparation of a large quantity of cFab against human hepatoma, which would lay a solid foundation for further studies of its application in hepatoma treatment.

MATERIALS AND METHODS

Materials

The pComb3/cFab vector containing cFd and cL genes of mAb HAb18 was previously constructed in our laboratory. Prokaryotic expression vector pET32a (+) and competent *E. coli* JM109(DE3) were purchased from Novagen Inc (USA). T vector, PCR reagents, restriction endonucleases and T4 DNA ligase were from Takara Inc. (DaLian, China). The mAb HAb18, chimeric IgG antibody chHAb18 and HRP-HAb18 were previously prepared in our laboratory. IPTG, FITC-labeled and HRP-labeled goat anti-human IgG were from SABIC Inc. (Luo Yang, China). Protein G affinity column was purchased from Pharmacia Inc (USA). Hepatoma cell line HHCC was from ATCC (Shanghai, China).

Primer design and synthesis

According to gene sequences of HAb18 cFd and cL which were previously constructed in our laboratory, PCR primers were designed by computer software Primer Premier 5.0, and relative restriction endonuclease sites were introduced into primers for the construction of prokaryotic non-fusion expression vectors of cFd and cL. All PCR primers were synthesized by Sheng Gong Inc. (Shanghai, China), and their sequences were as follows: cFd back: 5' GCGGAATTCATATGGTTAAGCTTGAAGAGTCTGGAGGAGGCTT 3'; cFd forward: 5' GGGGTCGACTCATTAAGTAGTTTGTGTCACAAGATTTGGGCT3'; cL back: 5' GCGGAATTCATATGAGTATTGTGATGACCCAGACTCCCA3'; cL forward: 5' GGGCCTCGAGTCATTAACATTCACCTCTGTTGAAGCTCT3'. Underlined sequences are restriction sites *Nde* I, *Sal* I and *Xho* I.

Construction of expression vectors

With the vector pComb3/cFab as template, cFd and cL genes were amplified using related primers. The PCR products were

purified by gel extraction. Then, the plasmid pET32a (+) and PCR amplified cFd or cL gene were digested by a pair of restriction endonucleases *Nde* I and *Sal* I or *Nde* I and *Xho* I. After the corresponding target fragments were purified by gel extraction, ligation, transformation and screening of the positive clones containing the recombinant vector pET32a/cFd or pET32a/cL were sequentially conducted. Finally, recombinant vectors were identified by restriction endonucleases digestion and DNA sequencing was completed by Shenggong Inc. (Shanghai, China).

Small-scale expression by IPTG induction

The *E. coli* cells containing pET32a/cFd or pET32a/cL or pET32a (+) were respectively inoculated with 1:100 into 5 mL LB medium containing ampicillin (100 µg/mL). When absorbance of $A_{600\text{ nm}}$ was up to 0.8 or so, 1 mL *E. coli* cultures were obtained for further assay. Then, IPTG was added to left cultures with 1 mmol/L of final concentration and another 10 h induction of expression (250 r/min, 37 °C) was conducted. After being treated by boiling and centrifugation, all *E. coli* samples after and before induction were loaded onto 120 g/L SDS-PAGE gel for further analysis. At the same time, Western blotting was done by HRP-labeled goat anti-human IgG (H+L). In addition, *E. coli* cells containing pET32a/cFd and pET32a/cL after induction were collected and treated by repeated freezing and thawing. Then, the location of expression products was investigated by SDS-PAGE.

Renaturation of cFab antibody

A total of 500 mL cultures of *E. coli* containing pET32a/cFd or pET32a/cL were induced for the protein expression under the same condition as mentioned above. Inclusion body was isolated and solubilized by 8 mol/L urea^[9]. The total protein concentration was determined by bicinchoninic acid (BCA) assay^[10] and the expression percentages of cFd and cL were evaluated by SDS-PAGE. cFd and cL dissolved in urea were mixed with equal molar, and the total protein concentration was adjusted to 100 µg/mL by adding the lysis solution. Renaturation was conducted by gradient dialysis as described by Lee *et al.*^[11]. The renatured products were centrifuged, and the supernatant was collected, then the precipitation was dissolved in the lysis solution again. Protein recovery was determined by BCA assay. Single cFd and single cL were set as control at the same refolding condition when cFab was renatured. All samples above were detected by SDS-PAGE, Western blotting and HPLC.

Effect of total protein concentration on renaturation of cFab antibody

After the total protein concentration was respectively adjusted to 200 µg/mL and 400 µg/mL, cFab antibody was renatured according to the method described above. The protein concentration of all samples was detected by BCA assay and protein recovery was evaluated. In addition, all samples were loaded onto SDS-PAGE gel for further analysis.

Purification of renatured cFab antibody

After dialysis in PBS overnight at 4 °C, renatured cFab was purified by protein G affinity chromatography according to manufacturer's protocol.

Detection of antigen-binding activity of purified cFab antibody

Indirect ELISA GST-HAb18GE, GST-fusion expression product of extracellular region of HAb18G^[12] was the antigen of mAb HAb18, and the purified GST expression products were coated on the ELISA plates for detecting the antigen-binding activity of purified cFab antibody. Detailed protocol was described by Yan *et al.*^[13].

Competitive binding assay GST-HAb18GE was coated on

ELISA plates overnight at 4 °C. After blocking, the mixture of HRP-HAb18 (0.1 mg/L) and gradiently diluted cFab was added into ELISA plates. After incubation for 1 h at 37 °C, the unbound antibody was washed away by PBST, followed by TMB staining. Finally, A_{450} was detected by an ELISA plate reader (Bio-Rad, USA), and inhibition rate and comparative affinity were determined according to the following method: Inhibition rate (%) = $[(A_{450} \text{ of control group} - A_{450} \text{ of experimental group}) / A_{450} \text{ of control group}] \times 100\%$; comparative affinity (%) = $[\text{concentration of cFab when inhibition rate is } 50\% / \text{concentration of HRP-HAb18}(0.1 \text{ mg/L})] \times 100\%$.

FACS detection The single-cell suspension of hepatoma cell line HHCC overexpressing HAb18G was prepared. The cell density was adjusted to $5 \times 10^9 - 1 \times 10^{10}$ /L. HAb18 cFab diluted with horse serum was added into 50 µL HHCC single-cell suspension. Then, the mixture was incubated for 30 min at 4 °C. After washed twice by PBS, FITC-labeled rabbit anti-human IgG was added and the reaction mixture was incubated for 30 min at 4 °C. Then, washing and detecting were performed. In this assay, human IgG was set as negative control and PBS was set as blank control.

RESULTS

Construction of recombinant expression vectors

cFd and cL genes were successfully amplified using designed primers. Agarose gel electrophoresis showed that the sizes of cFd and cL genes were about 700 bp and 680 bp, respectively (lanes 2,5, Figure 1), which was in accordance with their expected sizes. The recombinant vectors pET32a/cFd and pET32a/cL digested by restrictive endonucleases (Figure 1) indicated that cFd and cL genes were correctly inserted into corresponding cloning sites. The results of DNA sequencing (results not provided) proved that cFd and cL genes inserted in expression vector had no base mutation and the codon reading frame was completely exact.

Figure 1 Analysis of recombinant non-fusion expression vectors pET32a/cFd and pET32a/cL digested by restrictive endonucleases. 1: DNA marker; 2: cFd; 3: pET32a/ *Nde* I + *Sal* I; 4: pET32a/ cFd/ *Nde* I + *Sal* I; 5: cL; 6: pET32a/ cL/ *Nde* I + *Xho* I; 7: pET32a/ cL/ *Nde* I + *Xho* I; 8: DNA marker.

Expression induction and identification of cFd and cL

SDS-PAGE (Lanes 1-7, Figure 2) showed that a 21-ku new protein was expressed in *E. coli* transformed by control vector after induction, which is in accordance with the expression characteristics of the control vector, and that the recombinant cFd and cL with the same molecular weight of 24 ku were also successfully expressed after induced by IPTG. Scanning analysis by Smartview software indicated that the quantities of expressed cFd and cL were about 28.3% and 32.3% of the total bacterial protein, respectively. Western blotting (Lanes A-D, Figure 2) identified that both expressed cFd and cL were able to bind to anti-human IgG and the staining bands were at 24 ku. In addition, SDS-PAGE showed that the interested expression products existed in the form of insoluble inclusion body (Figure 3).

Renaturation of cFab antibody

The total protein concentrations of inclusion body solution in 8 mol/L urea containing cFd or cL determined by BCA assay were respectively 12.04 mg/mL and 9.66 mg/mL. The results (not provided) of SDS-PAGE analysis indicated that cFd and cL were up to 49.8% and 58.3% in the total protein of inclusion body solution, respectively. SDS-PAGE (Figure 4, lanes 1-7) also showed that the new 45-kDa protein band appeared under nonreduced condition after cFd and cL were mixed to refold. Western blotting (lanes A, B, Figure 4) also identified that the new protein bands could bind to anti-human IgG under reduced and nonreduced conditions. The recovery rate was about 75% when the starting concentration of total protein was 100 μ g/mL. In addition, when the starting total protein concentration was separately increased to 200 μ g/mL and 400 μ g/mL, recovery rate was respectively decreased to 70.5% and 61%. SDS-PAGE (Figure 5) demonstrated that precipitation rose rapidly with the increase of starting total protein concentration, and the percentage of elevated precipitation was more than that of increased starting total protein concentration. HPLC analysis (Figure 6) showed that two new elution peaks (1) and (2) emerged after cFd and cL were mixed to refold in comparison with single refolded cFd and cL. The largest absorbance value of elution peak (2) was at 260 nm, so it was possible that elution peak (2) was not protein peak. In addition, the position of elution peak (3) was the same as elution peak (4) of refolded cFd and elution peak (5) of refolded cL. ELISA (result not provided) demonstrated that only elution peak (1) had specific antigen-binding activity. The peak areas of elution peak (1) and (3) were 33.49% and 17.75%, respectively. Renaturation yield of cFab antibody was about 49% determined by the method described previously.

Figure 6 HPLC of cFd, cL and cFab after renaturation.

Analysis of antigen-binding activity of purified cFab antibody

cFab 1 mL (80 μ g/mL) was purified by protein G affinity chromatography. Indirect ELISA (Figure 7) showed that cFab was capable of specific binding to HAb18GE and the antigen-binding activity became higher with increasing concentration of cFab antibody. Competitive ELISA (Figure 8) indicated that the refolded cFab could competitively bind to the same antigen epitope as parental mouse antibody HAb18 and the binding ability improved with the increase of cFab antibody concentration. The affinity of cFab was evaluated to be 10% of parental mouse antibody HAb18 according to the concentration ratio of cFab and HAb18 when inhibition rate was 50%. FACS detection (Figure 9) demonstrated that cFab could bind specifically to hepatoma cell line HHCC and the binding capacity increased with the elevation of cFab antibody concentration.

DISCUSSION

In a previous study, we successfully expressed cFab antibody gene in the periplasmic compartment of *E. coli*. However, the productivity was rather low. So, we tried to improve the expression level of cFab. We separately expressed cFd and cL without signal peptide in cytoplasm of *E. coli* in the form of inclusion body. The expression levels of different fragment of antibody genes in *E. coli* were greatly diverse, which mainly depended on the design of translation initiation site, the type of antibody fragment, antibody gene sequence, sensitivity to proteases of expression products and the class of host

bacterium, *etc*^[14]. But high efficient expression of antibody genes was relatively easy to be obtained using prokaryotic expression vector. We successfully constructed recombinant vectors pET32a/cFd and pET32a/cL by cloning cFd and cL genes into the pET32a expression vector, and achieved high expression level of cFd and cL in *E. coli*. The expression products mainly existed in the form of the inclusion body, with 28.3% and 32.3% of expression percentages of total bacterial protein, respectively. Expression proteins in inclusion body could avoid being digested by proteases and were easy to be isolated and purified. cFd and cL must be refolded together in order to get active cFab.

As we know, effectively promoting the correct formation of intramolecular or intermolecular disulfide bond and inhibiting the formation of aggregation were key to protein renaturation^[15]. In order to promote the refolded protein to form the correct disulfide bond, some reducers, such as β-sulfhydryl ethanol and DTT, were added into detergent solution to unfold wrong disulfide bonds of expression proteins in inclusion body. These wrong disulfide bonds might be formed during the lysis of host bacterium or during the resolving process of expression protein. When the protein was renatured, correct disulfide bonds could be reformed only by air oxidation^[16]. In most cases, iron can promote the process of air oxidation^[17]. In addition, the repeated formation and unclosing of the disulfide bonds may increase the probability of obtaining protein with correct conformation. This process could be facilitated by some enzymes (such as disulfide isomerase)^[18] or oxidation-reduction response caused by the oxidation- and reduction-type sulfhydryl mixture^[17] (such as glutathione). During the renaturation, the formation of aggregation was the most common reason resulting in lower renaturation efficiency. However, the mechanism of aggregation formation is still unclear. De Bern ardez Clark *et al.*^[19] suggested that the hydrophobic action among protein molecules was the most likely explanation for the aggregation formation facilitated by the formation of wrong disulfide bonds. In the experiment of mixed protein renaturation involving two or more proteins, small aggregation was first caused by the hydrophobic action, and then by the disulfide bonds formation from unpaired cystines that resulted in the formation of big heterogeneous aggregation. The formation of large quantities of aggregation would result in more protein precipitation, therefore, renaturation efficiency decreased greatly^[11]. The previous study on renaturation also showed that arginine, a kind of stable reagent promoting protein dissolving during renaturation, could facilitate the correct folding of proteins possibly by inhibiting the formation of bigger aggregation^[20].

In this study, we mixed cFd and cL with equal molar. The detergent was slowly removed from the mixture by gradient dialysis in the presence of a given concentration of arginine, while glutathione was added into the mixture to delete wrong reduced disulfide bonds. The results showed that this strategy for renaturation was successful. At the starting total protein concentration of 100 μg/mL, cFd and cL were refolded into cFab with 75% of protein recovery rate. Protein loss was mainly due to protein precipitation and adsorption onto dialysis belt. Replacing dialysis materials could reduce the latter loss. We identified the renatured cFab by SDS-PAGE, Western blotting and ELISA. The results proved that cFd and cL were successfully refolded into cFab. SDS-PAGE indicated that the molecular weight of renatured cFab was about 45 ku under the unreduced condition, less than 48 ku (cFd+cL), which revealed that the formation of intramolecular disulfide bond happened in the renatured protein^[15]. HPLC of renatured products revealed that the renatured cFab produced two very different elution peaks. ELISA demonstrated that only elution peak (1) had antigen-binding activity. In addition, the biggest absorbance value of elution peak (2) was at 260 nm, which

revealed that elution peak (2) might be nuclear acid existing in inclusion body. It was estimated by HPLC that the renaturation efficiency was up to 49%, which was quite desirable in comparison with the generally 10–40% of renaturation efficiency for antibody protein. The desirable renaturation efficiency was mainly explained by good renaturation strategy and special antibody sequences, which are in accordance with the viewpoint of Wibbenmeyer *et al.*^[21]. It was also estimated that dozens of milligrams of active cFab could be gained from 1 L of *E. coli* cultures under the experimental condition described above. Therefore, further optimizing the preparation protocol can increase the yield.

When preparing a large quantity of active protein by dialysis renaturation method, another important influence factor must be taken into consideration, namely the volume of renaturation protein solution. The speed of protein aggregating and precipitating was positively correlated with the protein concentration, so protein precipitation would be predominant course when protein concentration was up to the highest point. As a result, the starting total protein concentration was generally very low, which would inevitably result in excessively large sample volume to be dealt with otherwise more troubles would arise. In this study, in order to explore the optimal renaturation condition of preparing a large quantity of cFab antibody, we increased the starting total protein concentration for renaturation to 200 µg/mL and 400 µg/mL, respectively, and investigated the renaturation efficiency after the protein concentration was increased. The results revealed that protein precipitation promptly increased with the increase of starting protein concentration, and increased percentage was more than that of protein concentration increase, which indicated that a part of renaturation efficiency was surely sacrificed in order to reduce the treatment volume and increase the speed of preparation during the large-scale production of cFab.

In conclusion, we successfully obtained cFab antibody with good activity by prokaryotic expression technique, followed by dialysis, which laid a solid foundation for further application in hepatoma treatment. In addition, based on this achievement, we are planning to modify cFab genes to produce another kind of more useful engineering antibody, bivalent chimeric F(ab')₂^[22]. It is expected to replace murine-derived F(ab')₂ antibody produced by protease digestion, and reduce clinical cost and improve therapeutic efficacy.

Abstract

AIM: To investigate the expression of cancer-testis (CT) antigens *MAGE-1*, *SSX-1*, *CTp11* and *HCA587* genes in hepatocellular carcinoma (HCC) and the possibility of applying these antigens as targets for specific immunotherapy for HCC.

METHODS: Expression levels of *MAGE-1*, *SSX-1*, *CTp11* and *HCA587* mRNA were detected with reverse transcription polymerase chain reaction (RT-PCR) in HCC tissues and corresponding adjacent non-cancerous tissues from 105 HCC patients, 40 samples of cirrhosis and normal liver tissues. Genes of five samples with positive PCR results were sequenced.

RESULTS: Of 105 HCC tissues, *MAGE1*, *SSX-1*, *CTp11* and *HCA587* mRNA expressions were detectable in 75.2%(79/105), 72.4%(76/105), 62.9%(66/105) and 56.2%(59/105) of HCC samples, respectively. About 93.3%(98/105), 72.4%(76/105), 48.6%(51/105) and 37.1%(39/105) of HCC tissues positively expressed at least one, two, three, and four members of CT antigens, respectively. Conversely, only *SSX-1* could be detectable in 2.9%(3/105) of the corresponding adjacent non-HCC tissues in which no metastatic lesion was found. Of the latter 3 patients, biopsy samples far from tumor were obtained in 2 patients and RT-PCR indicated no expression of *SSX-1* mRNA in these two samples. In addition, none of 40 samples of cirrhotic and normal liver tissues expressed CT antigen gene mRNA. DNA sequences confirmed that the RT-PCR products were true target cDNA. No relationship was found between expression of CT antigens and clinico pathological indicators such as age, gender, tumor size, degree of tumor differentiation, serum α -fetoprotein level and infection of hepatitis B virus or hepatitis C virus ($P>0.05$).

CONCLUSION: CT antigens genes (*MAGE-1*, *SSX-1*, *CTp11* and *HCA587*) are expressed with high percentage and specificity in HCC and their products are promising targets for antigen-specific immunotherapy of HCC. High frequent co-expression of multiple members of CT antigens in HCC

provides possibility of polyvalent vaccinations for HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a common tumor with a poor prognosis, irrespective of a variety of treatment options^[1,2]. So, there is a need to develop additional therapeutic approaches for the management of this disease. A proposed strategy is immunotherapy, which has the potency to eradicate systemic tumor cells in multiple sites in the body and the specificity to discriminate between neoplastic and non-neoplastic cells^[3,4]. Genes or antigens, which are either exclusively or preferentially expressed in malignant tissues, are a prerequisite for antigen-specific cancer immunotherapy^[4,5].

Recently, the integration of molecular and immunological techniques has led to the identification of a new category of tumor-specific antigens called cancer-testis (CT) antigens, such as MAGE superfamily, SSX family, GAGE, BAGE, SCP-1, NY-ESO-1, CTp11 and HCA587^[6,7]. The CT antigens share several distinct features including: (1) CT antigen mRNA is expressed predominantly in tumors of different origins with various frequencies but not in normal tissues except for testis; and (2) the genes encoding CT antigens locate at the X chromosome^[8,9]. The combination of CT antigen peptides and human leukocyte antigen (HLA), when efficiently presented by antigen presenting cells to cytotoxic T lymphocytes (CTL), is capable of eliciting cellular immune responses in cancer patients^[10,11]. Also, some members of CT antigens are capable of inducing humoral immunity^[12,13]. Both cellular and humoral immune response can kill tumor cells specifically. The testis is an immune privileged organ because spermatogenic cells do not express HLA class I antigen at their surface. Concomitantly, the testis has a so-called blood-testis barrier, which limits contact between testicular and immune cells, in the seminiferous tubuli generated by the Sertoli cells^[7,14]. Because of these features, CT antigens have the potential to provide specific antitumor immunity directly to malignant cells without harm to normal cells. At present, the application of tumor antigenic peptide vaccine based on CT antigens for cancer immunotherapy has become a hot spot^[15,16].

The screening of tumor antigens recognized by autologous cytotoxic T cells led to the isolation of *MAGE-1*, which has been identified as a member of *MAGE-A* genes family^[17]. Clinical trials targeting *MAGE-1* antigen are in progress for malignant melanoma and have shown favorable curative effect^[18,19]. *SSX* genes and *HCA* genes were originally identified using serological analysis of recombinant cDNA expression libraries (SERAX). SEREX was to define B cell epitopes in antigens that were specifically recognized by antibodies in cancer sera, suggesting that *SSX* and *HCA* antigens were immunogenic and capable of inducing an antibody response^[6,20]. In a recent report, Li *et al.* have proved HCC patients were able to develop humoral immune response to HCA587 antigen. Based on representational difference analysis of cDNA, Zendman *et al.*^[21]

first identified the expression of *CTp11* in melanoma cell lines. In another study (unpublished data), our group predicted HLA-A2-restricted CTL epitopes of *CTp11* by peptide supermotif prediction combined with quantitative motif^[22,23] and found the potential HLA-A2-restricted CTL epitopes of *CTp11* antigen (*HLA-A2* is the most common *HLA-A* allele in Asian population, especially in Chinese, with an estimated frequency of more than 50%^[24,25]), suggesting the possibility of *CTp11* antigen to trigger cellular immunity and a new potential vaccine candidate for HCC immunotherapy.

Several studies reported high frequent expression of CT antigens in the HCC tissues, such as *MAGE-1*^[26,27] and *SSX-1*^[4,28]. However, the expression of CT antigens is heterogenous in a variety of human tumors, which may be a way for malignant cells to evade from immunosurveillance^[7,29-31]. Screening highly and specifically expressed multiple CT antigens in tumors and using them as targets for immunotherapy are promising means to overcome the heterogenous expression of tumor cells, thus expanding patients' opportunities for cancer specific immunotherapy and establishing the basis of polyvalent vaccinations^[29].

In an effort to improve the efficiency of tumour vaccines and prevent immune escape, we investigated the expression of CT antigens *MAGE1*, *SSX-1*, *CTp11* and *HCA587* in HCC tissues.

MATERIALS AND METHODS

Data of patients

From October 2000 to September 2003, 105 patients receiving operation for HCC, including hepatectomy or orthotopic liver transplantation, at the 2nd Hospital of Peking University Health Science Center, were enrolled in this study. There were 90 men and 15 women with a mean age of 47.2±8.4 years (range 18-75). The hepatitis B surface antigen was positive in 98 cases. Among 105 cases, anti-HCV was positive in 5 cases. The serum α -fetoprotein (α -FP) level was normal (<20 ng/mL) or elevated slightly (<40 ng/mL) in 35 patients. Histopathological examination indicated that 18 HCC samples were well differentiated, 61 moderately and 26 samples poorly differentiated, respectively. According to TNM classification of the International Union Against Cancer^[32], there were 13 cases at stage I, 30 at stage II, 12 at stage III and 50 at stage IV, respectively. Seventy-nine patients had large-sized tumors (>5 cm), while the tumor size of the other 26 patients was equal to or less than 5 cm (\leq 5 cm). The control samples included 20 tissues from cirrhosis patients and 20 normal liver tissues from patients without liver disease by surgical biopsy. Testis tissues (kindly provided by Urological Department of the 2nd Hospital of Peking University Health Science Centre) were used as the positive control. Each sample was immediately frozen in liquid nitrogen after a surgical resection and stored at -80 °C until the extraction of total RNA. Informed consent was obtained from each patient before the study was conducted. The Ethic Committee of Peking University approved the study protocol.

Total RNA extraction and synthesis of cDNA

Total RNA was extracted from frozen tissue specimens (50-100 mg) using TRIzol reagent (GIBCOL BRL) according to the protocol provided by the manufacturer. Total RNA (2.5 μ g) was primed with an Oligo (dT) 15 oligonucleotide (Promega) and reverse-transcribed according to manufacturer's instructions.

PCR amplification of CT antigens

The amplification reaction contained 5 μ L of a 1:5 dilution of reverse-transcribed products, 1 μ L each of 10 μ mol/L specific primers, 1 μ L 10 mmol/L dNTP mixture (dATP, dGTP, dCTP, dTTP), 2.5 U *Taq* DNA polymerase (Gibco BRL) and PCR-

buffer solution. The total volume was brought to 50 μ L using water. The PCR amplifications were performed in a UNO II thermocycler (Perkin-Elmer, USA) under the following conditions: After an initial denaturation for 5 min at 94 °C, samples were subjected to 35 cycles of amplification, followed by a final extension of 8 min at 72 °C. The length of PCR products was 421 base pair (bp) (*MAGE-1*), 422 bp (*SSX-1*), 297 bp (*CTp11*) and 238 bp (*HCA587*), respectively. To verify that the RNA had not degraded, a PCR assay with specific primers for the gene β_2 -microglobulin (*B₂-MG*) was performed on each cDNA sample under the following conditions: After an initial heating for 2 min at 94 °C, samples were subjected to 30 cycles of amplification, followed by a final extension of 8 min at 72 °C. The product size was 335 bp. The PCR conditions and specific primer sets for *MAGE-1*^[33], *SSX-1*^[4], *CTp11*^[21], *HCA587*^[34] and *B₂-MG*^[26] used in this study are shown in Table 1.

At last, 10 μ L of reaction product was analyzed by electrophoresis on a 20 g/L agarose gel (Promega, USA), followed by ethidium bromide staining and digital camera photographing (Korda D3.5, USA).

Sequence analysis of PCR products

To confirm the specificity of the RT-PCR products of the CT antigen genes, we performed the sequence analysis. In brief, purified PCR products were cloned into pGEM-T Easy Vector (Promega) by *T4* DNA ligase and amplified in *E. coli*, JM109. Five cases of positive colonies were selected and assessed using *EcoRI* digestion of mini-prepared DNA. The putative *MAGE-1*, *SSX-1*, *CTp11* and *HCA587* cDNA samples were sequenced with T7 sequencing primers in Sangon Co, Shanghai, China.

Statistical analysis

The statistical analysis was assessed using the chi-square test and the Fisher's exact test, and the significant level was set at $P < 0.05$.

RESULTS

Expression of CT antigen genes

Among the 105 HCC tissues investigated, *MAGE1*, *SSX-1*, *CTp11* and *HCA587* mRNA was expressed in 75.2% (79/105), 72.4% (76/105), 62.9% (66/105) and 56.2% (59/105) of tumor samples from HCC patients, respectively. At least one CT antigen mRNA was positive in 93.3% (98/105) of HCC tissues. Conversely, only *SSX-1* could be detected in 2.9% (3/105) of the corresponding adjacent non-HCC tissues in which no metastatic lesions were found. Of the latter 3 patients, biopsy samples far from tumor were obtained in 2 patients and RT-PCR indicated no expression of *SSX-1* mRNA was detectable in these 2 samples. No expression of *MAGE-1*, *CTp11* and *HCA587* was detected in the samples of corresponding adjacent non-cancerous tissues. In addition, none of 40 samples of cirrhosis and normal liver tissue expressed each CT antigen mRNA. In consistent with Chen *et al.*'s findings^[4], the electrophoretogram analysis revealed the intensities of PCR products varied considerably among different samples, indicating HCC cells expressing tumor antigens at mRNA level are heterogeneous. The typical electrophoresis of RT-PCR products amplified from cDNA of tissue samples of some HCC patients is shown in Figure 1.

Highly synchronous expression of multiple CT antigens in HCC samples

Highly frequent co-expression of multiple members of CT antigens was observed in HCC samples, with synchronous expression of at least two, three, and four of these gene in

n¹: Number of samples; CT²: At least one of these 4 CT antigen genes; No relationship is found between the expression of CT antigens and clinical indicators such as age, gender, degree of tumour differentiation, serum α-FP level, TNM classification, tumor size, infection of hepatitis B virus or hepatitis C virus ($P>0.05$).

72.4%(76/105), 48.6%(51/105) and 37.1%(39/105) of HCC tissues, respectively. We also analysed the cases with expression of neither *MAGE-1* nor *SSX-1* genes to determine targets for cancer immunotherapy other than *MAGE-1* and/or *SSX-1*. Among 18 HCC patients with expression of neither *MAGE-1* nor *SSX-1*, 61.1% (11/18) of HCC samples expressed *CTp11* and/or *HCA587*.

Sequence analysis of PCR products

Sequence analysis of PCR products verified the nucleotide

sequences of *MAGE-1*, *SSX-1*, *CTp11* and *HCA587* cDNA fragments were identical to that in the database of the GenBank. It confirmed that the RT-PCR products were true *MAGE-1*, *SSX-1*, *CTp11* and *HCA587* cDNA (data not shown).

Expression of CT antigens and clinical indicators

No relationship was found between the expression of CT antigens and clinico pathological indicators such as age, gender, differentiation degree of tumour, serum α-FP level, TNM classification, tumor size, infection of hepatitis B virus or

hepatitis C virus ($P>0.05$). However, among 35 patients with the normal (<20 ng/mL) or slightly elevated (<40 ng/mL) serum α -FP level, 32 patients had *MAGE-1*, *SSX1*, *CTp11* or *HCA587* gene transcripts detected in their HCC tissues. The results are demonstrated in Table 2.

Figure 1 Electrophoresis of RT-PCR products amplified from cDNA of HCC tissues. M: Molecular marker, 100-bp DNA ladder (Gibco); P: Positive control, testis tissues; Ne: Negative control, PCR amplification in the absence of template; B₂-MG: 335-bp cDNA quality control; T: HCC tissues, arrows indicate the RT-PCR products of CT antigens; N: Corresponding adjacent non-tumor tissues. All the samples shown here except for the negative control are positive.

DISCUSSION

Tumor antigens should demonstrate high frequency expression in the tumor tissues and restricted expression in normal tissues, which is the prerequisite for being an ideal candidate antigen for antigen-specific cancer immunotherapy^[35]. The growing class of CT antigens is of particular interest for antitumor immunotherapy because of their specific expression on tumor cells. It has demonstrated high frequent expression of *MAGE-1* and *SSX-1* in HCC tissues, but little in nontumor tissues^[4,26-28]. However, the heterogeneous expression of *MAGE-1* and *SSX-1* antigens may cause problems for immunotherapy targeting these antigens, as tumor cases with a low percentage or negative expression of *MAGE-1* and/or *SSX-1* antigens may be less suitable for immunotherapy targeting these antigens. Furthermore, to our knowledge, so far little information is available on the *CTp11* and *HCA587* expression in HCC tissues. Therefore, we investigated the expression of CT antigens *MAGE1*, *SSX-1*, *CTp11* and *HCA587* in HCC tissues.

In the present study, we found highly positive rate of *MAGE-1*, *SSX-1*, *CTp11* and *HCA587* transcripts in HCC tissues (56.2-75.2%). No expression of *MAGE-1*, *CTp11* and *HCA587* was detected in the samples of corresponding adjacent non-cancerous tissues, while *SSX-1* mRNA could be detected in 2.9% (3/105) of the corresponding adjacent non-HCC tissues where no metastatic lesions were found, similar to Chen *et al.*'s findings^[4]. Of these 3 patients, biopsy samples far from tumor were obtained in 2 patients and RT-PCR indicated expression of *SSX-1* mRNA was not detectable in these two samples. The sensitivity of RT-PCR assay was much higher than that of conventional methods^[36], such as histochemistry and cytology, so we speculate that there might be micrometastasis in the adjacent non-tumor liver tissue. In addition, none of 40 samples of cirrhosis and normal liver tissues expressed each of these 4 CT antigen mRNAs. As *MAGE-1*, *SSX-1*, *CTp11* and *HCA587*

were expressed with a high percentage and specificity in HCC, their products might be ideal antigen targets for HCC immunotherapy. A high proportion (93.3%, 98/105) of the HCC tissue samples was positive for at least one of these 4 CT antigen genes, indicating using multiple CT antigens as targets will greatly increase the number of candidates for CT antigen-based HCC immunotherapy.

In the present study, we found relatively high frequency of expression of *CTp11* and *HCA587* mRNA, being 62.9% (66/105) and 56.2% (59/105) of tumor samples from HCC patients, respectively, while no expression of *CTp11* and *HCA587* was detected in the samples of corresponding adjacent non-cancerous tissues and control liver tissues, indicating their products may also be ideal antigen targets for HCC immunotherapy. Though frequency of expression of *CTp11* and *HCA587* mRNA was relative lower than that of *MAGE-1* and *SSX-1*, being 75.2% (79/105) and 72.4% (76/105), respectively, we found that samples with negative expression of *MAGE-1* and *SSX-1* showed expression of *CTp11* and *HCA587*. With respect to these HCC patients, vaccines based on *CTp11* and *HCA587* should be a desirable choice.

We also found a high frequency of synchronous expression of multiple CT antigens in HCC samples, with synchronous expression of at least two, three, and four of these genes in 72.4% (76/105), 48.6% (51/105) and 37.1% (39/105) of HCC tissues, respectively. High frequent co-expression of multiple members of CT antigens in HCC provides possibility of polyvalent vaccinations for HCC. The polyvalent vaccinations with multiple antigens, which avoid the heterogenous expression of tumor cells, might obtain better clinical results than a single antigen-based vaccination in cancer immunotherapy. Patients' opportunities for cancer specific immunotherapy can thus be expanded^[37]. However, our results showed no expression of CT antigens in 6.7% (7/105) of HCC tissues. For these patients, it is necessary to screen other CT antigens or tumor specific antigens serving as immune targets for HCC immunotherapy.

Concerning the issues of heterogenous expression of CT antigens and possibility of polyvalent vaccinations for HCC, Tahara *et al.*^[27] investigated the 10 CT antigens expression in HCC with RT-PCR and found that 86% (19/22) of HCC tissue samples expressed at least one CT antigen gene. Comparably, Luo *et al.*^[28] showed that 81% (17/21) of HCC tissue samples expressed at least one of the 10 CT genes. While in our present study, selecting just 4 CT antigens, we proved that 93.3% (98/105) of HCC patients were detectable of at least one positive CT antigen expression. Notably, the sample number of our study is 105, which is much more than the case number in the study of Tahara *et al.*^[27] (22 cases) or Luo *et al.*^[28] (22 cases), therefore our results should be more convincing.

Our previous report showed the prognostic value of *MAGE-1* and *MAGE-3* as tumor specific markers to detect blood dissemination of HCC cells after hepatectomy^[33]. In this study, our results indicated *SSX-1*, *CTp11* and *HCA587* were also expressed in HCC tissues with high percentage and sensitivity, and some cases with negative *MAGE* expression were positive for *SSX-1*, *CTp11* and/or *HCA587* transcripts. Therefore, we can combine *SSX-1*, *CTp11* and *HCA587* genes with *MAGE* genes and apply them as multiple-markers to detect hepatoma cells in circulation, which may improve the sensitivity of the assay.

In this study, the serum α -FP was normal (<20 ng/mL) or slightly elevated (<40 ng/mL) in 30.0% (35/105) of HCC patients. In these 35 patients, 32 had *MAGE-1*, *SSX1*, *CTp11* or *HCA587* transcripts in their HCC tissues, suggesting applying their mRNAs as tumour-specific markers to detect HCC cells in circulation might be an adjuvant diagnostic tool. This assay combined with the examination of serum α -FP level may improve the diagnosis of HCC patients.

Abstract

AIM: To construct a DNA vaccine against extracellular domains 1-3 of fetal liver kinase-1 (flk-1), and to investigate its preventive and therapeutic effect against H22 cell *in vivo*.

METHODS: Flk-1 DNA vaccine was produced by cloning extracellular domains 1-3 of flk-1 and by inserting the cloned gene into pcDNA3.1 (+). Fifteen mice were divided into 3 groups and inoculated by vaccine, plasmid and saline respectively to detect specific T lymphocyte response. Thirty Mice were equally divided into preventive group and therapeutic group. Preventive group was further divided into V, P, and S subgroups, namely immunized by vaccine, pcDNA3.1 (+) and saline, respectively, and attacked by H22 cell. Therapeutic group was divided into 3 subgroups of V, P and S, and attacked by H22, then treated with vaccine, pcDNA3.1 (+) and saline, respectively. The tumor size, tumor weight, mice survival time and tumor latency period were compared within these groups. Furthermore, intratumoral microvessel density (MVD) was assessed by immunohistochemistry.

RESULTS: DNA vaccine pcDNA3.1 (+) flk-1-domains 1-3 was successfully constructed and could raise specific CTL activity. In the preventive group and therapeutic group, tumor latency period and survival time were significantly longer in vaccine subgroup than that in P and S subgroups ($P < 0.05$); the tumor size, weight and MVD were significantly less in vaccine subgroup than that in P and S subgroups ($P < 0.05$). The survival time of therapeutic vaccine subgroup was significantly shorter than that of preventive vaccine subgroup ($P < 0.05$); the tumor size, and MVD of therapeutic vaccine subgroup were significantly greater than that of preventive vaccine subgroup ($P < 0.05$).

CONCLUSION: DNA vaccine against flk-1 domains 1-3 can stimulate potent specific CTL activity; and has distinctive prophylactic effect on tumor H22; and also can inhibit the tumor growth *in vivo*. This vaccine may be used as an adjuvant therapy because it is less effective on detectable tumor.

INTRODUCTION

Extensive studies by many investigators established that angiogenesis has a central role in the invasion, growth and metastasis of solid tumors^[1-3]. The inhibition of tumor growth by attacking the tumor's vascular supply offers a primary target for anti-angiogenic intervention. There are several advantages of targeting proliferating endothelial cells in the tumor vasculature rather than directly to tumor cells. First, endothelial cells are genetically stable and do not down regulate MHC-class I and II antigens. Second, the therapeutic target is tumor-independent. Thus, killing of proliferating endothelial cells in the tumor microenvironment can be effective against a variety of malignancies and clones^[3,4]. Vascular endothelial growth factor (VEGF) plays a center role in tumor angiogenesis, while fetal liver kinase-1 (flk-1), which expressed exclusively on the endothelial cells, is the key receptor that binds VEGF^[5,6]. Blocking the VEGF-flk-1 pathway may inhibit tumor angiogenesis. Hence, we constructed a DNA vaccine to target the extracellular domain 1-3 of flk-1 and tested its preventive and therapeutic effect against H22 cell *in vivo* with the hope that the vaccine might be able to inhibit angiogenesis via targeting flk-1 and flk-1 expressing endothelial cell. This research has no parallel reports at home.

MATERIALS AND METHODS

Materials

Cell line Tumor cell H22 cell line, constructed by Dalian Medical University from the mouse ascite, was heterogeneous cells with higher declination to spread by lymph vessel. COS7 cell is derived from African green monkey kidney and preserved by our laboratory. Endothelial cells were primarily cultured from mouse vessel by our laboratory.

Animal BALB/c mice were bought from Laboratory Animal Center of the Fourth Military Medical University. All mice were male, specific pathogen free animals, with age of 6-8 wk and weight of 15-20 g.

Main reagents pcDNA3.1(+) was purchased from Invitrogen (U.S.). CD31 antibody was a product of Santa Cruz (U.S.). pMDT-18 Vector, T4 DNA ligase, Taq^{EX} DNA polymerase, *Hind* III, *Eco*R I, and dNTP were products of TaKaRa (Japan). *M-MLV* reverse transcriptase was purchased from Promega (U.S.). E.Z.N.A^R gel extraction kit was purchased from Omega Bio-tek (U.S.). Trizol, lipofectamine 2000, DMEM and G418 were purchased from Gibco (U.S.). Western blot luminescence kit was purchased from NEN (Britain). Micro BCA protein assay was purchased from Pierce (U.S.).

Methods

Culture of cells H22 cell was transferred in abdomen cavity of

BALB/c mouse. The ascites were taken from the mouse in the super clean bench and then diluted with DMEM to 1×10^7 /mL. A total of 0.2 mL of 1×10^7 H22 cells were inoculated subcutaneously at the right armpit of mouse to establish a tumor model. The interval between the ascites taking and the last mouse inoculation was less than 2 h. COS7 cell was cultured in DMEM containing 100 mL/L FCS and 50 mL/L CO₂ at 37 °C. Primary culture of endothelial cells (ECs) were performed as follow: the mouse thoracic aorta was sterile dissociated, and sheared into small pieces about 0.5 cm×0.5 cm, washed with Hank's fluid, its EC surface was stuck to 1.5% gelatin culture medium, and then DMEM containing 100 mL/L FCS and benzylpenicillin (100 U/mL) and streptomycin (100 U/mL) was slowly added, then cultured at 37 °C under humidified atmosphere containing 50 mL/L CO₂ until the cells form a single layer. Transfer of cell culture was performed (≤ 3 generations).

Construction of the expression vector encoding murine flk-1 domain 1-3 Total cellular RNA of mouse liver tissue was extracted using TRIzol reagent and cDNA was prepared by random priming from 2 µg of total RNA using M-MLV according to the manufacturers' instructions. PCR was performed for 35 cycles as follows: denaturation at 94 °C for 30 s, annealing at 60 °C for 30 s and extension at 72 °C for 80 s. Oligonucleotide primers to amplify flk-1 domain 1-3 transcripts were designed on the mouse sequence: upstream primer: 5' -CGGATAACC TGGCTGACC-3' ; and downstream primer 5' -AGGGATT CGGACTTGACTGC-3. Then the cloned gene was inserted into the pMDT-18 vector, followed by cut out from pMDT-18 by *Eco*R I and *Hind* III and insertion into the pcDNA3.1 vector between the restriction sites *Eco*R I and *Hind* III generating pcDNA3.1 (+)-flk-1-Domain1-3. Reading frame and sequence were proved right by DNA sequencing.

Expression of the pcDNA3.1 (+)-flk-1-domain 1-3 in the COS7 cell COS7 cells were plated in antibiotic free growth medium and cultured until about 90% confluence at the time of transfection. A 4 µg of pcDNA3.1 (+)-flk-1-Domain1-3 was diluted and mixed in 250 µL of DMEM, 10 µL of lipofectamine™ 2000 was diluted and mixed in 250 µL of DMEM respectively. They were mixed together after 5 min of incubation at room temperature, and incubated for 20 min then poured into 35 mm wells plated with COS7. Mixed gently and incubated at 37 °C in 50 mL/L CO₂ incubator for 48 h. Cultured cells were incubated for 20 min and sonicated twice for 5 s in cold lysis buffer. Total extracts were cleared by centrifugation for 30 min at 4 °C at 14 000 g. Protein levels were quantified with Micro BCA protein assay. Samples were resolved by 120 g/L SDS-polyacrylamide gel electrophoresis (SDS-PAGE). In all gels, 80 µg of protein dissolved in sample buffer was loaded per lane. Immunoblotting was performed by electroblotting onto nitrocellulose membrane (0.2 mm) at 32 mA for 1 h using a semidry immunoblotter. Membranes were blocked for 2 h at room temperature with blocking buffer and subsequently incubated for 1 h at room temperature with anti-flk-1 polyclonal antibody at a 1:200 dilution with blocking buffer. The enhanced chemiluminescence system was used for the detection of bound antibody. Primary antibody-antibody-bound membranes were incubated for 1 h at room temperature with horseradish peroxidase conjugated antirabbit or antimouse IgG at a 1:1 000 dilution with blocking buffer. After washing with TBS and TBST, the membranes were treated with enhanced chemiluminescence reagents according to the manufacturer's protocol. The membranes were exposed to X-ray film for 2 min.

Analysis of specific cytolytic T lymphocyte (CTL) activity Fifteen mice were classified to three groups: vaccine group, plasmid group, and saline group, each group had 5 mice. Mice were injected with 100 µg of vaccine, 100 µg of plasmid, and 100 µg of saline respectively, at the concentration of 1 µg/µL once every 10 d. All the mice were killed on day 10 after the last

immunization and the spleen lymphocytes were separated and cultured in complete culture medium with interleukin-2 (1×10^5 U/L) and 100 mL/L FCS at saturated humidified atmosphere containing 50 mL/L CO₂ at 37 °C to induce the CTL. CTL and mouse ECs was mixed at 100:1 and 50:1 effector/target rate, respectively. In addition, there were a CTL control group, an ECs control group and a culture medium control group. The specimens of each group had 3 parallel wells on a 96-well culture plate and were cultured under conditions of saturated humidity at 37 °C containing 50 mL/L CO₂ for 48 h. Cell-mediated cytotoxicity was determined by using a standard ⁵¹Cr release assay. Briefly, target cells were pelleted and resuspended in 3.7 GBq of ⁵¹Cr per 10⁶ cells and incubated at 37 °C in a humidified 50 mL/L CO₂ incubator for 1 h. They were washed three times with media, resuspended to 5×10^4 /mL, and 0.1 mL was added to round-bottomed microtiter wells. Varying numbers of effector cells were added in 0.1-mL volume to achieve the desired E/T ratios. For a spontaneous ⁵¹Cr-release control, 0.1 mL of media was substituted for effector cells. Maximum release was determined by adding 0.1 mL of 1% NP-40 to the target cells. After 6 h at 37 °C, the plates were centrifuged at 1 200 r/min for 5 min, and 0.1 mL of supernatant was taken from each well and counted on a gamma counter. Data are presented as percent specific ⁵¹Cr-release = $100 \times [(\text{experimental group counts per minute (cpm)} - \text{spontaneous group cpm}) / (\text{maximum release cpm} - \text{spontaneous cpm})]$.

Preventive effect of pcDNA3.1 (+)-flk-1-domain1-3 against H22 Thirty BALB/c mice were randomly divided into V, P, and S subgroups, 10 mice in each subgroup, and immunized by 100 µg vaccine, plasmid, and saline, respectively, at concentration of 100 µg/µL, once every 10 d by intramuscular injection at left hip. Five days after the last immunization, all mice were injected with 1×10^7 of H22 cells at the right armpit subcutaneously. The mice weight, tumor formation, tumor size and mice survival time were recorded. Tumor volume was measured in 2 dimensions and calculated as follows: length/2×width². After mice death, tumor tissue was routinely fixed and embedded in paraffin and then performed CD31 staining. All mice were kept observation until death.

Therapeutic effect of pcDNA3.1 (+)-flk-1-domain1-3 against H22 Thirty BALB/c mice were randomly divided into V, P, and S subgroups, ten mice in each subgroup. All mice were injected with 1×10^7 of H22 tumor cell subcutaneously at right armpit. Four days later, tumor was formed in all mice, which demonstrated the successful construction of tumor model. Mice in different groups were treated with 100 µg of vaccine, plasmid, and saline, respectively, at the concentration of 1 µg/µL, two times every 5 d by intramuscular injection at left hip. The tumor weight and size were recorded each day. The mice weight, tumor formation, tumor size and survival period of mice were recorded. After mice death, tumor tissue was routinely fixed and embedded in paraffin for CD31 staining. All mice were kept observation until death.

Counting of microvessel density in H22 solid tumor Tumor tissue was washed with cold PBS, then fixed in 40 g/L buffered formaldehyde solution and embedded in paraffin. Tissue sections (4 µm thick) were preincubated for 30 min with PBS containing 3 mL/L hydrogen peroxide and then blocked with blocking solution containing 50 mL/L goat serum. CD3 staining was performed with a polyclonal rabbit anti-rat CD31 antibody diluted in PBS (1:50) supplemented with blocking solution for 24 h at 4 °C. Finally, sections were incubated with the biotinylated secondary antibody followed by streptavidin-horse-radish-peroxidase complex. Antibody binding was visualized with diaminobenzidine (DAB). Vessel counts within the tumor were assessed by light microscopy after CD31 staining. Based on the criteria of Weidner *et al.*^[7], a vessel lumen was not required for the identification of a microvessel.

The five areas with the highest number of discrete microvessels in each slide were identified by scanning tumor sections at low power. Then the number of microvessels were counted in these areas at 200 magnification (0.75 mm² area) to obtain accurate microvessel density. The average value of the five areas was counted as MVD.

Statistical analysis

Results were expressed as mean±SD. Data were analyzed by the method of ANOVA using SPSS 10.0 software. $P<0.05$ was considered statistically significant.

RESULTS

Cloning of flk-1 domain1-3 and construction of pcDNA3.1 (+)-flk-1-domain1-3

A 1 250 bp gene part was cloned from mouse liver tissue using RT-PCR technique (Figure 1). DNA sequencing showed that pcDNA3.1 (+) flk-1-domain1-3 was the right reading frame and sequence. Western blotting of the lipotransfected COS7 cell showed that the expression of a M_r 44 000 protein in the cell after transfection of the pcDNA3.1 (+)-flk-1-domain1-3 (Figures 2, 3).

Figure 1 Clone of flk-1-domain1-3 and construction of expressing vector. A: DNA marker; B: PCR results.

Activity of spleen CTL

CTL activity of mice in vaccine subgroup was significantly higher than that of plasmid and saline subgroup (Figure 4, $P<0.05$).

Protective effect of pcDNA3.1 (+)-flk-1-domain 1-3 against H22 in different subgroup

Observation of carcinogenesis Mice of different subgroups in immune preventive group were injected with H22 cells after 3 times inoculation, the tumor latent time, survival time of the vaccine subgroup were longer than that of plasmid subgroup and saline subgroup ($P<0.05$); The tumor weight and tumor volume of vaccine subgroup was the lowest among the 3 subgroups ($P<0.05$, Table1, Figure 5). The tumor latent time, survival time, tumor volume and tumor weight of plasmid subgroup and saline subgroup have no statistical significance compared with each other.

Figure 2 Functionality of the flk-1-domain 1-3 expressing vector. A: Western blotting of protein extracted from COS7 cell; B: Western blotting of protein from COS7 transfected with vaccine; C: Western blotting of protein from COS7 transfected with pcDNA3.1 (+).

Figure 4 CTL activity of each group at different effector/target rate.

Figure 3 COS 7 cell before and after transfection with vaccine, plasmid and saline, respectively. A, D: One day before and 2 wk after transfection with vaccine; B, E: One day before and 2 wk after transfection with plasmid; C, F: One day before and 2 wk after transfection with saline.

Table 1 Protective effect of DNA vaccine against H22 tumor cell *in vivo* (mean±SD)

Group	n	Tumor latency time (d)	Survival time (d)	Microvessel density	Tumor weight (g)
Vaccine	10	5.20±0.86 ^a	24.47±3.23 ^c	10.10±1.66 ^e	1.41±0.13 ^g
Plasmid	10	4.00±0.67	14.70±2.63	27.30±3.34	1.79±0.16
Saline	10	3.80±0.63	14.30±2.00	25.30±4.64	1.82±0.16

^a $P<0.05$, ^c $P<0.05$, ^e $P<0.05$, ^g $P<0.05$ vs plasmid group and saline group.

**Figure 5** Curve of tumor growth in preventive group.

MVD of different subgroups Macroscopic structure showed the tumor tissue was hard and adhered to the surrounding tissue. MVD of vaccine subgroup was the lowest among the three subgroups ($P<0.05$). MVD of the plasmid subgroup and saline subgroup have no statistical significance compared with each other ($P>0.05$). This indicates that V subgroup has the lowest micro vessel density (Figure 6).

Therapeutic effect of pcDNA3.1 (+)-flk-1-domain1-3 against H22
Inhibitory effect of pcDNA3.1 (+)-flk-1-domain1-3 in carcinogenesis Treated with DNA vaccine pcDNA3.1 (+)-flk-1-domain1-3, plasmid and saline. The survival time of the vaccine subgroup were longer than that of plasmid subgroup and saline subgroup ($P<0.05$); The tumor weight and tumor volume of vaccine subgroup was the lowest among the 3 subgroups

($P<0.05$, Table 2, Figure 7). The survival time, tumor volume and tumor weight of plasmid subgroup and saline subgroup have no statistical significance compared with each other. But the survival times of therapeutic vaccine subgroup were significantly shorter than that of preventive vaccine subgroup ($P<0.05$); the tumor size, and MVD of therapeutic vaccine subgroup were significantly greater than that of preventive vaccine subgroup (Table 3).

MVD of different subgroups Macroscopic structure showed the tumor tissue was hard and adhered to the surrounding tissue. MVD of vaccine subgroup was the lowest among the 3 subgroups ($P<0.05$). MVD of the plasmid subgroup and saline subgroup had no statistical significance compared with each other (Figure 8).

DISCUSSION

We successfully cloned the domains 1-3 of extracellular parts of flk-1, constructed the DNA vaccine pcDNA3.1 (+) flk-1-domains 1-3, which induced the immune response against endothelial cell, and finally blocked the growth of H22 tumor cells by blocking angiogenesis.

DNA sequencing and blast showed that the cloned gene completely matched the DNA sequence listed in GenBank. Western blot of lipotransfected COS7 showed that the cell transfected with vaccine could express a *M_r* 44 000 specific protein, which had no corresponding band in the control group, indicating that flk-1 could be expressed by the vaccine in eukaryotic cells. Standard 4-h ⁵¹Cr release test showed that the vaccine against domains 1-3 could generate specific immune response in mice through breaking tolerance to self-flk-1 antigen.

In the immune preventive group, mice were first inoculated with the vaccine and then challenged with tumor cells. The results showed that compared with the control group, the inoculated mice had a longer survival time, longer tumor latent period, lower tumor weight at death time and slower tumor growth rate. Furthermore, tumor in inoculated mice had low MVD. So we concluded that the vaccine inhibited tumor growth by its anti-angiogenic effects. In the therapeutic group, effects of the vaccine were supposed to investigate in the clinical conditions. The H22 cells were first injected to the mice and waited until tumor was well constructed, then the mice were treated with the vaccine. We found that, similar to the preventive group, the survival time, tumor weight at death time of mice and tumor growth rate all had significant difference compared with the control group. But compared with that of the preventive group, the vaccine was less effective in the therapeutic group. The MVD, survival time had significant difference between the vaccine subgroup of these groups, indicating that the vaccine might be less effective against well-structured tumors.

Recent advances in the understanding of the molecular control of angiogenesis have shown that this process is essential for tumor development and spread. VEGF is a highly specific mitogen for vascular endothelial cells, which can induce endothelial cell proliferation, promotes cell migration, and inhibits cell apoptosis and immune response against cancer^[8-11], and plays a central role in the tumor angiogenesis^[12-14].

Flk-1 is the main receptor through which VEGF could modulate tumor growth and metastasis^[15-18]. Flk-1 belongs to receptor

tyrosine kinases (RTKs) family and are expressed almost exclusively in endothelial cells and on various types of tumor cells^[19,20]. Flk-1 has a typical tyrosine kinase receptor structure with 7 immunoglobulin (Ig)-like domains in the extracellular region, as well as a long kinase insert in the tyrosine kinase domain^[20]. Evidence shows that IgG-like domains 2-3 are sufficient for tight binding, domain 1 is necessary for tight binding and domains 4-7 are not essential for signaling, and the residues within this region of domain 3 are critical for VEGF binding^[21,22]. Various studies have shown that VEGF and flk-1 expression are significantly associated with advanced stage, high incidence of distant metastases after surgery, and less favorable prognosis in a number of malignancies^[23-28]. As it directly involved in tumor angiogenesis, flk-1 is an appropriate target for suppression of solid tumor growth^[6].

Several approaches have been used to block flk-1, including dominant-negative receptor mutants, germ-line disruption of VEGFR genes, monoclonal antibodies, dendritic cell vaccine, and a series of synthetic RTK inhibitors^[29-33]. They all achieved the goal of blocking VEGF-flk-1 signaling pathway and inhibiting angiogenesis, but they all have some common defects, such as requiring constant drug injection, only blocking VEGF pathway and high cost. Our strategy was to construct DNA vaccine target flk-1 in order to inhibit angiogenesis by blocking VEGF-flk-1 pathway and destructing endothelial cell that expresses flk-1. Compared with strategies mentioned above, DNA vaccines against flk-1 could achieve similar results and are simpler and cheaper to produce and can induce very long-lasting immune responses^[34,35]. Furthermore, the immune response not only blocks VEGF-flk-1 pathway, but also blocks other angiogenesis pathway by destruction of endothelial cells^[33]. Also it has been reported that liver cancer cells and various types of other tumor cells could express flk-1 receptor, but in our study we could not amplify flk-1 gene from cultured H22 tumor cells, so we could not evaluate whether or not the vaccine had direct effect on the tumor cells. Our research showed that the vaccine was less effective against well-formed tumors. This may be contributed to the immune escaping capacity of well-structured tumors. This result was in consistent with previous reports at home and abroad^[33,36-38]. So we propose that the vaccine should be combined with other therapies, such as surgery, to prevent primary site from recurring and metastasis. Further research is needed in this direction.

In short, we constructed DNA vaccine against extracellular domain1-3 of flk-1, and evaluated its immune preventive and immune therapeutic effects against H22 tumor cell, suggesting that the vaccine could inhibit tumor growth through its anti-angiogenic effect. Further research is needed to increase the effectiveness of this vaccine.

Abstract

AIM: To examine 5' and 3' terminal sequences of hepatitis E virus (HEV) isolated from Morocco, to confirm 5' methylated cap structure of the genome, and to investigate whether the 3' UTR can be used to distinguish HEV genotypes instead of HEV complete genome sequence.

METHODS: RNA ligase-mediated rapid amplification of cDNA ends (RLM-RACE) was employed to obtain the 5' and 3' terminal sequences of HEV Morocco strain. The 3' UTR sequence of the Morocco strain was compared with that of the other 29 HEV strains using the DNASTar software.

RESULTS: The 5' PCR product was obtained only from the RLM-RACE based on the capped RNA template. The 5' UTR of the Morocco strain had 26 nucleotides, and the 3' UTR had 65 nucleotides upstream to the polyA. The 5' UTR between HEV strains had only point mutations of nucleotides. The phylogenetic tree based on the sequences of 3' UTR was not the same as that based on the complete sequences.

CONCLUSION: The genome of HEV Morocco strain was methylated cap structure. The 3' terminal sequence can not be used for distinguishing HEV genotype for all HEV strains in place of the whole HEV genome sequence.

INTRODUCTION

Hepatitis E virus (HEV) is an enterically transmitted agent that causes epidemic and sporadic cases of hepatitis predominantly in developing countries of Asia, Africa and North America^[1]. The disease generally affects young adults and has a high mortality rate, up to 20%, in infected pregnant women. Success in cloning and sequencing of the HEV genome allowed the elucidation of the HEV genetic organization^[2]. The HEV genome is a positive-sense, single-stranded, polyadenylated RNA of approximately 7.2 kb containing three open reading frames (ORFs). ORF1, located at the 5' end of the genome, is

about 5 kb in length and encodes for a putative nonstructural polyprotein that contains motifs characteristic for methyltransferase, papain-like protease, RNA helicase, and RNA-dependent RNA polymerase domains. ORF2 is about 2 kb in length and encodes for the structural protein(s). The small ORF3 of only 369 nucleotides overlaps ORF1 and ORF2 and encodes for a protein of unknown function^[3].

The genomes of several HEV strains from Asia and North America have been sequenced in their entirety^[4]. Partial sequences are also available for other strains from some of these geographic regions. In Africa, the HEV virus has been identified from Morocco, Tunis, Algeria, Chad, Egypt, Nigeria and Namibia^[5-10]. However, only a few short isolated nucleotide sequences from African strains of HEV were available for analysis. In 1997, Chatterjee *et al.* isolated an HEV strain in Morocco^[5]. In 1999, Meng *et al.* obtained the nucleotide sequences of HEV Morocco strain that spanned the extreme 3' terminal region of ORF1, full length ORF2 and ORF3, and a part of the 3' noncoding region^[11,12]. Although more similar to the Asian strains than to the Mexico strain, partial HEV sequences from Morocco strains were, nonetheless, distinct from all known Asian strains. It is urgent to obtain the complete sequence of the Morocco strain to elucidate its biological function.

Although the genomic coding regions of several HEV strains have been sequenced completely, the sequence of the 5' UTR has been reported only for a limited number of HEV strains^[13]. The 5' UTR of HEV strains were usually determined either by cDNA cloning and sequencing or by classical 5' rapid amplification of cDNA ends (RACE)^[13]. However, there still exists the possibility that the 5' UTR sequences are not complete because neither method has a control to detect premature termination of cDNA synthesis. Furthermore, by coupling a reverse transcription polymerase chain reaction (RT-PCR) assay with immune-capture of genomic RNA based on the ability of a monoclonal antibody to recognize 7-methylguanosine showed that the genomic RNA of HEV is capped^[14]. It is not clear how this structure will have affected previous assays used to determine the 5' terminal nucleotides. For getting the complete sequence of HEV Morocco strain, we employed a RLM-RACE technique to obtain the 5' and 3' terminal sequences in our study, and confirmed that the genome of Morocco strain was capped.

Furthermore, how to distinguish the genotypes of HEV is still an issue. Based on the complete sequence analysis, Burma-1, Burma-2, China-1 to -6, Pak-1, Pak-2, India-1 to -4, Nepal and Morocco strains are included in genotype I; Mexico strain belongs to genotype II; Genotype III holds US-1, US-2, US-SW, Japan-1 to -7, Japan-SW and Canada-SW; China-T1 belongs to genotype IV^[15-17]. Considering the difficulties in obtaining the complete sequences of each strain, we attempted to evaluate whether the 3' UTR can be used to analyze the HEV genotype in this study.

MATERIALS AND METHODS

Sample

The sample was obtained from Professor Pillot, Pasteur Institute, France, and treated as described in references 16 and

17. Aliquots of virus stock were prepared and stored at -70 °C.

Reagents

HEV RNA was extracted with TRIzol (GIBCO, USA). The 5' and 3' RLM-RACE was carried out with the GeneRacer kit (Invitrogen, USA). The nested PCR was carried out with high fidelity system DNA polymerase (Roche, USA). PCR products were purified with QIAquick PCR purification kit (Qiagen, German).

Primers

5' RACE primers: Two RNA 5' -adaptor primers supplied in the GenRacer kit were used as forward primers. The sequences of the reverse primers were: 5' -AGA AAA GGC CTA ACC ACC ACA GCA TTC G-3' (outer reverse primer) and 5' -CTA AAG CAG CCT GCT CAA TAG CAG TAG-3' (inner reverse primer).

3' RACE primers: Sequences of the forward primers were: 5' -GTT GTC TCA GCC AAT GGC GAG C-3' (outer forward primer) and 5' -AAG ATG AAG GTG GGT AAA ACT CGG GAG-3' (inner forward primer). Two RNA 3' -adaptor primers supplied in the GenRacer kit were used as reverse primers.

GenBank accession number and software

The GenBank accession number of 3' UTR sequence of HEV Morocco strain was AY220474. The 5' and 3' UTR sequence of Morocco strain were compared with that of other 29 strains, respectively, by the MegAlign in DNASTar software (DNASTAR Inc, USA). The phylogenetic trees of 3' and complete HEV sequences were also made with MegAlign in DNASTAR. The GenBank accession numbers of these sequences were: Jap-SW (AB073912)^[18], Japan-1 (AB074918), Japan-2 (AB074920)^[19], Japan-3 (AB089824)^[20], Japan-4 (AP003430)^[21], Japan-5 (AB074915), Japan-6 (AB074917)^[19], Japan-7 (AB080575)^[22], Nepal (AF051830)^[23], US-1 (AF060668), US-2 (AF060669)^[24,25], US-SW (AF082843)^[26], Canada-SW (AY115488)^[27], India-1 (X98292), India-2 (AF459438)^[28], India-3 (AF076239)^[29], India-4 (X99441), Pak-1 (M80581)^[30], Pak-2 (AF185822)^[31], Burma-1 (M73218)^[3], Burma-2 (D10330)^[32], China-1 (L25547), China-2 (L25595)^[33], China-3 (L08816), China-4 (M94177)^[34], China-5 (D11092)^[35], China-6 (D11093), Mexico (M74506)^[4] and China-T1 (AJ272108)^[36]. The RNA secondary structure was reconstructed with RNAstructure software (Isis Pharmaceuticals).

Extraction of HEV RNAs

One hundred microliters of the filtered supernatant of the Morocco strain was mixed with 400 µL of TRIzol reagent. The mixture was homogenized and incubated for 5 min at room temperature. One hundred microliters of chloroform was added and the mixture was vigorously shaken for 15 s and incubated at room temperature for 3 min. After centrifugation at 12 000 g for 15 min at 4 °C, the aqueous phase was transferred to a fresh microfuge tube. The RNA from the aqueous phase was precipitated by incubating with an equal volume of isopropyl alcohol and 1 µL of glycogen (20 mg/mL) at room temperature for 15 min, and centrifuging at 12 000 g at 4 °C for 15 min. After removing the supernatant, the RNA pellet was washed once with 800 µL of 750 mL/L ethanol and centrifuged again, dried, and then dissolved in 20 µL of diethylpyrocarbonate treated water.

5' RLM-RACE

The 5' RACE was carried out with the GeneRacer kit following the manufacture's instructions. Briefly, 14 µL of extracted RNA was treated with calf intestinal phosphatase (CIP) in a total 20 µL reaction mixture containing 2 µL of 10× CIP buffer

and 2 µL of CIP for 1 h at 50 °C. After extracted with phenol/chloroform, RNA was resuspended in 6 µL of nuclease-free water. The 6 µL of CIP-treated RNA was treated with tobacco acid pyrophosphatase (TAP) in a 10 µL of reaction mixture containing 1 µL of 10× TAP buffer and 2 µL of TAP for 1 h at 37 °C. Again after extracted with phenol/chloroform, the CIP/TAP-treated RNA was resuspended in 6 µL of nuclease-free water and ligated to 250 ng of RNA adaptor by T4 RNA ligase in a 10 µL reaction mixture for 1 h at 37 °C. Then the CIP/TAP/Ligated-RNA was extracted with phenol/chloroform and resuspended in 20 µL nuclease-free water and reserved at -70 °C. Another 6 µL non-treated RNA was ligated to 250 ng of RNA adaptor directly by T4 RNA ligase as a control. Ten microliters of the ligated RNA or control RNA was used as a template to synthesize cDNA with AMV reverse transcriptase for 1 h at 42 °C. The outer reverse primer was used to prime the cDNA synthesis. The cDNA was then amplified by nested PCR with high fidelity system DNA polymerase. The PCR reaction mixture was incubated for 2 min at 94 °C followed by 35 amplification cycles, comprising denaturation at 94 °C for 30 s, annealing at 65 °C for 30 s and extension at 72 °C for 30 s. The reaction was extended for another 7 min at 72 °C to insure the full extension. Based on our former work (data not shown), the expected size of the final PCR product was 100 bp or greater. PCR products were analyzed on 20 g/L agarose gel.

3' RACE

The 3' RACE was carried out with the GeneRacer kit following the manufacture's instructions. Ten microliters of the HEV RNA was used as a template to synthesize cDNA with AMV reverse transcriptase for 1 h at 42 °C. The oligo (dT)-adaptor primer supplied with the kit was used to prime the cDNA synthesis. The cDNA was then amplified by nested PCR with high fidelity system DNA polymerase. The PCR reaction mixture was incubated for 2 min at 94 °C, followed by 35 amplification cycles comprising denaturation at 94 °C for 30 s, annealing at 65 °C for 30 s, and extension at 72 °C for 30 s. The reaction was extended for another 7 min at 72 °C to ensure the full extension. Based on our former work (data not shown), the expected size of the final PCR product was 98 bp or greater. PCR products were analyzed on 20 g/L agarose gel.

Sequence analysis and comparison

PCR products were purified with QIAquick PCR purification kit and sequenced. The 5' and 3' UTR sequence of Morocco strain were compared with that of other 29 strains, respectively, using DNASTar software. The RNA secondary structure was reconstructed with RNAstructure software. The phylogenetic trees of 3' and complete HEV sequences were also made with DNASTAR.

RESULTS

5' UTR

As shown in Figure 1A, bands of the expected size were obtained. The band was obtained in 5' RLM-RACE reactions only when the template was CIP/TAP treated RNA.

The 5' terminus of Morocco had 26 nucleotides preceding the predicted start codon, including the 7-methylguanosine. The sequence of PCR product was: GGC AGA CCA CAT ATG TGG TCG ATG CC. A comparison of the 5' UTR sequence of 30 HEV strains was made as shown in Figure 2: there was a "T" at the position 4 preceding the predicted start codon in Morocco and other 25 strains while a "C" was found in other four strains; a "G" at the position 9 in the Morocco and other 28 strains turn out to be a "T" in US-SW strain; an "A" at the position 16 in Morocco and other 20 strains was replaced by a "G" or "C" in other nine strains; an additional

"A" at the terminus of eight strains except Morocco strain; and additional 9 nucleotides in the US-2 terminus.

As shown in Figure 3, the 26 nucleotides of 5' terminus could form a putative stem-loop structure. All single-nucleotide differences occurred within that loop structure.

Figure 1 RT-PCR products of 5' and 3' RNA of HEV Morocco strain. Figure 2 Comparison of sequence in the 5' UTR of different HEV strains. The translation initiation codon is underlined. The number in brackets following the strain name is the genotype designation. Changes from the consensus sequence are boxed.

Figure 3 RNA secondary structure of HEV 5' terminal sequence. Changes among HEV strains are boxed.

3' UTR

As shown in Figure 1B, 3' RACE bands of the expected size were obtained. The 3' terminus of Morocco had 65 nucleotides upstream of the polyA (the GenBank accession is AY220474). The sequence of 3' UTR was: TTT ATT TGC TTG TGC CCT CCT TCT TTC TGT TGC TTA TTT CTC TTT TCT GCG TTT CGC GCT CCC TG. The comparison of the 3' UTR sequence with the corresponding regions of other 29 HEV strains from different parts of the world revealed that the Morocco strain was most similar to the genotype 1 strains (92.3-97.4%) (Table 1). The 3' UTR nucleotide sequences of the HEV genotypes II, III and IV strains shared a lower similarity with that of Morocco strain: 80%, 65.6-83.1% and 84.6-89.2%, respectively. The phylogenetic trees also showed that the HEV Morocco strain was grouped together with all genotype I strains as a separate branch (Figures 4 and 5). Based on the 3' UTR analysis, Japan-5, -6, -7 belonged to genotype III. But according to the complete sequence analysis, they were included in genotype IV.

Table 1 Percent identity of 3' UTR of HEV genotypes (%)

	I	II	III	IV
Mor	92.3-97.4	80	65.6-83.1	84.6-89.2
I	92.3-100	74.4-81.5	25.6-84.6	79.5-90.8
II	-	100	37.5-71.8	55.1-83.8
III	-	-	75.9-94.4	41.4-80.0
IV	-	-	-	77.9-94.3

I, II, III, IV: HEV Genotype; Mor: HEV Morocco strain; -: blank well.

DISCUSSION

Variations in the length of the 5' UTR have been observed. The Burma strain was reported to have 27 nucleotides in its 5' UTR, compared with 35 nucleotides in the 5' UTR of US-2 and 26 nucleotides in the most of other strains^[13]. It remains to be determined if the extra nucleotides are really present in functional genomes. Maybe they just represented artifacts generated because the presence of a cap structure was not recognized at the time some of those strains were sequenced, or because of the additional "A" with the non-proofreading DNA polymerase in the PCR action. What was more interesting, the US-2 strain had additional nine nucleotides at the 5' terminus. They were included in the GenBank sequence but had not been discussed elsewhere, so they were difficult to evaluate. Except the US-2, all HEV strains had a comparable 5' UTR sequence with only point change from each other, and the single-nucleotide differences occurred within the loop structure. This structure may play a very important role either in replication or translation. It needs to be verified experimentally.

The 5' UTR sequences obtained by the methods of cDNA cloning/sequencing or classical 5' rapid amplification of cDNA ends (RACE) may be incomplete because neither method has a control to detect premature termination of cDNA synthesis. The finding of a 7mGpppG cap allowed reevaluation of 5' UTR sequences with a modified RACE technique called RNA ligase-mediated RACE (RLM-RACE). In RLM-RACE, an RNA sample was first treated with calf intestinal phosphatase (CIP) to remove the 5' -phosphate from all RNA species except those with a cap structure. Tobacco acid pyrophosphatase (TAP) was then used to remove the cap structure from RNA, leaving a 5' -phosphate. Next, a synthetic RNA adaptor was ligated to the CIP/TAP treated RNA. Because the adaptor ligates only to RNA containing a 5' -phosphate, RLM-RACE ensures that cDNA was amplified from decapped RNA predominantly, starting at the ultimate 5' terminus. In 2001,

Figure 4 Proposed phylogenetic trees using 3' UTR sequences of Morocco and other 29 HEV strains. The Roman number in the tree represents the genotype designation based on the 3' UTR sequence. The number in brackets following the strain name represents the genotype designation based on the full genome sequence.

Figure 5 Proposed phylogenetic trees using full sequences of 30 HEV strains. The Roman number in the tree represents the genotype designation.

Zhang *et al.* used the RLM-RACE method to confirm the capped HEV genome and extended the 5' terminal sequence of Mexico and Pak-1 strains^[13]. In the current study to obtain the complete sequence of HEV Morocco strain, we used a sequence amplification procedure that required the presence of an internal pyrophosphatase sensitive linkage in the 5' termini of HEV genome. The results indicated that the Morocco strain was capped.

The comparison of the 3' UTR sequence with the corresponding regions of other 29 HEV strains and the phylogenetic trees of those complete sequences of 30 HEV strains revealed that the HEV Morocco strain was grouped together with all genotype

I strains as a separate branch. The distribution of 3' UTR of genotypes I, II and IV was as same as that obtained by the comparison of the complete genome sequence. However, three strains isolated from Japan, Japan-5, -6, -7, which were included in genotype IV according to complete sequences analysis, clustered together with the genotype III strains based on the 3' UTR sequences analysis. This suggests that the comparison of HEV 3' UTR sequence can not represent the divergence of complete genome sequence perfectly, although this region is regarded as containing the majority of genotype-specific nucleotide positions, and easily and efficiently to amplify. So, the 3' terminal sequence upstream the polyA can not be used

for phylogenetic genotyping analysis of the HEV genome optionally. Because of the difficulties to get the complete sequences, many scientists preferred to analyze the HEV genotypes based on the partial sequences they obtained. It remains uncertain whether the partial sequences can replace the complete genome in distinguishing the HEV genotypes. So, it is prudent to analyze the HEV genotypes based on complete sequences to date.

Abstract

AIM: To investigate the role of human La protein in HBV mRNA expression.

METHODS: Three human La protein (hLa) specific siRNA expression cassettes (SECs) containing U6+1 promoter were prepared via one-step overlapping extension PCR. After transfection with SECs into HepG2 cells, inhibition effects on hLa expression were analyzed by semi-quantitative RT-PCR and Western blotting. Then, effective SECs were screened out and transfected into 2.2.15 cells, a stable HBV-producing cell line. HBV surface antigen (HBsAg) and e antigen (HBeAg) secretions into culture media were detected by microparticle enzyme immunoassay (MEIA) and HBs and HBe mRNA levels were analyzed by semi-quantitative RT-PCR.

RESULTS: SEC products containing U6+1 snRNA promoter, and 3 sites of hLa mRNA specific siRNA were obtained successfully by one-step overlapping extension PCR and could be directly transfected into HepG2 cells, resulting in inhibition of La protein expression in both mRNA and protein levels, among which U6+1-hLa833 was the most efficient, which reduced 18.6-fold mRNA and 89% protein level respectively. In 2.2.15 cells, U6+1-hLa833 was also efficient on inhibition of hLa expression. Furthermore, semi-quantitative RT-PCR showed that HBs and HBe mRNA levels were significantly decreased by 8- and 66-fold in U6+1-hLa833 transfected cells compared to control. Accordingly, HBsAg and HBeAg secretions were decreased partly posttransfection with SECs.

CONCLUSION: PCR-based SECs can be used to mediate RNAi in mammalian cells and provide a novel approach to study the function of La protein. The inhibition of La protein expression can result in a significant decrease of HBV mRNA, which implies that the hLa protein is also involved HBV RNA metabolism as one of the HBV RNA-stabilizing factors in human cells.

INTRODUCTION

Human La protein is a 47-ku phosphoprotein predominantly localized in nuclei. La protein is a member of RNA-binding proteins containing RNA recognition motifs (RRM) and interacts with RNA polymerase III transcripts such as pre-tRNA by binding to a small stretch of uridines at the 3' -end common to these transcripts and might be necessary for proper processing of these precursors^[1-3]. In addition, La protein is known to interact with a variety of viral RNAs for stabilizing various RNAs^[4-7], and is required for viral internal ribosomal entry site (IRES) -mediated translation^[8-12].

La protein has been identified as a host factor potentially involved in the cytokine-induced post-transcriptional down-regulation of hepatitis B virus (HBV) RNA^[13]. A strong correlation between cytokine-mediated disappearance of HBV RNA and cytokine-induced processing of full-length mouse La protein (mLa) was observed. The mLa binding site was mapped to a predicted stem-loop structure within a region located at the 5' -end of the post-transcriptional regulatory element of HBV shared by all HBV RNAs^[5,6]. In addition, HBV RNA was accessible to endoribonucleolytic cleavage near this mLa binding site and HBV RNA substrates were more efficiently cleaved after induction of mLa processing^[7]. All these findings indicate that La protein might be an HBV RNA-stabilizing factor. Determination of the high affinity interaction between human La protein (hLa) and HBV RNA *in vitro*^[14], which is similar to that of mLa-HBV RNA interaction, implied that hLa might be involved in HBV RNA metabolism. But the role of human La protein (hLa) in HBV RNA metabolism *in vivo* is still unknown at present.

RNA interference (RNAi) is a process of sequence-specific post-transcriptional gene silencing via double-stranded RNA (dsRNA) present in plants and invertebrates^[15]. With the increasing findings that 21-23 nt RNA duplexes known as small interfering RNA (siRNA) can also specifically and effectively knock down target gene expression in mammalian cells but short enough to evade host response^[16], RNAi has been promptly developed into a powerful tool for studying protein function.

In this report, we utilized PCR-based siRNA strategy^[17-19] to obtain several hLa-specific siRNA expression cassettes (SECs) containing U6+1 snRNA promoter and to deplete the hLa expression by transfection with SECs into human cells. In a stable HBV-producing cell line 2.2.15 cells^[20], the inhibition of hLa expression resulted in a significant decrease of HBV mRNA and partly reduction of HBV antigen secretion. This result suggests that human La protein also plays an important role in HBV expression.

MATERIALS AND METHODS

Reagents and materials

Pyrobest DNA polymerase was obtained from Takara Biotech (Japan). TaqPlus DNA polymerase was purchased from Dingguo (China). QIAquick PCR purification kit was obtained from Qiagen (Germany). M-MuLV reverse transcriptase was obtained from MBI fermentas (Lithuania). G418 was from

Clontech (USA). Fetal calf serum was from Hyclone (USA). Trizol reagent and Lipofectamine 2000 were obtained from Invitrogen Lifetechnology (USA). Mouse monoclonal antibody against human La protein was purchased from BD Biosciences (USA). Rabbit polyclonal antibody against actin was from Wuhan Boster Biological Technology (China). Donkey anti-mouse and goat anti-rabbit horseradish peroxidase (HRP)-IgG were from SantaCruz (USA). *Re-Blot Plus* Western blot recycling kit was obtained from Chemicon (USA). SuperSignal west dura extended duration substrate ECL kit and CL-Xposure film were obtained from Pierce Biotech (USA). AxSYM and detective kits of HBsAg and HBeAg were purchased from ABBOTT (USA). Polyvinylidene difluoride (PVDF) membranes were obtained from Millipore (USA). All PCR primers were synthesized by Shanghai Sangon Biological Company (China).

Plasmids and cell lines

Plasmid pAVU6+27 was a gift of Dr. Paul D. Good (Engelke Laboratory, Department of Biological Chemistry). Plasmid pcDNA3.1 was obtained from Clontech (USA). HepG2, a human hepatoblastoma cell line, and 2.2.15 cells derived from HepG2 cells and stably transfected with HBV DNA^[20] were maintained in our laboratory.

Selection of siRNA and shRNA design

Target sites of siRNA were determined by using on-line tool from Ambion Company. Three sites for hLa located downstream of the start codon were selected, their sequences are as follows: coding region 347-357 (5'-AAGGCTTCCC AACTGATGC AA-3') for hLa347, 833-843 (5'-AAGCCAAG GAAGCAT TGGGTA-3') for hLa833, 911-921 (5'-AAGTACTAGAA GGAGAGGTGG-3') for hLa911. 5'-AAGGGCGAGG AGCTGTTTACC-3' for EGFP10 siRNA site was used as control for studying the effect of hLa siRNA. Using 5'-TTCAAGAGA-3' as 9-nt loop, all short hairpin RNAs (shRNA) were designed according to the structure of siRNA sense strand-loop-siRNA antisense strand.

Preparation of SECs

U6+1 promoter was obtained from plasmid pAVU6+27 containing human U6 promoter. Oligonucleotides coding hairpin shRNA antisense were synthesized and used for PCR reaction as 3' specific extension primers. All extension primers have the 5' end 21-nt containing additional adaptor sequence and a stretch of 6 deoxyadenosines as transcription terminator. The 5' universal primer is complementary to 18 nt at the 5' end of the U6 snRNA promoter (bold italics) 5'-GGAAGA TCTGGATCCAAGGTCGGG-3' and the 3' universal primer is complementary to the first 21-nt at the 5' end of all extension primers 5'-CGGCT CTAGAGTTCAAAAAAG-3'. Both universal primers were 5'-phosphorylated and could be used for all PCR reactions. SEC was constructed by using one specific extension primer and two universal primers via overlapping extension one-step PCR as depicted in Figure 1.

Using Pyrobest polymerase 30 cycles of PCR reactions were carried out, each at 94 °C for 30 s, at 58 °C for 30 s, and at 72 °C for 30 s. The PCR products were purified using QIAquick PCR purification kit (Qiagen) and stored at -20 °C prior to use.

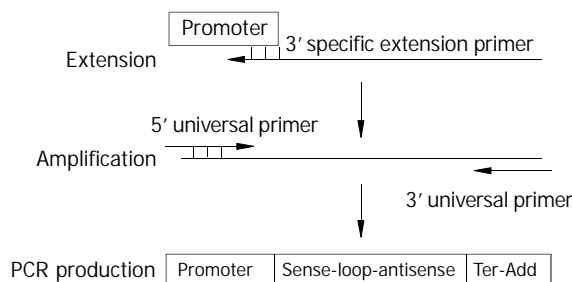

Figure 1 Schematic representation of one-step overlapping extension PCR strategy used to yield SECs.

Cell culture and cotransfection

HepG2 cells were maintained in Dulbecco's modified Eagle's minimal essential medium (DMEM) supplemented with 100 mL/L FCS, streptomycin (100 µg/mL) and penicillin (100 IU/mL) at 37 °C in a humidified atmosphere containing 50 mL/L CO₂. 2.2.15 cells were grown in DMEM with 100 mL/L FCS, 400 µg/mL G418. HepG2 and 2.2.15 cells were seeded into 24-well plates 24 h or 48 h prior to transfection. HepG2 cells at 50% confluence and 2.2.15 cells at 70% were prepared for transfection. For all co-transfections, a total of 0.05 µg pcDNA3.1+ (used as carrier DNA) and 0.2 µg SEC was delivered using Lipofectamine 2000 according to the manufacturer's instructions. HepG2 cells were harvested for analysis of La mRNA and protein expression. 2.2.15 cells and supernatants were harvested for detection of HBV mRNA and antigen.

RNA extraction and semi-quantitative RT-PCR analysis

Total RNA was extracted from cells with Trizol reagent according to the manufacturer's instructions, 1.0 µg of total RNA was reverse transcribed to cDNA using oligo (dT) 18 as primer and Mu-MLV reverse transcriptase, and 0.5 µL of the cDNA template was separately used to amplify different mRNA. Information of primers is shown in Table 1. The PCR conditions for different target were as follows. A total of 28 cycles for GAPDH were performed, each at 94 °C for 30 s, at 60 °C for 30 s, and at 72 °C for 30 s. A total of 26 cycles for hLa were performed, each at 94 °C for 30 s, at 58 °C for 30 s, and at 72 °C for 30 s. A total of 26 cycles for HBs were performed, each at 94 °C for 30 s, at 56 °C for 30 s, and at 72 °C for 30 s. A total of 30 cycles for HBe were performed, each at 94 °C for 30 s, at 46 °C for 30 s, and at 72 °C for 45 s. After electrophoresis and scanning, all PCR product bands were analyzed by using the software Gel Pro analyzer32 and relative mRNA expression was estimated by normalization with GAPDH.

Table 1 PCR primers for amplification

Primer	GenBank accession No	Sequence of primer pair
GAPDH	BC023632 (26-260)	Sense: 5' -TGGGGAAGGTGAAGGTCGGA -3' Antisense: 5' -GGGATCTCGCTGCTCGAAGA-3'
hLa	BC001289 (871-1313)	Sense: 5' -GGATAGACTTCGTCAGAGGAGCA -3' Antisense: 5' -CTGGTCTCCAGCACCATTCTG -3'
HBs	U95551 (232-681)	Sense: 5' -CTCACAATACCGCAGAGTC-3' Antisense: 5' -TAAACTGAGCCAGGAGAGAAA-3'
HBe	U95551 (1816-2452)	Sense: 5' -ATGCAACTTTTTCACCTC-3' Antisense: 5' -AACATTGAGGTTCCCGAG-3'

Western blot analysis

Cells were harvested and lysed in lysis buffer (0.1 mol/L Tris, pH 7.6, containing 0.15 mol/L NaCl, 2 mmol/L EDTA, 5 g/L Nonidet P-40, 5 g/L Triton X-100, 100 μ mol/L sodium vanadate, 10 μ g/mL aprotinin, and 20 μ g/mL soybean trypsin inhibitor). The cell lysate (10-15 μ g protein) was separated by sodium dodecyl sulfate-polyacrylamide (SDS-PAGE) gel electrophoresis and electrophoretically transferred onto PVDF membrane. After non-specific binding sites were blocked with 50 g/L non-fat milk, the membrane was incubated with mouse anti-hLa monoclonal antibody (1:600 dilution) overnight at 4 °C. After washed, the blot was incubated with HRP-conjugated anti-mouse IgG for 1 h at room temperature, and immunoreactive bands were visualized with the ECL reagent. After the blot was stripped with stripping solution, the blot was reprobed with rabbit anti-actin polyclonal antibody for comparison of protein load in each lane. Densitometric scanning of the X-ray film following chemiluminescence was done and La protein expression level was estimated after normalization with actin.

Microparticle enzyme immunoassay (MEIA) analysis

Supernatants of 2.2.15 cells were harvested on days 1, 2, 3, 6 and 9 posttransfection respectively in same wells. Each experiment well was performed in triplicate. A microparticle enzyme immunoassay (MEIA) method was applied for the detection of HBsAg and HBeAg according to the kit's instructions. Sample with S/N values great than or equal to 2.0 for HBsAg, and S/CO values great than or equal to 2.1 for HBeAg were considered reactive as described previously^[21].

RESULTS

RNAi inhibited hLa protein expression in cultured HepG2 cells

To determine whether siRNA specific to the hLa gene sequence could inhibit hLa expression, we screened the activity of three sites of hLa-specific siRNA by semi-quantitated RT-PCR of hLa mRNA in HepG2 cells 36 h posttransfection with SECs. Two of them, SEC U6+1-hLa347 and U6+1-hLa833 significantly decreased hLa mRNA levels by about 8.8- and 17.6-fold respectively as compared with the control (Figure 2A). However, SEC U6+1-hLa911 only slightly affected hLa mRNA expression (1.3-fold reduction). No significant inhibition of hLa mRNA expression was detected in cells transfected with SEC U6+1-EGFP10 (Figure 2A). Furthermore, we performed Western blot analysis to verify the inhibitory effects on hLa protein expression levels 72 h posttransfection with SEC U6+1-hLa347 and U6+1-hLa833. As shown in Figure 2B, hLa protein expression almost could not be detected in cells transfected with U6+1-hLa833. After normalized to actin, the level of hLa protein expression was reduced to approximately 11% and 49% of the control cells for U6+1-hLa833 and U6+1-hLa347 respectively, and no reduction was found for U6+1-EGFP10. These data demonstrated that SEC-mediated RNAi could effectively inhibit human La protein expression in cultured HepG2 cells and the down-regulation in hLa was sequence-specific and highly site-dependant.

RNAi inhibited hLa mRNA expression in cultured 2.2.15 cells

As SEC U6+1-hLa833 could greatly specific inhibit hLa mRNA and protein expressions in HepG2 cells, we then assessed its inhibitory effects on 2.2.15 cells derived from HepG2. As shown in Figure 3A, inhibition of hLa mRNA levels was detected with the reduction of about 22- and 3.4-fold on days 1 and 2 posttransfection, but no inhibitory effects were observed from days 3 to 9 posttransfection. In addition, no significant inhibition of hLa mRNA levels was detected in cells posttransfection with the SEC U6+1-EGFP-10 (Figure 3A).

This result indicates that SEC-mediated RNAi could also effectively inhibit hLa mRNA expression in cultured 2.2.15 cells, but the inhibitory effects could last only for a short time.

Figure 2 Effect of RNAi on hLa expression in HepG2 cells. A: Total RNA isolated from HepG2 cells transfected with various SECs for hLa and EGFP. The number was the ratio between the signal intensity for GAPDH and hLa mRNA amplified in parallel. B: Western blotting of total cell lysates harvested from SECs-transfected HepG2 cells 72 h posttransfection. Actin was used as loading control. The number was the percentage of the signal intensity of hLa and actin protein (%).

Inhibition of hLa expression led to reduction of HBV mRNA levels in cultured 2.2.15 cells

In order to investigate the relationship between hLa mRNA and HBV RNA expression, using the same samples, the levels of HBs and HBe mRNA expression in SEC-transfected 2.2.15 cells were detected by semi-quantitative RT-PCR. The HBs mRNA levels were also decreased about 8- and 2.8-fold in the first 2 d posttransfection, which were associated with a parallel reduction of hLa mRNA levels (Figure 3B). Moreover, HBe mRNA decreased dramatically, and almost could not be detected in the first 2 d and the inhibitory effect could last for at least 9 d (Figure 3C). In contrast, no significant changes in HBs and HBe mRNA levels were observed in cells posttransfection with SEC U6+1-EGFP-10 (Figures 3B and 3C). These results demonstrated that RNAi against hLa could lead to reduction of HBV mRNA levels in 2.2.15 cells.

Figure 3 Effect of RNAi on hLa mRNA expression and levels of HBV mRNA expression in 2.2.15 cells. The number was the ratio between the signal intensity for hLa, HBs, HBe, and GAPDH mRNA amplified in parallel.

Inhibition of hLa expression affected HBsAg and HBeAg secretion in 2.2.15 cells

If the inhibition of hLa expression could affect HBs and HBe

mRNA expressions in 2.2.15 cells, HBsAg and HBeAg secretion would be affected accordingly. Supernatant of SEC-transfected and control cells was harvested in the same period of posttransfection, HBsAg and HBeAg concentrations in the culture media were measured by MEIA method. Figure 4A shows that transfection with SEC U6+1-hLa833 inhibited the secretion of HBsAg in 2.2.15 cells from days 3 to 9 posttransfection in comparison with that of SEC U6+1-EGFP10 ($P<0.05$). The maximal inhibitory effect on day 6 posttransfection was 40%, and returned to 26% on d 9. HBeAg secretion was inhibited 38% on d 3 posttransfection with SEC U6+1-hLa833 and remained 46% and 51% on d 6 and 9 respectively (Figure 4B). There was a significant difference ($P<0.05$) in HBeAg secretion between SEC U6+1-hLa833- and U6+1-EGFP10-transfected cells on d 3, 6 and 9 posttransfection.

Figure 4 Time-efficiency inhibition course of SECs on HBsAg and HBeAg in 2.2.15 cells. The inhibition rate (IR) was calculated according to the following formula:

$$\text{IR} = \frac{\text{X of wells for control} - \text{X of wells for transfection}}{\text{X of wells for control} - \text{N}} \times 100\%$$

X represents S/N or S/CO for HBsAg or HBeAg, and $n=2.0$ for HBsAg and 2.1 for HBeAg respectively.

DISCUSSION

Results showed here from studies in 2.2.15 cells using siRNA against human La protein revealed a significant reduction in hLa expression, that resulted in HBV mRNA level reduction simultaneously, especially the expression of HBe mRNA, which was markedly decreased in the first 3 d and maintained at a lower level on the 9th d after inhibition of hLa expression. Following HBV mRNA reduction, HBsAg and HBeAg secretions were decreased accordingly though reduction of HBV antigen was less significant than that of corresponding mRNA. The relevance of RNAi-mediated knockdown of hLa towards reduction of HBV mRNA level suggested that human La protein might also be involved in HBV RNA metabolism. Based on the previous findings of the high affinity interaction between human La protein (hLa) and HBV RNA *in vitro*^[14], and mouse La protein might be an HBV RNA-stabilizing factor in HBV-transgenic mouse model^[5,7]. Our results invited a

presumption that La protein might also play a role in stabilizing HBV RNA in human cells. However, HBsAg and HBeAg secretions could be affected slightly by hLa expression level, indicating that La protein is not a unique factor, and additional factors could contribute to viral RNA stability or HBV expression regulation. Therefore, using only hLa as targets for a novel antiviral strategy^[14] would not be practical. Experiments to investigate the role of other RNA-binding proteins in HBV RNA metabolism might gain better insights into this problem.

We also observed that downregulation of HBe seemed more significant than HBs, implying more abundant HBs mRNA could generate HBsAg than HBe in 2.2.15 cells, which was in accord with the redundant HBsAg expression and secretion from patients with HBV infection. So HBs might be poorly susceptible to interfering factors. In addition, the feature of overlapping reading frames made entire 2.1-kb mRNA sequence encode HBs that was contained in 3.5-kb mRNA sequence encoding Hbe^[22,23]. In fact, HBs mRNA level detected by RT-PCR in our experiments represented the total transcript level containing HBe and HBs. Therefore, instead of RT-PCR, Northern blot analysis should reflect the truth of all HBV transcripts in more detail.

As to siRNA application in RNAi technology, besides chemically synthesized 21-nt siRNA duplexes^[16], some approaches could generate siRNA for various needs, such as *in vitro* transcribed siRNA^[24,25], plasmid DNA expression vector-based siRNA^[26, 27], viral vector-based siRNA^[28-30], and PCR-based siRNA expression cassette (SEC)^[17-19] which was proved to be a rapid, facile and cheap approach for identification of optimal siRNA-targets. In this report, we attempted to simplify the commonly used two-step PCR into overlapping-extension one-step PCR reaction by using three primers: a long specific extension primer and two universal primers, and also successfully prepared SECs targeting three sites of hLa mRNA. After transfection with these SECs into HepG2 cells, SEC U6+1-hLa833 demonstrated that strong RNAi effect was promptly screened out as optimal SEC to be used for further study. As a 347-bp in length of SEC DNA, it is often difficult to transfect them into mammalian cells, but using plasmid as carrier DNA, the efficiency of transfection seemed to be improved significantly (data not shown). On the other hand, stability of SEC DNA in cells should be considered. Despite SECs were phosphorylated for enhancing resistance to nuclease in cells, but target mRNA level still returned to normal on day 3 posttransfection, which maintained RNAi effect not as long as reported in application of vector-based siRNA^[26], indicating that SEC strategy should be just adapted to transient gene silencing at present and the better modification strategies should be developed for its stability.

To our knowledge, this is the first report that describes the role of human La protein in HBV expression in cultured human cells. Elucidating the mechanism of human La protein affecting HBV expression and replication will allow a deeper understanding of the interaction between host factors and HBV during HBV infection and clearance, and will provide useful clues for controlling HBV infection.

Abstract

AIM: To determine the biological activity of *Helicobacter pylori* (*H pylori*) lipopolysaccharide (H-LPS) and understand pathological correlation between H-LPS and human chronic gastritis and peptic ulcer.

METHODS: H-LPS of a clinical *H pylori* strain and LPS of *Escherichia coli* strain O55:B5 (E-LPS) were extracted by phenol-water method. Biological activities of H-LPS and E-LPS were detected by limulus lysate assay, pyrogen assay, blood pressure test and PBMC induction test in rabbits, cytotoxicity test in NIH 3T3 fibroblast cells and lethality test in NIH mice. By using self-prepared rabbit anti-H-LPS serum as the first antibody and commercial HRP-labeled sheep anti-rabbit sera as the second antibody, H-LPS in biopsy specimens from 126 patients with chronic gastritis (68 cases) or gastric ulcer (58 cases) were examined by immunohistochemistry.

RESULTS: Fibroblast cytotoxicity and mouse lethality of H-LPS were weaker than those of E-LPS. But the ability of coagulating limulus lysate of the two LPSs was similar ($+/0.5$ ng/mL). At 0.5 h after H-LPS injection, the blood pressures of the 3 rabbits rapidly declined. At 1.0 h after H-LPS injection, the blood pressures in 2 of the 3 rabbits fell to zero causing death of the 2 animals. For the other one rabbit in the same group, its blood pressure gradually elevated. At 0.5 h after E-LPS injection, the blood pressures of the three rabbits also quickly declined and then maintained at low level for approximately 1.0 h. At 0.5 h after injection with H-LPS or E-LPS, PBMC numbers of the rabbits showed a remarkable increase. The total positivity rate of H-LPS from 126 biopsy specimens was 60.3% (76/126). H-LPS positivity rate in the biopsy specimens from chronic gastritis (50/68, 73.5%) was significantly higher than that from gastric ulcer (26/58, 44.8%) ($\chi^2=10.77$, $P<0.01$). H-LPS positivity rates in biopsy specimens from chronic superficial gastritis (38/48, 79.2%) and chronic active gastritis (9/10, 90.0%) were significantly higher than that of the patients with atrophic gastritis (3/10, 30.0%) ($\chi^2=7.50-9.66$, $P<0.01$).

CONCLUSION: The biological activities of H-LPS were

weaker than those of E-LPS, the activities of H-LPS of lowering rabbit blood pressure and inducing rabbit PBMC were relatively stronger. H-LPS may play a critical role in inducing inflammatory reaction in human gastritis.

INTRODUCTION

Gastritis and peptic ulcer are the most prevalent gastric diseases. Gastric cancer is one of the malignant tumors with high morbidities in China^[1]. *Helicobacter pylori* (*H pylori*) is recognized as a human-specific gastric pathogen that colonizes the stomachs of at least half of the world's populations^[2]. Most infected individuals are asymptomatic. However, in some subjects, the infection causes acute, chronic gastritis or peptic ulceration, and plays an important role in the development of peptic ulcer and gastric adenocarcinoma, mucosa-associated lymphoid tissue lymphoma and primary gastric non-Hodgkin's lymphoma^[3-7].

H pylori is a microaerophilic Gram-negative bacillus. It is well known that lipopolysaccharide (LPS) is a common and essential component in outer membrane of most Gram-negative bacteria responsible for the toxicity of endotoxin. Some literatures revealed *H pylori* possesses LPS (H-LPS) with a lower virulence compared to the typical bacterial endotoxins such as *Escherichia coli* LPS (E-LPS)^[8-12]. However, some biological activities such as regulating blood pressure and inducing peripheral blood mononuclear cell (PBMC), which are clinically important in local tissue inflammation and injury, and pathological importance of H-LPS in human gastric diseases are still little understood. Besides, some previously published data demonstrated that different strains of the same bacterium and different extraction methods would significantly affect the biological activity of LPS^[13,14].

For measurement of the biological activities of H-LPS *in vivo* and *in vitro* compared to a typical LPS from *E. coli*, we used phenol-water method to extract LPS from a clinical isolated *H pylori* strain and applied routine assays for determining the endotoxin activity of H-LPS such as limulus lysate agglutination, rabbit pyrogenicity and mouse lethality. Furthermore, we also examined H-LPS activities on blood pressure regulation and PBMC inducement. To obtain direct evidence for the correlation of H-LPS and human chronic gastritis and peptic ulcer, we detected H-LPS in gastric biopsy specimens from patients with different gastric diseases.

MATERIALS AND METHODS

Bacterial strains and culture

A clinical *H pylori* strain named as Y06 was isolated from a

biopsy specimen of a male patient with chronic superficial gastritis and duodenal ulcer by using selected Columbia agar (bioMérieux) supplemented with 80 mL/L sheep blood, 5 g/L cyclodextrin, 5 mg/L trimethoprim, 10 mg/L vancomycin, 2.5 mg/L amphotericin B and 2 500 U/L cefsulodin. This strain was identified as *H. pylori* based on its typical Gram staining morphology, positivity for both urease and oxidase, and agglutination with a commercial rabbit antibody against whole cell of *H. pylori* (DAKO). *E. coli* strain O55:B5 was offered by the National Institute for the Control of Pharmaceuticals and Biological Products of China (NICBPB) and cultured with BL agar.

LPS extraction

H-LPS from *H. pylori* strain Y06 and E-LPS from *E. coli* strain O55:B5 were extracted by phenol-water method. Briefly, the two bacteria collected from Columbia agar and BL agar were ultrasonically broken, respectively. Each of the broken bacterial solutions was added with an equal volume of pre-warmed phenol-water (9:1, V:V) and then vibrated for 30 min at 68-70 °C. The aqueous phase was collected after centrifugation at 3 000 r/min for 30 min. This extraction step was repeated for 3 times. All the aqueous phases were combined and then dialyzed against distilled water for 48 h. This rough LPS extract was concentrated to 1/6 of the original volume and then digested with RNase H and DNase I (Sigma) to both the final concentration of 50 µg/mL at 37 °C for 4 h. The digested extract was bathed in boiling-water for 15 min and then placed at 4 °C overnight. The supernatant obtained after centrifugation at 3 000 r/min for 30 min was dialyzed against distilled water for 48 h and then precipitated with 6-fold volumes of anhydrous alcohol at 4 °C for 12 h. The precipitate was collected by centrifugation at 5 000 r/min for 30 min and then re-suspended with distilled water and dialyzed against distilled water for 24 h to remove residual alcohol. The LPS extract was ultra-centrifuged at 110 000 g for 3 h (4 °C) and the pellet was dialysed in distilled water and freeze-dried. The purified H-LPS and E-LPS were dissolved in pyrogen-free water or normal saline prepared with pyrogen-free water just before different uses.

Limulus lysate assay

Limulus lysate assay was applied by using E-TOXATE Reagent Kit (Sigma) to detect the H-LPS and E-LPS preparations according to the manufacturer's instruction (Sensitivity = +, 1 ng/mL *E. coli* O55:B5 LPS). In this assay, *E. coli* O55:B5 LPS (Sigma) and pyrogen-free water were used as the positive and negative controls, respectively.

Rabbit pyrogen assay

Anal temperatures of normal New Zealand rabbits with 3.0±0.2 kg of body mass were detected for 3 times at an interval of 30 min before performing the test. A rabbit was suitable for the test if the fluctuant range of the three detected temperatures was ≤0.2 °C. The qualified rabbits were randomly divided into three groups and each group contained three animals. Each of the three rabbits in one group was injected with 0.5 mL normal saline containing H-LPS or E-LPS at the same dosage of 100 µg/kg through ear vein. Each of the three rabbits in the 3rd group was injected with an equal volume of pyrogen-free normal saline as a negative control. Anal temperature in each of the tested rabbits was detected at an interval of 30 min for 5 h after injection. The positive standard for rabbit pyrogen assay was described as following: body temperature for any one of the three rabbits in one group showed ≥0.6 °C elevation, or the total elevated body temperature for the three rabbits in one group was ≥1.4 °C.

Rabbit blood pressure regulation test

Normal New Zealand rabbits with 3.0±0.2 kg of body mass were ear-intravenously injected with 0.5 mL pyrogen-free normal saline. Then blood pressures of the animals were observed for three times at an interval of 30 min. A rabbit was suitable for this test if its blood pressure fluctuation was within 0.2 kPa. The qualified rabbits were divided into three groups and each contained three animals. Each of the three rabbits in one group was ear-intravenously injected with pyrogen-free saline containing H-LPS or E-LPS at the same dosage of 100 µg/kg and each of the three rabbits in the 3rd group were ear-intravenously injected with an equal volume of pyrogen-free saline as a negative control. The changes of blood pressure in the tested rabbits were observed.

PBMC inducement test

PBMC numbers in blood from ear vein of normal New Zealand rabbits with 3.0±0.2 kg of body mass were counted with hemacytometer twice at an interval of 30 min before performing the test. These rabbits were randomly divided into three groups and each contained 5 animals. Each of the five rabbits in one group was ear-intravenously injected with pyrogen-free saline containing H-LPS or E-LPS at the same dosage of 100 µg/kg and each of the five rabbits in the 3rd group were ear-intravenously injected with an equal volume of pyrogen-free saline as a negative control. The change of PBMC numbers for each of the tested rabbits was counted at an interval of 30 min after injection.

Cytotoxicity test

Microtiter plates were inoculated with 1×10⁴ mouse 3T3 fibroblast cells in RPMI 1640 medium containing 100 mL/L bovine serum per well and then incubated at 37 °C overnight in 50 mL/L CO₂ atmosphere. The medium in the plates was discarded and then added with 200 µL of fresh medium containing H-LPS or E-LPS with different double dilutions. For each of the dilutions, 3 wells were repeated and then incubated for 48 h under the same conditions as mentioned above. In this test, the other 5 wells added with the same volume of LPS-free medium were set up as a negative control. ³H-TdR per well (37 kBq) was added and then continuously incubated for 24 h. CPM value for each of the wells was detected by using ³H-TdR incorporation method to compare the cytotoxicity of H-LPS and E-LPS.

Mouse lethality test

NIH mice weighing 20±2 g were randomly divided into 7 groups and each contained 8 animals. For 6 of the 7 groups, each of the mice in one group was intraperitoneally injected with 0.2 mL pyrogen-free normal saline containing H-LPS or E-LPS at the different dosages of 0.25, 0.50 and 1.0 mg, respectively. Each of the mice in the last group was intraperitoneally injected with 0.2 mL pyrogen-free saline as a negative control. All the tested animals were observed for 7 d.

Detection of H-LPS in biopsy specimens from patients with chronic gastritis and gastric ulcer

Biopsy specimens with positive urease from 126 patients (86 male, 40 female, mean age: 40±18 years) with gastric diseases during January to September of 2003 were collected from three hospitals in Hangzhou. Among these patients, 68 suffered from chronic gastritis (48 cases with chronic superficial, 10 active and 10 atrophic gastritis) and 58 cases suffered from gastric ulcer (12 cases with gastric, 40 duodenal and 6 complex ulcer). The biopsy specimens were fixed with 50 g/L glutaraldehyde. Rabbit anti-H-LPS serum was prepared by using routine subcutaneous immunization. By using the

rabbit anti-H-LPS serum (1:200 dilution, self-prepared) as the first antibody and HRP-labeled sheep anti-rabbit serum (1:3 000 dilution, ImmunoResearch) as the second antibody, H-LPS in the biopsy specimens was detected by routine immunohistochemistry. Cells with at least one whole gastric gland in a biopsy section showing exactly brown color could be considered as positive.

RESULTS

Limulus lysate coagulation

The ability of coagulating limulus lysate of H-LPS was as low as 0.5 ng/mL, which was similar to E-LPS (Table 1).

Table 1 Results of limulus lysate assay of H-LPS and E-LPS

Group	LPS (ng/mL)							
	10.0	5.0	2.5	1.0	0.5	0.25	0.1	0.05
H-LPS	+	+	+	+	+	-	-	-
E-LPS	+	+	+	+	+	-	-	-
Pyrogen-free water	negative in two repeated samples							

Pyrogenic response

The rabbits injected with H-LPS or E-LPS showed a similar biphasic fever but E-LPS could induce a stronger pyrogenic response. The animal temperature reached a peak at 1.5 h after injection and then showed a slight fall. At 3 h after injection, the second fever peak occurred (Figure 1).

Figure 1 Fever curves of rabbits after injection with H-LPS or E-LPS.

Regulation of rabbit blood pressure

At 0.5 h after H-LPS injection, the blood pressures of the three rabbits rapidly declined from originally 11.331 ± 0.152 kPa to 5.999 ± 1.855 kPa. At 1.0 h after H-LPS injection, the blood pressures in two of the three rabbits fell to zero causing death of the two animals. For the other one rabbit in the same group, its blood pressure gradually elevated. At 0.5 h after E-LPS injection, the blood pressures of the three rabbits also quickly declined from originally 11.197 ± 0.163 kPa to 8.531 ± 2.424 kPa and then maintained the similar low blood pressure levels for approximately 1.0 h. At 2.5 h after injection, the blood pressures in all the three rabbits began to rise and returned to the original levels gradually.

PBMC inducement

At 0.5 h after injection with H-LPS or E-LPS, PBMC numbers of the rabbits showed a remarkable increase. From 1.0 h after injection with H-LPS or E-LPS, the PBMC numbers gradually and continuously decreased to low levels (Table 2).

Cytotoxicity to mouse fibroblast

Very low dosage of H-LPS or E-LPS (1 μ g/mL) could show

an obvious cytotoxicity to NIH 3T3 fibroblast. According to the counting per minute (CPM) of scintillation at the same concentrations, cytotoxicity of H-LPS seemed to be a little weaker than that of E-LPS (Table 3).

Table 2 PBMC number changes in the rabbits injected with H-LPS or E-LPS

Time (h)	PBMC (mean \pm SD, $\times 10^9$ /L)		
	H-LPS	E-LPS	Saline
Before injection	4.52 \pm 1.28	4.38 \pm 1.35	4.05 \pm 1.42
After injection			
0.5	12.51 \pm 0.54	8.22 \pm 0.68	4.25 \pm 1.28
1.0	2.55 \pm 0.87	2.23 \pm 1.32	4.40 \pm 1.19
1.5	1.56 \pm 1.33	1.58 \pm 1.27	4.08 \pm 1.24
2.0	1.62 \pm 0.93	1.64 \pm 0.89	4.05 \pm 1.06
2.5	1.65 \pm 1.12	1.60 \pm 1.34	4.35 \pm 1.17
3.0	1.56 \pm 1.45	1.52 \pm 1.10	4.16 \pm 1.22

Table 3 Cytotoxicity of H-LPS and E-LPS to mice fibroblast

Group	LPS (μ g/mL)	CPM (mean \pm SD)	<i>t</i>	<i>P</i>
H-LPS	1.0	7 722 \pm 819	3.74	<0.05
	5.0	4 724 \pm 726	7.29	<0.01
	10.0	4 328 \pm 1 194	6.56	<0.01
	50.0	3 618 \pm 434	9.27	<0.001
	100.0	2 963 \pm 764	9.20	<0.001

	5.0	4 290 \pm 474	8.37	<0.005
	10.0	3 516 \pm 645	8.96	<0.001
	50.0	3 224 \pm 534	9.55	<0.001
	100.0	2 513 \pm 630	10.72	<0.001
Control	0	11 083 \pm 1 324		

Mouse lethality

H-LPS showed a significantly weaker virulence to mice than E-LPS. Although the injecting dosage was as high as 1 mg H-LPS per mouse, 2 of the 8 mice survived (Table 4).

Table 4 Toxicity test results in mice injected with H-LPS or E-LPS

Group	Number (n)	Dosage (mg/mouse)	Death/Survival (n/n)	Mortality (%)
H-LPS	8	0.25	0/8	0
	8	0.50	4/4	50.0
	8	1.00	6/2	75.0
E-LPS	8	0.25	2/6	25.0
	8	0.50	7/1	87.5
	8	1.00	8/0	100
	8	/	0/8	0

Positivity rate of H-LPS in biopsy specimens

The total positivity rate of H-LPS in the 126 biopsy specimens was 60.3% (Table 5). Totally 73.5% of the biopsy specimens from chronic gastritis patients (50/68) were H-LPS positive, which was significantly higher than that (44.8%) from gastric ulcer patients (26/58) ($\chi^2=10.77$, $P<0.01$). H-LPS positivity rate in biopsy specimens of the patients with chronic superficial gastritis (38/48, 79.2%) was similar to that of the patients with chronic active gastritis (9/10, 90.0%) ($\chi^2=0.63$, $P>0.05$), but both positivity rates were much higher than that of the patients with atrophic gastritis (3/10, 30.0%) ($\chi^2=7.50$ -9.66, $P<0.01$). Among the biopsy specimens from patients with any one of

the three types of gastric ulcer, the H-LPS positive rates were similar to each other ($\chi^2=0.11-1.25$, $P>0.05$). A H-LPS positive biopsy specimen is shown in Figure 2.

Figure 2 H-LPS positive biopsy specimen (Original magnification: $\times 600$).

Table 5 H-LPS detection rates in the biopsy specimens from patients with chronic gastritis and gastric ulcer

Group	Number (n)	Positivity (n)	Positive rate (%)
Chronic gastritis			
Superficial	48	38	79.2
Active	10	9	90.0
Atrophic	10	3	30.0
Gastric ulcer			
Gastric	12	7	58.3
Duodenal	40	16	40.0
Complex	6	3	50.0
Total	126	76	60.3

DISCUSSION

Bacterial endotoxin possesses broad biological activities and its toxicity is mainly dependent on lipid A^[15]. Among the biological activities of LPS, limulus amoebocyte lysate coagulation, rabbit pyrogen and mouse lethality are most typical and important^[16,17]. In some of the previously published data, H-LPS showed much lower activities of coagulating limulus lysate, pyrogenic response in rabbit and lethal potential in mice^[8,9]. In our study, we found that the effect of H-LPS on causing fever in rabbits, death in mice and its cytotoxicity to NIH 3T3 fibroblast were less compared to the LPS from *E. coli*. However, the ability of coagulating limulus lysate of H-LPS ($+0.5$ ng/mL) was similar to that of E-LPS based on several repeated results. As mentioned in Introduction, LPS preparations might have various biological activities if different extraction methods were used^[13,14]. The result in limulus lysate assay of this study differed from the previously reported probably due to H-LPS from different strains and the distinction in LPS extraction methods.

Salgado *et al.* revealed that H-LPS from different strains could be divided into two types: One of low biological activity and one of high biological activity of inducing the mitogenicity and TNF- α synthesis of cells. And the strains with the high activity were demonstrated belonging to the low virulence genotypes with *cagA*⁻ and s1bm2 or s2m2 for *vacA*^[18]. To our surprise, at the same injected dosage (100 μ g/kg·b.w.) in our study, H-LPS caused death in two of the three tested rabbits in blood pressure regulation test but E-LPS did not. In addition, the ability of H-LPS of inducing PBMC at 0.5 h after injection ($12.51\pm 0.54\times 10^9/L$) was also stronger than that of E-LPS [$(8.22\pm 0.68)\times 10^9/L$]. These data, including the results reported

by Salgado *et al.*, indicated that the role of the LPS as a virulence factor from some *H. pylori* strains should be re-evaluated.

It was reported that H-LPS acted as a modulator of host-dependent gastritis through inducing both gastric epithelial cells and macrophages to secrete IL-1, TNF and IL-8^[19-21]. In this study, a high frequency of H-LPS in the biopsy specimens from chronic gastritis patients (73.5%) was found. However, the positivity rate of H-LPS in the biopsy specimens from gastric ulcer patients (44.8%) was relatively lower ($\chi^2=10.77$, $P<0.01$). Furthermore, the biopsy specimens from chronic superficial gastritis (79.2%) and chronic active gastritis (90.0%) showed significantly higher H-LPS positive rates compared to those from chronic atrophic gastritis (30.0%) ($\chi^2=7.50-9.66$, $P<0.01$). These data indicated that H-LPS might play a more important role in inducing human gastric inflammation than previously considered. It is well known that PBMC are a mixture of neutrophilic granulocytes, mononuclear macrophages and lymphocytes^[22-24]. Mononuclear macrophages and lymphocytes are the major cells to produce IL-1, TNF and IL-8^[25-27]. The result from our study showed that H-LPS had a stronger ability of inducing PBMC than E-LPS, suggesting the critical effect of H-LPS on inducing inflammatory reaction in human gastritis.

Abstract

AIM: To determine the prevalence of genotypes of *cagII* in *Helicobacter pylori* (*H pylori*)-infected patients in Zhejiang Province and investigate the relationship between these genotypes and the types of gastroduodenal diseases.

METHODS: One hundred and seventy one clinical isolates were collected from 70 chronic superficial gastritis, 31 chronic atrophic gastritis, 41 gastric ulcer, 21 duodenal ulcer, 3 gastric and duodenal ulcer, and 5 gastric adenocarcinoma patients. Polymerase chain reaction assays were performed for analysis of *cagT*, *ORF13* and *ORF10* genes in the *cagII* region.

RESULTS: Of 171 *H pylori* isolates from Zhejiang patients, 159(93.0%) were positive for all the three loci. One isolate (0.6%) was negative for all the three loci, and 11(6.4%) were partially deleted in *cagII*. The positive rates of *cagT*, *ORF13* and *ORF10* genes were 97.1%, 94.7% and 99.4%, respectively. In the strains isolated from the patients with diseases including chronic superficial gastritis, chronic atrophic gastritis, gastric ulcer and duodenal ulcer, the positive rates of *cagT* were 95.7%, 100.0%, 95.1% and 100.0%, respectively. The positive rates of *ORF13* were 94.3%, 93.5%, 95.1% and 100.0%, respectively. The positive rates of *ORF10* were 98.6%, 100.0%, 100.0% and 100.0%, respectively. The three genes were all positive in the three *H pylori* strains isolated from the patients with both gastric and duodenal ulcer. In the five strains isolated from the patients with gastric adenocarcinoma, only one isolate was negative for *ORF13*. There were no significant differences of the *cagT*, *ORF13* and *ORF10* genes among the different gastroduodenal diseases including chronic superficial gastritis, chronic atrophic gastritis, gastric ulcer, duodenal ulcer, both gastric and duodenal ulcer and gastric adenocarcinoma ($\chi^2=3.098$, $P>0.05$ for *cagT*; $\chi^2=3.935$, $P>0.05$ for *ORF13* and $\chi^2=6.328$, $P>0.05$ for *ORF10*).

CONCLUSION: The *cagII* is not a uniform and conserved entity. Although the genes in *cagII* are highly associated with the gastroduodenal diseases, the clinical outcome of *H pylori* infection is not reliably predicted by the three genes in *cagII* in patients from Zhejiang Province.

INTRODUCTION

Although more than 50% of the world population are infected with *Helicobacter pylori* (*H pylori*), most of the carriers are asymptomatic^[1,2]. Only a minority of infected persons may develop serious gastroduodenal diseases. Though the pathogenesis of *H pylori* infection is not well understood, there are several putative virulence factors that may contribute to mucosal damage by *H pylori* infection such as the cytotoxin associated gene (*cag*) pathogenicity island (*PAI*)^[3]. The *cag PAI* was reported to be a major virulence factor of *H pylori*^[4,5]. The *cagII* is located on the left of *cag PAI*. There is growing evidence that genetic differences among strains determine the clinical outcome of infection^[6,7]. Some of the genes in *cagII* are believed to encode proteins that have similarities to recognized virulence factors in other bacteria. However in mainland China the distribution of these genes in *cagII* of *H pylori* and their relationship with gastroduodenal diseases remain unclear. In this work, we attempted to determine the structure of *cagII* of *H pylori* isolated from Zhejiang Province and the relationship between the genes in *cagII* and the types of the gastroduodenal diseases. The genes of *cagT*, *ORF13* and *ORF10* that have representative spacing sequences along the *cagII* were selected and amplified by polymerase chain reaction (PCR) to evaluate the *cagII* distribution in 171 isolates from *H pylori*-infected patients with different gastroduodenal diseases in Zhejiang Province.

MATERIALS AND METHODS

H pylori isolates

A total of 171 *H pylori* isolates were obtained from *H pylori*-infected adults who had undergone upper gastrointestinal endoscopy at the Second Affiliated Hospital of Zhejiang University and the Hospital of Daishan County in Zhejiang Province. The patients consisted of 115 men and 56 women with a mean age of 42.9 years (ranging from 16 to 71 years). The patients were classified into 6 groups of chronic superficial gastritis ($n=70$), chronic atrophic gastritis ($n=31$), gastric ulcer ($n=41$), duodenal ulcer ($n=21$), both gastric and duodenal ulcer ($n=3$) and gastric adenocarcinoma ($n=5$). The classification of patients was based on the results of endoscopic and histological examinations.

Culture of *H pylori*

Biopsy specimens were cultured on ECY-selective agar plates at 37 °C for 5 d under 100% humidity and microaerophilic conditions (50 mL/L O₂, 100 mL/L CO₂, and 850 mL/L N₂). *H pylori* was identified by the following criteria: characteristic of colony, rapid urease test, catalase test and morphology on Gram staining.

Genomic DNA extraction

H pylori genomic DNA was extracted by phenol/chloroform method.

Detection of *cagT*, *ORF13* and *ORF10* with PCR

For the detection of *cagT*, *ORF13* and *ORF10* genes, PCR was performed in a volume of 25 μ L containing 2.5 μ L of 10 \times buffer, 2 μ L of 25 mmol/L MgCl₂, 2.5 μ L of 2 mmol/L dNTPs, 0.2 μ L of *Taq* DNA polymerase, 0.5 μ L of 20 μ mol/L primer sets (Table 1), 1 μ L of genomic DNA, 15.8 μ L of water. The primers for *cagT*, *ORF13* and *ORF10* were synthesized as described in Table 1. The PCR amplification of *cagT*, *ORF13* and *ORF10* genes was as follows: initial denaturation at 95 $^{\circ}$ C for 3 min; 30 cycles of at 94 $^{\circ}$ C for 30 s, at 56 $^{\circ}$ C for 30 s and at 72 $^{\circ}$ C for 45 s; and a final extension at 72 $^{\circ}$ C for 7 min. PCR was performed in a thermal cycle (GeneAmp PCR system 9 600; Perkin-Elmer, Norwalk, Conn, USA). After amplification, 5 μ L of PCR products was electrophoresed on 17 g/L agarose gel and examined under UV illumination.

Table 1 PCR primers for amplification of *cagT*, *ORF13* and *ORF10*

Gene	Strand	Primer sequence	Length (bp)
<i>cagT</i>	+	5' TCTAAAAAGATTACGCTCATAGGCG 3'	490
	-	5' CTTTGGCTTGCATGTTCAAGTTGCC 3'	
<i>ORF13</i>	+	5' CGTTCATGTTCCATACATCTTTGGC 3'	617
	-	5' GATTTATAGCGATCTAAGAAACCGC 3'	
<i>ORF10</i>	+	5' AATAGTGCTTTCTTTAGGATTAGCG 3'	658
	-	5' CCGATTAAATCCTTTCGCTTATGTG 3'	

Statistical analysis

Statistical analysis was performed using the χ^2 test. Values of $P < 0.05$ were considered to be statistically significant.

RESULTS

Amplification of *cagT*, *ORF13* and *ORF10* genes

After PCR amplification of the *cagT*, *ORF13* and *ORF10* genes, the products were electrophoresed on 1.7% agarose gels, and stained with ethidium bromide (Figure 1).

Figure 1 Electrophoresis of *cagT*, *ORF13* and *ORF10* after PCR. Lane 1: 100 bp DNA ladder; Lane 2: *cagT* (490 bp); Lane 3: *ORF13* (617 bp); Lane 4: *ORF10* (658 bp).

Distribution of selected genes within *cagII* in *H pylori* isolates from patients with gastroduodenal diseases

Of 171 *H pylori* isolates from Zhejiang Province, 159 (93.0%)

were positive for all the three loci. One isolate (0.6%) from a patient with chronic superficial gastritis was negative for all the three loci, and 11 (6.4%) were partially deleted in *cagII*. Among the latter 11 isolates, 6 were from chronic superficial gastritis, 2 from chronic atrophic gastritis, 3 from gastric ulcer and 1 from gastric adenocarcinoma. The positivity rates of *cagT*, *ORF13* and *ORF10* gene expression and their relationship with gastroduodenal diseases are listed in Table 2. There were no significant differences among the three selected genes in different gastroduodenal diseases ($\chi^2 = 3.098$, $P > 0.05$ for *cagT*; $\chi^2 = 3.935$, $P > 0.05$ for *ORF13* and $\chi^2 = 6.328$, $P > 0.05$ for *ORF10*).

DISCUSSION

H pylori is a Gram-negative, spiral-shaped, microaerophilic bacterium that infects human gastric mucosa and is recognized as a major cause of chronic active gastritis and most peptic ulcer diseases^[8,9]. It is also closely related with gastric adenocarcinoma, gastric mucosa-associated lymphoid tissue lymphoma and primary gastric non-Hodgkin's lymphoma^[10]. The *cag PAI* is an approximately 40-kb cluster of genes on the *H. pylori* chromosome^[3,11] and divided into two regions, *cagI* and *cagII*. There are 14 open reading frames in *cagII*. Some of the genes within *cagII* are believed to encode proteins, which have homologue of recognized virulence factors in other bacteria by amino acid database search and analysis. The protein encoded by *cagT* gene is similar to *Shigella flexnerii* 42-kDa surface antigen IPAC. It was reported that IPAC of *Shigella* was essential for initial bacterial entry into epithelial cells by interacting with beta-catenin and destabilizing the cadherin-mediated cell adhesion complex^[12], thus the epithelial cell-cell tight adhesion was disrupted. These events might facilitate the further basolateral invasion of bacteria through the disrupted space and/or modulate the cell-to-cell spread of *Shigella*. We propose that *cagT* may play a similar role in the pathogenesis of *H pylori*. Moreover the proteins encoded by *cagT*, *ORF13* and *ORF10* are similar to *virB7*, *virB10* and *virD4* of *Agrobacterium tumefaciens* that are needed for the transferring of the Ti plasmid DNA from the bacterium to the nucleus of the plant cell^[1,13]. The products of the *virB7*, *virB10* and *virD4* genes are considered to be important components in type IV secretion system^[14]. Several lines of evidence suggest that the type IV secretion system encoded by the *cag PAI* of *H pylori* is recognized as a major virulence determinant, governing the translocation of the CagA protein to eukaryotic cells and inducing strongly the expression and secretion of IL-8 in gastric epithelial cells^[2,15,16]. Deletion of the *cagII* segment from strain 26695 reduced IL-8 synthesis to about 10-20% of the wild-type control. Inactivation of *ORF13* or *cagT* also caused similar reduction in IL-8 synthesis after infection. In addition, the products of *cagT*, *ORF13* and *ORF10* were absolutely essential for the translocation of CagA and tyrosine phosphorylation^[13,17,18]. IL-8, a potent neutrophil and T-cell chemoattractant and activator, is believed to play a key role in the pathogenesis of *H pylori*-induced tissue damage^[19,20]. These

Table 2 Relationship between *cagT*, *ORF13*, *ORF10* gene expression and clinical diagnosis in patients of Zhejiang Province

Group	n	<i>cagT</i> n	%	<i>ORF13</i> n	%	<i>ORF10</i> n	%
Chronic superficial gastritis	70	67	95.7	66	94.3	69	98.6
Chronic atrophic gastritis	31	31	100.0	29	93.5	31	100.0
Gastric ulcer	41	39	95.1	39	95.1	41	100.0
Duodenal ulcer	21	21	100.0	21	100.0	21	100.0
Both gastric and duodenal ulcer	3	3	-	3	-	3	-
Gastric adenocarcinoma	5	5	-	4	-	5	-
Total	171	166	97.1	162	94.7	170	99.4

results indicate that the genes in *cagII* participate in the translocation of CagA and induction of IL-8 synthesis and then a resultant severe inflammatory response. The presence of *cagII* is highly associated with the gastroduodenal diseases^[21].

In the present study, we have shown that the overall prevalence of the *cagT*, *ORF13* and *ORF10* is 97.1%, 94.7% and 99.4%, respectively. Although the genes in *cagII* are highly associated with the gastroduodenal diseases, the clinical outcome of *H. pylori* infection is not reliably predicted by the genes of *cagT*, *ORF13* and *ORF10* in the *cag II* in Zhejiang Province. These results are in agreement with those of studies in Japanese and Taiwanese. The distribution of presence of *cagT*, *ORF13* and *ORF10* in Japan has been shown to be about 94%, 98.4% and 98.4%, respectively^[16]. In Taiwanese, all strains were positive for *cagT* and *ORF13* genes^[22]. However, in South Africa the overall positivity rate of *cagT* in clinical isolates was 81.7%, lower than our report. And the prevalence of *cagT* in patients with peptic ulceration and gastric adenocarcinoma was significantly higher than that in gastritis^[21]. In Europe the prevalence of *cagT*, *ORF13* and *ORF10* in clinical isolates was 79.5%, also lower than the one of our report^[23]. These results indicate that *H. pylori* isolated from Asia is different from the ones isolated from South Africa and Europe. In the present study, of 171 *H. pylori* isolates from Zhejiang patients, 159(93.0%) were positive for all the three loci. One isolate (0.6%) from a patient with chronic superficial gastritis was negative for all the three loci, and 11(6.4%) were partially deleted in *cagII*. It appears that the *cagII* is not a uniform, conserved entity.

In conclusion, we speculate that the distribution of *cagT*, *ORF13* and *ORF10* in Zhejiang Province is in accordance with those in other Asian countries. The clinical outcome of *H. pylori* infection can not be reliably predicted by the genes of *cagT*, *ORF13* and *ORF10* in *cag II*. Many factors such as the genetic factors of both *H. pylori* and the host cell and the circumstance may contribute to the clinical outcome of *H. pylori* infection. Nevertheless, Further work is required to illustrate pathogenesis of *cagII* in *H. pylori* associated gastroduodenal diseases.

Abstract

AIM: To evaluate the effects of animal milk containing fucosylated antigens on *Helicobacter pylori* (*H pylori*) binding to Lewis b antigen.

METHODS: A mammary gland expression vector containing human α 1-3/4-fucosyltransferase cDNA sequences was constructed. Transient expression of human α 1-3/4-fucosyltransferase cDNA in goat mammary cell and establishment of transgenic mice were performed. The adhesion inhibitory properties of milk samples were analyzed by using *H pylori*.

RESULTS: Goat milk samples were found to inhibit bacterial binding to Lewis b antigen. The highest inhibition was observed 42 h after injection of the plasmid. The binding activity of *H pylori* to Lewis b antigen reduced mostly, by 83%, however milk samples from transgenic mice did not inhibit *H pylori* binding to Lewis b antigen.

CONCLUSION: The use of "humanized" animal milk produced by the transgenic introduction of fucosylated antigen can perhaps provide an alternative therapy and preventive measure for *H pylori* infection.

INTRODUCTION

Helicobacter pylori (*H pylori*), a human specific gastric pathogen, was first isolated in 1983^[1]. Twenty years of research has found that *H pylori* infection is one of the major causes of upper gastrointestinal tract diseases, such as chronic active gastritis

and peptic ulcer disease^[2-6]. In chronic active gastritis, gastric ulcer and gastroduodenal ulcer, the incidences of *H pylori* infection are 71-94%, 72-100% and 73-100% respectively. In addition, *H pylori* infection has been linked with the development of gastric adenocarcinoma and mucosa-associated lymphoid tissue (MALT)^[7-13]. It has been defined as a Class I carcinogen by WHO^[14,15].

H pylori colonize human gastric mucosa by adhering both to the mucous epithelial cells and to the mucus layer^[16]. Specific receptor structures in combination with the unique tissue-specific distribution of receptors can restrict microbial colonization to a limited number of hosts, tissues and cell lineages^[17]. *H pylori* can bind tightly to epithelial cells using various bacterial surface components^[18-20]. The best characterized adhesin, BabA, is a 78-kD outer-membrane protein that binds to the fucosylated Lewis b (Le^b) blood group antigen^[21]. Accumulating evidence in animal models suggests that BabA is relevant to *H pylori*-associated diseases^[22]. Le^b antigen is one of the most important receptors, governing adhesion of *H pylori* to gastric mucosa. Boren *et al.* found that the fucosylated Lewis blood group antigens Le^b and H-1 were the carbohydrate structures that specifically mediated the adherence of *H pylori* to human gastric epithelial cells *in situ*.

Le^b antigen is a human blood group antigen. In human cells, the synthesis of Lewis antigens is regulated by a series of glycosyltransferases that act sequentially upon a precursor molecule. The fucosyltransferases are responsible for the final step in this process. Their function is to add a fucose residue to precursor molecules to form human blood antigens, such as Le^a, Le^b and H1 antigen (Figure1). Addition of fucose to the terminal galactose residue of the lacto series core chain oligosaccharide results in the H1 antigen. Le^b antigen is formed by the addition of a "branched" fucose residue to H1-antigen, catalyzed by α 1-3/4-fucosyltransferase. The fucosylated blood group antigens, typically found on erythrocytes, are also expressed on the gastro-intestinal epithelium. Le^b is the dominant fucosylated blood group antigen expressed on the gastric surface mucous cells in the gastric epithelial lining. The fucosylated blood group antigens are also present in the mucins of the gastric mucus layer and, in addition, as natural "scavengers" or clearance factors in secretions such as saliva, tears, and human milk.

Figure 1 Formation of fucosylated blood group antigens.

H. pylori infection is one of the most common infections in humans. Epidemiological data show that it affects about half of the human population. Without specific therapy, *H. pylori* infection can persist for decades or even the host's lifetime. But only about 15% of *H. pylori*-infected individuals actually have *H. pylori*-associated diseases. It is likely to be associated with other additional factors such as genetic predisposition, age of infection, and the genotype of infective strain. The prevalence varies greatly among countries and among population groups within the same country. The overall prevalence of *H. pylori* infection is strongly correlated with socioeconomic conditions. Eighty-five percent of *H. pylori* can be eradicated by combination therapy in clinic, however, using antibiotics for several weeks may bring about other problems such as bacterial resistance. So many researchers are looking for other methods to prevent *H. pylori* infection, such as preventing *H. pylori* binding to or colonizing the gastric mucosa.

If we can add some *H. pylori* specific receptor, for example, Le^b blood antigen or its analog to food, then *H. pylori* binding to the human gastric mucosa may be prevented or reduced, and the bacteria will be excreted by the alimentary tract or destroyed by human antibody. Flak *et al.* reported that the α 1-3/4-fucosyltransferase was expressed in the gastric mucosa of mice and that *H. pylori* could bind to the mice gastric mucosa. At present, there are no reports of α 1-3/4-fucosyltransferase being expressed in animal galactophore. Therefore, our aim was first to introduce human α 1-3/4-fucosyltransferase into animals and get them expressed in the animal mammary gland and thus produce Le^b antigen in milk. This kind of milk does not only have nutritional value, it is also a natural source of lectin, a molecule that can block *H. pylori* binding to the human gastric mucosa, and therefore prevent *H. pylori* infection and reduce the severity of the infectious process. In this way, people can prevent *H. pylori* infection by drinking this kind of milk daily.

This paper describes the transient expression of human α 1-3/4-fucosyltransferase gene in goat mammary gland and the establishment of transgenic mouse model. A new test to prevent and cure *H. pylori* infection and gastrointestinal diseases associated with *H. pylori* infection is put forward in our study.

MATERIALS AND METHODS

Experimental animals

Kunming white mice were purchased from Beijing Laboratory Animal Research Center. Laoshan goats were provided by Beijing Sangao Corporation.

Figure 2 Map of expression vector: pBC1-fut.

Construction of expression vectors

A 1 115-bp α 1-3/4-fucosyltransferase cDNA encompassing the entire 1 086-nt coding region specifying the 361-AA transmembrane glycoprotein, containing an upstream Kozak consensus sequence and *Xho*I site, a downstream *Xho*I site,

was generated by PCR from a Fut/pCDM8 plasmid. The PCR product was then purified and digested by *Xho*I, and the digestion product was subcloned into pBC1 vector, which had been treated previously with *Xho*I, and transformed into *E. coli* DH5 α . pBC1 is a specific milk expression vector which contains the goat β -casein promoter and other proprietary DNA sequences. The positive transfected clone containing the properly oriented α 1-3/4-fucosyltransferase cDNA was screened by colony PCR. The expression vector, named pBC1-fut, allowed the α 1-3/4-fucosyltransferase cDNA to be placed in its downstream of the β -casein promoter (Figure 2).

Transient expression

pBC1-fut was purified using Qiagen Plasmid Maxi kit. About 1 mg pBC1-fut was injected into a lactating goat's right and left mammary glands from the goat glandular duct. Milk samples at different times were then collected over a 100-h (4 d) period from both right (R) and left (L) udders. Then, milk samples were analyzed in a dilution series (25-, 50-, 100- and 200-fold) for adhesion inhibition properties.

Transgenic mice production

The 16-kb DNA fragment inserted was isolated by agarose gel electrophoresis and recovered by electro-elution. To remove any contamination, products were spot dialyzed against 40 mL TE (10 mmol/L Tris, 0.1 mmol/L EDTA, pH7.4) for 30 min (VSWP02 500 membrane, Millipore). Purified DNAs were diluted to 2-3 ng/ μ L in TE buffer and microinjected into the pronuclei of fertilized eggs of Kunming white mice.

Genomic DNAs were isolated from the tails of transgenic mice using a standard method. A pair of primers was designed to screen for transgenic mice: upper primer: 5' - GATTGACAA GTAATACGCTGTTTCCTC-3' and downstream primer: 5' - CATCAGAAGTTAAACAGCACAGTTAG-3'. PCR reactions using genomic DNAs as template were performed under the following condition: 30 cycles of 94 °C for 1 min, 58 °C for 1 min, and 74 °C for 1 min. After PCR screening, transgenic mice were confirmed by Southern hybridization. The probe was created by ³²P labeling α 1-3/4-fucosyltransferase cDNA. Genomic DNA from transgenic mice and negative mouse as well as expression vector DNA were digested by *Bam*HI. Copies of the transgene were estimated by comparing the band density of the vector control with that in transgenic mice. Hybridizations were at 65 °C in Church (10 g/L BSA, 70 g/L SDS, 1 mmol/L EDTA, 0.5 mol/L sodium phosphate, pH 7.2). Final washes were in 2 \times SSC, 0.5 \times SDS at 65 °C. Signal from the membrane was detected using a Phosphor Screen (Molecular Dynamics, US).

Analysis of adhesion inhibitory properties of the milk

Goat milk was collected at different time points for 100 h from both right (R) and left (L) udders. The transgenic milk was collected at the 7 th day of lactation. The milk was centrifuged at 18 000 r/min for 1 h at 4 °C. The fat on the surface was removed and the clear part of the supernatant was put in a new tube and used as the sample. Le^b antigen was labeled with ¹²⁵I by the chloramine T method. Milk samples were analyzed in dilution series (25-, 50-, 100- and 200-fold). The samples were mixed with an *H. pylori* strain (CCUG17875), which bound bind Le^b antigen efficiently, on a cradle for 17 h at room temperature. After this period, ¹²⁵I radioactivity in bacterial pellet was measured with a gamma counter.

Western blotting

After electrophoresis on 80 g/L SDS-PAGE, proteins were transferred to a nitrocellulose extra blotting membrane (Sartorius, Germany). Le^b monoclonal antibodies (Immucor, GA) and HRP-conjugated goat anti-rabbit-IgG (Cappel Laboratories, US) were used to detect Le^b antigen.

RESULTS

Transient expression

As shown in Table 1 and Figure 3, milk samples from experimental goats inhibited *H pylori* binding to Le^b antigen, and the time of the highest inhibition efficacy was at 42 h after DNA immunization. Furthermore, milk collected from both right (R) and left (L) udders had inhibitory effect on *H pylori* binding to Le^b. Unimmunized goat (the negative controls) did not inhibit bacterial binding. The binding activity of *H pylori* to Le^b antigen reduced mostly, 83 % in the 25-fold diluted milk samples.

Figure 3 Blocking effect on *H pylori* binding to Lewis b antigen by goat milk. Abscissa: Goat milk collected at different time points and control milk. Ordinate: Rate of *H pylori* binding to Lewis b antigen.

Production of transgenic mice

Five of 84 mice including 2 males and 3 females were identified as being transgenic mice by PCR (Figure 4). The serial numbers of the positive mice were 15, 42, 47, 63 and 71. Efficiency of microinjection was about 6%, within the usual range of 5-20%. These transgenic mice were confirmed by using human α 1-3/4-fucosyltransferase cDNA as a probe in Southern blotting (Figure 5). Transgene copy numbers were also determined by Southern blotting. We analyzed three female's milk for the blocking effect on binding of *H pylori* to Le^b antigen, but no inhibitory activity was detected by our experimental system.

Figure 5 Southern blotting of transgenic mice. M: DNA ladder; CK: Non-transgenic mouse; P1, P2, P5 and P10: pBC1-fut plasmid equivalent to 1, 2, 5 and 10 gene copies, respectively. 15, 42, 47, 62 and 71: Serial numbers of gene positive mice.

Western blotting

We performed Western blotting and stained the membranes of the goat and transgenic mice milk protein with Le^b monoclonal antibody. The goat milk sample blot showed a beautiful, time-dependent induction of the blood group antigens secreted into milk (Figure 6). The band densities at different time points were consistent with the results of the transient expression described above. The band density was strongest at the 42 h after DNA immunization. But the transgenic mice milk did not give a positive signal, suggesting that this milk did not contain Le^b antigen or its analog.

Figure 6 Western blotting of the transient expression milk of goat. Lanes 1-8: Milk collected at different time points of 6, 18, 30, 42, 60, 78, 90, 100 h postinjection, respectively.

DISCUSSION

In our experiment, goat milk could block *H pylori* binding to Le^b antigen, which is one of the most important receptors governing adhesion of *H pylori* to gastric mucosa. The activity of *H pylori* binding to Le^b antigen reduced as much as 83% in some samples. The result showed that some milk proteins might be fucosylated and structurally similar to human Le^b blood group antigen, so they were able to bind the bacteria. Goat milk fucosylated protein can bind *H pylori* *in vitro*. So “humanized” goat milk, in which human α 1-3/4-fucosyltransferase has been introduced into goat mammary gland, may be an alternative therapy and a prevention method for *H pylori* infection.

Unfortunately, the transgenic mice milk collected did not block *H pylori* binding to Le^b antigen. The reasons might be as follows: (1) Level of α 1-3/4-fucosyltransferase gene expression in mammary gland of mice was very low. Thus the quantity of Le^b antigen in the milk was so low that the milk could not effectively block *H pylori* binding to Le^b antigen. One way to increase the expression of α 1-3/4-fucosyltransferase would be to introduce the complete genomic sequence of the α 1-3/4-fucosyltransferase gene to mammary gland of mice. (2) There is no precursor of Le^b antigen in mice milk, so, even if α 1-3/4-fucosyltransferase was expressed in mouse galactophore, the transgenic glycosylation patterns that were generated by the activity of α 1-3/4-fucosyltransferase did not form epitopes that were recognized by the *H pylori* Le^b-binding adhesions. Therefore the milk could not block *H pylori* binding to Le^b antigen. Since other results have shown that α 1-3/4-fucosyltransferase expression in the gastric mucosa of mice can block the binding of *H pylori* to mouse gastric mucosa, it is possible that there might be differences between the carbohydrate core chains of the Le^b antigen in milk glands and gastric mucosa in mice.

Although the results for the transgenic mice were not positive, the successful introduction of α 1-3/4-fucosyltransferase cDNA into goat mammary cell and expression of Le^b antigen analog were an important finding. The “humanized” milk by the transgenic introduction of fucosylated antigens can be an alternative therapy and a prevention method for *H pylori* infection.

Abstract

AIM: To confirm the xenotransplantation of microencapsulated hepatocytes and islets as a temporary bioartificial liver support system for mice with acute liver failure (ALF).

METHODS: Mice were rendered ALF by a single intra-peritoneal injection of D-galactosamine (D-gal) and their tail blood was sampled to examine differences in blood ALT, albumin (ALB), total bilirubin (TB) and glucose (GLU) between 4 experimental groups. Rat hepatocytes and islets were collected and microencapsulated referring to both Sun's and Fritschy's methods. Mice were grouped into control group (CG), free hepatocyte group (FHG), microencapsulated hepatocyte group (MHG) and microencapsulated hepatocyte plus islet group (HIG). Tissue samples were subjected to microscopic and electron microscopic (EM) examinations.

RESULTS: The highest survival was observed in HIG, surprisingly at 100%(16/16), while the lowest was in CG at 12.5%(2/16), with inter-group statistical difference $P < 0.05$. ALT levels revealed no statistical difference between groups but the ALB level of HIG descended by the slightest margin $\{q = (0.54, 0.24, 1.33), P < 0.05\}$ at the time when it reached the lowest point in all groups. TB of HIG returned to normal reference range (NRR) statistically sooner than that of others after a fierce elevation. No statistical inter-group difference was observed in GLU levels. Fusion between hepatocytes and beta cells was demonstrated giving rise to theoretical assumptions.

CONCLUSION: Hepatocytes to be microencapsulated together with islets should be a preferred *in vivo* hepatic functional supporting system, which can dramatically prolong survival and improve living status.

INTRODUCTION

Currently, temporary liver support is crucial to medical treatment for acute liver failure^[1,2]. In this point, hepatocyte transplantation as a kind of bioartificial liver holds a bright

prospect, but how to enhance graft functional status and neutralize immune rejection remains unsettled. Several authors have reported the "mutual benefit" between hepatocytes and pancreatic islets at co-transplantation^[3-5], whereas Lim and Sun's^[6] microencapsulating technique for immunoisolation opened a new era for cell transplantation. We suppose that hepatocytes and islets can be co-microencapsulated and transplanted to act as a bioartificial liver support system (BALSS), thus taking advantages of both the "mutual benefit" and the immunoisolation, simultaneously. If succeeded, this method would be a valuable alternative for *en bloc* organ transplantation and alleviate the donor shortage dilemma.

MATERIALS AND METHODS

Animals and ALF induction

Male Wistar rats weighing 150 g (as donor of hepatocytes) or 250 g (as donor of islets) and Kunming mice weighing 30-36 g served as donors and recipients, respectively. D-gal (Sigma) was dissolved in bacteriostatic normal saline and adjusted to pH 7.4 with 1 mol/L NaOH. The final concentration of the solution was 0.1 g/mL. Acute liver failure (ALF) mice was induced by a single intra-peritoneal injection of D-gal at a dose of 2 500 mg/kg without anesthesia, after which free access to aseptic water containing 100 g/L glucose was provided and models were fed on standard mouse chow.

Hepatocyte isolation

Donor hepatocytes were isolated by Seglen's *in situ* collagenase perfusion technique. Under pentobarbital anesthesia (35 mg/kg), the portal vein and the before-liver inferior vena cava (IVC) were cannulated and after liver IVC was ligated. The liver was perfused *in situ* first with 4 °C D-Hanks solution for 3 min and then with 37 °C Hanks solution containing 200 U/mL collagenase IV (Sigma) for 10 min at a flow rate of 20 mL/min until the effluent turned opaque. The perfusion route began at the portal vein and ended before liver IVC. The liver was removed, softly shattered and filtered through a hepatocyte dispersing instrument (containing a 105 µm stainless steel mesh) to produce a homogenous suspension. The hepatocytes were washed 3 times in 4 °C D-Hanks solution and centrifuged at 50 r/min for 2 min between washes, $(3.5-5.0) \times 10^8$ hepatocytes were obtained through this process. After the cell viability (82-93%) was determined by trypan blue exclusion test, the hepatocytes were cultured in 100 g/L fetal calf serum (FCS, Hyclone) enriched RPMI-1640 medium containing 10^{-7} mol/L insulin, 0.1 mg/mL streptomycin sulfate and 100 U/mL penicillin G at 37 °C in a humidified atmosphere (950 mL/L O₂ and 50 mL/L) awaiting transplantation.

Islet isolation

Donor islets of Langerhans were extracted by Sutton's method. The common bile duct (CBD) was cannulated and the rat was killed by a heart incision before the whole pancreas was distended uniformly with 4 mL 4 °C Hanks solution (buffered by 20 mmol/L HEPES at pH 7.8). The pancreas was removed, further distended by 16 mL 4 °C Hanks solution containing

2 mg/mL collagenase V (Sigma) and then put in an incubator at 38 °C for 8 min before the tissue was dispersed. The pelleted tissue was filtered through a steel mesh with 40 pores per inch and washed twice in 4 °C Hanks solution with centrifugation at 50 r/min for 1 min between washes. The last centrifugation was performed at 350 r/min for 2 min before the tissue was re-suspended in 25% Ficoll solution, on which 23%, 20% and 11% Ficoll densities were layered in sequence. The discontinuous density gradient containing the tissue pellets was spun at 800 r/min for 15 min at 4 °C. Islets from 20-23% interface were collected, 721±153 islets could be isolated through this procedure with a purity higher than 87% and the ones with a diameter of 50-250 µm were handpicked and cultured in 100 g/L FCS enriched RPMI 1640 medium containing 0.1 mg/mL streptomycin sulfate and 100 U/mL penicillin G at 37 °C in a humidified atmosphere (950 g/L O₂ and 50 mL/L CO₂).

Microencapsulating procedure

Cells were microencapsulated according to Sun's and Fritschy's methods. The cells were centrifuged before re-suspension in 30 g/L alginate (ALG)-normal saline solution (pH 7.4) at a concentration of 1×10⁷/mL (according to hepatocytes). Then the mixture was put into the container of a bi-nozzle air-jet droplet generator and sprayed into 100 mmol/L calcium chloride solution (HEPES buffered, pH 7.4) under the disturbance of a co-axial oxygen flow at 4 L/min to form round droplets, which were then washed in 4 °C D-Hanks solution and reacted in sequence with 2 g/L poly-L-lysine (PLL) for 8 min, 2 g/L ALG for 4 min and 30 mmol/L sodium citrate for 8 min, all were kept at 4 °C and adjusted to pH 7.4. The microcapsules (MCs) with a diameter of 0.3-0.5 mm were cultured in aforementioned medium for 24 h. Every mouse received MCs equal to 3×10⁶ hepatocytes and the ratio of hepatocytes to islets was 10⁶/40 at co-transplantation^[7]. Through a 12 G needle, the MCs were injected into the recipient's abdomen through a 3 mm incision under light ether anesthesia. All mice underwent the same procedure.

Experimental design

Sixty-four mice with ALF were randomly divided into 4 groups,

16 mice in each: CG, FHG, MHG and HIG. Each mouse in a certain group received only 1 mL sterilized normal saline in CG, 3×10⁶ free hepatocytes transplantation in FHG, 3×10⁶ microencapsulated hepatocytes in MHG, MCs containing 3×10⁶ hepatocytes together with 120 islets in HIG.

Each group was randomly divided into 4 subgroups, 4 mice in each: ALT group, ALB group, TB group and GLU group so that every index was observed in 4 mice and documented by their average. Blood samples were collected from tail veins and indexes were recorded before and every 12 h after administration of D-gal (time "0") until the 4th d, then once on the 7th d and finally once on the 14th d. The body mass was measured daily.

Histological studies

All animals that died after D-gal injection were autopsied and those alive were sacrificed weekly until the 2nd mo. Then all the remaining ones were cervically dislocated to collect samples from livers, MC aggregates and floating MCs, which were fixed either in 100 g/L phosphate-buffered formaldehyde and stained with hematoxylin/eosin for histological examination or in 2.5% osmium tetroxide for transmission EM examination.

Statistical analysis

One-way ANOVA, *q* test and χ^2 test were used to establish inter-group difference and data were expressed as mean±SD.

RESULTS

Survival

Mice still alive after 72 h secured unlimited survival. Compared with CG, the survival rates of FHG, MHG and HIG were statistically higher ($P<0.05$), while FHG held a survival rate significantly lower than MHG and HIG ($P<0.05$), between which no statistical difference was observed ($P>0.05$) (Figure 1A).

Biochemical findings

ALT in 4 groups similarly elevated to a peak of 1 912±344 U/L in 12 h, then dropped quickly to NRR (50.04±7.72 U/L) in 48 to 72 h. The sub-group of ALT in CG had only one mouse (1/4)

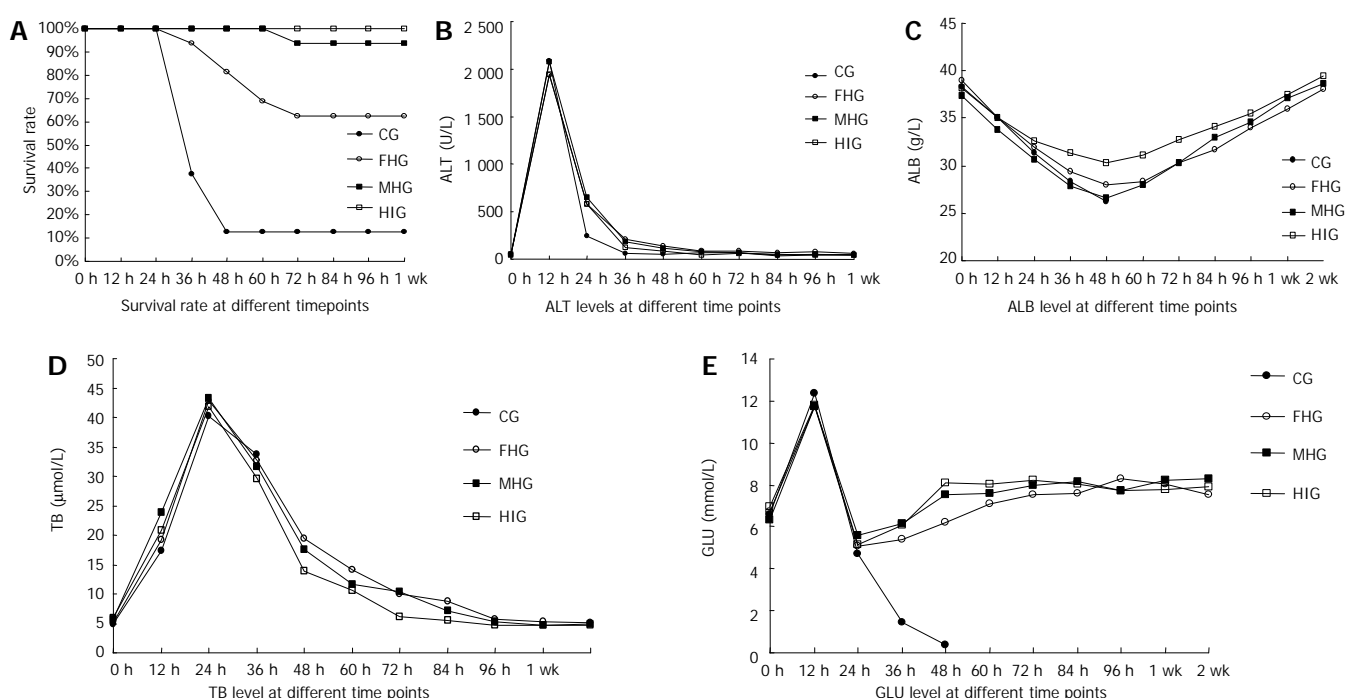

Figure 1 Survival rate, levels of ALT, ALB, TB and GLU at different time points. A: Survival rate; B: ALT level; C: ALB level; D: TB level; E: GLU level.

alive after 36 h. No relevant statistical difference was observed (Figure 1B).

Serum ALB gradually decreased after D-gal administration and reached the lowest point in 48 h, then stably returned to NRR of 38.19 ± 1.68 g/L in 96 h (Figure 1C). The maximum decrease in ALB of HIG was 7.85 ± 1.10 g/L, statistically smaller than that of other groups ($P < 0.05$). No statistical difference was found in ALB reduction between CG, FHG and MHG ($P > 0.05$).

TB in all groups ascended quickly after D-gal administration to the maximum of 36.64 ± 5.08 $\mu\text{mol/L}$ ($P > 0.05$) in 24 h, then began to descend. All the 4 mice in TB sub-group of CG died in 36 h bringing its curve to a stop, while TB of other groups continued to descend to NRR (5.42 ± 0.68 $\mu\text{mol/L}$) at different intervals. TB of HIG fell into NRR in 72 h, while FHG and MHG in 96 h (Figure 1D).

The non-fasting blood glucose of ALF mice temporarily elevated by 5.27 ± 1.56 mmol/L in 12 h after D-gal administration, then fell down to 5.14 ± 0.48 mmol/L at the 24th hour, when the mice underwent scheduled treatments. After 24 h, when the GLU of other groups began to increase, that of CG kept decreasing until all the four responsible mice died. The GLU of HIG ascended to NRR (8.31 ± 0.93 mmol/L) in 48 to 60 h, while that of FHG and MHG normalized after 72 h (Figure 1E). No statistical inter-group difference was observed at any time point ($P > 0.05$).

Liver destruction

Massive degenerative changes, ballooning and necrosis of the hepatic cells with vanishing nuclei were apparent under optical microscopy accompanied with closing sinusoids, widened Disse space and distorted hepatic lobules in tissue samples from mice died after administration of D-gal. Numerous bulbs, slightly distended mitochondria, shrinkage of nuclei and pigmentation of heterochromatin came under EM with cholangitis, exfoliation of microvilli and disappearance of tight junctions between adjacent hepatocytes dominating the view, as reported by Takenaka^[8] (Figure 2).

Figure 2 Transmigration of platelets (P) and red cells (R) into the Disse space.

Figure 3 Association between hepatocytes (H) and a beta cells (B), and microvilli of hepatocytes (H) in beta cells (B). A: "Intimate association" between hepatocytes (H) and beta cells (B); B: Microvilli of hepatocytes (H) in beta cells (B).

Gross or microscopic microcapsules

Up to 90% of microcapsules remained free floating in 1 to 2 wk posttransplantation. Histological examination revealed smooth surface of most MCs, but mild fibroblasts were also observed on some MCs. Few hepatocytes were still alive inside the MCs from MHG, which were still free floating in the 4th week. Fewer free-floating MCs were observed in the HIG, blood vessels originated from the portal vein or the liver surface were easily seen with naked eyes polarizing huge aggregates of MCs attached to them. Till the 8th week, red aggregates of MCs were easily found in the vicinity of the portal vein in 67.5% (7/8) mice from HIG group. Though not abundant, aggregates attached to the diaphragmatic side of the liver, spleen or other organs were also seen. Smaller aggregates of MCs were seen on samples from MHG but without visible vascularization.

Figure 4 Connection of hepatocytes (H) and beta cells (B) by a network of plasmatic "bridges" formed by adjacent membranes of a string of vesicles (\rightarrow) lining up along their original border.

EM findings

Generally, the wall of the MCs was 6–8 μm thick and could be divided into 3 layers, but hepatocytes were always embedded in it de-homogenizing the thickness and disarranging the layers. Mostly, a very thin feather-like structure with a medium density formed the outer layer, inside was a section with a very high density and a thickness of approximately 0.5 μm , then a flocculent low density structure formed the inner layer. There was no clear boundary between the later two layers, instead, the density of the middle layer lowered until it changed into the inner one, to which the encapsulated hepatocytes attached with their microvilli. A small number of hepatocytes of MHG group survived inside the MCs until the 8th week but their microvilli shortened or disappeared and mitochondria distended. The MCs from HIG attached to the liver surface were totally covered by fibroblasts in the 8th week, but capillaries originated from the liver were seen encircling the MCs or entering them. Inside these MCs, living beta cells were found surrounded by transformed hepatocytes, whose many microvilli thrust deeply into the former and the membranes of

both cells morphologically vanished at some places where two plasmas mixed (Figures 3A, 3B). Some hepatocyte-like cells recognized by their big round mitochondria and glycogen had well formed insulin granules inside their plasma but with a smaller size (Figure 4). No desmosome mentioned by Ricordi was found. Several ball-shaped hepatocytes with long microvilli and normal organella were seen attached to the MC wall in distance of the aggregates of hepatocytes and beta cells.

DISCUSSION

Life sustaining is of the greatest importance to patients with ALF during life threatening period and patients with end stage chronic liver failure (CLF) awaiting proper donors, so liver function support in a limited period is crucial to the management of both ALF and CLF.

Based on this principle, many kinds of artificial liver were developed such as charcoal hemoperfusion or high porosity hemodialysis, but optimistically speaking, these methods could only partially substitute for the original liver because besides functioning living hepatocytes, any man-made device could provide but an incomplete liver function support^[9].

Artificial liver based on living hepatocytes has become a hot point of current researches aimed at substitution for liver function by hepatocytes. There are two kinds of BALSS currently in research: *ex vivo* bio-hemodialysis system and *in vivo* hepatocyte transplantation strategy. In recent years, great progress has been made in the *ex vivo* systems. Chen *et al.*^[10] demonstrated the successful application of BALSS to canine liver failure and Ding *et al.* reported their initial success on human patients. But, unfortunately, the viability of hepatocytes was hard to sustain extracorporeally and they gradually lost their original functions and de-differentiated in 1 to 2 wk *in vitro*^[11], so that frequent refreshing of the working hepatocytes is necessary to secure satisfactory efficiency, which adds extra-cost to the BALSS besides its already expensive electromechanical system. As for hepatocyte transplantation strategy, rejection aggressively reduced hepatocytic viability to almost zero in 1 wk^[12] after allo-transplantation. Great attention has been paid to the mechanism of hepatocytic rejection and a recent study showed that recombinant ribonuclease P remarkably reduced the expression of MHC-II molecules on transplanted hepatocytes, thus obviously alleviating rejection and prolonging hepatocytic survival. But before the entire truth of human genome is unveiled, no induction of gene or genetic products into human body would be ethically accepted and clinically approved. Genetic interference with transplantation may be preserved for far future. The microencapsulating technique initiated by Lim and Sun brought a bright new hope for artificial liver and hepatocyte transplantation. The microcapsules act as a selective barrier between the hepatocytes inside and the killing molecules such as antibodies outside, reserving the permeability of nutrients and small active cellular products such as albumin and insulin, so that cell transplantation under immunoisolation is realized. In addition, it has been proved that through some uncertain pathways islets could enhance the viability and function of isolated hepatocytes^[13,14]. We deem that microencapsulated hepatocytes and islets can be xenotransplanted to act as an *in vivo* BALSS, thus taking advantages of both the "mutual benefit" and the immunoisolation simultaneously. If succeeded, this method would be a valuable alternative for *en bloc* organ transplantation and alleviate the donor shortage dilemma.

In this work, we initially studied the feasibility of xeno-transplantation of co-microencapsulated hepatocytes and islets between closely related species (Wistar rats to Kunming mice) and its therapeutic effects on D-gal induced ALF. Drug-induced ALF could better imitate clinical ALF, mostly toxic, than surgically induced ALF, since it presented with similar

pathological development^[15].

ALT is a sensitive index to hepatocytic destruction, which sharply ascended after administration of D-gal and peaked at the 12th hour but the amplitude greatly varied between individual mice. No significant influence upon ALT curve by cell transplant was observed in this study indicating that ALT could reflect the extent of cell destruction instead of the therapeutic effect of different interventions, as confirmed by Yu's studies^[16]. Anti-apoptotic agent etoposide was given prior to the administration of D-gal in Nakama's study^[17], which would possibly have changed the metabolism of D-gal in hepatocytes and the pathological process of hepatocytic destruction, preventing a considerable proportion of hepatocytes from apoptosis, so that a lowered ALT peak was documented. In fact, to give hepatocytic protective agents prior to the establishment of ALF model could only demonstrate the protecting effects of such agents instead of their therapeutic attributes, which has attracted much more attention from medical community since ALF patients would not take liver protective medications before they got trapped in ALF.

ALB is not a frequently used index to hepatic failure, but it changes with a steady pace giving concrete confirmation to the status of hepatic anabolism. In this study, ALB levels in HIG group decreased by a margin significantly smaller than those in other groups after administration of D-gal, indicating that under the influence of xenografted islets, at least the production of ALB of the remaining liver cells of the model mouse or the transplanted hepatocytes was improved. Wang *et al.*^[18] also confirmed the enhanced ALB synthesis in hepatocirrhotic rats after combined hepatocyte-islet transplantation.

TB level reflects the metabolic and detoxicating abilities of hepatocytes. It descended into NRR much earlier in HIG than in other groups, demonstrating a sooner recovery of hepatocellular metabolism in the existence of islets as stated by Wang *et al.*^[19].

Temporary increase of blood glucose after D-gal administration, was rarely reported because most researchers took rats as subjects and kept an interval between blood samplings as long as 24 h or more, missing this phenomenon. It might have resulted from the release of a great amount of glycogens at massive hepatocytic destruction, which was absent in studies adopting 90% partially hepatectomized models as in Demetriou's^[20]. Though curves in Figure 1E show a sooner extrication from hypoglycemia in HIG group than in MHG group, no statistical difference in GLU was noticed between experimental groups, which might have been the result of inadequate samples or large scale fluctuation of non-fasting blood glucose of ALF mice.

All mice in HIG group survived and the survival rate in MHG group was 93.75%, astonishingly higher than that in other reports, which used rat models. The first reason for such a high survival might be a larger amount of hepatocytes transplanted, say, 3×10^6 hepatocytes were nearly 3-5% of total hepatocytes per mouse liver and the second reason might be a much shorter hepatocytic regeneration cycle in mouse, which resulted in a quicker recovery of liver function and a shorter life threatening period. In this point of view, it may be conjectured that the shorter the hepatocytic regeneration cycle is, the better the therapeutic effect of bio-artificial liver can be expected, thus to shorten the regeneration cycle of liver cells by means of some genetic method may further enhance the survival rate after ALF.

A close functional relation between hepatocytes and islets has been proved both experimentally and clinically. An "intimate association" between hepatocytes and beta cells was discovered by Ricordi^[21] and then confirmed by others^[22]. In this study, an even closer relationship was proved morphologically inside the microcapsules 2 mo after hepatocyte-islet co-transplantation.

Under EM, the hepatocytes were easily recognized with their wheel-shaped mitochondria, smooth reticulum, rose-petal-

shaped glycogens and Golgi complexes while beta cells with their homogeneous eyeball-like insulin granules, which accommodated high-density crystalloids at the center with a wide vacuum space around. The hepatocytes abandoned their original hexagon or cubic shape and flattened to wrap on the beta cells thrusting numerous finger-like microvilli deeply into the latter. No matter how complicatedly the microvilli wound in three-dimensional space on a cross-section, we should see two layers of complete membrane separating these “fingers” from the plasma of the victim beta cells, but discontinuous membranes were noticed where direct exchange of cellular content was suspected. Much more interestingly, the boundary between some hepatocytes and beta cells was replaced by a complicated network of plasmatic “bridges” formed by adjacent membranes of a string of vesicles lining up along the original border. Meanwhile morphologically intact beta granules were found inside such hepatocytes in direct contact with their plasma, seemingly having been swallowed. Generally, this was a kind of “hybridization” between these two kinds of cells, as mentioned by Cossel^[23]. No desmosomes were found connecting these cells as mentioned by Ricordi. They might have functioned as anchors in the earlier stage (in 7 d as said by Ricordi) to immobilize cells giving rise to further interactions, then disappeared together with part of the membrane initiating hybridization in the later stage as found in our study. Direct plasmatic connection must be the best way for intercellular communication and exchange of substances, so contacting cells, which have close functional ties like hepatocytes and beta cells, would eventually establish such connections though neither the underlying mechanism nor its prognosis is clear. On the other hand, this phenomenon urges us to take good care of transplanted cells since it is still unknown whether such a “hybridization” produces pathogenic outcomes, say malignancies, or whether it undermines long-term effects of transplanted cells, though the outcome of such an association was fairly acceptable in our study. So that to separate transplanted cells by way of micro- or macro-encapsulation may be a good choice, which deprives them of direct contact with host cells and at the same time realizes functional support under immunoisolation.

In this study, we observed the hybridization between hepatocytes and beta cells inside microcapsules after co-transplantation. Better therapeutic effect of hepatocyte-islet co-transplantation than hepatocytes alone was also evidenced both histologically and biochemically. Though operative principles have not been fully established, co-transplantation of hepatocytes and islets by way of microencapsulation as a kind of BALSS holds a bright prospect.

Abstract

AIM: To investigate whether P28 derived from C3d can enhance the immune response to HBV-preS2/S induced by directly injection of naked plasmids containing variable repeats of P28 and HBV-preS2/S in fusion form.

METHODS: One to four copies of C3d-P28 coding gene, amplified by PCR and modified by restriction endonucleases digestion, were subcloned into a eukaryotic expression vector pVAON33 to construct pVAON33-P28, pVAON33-P28.2, pVAON33-P28.3 and pVAON33-P28.4 (pVAON33-P28.[1-4]). HBV-preS2/S coding sequence was then introduced into the pVAON33-P28.[1-4] and identified by both PCR and DNA sequencing. BALB/c mice were primed by intramuscular gene immunization with 100 µg different recombinant plasmids on day 0 and were boosted by subcutaneous inoculation with HBsAg protein (1 µg) 12 wk post-priming. The levels and avidity of specific IgG in sera collected at the indicated times from each group were determined by ELISA and NaSCN-displacement ELISA, respectively.

RESULTS: HBsAg specific antibody response was elicited in groups primed with plasmids pVAON33-S2/S-P28.[1-4] and pVAON33-S2/S. However, the response against HBsAg in the groups primed with pVAON33-S2/S-P28.[1-4] was significantly higher than that in pVAON33-S2/S group, the highest level of the specific antibody response was observed in the groups primed with pVAON33-S2/S-P28.4 ($P < 0.01$). After secondary immunization with specific antigen, the acceleration of antibody levels was significantly higher and faster in the mice primed with DNA expressing preS2/S-P28 fusions than that with DNA expressing preS2/S only ($P < 0.05$). Interestingly, mice primed with DNA expressing preS2/S-P28.4 fusions maintained the highest levels of anti-HBs antibodies in all animals. The avidity assay showed that the avidity index (AI) collected at 18 wk from mice primed with pVAON33-S2/S-P28.3 and pVAON33-S2/S-P28.4 were significantly higher than that from preS2/S-DNA vaccinated mice ($P < 0.01$).

CONCLUSION: Different repeats of C3d-P28 can enhance both humoral immune response and avidity maturation of specific antibodies induced by gene immunization, in which four copies of C3d-P28 may be necessary to achieve the most modest antibody response.

INTRODUCTION

The third complement protein (C3) plays a major role in the complement activation pathway, the critical role of the cleavage fragments of C3 in the humoral immune response for both T-dependent and T-independent antigens was reported in studies performed over a quarter of a century ago^[1,2]. Complement's potential use as an adjuvant in vaccines was first suggested when Dempsey *et al.*^[2] demonstrated that mice, vaccinated with a genetically engineered construct containing three copies of mouse C3d fused to a model antigen, hen egg lysozyme, increased the efficiency of immunizations by more than 1 000-fold. Subsequent studies by Test *et al.*^[3] showed that covalent conjugates of C3d and the capsular polysaccharide of serotype 14 *streptococcus pneumoniae* (PPS14) elicited higher titers to PPS14 in mice than PPS14 only, and furthermore induced a class switch in anti-PPS14 from predominantly IgM to IgG1, which extended the adjuvant effects of C3d to T-independent antigen as well as T-dependent antigen. Recently, studies have further shown that gene immunization with C3d is an effective molecular adjuvant for inducing antibody responses to a range of viral pathogens, including influenza virus^[4,5], human immunodeficiency virus^[6], and measles virus^[7]. The mechanism, by which C3d increases antibody responses, has been hypothesized to reflect the binding of C3d to cluster of differentiation 21 (CD21) on the surface of B-cells or follicular dendritic cells (FDC)^[4,5,8,9].

The complement receptor 2 (CR2)-binding site on C3d was located, using chemical fragmentation and peptide mapping studies, between residues 1 199 and 1 210 of the complement C3 sequence (mature C3 numbering)^[10]. A synthetic peptide corresponding to the CR2-binding site on C3d, P28 (C3^{K1,187-A1,214,1187}KFLTTAKDKNRWEDPGKQLYNVEATSYA¹²¹⁴), as well as other C3d homologous, specifically binds to CR2 expressed on B cell lines, such as Raji cells^[10,11]. Binding of P28 stimulates the proliferation of peripheral resting B lymphocytes or CR2-positive B cell lines^[11-13]. In addition, the binding of CR2 to P28 peptides and the proliferative response of B cells by these peptides were dose dependent and could be inhibited by soluble C3d or anti-CR2 mAb^[12,14]. Furthermore, when a P16 peptide (equivalent to residues 1 195-1 210 of C3) was coupled to anti-idiotypic antibody, it induced a strong idiotypic and antigen-specific response in mice^[15].

In present study, we selected this active C3d-P28 peptide as a molecular adjuvant according to its binding-ability to CR2

on the B-cells or FDC^[10-13,15], and HBV-preS2/S as a model antigen, to seek an enhanced anti-preS2/S antibody response following vaccination with DNA expressing fusions of HBV-preS2/S to variable copies of C3d-P28. Our results showed that immunizations with the preS2/S-P28 fusions DNA not only induced higher primary humoral responses as well as a faster and stronger memory reaction, but also accelerated the avidity maturation of anti-HBs compared with that resulting from immunization with preS2/S only. Our findings argue that four or more repeats of C3d-P28 may be necessary for efficient enhancement of antigen-specific immune responses.

MATERIALS AND METHODS

Plasmid

A eukaryotic expression vector pVAON33 was reconstructed from pVAX1, a kind gift from professor Zhongming Li (Food and Drug Administration, Bethesda, MD, USA). It contained the cytomegalovirus immediate-early (CMV-IE) promoter for initiating transcription of eukaryotic inserts and the bovine growth hormone polyadenylation signal [BGH poly(A)] for termination of transcription. It also contained pMB1 origin of replication for prokaryotic replication as well as the kanamycin resistance gene (*Kan^r*) for selection in antibiotic media. Moreover, a synthetic oligonucleotide (ON33) containing the Kozak's translation initiation sequence was inserted into pVAX1 for the convenience of cloning four tandem repeats of the C3d-P28 in-frame with the gene encoding HBV-preS2/S (Figure 1). Plasmid pTG825 (tPA-C3d₃) containing the encoding gene of C3d was a gift from Dr. Ted M. Ross (University of Pittsburgh, Pittsburgh, PA, USA). Plasmid pcDNA-preS2/S containing the encoding gene of HBV-preS2/S was constructed and conserved by our laboratory. pGEM-T vector was purchased from Huashun Biotechnology (Shanghai, China).

Figure 1 Schematic illustration representation of vector DNA vaccine constructs. A: A synthetic oligonucleotide (ON33) was inserted into the pVAX1 vector by the *Hind*III and *Bam*HI restriction endonuclease sites. Inserts were cloned into the vector using the *Bgl*II and *Bam*HI sites. B: The scheme represents constructs expressing fusions of HBV-preS2/S to variable copies of C3d-P28.

Cell lines

Human hepatocellular carcinoma cell lines SMMC-7721 was obtained from the Department of Biochemistry and Molecular Biology, Shanghai Medical College, Fudan University (Shanghai, China). SMMC-7721 cells were grown in RPMI 1640 medium (Gibco BRL) supplemented with 100 mL/L calf bovine serum (CBS), 100×10³ U/L penicillin and 100×10³ U/L streptomycin sulfate. *Escherichia coli* strain, DH5 α , was kept in our laboratory and maintained in LB medium.

Animals

Female BALB/c mice (H₂d, 6 to 8-week-old) were purchased

from the Center of Experimental Animal, Fudan University (Shanghai, China). They were randomly divided into 6 groups (6 mice per group) and fed with a standard laboratory diet under a specific pathogen-free (SPF) condition.

Main reagents

AMV reverse transcriptase, dNTP, Taq polymerase and PCR production-purified kits were purchased from Shanghai Biostar Co.. *Hind*III, *Bam*HI and *Bgl*II restriction endonuclease, T4 DNA ligase, DNA marker 2000 and RNase-free DNase I were purchased from MBI Co. (Ukraine). Horseradish peroxidase-labeled goat anti-mouse IgG were purchased from Southern Biotech (USA). Lipofectamine was purchased from the Invitrogen Co. (USA). The anion-exchange resin columns were purchased from Qiagen (Germany). The synthetic oligonucleotide (ON) and the PCR primers used were as follows: ON33, 5' - AGCTT GCCAC CATGA GATCT GGATC CTAGT AAG-3' (sense) and 5' -GATCT TACTA GGATC CAGAT CTCAT GGTGG CA-3' (antisense), which was used for reconstruction of the pVAX1 plasmid; C3d-P28, 5' -GAAGA TCTAA GTTTC TGAAC ACAGC-3' (sense) and 5' -CGGGA TCCGG CCTAG GATGT G-3' (antisense), which permitted the amplification of a 84-bp cDNA of C3d-P28; HBV-preS2/S, 5' -GGAAG ATCTC AGTGG AATTC CACAA C-3' (sense, bases 3 082 to 3 100) and 5' -GGAAG ATCTA ATGTA TACCC AAAGA CAA-3' (antisense, bases 706 to 688), which permitted the amplification of the entire coding region of HBV-preS2/s cDNA; T7 primers, 5' -CGATG AAGAT CTCT-3' (sense) and 5' -CGATG AAGAT CTCT-3' (antisense), which were used for identification of recombinant plasmids by PCR; GAPDH primers, 5' -CTGCA CCACC AACTG CTTAG-3' (sense) and 5' -CCACT GACAC GTTGG CAGTG-3' (antisense), which permitted the amplification of a 275-bp band corresponding to human GAPDH transcripts as described previously.

Construction of plasmid

The HBV-preS2/S gene was amplified by PCR from plasmid pcDNA-preS2/S. The gene encoding C3d-P28 amplified from plasmid pTG825 by PCR was cloned into the cloning vector-pGEM-T. Each gene was inserted into pVAON33 genetic immunization vector using standard molecular biological technology (Figure 1). Briefly, a 858 bp PCR-amplified preS2/S fragment was digested with *Bgl*II and ligated into the *Bgl*II restriction enzyme sites in the pVAON33. The vector expressing preS2/S-P28-fusion proteins was constructed by cloning four tandem repeats of the P28-encoding gene in-frame with preS2/S fragment and was designed based upon Dempsey *et al*^[2]. Potential proteolytic cleavage sites between the junctions of HBV-preS2/S and P28 and the junction of P28 were mutated by ligating *Bam*HI and *Bgl*II restriction endonuclease sites to replace an arginine codon with a glycine codon. All recombinant plasmids amplified in *Escherichia coli*, DH5 α , were verified by PCR, restricted endonucleases digestion and DNA sequencing, and then were purified using anion-exchange resin columns. Purity of DNA preparations was determined by optical density reading at 260 nm and 280 nm. All the plasmid DNA were stored at -20 °C in sterile saline at 1 mg/mL for experimental use.

Cell transfection and plasmid gene expression analysis

SMMC-7721 cells (5×10⁵ cells), a human hepatocellular carcinoma cell line, were transfected with 2 μ g of the different plasmids DNA mixed with 100 g/L lipofectamine according to the manufacturer's guidelines. Semiquantitative RT-PCR was used to analyze the transcription of HBV-preS2/S or preS2/S-P28 fusions and ensure the correct size of fusions containing variable copies of C3d-P28. Total RNA was extracted from the transfected cells (1×10⁶ cells) using

guanidinium isothiocyanate-based buffer system according to the manufacturer's instructions and then treated by RNase-free DNase I. First-strand cDNA was synthesized from 5 μ L of total cellular RNA with a GeneAmp PCR system 2400 cyclor (Perkin Elmer company, USA) using the following protocol: one cycle at 42 °C for 60 min and 70 for 10 min^[16]. The cDNA was subjected to 30 cycles of amplification using the appropriate primers: (1) sense and antisense of HBV-preS2/S, which permitted the amplification of the HBV-preS2/S cDNA; (2) HBV-preS2/S sense and C3d-P28 antisense, which permitted the amplification of the preS2/S-P28 fusions cDNA; (3) sense and antisense of GAPDH, which permitted the amplification of the GAPDH cDNA. After initiate denaturation at 94 °C for 5 min, the amplification conditions were as follows: denaturation at 94 °C for 1 min, primers annealing at 58 °C for 1 min, and extension at 72 °C for 2 min. Final PCR products were analyzed on 10 g/L agarose gel electrophoresis and the intensity of the preS2/S and GAPDH PCR products was assessed by densitometry and quantitated by using UV-2000 (Tanon Science and Technology Ltd., China); preS2/S mRNA expression was calculated as the ratio of the intensity of the preS2/S band to the GAPDH band. At the same time, direct PCR reaction was performed to exclude the contamination of potential plasmid DNA in the RNA extracted from the transfected cells.

Immunization

The quadriceps of mice were first injected with a total of 100 μ L of 2.5 g/L bupivacaine to enhance the cellular uptake of plasmid DNA one day before the first immunization. Then 100 μ g of each plasmid DNA dissolved in 100 μ L of normal saline was injected into the same region. Twelve weeks later, each mouse was boosted by subcutaneous injection with 1.0 μ g of purified HBsAg protein diluted in 100 μ L of sterile PBS. Sera were collected at 2-week intervals after primary immunization for antibody analysis.

Measurement of anti-HBs antibody levels

The anti-HBs antibody response elicited in mice was evaluated by ELISA. In brief, microtiter plates were coated with purified HBsAg protein (0.5 μ g/well). After incubation with 100 mL/L FBS in PBS for 60 min at 37 °C to prevent nonspecific binding, 1:10 dilution of mouse serum were added to the plates and incubated at 37 °C for an additional 60 min. After the samples were washed with PBS containing 0.5 g/L Tween-20, a horseradish peroxidase-labeled goat anti-mouse antibody was added at a dilution 1:5 000. After 60 min incubation, plates were washed, and substrate was added for color development. Absorbance (A_{490}) of each plate wells was read at 490 nm that indicated the levels of specific antibody.

Measurement of anti-HBs antibody avidity

Relative antibody avidity was determined by a modified elution ELISA that was similar to serum antibody determination ELISAs up to the addition of samples as previously described^[11,12]. Plates were washed 3 times with 0.5 g/L PBS-Tween 20. Sodium thiocyanate (NaSCN), a chaotropic compound that interferes with the antigen-antibody reaction, was added subsequently in concentrations ranging from 0.5 mol/L to 3.5 mol/L. Plates were allowed to left for 15 min at room temperature and then washed six times with PBS-Tween 20. Subsequent steps were performed similarly to the serum antibody determination ELISA. The avidity index (AI) corresponded to the effective concentration of NaSCN required to give a 50% reduction in absorbance at 490 nm.

Statistical analysis

Data were expressed as mean \pm SD. Experimental results were analyzed by variance analysis or *t* test with SPSS software. *P*<0.05 were considered statistically significant.

RESULTS

Construction and identification of the recombinant plasmids

To test for an effect of C3d-P28 on the immune responses to a DNA vaccine, we selected plasmids encoding HBV envelope proteins as a model system. Then the genes encoding middle (preS2 plus S) HBV envelope proteins (858 bp) were cloned into a eukaryotic expression vector pVAON33. One to four tandem repeats of the C3d-P28 fragment were inserted into pVAON33 plasmid to construct the recombinant plasmids pVAON33-P28, pVAON33-P28.2, pVAON33-P28.3 and pVAON33-P28.4 (pVAON33-P28.[1-4]), respectively. HBV-preS2/S coding sequence was then introduced into the pVAON33-P28.[1-4], respectively. The results of identification by both PCR and DNA sequencing showed that the coding-codon of HBV-preS2/S coding gene, repeats of the P28-coding gene and their junctions were correct (data not shown).

Expression of plasmids

SMMC-7721 cells were transiently transfected with preS2/S and preS2/S-P28.4 protein expression vectors, with the plasmid pVAON33 serving as a negative control. At 2 d after transfection, the preS2/S mRNA could be detected in SMMC-7721 cells transfected with both plasmid pVAON33-S2/S and pVAON33-S2/S-P28.4, but not in mock plasmid (Figure 2). However, mRNA representing fusions of preS2/S to various copies of P28 could only be detected in SMMC-7721 cells transfected with pVAON33-S2/S-P28.4 plasmid. Digested with DNase I, RNA samples extracted from the cells transfected with both pVAON33-S2/S and pVAON33-S2/S-P28.4 were confirmed the exclusion of potential plasmid DNA contamination (Figure 2). These results suggested that various copies of P28 had fused with the HBV-preS2/S. Semiquantitative RT-PCR analysis showed that preS2/S expressed by pVAON33-S2/S-P28.4-DNA was 29.61% lower than that expressed by pVAON33-S2/S-DNA.

Figure 2 Semiquantitative RT-PCR for expression of the preS2/S-P28 fusion proteins. Lane 1: DNA marker; Lanes 2,3 and 5: RT-PCR with preS2/Ss and preS2/Sa primers that amplified an entire coding region (858 bp) of preS2/S, using RNA extracted from pVAON33, pVAON33-S2/S and pVAON33-S2/S-P28.4 transfected-cells, respectively; Lanes 4 and 6: RT-PCR with preS2/Ss and P28a primers that amplified a 1 230 bp cDNA fragment of preS2/S-P28.4 fusion cDNA (the ladder showed the RT-PCR production due to 4 copies of P28), using RNA extracted from pVAON33-S2/S and pVAON33-S2/S-P28.4 transfected-cells, respectively; Lanes 7 and 9: RNA extracted from pVAON33-S2/S and pVAON33-S2/S-P28.4 transfected-cells was founded to exclude the potential contamination of potential plasmid DNA by PCR with preS2/Ss and preS2/Sa primers, respectively; and Lane 8: pVAON33-S2/S plasmid DNA was taken as positive control.

Anti-HBs IgG levels after primary immunization

The preS2/S-P28-expressing DNA plasmids showed higher levels of anti-HBs antibody than the preS2/S-expressing DNA (Figure 3). When sera were assayed on HBsAg-coated plates, there were various degrees of enhancement of anti-HBs IgG antibody levels in the mice with DNA expressing fusions of HBV-preS2/S to variable copies of P28 compared to the mice

primed with DNA expressing HBV-preS2/S only (Figure 3). Interestingly, at 12 wk after the primary immunization, the highest level of the specific antibody response (A_{490} , 1.049 ± 0.186) was observed in the groups primed with DNA expressing fusions of HBV-preS2/S to four copies of P28, which was not only significant higher than the level of antibody response from the group primed with preS2/S-expressing DNA (A_{490} , 0.621 ± 0.064 ; $P < 0.01$), but also obviously higher than the level of antibody response from the groups primed with preS2/S-P28.1-expressing DNA (A_{490} , 0.764 ± 0.143 ; $P < 0.01$), preS2/S-P28.2-expressing DNA (A_{490} , 0.915 ± 0.275 ; $P < 0.05$) and preS2/S-P28.3-expressing DNA (A_{490} , 0.696 ± 0.091 ; $P < 0.01$), respectively. It was suggested that P28, when fused with HBV-preS2/S, could enhance the specific antibody response against HBsAg following primary DNA immunization. Differences in the enhancement of the antibody levels raised by the fusions of preS2/S-P28 to variable repeats of P28 appeared to be determined by the different repeats of P28, in which four copies of P28 might be necessary to achieve the most modest antibody response.

Figure 3 Determination of anti-HBs IgG of sera from mice primed by the plasmid vectors containing different copies of C3d-P28. BALB/c mice (6 animals per group) were primed im at week 0 with 100 μ g of mock DNA (O), pVAON33-S2/S plasmid (●), pVAON33-S2/S-P28 plasmid (Δ), pVAON33-S2/S-P28.2 plasmid (\square), pVAON33-S2/S-P28.3 plasmid (\diamond) and pVAON33-S2/S-P28.4 plasmid (\blacksquare), separately. Sera collected at the indicated weeks from each group were diluted 1:10 for determination of specific IgG levels by ELISA. Data were represented as the average for each group of mice. Error bars were represented as 95% CI of the geometric mean for each group of sera.

Anti-HBs IgG levels after secondary vaccination

To further observe the effects of P28 peptides on the memory responses against HBsAg, mice from each group were boosted subcutaneously with 1 μ g of HBsAg purified at the twelfth week after the primary immunization. The results showed that the mice of the groups vaccinated primarily with preS2/S-expressing DNA produced an increased levels of anti-HBs antibody compared to the mice immunized primarily with mock DNA after the second immunization with specific antigen (Figure 4). However, the acceleration of antibody levels was significantly higher and faster in the mice immunized with DNA expressing preS2/S-P28 fusions than that in the mice immunized with DNA expressing preS2/S only ($P < 0.05$). Interestingly, at the eighteenth week after the primary immunization, mice immunized primarily with DNA expressing preS2/S-P28.4 fusions maintained the highest levels of anti-HBs antibodies in all animals (A_{490} , 1.273 ± 0.106). It was suggested that the mice immunized with DNA expressing preS2/S-P28 fusions not only enhanced primary humoral responses against HBsAg, but also produced a quicker and stronger memory responses than that with DNA expressing

preS2/S only, in which four copies of P28 might also be necessary to obtain the most modest antibody memory reaction.

Figure 4 Determination of anti-HBs IgG of sera from mice primed by the different plasmid DNAs and boosted with HBsAg protein. Each group of mice ($n=6$) was primed im at week 0 with 100 μ g of mock DNA (O), pVAON33-S2/S plasmid (●), pVAON33-S2/S-P28 plasmid (Δ), pVAON33-S2/S-P28.2 plasmid (\square), pVAON33-S2/S-P28.3 plasmid (\diamond) and pVAON33-S2/S-P28.4 plasmid (\blacksquare), separately. And then boosted sc at week 12 with HBsAg (1 μ g per mouse). Sera collected at the indicated times from each group were diluted 1:10 for determination of specific IgG levels by ELISA.

Avidity of anti-HBs IgG

To observe whether P28 enhances the avidity maturation of the antibody response after immunization with P28-preS2/S fusions, NaSCN-displacement ELISA, a well-accepted approach, was used to evaluate the avidity of the anti-HBs antibodies^[11-13]. The results demonstrated that the AI collected at 18 weeks from mice immunized primarily with preS2/S-P28.3 and preS2/S-P28.4 expressing DNA, separately was significantly higher than that from preS2/S-DNA vaccinated mice (Figure 5, $P < 0.01$). However, no significant increases in the AI were found in either preS2/S-P28.1 expressing or preS2/S-P28.2 expressing DNA vaccinated mice compared to the mice immunized with DNA expressing preS2/S only. These results suggested that C3d-P28 could enhance the avidity maturation of antibodies against HBsAg following gene immunization with DNA expressing fusions of HBV-preS2/S to three or four repeats of C3d-P28.

Figure 5 Determination of avidity of anti-HBs IgG of sera from immunized mice. Mice (six mouse per group) were primed im at week 0 with 100 μ g of different plasmid DNAs and then boosted sc at week 12 with HBsAg (1 μ g per mouse). Sera were obtained at week 18. The pooled serum samples from each mouse group were diluted 1:10 for determination of avidity of the anti-HBs IgG by an HBsAg-specific NaSCN-displacement ELISA. Data were represented as the average of three independent experiments plus standard errors (mean \pm SD).

DISCUSSION

Recently, several studies demonstrated that DNA vaccines encoding the small or middle viral envelope proteins of HBV elicited higher titer antibody, as well as cell-mediated immune responses compared with HBV subunit vaccines^[17-19]. Moreover, DNA immunization was able to break immune tolerance in the HBV transgenic mouse model^[20] and induces protective antibody responses in human non-responders to conventional vaccination^[17], indicating that DNA vaccines might be beneficial for immunotherapy for individuals with chronic HBV infections. DNA vaccines for HBV infection are efficacious, as well as inexpensive, and therefore, may be a promising tool in controlling the viral infections and liver diseases^[21].

However, one of the drawbacks that prevents the wide spread use of DNA vaccines is slower rise in humoral immunity compared with other vaccine strategies for HBV infection. This may be due to the low levels of antigen expression and presentation by inoculated DNA plasmids compared to the inoculation of HBsAg^[22]. In order to enhance the efficacy of antigens expression and presentation in the DNA immunization, several studies have shown that three copies of C3d, as a molecular adjuvant when fused to an antigen, could enhance the immune responses and accelerate the antibody avidity maturation^[2-7]. However, Suradhat *et al.*^[23] reported that fusions of one or two copies of C3d with either bovine rotavirus VP7 or bovine herpesvirus type 1 glycoprotein D inhibited the specific humoral response following DNA immunization, and suggested that using three or more copies of C3d molecule may be necessary for efficient enhance of antigen-specific immune responses following DNA immunization. These results indicated that different repeats of C3d in the fusions of target antigen to C3d might influence efficient enhancement of antigen specific immune response following DNA immunization^[2-7,23].

HBsAg is encoded by a single gene which is divided into S, preS2 and preS1 regions. preS vaccines have been most extensively applied in humans and shown to confer certain protective immunity. Recently more researches indicated that addition of the preS2 sequence could enhance the immunogenicity of the vaccines in human^[24,25]. Therefore in this study, we selected HBV-preS2/S as a model antigen and different repeats of P28 peptide, an active peptide corresponding to the CR2-binding site on C3d^[10-13], as a molecular adjuvant to explore enhancing effects on the immune response. As expected, mice vaccinated with DNA expressing fusions of preS2/S to P28 (one, two, three or four repeats) elicited a higher level of primary humoral response compared to mice vaccinated with DNA expressing only the preS2/S protein. Moreover, the mice immunized with DNA expressing preS2/S-P28 fusions produced a quicker and stronger memory responses than that with DNA expressing preS2/S only after second immunization. Interestingly, the results showed that the enhancing effect of various repeats of P28 in fusions of preS2/S to P28 on primary response as well as memory reaction was different, in which four copies of P28 might be necessary to achieve the most modest antibody response. It was indicated that the most modest antibody response appeared to be determined by the different repeats of P28. These results acquired here further explained the conflict between reports by Ross *et al.*^[4] and by Suradhat *et al.*^[23]. The increase in antibody response elicited by four copies of P28, similar to previous studies using antigen-C3d3 fusions^[3-7], was even more intriguing, since the preS2/S-expression at the mRNA level by preS2/S-P28.4-expressing plasmid was 29.61% lower than the expression by plasmid expressing HBV-preS2/S only. The most likely mechanism by which P28 increases antibody responses is similar to C3d, which has been hypothesized to reflect the binding of C3d to

CD21 on the surface of B-cells or follicular dendritic cells (FDC)^[3,4,8].

Surprisingly, immunization with the preS2/S-P28 fusions also resulted in enhanced avidity maturation of anti-HBs antibody. The results demonstrated that the AI of sera collected from mice immunized primarily with preS2/S-P28.3 and preS2/S-P28.4 expressing DNA, separately, was significantly higher than that from preS2/S-DNA vaccinated mice. Avidity is a term used to describe the strength of interaction between multivalent antigens and antibodies in serum and is dependent on the individual affinities of the polyclonal antibodies^[3]. Avidity maturation occurs in germinal centers where the somatic hypermutation of immunoglobulin results in a large repertoire of Ag-specific B cells that undergo inducing or selection for high-affinity B cell receptors by T helper cells or follicular dendritic cells (FDC)^[8,9,26-28]. The most likely mechanism by which P28 enhanced the avidity maturation of anti-HBs antibodies might relate to multiple interactions of cells responsible for humoral immunity, including B cells, T helper cells, and FDC. These interactions, coupled with the enhancing effects of CR2 ligation on germinal center formation^[29] and the enhancing effects of specific Th cells on somatic hypermutations of B cells^[30], could promote the selection of antigen-specific B cells with high-affinity B cell receptors, resulting in the avidity maturation of anti-HBs antibodies and the development and maintenance of memory B cells^[31].

Taken together, this is the first report to demonstrate that immunization with DNA expressing antigen-P28 fusions results in enhancing antibody response and enhancing antibody avidity maturation. These findings argue that four or more repeats of C3d-P28 may be necessary for efficient enhancement of antigen-specific immune responses, and thus C3d-P28, a short, active peptide derived from the CR2-binding site on complement C3d, may be another promising molecular adjuvant and may assist the future design of vaccines for health-threatening pathogens.

ACKNOWLEDGEMENTS

We sincerely thank Dr. T.M. Ross from University of Pittsburgh School of Medicine for helpful advice in this study and for providing the plasmid. We also thank Jin-Ping Zhang, Cong-Feng Xu, Huan-Bin Xu for their technical assistance.

Abstract

AIM: To prepare hammerhead ribozymes against mouse caspase-7 and identify their cleavage activity *in vitro*, in order to select a ribozyme with specific cleavage activity against mouse caspase-7 as a potential gene therapy for apoptosis-related diseases.

METHODS: Anti-caspase-7 ribozymes targeting sites 333 and 394 (named Rz333 and Rz394) were designed by computer software, and their DNA sequences encoding ribozymes were synthesized. Caspase-7 DNA sequence was acquired by RT-PCR. Ribozymes and caspase-7 DNA obtained by *in vitro* transcription were cloned into pBSKneo U6' and pGEM-T vectors, respectively. The cleavage activity of ribozymes against mouse caspase-7 was identified by cleavage experiments *in vitro*.

RESULTS: Rz333 and Rz394 were designed and their DNA sequences were synthesized respectively. The expression vector of caspase-7 and plasmids containing Rz333 and Rz394 were reconstructed successfully. Ribozymes and caspase-7 mRNA were expressed by *in vitro* transcription. *In vitro* cleavage experiment showed that 243-nt and 744-nt segments were produced after caspase-7 mRNA was mixed with Rz333 in equivalent, and the cleavage efficiency was 67.98%. No cleaved segment was observed when caspase-7 mRNA was mixed with Rz394.

CONCLUSION: Rz333 can site-specific cleave mouse caspase-7 mRNA, and it shows a potential for gene therapy of apoptosis-related diseases by down-regulating gene expression of caspase-7.

INTRODUCTION

Apoptosis, or programmed cell death, is characterized by a series of morphological features such as chromatin

condensation, nuclear fragmentation, and the appearance of membrane-enclosed apoptotic bodies, *etc.*^[1,2], most of which are caused by the activation of caspases, a family of aspartate-specific cysteine proteases^[3,4]. Caspases are constitutively present in cells as inactive zymogens and require proteolytic cleavage into the catalytic active heterodimer^[5]. All activated caspases are comprised of a large subunit with M_r 17 000-20 000 that contains a redox-sensitive cysteine at the active site and a small subunit with M_r 10 000 approximately. According to their function and sequence of activation, caspases can be grouped into three categories: Caspases that function primarily in cytokine maturation (such as caspases-1, -4, and -5); initiator caspases involved in the early steps of apoptotic signaling (caspases-8, -9, and -10) and effector proteases in the execution phase of apoptosis (caspases-3, -6, and -7). The initiator caspases lead to the activation of executioner caspases following characteristic apoptotic stimuli. The substrates of executioner caspases include many proteins, the cleavage of which causes the characteristic morphology of apoptosis^[6,7]. Because apoptosis is a regulated cellular process, it offers some opportunities for therapeutic intervention^[8,9]. Indeed, eliminating caspase activity, either through mutation or the use of small pharmacological inhibitors, will slow down or even prevent apoptosis.

Ribozymes are small RNA molecules that hybridize to the target RNA around the cleavage site, and catalyze site-specific cleavage of substrate. Cleaved mRNA is rapidly degraded, allowing ribozyme to react with new targets. Various ribozymes have been used to down-regulate gene expression in a sequence-specific manner. Among them the hammerhead ribozyme, composed of only 30 to 40 nucleotides, is the smallest and simplest one, and has been used extensively to down-regulate gene expression^[10-13].

Caspase-3 and caspase-7 are both important executioner caspases^[14]. Expression pattern of caspase-7 is distinguishable from that of caspase-3, suggesting that they may regulate apoptosis in disparate tissues, although they share strong homology. In the past years, many researches have been concentrated on interfering with the activity or expression of caspase-3 so as to intervene in apoptosis^[15-17]. Following its activation, caspase-7 was translocated into the microsomal and mitochondrial fractions, where it was responsible for the cleavage of specific substrates in those distinct subcellular compartments^[18]. Recent results suggested that as one of important executioner caspases, caspase-7 is also essential in apoptotic signaling^[19,20]. In this study, we designed and synthesized two hammerhead ribozymes against mouse caspase-7 at sites 333 and 394 (named Rz333 and Rz394), studied their *in vitro* transcription and cleavage activity, and selected the one that could site-specifically cleave caspase-7 mRNA as a hopeful gene therapy tool for apoptosis-related diseases.

MATERIALS AND METHODS

Materials

TRIzol reagent was product of Gibco. RT-PCR kit, T4 DNA ligase and restriction endonucleases were Takara products. *In vitro* transcription kit and pGEM-T vector were purchased from

Promega. pBSK neo-U6' was kindly donated by Dr. Youxin Jin. Plasmid extraction kit and gel purification kit were products of Shanghai Sangon Biotechnology Co.

Methods

Target mRNA secondary structure analysis and design of anti-caspase-7 ribozymes Caspase-7 gene sequence of BALB/c mouse searched in GenBank (gi: 6680849) was analyzed, and its secondary structure was simulated in computer. Ribozymes against caspase-7 mRNA were designed by software and DNA sequences encoding ribozymes were synthesized. A restriction site of *Xba*I was introduced into 5' end of sense strand. And a *Bam*HI restriction site was introduced into the 5' end of antisense strand. Two DNA strands were mixed at equal molar ratio after synthesis, and annealed by cooling to room temperature naturally after placed in boiling water for 2 min, then double strand DNA encoding ribozymes was obtained.

Ribozyme gene cloning Double-strand ribozyme DNAs designed by computer were inserted into pBSKneo U6' with T4 DNA ligase after pBSKneo U6' was cleaved by *Bam*HI and *Xba*I (Figure 1). The reconstructed plasmids containing ribozyme genes were identified by *Sal*I digestion and sequencing.

Figure 1 Ribozyme gene cloning.

Construction of caspase-7 expression vector Total RNA was extracted with TRIzol reagent from Balb/c mouse liver. Caspase-7 gene segment (841 bp) was amplified by RT-PCR with specific primers. The segment was cloned into pGEM-T vector downstream from T7 promoter, and the transformed clones selectively grew at 37 °C overnight in LB plate (Ampicillin resistance) containing IPTG and X-gal on plate's surface. Clones in blue were selected for sequencing. Caspase-7 primers were: P1 5'-GGATCCGAACGATGACCGATGATCAG-3', P2 5'-AAGCTTGTGAGCATGGACACCATAC-3'.

In vitro transcription of ribozyme and caspase-7 cDNAs Constructed caspase-7 plasmid was linearized with *Hind*III. Reconstructed ribozyme plasmid was considered as PCR template and a pair of primers containing T7 promoter was designed. P1 5'-TCTAGAGTAATACGACTCACTATAGG GCCTTCGGCAGCACATATAC-3', P2 5'-TATGGAACG CTTTCAGGAT-3' (The italic is T7 promoter sequence). Both caspase-7 linearized plasmid and pRz PCR product were phenol-chloroform extracted, and ethanol precipitated. *In vitro* transcription was performed using T7 RNA polymerase. Transcript of caspase-7 labeled with α -³²P-UTP was heated (2 min, 95 °C) before loading and electrophoresed on 6% polyacrylamide gel denatured by 8 mol/L urea. Transcript band was observed after autoradiography. *In vitro* transcription of ribozyme was not labeled with isotope. After electrophoresis on 60 g/L polyacrylamide gel, the transcript bands were observed

under ultraviolet. All transcript bands in gel, labeled with isotope or not, were cut and dipped into nucleic acid (0.5 mol/L NH₄Ac, 1 mmol/L EDTA, 1 g/L SDS), precipitated in ethanol and dissolved in DEPC-H₂O. Concentrations of substrate and ribozyme were calculated through cpm counting and A₂₆₀ measurement, respectively.

In vitro ribozyme cleavage assays Ribozymes and caspase-7 mRNA were incubated at equal molar ratio at 37 °C for 90 min in a system of 5–10 μ L containing 50 mmol/L Tris-HCl pH 7.5, 20 mmol/L MgCl₂, 20 mmol/L NaCl and 2 mmol/L EDTA. The products after cleavage were electrophoresed on 10% polyacrylamide gel, and the cleavage results were analyzed by autoradiography. Cleavage efficiency may be estimated according to cpm of both substrates (S) and cleaved products (P).

$$\text{Cleavage ratio} = [P/(S+P)] \times 100\%$$

RESULTS

Design of ribozymes

According to the results of computer simulation, triplet GUC at site 333 and GUA at site 394 of caspase-7 mRNA were chosen as the cleavage sites of ribozyme. So ribozymes targeting site 333 and site 394 (named Rz333 and Rz394) were designed to cleave the target mRNA. Both designed ribozymes were comprised of a catalytic core and two flanking sequences (Figure 2).

Figure 2 Sequences, structures and targets of ribozymes against caspase-7. Hammerhead ribozymes (bottom strand) binding to their targets (top strand) to form a typical three-stem structure that leads to the cleavage of caspase-7 RNA at the targets of GUC (Rz333) and GUA (Rz394).

Identification of reconstructed plasmid containing ribozyme

Reconstructed plasmids pU6Rz333 and pU6Rz394 were both incubated with *Sal*I at 37 °C for 2 h and then electrophoresed on 12 g/L agarose gel (Figure 3). Clones without 200 bp segment were sent for sequencing, and the results indicated that clones 2, 4 were correctly constructed.

Figure 3 Restriction enzyme cleavage of reconstructed ribozyme plasmid. Lanes 1, 2: pU6Rz333 digested by *Sal*I; lanes 4, 5: pU6Rz394 digested by *Sal*I; lane 3: Marker (DL2000).

Caspase-7 DNA and its clone

Extracted total RNA was amplified by RT-PCR and a 891-bp caspase-7 DNA segment was seen on 20 g/L agarose gel (Figure 4).

It was cloned into pGEM-T vector, and white and blue monoclonal colonies were seen in LB medium after incubated at 37 °C overnight. Blue clones were selected and sent for sequencing.

Figure 4 Agarose gel electrophoresis of RT-PCR products. Lane 1: A 891-bp caspase-7 gene segment; lane 2: Marker (DL2000).

In vitro transcription of target mRNA and ribozymes

Transcript of target mRNA was electrophoresed on 60 g/L polyacrylamide gel. After autoradiography, a black band of 987 nt was observed, including 891-nt caspase-7 mRNA and 96-nt U6 segment (Figure 5). *In vitro* transcripts of the two ribozymes were not labeled with isotope. The results of transcription were analyzed under ultraviolet. Black bands of 47 nt (Rz333) and 50 nt (Rz394) could be seen.

Figure 5 *In vitro* transcription of target RNA. The transcript is 987 nt.

In vitro cleavage of ribozymes

Products of cleavage assays were electrophoresed on 100 g/L polyacrylamide gel, and analyzed by autoradiography. Rz333 cleaved caspase-7 mRNA and produced two cleaved segments of 243 nt and 744 nt, with a cleavage efficiency of 67.98%. Rz394 could not cleave target RNA (Figure 6).

Figure 6 *In vitro* cleavage experiments of anti-caspase-7 ribozymes. Lane 1: Caspase-7 mRNA was mixed with Rz333 and two segments of 243 nt and 744 nt produced by cleavage reaction. Lane 2: Caspase-7 mRNA was mixed with Rz394 and no segment was seen after cleavage. Lane 3: Caspase-7 mRNA was mixed with neither Rz333 nor Rz394. The 110-nt marker is indicated by a short arrow.

DISCUSSION

RNA catalysis was first described by Altman and Cech with the discovery of RNase P and the group I intron, respectively^[21,22]. This makes RNA the only molecule with an information-carrying capacity and inherent catalytic activity. So far, several natural ribozyme motifs have been identified and their physical structure, biological and biochemical properties have been the subject of reviews^[23,24]. In general, however, natural ribozymes have been divided into groups based on their specialized catalytic properties. As the smallest one, the hammerhead ribozyme, with its capability of self-cleavage of a particular phosphodiester bond, has been studied extensively to understand the structure-activity relationship^[25-29]. It provides a very valuable tool for genetic therapy through its RNA-mediated inhibition of gene expression. Hammerhead ribozyme has been used extensively to down-regulate cellular and viral gene expression^[30,31], and recognized as a novel molecular therapeutic drug in the treatment of cancer or viral infection.

Apoptosis is essential to the normal development of multicellular organisms as well as physiologic cell turnover. In pathologic states, a failure to undergo apoptosis may cause abnormal cell overgrowth and malignancy, while excessive apoptosis may lead to organ injury. Apoptosis involves the activation of the caspases, which are hallmarks of apoptosis. Central to the execution phase of apoptosis are the two closely related caspase-3 and caspase-7, which share common substrate specificity and structure. Many cellular proteins are cleaved during the execution phase of apoptosis at a DXXD motif by the effector caspases-3 and -7. Caspase-3 has been extensively studied as gene therapeutic target. Caspase-7, as another crucial executioner caspase, has been chosen to be the gene therapy target of ribozyme.

In our experiment, we only discovered two sites (333 and 394) in caspase-7 gene suitable for hammerhead ribozymes to cleave, so Rz333 and Rz394 were synthesized and cloned. Caspase-7 gene segment (891 bp) was amplified by RT-PCR from total RNA of mouse liver, and was cloned into an expression plasmid. Ribozymes and substrate were both gained by *in vitro* transcription. The results of cleavage assays indicated that Rz333 could catalyze site-specific cleavage of caspase-7 mRNA, and produced 243-nt and 744-nt cleaved segments, but Rz394 could not cleave the substrate. This might be because the secondary structures of ribozymes and substrate simulated by computer could not reflect the real situation. Rz333 could site-specifically cleave caspase-7 mRNA with a cleavage efficiency of 67.98%. It may prevent apoptosis solely or in association with anti-caspase-3 ribozyme synthesized and selected in our previous study. Rz333 may become a candidate for gene therapy of apoptosis-related diseases.

Abstract

AIM: To assess the role of oxygen-derived free radicals and cytokines in the pathogenesis of taurocholic acid-induced acute pancreatitis, and to evaluate the preventive effects of octreotide towards the development of acute pancreatitis.

METHODS: Acute pancreatitis was induced in male New Zealand white rabbits by retrograde injection of 0.8 mL/kg b.m. of 50 g/L sodium taurocholate (NaTC) in the pancreatic duct. Sham-operated animals served as control. Octreotide 1 mg/kg b.m. was administered subcutaneously before the induction of pancreatitis. Blood was taken from the jugular vein before and at 1, 3, 6, 12 and 24 h after pancreatitis induction. Serum activities of amylase, IL-6 and TNF- α and levels of malonyl dialdehyde (MDA), glutathione (GSH), glutathione peroxidase (GPx), catalase and superoxide dismutase (Mn-, Cu-, and Zn-SOD) in pancreatic tissue were measured.

RESULTS: Serum TNF- α and IL-6 levels increased significantly 3 h after the onset of pancreatitis, and then returned to control level. The tissue concentration of MDA was significantly elevated at 24 h, while the GSH level and GP-x, catalase, Mn-SOD, Cu-, Zn-SOD activities were all significantly decreased in animals with pancreatitis as compared to the control. Octreotide pretreatment significantly reversed the changes in cytokines and reactive oxygen metabolites. Octreotide treatment did not alter the serum amylase activity and did not have any beneficial effects on the development of histopathological changes.

CONCLUSION: Oxygen-derived free radicals and proinflammatory cytokines are generated at an early stage of NaTC-induced acute pancreatitis in rabbits. Prophylactic octreotide treatment can prevent release of cytokines and generation of reactive oxygen metabolites, but does not have any beneficial effects on the development of necrotizing pancreatitis.

INTRODUCTION

Acute pancreatitis is clinically classified into mild and severe forms. Mild or edematous acute pancreatitis is a self-limiting disease with a low complication and mortality rate. However, severe necrotizing pancreatitis has an unacceptably high morbidity and mortality rate. Multiple therapeutic modalities have been suggested for acute pancreatitis, but none has been unambiguously proven to be effective yet. The major problem is that the pathophysiology of the disease is not fully understood and hence, there is no specific casual treatment yet. The treatment of acute pancreatitis to date is essentially supportive^[1-3].

Theories on the pathogenesis of acute pancreatitis suggest that autodigestion of the gland and peripancreatic tissues by activated digestive enzymes is a key component^[4,5]. Furthermore, stimulation of exocrine pancreatic secretion in experimental acute pancreatitis has been demonstrated to worsen the disease. Prevention of release and activation of enzymes by inhibition of pancreatic exocrine secretion has been therefore suggested as a specific treatment. Somatostatin and its long-acting analogue octreotide are potent inhibitors of pancreatic secretion^[6,7]. The efficacy of somatostatin and octreotide in the management of acute pancreatitis has been studied for decades, yet the data still remain inconclusive. Some experimental^[8,9] and clinical^[10] studies have shown beneficial results, but others^[11-14] demonstrated no benefit^[15,16].

Somatostatin and octreotide increase the tone of the sphincter of Oddi, which can be reversed by administration of glyceryl trinitrate^[17,18]. Furthermore, octreotide may trigger acute pancreatitis and worsen the disease^[19].

We studied the effects of octreotide on necrotizing pancreatitis in rabbits. In these animals the pancreatic duct enters the duodenum at its distal part, and is completely separated from the common bile duct. Therefore, we can exclude the effect of octreotide on the sphincter of Oddi. The present study was to assess the roles of oxygen-derived free radicals and cytokines in the pathogenesis of taurocholic acid-induced acute pancreatitis, and to evaluate the preventive effects of octreotide on the development of acute pancreatitis.

MATERIALS AND METHODS

Animals

New Zealand white rabbits weighing 2.5-3.5 kg were used. The animals were kept at a constant room temperature of 27 °C, and had free access to water and a standard laboratory chow [LATI, Gödöllő, Hungary]. The experimental protocol followed the principles of Laboratory Animal Care of the National Institute of Health, USA.

Experimental protocol

Overnight fasted animals were anesthetized with an intravenous

injection of pentobarbital 20 mg/kg and urethane 1 g/kg, and supplemented when needed. Four groups of animals were prepared through a midline incision; the pancreatic duct was cannulated transduodenally with a polyvinyl catheter. Acute pancreatitis was induced by retrograde intraductal infusion of 0.8 ml/kg·b.m. of 50 g/L sodium taurocholate (NaTc) (Reanal, Budapest) dissolved in 0.15 mol/L NaCl under steady manual pressure over a period of 30 s (Group I)^[20]. After infusion the catheter was removed, and the abdomen was closed in two layers. In control animals, laparotomy was performed with visualization of the pancreatic duct before closure of the abdomen [Group II]. Animals in which pancreatitis was induced by administration of NaTc were injected subcutaneously with 1 mg/kg·b.m. octreotide (SANDOSTATIN Novartis, Basel, Switzerland) before pancreatitis induction (Group III). In Group IV animals were treated with saline before induction of pancreatitis. The body temperatures and weights of the animals were measured every 6 h. Blood was taken from the jugular vein before and at 1, 3, 6, 12 and 24 h after pancreatitis induction. Physiologic saline was injected into the jugular vein during the experiment in order to avoid severe hypovolemia. Twenty-four hours after the abdominal operation, the animals were sacrificed by aorta exsanguination. The pancreas was removed.

Assays

Serum amylase activity was measured by the Phadebas test method^[21]. TNF- α levels were titrated in a bioassay on the WEHI-164 cell line^[22]. IL-6 concentrations were measured via their proliferative action on the IL-6-dependent mouse hybridoma cell line B-9^[23]. The activities were calibrated against recombinant TNF [Genzyme, Cambridge, UK] and recombinant IL-6 [Sigma-Aldrich, Munich, Germany].

The pancreata were homogenized. The homogenates were centrifuged at 3 000 r/min for 10 min and the supernatants were used for measurements.

Lipid peroxide MDA level was measured after reaction with thiobarbituric acid, according to the method of Placer *et al.*^[24], and was corrected for the protein content of the tissue.

Superoxide dismutase (SOD) activity was determined on the basis of the inhibition of epinephrine-adrenochrome autoxidation^[25]. Mn-SOD activity was measured by the autoxidation method in the presence of 5×10^{-3} mol/L KCN^[26]. Cu-, Zn-SOD activity resulted from the deduction of Mn-SOD from SOD activity.

Catalase activity was determined spectrophotometrically at 240 nm by the method of Beers *et al.*^[27] and expressed in Bergmeyer units (BU) (1 BU=decomposition of 1 g H₂O₂/min at 25 °C).

Glutathione (GSH) level was measured spectrophotometrically with Ellman's reagent from the supernatant, and was corrected for the protein content of the tissue^[28]. Glutathione peroxidase (GPx) activity was determined according to the 'chemical' method, using cumene hydroperoxide and reduced GSH as substrates of GPx^[29].

Protein concentration of the pancreatic tissue was determined by the method of Lowry *et al.*^[30].

Histologic examination

A portion of the pancreas was fixed overnight in a 6% neutral formaldehyde solution and embedded in paraffin. Tissue slices were subjected to hematoxylin and eosin staining and histologic study by light microscopy. Slides were coded and examined blind by the pathologist for the grading of histologic alterations. Grading of intestinal edema, vacuolization, inflammation, hemorrhage and acinar cell necrosis was performed on a scale of 1 to 4.

Statistical analysis

Results are expressed as mean \pm SE. Experiments were evaluated

statistically with two-way analysis of variance (ANOVA). *P* value less than 0.05 was statistically significant.

RESULTS

Seven animals died (2 within 1 h, 3 at 1 h, and 2 at 6 h after pancreatitis induction). Two of them were in the octreotide pretreatment (Group III), 2 in the saline pretreatment (Group IV), and 3 in the acute pancreatitis group (Group I). Thus, the results were the data on the surviving 32 animals (8 rabbits in each group). The results of Group III did not statistically differ from those of Group IV, therefore they were not depicted in figures and tables.

The body weights of the animals in the 3 groups did not change significantly during the experiments, indicating that the parenteral fluid supplementation during the observation period was sufficient.

The serum amylase activity was already increased significantly at 1 h, and increased gradually up to 24 h after the induction of pancreatitis in Group I as compared with the control group ($5\,678 \pm 881$ vs 517 ± 99 U/L) (Figure 1). Pretreatment of pancreatic animals with octreotide (Group III) did not alter the serum amylase activity as compared with Group I at any time point. Since the amylase, TNF- α and IL-6 levels in Group IV did not differ significantly from those in Group III, they were not shown.

Figure 1 Effects of octreotide on serum amylase levels in rabbits with NaTc-induced acute pancreatitis. Group I: ●; Group II as control: ▲; Group III treated with octreotide: ■. ^a*P*<0.05 vs Group II; ^c*P*<0.05 vs Group I.

The serum TNF- α level increased significantly 3 h after the onset of pancreatitis in Group I ($3\,120 \pm 340$ vs 85 ± 15 U/L in Group II), and returned to the control level by 6 h (Figure 2). There was no significant serum TNF- α level elevation in the octreotide treated group.

Figure 2 Effects of octreotide on serum TNF- α levels in rabbits with NaTc-induced acute pancreatitis. Group I: ●; Group II as control: ▲; Group III treated with octreotide: ■. ^a*P*<0.05 vs Group II; ^c*P*<0.05 vs Group I.

Table 1 Effects of octreotide on pancreatic level of MDA and endogenous scavengers in rabbits with NaTc-induced acute pancreatitis

	Control	NaTc	NaTc+octreotide
MDA (nmol/mg protein)	2.24±0.51	7.52±1.05 ^a	4.14±0.86 ^{a,c}
GSH (nmol/mg protein ×10 ⁻²)	2.76±0.45	1.68±0.24 ^a	2.23±0.48 ^{a,c}
GPx (U/mg protein ×10 ⁻²)	1.18±0.34	0.53±0.08 ^a	0.82±0.16 ^{a,c}
Catalase (U/mg protein × 10 ⁻⁴)	3.08±0.54	2.79±0.41 ^a	3.16±0.14 ^{a,c}
Mn-SOD (U/mg protein)	1.03±0.22	0.43±0.08 ^a	0.53±0.08 ^a
Zn-,Cu-SOD (U/mg protein)	4.96±0.76	3.34±0.56 ^a	4.12±0.84 ^{a,c}

^a*P*<0.05 vs control group; ^c*P*<0.05 vs NaTc treated group.

Table 2 Effects of octreotide on histologic score in rabbits with NaTc-induced acute pancreatitis

Group	Vacuolization	Edema	Necrosis	Inflammation	Congestion
Control	0	0	0	0	0
NaTc	1.12±0.16	2.00±0.35	2.37±0.42	3.15±0.48	1.57±0.33
NaTc+ somatostatin	1.57±0.45	2.14±0.32	2.43±0.58	3.05±0.36	1.50±0.25

The serum IL-6 level increased significantly 3 h after the onset of pancreatitis in Group I (690±88 vs 25±15 U/L in Group II), and returned to the control level by 24 h (Figure 3). Octreotide pretreatment attenuated the increase in IL-6 level throughout the study.

**Figure 3** Effects of octreotide on serum IL-6 levels in rabbits with NaTc-induced acute pancreatitis. Group I: ●; Group II as control: ▲; Group III treated with octreotide: ■. ^a*P*<0.05 vs Group II; ^c*P*<0.05 vs Group I.

The tissue concentration of MDA was elevated significantly at 24 h as compared to the control. Octreotide pretreatment prevented the increase in MDA level. The GSH level and the activities of endogenous scavengers (GPx, catalase, Mn-SOD and Cu-, Zn-SOD) were all decreased significantly in pancreatitis animals in comparison with the control. Octreotide treatment significantly reversed the decrease of GPx, catalase and Cu-, Zn-SOD, but not Mn-SOD activity in comparison with Group I (Table 1).

Histological examination revealed acinar cell necrosis, hemorrhage, inflammatory cell infiltration and edema. Octreotide pretreatment did not exert any beneficial effect on the histological score (Table 2).

DISCUSSION

The results of our study can be summarized as follows. In our model, a short-lasting infusion of taurocholic acid in the pancreatic duct of rabbits produced a rapidly evolving necrotizing pancreatitis with mortality, as described earlier^[20]. Proinflammatory cytokines were generated early in NaTc-induced acute pancreatitis. Tissue imbalance of the offense

system represented by MDA and the defense system represented by GSH, SOD, GPx and catalase was observed. Prophylactic octreotide treatment prevented the release of cytokines, the increase in MDA and the decrease in GSH, SOD, GPx and catalase activities, but did not reduce the serum amylase level, and did not have beneficial effects on the development of histopathological changes.

Oxygen-derived free radicals have been reported to play an important role in the pathogenesis of acute pancreatitis^[31,32]. In the present study, oxidative stress was assessed by measuring the MDA, a product of lipid peroxidation, the intracellular antioxidant GSH, and the endogenous scavengers SOD, GPx and catalase in pancreatic tissues, in order to elucidate the participation of free radicals in the process of NaTc-induced pancreatitis in rabbits. In agreement with previous studies made in other animals^[31,32], this study revealed that the elevation of MDA as an offense system, and lowered GSH, SOD, GPx and catalase activities as a defense system, might be one cause of pancreatic injury induced by NaTc in rabbits.

Published data suggest that activated pancreatic macrophages can release proinflammatory cytokines in response to local tissue damages. These cytokines may act locally to aggravate acute pancreatitis, and both locally and systemically to increase the capillary permeability and to promote leukocyte adherence and extravasation^[33, 34]. TNF- α , a major proinflammatory cytokine, is considered to be important in orchestrating the early events in the inflammatory cascade and contributes to the induction of systemic inflammatory response syndrome (SIRS) which is responsible for multiple organ failure in severe acute pancreatitis. IL-6 is the most potent inducer of acute-phase protein synthesis in the liver, and it has been shown that its level reflects the severity of acute pancreatitis^[35]. This study confirmed the observations of others in rabbits that TNF- α and IL-6 were released in the early phase of NaTc-induced pancreatitis.

There is a growing evidence that somatostatin could inhibit the production of different cytokines, especially TNF- α and IL-6^[36-38] and reduce the local generation of free radicals^[39]. Nuclear factor- κ B (NF- κ B) plays a pivotal role in inducing the expression of multiple genes involved in immune and inflammatory responses, such as cytokines. NF- κ B transcription pathway has been found to be activated by reactive oxygen species^[39]. Therefore, somatostatin may also reduce indirectly the production of cytokines by inhibiting the generation of reactive oxygen metabolites. Furthermore, somatostatin could exert a direct cyto- and organoprotective

action in several models of toxic organ injury and stimulate on the reticulo-endothelial system^[40-43].

In our study, octreotide completely reversed the pancreatitis-induced changes in cytokines, MDA, GSH, SOD, GPx and catalase activities. However, we were unable to detect a significant improvement both in the serum amylase level and in the histologic score in octreotide-treated group. This could be explained by severe chemical and mechanical destruction of the pancreatic gland induced by taurocholic acid. The severity of this local injury exceeded the pancreatic damage induced by inflammatory mediators. Overproduction of cytokines can lead to the development of SIRS, which is responsible for the mortality of the disease. However, reduction of cytokine production in octreotide-treated group did not result in a significant decrease in the morbidity or mortality. This suggests that liberation of other vasoactive and toxic mediators [e.g. phospholipase A2, platelet activating factor, nitric oxide, leukotrienes *etc*] by the necrotizing process plays an essential role in the development of SIRS. Therefore, blockade of one particular part of this complex inflammatory process is not beneficial.

Octreotide has been suggested for the treatment of acute pancreatitis on the basis of its inhibitory effect on pancreaticobiliary secretion. However, a number of experimental studies have demonstrated that pancreatic enzyme secretion is almost abolished after induction of acute pancreatitis^[44-46]. Therefore, the use of drugs inhibiting exocrine pancreatic secretion does not have a beneficial effect on the progression and outcome of the disease. In contrast, the basal pancreatic fluid secretion was greatly increased during the early stages of acute experimental pancreatitis^[45, 46]. This fluid hypersecretion was resistant to cholecystokinin, secretin and cholinergic antagonists, and was probably caused by acinar cell proliferation^[46]. Fluid hypersecretion can wash out inflammatory mediators and activated pancreatic enzymes from the pancreas, thereby serving as a natural host protective mechanism after a pancreatic injury. Accordingly, it seems unnecessary to attempt to suppress the basal pancreatic enzyme secretion further since it is already blocked. If the fluid hypersecretion is interrupted after the onset of acute pancreatitis, this might exacerbate the inflammatory process.

Furthermore, somatostatin could reduce splanchnic blood flow and the impairment of pancreatic microcirculation could lead to further deterioration in acute pancreatitis^[47, 48].

Octreotide might worsen acute pancreatitis and even cause the disease by increasing the contractility of the sphincter of Oddi^[18,19]. The most commonly used animals to study the effects of octreotide in acute pancreatitis were rats, whereas rabbits have never been used. However, rabbits seem to be the excellent animals for this research. Since the pancreatic duct enters the duodenum at its distal part, and is completely separated from the common bile duct, we may avoid the harmful effect of octreotide on the sphincter of Oddi. However, we can not exclude the effect of octreotide on pancreatic sphincter.

In conclusion, proinflammatory cytokines are generated early in NaTc-induced acute pancreatitis in rabbits. Tissue imbalance of the offense system represented by MDA and the defense system represented by GSH, SOD, GPx and catalase was detected in the pancreas. Prophylactic octreotide treatment can prevent the release of cytokines, the increase in MDA and the decrease in GSH, SOD, GPx and catalase activities, but does not have any beneficial effects on the development of necrotizing pancreatitis. The pancreatic duct injection model in rabbit is a useful model to exclude the effect of sphincter of Oddi on the course of acute pancreatitis.

Abstract

AIM: To investigate the changes of gut microflora and endotoxin levels in rats with acute liver failure (ALF) induced by D-galactosamine (GalN).

METHODS: Flora and endotoxin levels in the jejunum, ileum and colon in normal rats (group A) and rats with GalN-induced ALF were determined at 24 h (group B) or 48 h (group C) after GalN injection, as well as the endotoxin level in portal venous blood (PVB) and right ventricle blood (RVB) were determined by chromogenic limulus amoebocyte assay.

RESULTS: Intestinal (jejunum, ileum, colon) *Lactobacillus* count was statistically reduced in group B compared with those in group A (3.4 ± 0.3 vs 4.9 ± 0.3 , 6.1 ± 0.4 vs 8.0 ± 0.3 , 8.1 ± 0.2 vs 9.3 ± 0.2 , $P < 0.001$, $P < 0.001$ and $P < 0.001$ respectively) and recovered partially in the group C compared with those in the group B, whereas the count of *Enterobacteriaceae* in the jejunum, ileum and colon in group B was increased markedly compared with those in the group A (5.1 ± 0.3 vs 3.6 ± 0.2 , 6.9 ± 0.5 vs 5.3 ± 0.3 , 8.7 ± 0.2 vs 7.6 ± 0.1 , $P < 0.001$, $P < 0.05$ and $P < 0.05$ respectively) and restored partially in the group C compared with those in the group B. The endotoxin level in ileum was increased in the group B compared with those in the group A (111.3 ± 22.8 vs 51.5 ± 8.9 , $P < 0.05$). In addition, the endotoxin level in PVB was obviously increased in group B compared with that in the group A (76.8 ± 9.1 vs 40.6 ± 7.3 , $P < 0.01$) and reduced to the baseline at 48 h (group C).

CONCLUSION: Severely disturbed gut flora in rats with GalN-induced acute liver failure plays an important role in the elevation of endotoxin level in PVB.

INTRODUCTION

Patients with acute liver failure are prone to occurrence of

endotoxemia^[1], which is usually associated with Gram-negative infection. However, previous studies have showed that some patients with acute liver failure have a high level of endotoxin without clinical evidences of Gram-negative bacterial infection^[1,2]. Recent studies have proposed that the elevation of plasma endotoxin is related to the translocation of endotoxin from the gut^[3,4].

Gut contains numerous endotoxin, about 90% of which is released by aerobic Gram-negative bacteria, especially the family of enterobacteriaceae^[5]. Normally, intestinal anaerobic flora such as *Bifidobacterium* and *Bacteriodes* can prevent the adherence of potential pathogenic enteric bacilli and limit bacterial overgrowth by occupying the space closest to intestinal epithelial cells^[6], which is called microbial colonization resistance^[7]. Disrupted gut flora observed in severely disease, such as hepatic cirrhosis and hemorrhagic shock, resulted in decrease of microbial colonization resistance and subsequent bacterial overgrowth^[8,9]. Wang *et al.*^[10] showed the *Escherichia coli* overgrowth in the distal small intestine from 1 h onward after hepatectomy. Researchers suggested that impaired components of the gut barrier, including normal intestinal microflora, could translocate both endotoxin and bacteria from lumen to circulation or other distant organs^[6]. Moreover, manipulating gut contents with lactulose or neomycin sulfate with cefazolin could reduce the level of endotoxemia and enhance the survival of rat receiving partial hepatectomy^[11]. But to the author's knowledge, the relationship between the changes of gut flora and the fluctuations of the endotoxin levels both in intestine and plasma in rats with GalN-induced acute liver failure has not been reported. In the present study, the changes of gut flora and endotoxin level in the jejunum, ileum and colon, as well as the levels of endotoxin in PVB and RVB of rats with GalN-induced ALF were estimated at various time points.

MATERIALS AND METHODS

Animals and treatment

Male Sprague-Dawley rats weighing about 200-300 g provided by Zhejiang Academy of Medical Sciences, Hangzhou, China, were acclimated to the animal laboratory for 5 d before experiments. They were fed with standard rat chow and water *ad libitum*. All procedures were approved by the Institutional Review Board according to the Animal Protection Act of China.

Acute liver failure in the rats was induced according to the protocol described previously^[12]. Briefly, GalN (Chongqing Medical University, Chongqing, China) was dissolved in 0.5 mL of saline and adjusted to pH 6.8 with 1 mol/L NaOH. Then, 20 rats were intraperitoneally given 1.4 g/kg GalN twice at a 12-h interval, and fed with food and water after injection. Since the highest mortality of GalN-induced acute liver failure in rat is between 24 h and 48 h after drug administration^[12], and we ensure that the number of survival rat is more than 9^[13] at various time points after GalN administration, 40 rats were randomly divided into 3 groups according to the reported mortality^[12]: group A with 10 rats without administration of GalN was chosen as normal control, group B with 12 rats that were sacrificed 24 h after GalN injection and group C with 18 rats that were killed at

48 h after injection. Under light ether anesthesia and aseptic conditions, plasma was separated from the portal vein and right ventricle at various time points after laparotomy, then stored immediately at -80°C for analysis of endotoxin. The rats were killed by anaesthetic overdose after blood sampling, the segments of the jejunum, ileum and colon were removed as described by Wang *et al*^[10]. Briefly, the segments of the jejunum (5 cm in length, including intestinal wall) and ileum including intestinal wall 5 cm long as well as colon contents were immediately collected from the proximal intestine (5 cm distal of the ligament of Treitz), distal small intestine (5 cm proximal to the ileocecal valve), and descending colon, respectively. After weighting, the samples were placed in pyrogen-free saline (1:9 w/v) in an anaerobic chamber (Forma Scientific Co, USA), mixed by a vortex mixer, and aliquots of 1 mL of mixture were subsequently put into anaerobic solution A (1:9 v/v, decimal dilutions up to 10^{-8}). The remnant was kept at -80°C for detecting endotoxin.

Gut flora analysis

The specimens were cultured within 30 min after collection by modified Mitsunaka's method^[14]. A total volume of 50 μL of the serial dilution (10^{-1} , 10^{-3} , 10^{-5} , 10^{-6} , 10^{-7} , 10^{-8}) was spread on 3 non-selective agar media: glucose blood liver (BL) (Nissui Pharmacy Co., Tokyo, Japan) agar with 60 mL/L defibrinated sheep blood for all lactic acid-producing bacteria; Eggerth Gagnon (EG) (Nissui Pharmacy Co.) agar with 60 mL/L defibrinated sheep blood for most obligate and facultative anaerobes; and trypticase soy (TS) agar (BioMerieux, Paris, France) with 60 mL/L defibrinated sheep blood for all aerobes and facultative anaerobes, and 4 selective agar media: neomycin sulfate-brilliant green-taurocholate-blood (NBGT) agar prepared with EG agar at our laboratory for members of the family *Bacteroidaceae*; MRS with vancomycin and bromocresol green (LAMVAB) medium^[15] for *Lactobacillus* sp.; eosin methylene blue (EMB) agar (Hangzhou microbiological Co., Hangzhou, China) for members of the family of *Enterobacteriaceae*; and *Enterococcus* (Ec) agar prepared at our laboratory for *Enterococcus* sp. The plates for the recovery of obligate anaerobes were incubated in an anaerobic chamber ($\text{N}_2:\text{CO}_2:\text{H}_2=8:1:1$) at 37°C for 48-72 h. The media used for the isolation of aerobes and facultative species were incubated in air for 48 h at 37°C . After incubation, morphologically distinct colonies were enumerated, isolated and identified. Identification was performed in most cases at family or genus levels using standard bacteriologic techniques^[16]. In our study, the lowest detection limit was 2×10^2 organisms per gram of the samples. The results were expressed as the \log_{10} of the number of bacteria per gram weight of the samples.

Chromogenic limulus amoebocyte assay for detecting endotoxin

Intestinal specimens were prepared for endotoxin detection according to the described method^[5]. The frozen specimens were thawed at room temperature. Limulus quantitative azo color (LQAC) test^[17] with limulus lysate reagent (Eihua Medical Co, Shanghai, China) was used.

Statistical analysis

Data were expressed as the mean \pm SE. One-way ANOVA was used to compare gut flora data among individual groups. Frequency data were compared using Chi-square test or the Fisher's exact test when necessary. $P < 0.05$ was considered statistically significant.

RESULTS

Degree of hepatic injury and mortality

To study the alterations in intestinal microflora and its relationship with plasma endotoxin, ALF model of rat was successfully established by GalN administration as mentioned

previously^[12]. The concentrations of alanine aminotransferase (ALT), aspartate aminotransferase (AST) and total bile acid (TBA) were increased significantly at 24 h and gradually decreased at 48 h, whereas those of alkaline phosphatase (AKP) and total bilirubin (TbIL) were increased continuously after GalN injection (Table 1). At the same time, the levels of serum total protein (TP) and albumin at 24 h after GalN administration were lowered markedly compared with those in control group ($P < 0.01$, respectively) (Table 1), and increased at 48 h without significance compared with those at 24 h. The mortality rate of group C was higher than group B ($P < 0.01$) (Table 1). The general conditions, such as activity and appetite, in survivors were restored partially after 48 h.

Table 1 Degree of hepatic injury and mortality in ALF rats at various time points after injection of GalN

	Group A (n=10)	Group B (n=11)	Group C (n=10)
TP (g/L)	62.6 \pm 1.3	48.9 \pm 1.2 ^d	51.0 \pm 3.1 ^d

Colon	6.8 \pm 0.2	5.8 \pm 0.4 ^c	6.7 \pm 0.3

Data are expressed as mean \pm SE. ND: Not detected; ^a $P < 0.05$, ^b $P < 0.01$ vs group B, ^c $P < 0.05$, ^d $P < 0.01$, ^f $P < 0.001$ vs group A.

Intestinal microflora analysis

To explore the variability in intestinal flora under ALF condition, we analyzed the microbiota from different intestinal segments including jejunum, ileum and colon of the rats at different time points. The count of *Enterobacteriaceae* in the jejunum, ileum and colon was significantly higher in the group A than that in control group ($P < 0.001$, $P < 0.05$, and $P < 0.05$, respectively), whereas the count of *Lactobacillus* in the jejunum, ileum and colon, and that of *Enterococcus* in colon were greatly decreased

($P<0.01$, $P<0.001$, $P<0.001$, and $P<0.05$, respectively) (Table 2). The count of *Enterobacteriaceae* in the jejunum and colon was lower in the group C than in the group B ($P<0.01$ and $P<0.05$, respectively), but the count of *Lactobacillus* in the jejunum in the group C was significantly elevated ($P<0.05$) (Table 2). The count of *Lactobacillus* in the ileum and colon in the group C was decreased more evidently than that in the group A ($P<0.001$ and $P<0.01$, respectively). These results indicated that the disturbed gut flora existed in rat with ALF, and the extent of changes in flora was correlated with the severity of liver injury.

Changes of endotoxin in intestine, portal venous and right ventricle blood

Gut endotoxin is usually translocated into the portal vein. To determine the relations of the levels of endotoxin in blood and in gut in rats with ALF, we measured the endotoxin levels of the intestine, PVB and RVB at various time points after GalN by LQAC test (Table 3). The levels of endotoxin in the ileum and PVB in group B after administration of GalN were increased more significantly than those in the group A ($P<0.05$ and $P<0.01$, respectively). At the same time, the level of endotoxin in the colon was increased, but not significantly. The levels of endotoxin in the ileum and colon in the group C were increased more significantly than those in the group B, and higher than those in the group A ($P<0.01$, respectively). The level of endotoxin in PVB in the group C was decreased significantly compared with those in the group B ($P<0.05$). Although there was an increase of endotoxin level in RVB after GalN, no statistically significant difference was observed.

Table 3 Levels of endotoxin in intestine, PVB and RVB in rats with ALF at different time points after injection of GalN

	Group A (n=10)	Group B (n=11)	Group C (n=10)
Jejunum (ng/g)	67.8±13.0	56.7±18.6	88.1±15.2
Ileum (ng/g)	51.5±8.9	111.3±22.8 ^a	146.7±27.0 ^b

Data are expressed as mean±SE. ^a $P<0.05$, ^b $P<0.01$ vs group A; ^c $P<0.05$ vs group B. PVB: Portal venous blood; RVB: Right ventricle blood.

DISCUSSION

The present study showed that the count of *Enterobacteriaceae* at 24 h after injection of GalN was significantly increased, whereas that of *Lactobacillus* was markedly lowered. The whole intestinal microflora trended to recover at 48 h after GalN administration. These results indicated that there were intestinal microbial disturbance and overgrowth of *Enterobacteriaceae* in the rats with ALF. The tendency of changes in flora from the jejunum and ileum was consistent with that from the colon, and the extent of imbalance of intestinal microflora was correlated with the severity of liver injury. The alterations of intestinal bacterial flora might be due to the diminished bile secretion and the impaired intestinal motility, which were usually observed in rats with acute liver failure^[18]. But the exact mechanisms need further study.

The level of endotoxin in the portal vein reflects the extent of translocation of endotoxin from gut^[19]. Our findings showed that the levels of endotoxin in the ileum and colon increased continuously after administration of GalN, and the level of endotoxin in the portal vein was significantly elevated at 24 h, but lowered to the baseline value at 48 h. Interestingly, the elevation of the endotoxin in PVB was accompanied by the imbalance of intestinal flora and the overgrowth of

Enterobacteriaceae, whereas a decrease of the level of endotoxin in PVB was paralleled with the partial restoration of disturbed flora. The present findings showed that an increase of endotoxin in PVB was closely related to the imbalance of intestinal flora in rats with ALF, and implied that ecological imbalance and bacterial overgrowth in ALF rats might play important roles in dysfunction of gut barrier, which could lead to translocation of endotoxin from gut. Our findings are supported by the previous study^[20] that gut bacterial overgrowth is one of the etiological factors of bacteria and endotoxin translocation from gut. Moreover, it has been reported that an increase in gut permeability is related to histamine released by intestinal mast cell in rat with GalN-induced acute liver injury^[21]. In addition, effect of bacterial proteases on microvillus membrane proteins contributes to the breakdown of the intestinal barrier^[22]. Another reason that should be considered is that edema of intestinal wall resulting from digestive congestion and hypoproteinemia in ALF can injure the function of gut barrier^[23]. In the present study, the levels of endotoxin in intestine increased continuously after GalN administration; this might be associated with the *Enterobacteriaceae* overgrowth^[5]. Nevertheless, our findings indicated that enlargement of gut endotoxin pool had no impact on endotoxin translocation. In addition, the present data suggested that restoration of the disturbed gut flora might play an important role in inhibiting the endotoxin translocation from gut.

The present data showed there was no significant change of the concentrations of endotoxin in RVB after GalN administration, which was in agreement with Nakao *et al.*^[24]. In contrast, the results by van Leeuwen *et al.*^[11] showed that arterial plasma endotoxin levels increased in rats with hepatic failure induced by two-third partial hepatectomy. The discrepancy between two types of ALF seemed that the count of Kupffer cell in the latter reduced significantly because of hepatectomy. Plasma endotoxin is removed primarily by the Kupffer cells. Then, GalN exerted a minor effect on the function of kupffer cells, because the nucleotide contents of Kupffer cells were smaller than that those of hepatocytes^[25]. Logically, Kupffer cells in rats after GalN administration can phagocytose the gut-derived endotoxin.

At present, we could not measure the pretreatment effect of probiotics on endotoxin translocation for lack of *Lactobacillus* preparation suitable for rats. However, it was demonstrated that administration of the probiotics *Lactobacillus plantarum* could reduce the circulating antibody to endotoxin in patients with ulcerative colitis^[26]. Adawi *et al.*^[27] showed that administration of *Lactobacillus* could reduce bacterial translocation and hepatocellular damage in rats with acute liver injury. Moreover, our previous work demonstrated that administration of probiotics *Bifidobacterium* (DM8504) could decrease significantly the levels of plasma endotoxin in patients with chronic hepatitis B^[28].

In conclusion, severely disturbed intestinal flora disorders are observed in rats with GalN-induced acute liver failure, and related to the extent of injury of liver. Ecological imbalance of intestinal flora is one of the main causes of the translocation of endotoxin from lumen. Additionally, the present study implies that modulation of the intestinal flora using probiotics may be the optional treatment in preventing gut endotoxin translocation in patients with ALF.

ACKNOWLEDGEMENTS

We thank Dr. MH Wang (University of Colorado School of Medicine, USA) for revision the manuscript.

Abstract

AIM: To investigate the cytotoxic activity of extracts of trichosanthes root tubers (EOT) on HepA-H cells and HeLa cells compared with trichosanthin (TCS), and to explore the possible mechanism of growth inhibitory effect of EOT on HeLa cells.

METHODS: Tumor cells were cultured *in vitro*, and then microculture tetrzoalium assay (MTT) was used to investigate drugs' cytotoxic activity. Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) were used to observe ultrastructural changes of cells, and electrophoresis was performed to detect changes of biochemical characteristics of intercellular DNA.

RESULTS: TCS and EOT had no obvious effects on HepA-H cells ($P>0.05$), but had remarkable effects on HeLa cells in a time and dose dependent manner ($r>0.864$, $P<0.05$ or $P<0.01$). The inhibitory rate of EOT was much higher than that of TCS ($P<0.01$). Median inhibitory rates (IC₅₀) of TCS and EOT on HeLa cells were 610.9 mg/L and 115.6 mg/L for 36 h, and 130.7 mg/L and 33.4 mg/L for 48 h respectively. Marked morphologic changes were observed including microvillus disappearance or reduction, cell membrane bleeding, cell shrinkage, condensation of chromosomes and apoptotic bodies with complete membranes. Meanwhile, apoptosis of HeLa cells was confirmed by DNA ladder formation on gel electrophoresis.

CONCLUSION: TCS and EOT have no obvious effects on HepA-H cells, but have significant inhibitory effects on HeLa cells, indicating that EOT is superior to TCS in anti-tumor activity.

INTRODUCTION

Trichosanthes Kirilowii Maximowii is a kind of liana of the Cucurbitaceae family, whose root tuber was a Chinese herbal medicine Tianhuafen (THF) that has been used to reset menstruation and expel retained placenta^[1]. In the 1980 s,

Trichosanthin (TCS) was isolated from the root tuber and proved to be the active component, a type I ribosome-inactivating protein (RIP) with 247 amino acids which inactivates eukaryotic ribosomes *via* its N-glycosidase activity. TCS has been used to induce mid-term abortion and to treat ectopic pregnancies, hydatidiform and trophoblastic moles in China^[2]. In recent years, TCS has also been found to possess various pharmacological properties including immunomodulatory, anti-tumor and anti-HIV activities^[3-6]. Clinical trials have also been performed. TCS has aroused extensive attention.

In the present study, we were interested in its anti-tumor activity *in vitro*. TCS has already been regarded as an effective anti-tumor agent highly specific to choriocarcinoma cells from trophoblasts^[7]. However, researches and clinical application about TCS on tumor are mainly on gastrointestinal tumor and seldom on others^[8]. TCS is an active anti-tumor component of *Trichosanthes*, yet there is no report of extracts of trichosanthes root tubers (EOT) on tumor cells. So in this study, we chose two tumor cell lines, HepA-H cells and HeLa cells, to investigate the growth inhibitory effect of EOT and TCS on the two cell lines and further compared their anti-tumor activity.

In recent years, screening of anti-tumor drugs from natural resource, especially from traditional Chinese medicines, has drawn worldwide research interest, and many exciting goals have been achieved^[9]. As a research focus of life science and medicine, apoptosis has revealed its promising future^[10-12]. Nowadays apoptosis has been considered as the most ideal path to conquer tumors. Therefore, in our study, we initially investigated the induction of apoptosis of HeLa cells by EOT. The present study may provide experimental bases for further researches and seeking novel anti-tumor agents.

MATERIALS AND METHODS

Drugs

TCS (1.2 mg/mL) was purchased from Jinshan Pharmacy Ltd, Shanghai. EOT was extracted from fresh root tubers of *Trichosanthes kirilowii* Maxim collected in Hangzhou^[13], Zhejiang Province in November 2002. SDS-PAGE (100 g/L) was performed to detect the components of EOT samples in comparison with TCS and protein marker. Gel was stained by Coomassie brilliant blue. After decolorized, the gel was visualized and photographed under gel imaging assay apparatus. Then straps in the gel were scanned to evaluate the content of relative proteins. Drugs were diluted with culture medium and sterilized before use.

Reagents and apparatus

RPMT-1640 and fetal calf serum (FCS) were from GIBCO, USA. 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), DMSO and all electrophoresis reagents were from Sigma Co., USA. Animal cell PCD ladder isolation kit was purchased from Dingguo Biological Products Ltd, Beijing. CO₂ incubator was the product of FORMA Company. TECNAI 10 TEM was from PHILIPS and STEREOSCAN 260 was from CAMBRIDGE Company. Electrophoresis apparatus was made by E-C Apparatus Corporation. Mini gel electrophoresis system was the product of Bio-Rad Company. Image analysis system was

purchased from Shanghai Tianneng Science and Technology Ltd.

Cell lines and cell culture

HepA-H and HeLa cells were preserved in our laboratory. The cell line of high lymphatic metastasis ascitic liver cancer was established and cultivated by professor Li and Yang^[14]. Cells were grown in RPMI-1640 culture medium containing 100 mL/L FCS, 100 U/mL penicillin and 100 U/mL streptomycin at 37 °C in a humidified atmosphere of 50 mL/L CO₂.

Cytotoxic activity

Growth inhibitory effects of HepA-H and HeLa cells with various treatments were determined by MTT assay. Cells at exponential phase were seeded into 96-well plates, 100 µL (1×10⁵/mL) per well. Then different concentrations of EOT and TCS in 100 µL culture medium were added and the final concentration in each well was 0.1 mg/L, 1 mg/L, 10 mg/L, 100 mg/L, and 500 mg/L respectively. Each treatment was tested in tetrad wells and the control group was given only culture medium containing no drug. All the above plates were placed in a 50 mL/L CO₂ humidified-atmosphere incubator at 37 °C for 24, 36 and 48 h. At the end of exposure, 20 µL MTT (5 g/L) was added to each well and the plates were incubated at 37 °C for 4 h. Then all culture medium supernatant was removed from wells and replaced with 100 µL DMSO. The plates were shaken for 15 min so that all the production of formazan reduced by MTT could be dissolved out from cells. Following thorough formation dissolved, the absorbance of each well was measured by standard enzyme-linked immunosorbent assay at 492 nm. The inhibition of tumor cell growth was calculated by the equation: Growth inhibitory rate=(1-A_{492 treated}/A_{492 control})×100%.

Based on the growth inhibitory rates of each group of drugs on cells, SPSS software was used to calculate 50% inhibitory concentrations (IC₅₀).

Specimens for electron microscope

HeLa cells at exponential phase were used and cultivated with various concentrations of EOT for 24 h. Then cells were harvested and fixed with 25 g/L glutaraldehyde in 0.1 mol/L phosphate buffer (pH 7.4) for 2 h at 4 °C. For TEM examination, the specimens were postfixed in 10 g/L osmium tetroxide in 0.1 mol/L phosphate buffer (pH 7.4) for 1 h at 4 °C. After dehydration in a graded series of ethanol and infiltration in propylene oxide, they were embedded in Epon 812. Fine sections were cut with an LKB 2088 ultramicrotome and stained with uranyl acetate and lead citrate. The sections were examined with a PHILIPS TECNAI 10 TEM at 60 kV. For SEM examination, the specimens were postfixed for 1 h in 10 g/L OsO₄, dehydrated in a graded series of alcohol, CO₂ critical-point dried, mounted on aluminum stubs and sputter-coated with gold. Specimens were examined with a STEREOSCAN 260 SEM at 25 kV.

Agarose gel electrophoresis of DNA

HeLa cells at exponential phase were exposed to different concentrations of EOT for 24, 36 and 48 h respectively. Then cells were harvested, washed twice with PBS, and DNA was extracted according to the directions of the kit. DNA was analyzed by electrophoresis at 75 mA on 8 g/L agarose gel containing 0.5 mg/L ethidium bromide. After about 1.5 h, the gel was visualized and photographed under transmission UV light.

Statistical analysis

Data were expressed as mean±SD. Statistics software package SPSS 11.5 was employed to process the data. Differences between groups were described by Student t test. *P* values less than 0.05 were considered statistically significant.

RESULTS

Protein electrophoresis of EOT and TCS

1 kg fresh trichosanthes root tubers was used in the present study and we got 0.83 g EOT. As the result of SDS-PAGE showed, sample EOT had an obvious major strap and several other minor straps. All the straps were scanned, sample EOT had a content of 70.93% of TCS and other unknown proteins. However, sample TCS had only a minor strap and its purity was 99.81%. Protein marker further conformed to protein TCS (Figure 1).

Figure 1 Analysis of EOT and TCS by SDS-PAGE. Lane 1: EOT, Lane 2: TCS, Lane 3: Protein Marker.

Cytotoxic activity of EOT and TCS in HepA-H and HeLa cells

After exposure to EOT and TCS, HepA-H cells had no growth arrest of significant importance. After 24 h, most growth of HepA-H cells was promoted, but the effect did not depend on the dose (*P*>0.05). After 36 h, all the cells were led to growth arrest, which also had no statistical relation with the dose. After 48 h, some were promoted, while the others were inhibited, and the relationship between the effect and dose was not found. All the three groups of data showed no statistical significance (*P*>0.05), suggesting HepA-H cells were not susceptible to EOT and TCS (Table 1).

Table 1 Cytotoxic activity of EOT and TCS in HepA-H cells (*n*=4, mean±SD)

Drug	Concentration (mg/L)	Inhibitory rate (%)		
		24 h	36 h	48 h
EOT	0.1	-3.1±2.9	19.1±2.6	15.7±0.8
	1.0	-3.6±8.1	7.9±11.5	5.1±2.6
	10	-25.0±1.7	6.8±0.1	3.8±3.6
	100	9.6±3.3	21.0±2.2	16.2±6.3
	500	7.6±7.6	17.0±3.0	13.4±0.7
TCS	0.1	-19.9±6.7	6.9±5.2	-3.7±4.9
	1.0	-6.1±6.4	4.7±0.6	7.4±2.7
	10	-16.1±19.1	0.7±2.4	-11.4±4.7
	100	-6.8±1.0	11.9±4.1	2.6±2.3
	500	-3.4±3.3	10.8±5.2	5.9±3.8

EOT and TCS had good effects on HeLa cells in a time and dose dependant manner (*r*>0.864). When the concentration of drugs was increased and the time was prolonged, the growth inhibitory rate increased gradually (*P*<0.01). EOT was superior to TCS in the effect on HeLa cells when the time and concentration were identical (*P*<0.01). The median inhibitory rates (IC₅₀) of TCS and EOT for HeLa cells were 610.9 mg/L and 115.6 mg/L after 36 h, and 130.7 mg/L and 33.4 mg/L after 48 h, respectively. The results suggested that EOT and TCS could inhibit the growth of HeLa cells, while EOT had much stronger cytotoxic activity (Table 2).

Table 2 Cytotoxic activity of EOT and TCS in HeLa cells ($n=4$, mean \pm SD)

Drug	Concentration (mg/L)	Inhibitory rate (%)		
		24 h	36 h	48 h
EOT	0.1	3.4 \pm 4.1	9.7 \pm 7.0	9.9 \pm 3.1
	1.0	4.5 \pm 3.7	11.1 \pm 2.0	11.3 \pm 1.9
	10	16.3 \pm 3.2	20.9 \pm 6.8	29.4 \pm 4.1
	100	36.7 \pm 4.0	44.2 \pm 1.7	54.6 \pm 3.0
	500	57.9 \pm 3.4	71.8 \pm 3.9	89.4 \pm 1.9
TCS	0.1	2.2 \pm 1.7	2.9 \pm 2.7	4.4 \pm 3.1
	1.0	2.9 \pm 2.0	5.5 \pm 1.2	6.0 \pm 2.7
	10	16.4 \pm 4.1	6.7 \pm 2.4	13.0 \pm 3.3
	100	26.3 \pm 2.5	29.3 \pm 3.9	47.9 \pm 5.2
	500	39.6 \pm 4.8	53.8 \pm 4.0	70.2 \pm 2.9

Morphological observation

After exposure to EOT for 24 h, HeLa cells were observed under SEM, typical apoptotic characteristics were found, including cell membrane blebbing, microvilli disappearance or reduction, and separated apoptotic bodies (Figure 2, A-B). Also treated HeLa cells were observed under TEM, and shrinkage of cells, condensation of chromosomes and apoptotic bodies with complete membrane were found (Figure 2, C-D).

**Figure 3** Analysis of DNA fragments of HeLa cells treated with EOT. M: DNA marker, lane 1: normal control, lane 2: 500 mg/L for 24 h, lane 3: 100 mg/L for 24 h, lane 4: 50 mg/L for 48 h, lane 5: 50 mg/L for 24 h, lane 6: 100 mg/L for 48 h, lane 7: 500 mg/L for 48 h.**DNA fragmentation**

After HeLa cells were exposed to EOT 50 mg/L, 100 mg/L, 500 mg/L respectively for 24 h, DNA agarose gel electrophoresis showed the typical “DNA ladder” pattern of apoptosis. With time delayed, 48 h later, DNA ladder was much more obvious in the cells treated with EOT 50 mg/L, 100 mg/L, but DNA of cells treated with high concentration, 500 mg/L, took on a shape of smear, suggesting that cells underwent secondary necrosis (Figure 3). Results of DNA agarose gel electrophoresis further confirmed that EOT could induce HeLa cell apoptosis.

DISCUSSION

To our knowledge, researches of the effects of TCS on liver cancer arrived different conclusions, while studies on HeLa cells were scarcely reported^[15,16]. In the present work, we investigated and analyzed the effect of EOT and TCS on HepA-H and HeLa cells. We found that TCS and EOT had no significant effect on HepA-H cells but had remarkable effect on HeLa cells in a time and dose dependant manner. The data suggested EOT had a much higher anti-tumor effect on HeLa cells than TCS. After 48 h, the growth inhibitory rate of HeLa cells exposed to EOT and TCS (500 mg/L) was 89.4% and 70.2%, respectively. The median inhibitory rates (IC₅₀) were 610.9 mg/L and 115.6 mg/L after 36 h, and 130.7 mg/L and 33.4 mg/L after 48 h, respectively. SDS-PAGE showed, EOT contains 70.93% TCS and several other components. In contrast, TCS had a higher purity almost to 100%. It is generally believed TCS, a type I RIP, is the active component. So the results make us consider why EOT has a better inhibitory effect on the growth of tumor cells than TCS. Whether the good anti-tumor activity of EOT is correlated with the cooperation of other proteins or any other factors. As was reported, cytotoxicity of TCS was dependent on its intracellular concentration, and variation of cytotoxicity in different cells might be related to the mechanisms affecting its internalization^[17]. So there might be some active factors in EOT that promote internalization of TCS. Of course, the actual mechanism needs further researches to clarify.

It has been reported that TCS has strong effects on cytotoxicity and induction of apoptosis of gastric cancer cells, human choriocarcinoma cells and leukemia cells^[8,18,19]. Also relative genes inducing apoptosis have been isolated with their mechanism elucidated^[20]. In this study, we investigated

**Figure 2** HeLa cells under SEM and TEM. A: HeLa cells under SEM in control group. B: HeLa cells under SEM treated with EOT (100 mg/L) for 24 h. C: HeLa cells under TEM in control group. D: HeLa cells under TEM treated with EOT (100 mg/L) for 24 h.

apoptosis of HeLa cells induced by EOT. Experiments on morphology and biochemistry revealed typical apoptotic characteristics, such as microvilli disappearance, cell membrane blebbing, apoptotic body and DNA ladder pattern. The results suggested that the anti-tumor effect of EOT on HeLa cells was related with the induction of apoptosis.

In conclusion, EOT has stronger anti-tumor effects and can induce apoptosis of HeLa cells. EOT would have a bright future in the treatment of tumors and further work may lead to relative anti-tumor agents to be used in clinic.

Abstract

AIM: To elucidate the role of COX-2 in the development of capillary leakage in rats with acute interstitial pancreatitis.

METHODS: Rats with acute interstitial pancreatitis were induced by caerulein subcutaneous injection. Reverse transcription-polymerase chain reaction (RT-PCR) was used to determine the gene expression of COX-2 in pancreatic tissues, spectrophotometry was used to assay the parameters of acute pancreatitis such as the serum amylase and plasma myeloperoxidase, and determination of capillary permeability in the pancreas by quantifying the permeability index (PI) assisted response of pancreatic microvascular via intravital fluorescence microscope video image analysis system.

RESULTS: A significant increase of COX-2 expression, elevation of serum amylase, and plasma myeloperoxidase were detected in rats with acute edematous pancreatitis compared with control rats. The changes of pancreatic microvascular after caerulein injection were as following: (a) the decrease of pancreatic capillary blood flow (4th h, 0.56 ± 0.09 nL/min, $P < 0.05$; 8th h, 0.34 ± 0.10 nL/min, $P < 0.001$); (b) reduction of functional capillary density (4th h, 381 ± 9 cm⁻¹, $P > 0.05$; 8th h, 277 ± 13 cm⁻¹, $P < 0.001$); (c) irregular and intermittent capillary perfusion was observed at the 8th h and these vessels were also prone to permeation.

CONCLUSION: COX-2 plays an important role in mediating capillary permeability in pancreatitis, thereby contributing to capillary leakage.

INTRODUCTION

Pancreatic microcirculatory disturbance has been considered as one of the possible and important causative factors for the

development of acute pancreatitis (AP)^[1-5], although the underlying mechanism is unclear. COX-2, known as prostaglandin endoperoxide synthase-2, is a rate-limiting enzyme in the production of prostaglandins and an important regulator of vascular function^[8,9]. Under resting conditions, the level of COX-2 was undetectable. COX-2 expression can be inducible by a wide range of extracellular and intracellular stimuli, including lipopolysaccharide, forskolin, interleukin-1 (IL-1), tumor necrosis factor (TNF), epidermal growth factor, interferon- γ , platelet activating factor and endothelin, suggesting that COX-2 plays a critical role in inflammatory disorder^[6,7]. Previous studies demonstrated that COX-2 was a classic example of immediate early or primary response gene activation and generally considered as a proinflammatory enzyme^[10-15], suggesting COX-2 may serve as one of triggering factors of inflammation. Studies showed that inducible cyclooxygenase (COX-2) might indirectly involve in the regulation of human vascular endothelial cells (HUVEC) inflammation^[16,17]. However, no further studies examined it. For the purpose of verification of the result, reverse transcription polymerase chain reaction (RT-PCR) and intravital fluorescence microscopy with fluorescein isothiocyanate (FITC) labeled erythrocytes were used to study COX-2 gene expression and pancreatic microvasculature, with the aim of consolidating the relevance between the gene expression of COX-2 and dysfunction of pancreatic local microvasculature during acute edematous pancreatitis (AEP).

MATERIALS AND METHODS

Animal

A total of 96 male Wistar rats (250-350 g) were starved 15 h prior to the experiments with water *ad libitum* and randomly divided into 2 groups: (1) AEP group ($n=72$), 24 rats for extraction of total RNA from pancreatic tissue and 3 mL blood samples of portal venous for assay of serum amylase (AMS) and plasma myeloperoxidase (MPO); 24 rats for studying pancreatic microvasculature by intravital fluorescence microscope with fluorescein FITC-RBC; 24 rats for accessing the pancreatic microvasculature permeability and water content. (2) Normal control group ($n=24$). The model of AEP was established by subcutaneous injection of caerulein (Sigma) as previously described^[1]. 1 h and 2 h after the beginning of experiment all experimental groups were injected caerulein 5.5 μ g/kg and 7.5 μ g/kg respectively, while control group received the same volume of 9 g/L sodium chloride.

Total RNA extraction from pancreatic tissue

After 2, 4, 8, 16 and 24 h of caerulein injection, the rats were anesthetized with intraperitoneal injection of 30 g/L barbitone sodium (35 mg/kg) and the sacrificed for extraction of total RNA. The isolation of total RNA was prepared from 100 mg pancreatic tissue, using Trizol reagent Kit (Gibco BRL). Yield and purity of RNA preparations were checked spectrophotometrically at 260 nm and 280 nm and quality was inspected visually on 13 g/L agarose gels after ethidium bromide staining.

Semi-quantitative RT-PCR analysis for COX-2 mRNA

RT-PCR was performed in combined one-tube reaction kits (Takara™) according to the manufacture's suggestions. β -actin was used as an internal control. The primers for control and COX-2 were as follows: β -actin (sense) 5'-GAT GGT GGG TAT GGG TCA GAA-3', (antisense) 5'-CTA GGA GCC AGG GCA GTA ATC-3'; COX-2 (sense) 5'-CTG TAT CCC GCC CTG CTG GT-3', (antisense) 5'-GAG GCA CTT GCG TTG ATG GT-3'. All the primers were synthesized by Life Technology (HongKong, China). RT-PCR was run in GeneAmp 9600 (Perkin-Elmer), following procedures: 50 °C for 30 min, 1 cycle; 94 °C for 2 min, 1 cycle; 94 °C for 30 s, 55 °C for 30 s, 72 °C for 40 s, 30 cycles; 72 °C for 10 min, 1 cycle. 5 μ L PCR products was placed onto 13 g/L agarose gels with ethidium bromide staining, using an ultraviolet illuminator, and the level of COX-2 mRNA was expressed as the quotient (Q) of the integrated optical density values (IOD) for the COX-2 and the β -actin bands ($Q = \text{IOD COX-2 band} / \beta\text{-actin band}$).

Assay of plasma myeloperoxidase (MPO)

The activity of MPO, an index of tissue leukocyte recruitment, is a marker of inflammation of tissue. The activity of MPO in the pancreatic tissues was determined following the method described by Calkins^[23] with minor modifications.

Response of pancreatic local microvessel

For studying response of pancreatic microvasculature we adopted erythrocytes (RBC) labeled by FITC using the approach as previously described. Briefly, washed RBC obtained from an experimental rat was incubated with PBS (137 mmol/L NaCl, 6.4 mmol/L Na_2HPO_4 , 2.7 mmol/L KCl, 1.5 mmol/L KH_2PO_4 , pH 7.8) solution containing 1 mg/mL FITC. The labeled cells were then washed twice with a saline solution containing 10 g/L bovine serum albumin (Sigma) to remove unconjugated fluorescent dye. The final volume percentage of the labeled cells was adjusted approximately to 50% by adding an isotonic saline solution, and an aliquot 91 mL/kg of these suspensions was injection through a tail vein of the rats to observe density and capillary perfusion by intravital fluorescence microscope (OLYMPUS X-70).

Assay for microvascular permeability

Half an hour before caerulein injection, the rats were given an intravenous injection of Evans blue (20 mg/kg) via a tail vein. Briefly, the lungs and pancreas were excised, weighted, and placed in 5 mL of formaldehyde solution and homogenized for 1 min. After incubated at room temperature for 16 h, the pancreas and lungs were measured at 650 nm in Beckman spectrophotometer. The concentration of Evans blue (EB) was determined by calculation against a standard curve. The blood was centrifuged at 600 r/min for 10 min and the concentration of EB in the serum was determined as described above. The permeability index (PI) = $[\text{Evans blue}]_{\text{tissue}} / [\text{Evans blue}]_{\text{serum}}$. Water mass fractions in the pancreas were used as a parameter of organ water accumulation after pancreatitis induction. The tissues were removed in a humidity chamber and the wet mass was measured immediately. The tissue was dried at 70 °C to a constant mass for the determination of dry mass. Organ edema was determined by calculating tissue water content according to the following formula: Water mass fraction (%) = $(1 - \text{dry mass} / \text{wet mass}) \times 100\%$.

Statistics analysis

All results were represented as mean \pm SD. The significance of changes were evaluated by means of a *F* test in comparisons of the same time point in two groups or by analysis of variance (Newman-Keuls) when different time points in the same group were compared. Differences were considered significant when the $P < 0.05$.

RESULTS

RT-PCR detection of COX-2 in the pancreas

COX-2 transcription remained at a low level in normal control (Figure 1). Whereas, after injection of caerulein, the expression of COX-2 mRNA in AEP was increased, with peaked at the 8th h, and kept at high level within 24 h. Setting the level of COX-2 expression at 2nd h as baseline, COX-2 expressions of the 4th h and 8th h in AEP were significant higher (2nd h, 0.23 ± 0.03 , $P < 0.05$; 4h, 1.55 ± 0.93 , 8th h, 4.04 ± 1.05 , 16th h, 3.73 ± 0.15 and 24th h, 3.37 ± 0.23 , $P < 0.01$ respectively). Compared with controls, this increase was also significant ($P < 0.01$).

Figure 1 Time course of COX-2 gene expression in pancreas. After induction by caerulein, the expression of COX-2 mRNA in AEP was increased, which peaked at the 8th h and remained at a high level.

Inflammatory indicators for pancreatitis

The activity of serum AMS and MPO in AEP and controls are shown in Table 1.

Table 1 Levels of amylase (AMS) and myeloperoxidase (MPO) in AEP and control groups (mean \pm SD)

Group	n	MPO (U/mL)	AMS (U/dL)
Control (0 h)	24	0.32 \pm 0.13	40 \pm 37
AEP 2nd h	6	0.60 \pm 0.20	313 \pm 130 ^a
4th h	6	0.74 \pm 0.39 ^b	391 \pm 96 ^a
8th h	6	0.85 \pm 0.56 ^b	255 \pm 92 ^a
16th h	6	0.88 \pm 0.29 ^b	291 \pm 73 ^a
F		4.542	12.322

^a $P < 0.05$, ^b $P < 0.01$ vs control.

In vivo fluorescent microscopy

Compared with the control, the pancreatic microvasculature changes at the 4th, 6th and 8th h after caerulein were as follows: (a) the reduction of the density and velocity of FITC-RBC (4, 6 and 8th h $P < 0.001$); (b) the decrease of the pancreatic capillary blood flow (4, 6, and 8th h, $P < 0.001$); (c) diminution of functional capillary density (4th h, $P > 0.05$; 6th h, $P < 0.05$; 8th h, $P < 0.001$) and arterioles diameter (4th h, $P > 0.05$; 6th h and 8th h, $P < 0.05$); (d) insufficient capillary perfusion appeared at the 8th h; (e) arterioles of pancreatic lobules and capillary density at the 6th h experienced significant changes, while the calibers of venules and capillaries shown no marked change (Table 2).

Microvascular permeability in pancreas and lungs

The PI from rats of control were shown little changes before and after injection of 0.9% sodium chloride, while both pancreas and lungs showed a significant increase in microvasculature from the 4th h to 16th h in rats of AEP and the increase in the lungs was higher than that in the pancreas (Lungs, 8th and 16th h, $P < 0.001$, respectively; pancreas 8th and 16th h, $P < 0.01$,

respectively) (Figure 2). The water mass fractions in the pancreas were increased after caerulein injection compared with controls (2ndh, 19.18±2.10; 4thh, 24.81±1.31; 8thh, 25.86±1.97; 16thh, 30.71±5.80, *P*<0.05), while the water mass fraction in normal remained relative stable.

Figure 2 Microvascular permeability index (PI) in the pancreas and lungs in AEP and control group. The figures indicate the increase of PI in the lungs is higher than that in the pancreas ^a*P*<0.05 vs control; ^b*P*<0.001 vs control; ^d*P*<0.01 vs control.

DISCUSSION

Previous studies have discovered that COX-2 is the principal isoform of cyclooxygenase that participates in inflammation, while there is little COX-2 activity present in the stomach, kidney, or platelet. COX-2 is usually barely detectable during normal physiologic conditions. However, in response to several pro-inflammatory stimuli, the level of COX-2 expression can be rapidly induced to increase^[18-20]. In our study, we found that COX-2 transcription remains at a very low level in normal pancreatic tissue. In contrast, COX-2 expression was increased rapidly after induction of pancreatitis by caerulein. COX-2 may serve as one of factors of at the early phase of inflammation. During the active inflammation, the synthesis of PGE₂ (an important inflammatory mediator), the increase of vaso-permeability, sequestration of inflammatory cells and pyrogen are likely resulted from COX-2.

It has been reported that a strong correlation between the number of intra-vascular neutrophils and MPO existed. Thus these parameters were measured to quantify the total neutrophil

sequestration to the pancreas^[21-23]. In our previous study, we found the positive correlation between COX-2 and MPO in AEP (*r*=0.5449, *P*<0.05). From this study, the elevation of plasma myeloperoxidase was present in the experiment, suggesting MPO can serve as an indicator of AEP.

There is increasing evidence that the vascular endothelium, which is directly exposed to various fluid mechanical forces generated by pulsatile blood flow, can discriminate among these stimuli and transduce them into genetic regulatory events, as COX-2 gene can be upregulated by steady laminar shear stress stimulation^[25]. However little is known about the upregulation of COX-2 disturbing microcirculation. It is generally accepted that the dysfunction of pancreatic microcirculatory serves as an important causative factor for the development of acute pancreatitis. The morphology of pancreatic microcirculation revealed that pancreatic lobule is supplied by a single intralobular arteriole, which is considered end-artery^[21,24-26]. This characteristic suggested that pancreatic lobules are susceptible to ischemic injury due to spasm of intralobular arterioles. In this study, we observed the responses of pancreatic microvascular after caerulein induction, which demonstrated that the enhanced COX-2 mRNA might involve in modulating the dynamical changes of the pancreatic microcirculation. The decrease of pancreatic capillary blood flow, the reduction of functional capillary density, and capillary perfusion irregular intermittent perfusion and capillary artery hypoperfusion were observed, especially at 8th h, which was coincident with the enhanced expression of COX-2 mRNA after AEP.

Based on the pathologic changes above, we postulate that COX-2 induce the inflammation of vascular endothelia, result in increase of vasopermeability, sequestration of leukocyte and water content in the pancreatic tissue. A functional role of the COX-2, mediating the changes of pancreatic microcirculation has several possible explanations: (1) it may be cooperated with inducible nitric oxide synthase (iNOS), and both mediators can activate platelets and leukocytes, promote the occurrence of microthrombus and affect microcirculatory stability^[27]; (2) it may be in linkage with the overexpression of adhesion molecules (e.g. ICAM-1, PCAM-1). Adhesion molecules are known to regulate partly the disturbance of microvascular barrier both *in vivo* and *in vitro*^[28,29]. Treatment with the monoclonal antibodies against ICAM-1, PECAM-1 to rats with gut barrier failure caused by intestinal ischemia and reperfusion (I/R) seemingly

most efficiently reduces the severity of I/R (i.e., enhanced capillary blood flow in the pancreas, reduced leukocyte rolling and stabilized capillary permeability)^[30,31]; (3) it may be feedback control of COX-2 expression through peroxisome proliferator-activated receptor- γ (PPAR- γ). PPAR- γ expressed in macrophages has been postulated as a negative regulator of inflammation^[9]. Additional investigation will be necessary to distinguish between these mechanisms of action.

Abstract

AIM: Acute hepatitis may seldom have a fulminant course. In the treatment of this medical emergency, potential liver support measure must provide immediate and sufficient assistance to the hepatic function. The goal of our study was to study the adequacy of hepatocyte transplantation (HCTx) in two different anatomical sites, splenic parenchyma and peritoneal cavity, in a rat model of reversible acute hepatitis induced by carbon tetrachloride (CCl₄).

METHODS: After CCl₄ intoxication, 84 male Wistar rats used as recipients were divided in to four experimental groups accordingly to their treatment: Group A (*n*=24): intrasplenic transplantation of 10x10⁶ isolated hepatocytes, Group B (*n*=24): intraperitoneal transplantation of 20x10⁶ isolated hepatocytes attached on plastic microcarriers, Group C (*n*=18): intrasplenic injection of 1 mL normal saline (sham-operated controls), Group D (*n*=18): intraperitoneal injection of 2.5 mL normal saline (sham-operated controls). Survival, liver function tests (LFT) and histology were studied in all four groups, on d 2, 5 and 10 post-HCTx.

RESULTS: The ten-day survival (and mean survival) in the 4 groups was 72.2% (8.1±3.1), 33.3% (5.4±3.4), 0% (3.1±1.3) and 33.3% (5.4±3.6) in groups A, B, C, D, respectively (*P*_{AB}<0.05, *P*_{AC}<0.05, *P*_{BD}=NS). In the final survivors, LFT (except alkaline phosphatase) and hepatic histology returned to normal, independently of their previous therapy. Viable hepatocytes were identified within splenic parenchyma (in group A on d 2) and both in the native liver and the fatty tissue of abdominal wall (in group B on d 5).

CONCLUSION: A significantly better survival of the intrasplenically transplanted animals has been demonstrated. Intraperitoneal hepatocytes failed to promptly engraft. A different timing between liver injury and intraperitoneal HCTx may give better results and merits further investigation.

INTRODUCTION

Acute hepatitis may seldom have a fulminant course. In the treatment of this medical emergency, potential liver support measure must provide immediate and sufficient assistance to the hepatic function. Hepatocyte transplantation (HCTx) is a mainly experimental and minimally invasive method for liver support, offering the opportunity for native liver regeneration in cases of reversible failure or serving as a “bridge” to whole liver transplantation in cases of irreversible damage. However, for the clinical implementation of this newly developed technique both theoretical and practical aspects have to be further elucidated.

Various anatomical sites for cell implantation such as native liver, spleen, peritoneal cavity, kidney, lung, pancreas and fat pads have been investigated by different teams since the introduction of the method, but their results are not conclusive due to the great methodological diversity^[1-7]. The spleen is considered as the most privileged anatomical site for HCTx. It is accessible by means of laparotomy. It can entrap a limited, but a sufficient number of hepatocytes within its sinusoids, providing conditions very similar to natural cell microenvironment. This process has been described by Mito in the early 1980's, by the term “splenic hepatization”^[8]. On the other hand, peritoneal cavity is very promising as it can be accessed by minimally invasive means and allows the injection of a greater number of cells. However, the major disadvantage of intraperitoneal route was the inability of injected cells to promptly engraft and thus to receive an adequate vascular supply. This led to cell death in three days following transplantation^[9]. To overcome this limitation, Demetriou *et al.* introduced the technique of cell attachment on collagen-coated dextran-microcarriers, prior to transplantation^[10]. Since then, most experimental studies have relied on this concept. Microcarrier-attached hepatocytes can survive for a long time, forming neovascularized aggregates^[11].

The aim of our study was to study the adequacy of HCTx in two different anatomical sites, splenic parenchyma and peritoneal cavity, in a rat model of reversible acute hepatitis induced by carbon tetrachloride (CCl₄).

MATERIALS AND METHODS

Donors

Hepatocyte isolation Fifteen male Wistar rats (Institute Pasteur-Athens), weighing 300-450 g were used as donors of hepatocytes. For cell isolation, we used collagenase perfusion/incubation technique, which was previously described by our team^[12]. Aliquots were taken for cell count (Neubauer hemocytometer) and determination of cellular viability (Trypan Blue Exclusion Test).

Recipients

Development of acute hepatitis model In preliminary experiments, we tested a wide range of CCl₄ doses (0.5-4 mL/kg) given intraperitoneally in 35 controls. Total bilirubin, SGOT,

SGPT and ALP levels were measured before and after CCl₄ administration and correlated with the histological severity of liver damage. A single dose of 1 mL/kg CCl₄, dissolved in olive oil in a ratio of 1:5 v/v, resulted in approximately 10% mortality of acute hepatic injury within 24 h. This dosage allowed liver support measures to be initiated before animal death and was used for all experiments reported herein.

Experimental groups

One hundred male Wistar rats (Institute Pasteur-Athens) weighing 300-450 g were used as candidate recipients. They were maintained in a 48-h dark/light cycle, had free access to food and water and were given CCl₄ at the above-mentioned dose (d 0). Twenty-four hours later (d 1), 84 survivors were divided into 4 groups accordingly to their subsequent therapy: Group A (*n*=24): intrasplenic transplantation of 10×10⁶ isolated hepatocytes, Group B (*n*=24): intraperitoneal transplantation of 20×10⁶ isolated hepatocytes attached on plastic microcarriers, Group C (*n*=18): intrasplenic injection of 1 mL normal saline (sham-operated controls), Group D (*n*=18): intraperitoneal injection of 2.5 mL normal saline (sham-operated controls).

Transplantation technique

All rats were transplanted under ketamine and midazolame anesthesia. For intrasplenic HCTx, cell suspension was diluted in 1 mL of Hank's solution and injected after laparotomy using a 27G needle. Leakage was prevented with suture at the point of injection. Prior to intraperitoneal HCTx, cells were attached onto gelatin-coated plastic beads (Sigma, 1.5 g/10 g of liver tissue) by incubation at 37 °C for 45 min. Cell suspension was diluted in 2.5 mL of Hank's solution and subsequently injected using an 18G needle.

Survival, liver function tests and histological study

Eighteen rats in groups A and B and nine rats in control groups C and D were observed for a 10-day period, in order to determine survival (survival rate and mean survival). Three animals from each group were sacrificed on d 2 and 5 respectively for biochemical and histological study. Final survivors were also sacrificed on day 10 for both biochemical and histological study. Sacrifice was achieved under general anesthesia according to the guidelines of the Hellenic National Research Council. Blood samples were taken directly from the left ventricle. Total bilirubin, SGPT, SGOT and alkaline phosphatase were measured in all groups. Liver, spleen and cell aggregates (when macroscopically visible) were taken for anatomical study. After fixation in buffered formaldehyde 40 g/L, they were stained with hematoxylin/eosin. The prepared sections were assessed systematically under code by one hepatopathologist, who was unaware of protocol features.

Determination of normal and baseline values

Normal and baseline values (24 h after CCl₄ administration) of liver function tests were measured in ten controls before and 24 h after CCl₄-intoxication.

Statistical analysis

For statistical analysis of mean survival and liver function tests we used Student's *t*-test. For statistical analysis of 10-day survival rate we used chi-square test. Statistical significance level was set at *P*<0.05.

RESULTS

Number and viability of isolated hepatocytes

A mean of approximately 250×10⁶ of liver cells was harvested from each donor, with a mean viability greater than 90%.

Survival rate

In all 4 groups, the 10-day survival rate was: 13/18 (72.2%), 6/18 (33.3%), 0/9 (0%) and 3/9 (33.3%) in groups A, B, C, D, respectively. Furthermore, the mean survival was 8.1±3.1 d, 5.4±3.4 d, 3.1±1.3 d and 5.4±3.6 d in groups A, B, C, D, respectively (Figures 1 and 2). Statistically significant difference between transplanted groups (A and B) and their respective controls (C and D) was proven only for the intrasplenic HCTx (*P*_{AC}<0.05, *P*_{BD}=NS). Differences in 10-day survival rate and mean survival between groups A and B were also statistically significant (*P*_{AB}<0.05). All animals with a decreased survival time died within six days after CCl₄ poisoning.

Figure 1 Mean survival in all four groups (*P*_{AC}<0.05, *P*_{BD}=NS, *P*_{AB}<0.05).

Figure 2 Survival curves in all four groups. Notice that all animal deaths occurred within the first 6 d after poisoning.

Table 1 Liver function tests during the 10-day observation period

		Day 2	Day 5	Day 10
Total Bilirubin (mg/dL)	A	0.53±0.05	0.33±0.05	0.35±0.10
	B	0.60±0.10	0.46±0.05	0.37±0.14
	C	0.86±0.10	0.76±0.10	¹
	D	0.86±0.15	0.66±0.15	0.20±0.10
SGPT (IU/L)	A	273±76.2	67.5±32.1	29.2±11
	B	400.3±155	61.6±27.7	54.8±25.0
	C	710±29.3	90.3±23.1	¹
	D	507.3±91.2	66±22.7	56.3±14.9
SGOT (IU/L)	A	380.6±63.4	68.3±24.1	84±13.3
	B	779.3±235.2	287.6±114	76.8±30.9
	C	1 088.3±131.7	610.6±148.6	¹
	D	836.6±171.2	250.6±139.6	112±63.2
Alkaline Phosphatase (IU/L)	A	469.3±157.5	427.6±129.5	343.1±180.5
	B	88.6±50	58.6±39	564.3±142.7
	C	123.6±50.5	116.3±37.4	¹
	D	104±31.1	129.3±41.7	792.3±246.5

All differences between final and baseline values were statistically significant. ¹All animals died before d 10. (Normal Values: Total Bilirubin: 0.18±0.07 mg/dL, SGPT: 44.1±24.8 IU/L, SGOT: 53.4±23.6 IU/L, Alk. Phosphatase: 86.8±49.6 IU/L -Baseline)

Value: Total Bilirubin: 0.6 ± 0.09 mg/dL, SGPT: 616.1 ± 117.5 IU/L, SGOT: 1296.7 ± 381.2 IU/L, Alk. Phosphatase: 91.4 ± 63 IU/L).

Laboratory findings

After CCl₄ administration the rats responded with a marked increase in both serum aminotransferases, a moderate elevation in total bilirubin, while alkaline phosphatase was not affected. Table 1 summarizes the mean total bilirubin, SGPT, SGOT and alkaline phosphatase values during the whole period of the experimental observation.

On d10, in all experimental groups total bilirubin and aminotransferase levels were significantly lower than their pre-transplantation levels. In contrast, all final survivors presented significantly higher levels of alkaline phosphatase, independently of their previous therapy.

Histological findings

Twenty-four hours following CCl₄ intoxication, liver submassive necrosis affecting zone 3 of the hepatic lobule was the main histological finding. The type of cell injury leading to necrosis was more often ballooning degeneration and apoptosis. Normal hepatic histology was present in all final survivors. Viable hepatocytes were found within splenic parenchyma by d 2, forming structures similar to liver plates (Figure 3). Microcarrier-cell aggregates were macroscopically detected by d 5, within the native liver and the fatty tissue of the abdominal wall. The histological study of implants revealed presence of viable hepatocytes and formation of neo-vessels in the surrounding tissues (Figure 4).

Figure 3 Viable hepatocytes within splenic parenchyma, forming structures similar to liver plates on d 2 (the so-called "splenic hepatisation").

Figure 4 Microcarrier-cell aggregates within native liver parenchyma. Formation of neo-vessels in surrounding tissue on d 5.

DISCUSSION

To the best of our knowledge, this is the first experimental study, investigating two of the most popular anatomical sites for HCTx, in a model of chemically induced acute hepatic

injury. In their original work, te Velde *et al.* compared and found equivalent intrasplenic and intraperitoneal HCTx, in a model of liver ischemia-induced failure^[13]. However, liver ischemia based on liver devascularization in rodents is a model that induces massive hepatic necrosis within a few hours, but in contrast to hepatic failure in humans, the damage is always irreversible. Thus, we have chosen to work on CCl₄-induced acute hepatitis model, although it did not strictly meet the criteria of acute liver failure, because the induced liver damage was potentially reversible, mostly resembling the clinical course of the syndrome in humans and consequently was considered more realistic^[14,15].

A significantly better survival of intrasplenically transplanted animals has been demonstrated, suggesting the superiority of the spleen as a site for cell implantation in this experimental model. Intraperitoneal hepatocytes failed to promptly engraft and provided a delayed and probably useless liver support, indicating that the right timing between induction of liver injury and HCTx seems to be of major importance. Actually, Demetriou *et al.* observed that when microcarrier-attached hepatocytes were transplanted 3 d prior to 90% hepatectomy in rats, they induced a marked improvement in long term survival, whereas when they were transplanted after hepatectomy they did not^[16].

Furthermore, the rats succeeding to survive until d 6, remained alive for the whole 10-day period and their liver function tests and histology returned almost to normal, independently of their previous therapy. These survival data and laboratory findings are highly suggestive of the presence of a "crucial period" (extending from d 0 to d 6 in this experimental model), during which liver support measures must be initiated. Reversal of hepatic damage seems to be due initially to the direct action of engrafted hepatocytes during this "crucial period" and subsequently to the host liver recovery, taking place in all survivors beyond this period, independently of their initial treatment. Actually, the significant increase in alkaline phosphatase levels, occurring after d 5, could more possibly be attributed to the native liver regeneration than to a late cholestasis^[17].

In conclusion, intrasplenic HCTx has been proved effective on providing liver support, after CCl₄-intoxication. In contrast, a certain inability of intraperitoneally transplanted hepatocytes for immediate engraftment and vascularization, even after attachment onto microcarriers was observed in this experimental model. A different timing between liver injury and HCTx might give better results and merits further investigation. Theoretically, the intraperitoneal route has many advantages, such as easy accessibility and great capacity for cells implantation. To our opinion research should be encouraged towards this direction. It seems highly possible that the recent advances in various fields, such as the development of new biomaterials and especially the introduction of humoral factors accelerating the process of neovascularization, may overcome the current limitations of the intraperitoneal HCTx^[18,19].

Abstract

AIM: To obtain the entire gene open reading frame (ORF) and to construct the expression vectors for recombinant allergen production.

METHODS: Gene fragments corresponding to the gene specific region and the cDNA ends of pollen allergens of short ragweed (Rg, *Ambrosia artemisiifolia* L.) were obtained by pan-degenerate primer-based PCR and rapid amplification of the cDNA ends (RACE), and the products were mixed to serve as the bridging PCR (BPCR) template. The full-length gene was then obtained. Partially overlapping primer-based PCR (POP-PCR) method was developed to overcome the other problem, i.e., the non-specific amplification of the ORF with routine long primers for expression insert decoration. Northern blot was conducted to confirm pollen sources of the gene. The full-length coding region was evaluated for its gene function by homologue search in GenBank database and Western blotting of the recombinant protein Amb a 8 (D106) expressed in *Escherichia coli* pET-44 system.

RESULTS: The full-length cDNA sequence of Amb a 8(D106) was obtained by using the above procedure and deduced to encode a 131 amino acid polypeptide. Multiple sequence alignment exhibited the gene *D106* sharing a homology as high as 54-89% and 79-89% to profilin from pollen and food sources, respectively. The expression vector of the allergen gene *D106* was successfully constructed by employing the combined method of BPCR and POP-PCR. Recombinant allergen rAmb a 8(D106) was then successfully generated. The allergenicity was hallmarked by immunoblotting with the allergic serum samples and its RNA source was confirmed by Northern blot.

CONCLUSION: The combined procedure of POP-PCR and BPCR is a powerful method for full-length allergen gene retrieval and expression insert decoration, which would be useful for recombinant allergen production and subsequent diagnosis and immunotherapy of pollen and food allergy.

INTRODUCTION

Atopic diseases such as asthma, rhinitis, eczema, pollen allergies and food allergies have been increasing in most industrialized countries of the world during the last 20 years^[1]. In the past years, we have improved our ability to recognize certain aspects of the pathogenesis of inflammatory bowel diseases, but our ability to effectively treat food and pollen allergy remains limited. The limitations for developing effective treatment regimens are due to some still unresolved and ambiguous aspects of the cross-reactivity of food and pollen allergy^[2]. Among the "cross-reactivity" food allergies, the so-called pollen-related food allergies are the most important. Patients with pollinosis have a high risk of developing a related food allergy, up to 70% of the patients are also allergic to fruits, vegetables or nuts^[3,4]. Short ragweed (Rg, *Ambrosia artemisiifolia* L.) is an important source of airborne allergens all over the world and has become an immunodominant allergen in China. Allergen-specific immunotherapy (SIT) represents one of the few curative approaches towards allergy^[5], for which a powerful method is to express the recombinant allergen proteins *in vitro*. Therefore, it is pivotal to obtain full-length allergen gene and to construct the expression vector. Generally, many full-length genes are acquired by prior acquisition of the specific fragments, and subsequently constructed in conception with computers by joining the amphi-end sequences obtained by rapid amplification of cDNA end (RACE)^[6]. In the process, a frequently occurred problem is the existence of alternatives in the amplification template. That is to say, though the length of amplified sequences is consistent with anticipation, the nucleotide compositions in different sequences are dramatically different and the existence of polymorphism is usually observed^[7-11]. Screening and detection of different clones obtained would account for the main expenditure of the prophase work of gene cloning. As for the expression vector construction, specific primers needed usually comprise two parts. One is the region for restriction recognition or the vector specific sequences for ligation-independent cloning (LIC), like newly developed pET-44 EK/LIC system. The other is the gene specific region for stringent polymerase chain reaction (PCR). The melting temperature (T_m) of such primers always goes beyond the ordinary limit of 72 °C, and the amplification specificity hence is reduced. It would be more disturbing when the GC content of the open reading frame (ORF) ends greatly deviates from 50%, which would usually occur in the 5' end of the ORF. To obviate the aforementioned problems, we have developed the *partially overlapping primer-PCR* (POP-PCR) method to surmount the non-specificity problem for long primers. This was then combined with bridging PCR (BPCR), which was coined for the PCR assay on joining two fragments containing a region of sequence similarity^[12,13], to conquer the difficulty in retrieving the full-length gene in cDNA pool that was originally used for gene fragments cloning. In the current study, we successfully constructed the expression vector and expressed the allergen protein from Rg pollens, and hallmarked the allergenicity on the purified fusion protein.

MATERIALS AND METHODS

Subjects

Eight selected sera of patients with a well-defined case history of Rg pollen allergy and specific IgE antibodies against Rg pollen allergen (higher than 3.5 kU_A/L) were taken in Allergy Clinics, Shenyang North Hospital, Shenyang, China and used in this study. Thirteen sera from non-allergic individuals were recruited from the First Affiliated Hospital of Medical College, Shantou University, Shantou, China and used as negative controls.

Preparation of PCR template

Pollens of Rg were harvested from Wuhan, one of the four pervasive areas of short ragweed in China, and immediately submerged in liquid nitrogen. Following powder-grinding, total RNA was extracted by using RNeasy Maxi kit (Qiagen Valencia, CA, USA) according to the manufacturer's instructions. Reverse transcription (2 µg total RNA per sample) was then performed by using ProtoScript first strand cDNA synthesis kit (New England Biolabs, Beverly, MA, USA) according to the manufacturer's instructions. Subsequently, the 5' end of the gene (gene fragment A, Figure 1) was obtained by RT-PCR with primer pair Sg1P5/S3D10 (Table 1). Whereas the 3' end (gene fragment B in Figure 1) was acquired by RACE (rapid amplification of the cDNA end) method^[6]. The cDNA pool, along with fragment A and fragment B would be used for the subsequent PCR templates.

Full-length gene cloning: BPCR

The amplification products A and B were mixed in equal volume and diluted 15-fold in distilled water. Bridging PCR (BPCR) outlined in Figure 1 was carried out by using 5 µL of the above diluents as template in 25 µL of the reaction mixture containing 1.25 U HotstarTaq DNA polymerase (Qiagen), 1×PCR buffer (Qiagen), 0.2 mmol/L dNTP, 0.4 µmol/L each of the primer pair Sg1P5 and RAC3 (Table 1). Thermal cycling was performed in a Peltier thermal cycler PTC-200 (MJ Research, Watertown, MA, USA) as follows. After an initial step at 95 °C for 15 min as recommended to activate the enzyme, the reaction temperature was decreased to 66 °C at the rate of -0.1 °C/s followed by an extension at 72 °C for 5 min, then 7 touchdown cycles were carried out at 94 °C for 45 s, at 68 °C for 30 s and at 72 °C for 30 s, with the annealing temperature decreased by 1 °C per cycle. Subsequently, the reaction mixture was subjected to 30 conventional cycles at 94 °C for 45 s, at 66 °C for 30 s, and at 72 °C for 2 min. Conventional PCR was also conducted as a control by using cDNA pool aliquot as template. As visualized on a 12 g/L

agarose gel, the target bands were recovered with a QIAquick™ gel extraction kit (Qiagen), cloned into pGEM-T easy vector (Promega Company, Madison, WI, USA), and transformed into *E. coli* strain JM109 (Promega). Sequencing of the positive clones was performed by BioAsia Biotechnology Co., Ltd (Shanghai, China). Sequence BLAST was performed in GenBank database.

Figure 1 Experimental design and steps involved in bridging PCR (BPCR) and partially overlapping primer-based PCR (POP-PCR). Gene fragments A and B had the junction region C. Under specific temperature conditions, the fragments would anneal together to form the template molecule, thus triggering the amplification cascade. The partially overlapping primers at each site of the template ends contained two primers premixed in a certain molar ratio that had sequence identity but with different lengths. All the short primers located at the outward overhang region. The sequences of all primers used are shown in Table 1.

Expression insert decoration: POP-PCR

To decorate the expression insert, primers were designed according to the sequence of the gene-coding region and the specific sequence of the expression vector as recommended by the manufacturer's instructions. The melting temperature (*T_m*) of all primers was calculated by using the software Omega 2.0 (Oxford Molecular Ltd, Oxford, UK). Shorter overlapping primers were additionally designed for the long primers with the *T_m* beyond 72 °C (Table 1). The sequences of this kind of primers each were identical to the 5' terminal sequence of their corresponding longer ones. Pooling together the shorter and longer ones in different molar ratio formed the partially

Table 1 Primers used in bridging PCR (BPCR) and partially overlapping primer-PCR (POP-PCR)¹

Code	Definition	Sequence (5' 3')	<i>T_m</i> (°C)

¹Fragments A and B were derived from allergen gene D106. The relationship thereof and the PCR steps are shown in Figure 1. The underlined oligonucleotides were for the specific sequences of the expression vector. Oligonucleotides in italic bold were gene specific sequences. Primers POP51 and POP52, POP31 and POP32 formed the partially overlapping primers, respectively, which were corresponding to the 5' and 3' end of the target gene.

overlapping primers (Figure 1). Pilot assays were conducted to optimize the molar ratio of the two primers in the partially overlapping primer pairs for PCR. The optimal proportion was subsequently chosen for partially overlapping primer PCR (POP-PCR), by using the product recovered from BPCR as a template. As a control, the cDNA pool, originally used for fragment gene cloning, was also used as the PCR template in parallel. The PCR mixture and the initial step were similar to those for BPCR, but with some changes in denaturing temperature and extension time. Following the initial denaturing step, 12 touchdown cycles at the initiative annealing step at 72 °C for 45 s, and an extension at 72 °C for 5 min were performed, followed by 30 extenuation cycles, which were initiated at 95 °C for 45 s, at 72 °C for 1 min and at 72 °C for 30 s, with the annealing time decreased by 1 s per cycle, and ended by a final extension at 72 °C for 10 min. The annealing temperature was usually adjusted according to the T_m of the primer being used in the reaction. The target bands visualized on the gel were purified and sequenced as described above. However, the plasmids were cloned into *E. coli* strain NovaBlue Singles™ cells (Novagen, Madison, WI, USA), according to the manufacturer's instruction.

Northern blot

Northern blot was performed according to the manufacture's manual with a slight modification. Briefly, 20 µg RNAs from pollen and the mixture of calyx and pedicel was loaded on a formaldehyde-containing gel. After running at 40 volts for 3 h or so, the RNA bands were electrically transferred onto Nytran SuPerCharge nylon transfer membranes (Schleicher & Schull BioScience, Inc. New Hampshire, USA). Before stained with methylene blue [0.2 g/L in 0.3 mol/L sodium acetate (pH 5.5)] to investigate the transferring efficiency, RNA was UV cross-linked onto the membrane. After destaining, BrightStar™ Psoralen-biotin (Ambion Inc., Austin, TX, USA) labeled probe D106 was applied for hybridization in the ULTRhyb™ hybridization buffer (Ambion Inc., USA). Subsequent washing was performed twice with a buffer containing 2×SSC (0.3 mol/L NaCl, 0.03 mol/L sodium citrate) and 1 g/L SDS, before its probe was detected by Phototope star detection kit (Ambion). Finally, the filter was exposed to Fuji medical X-ray film at room temperature for several min.

Protein expression

After confirmation of the in-frame insertion, the positive clones were incubated overnight at 37 °C on an orbital shaker. The

plasmids therein were extracted by using QIAprep Miniprep kit (Qiagen) and transformed into *E. coli* strain BL21(DE3) (Novagen) for expression according to the manufacturer's instructions with a minor modification. Following overnight proliferation of the expression transformants, the cells were inoculated in liquid LB medium at the rate of 1%. After a further incubation for 4 h or so, expression of protein D106 was induced with 0.5 mmol/L isopropyl-*D*-thio-galactopyranoside (IPTG) for 2 h at 30 °C before harvest. The expression results were analyzed on 150 g/L SDS-PAGE.

Western blotting

After induced expression was confirmed, the recombinant allergen Amb a 8(D106) was purified with S-Tag thrombin purification kit (Novagen). Fifteen micrograms of fusion protein was resolved on 150 g/L SDS-PAGE and electrically transferred to PVDF membrane (Amersco, Solon, Ohio, USA). After the membrane was blocked overnight with 40 g/L BSA solution, Rg allergic serum (diluted 1:7) was added to each membrane strip for 8 h before addition of peroxidase conjugated goat anti-human IgE (Sigma-Aldrich, Inc., Saint Louis, MO, USA). The blotted band was visualized with DAB chromogenic substrate solution^[14] (Amersco).

RESULTS

Fragment gene cloning

Gene fragments A and B corresponding to the 5'- and 3'-ends of the gene were enriched by RT-PCR and subsequently inserted into the vector. The sequence analysis demonstrated that fragments A and B, sized 363 bp and 431 bp respectively, contained a common region of 126 bp, which would provide the junction region for BPCR. The theoretical full-length gene joined contained the stop codon, poly (A) tail and primer sequences (Figure 2). Bridging the two fragments produced a novel theoretical full-length gene, which can be available under GenBank Accession No AY268426. BLAST with the amino acid sequence deduced from the full-length cDNA sequence of *D106* retrieved a large number of homologous proteins corresponding to pollen, food and contact allergens from different species, all of which belonged to profilin family. The BLAST data also showed that Amb a 8(D106) shared a homology of 54-89% with pollen allergens and of 79-89% with food allergens, which could help to cluster Amb a 8(D106) into both pollen and food allergen groups with short distances (Figure 3).

Figure 2 cDNA sequence of novel allergen gene *D106* from short ragweed pollens. The five shadowed regions represent the primer sites, Sg1p5, S5D106, S3D10, DEN3 and RAC3.

Figure 3 Phylogenetic relationships between newly obtained pollen allergen D106 (Amb a 8(D106)) and its cognates from GenBank as inferred from CLUSTAL W (1.82) alignment of the amino acid sequences. Amb a 8(D106) shared a homology as highly as 54-89% with different pollen allergens (from mugwort CAD12862 to apple Q9XF41) and as 79-89% with different food allergens (from peanut Q9SQI9 to peach Q8GT39).

Northern blot

To confirm the RNA derivation of cDNA of D106, Northern blot was performed. After blotting and UV-cross linking, methylene blue-staining of the membrane exhibited the sharp rRNA bands, suggesting the successful transferring and good quality of RNA. The sharp hybridization bands proved the pollen derivation of the cloned allergen cDNA (Figure 4). D106 could be detected both from pollen RNA and the RNA mixture from calyx and pedicel, which ruled out the PCR false derivation of D106.

Figure 4 Northern blot profile confirming RNA derivation of cDNA of the newly obtained gene D106. Lane 1, total RNA from calyx and pedicel; Lane 2, total RNA from pollen. Both lanes exhibit obvious bands, suggesting the real RNA derivation of D106.

Enhanced amplification specificity

In order to clone the full-length gene coding region for expression vector construction, we first resorted to general PCR by using the cDNA pool as a template with the primers formerly used. However, no sharp bands of expected sizes were exhibited on the loaded agarose gel for general PCR, though a number of PCR conditions were applied. After the template was changed to the mixture of gene fragments A and B previously acquired, the bridging PCR (BPCR), as outlined in Figure 1, produced the optimal results with sharp bands and exact size observed (Figure 5). The gene sequence achieved was identical to that

spliced from gene fragments A and B, indicating that the ORF of the target gene D106 was contained.

Figure 5 Agarose gel electrophoresis of PCR products. The PCR steps were depicted in Figure 1. Template in lanes 1, 2 and 5 is the mixture from gene fragments A and B; while template in lanes 3 and 4 is the BPCR product (lane 5). Lane 1, primer Sg1P5/RAC3; lane 2, primer POP51/POP31; lane 3, POP-PCR with primer POP51+POP52/POP31+POP32; lane 4, general PCR of the ORF of D106 with primer pair Sg1P5/DEN3; lane 5, BPCR of full-length D106 with primer Sg1P5/RAC3; M, molecular marker.

Decoration of expression insert

For comparison between conventional megaprimers and partially overlapping primers (POP), their amplification products were exhibited in parallel on the agarose gel (Figure 5). Longer primers and their relative shorter ones for POP-PCR listed in Table 1 were pre-mixed in a molar ratio of 1:1, 1:10, 1:50, 1:100. Hence 16 POP-pairs in different molar ratios were formed corresponding to both ends of the ORF of the gene, each of them was used for one reaction only. Comparison of the parallel PCR results showed that forward and reverse POPs in the molar ratios of 1:10 and 1:1 could produce the optimal amplification results, while conventional PCR exhibited the smear products with wrong sizes (Figure 5). The products recovered from target bands were successfully introduced into the expression vector pET-44 EK/LIC (Novagen) and transformed into *E. coli* strain NovaBlue Singles™ competent cells. Sequencing of the positive clones demonstrated that the

insert was in-frame and identical to those splices from gene fragments A and B and flanked by the vector specific sequence at both sides, indicating that the insertion was correct.

Protein expression and immunoblotting

Following proliferation of the clones selected, plasmids were extracted and successfully transformed into *E. coli* strain BL21 (DE3) for expression. SDS-PAGE analysis showed that the fusion protein was expressed mainly in a soluble form, with a molecular weight of 70 kDa as expected (Figure 6A). Immunoblotting result showed that the purified fusion protein could bind to IgE in the sera of allergic patients (Figure 6B), suggesting the allergenicity and the correct expression of the allergen protein.

Figure 6 SDS-PAGE analysis (150 g/L) for expression (panel A) and immunoblot of fusion pollen allergen D106 (panel B). Panel A: 1. Lysate pellet of induced cells; 2. Cells without IPTG induction; 3. Supernatant of induced cell lysate; 4. Purified fusion pollen allergen D106; M. Broad range prestained SDS-PAGE standards (Bio-Rad, Hercules, CA, USA). Panel B: Fusion protein D106 was blotted with 8 serum samples from pollen allergic patients. Each strip represents one serum sample.

DISCUSSION

As industrialization developed, atopic diseases have been increasingly concerned in the past decades^[1]. It is known that pollen-allergic patients frequently present allergic symptoms after ingestion of several kinds of plant-derived foods. The majority of these reactions were caused by cross-reactive structures that are present in pollens^[2]. Allergic proteins containing these structures are often called 'panallergens'. Cloning the panallergen gene and expressing the recombinant protein would be one of the fewer prospective ways to pollen-food allergy diagnosis and immunotherapy^[15]. This study aiming this goal successfully cloned an allergen gene D106 from short ragweed pollens and expressed the recombinant protein. Interestingly, the newly cloned gene showed a high homology not only with other pollen-derived profilins but also with food-derived profilins from numerous species. The allergenicity of the recombinant protein was primarily detected by its binding to the serum IgE from the Rg pollen allergic patients, of which 20% of the chief complaints expressed the food allergy of different kinds. Based on the homology results and the widely accepted rule-of-thumb that 30% or 35% identity over aligned regions could suffice for the structural or functional deduction^[4,16,17], it is therefore tempting to speculate that the recombinant protein acquired in this study would be a useful tool both for pollen and food allergy study, and for diagnosis and immunotherapy.

The novel gene discovery by using suppression and subtractive hybridization (SSH)^[18,19] and/or reverse genetic method^[20] could clearly validate the overall strategy for the preparation of gene fragments. However, obtaining the full-length genes is needed for more investigations of gene functions. One of the pivotal steps in the process of obtaining the full-length genes is to generate the target genes from their

fragments. The most commonly used methods for this at present were to screen the cDNA library^[21-23], or back to the cDNA pool that was originally used for gene fragment detection^[23]. Numerous polymorphic clones obtained would render these methods to time-consuming, expensive and liable to produce the microheterogeneity of the genes. In BPCR, only if an appropriate length region of sequence similarity existed, the two fragments could be spliced together. Obviously, the spliced sequence would be faithfully identical to that of the fragments originally used. Therefore no more screening work was needed. In order to anneal the two fragments and form a template molecule, it is a key point to optimize the annealing temperature according to the T_m of the junction regions of two gene fragments to be spliced, with the primers used in the reaction. Following this principle, BPCR would splice any two gene fragments with homology junction. Notably for the junction sequences either coming from the nature, or intentionally synthesized (see below), exact identity is not necessary but it does require a certain degree of homology to anneal the two fragment genes. Therefore, two heterogeneity genes could be spliced by BPCR method to form a novel chimeric gene or hybrid gene, which would be useful for gene function study and disease treatment.

Introducing restriction site and/or the specific sequences of vector to the primers is considered as a crucial step for exact insertion of exogenous gene into the vector, through which relatively long primers could be produced. It was well known that these longer primers would be easier to enhance the chance of non-specific amplification. To eliminate the potential non-specific amplification, partially overlapping primer technique was developed in the current study. According to the outward overhang sequence of the longer primers, the shorter identical sequence was synthesized and mixed in an appropriate molar ratio with the longer ones, thus forming the partially overlapping primer mixture. With this technique, increased amplification specificity was achieved, and the tedious screening process of target clones was avoided. According to the protocol of the partially overlapping primer, POP-PCR can be used for the amplification assays that are relevant to the addition of a length of extending sequence. It is therefore tempting to suggest that any genes that have no sequence similarities can be accommodated with the junction sequence and spliced together with repeated use and reciprocal combination of BPCR and POP-PCR to form a novel gene (or full-length gene). As this is concerned, a relatively more complicated procedure but with different efficiencies and proposes has been recently developed^[24].

Abstract

AIM: To clone and express mouse peroxiredoxin I in IEC-6 cells.

METHODS: Total RNAs were isolated from cultured IEC-6 cells, and the coding region of peroxiredoxin I was amplified by RT-PCR. After it was cloned into T-vector and sequenced, pSG5 was used to transiently express peroxiredoxin I in IEC-6 by liposome-mediated transfection, and the expression of peroxiredoxin I was evaluated by RT-PCR and Western blot.

RESULTS: A DNA fragment about 750 bp was amplified from total RNAs of IEC-6 cells using specific primers of peroxiredoxin I. The sequencing confirmed the coding region was successfully cloned into T-vector, which was completely coincident with the sequence in GeneBank. After the *EcoRI-BamHI* fragment of T-vector containing peroxiredoxin I was inserted into pSG5, the recombinant plasmid was transferred to IEC-6 cells. RT-PCR assay showed that a DNA fragment of 930 bp could be amplified, which indicated the transcription of pSG5-Prx. Western blot confirmed the expression of peroxiredoxin I in IEC-6 cells.

CONCLUSION: Mouse peroxiredoxin I can be successfully expressed in IEC-6 cells.

INTRODUCTION

Peroxiredoxin (Prx) is a novel defined protein family which plays a critical role in reducing hydrogen peroxide with hydrogen derived from NAD(P)H^[1-3]. The first member of this family was discovered as a 25 ku protein in yeast^[4]. All Prx proteins contain a conserved cysteine residue in the *N*-terminal region that is the active site of catalysis. In mammal cells, there are six isoforms of peroxiredoxin, which can be divided into two subgroups, termed as 1-Cys Prx (VI) and 2-Cys Prx (I-V)^[5,6]. The proteins of 2-Cys Prx subgroup contain another cysteine residue in the C-

terminal portion of the molecule. Prx isoforms are distributed differently within cells and therefore with different functions. Prx I and II are localized to the cytosol^[7,8], whereas Prx III has a mitochondrial-targeting signal and is localized in mitochondrion^[9]. Prx IV is secreted out of cells because of its *N*-terminal sequence for secretion. Prx V is found in mitochondrion as long form of this protein, but it also exists in peroxisome as short form^[10]. Same as Prx I and II, Prx VI is also found in cytosol^[11].

Prx I, which belongs to 2-Cys subgroup, is also known as MSP23, PAG and NEEF-A^[12-14]. Prx I is involved in redox regulation of the cell, such as reducing peroxides by reducing equivalents provided through the thioredoxin system but not from glutaredoxin. Prx I is found in abundance in the cytoplasm of cells as homodimers. Its cDNA was first cloned from mouse peritoneal macrophage encoding a protein of 23 ku. Now the antioxidative molecular mechanism of Prx I is elucidated by several researches on molecular structure has been performed. From the results of biochemical and physiological studies, Prx I has been implicated in a number of cellular functions, such as cell proliferation and differentiation, enhancement of the natural killer cell activity, and intracellular signaling, in addition to the antioxidant activity^[15-17]. Further studies have shown that the expression of Prx I is increased in cancer cells, indicating it may be related to cancer development or progression^[18]. We postulate that it may have an activity of anti-tumor development.

In our previous study, we found the expression of Prx I was up regulated by ionizing radiation in mouse intestinal epithelia^[19]. This was coincident with the results of other researchers^[20]. As a step to further study the biochemical functions of Prx I, we cloned the coding region of this gene and expressed it in IEC-6 cells. Our data showed that Prx I could be successfully expressed in this kind of cells.

MATERIALS AND METHODS

Materials

Male BALB/c mice, 58-62 d of age (weight 20-24 g), were purchased from Animal Center in Third Military Medical University, and housed in conventional cages with free access to drinking water and standard chow. Dulbecco's modified Eagle's medium (DMEM) and fetal bovine serum were purchased from Hyclone (Logan, USA). RNA PCR kit and T-vector were obtained from Takara (Dalian, China), and antibodies were from Santa Cruz (California, USA). Reagent for RNA isolation was from Roche Ltd. (Roche, USA). Plasmid pSG5 was a kindly gift from Dr. Chen Jian (Department of Biochemistry, Third Military Medical University). The specific primers were synthesized by Shanghai Shenyong Shengwu Jishu Corporation. Other chemicals not mentioned above were domestic made.

Isolation of total RNAs

Mouse intestinal epithelial cells were isolated as previously described^[21]. After the cell pipette washed with cold PBS (0.01 mol/L, pH7.4), the cells were lysed with Tripure solution. All performs were according to the manufacturer's instructions. The quality of isolated RNAs was checked by electrophoresis.

RT-PCR

The coding region of Prx I was amplified by RT-PCR with forward primer, 5' **CGAATTCGTTCTCACGGCTCTTTCTGTTT3'** (P1) and backward primer, 5' **AGGATCCTTCTGGCTGCTCAATGCTGC3'** (P2). One microgram of total RNAs was added into each reaction. After the reverse transcription was performed at 50 °C for 30 min, the amplification was carried out with one denaturing cycle of 3 min at 94 °C, then 28 cycles consisting of denaturation at 94 °C for 40 s, annealing at 58 °C for 40 s, and extension at 72 °C for 40 s, and one additional extension at 72 °C for 5 min. RT-PCR products were analyzed on 12 g/L agarose gel. To validate the transcription of recombinant plasmid, the mRNA of transfected IEC-6 cells was amplified by RT-PCR with primers P2 and P3 (5' **AAAGCTGGATCGATCCTGAG3'**). The procedure in details was performed according to the manufacturer's instructions.

Construction of expression vector

The amplified DNA was separated by electrophoresis and purified from gels. Then 1 µL of T-vector, 1 µL of T4 DNA ligase and 2 µL of 10×buffer were added to the purified RT-PCR product, and incubated at 16 °C overnight. Competent bacteria of *E. coli* JM109 were transformed with the linkage product, and then spread on a LB agarose plate containing ampicillin and X-gal. The inserted DNA into T-vector of 3 random monoclonal colonies was sequenced, and the colony was termed as pT-Prx. To construct the recombinant expression vector, the *EcoRI*-*Bam*HI fragment of pT-Prx was inserted into vector pSG5, which could transfect IEC-6 cells.

Cell culture and transfection

IEC-6 cells were cultivated at 37 °C in an atmosphere containing 100 mL/L CO₂ in air. The culture medium comprised of DMEM containing 100 mL/L fetal calf serum, penicillin (100 U/mL), and streptomycin (100 µg/mL). Exponentially growing cells were transferred to 100 mL culture dishes and cultured for 24 h to yield about 40% confluency at the time of transfection. Before transfection, 30 µg of DOTAP was diluted with 70 µL of HBS solution (20 mmol/L HEPES, 150 mmol/L NaCl, pH 7.4), and 5 µg of DNA was diluted to 0.1 µg/µL with the same solution. The mixture of DNA and DOTAP was prepared by gently mixing them together and incubated for 15 min at room temperature. To prepare cells for transfection, IEC-6 cells were washed twice with serum-free medium. After the cells were incubated with the mixture of DNA and DOTAP in 2 mL of serum-free medium for 4 h, the cells were washed with serum-free medium, followed by further culture for 16 h. Transfection was repeated one more time. At the time of 24 h after the second transfection, the cells were collected for RNA and proteins isolation.

Immunoblotting

IEC-6 cells were collected and washed with ice-cold PBS

(0.01 mol/L, pH 7.4) after transfection. Total proteins were isolated with RPI solution. The extraction mixture was centrifuged at 12 000 g at 4 °C for 20 min. The supernatants were transferred to a clean tube and stored at -70 °C as aliquots. The protein concentration was determined using Bradford dye-binding assay with bovine serum albumin as a standard. Total proteins were separated on 120 g/L SDS-polyacrylamide gel, and then transferred to nitrocellulose membranes. After being blocked for 1 h with the Tris/NaCl (50 mmol/L Tris-HCl, 200 mmol/L NaCl, 0.5 g/L Tween-20, pH 7.4) containing 20 g/L BSA, the membranes were probed with the goat anti-mouse Prx I polyclonal antibody. Immunoreactive bands were visualized with solution containing 1 mg/mL DAB and 0.1 mL/L H₂O₂. The expression of Prx I was normalized by that of GAPDH.

RESULTS

Amplification of the cDNA of Prx I

Total RNAs were isolated with 3 main bands appeared on agarose gels electrophoresis (Figure 1A). Message RNAs were smeared on the gel. After 28 cycles of RT-PCR, the products were run on 12 g/L agarose gel. A DNA band about 750 bp was visualized which was coincident with the length of the PrxI cDNA and could be cloned in the next step (Figure 1).

Figure 1 Amplification of Peroxiredoxin I by RT-PCR. A: total RNAs were isolated from mouse intestinal epithelia; three bands were visualized on agarose gel, which represented the main ribosome RNA of the cells. B: amplification of the coding region of peroxiredoxin I applying RT-PCR.

Cloning of Prx I

After the PCR product was ligated to T-vector, the linkage mixture transformed competent bacteria of JM109, and white colonies grew on LB plate containing ampicillin, X-gal and IPTG. Inserted DNA of 3 random colonies was sequenced, and the DNA was completely coincident with the sequence in GeneBank (data not shown). Then the inserted DNA of pT-Prx was digested with *EcoRI* and *Bam*HI, purified, and inserted into

vector pSG5. The recombinant expression vector was termed as pSG5-Prx (Figure 2). This recombinant plasmid was directly applied in cell transfection.

Transcription of pSG5-Prx in IEC-6 Cells by RT-PCR

We transfected IEC-6 cells with pSG5-Prx using pSG5 as a control. The cells grew very well during the period of transfection. Total RNAs of transfected IEC-6 cells were isolated after the second transfection using TriPure solution. Transcription of the recombinant plasmid was detected by applying RT-PCR with primers P2 and P3. The result showed that 2 DNA bands were visualized on agarose gel. Because the beta-globin intron (Figure 2A) in the primary transcript was spliced, the length of RT-PCR product based on mature mRNA was about 817 bp. However, the length of the other DNA band was about 1 399 bp, which was the PCR product using the recombinant plasmid as template (Figure 3).

Lane 1: DNA marker DL 2000, Lane 2: RT-PCR product, Lane 3: PCR product using purified recombinant vector as template.

Expression of Prx I in IEC-6 Cells

Total proteins of transfected IEC-6 cells were isolated after the second transfection and separated by SDS-PAGE. The blots were probed with specific antibodies against PrxI and GAPDH. Relative protein level was determined by quantitating the intensity of the bands with a densitometer. The ratio of the intensity of Prx I/GAPDH was automatically compared by Quantity One software (Bio-Rad Corp.). The result showed that the expression of Prx I was increased in pSG5-Prx transfected IEC-6 cells (50% more than the control cells) (Figure 4). This indicated that the recombinant plasmid could be transcribed and translated in IEC-6 cells.

DISCUSSION

IEC-6 cell line was derived from normal rat intestinal epithelia.

Its living condition for stable passage was successfully established after trials. The cell line was testified to be the small intestinal epithelial cell by electron microscopy and immunohistochemistry, and has been applied to some related research work^[22]. It is rational to apply this cell line *in vitro* to mimic the intestinal epithelia *in vivo*.

To further study the biochemical and physiological function of Prx I, we cloned the coding region of this protein and over expressed it in IEC-6 cells in this study. The cDNA of Prx I was first cloned in 1994 applying differential hybridization technique, which was named as *MSP23*^[23]. Treatment with diethylmaleate or glucose/glucose oxidase markedly enhanced the induction of its transcription, and the amount of its protein in the cells rapidly increased. Moreover, the cDNAs corresponding to the thiol-specific antioxidant (TSA), which encoded a protein termed as Prx, has been cloned and sequenced in yeast and mammalian cells^[24]. From the results of biochemical and physiological studies, Prx I has been involved in association with a variety of diverse cellular functions including proliferation, differentiation, and immune response. However, the detailed pathophysiological functions of this protein remain unknown.

The most striking finding of Prx I was that it was increased in many kinds of tumor cells. Moreover, some researchers thought it might be a potential tumor marker^[25]. Prx I was over-expressed in human breast cancer tissues compared to normal tissues^[26]. Using comparative proteome analysis between human normal (BEAS 2B) and malignant (A549) lung epithelial cells, Chang *et al.*^[27] found that Prx I was increased more than twofold reproducibly. Additionally, Prx I expression levels in follicular neoplasm and thyroiditis group were significantly higher than that of the control group, though papillary carcinoma group did not show statistical significance^[25]. All these data suggested Prx I was involved in tumor development or progression, and it might be a new target for gene therapy of tumor cells.

It was suggested that Prx I was a radiation responsive gene. Lee *et al.*^[28] demonstrated, when the irradiated testis was examined, Prx I was found to be transiently up-regulated. Its highly homologous gene Prx II was increased in tissues isolated from the patients who did not respond to radiation therapy. However, treatment with a Prx II antisense decreased the expression of Prx II, enhancing the radiation sensitivity of cells^[29].

In this study, we found pSG5 was an efficient expression vector of mammal cells^[30]. Though it has no screen marker, the expression of recombinant plasmid can be easily verified at mRNA level applying RT-PCR technology owing to the globin intron of this vector. Because of the existence of the vector DNA in the sample purified by applying Tripure solution, two kinds of RT-PCR product were displayed on agarose gel, which represented different PCR template. After the second transfection, most of the cells expressed the exogenous vector, and the protein was accumulated in these cells, which could be detected by immunoblotting. We will further study the biochemical and physiological role in radiation response of this protein.

Abstract

AIM: To compare the prevalence of *Helicobacter pylori* (*H pylori*) infection in autoimmune thrombocytopenic purpura (AITP) patients with that of nonthrombocytopenic controls, and to evaluate the efficacy of the treatment in *H pylori*(+) and *H pylori*(-) AITP patients.

METHODS: The prevalence of gastric *H pylori* infection in 38 adult AITP patients (29 female and 9 male; median age 27 years; range 18-39 years) who consecutively admitted to our clinic was investigated.

RESULTS: *H pylori* infection was found in 26 of 38 AITP patients (68.5%). *H pylori* infection was found in 15 of 23 control subjects (65.2%). The difference in *H pylori* infection between the 2 groups was not significant. Thrombocyte count of *H pylori*-positive AITP patients was significantly lower than that of *H pylori*-negative AITP patients ($P<0.05$). Thrombocyte recovery of *H pylori*-positive group was less than that of *H pylori*-negative group ($P<0.05$).

CONCLUSION: *H pylori* infection should be considered in the treatment of AITP patients with *H pylori* infection.

INTRODUCTION

Autoimmune thrombocytopenic purpura (AITP) is an acquired bleeding disorder in which autoantibodies bind to platelet surface, leading to platelet destruction^[1,2]. The mechanism triggering the production of platelet autoantibodies are poorly understood^[2].

Helicobacter pylori (*H pylori*) is a spiral shaped bacterium that resides in the stomach mucosa. *H pylori* has been considered for years as the etiologic agent of gastritis, peptic ulcer, gastric cancer, and mucosa-associated lymphoid tissue (MALT) lymphoma^[3-5]. More recently, *H pylori* has been found to be associated with a number of autoimmune disorders, such as rheumatoid arthritis^[6], autoimmune thyroiditis^[7], Sjogren's syndrome^[8], Schonlein-Henoch purpura^[9], and AITP^[10,11].

There are data consistent with an association between *H pylori* infection and AITP^[12-14]. In addition a significant increase of platelet count following *H pylori* eradication has been reported in a proportion of AITP patients^[12]. AITP in adults is most often chronic, and up to 25% of cases of chronic AITP are refractory to standard therapy^[1]. However, although there is some evidence implicating *H pylori* in some autoimmune disorders, the association between AITP and *H pylori* infection is speculative.

The aim of this study was to compare the prevalence of *H pylori* infection in AITP patients with that of nonthrombocytopenic controls and to evaluate the efficacy of the treatment in *H pylori*(+) and *H pylori*(-) AITP patients.

MATERIALS AND METHODS

Between May 2001 and October 2003 we investigated the presence of gastric *H pylori* infection in 38 adult AITP patients (29 females, 9 males, median age: 27 years, range: 18-39 years) consecutively admitted to our clinic. AITP was diagnosed on the basis of the presence of isolated thrombocytopenia ($<100\times10^9/L$) and megakaryocytic hyperplasia in bone marrow. Other causes of thrombocytopenia (drugs, pseudothrombocytopenia, hepatitis B and C virus infections, human immunodeficiency virus infection, malignancy) were excluded. Patients considered at bleeding risk who would require active treatment were also excluded. Age- and sex-matched 23 (18 females, 5 males, median age: 26 years, range: 18-35 years) nonthrombocytopenic patients without dyspeptic complaints were used as control group. None of the patients and controls had received antibiotics, proton pump inhibitors, and H_2 -receptor blockers during 4 wk before the onset of AITP.

All patients underwent 1 mg/(kg.d) steroid therapy for 3 wk following diagnosis, and then the dose gradually tapered every week until withdrawal. Our second choice of therapy was intravenous immunoglobulin administration [400 mg/(kg.d) for 5 d], but we did not use it.

An agglutination method was used to detect anti-*H pylori* antibodies of IgG type in both patients and controls (Ridascreen® R-Biopharm, Darmstadt, Germany). Hemogram analysis was done by Coulter®STKS (Coulter Corporation, Miami, Florida, USA).

Although demonstration of *H pylori* in gastric biopsies is the gold standard of *H pylori* detection, we preferred blood antibody detection due to following reasons. Endoscopy might cause unexpected bleeding in thrombocytopenic patients especially in those whose thrombocyte counts were less than $50\times10^9/L$. Urea breath test could not allow the detection of *H pylori* infection retrospectively. Both sensitivity and specificity of such kits were demonstrated in previous studies ($95\%<$)^[15].

Statistical analysis

Statistical analysis was performed using Kruskal-Wallis and Mann-Whitney *U* tests. Mean values were calculated for every variable in each group and compared between different groups. $P<0.05$ was considered as statistically significant.

RESULTS

There was no age or sex difference between controls and patients. *H pylori* infection was found in 26 of 38 patients with AITP (68.5%), and in 15 of 23 control subjects (65.2%). The difference between the 2 groups for *H pylori* infection was not significant (Table 1). Thrombocyte count of *H pylori*-positive AITP patients was lower than that of *H pylori*-negative AITP patients ($P<0.05$). Thrombocyte recovery of *H pylori*-positive group was less than that of *H pylori*-negative group (Table 2) ($P<0.05$).

Table 1 General characteristics of subjects in the study

Subjects	n	%	Mean age (range)	Sex (F/M)
<i>H pylori</i> -negative controls	8	(34.8)	25 (18-32)	6/2
<i>H pylori</i> -positive controls	15	(65.2)	27 (25-35)	12/3
<i>H pylori</i> -negative patients	12	(31.5)	29 (24-34)	8/4
<i>H pylori</i> -positive patients	26	(68.5)	26 (22-37)	21/5

Table 2 Platelet counts ($\times 10^9/L$) of AITP patients before and after steroid therapy

Parameters	<i>H pylori</i> -positive patients (n=26)	<i>H pylori</i> -negative patients (n=12)
Platelet counts ($\times 10^9/L$) (mean, range)	15 (10-22) ^a	29 (21-42)
Response to steroid (number, %)	17 (65) ^a	10 (83)
Post-treatment platelet counts ($\times 10^9/L$) (mean, range)	77 (61-112)	140 (124-180)

^a $P<0.05$ vs *H pylori* negative patients.

DISCUSSION

AITP is an autoimmune disease caused by autoantibodies against platelets^[16]. Several lines of direct and indirect evidences suggest that infectious agents may influence the occurrence or the course of some autoimmune diseases^[17]. The role of some bacterial or viral agents in the pathogenesis of AITP is well known. It has been demonstrated that the mimicry of human antigens by infectious agents represents the mechanism underlying this phenomenon^[18].

H pylori is a ubiquitous Gram-positive bacterium involved in the pathogenesis of gastric and duodenal ulcers. Recently, the involvement of *H pylori* has also been suggested in various autoimmune diseases^[6-9]. *H pylori* has been shown to cause immunological responses to the production of large amounts of proinflammatory substances and mucosal damage through autoimmunity^[19]. Previous *in vitro* studies suggested that *H pylori* has the potential to initiate autoreactivity through molecular mimicry. Recently, a role of *H pylori* in the pathogenesis of AITP has been suggested because significant increases in thrombocyte count were reported after eradication of *H pylori*^[10,11]. Michel *et al.*^[2] and Jargue *et al.*^[14] found no evidence of an association between *H pylori* infection and AITP. But the role of *H pylori* in the pathogenesis of AITP is still controversial.

Regarding the association between *H pylori* and AITP, Gasbarrini *et al.*^[11] reported that 61% of 18 AITP cases were infected with *H pylori*. Emilia *et al.*^[10] then reported that 43% of 30 AITP patients were *H pylori* positive. Kohda *et al.*^[18] found that *H pylori* was positive in 62.5% of 40 AITP patients in Japan. The prevalence of *H pylori* in our series was 68.5%. The prevalence of *H pylori* infection in healthy population of Italy, where Gasbarrini's and Emilia's studies were held, was

about 63%^[20]. In Japan the prevalence of *H pylori* infection was about 25-45%^[21]. We found *H pylori* infection in 65.2% of healthy controls in Turkish population.

Steroid is considered as the most effective treatment for AITP in adults. But, most patients relapsed when steroids were withdrawn and only 10-30% of them maintained a long lasting remission^[22]. Kohda *et al.*^[18] and Michel *et al.*^[2] found that there was no significant difference regarding thrombocyte counts between *H pylori*-positive and *H pylori*-negative AITP patients. In our series the thrombocyte count of *H pylori*-positive group was higher than that of *H pylori*-negative group at the initial presentation, and the difference between two groups was significant ($P<0.05$). Following treatment increase in the thrombocyte count of *H pylori*-positive patients was less than that of *H pylori*-negative patients. The difference was also significant ($P<0.05$).

Although the pathogenetic mechanism underlying *H pylori*-induced thrombocytopenia remains obscure, *H pylori* has been presumed to induce the formation of autoantibodies by way of a chronic immunological stimulus or cross mimicry between itself and platelets^[23]. It has been demonstrated that autoantibodies against *H pylori* can also react with some extragastric tissues, such as glomerular capillary membrane, ductal cells of salivary glands, and renal tubular cells^[24]. Platelets may also be a target of such antibodies although there is no proof for this cross reactivity.

In conclusion, *H pylori* infection should be searched in all AITP patients, and we suggest that *H pylori* should be eradicated in *H pylori*-positive AITP patients.

Abstract

AIM: To investigate the association between curative effects of interferon- α and partial human leucocyte antigen (HLA) II alleles in chronic viral hepatitis B.

METHODS: Sixty patients with chronic viral hepatitis B in Shanghai were treated with a standard course of treatment with interferon- α for 6 mo. HLA-DRB1, -DQA1, and -DQB1 alleles were detected by polymerase chain reaction-sequence specific primer (PCR-SSP) method.

RESULTS: Frequencies of HLA-DRB1*04 ($P<0.025$) and HLA-DQA1*0303 ($P<0.01$) in non-responders were significantly higher than those in partial and complete responders. Frequencies of HLA-DQA1*0505 ($P<0.025$) and HLA-DQB1*0301 ($P<0.005$) in partial and complete responders were significantly higher than those in non-responders.

CONCLUSION: Non-response to interferon- α therapy is positively correlated with HLA-DRB1*04 and HLA-DQA1*0303, and negatively correlated with HLA-DQA1*0505 and -DQB1*0301 in patient with chronic viral hepatitis B. HLA II genes of the identification alleles provide a method for evaluating outcome of interferon- α treatment.

INTRODUCTION

Chronic viral hepatitis B is a contagious disease with the higher infection and incidence rate in China, and approximately 0.3 million peoples died of chronic viral hepatitis B per year^[1]. Currently, it is mainly treated with interferon- α , lamivudine, etc. However, the effect of treatment is varying in different patients. Normally, complete response rate is about 30-40%, complete curability is less than 10%. What is the determinant of interferon- α curative effect on different individuals? Reports from domestic and overseas showed that individuals had

different endings after being infected by HBV and HCV^[2-3] and different response after being treated with interferon- α ^[4]. Researches indicated that these phenomenons were correlated with HLA alleles^[5]. HLA gene contributes to the host response against HBV. Individuals with different HLA alleles may differ in susceptibility or resistance to HBV^[6-8]. Our study tried to analyze HLA-DRB1, -DQB1, -DQA1 alleles in chronic viral hepatitis B to be treated with interferon- α for 6 mo, and study the association between curative effects of interferon- α and partial HLA alleles, which will help to direct the treating process of anti-virus in clinic.

MATERIALS AND METHODS

Research subjects and prescription

Sixty patients with chronic viral hepatitis B were enrolled in this study. The diagnosis of all the cases was made according to the criteria established on the Viral Hepatitis Conference held in 2000^[9]. All patients had abnormal serum transaminase levels. HBsAg, HBeAg, HBcAb in serum were detected by ELISA and HBV-DNA was detected by immunofluorescent semi-quantitative polymerase chain reaction. All patients' HAV, HCV, HDV and HEV in serum were negative, and did not have a history of using adrenal cortical hormone before. There were 41 male and 19 female patients with average age 35 \pm 8 years. They were all treated with 5.0 million units interferon- α daily for 2 wk and then every other day for an additional 22 wk. Liver function was detected every 2 wk. Hepatitis B viral marks were detected by Abbott Laboratories and HBV-DNA was determined by PCR at every 3-mo therapy.

Sampling and action

Five milliliter blood from each research subject was taken, and treated with EDTA for anti-coagulation. After mixed with 1 mL cell membrane cracking solution, the samples were centrifuged for 30 s, and then the supernatant was removed. Another 1 mL of cell membrane cracking solution was added after drying the test tube by bibulous paper. Centrifuged for 20 s and the top clear water was removed again. The cell mass at the bottom of the tube was vibrated and dissolved thoroughly. When mixed equally with 0.4 mL karyen cracking solution, separated out floccule DNA by adding 1 mL absolute ethanol. Supernatant was abandoned, and washed with 70% ethanol. After drying by blot paper, put it under room temperature to let ethanol volatilize. Then 0.1 double distilled water was added, and kept at -40 °C for testing.

Study method

HLA-DRB1, HLA-DQA1, and HLA-DQB1 alleles were detected by applying the PCR-SSP technique^[10]. PCR buffer solution was vibrated and mixed. Taq enzyme was put on the icebox. Distilled water 67 μ L and 1.8 μ L of Taq enzyme were added to the PCR buffer solution and vibrated. Then the solution was aspirated and added to the monitor hole. And 19 μ L of DNA samples were added to the spare mixing solution. Except negative contrast hole, the solution was added

to every hole. Color changed from yellow to pink. The reagent was sealed up, and sent to PCR apparatus for amplification. Sample solution 6 μ L was electrophoresed on 20 g/L agarose gel for 12 min under 150 V, and observed the under ultraviolet light.

Statistical analysis

HLA-DRB1, -DQA1, and -DQB1 alleles frequencies for the partial and complete responders were compared with those of the non-responders using the χ^2 test. $P < 0.05$ was considered statistically significant.

RESULTS

Based on the results of HBV markers and HBV-DNA after 6-mo therapy with interferon- α , patients were divided into 3 groups: (1) Complete response group: HBeAg and HBV-DNA were negative, while HBeAb was positive, and ALT was normal; (2) Partial response group: HBeAg and HBV-DNA level decreased, while ALT was normal; (3) Non-response group: HBeAg and HBV-DNA were stable. After inspection, it was found that the frequencies of HLA-DRB1*04 ($P < 0.025$) and HLA-DQA1*0303 ($P < 0.01$) in non-responders were significantly higher than those in partial and complete responders, and the frequencies of HLA-DQA1*0505 ($P < 0.025$) and HLA-DQB1*0301 ($P < 0.005$) in partial and complete responders were significantly higher than those in non-responders (Tables 1, 2 and 3).

DISCUSSION

Different individuals infected with HBV show different complicated symptoms. This is not only due to virus itself, but immunity itself^[11]. A great deal of evidences suggested that both cellular and humoral immunities were required for viral clearance. The latter is mainly subjected to major histocompatibility complex (MHC). HLA, the genetic offspring of MHC, is the first inherited system discovered to be associated with diseases definitely. Genes for HLA are located on the short arm of chromosome 6 with high polymorphism, and it is closely associated with immunoreactions of anti-HBV^[12]. Some special HLA genes may have influence on the rate of HBV infection and strength of immunoreactions^[13]. Patients who have successfully recovered from acute hepatitis B develop strong HLA classes I and II restricted T cell response, whereas these responses are weak or absent in patients with chronic hepatitis B^[14]. Jiang *et al.*^[15] found that HLA-DRB1*0301, -DQA1*0501 and -DQB1*0301 might be the susceptible genes, and HLA-DRB1*1101/1104 and -DQA1*0301 might be the resistant genes to chronic hepatitis B, and that host HLA class II gene was an important factor for determining the outcome of HBV infection. HLA spread on the cell surface through membrane protein with function of integrating with inner and outer antigen peptide and taking immune response when detected by CD4⁺ (cluster of differentiation) or CD8⁺ T cell on the surface of antigen presenting cells and target cells. Class II molecule, on the surface of antigen presenting cells, submits outer antigen including virus molecule group to the CD4⁺ T cell, which stimulates the releasing of the cell gene to take the effect of adjusting CD8⁺ cytotoxic T lymphocyte response and determine the antibody produce. Diepolder *et al.*^[16] found that people carrying HLA-DR13 had stronger CD4⁺ T cell response. That might be depended on the more accurate submission function of DR13, or associated with multiple peptide property of immunity adjusting gene chain near DR13. Thursz *et al.*^[17] discovered that DRB1*1302 possessed high frequency of clearance of hepatitis B virus in the Gambia people. Cotrina *et al.*^[5] also reported that predominance of the DRB1*1302 allele was observed in acute viral hepatitis B versus chronic viral hepatitis B in adult American. And the HLA-DRB1*0401 antigen was lower in the cases of chronic viral hepatitis B and C than that in the controls. Hohler *et al.*^[18] reported that the MHC class II allele DRB1*1301-02 was associated with protection from chronic viral hepatitis B in African Americans. Furthermore Bhimma *et al.*^[19] demonstrated that there was a high frequency of DQB1*0603 in subjects compared to controls in black children with hepatitis B virus-associated membranous nephropathy. Jiang *et al.*^[20] recently found that the possibility of fulminant hepatitis was increased in chronic hepatitis B with HLA-DRB1*1001. Tibbs *et al.*^[21] showed that the HLA-DQB1*0302 and HLA-DQA1*03 alleles conferred protection from chronic HCV-infection in Northern European

Caucasoid. These studies showed that HLA-II molecules were associated with clearance and prognosis of chronic viral hepatitis.

Currently, factors for forecasting interferon treating effect are as follows: ALT level before treatment; level of HBV-DNA; gene types of hepatitis B virus; sex of patients; and the duration of virus infection, etc. Interferon can induce the expression of IL-12 (interleukin-12) β_2 subpopulation, which induce Th0 (help T cell) cell to differentiate into Th1 cell. Previous studies showed that Th1 type response was beneficial for the clearance of chronically infected viruses^[7]. The balance of HBV differential antigen may influence the persistent HBV infection. Superiority of Th1 tends to occur acute hepatitis, while superiority of Th2 tends to occur persistent infection^[22]. There were fewer reports about association between curative effects of interferon- α with partial HLA allele. Qian *et al.*^[23] reported that the frequency of HLA-DRB1*07 in non-responders was higher than that in partial and complete responders in Guangdong Province of China, and the level of IL-4 and IFN- γ of each patient was higher than that of pre-treatment. It indicated that after treatment of chronic viral hepatitis B with IFN- γ , TH1 expression was relevant to the HLA-DRB1*07. Dincer *et al.*^[24] reported that in the HCV patient treated with interferon- α for 6 mo, the frequency of HLA-DRB1*13 was significantly higher in the non-responder group compared to the responder group. Our study showed that the frequency of HLA-DRB1*04 and HLA-DQA1*0303 in non-responders were obviously higher than those in partial and complete responders, and the frequency of HLA-DQA1*0505 and HLA-DQB1*0301 in partial and complete responders were markedly higher than those in non-responders. HLA-II molecules might be used for the treatment prognosis of interferon- α in patients with chronic hepatitis B.

Abstract

AIM: To induce efficient expansion of natural killer (NK) cells from peripheral blood mononuclear cells (PBMCs) using a culture of anchorage-dependent Wilms tumor cell lines, and to provide a reliable supply for adoptive immunotherapy of hepatocellular carcinoma.

METHODS: Culture expansion of NK cells was achieved using PBMCs cultured with Wilms tumor cells. Cytotoxicity was measured using a standard ^{51}Cr release assay and crystal violet staining technique. The proportions of CD3+, CD4+, CD8+, CD16+, and CD56+ cells were determined by flow cytometry.

RESULTS: After PBMCs from healthy donors and hepatocellular carcinoma (HCC) were cultured with irradiated HFWT cells for 10-21 d, CD56+ CD16+ cells shared more than 50% of the cell population, and more than 80% of fresh HFWT cells were killed at an effector/target ratio of 2 over 24 h. NK-enriched lymphocyte population from HCC patients killed HCC-1 and 2 cells with sensitivities comparable to fresh TKB-17RGB cells. HCC cells proliferated 196-fold with the irradiated HFWT cells at 18 d. Stimulation by HFWT cells required intimate cell-cell interaction with PBMC. However, neither the soluble factors released from HFWT cells nor the fixed HFWT cells were effective for NK expansion. The lymphocytes expanded with IL-2 killed fresh HFWT target cells more effectively than the lymphocytes expanded with the 4-cytokine cocktail (IL-1 β , IL-2, IL-4 and IL-6). IL-2 was the sole cytokine required for NK expansion.

CONCLUSION: Wilms tumor is sensitive to human NK cells and is highly efficient for selective expansion of NK cells from PBMCs.

INTRODUCTION

Natural killer (NK) cells are CD3- CD56+ and/or CD16+ cytotoxic

lymphocytes that mediate first-line defense against various types of target cells without prior immunization^[1,2]. The regulation mechanism of human natural killer (NK) cell growth has not been well characterized despite the importance of NK cells in immune response^[3]. One reason is that the currently used culture system for human NK cells is relatively poor at inducing a strong growth response compared with culture systems for other lymphocytes, such as T cells.

Since K562 cells expressing scarcely MHC-class I on their surface are highly sensitive to natural killer (NK) cells, they have been widely used for the assay of NK killing activity^[4-6]. When K562 cells are killed by NK cells *in vitro*, apparent growth response of NK cells follows. The stimulation by K562 requires direct cell-cell contact and is not reconstituted by cell-free supernatants. However, the stimulation is not necessarily sufficient for the NK selective expansion in peripheral blood mononuclear cells (PBMCs) of every subject. Reports from Perussia *et al.*^[7] and Silva *et al.*^[8,9] suggested that human B lymphoblastoid cell lines and leukapheresed peripheral blood stem cell grafts were also useful for human NK cell expansion. Sekine *et al.*^[10] developed an alternative method for lymphocyte expansion from peripheral blood by cultivating cells with IL-2 and immobilized anti-CD3 monoclonal antibodies. Application of expensive anti-CD3, anti-CD16 bispecific antibodies may avoid the dilution of NK cells in the lymphocyte populations^[11]. Coculture of NK cells with dendritic cells (DCs) resulted in significant enhancement of NK cell cytotoxicity and IFN- γ production^[12]. Coexpression of GM-CSF and B70 may enhance NK-mediated cytotoxicity, and then induce the antitumor immunity in hepatoma transplanted into nude mice^[13]. We consider that, for further use of the NK cells in adoptive immunotherapy of human tumors, clear separation of expanded NK cells and suspension cultured allogeneic EB virus-transformed cells that may have escaped from the killing by NK cells will be difficult.

In this study, we screened anchorage-dependent virus-free human tumor cell lines as an appropriate target in the NK cell expansion culture. We found that an anchorage-dependent cell line derived from Wilms tumor (HFWT) was sensitive to human NK cells.

MATERIALS AND METHODS

Cell lines and reagents

All the cell lines were from routine stock cultures in the RIKEN Cell Bank. Cell lines were maintained in basal medium containing 100 mL/L or 150 mL/L fetal bovine serum (FBS). Peripheral blood was taken from healthy volunteers and hepatocellular carcinomas (HCCs) were from patients who gave their informed consent. Recombinant human IL-1 β , -2, -4, -6, -7, -12, and -15 were purchased from Genzyme (Tokyo, Japan). Mouse anti-human-CD3, CD4, -CD8, CD56 and CD16 monoclonal antibodies were purchased from Nichirei Co., (Tokyo, Japan). ^{51}Cr was purchased from NEN Life Science Products Inc. (Boston, USA).

Flow cytometry

Suspended cells (1×10^6) were washed three times with PBS, incubated for 30 min with monoclonal antibodies, 30 min with

FITC-labeled goat anti-mouse IgG polyclonal antibody. The cells were again washed with PBS containing 40 mL/L FBS. They were re-suspended in the same buffer at a concentration of 1×10^6 /mL and were immediately analyzed by FACS (Becton-Dickinson, Co.). The proportion of CD3+, CD4+, CD8+, CD16+, and CD56+ cells was detected with corresponding monoclonal antibodies.

Fixation of HFWT cells

HFWT cells (1×10^5 /mL, 1 mL) were plated in a 24-well plate and incubated overnight in a humidified 50 mL/L CO₂ incubator. The culture medium was replaced with PBS, and the cells were fixed with 0.5 mL of 40 g/L formaldehyde or 3:1 methanol-acetic acid mixture for 1 h, and then thoroughly washed with water.

HFWT cells were subjected to heat treatment at 100 °C for 2 s in a microwave oven after the replacement of the culture medium with PBS. The treated HFWT cell concentration was adjusted to 1×10^5 /well for the NK expansion experiments.

Expansion culture of NK cells

PBMCs were prepared from heparinized peripheral blood with the conventional preparation kit (Lymphoprep, Nycomed Pharma A.S., Norway). The cells were washed once with PBS, then once with RHAM alpha medium supplemented with 50 mL/L autologous plasma, and centrifuged at 1 400 r/min (240 g) for 10 min at room temperature. Before addition of PBMCs to the NK cell expansion cultures, the confluent target tumor cells maintained in a 24-well plate were irradiated with 50 Gy of X-rays. The PBMCs (1×10^6 /mL, approximately 1 mL/well) were then cultured with the tumor cells (at this stage, the responder/stimulator ratio was adjusted to 10 in the culture medium, i.e. the RHAM α medium was supplemented just before adding 50 mL/L autologous plasma and a 4-cytokine cocktail of IL-1 β (167 U/mL), IL-2 (67 U/mL), IL-4 (67 U/mL), and IL-6 (134 U/mL)). When IL-2 alone was used, the concentration was adjusted to 200 U/mL. IL-7, IL-12, and IL-15 were used at a concentration of 10 U/mL, 10 ng/mL, and 20 U/mL, respectively.

NK expansion culture was continued with appropriate changes of the medium, including addition of the indicated cytokines (at least half of the medium was changed every 2 d), until the adherent target cells disappeared. When K562 cells were the targets, this period was set at 7 d. The cell suspension was diluted to 5×10^5 /mL and the culture continued. Whenever the cell suspension reached 5×10^6 /mL, the dilution was repeated.

Cytotoxicity assay

A standard ⁵¹Cr release assay was performed in the 4-h co-culture of the effector lymphocytes and the target K562 cells as described^[14]. The crystal violet staining was also used^[15]. Briefly, the target cells, 1×10^4 /well suspended in 200 μ L RHAM α medium containing 50 mL/L plasma from the lymphocyte donor (or 50 mL/L PPF whenever the plasma was in short supply), were seeded in a 96-well plate and were pre-cultured overnight. The cultured target cells were washed once with PBS, then the cultured lymphocytes suspended in 200 μ L of RHAM α medium containing 50 mL/L autologous plasma (or 50 mL/L PPF) were added as effector cells to each well at the indicated effector/target (E/T) ratio. The cells were co-cultured for 4 or 24 h. Then, the wells were washed once gently with appropriate amounts of Dulbecco's PBS containing calcium and magnesium. The target cells remaining adhered were fixed for 1 h with 40 g/L formaldehyde (200 μ L/well), and then stained with crystal violet solution (4 g/L in water, 100 μ L/well) for 30 min at room temperature. The plate was washed with water and dried at room temperature. A 200 μ L of 800 mL/L methanol was added into each well and the absorbance at 570 nm (A_{570}) of each well was determined. As a 100% control, the A_{570} of the

target cells cultured in a separate plate was determined just before the addition of the effector cells.

Percentage of surviving target cells was defined as follows:

$$\text{Surviving target cells (\%)} = (A-B)/(C-D) \times 100\%$$

Where A is the A_{570} of the well containing the target cells and the effector cells, B is the A_{570} of the well containing only the effector cells which remained in the well after the washing with calcium- and magnesium-containing Dulbecco's PBS, C is the A_{570} of the 100% control target cells just before the addition of the effector cells, and D is the A_{570} of the well containing medium alone. The target cells cultured at an E/T ratio of 0 grew rapidly over the 24-h incubation period and, therefore, showed more than 100% survival.

RESULTS

Proportion of NK cells in the lymphocyte culture

Two hundred and forty kinds of human cell lines from RIKEN Cell Bank were screened for their expression of MHC-class I and class II surface molecules. Ten cell lines including leukemia cell line K562, HFWT (Wilms tumor), HMV-II (melanoma) and NB 19 (neuroblastoma) were found that weakly expressed MHC molecules of both.

Subsequently, PBMCs taken from healthy subjects were co-cultured with these cell lines after the target cells had been irradiated with 50 Gy of X-rays. HFWT cultures demonstrated a striking change in anchorage-dependent HFWT cells that were totally killed and disappeared after 13-14 d. CD3- CD56+ cells occupied 64.6%, 54.6%, and 75.9% of the lymphocyte population in the three experiments, respectively. However, K562 and HMV-II in experiments 2 and 3 only raised the proportion of CD3-CD56+ cells to 17.6% and 18.9%, respectively, though these proportions were higher than those (5.4-13.0%) in the control cultures containing no target cells. In contrast, irradiated TKB-17RGB cells increased CD3+CD56 T cells in the lymphocyte populations in the three experiments to 95.1%, 96.0%, and 84.8%, respectively as compared to 74.4%, 58.2% and 60.9% in controls.

Assay for NK cytotoxicity activity

Figure 1A depicts a typical dose-response curve for the 4-h ⁵¹Cr release assay. The NK-enriched population lysed 31.3% and 76.5% of the fresh HFWT cells at E/T ratios of 2 and 8, respectively. A mirror image of this curve was observed in crystal violet staining (Figure 1B). The target cells showed 100% survival in crystal violet staining and 20% lysis in the ⁵¹Cr release assay when E/T ratio was 1.

Effect of extending co-culture time to 24 h was also examined. The percentage of the surviving control target cells usually exceeded 100% (Figure 1C) at an E/T ratio of 0, but the shoulder portion of the dose-response curve in Figure 1B disappeared and fewer surviving target cells were observed at larger E/T ratios. Only 17.0% of the target cells remained at E/T ratio of 4, whereas 42.5% remained in the 4-h crystal violet staining. Therefore, for determination of killing activity, 24-h crystal violet staining had a higher sensitivity than 4-h crystal violet staining at low E/T ratios.

PBMCs grown on TKB-17RGB target cells could efficiently kill fresh TKB-17RGB cells but not fresh 17 RGB cells. Lymphocytes grown on the HFWT target cells could efficiently kill both fresh TKB-17RGB cells and fresh HFWT cells (Figure 2, 8 columns on the right), indicating that the lymphocytes contained nonspecific NK cells. The latter lymphocyte population, at an E/T ratio of 2 at 24 h, reduced TKB- 17R GB target cells to 60.5% and HFWT target cells to 18.5% compared to the control tumor cells (E/T ratio of 0) that proliferated to 175-180% of starting levels.

Figure 1 Dose-response relationships of ^{51}Cr release assay and the two crystal violet staining assays. PBMCs were detected after 15-d culture with irradiated HFWT cells. A: ^{51}Cr release assay, in which the effector lymphocytes and the fresh target cells pre-labeled with ^{51}Cr were incubated for 4 h. B and C: crystal violet staining, in which effector lymphocytes and fresh target HFWT cells were incubated for 4 and 24 h, respectively. Each point and bar represent mean and SD (3-6 replicates), respectively.

Figure 2 Killing by T cell- and NK-enriched lymphocytes. Lymphocytes derived from PBMC of the Subject-1 (taken from Experiment-1 of Table 1) were used in this 24-h crystal violet staining with various E/T ratios. Eight columns on left side are the results from assays of lymphocytes grown on irradiated TKB-17RGB cells (MHC class I positive). Major lymphocyte population was CD3+ CD56- (T cell-enriched, see Table 1). For the killing assay, fresh TKB-17RGB (left-end 4 columns) or cells (mid-left 4 columns) were submitted as the target. Right side 8 columns are the results from assays of lymphocytes grown on irradiated HFWT cells (MHC class I negative). Major lymphocyte population was CD3-CD56+ (NK-enriched, see Table 1). For the killing assay, fresh TKB-17RGB (mid-right 4 columns) or HFWT cells (right-end 4 columns) were used as the target. Each column represents the mean value of triplicate measurements.

Lymphocytes from PBMC of HCC patient were cultured on the irradiated cells and proliferated 196-fold at 18 d. This was about 6 times the proliferation of lymphocytes suspended with the irradiated K562 cells (data not shown) and the proliferation ceased after 14 d in the NK expansion culture. X-ray irradiated HCC-1 cells (MHC class I positive) and HCC-2 cells (MHC class I negative) obtained from the same hepatocellular carcinoma were used in place of HFWT cells, and neither of the two cell lines could support efficient growth of the lymphocytes from PBMC of HCC patient. NK-enriched lymphocyte population from HCC patient, however, killed HCC-1 and 2 cells with sensitivity comparable to fresh TKB-17RGB cells (Figure 3). About half of the control HCC-2 cells detached spontaneously

after 24-h incubation. The NK-enriched population derived from the patient and expanded on the irradiated HFWT cells could also kill fresh K562 cells with high efficiency (data not shown).

Figure 3 Killing activity of the NK-enriched population on MHC class I-positive and -negative cell lines. PBMCs of HCC patient were expanded on irradiated T cells and submitted to the 24-h crystal violet staining. Target cells were MHC class I-negative HFWT and HCC-2 cells, MHC class I-positive HCC-1 and TKB-17 RGB cells. HCC-1 and HCC-2 cells were derived from the same human hepatocellular carcinoma tissue.

In a separate experiment, the effect on NK expansion of HFWT and MHC class I-non-expressing HCC-2 cells were compared using a medium containing IL-2 (Table 1). After 10 d of co-culture with PBMCs from Subject 1, irradiated HFWT cells induced 72.0% concentration of CD3-CD56+ cells, whereas irradiated HCC-2 cells induced only 18.5% concentration of CD3-CD56+ cells. CD16+CD56+ cells co-cultured with HFWT grew to 72.7% of the lymphocyte population, whereas CD16+CD56+ cells co-cultured with HCC-2 grew to 22.8% of the lymphocyte population. All the other tumor cell lines showed lower similar efficiency for NK cell expansion.

Cell-cell interaction between PBMC and HFWT cells

After PBMCs from Subject 1 were grown for 10 d in direct-contact co-culture, the final proportion of CD16+ CD56+ cells reached 71.7%, but in the case of PBMCs separated from HFWT cells with a membrane filter, the final proportion reached only

Table 1 Proportion of CD16+ CD56+ cells compared to other cell groups after NK cell expansion cultures

Irradiated target cells used for expansion culture	Cell proportion in lymphocyte populations (%)			
	CD3+CD56-	CD3-CD56+	CD3+CD56+	CD16+CD56+
HFWT	15.2	72.0	12.3	72.7
HCC-2	49.7	18.5	31.1	22.8

Table 2 Proportion of CD16+CD56+ after co-culture of PBMC with irradiated HFWT cells with and without separation by a membrane filter

PBMCs and HFWT co-culture conditions	Cell proportion in the final lymphocyte populations (%)		
	CD3+CD56-	CD3-CD56+	CD16+CD56+
Without separation	13.4	78.2	71.7
Separated by a membrane filter	83.4	5.3	3.9

3.9% (Table 2). Most of the lymphocytes in the latter culture were T lymphocytes. These results demonstrate that direct cell-cell interaction is crucial for NK expansion.

Cytokine requirements for NK cell induction

The highest increase in lymphocyte number from Subject-2 reached 401-fold after 15 d in the expansion culture. Lymphocytes derived from both Subject-2 and Subject-3 expanded with IL-2-containing medium killed fresh HFWT target cells more effectively than the lymphocytes expanded with the 4-cytokine cocktail (data not shown). Without the presence of target HFWT cells, lymphokine activated killer (LAK) cells grew slower than those cultured on the target cells. Unlike IL-2, IL-12 inhibited and IL-15 stimulated the growth of lymphocytes cultured on target HFWT cells. IL-7 (10 U/mL) was not effective on lymphocyte growth. Without addition of IL-2 to the culture medium, the irradiated HFWT cells themselves could not support survival of the lymphocytes for several days.

We compared the effects of HFWT and MHC class I-non-expressing HCC-2 cells on NK cell expansion using IL-2-containing medium. For 10 d in the culture of PBMC from Subject-1, irradiated HFWT cells induced 72.0% of CD3-CD56+ cells, but irradiated HCC-2 cells could induce only 18.5% of CD3-CD56+ cells. CD16+ CD56+ cells shared 72.7% in the former lymphocyte population and, in the latter, 22.8%.

DISCUSSION

Expansion of human NK cells from PBMCs has long been investigated but large-scale expansions for adoptive immunotherapy of human tumors deserve further investigation. LAK cells have been applied to tumor immunotherapy. However, LAK cell expansion in culture for more than 2 wk usually resulted in the loss of killer cell activity. T cells without killing activity formed a major part of the resulting lymphocyte populations^[16]. Similar problems have been found in expansion cultures of tumor-infiltrating lymphocytes, in which cells bearing B cell, NK cell and macrophage markers disappeared early in the culture^[17].

The K562 cell line in suspension culture has long been adopted as the common target cell line for determination of the killing activity of human NK cells by the standard ⁵¹Cr release assay. For ecological reasons, a nonradioisotopic crystal violet staining assay was used in our experiments for determining the killing activity of CTLs against anchorage-dependent target tumor cells. The crystal violet staining assay is safe and amenable to coculturing effectors and targets for more than 4 h. Since HFWT cells disappeared completely during NK expansion culture described above, crystal violet staining using non-irradiated fresh T cells as the target, was considered as sensitive for assessment of the cytotoxic activity of the NK cells as the standard ⁵¹Cr release assay.

The results demonstrated that an anchorage-dependent Wilms tumor cell line is a highly efficient target for selective expansion of human NK cells from PBMCs. After culturing PBMCs from healthy donors for 10-21 d, the number of lymphocytes increased extensively. More than 50% of the resulting population consisted of CD16+ CD56+ NK cells that could efficiently kill the MHC class I-non-expressing K562.

Moreover, these expanded NK cells also appeared to kill MHC class I-expressing tumor cells (Figure 2, TKB-17 RGB target cells), suggesting the probability of using these highly active NK cells for adoptive immunotherapy of human tumors.

We have already repeated more than 20 times the 2-week cultures for NK expansion from PBMCs on HFWT cells. Under microscopic examination, we observed that anchorage-dependent target HFWT cells always disappeared completely, the advantage of which was adoptive immunotherapy with NK cells when compared to the methods of NK cell proliferation with suspension-cultured target tumor cells such as K562 and B lymphoblastoid cell lines.

For NK expansion, direct contact of PBMCs with HFWT cells was required (Table 2), suggesting that factors released from target cells do not contribute to NK cells expansion. The need for direct cell-cell contact had been noted in experiments using K562 cells^[18]. Growth stimulation through direct cell-cell contact might not be ascribed simply to molecules on the HFWT cell surface preserved after fixation, although Pierson *et al.*^[19] reported that NK cells plated directly on ethanol/acetic acid-fixed M2-10B4, which leaves stromal ligands (cell membrane components and ECM) intact, resulted in increased NK cells expansion compared with medium alone. The variety of the fixation methods used in the present experiments conserved, at least partially, reactivity of the surface molecules. Therefore, some interactions between the surface molecules of HFWT cells may contribute to NK expansion. In any case, contact between PBMCs and live HFWT cells were found to be a key requirement.

NK cells are cytotoxic to tumor and virus-infected cells that have lost surface expression of MHC class I proteins. Target cell expressing MHC class I proteins inhibits NK cytotoxicity through binding to inhibitory NK cell receptors^[20,21]. Therefore contrasting properties of NK cell inhibitory receptors compared to CTL T-cell receptors (MHC class I receptors that stimulate, rather than inactivate, the CTL cytotoxic response) are expected to provide complementarity in the cytotoxic response to tumor cells^[22,23]. In humans, natural killer (NK) cell function is regulated by a series of receptors and coreceptors with either triggering or inhibitory activity^[24].

HFWT cells were more effective targets for NK cell expansion than K562 cells. Since it has been reported that NK cells differentiate from CD34+ progenitor cells^[25,26], HFWT cells must stimulate NK cells differentiation from the progenitor cells included in PBMC but not in the CD3-CD56+ subset. Further investigation needs to be conducted to identify the NK precursor cells to which HFWT cells transmit the proliferative signal.

Since the present NK cell expansion culture started as one of variation of the human CTL induction culture from PBMC, the present study has shown that IL-2 is the sole cytokine required for the NK expansion on the T cell layer^[27]. In other reports, IL-15 was found to stimulate NK development from CD34+ hematopoietic progenitor cells^[28-30], IL-7 as a cofactor during myelopoiesis, is capable of activating monocytes/macrophages and NK cells^[31]. IL-12 showed an inhibitory effect on NK cell growth^[32,33], TGF β was reported to be similarly inhibitory^[34]. The present results suggest that expansion and activation of NK cells may provide an effective immunotherapy of hepatocellular carcinoma.

Abstract

AIM: To observe the relationship between intestinal lumen colonization with *Candida albicans* and mucosal secretory IgA (sIgA).

METHODS: A total of 82 specific-pathogen-free mice were divided randomly into control and colonization groups. After *Candida albicans* were inoculated into specific-pathogen-free mice, the number of *Candida albicans* adhering to cecum and mucosal membrane was counted. The lymphocyte proliferation in Peyer's patch and in lamina propria was shown by BrdU incorporation, while mucosal sIgA (surface membrane) isotype switch in Peyer's patch was investigated. IgA plasma cells in lamina propria were observed by immunohistochemical staining. Specific IgA antibodies to *Candida albicans* were measured with ELISA.

RESULTS: From d 3 to d 14 after *Candida albicans* gavaging to mice, the number of *Candida albicans* colonizing in lumen and adhering to mucosal membrane was sharply reduced. *Candida albicans* translocation to mesenteric lymph nodes occurred at early time points following gavage administration and disappeared at later time points. Meanwhile, the content of specific IgA was increased obviously. Proliferation and differentiation of lymphocytes in lamina propria were also increased.

CONCLUSION: Lymphocytes in lamina propria play an important role in intestinal mucosal immunity of specific-pathogen-free mice when they are first inoculated with *Candida albicans*. The decreasing number of *Candida albicans* in intestine is related to the increased level of specific IgA antibodies in the intestinal mucus.

INTRODUCTION

Candida albicans are the common opportunistic pathogens^[1];

one of their infection routes is overgrowth and translocation in intestinal lumen. So, inhibition of the translocation of *Candida* is an important way to prevent the deadly systemic infection. With the development of the study on mucosal immunity, local antibody production of sIgA has attracted much attention in preventing pathogen^[1] and bacterial translocation^[2,3]. It has been reported that *Candida albicans* infection of vaginal and oral mucus membrane was specifically inhibited by anti-*Candida albicans* sIgA. But, the mechanism still remains unclear. In the present study, by using *Candida*'s colonization model, we observed lymphocytes proliferation and differentiation in gut-associated lymphatic tissue (GALT) and the relationship between specific IgA and change of *Candida albicans* in the intestine, and further explored the mechanism of host defense against opportunistic pathogen and the effect of specific IgA against *Candida albicans* in intestinal lumen.

MATERIALS AND METHODS

Candida albicans

Candida albicans strain cmcc44104 provided by the Burn Institute of Southwest Hospital was amplified in the special selective culture medium. The *Candida albicans* suspension density was modulated to 1.5×10^9 cfu/mL, and stored below 4 °C.

Grouping of animals

A total of 82 specific-pathogen-free mice (BALB/c) were provided by the Animal Center of Third Military Medical University, and randomly divided into the control and colonization groups. Mice in colonization group were gavaged 0.5 mL *Candida albicans*, and killed on days 3, 7 and 14 after gavage by cervical dislocation. The control animals were treated in a similar way with a vehicle alone, and killed on day 14 after sham-treatment. The mesenteric lymph nodes, cecum and ileum of the mice were taken out.

Candida albicans adhering to ileum

Ilea of 10 cm were rinsed in PBS (0.01 mol/L, pH 7.2) three times until the ilea were translucent, then weighed and homogenized. Homogenized suspension (0.1 mL) was applied on the surface of the selective culture medium at 37 °C for 72 h.

Adherence result (cfu/g) = Colony-forming units × dilution / Ileum weight (g).

Quantity of *Candida albicans* in cecum

Ceca were weighed and homogenized in 5 mL PBS, then the suspension was cultured in the selective medium at 37 °C for 72 h. *Candida albicans* quantity (cfu/g) = Colony-forming units × dilution / Cecum weight (g).

Translocation of *Candida albicans*

Mesenteric lymph nodes (MLN) were taken to be weighed and homogenized and the suspension was applied on the selective medium at 37 °C for 72 h.

Lymphocytes proliferation in Peyer's patch and lamina propria

Mice were intraperitoneally injected 5-bromo-2'-deoxyuridine

(BrdU, 10 µg/g bm) at 12 h before cervical dislocation, the intestine and Peyer's patch (PP) were taken for immunohistochemistry staining. BrdU-positive cells in PP and in lamina propria (LP) of intestinal villi were counted.

Number of IgA plasma cell in LP

IgA plasma cells were counted after immunohistochemical stain as 40 villi/per mice and 5 mice/per time-point.

Expression of IgA of Peyer's patch lymphocyte

Peyer's patch lymphocytes were isolated, pooled, washed in RPMI 1640. Then IgA of lymphocytes was measured by flow cytometry.

Specific IgA to *Candida albicans* in intestinal mucus

Intestinal mucus (0.1 mL) was homogenized in 0.5 mL cold PBS, then centrifuged at 5 000 r/min for 5 min, the supernatant was taken as 1:1 mucus onto 96-well plates and coated by *Candida albicans* as immobilized antigen, which had been fixed in 40 g/L formaldehyde overnight at 4 °C for 72 h. Then plates were washed three times with PBS, and blocked by 5 g/L BSA for 0.5 h, the mucus samples were applied to ELISA plates for 1 h below 37 °C. After that, 96-well plates were washed with PBS, and goat anti-mouse IgA antibodies which coupled with horseradish-peroxidase were added to the wells, 100 µL/well and incubated at 37 °C for 1 h. Reaction was stopped by adding one drop of 2 mol/L H₂SO₄ and the result was shown by optical density (OD) at 492 nm.

Relative quantity of specific IgA^[4]

The specific IgA positive mucus measured before were serially diluted from 1:1 to 1:16, the content of specific IgA to *Candida albicans* in 1:1 mucus was regarded as 1 U/mL. The mucus was applied to ELISA in order to produce a standard curve. Specific IgA activity to *Candida albicans* was counted as follows:

$\text{IgA(U/mg)} = \text{IgA relative quantity (U/mL)} / \text{Protein content in the mucus (mg/mL)}$.

Statistic analysis

Data were analysed using analysis of variance (ANOVA).

RESULTS

Change of *Candida*' adherence and translocation

In the colonization group, the total quantities of *Candida albicans* in intestine were larger on d 3 and 7 after gavage administration, about $(34-39) \times 10^5$ cfu/g, declined to 3.2×10^5 cfu/g on d 14. At the early phase after gavaging the mice, *Candida albicans* was found in the MLN, and then disappeared from day 7 to 14. Adherence also showed a declined tendency from the highest on day 3 to the lowest on d 14.

Proliferation of lymphocyte in PP and LP

BrdU incorporation of PP was found in both control and

colonization group. BrdU-positive cells were mainly at the verge sites of PP; there were no obvious changes in the colonization group compared with that in the control group. On d 14 after gavaging, LP lymphocytes proliferation in colonization group was significantly higher than that in the control mice (Table 1).

IgA plasma cell in LP

IgA plasma cells increased at all times, the highest was on day 14 (Table 1).

Flow cytometry of mucosal sIgA

There was no difference between the control and the colonization group in the level of mucosal sIgA (Table 1).

Specific IgA to *Candida albicans*

Specific anti-*Candida albicans* IgA contents on day 14 in colonization group were higher than that in the control group (Table 2).

Table 2 Specific IgA to *Candida albicans* in intestinal mucus membrane

Group	n	Positive rate	Content (U/mg)
Colonization			
3 d	20	5/20	33±8

14 d	25	10/25	69±25 ^a
Control	19	6/19	18.6±6.9

^aP<0.05 vs control.

DISCUSSION

Candida albicans is an opportunistic pathogen, which could survive in the intestine and keep the balance of body. sIgA prevents the body from some pathogen infection such as typhoid fever and cholera^[5,6], but its role in the balance between opportunistic pathogen and host is not clear yet^[7,8]. So we investigated the relationship between *Candida albicans* colonization and the change of local intestinal mucosal immunity by using SPF mice model, in order to understand the mechanism of the balance. We have found that in the early period of *Candida albicans* colonization, *Candida albicans* adherence was serious, while the specific IgA content was lower. Accompanying the increase of specific IgA to *Candida albicans*, quantity of *Candida albicans* adherence and in the cecum decreased, there was negative correlation between specific IgA and quantity of *Candida albicans* adherence, that is to say that specific IgA was the important factor to keep the balance between opportunistic pathogen and host^[9]. The colonization of *Candida albicans* could elicit a local mucosal immune reaction and finally limit *Candida albicans*' overgrowth^[10,11].

Table 1 Proliferation and differentiation of lymphocytes

Group	Number of BrdU-positive cells sIgA in PP				Number of IgA plasma cells in LP
	n	PP	LP	Positive rates	
Colonization					
3 d	5	75±12	0.30±0.46	7.7±1.2	0.68±0.37
7 d	5	58±20	1.05±1.00	7.7±2.5	0.67±0.54
14 d	5	37±10	3.34±2.35 ^a	ND	1.63±0.52 ^a
Control	5	70±15	0.78±1.04	10.3±1.8	0.35±0.15

^aP<0.05 vs control; PP: Peyer's patch; LP: Lamina propria; IgA plasma cells were counted after immunohistochemical stain as 40 villi/per mice and 5 mice/per time-point.

In the lamina propria, there was B lymphocyte clone that could secrete specific IgA against *Candida albicans*^[12], but the content was very lower. After *Candida albicans* were gavaged, stronger stimulation of *Candidas'* antigen induced specific B lymphocyte clone proliferation and differentiation, while the number of IgA plasma cell increased. Plenty of specific IgA against *Candida* secreted to the surface of intestinal mucus membrane and formed the antibody barrier. sIgA antibodies were thought to provide mucosal defense by immune exclusion^[13]; this refers to their ability to prevent contact between pathogens and epithelial surfaces through agglutination in the intestinal lumen, entrapment of immune complexes in mucus, and clearance by peristalsis. We could draw the conclusion that though *Candida albicans* infection is more common recently, it is possible to prevent *Candida albicans* infection by setting up a specific sIgA antibody barrier in the host.

Abstract

AIM: To assess the value of multidetector-row computed tomography (MDCT) in choosing retreatment methods of hepatocellular carcinoma (HCC) through evaluating the blood supply of low-density area of HCC after transcatheter arterial chemoembolization (TACE).

METHODS: Thirty-two patients with HCC after TACE treatment were examined by plain scanning and hepatic multidetector-row CT. The location of low-density area on plain scanning and the enhancement patterns on dynamic contrast-enhanced scanning were observed. At the same time, three-dimensional CT (3D CT) models of the volume rendering, curved multiplanar reformations, surface shaded display and maximum intensity projection reconstruction of the hepatic artery and portal vein were performed in 6 cases.

RESULTS: In CT plain scanning data, low density areas of 32 cases of HCC after TACE treatment were divided into three types: peripheral, one-side-located and mixed types. In contrast-enhanced CT scans, the blood supply of low-density area was classified into four types: arterial blood supply (20 cases), portal blood supply (5 cases), arterial combined with portal blood supply (5 cases) and poor blood supply (2 cases). In 6 cases, the relationship between the low-density area and branches of hepatic artery as well as portal vein was shown by 3D CT.

CONCLUSION: Hepatic MDCT is an effective method for evaluating the blood supply of low-density area and therapeutic effect of HCC after TACE treatment. Types of blood supply is helpful for the selection of retreatment.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignant neoplasms. In China, HCC was the second cancer

killer in rural areas, and ranked the third in urban areas and 110 000 patients were killed annually, accounting for 40% of the HCC deaths in the world^[1]. The majority of HCC patients are treated with palliative approaches because surgery is sometimes limited by poor liver function. Transcatheter arterial chemoembolization (TACE) has been one of the most common and effective palliative therapies^[2-11]. To evaluate the blood supply types of the low-density area of HCC pretreated by TACE and to explore its value in selecting appropriate retreatment, we studied MDCT and 3D CT image characteristics of 32 HCC cases pretreated with TACE.

MATERIALS AND METHODS

Patients

From January to November 2003, 32 consecutive patients with HCC who underwent TACE (28 men and 4 women, age range 15-61 years, mean age 37 years) were enrolled into this study. The diagnosis of HCC was based on the results of percutaneous needle biopsy ($n=13$) and operation ($n=2$) or test of serum alpha-fetoprotein level in combination with imaging appearance and follow-up images ($n=17$) according to the diagnostic criteria for HCC formulated by Chinese National Association of Anticancer Committee (1990).

TACE

TACE procedure was performed as follows: the focal segmental or sub-segmental artery was detected carefully by celiac arteriography, and variants were excluded by superior mesenteric arteriography and phrenic arteriography. When the tip of the catheter arrived at the appropriate focal artery, one or two anticancer agents were injected, followed by 8-15 mL iodized oil (Huaihai Pharmaceutical Factory, Shanghai, China) injected under fluoroscopic monitoring. Some patients were embolized with a gelatin sponge (1 mm ×1 mm ×10 mm) at the same time. TACE procedures were performed followed by MDCT within 4 to 6 wk.

MDCT

MDCT was performed with an MDCT scanner after TACE within 4 to 6 wk (Sensation16, Siemens Medical System, Germany). Multidetector row helical technique was applied to the scanning in cranial to caudal direction. Plain scanning of the liver was carried out. Then, after injection of the contrast media for hepatic arterial phase and portal venous phase image acquisition, enhanced scanning of 1.5 mm axial section was performed at 25 and 60 s, respectively. A total of 100 mL contrast medium (Ultravist 300, Schering Pharmaceutical Ltd., Guangzhou, China) was administered to each patient at a rate of 3.0 mL/s through a catheter placed in the peripheral vein of the antecubital fossa. Three dimensional CT models including the volume rendering technique, multiplanar reconstruction, shaded surface display and maximum intensity projection of the hepatic artery and portal vein were simultaneously completed in 6 cases.

Diagnostic criteria for low-density area

Diagnostic criteria for low-density area were the CT of 30 to 50 HU on non-enhanced CT.

Determination of low-density area and blood supply types

According to the location in CT plain scan, low-density area was divided into three types. The peripheral low-density area was the viable area around the portion that retained iodized oil. The one-side-located type was determined by the low-density area located in any one side of the lipiodol area. The mixed low-density area showed both peripheral and one-side-located types in which the lipiodol retention in the tumor was heterogeneous.

According to the showing time of low-density area on enhanced CT at biphasic MDCT, blood supply of low-density area was divided into four types. The arterial blood supply of low-density area could be enhanced early during contrast administration (during the hepatic arterial-dominant phase, HAP) as a hyperattenuating or a mixed attenuating area against a background of slightly enhanced liver parenchyma before the liver enhanced substantially from the portal venous delivery of contrast material. Furthermore, the area must be hypoattenuating during the portal venous-dominant phase (PVP). In the same way, the portal blood supplying low-density area could be enhanced during PVP as a hyperattenuating or a mixed attenuating area but hypoattenuating during HAP. If the low-density area was enhanced during both PVP and HAP, the type of arterial combined with portal blood supply was determined. The poor blood supply was defined as non-enhanced on biphasic MDCT.

Image analysis

MDCT of all the patients was retrospectively and blindly reviewed by two experienced radiologists. Image analysis included the presence/absence and patterns of low-density area at non-enhanced examination. After these results were recorded, the HAP and PVP images were reviewed. Lesions were categorized as hyperattenuating or hypoattenuating relative to adjacent liver parenchyma. If lesions exhibited in both hyper- and hypo-attenuating areas, they were categorized as having mixed attenuation.

RESULTS

Appearances and patterns of low-density area

Thirty-two patients with low-density area after TACE were divided into three types: sixteen patients were peripheral type; 5 were one-side location type and 11 were mixed type.

Types of blood supply

The appearances of the low-density area at each phase of imaging are shown in Table 1. According to the appearance of low-density area at biphasic MDCT, the cases of arterial blood supply, portal blood supply, arterial combined with portal blood supply and poor blood supply were 20, 5, 5, 2, respectively.

Table 1 Appearance of low-density area at biphasic MDCT

Phase of imaging	Appearance at MDCT (cases)		
	Hyperattenuating	Hypoattenuating	Mixed attenuating
HAP	17	7	8
PVP	4	22	6

HAP: hepatic arterial-dominant phase; PVP: portal venous-dominant phase.

DISCUSSION

Although surgery remains the best treatment of HCC, it is unsuitable for most of the cases who would be better treated with interventional therapy. However, as the blood supply of

HCC includes regular, variant, extrahepatic and collateral arterial blood supply, the portal vein is involved in some patients^[12,13]. Furthermore, the development of compensatory circulation after the occlusion of hepatic artery and the changes of the portal venous blood supply to tumor after TACE, will both result in incomplete tumor necrosis or recurrence^[14-18].

MDCT is a breakthrough in medical imaging examination technology. Equipped with a multidetector array, MDCT can perform multislice data acquisition simultaneously, which greatly reduces the time of volume scanning. Image quality is improved due to increased image resolution and clarity. MDCT could therefore provide a technique of thin-slice and dynamic enhancement scanning of liver at hepatic arterial phase and portal venous phase. In addition, multiplanar reformations, 3D renderings, and high-quality CT angiographic displays have opened a new vista in clinical applications. Its performance has been improved in several problem-solving tasks and become extremely valuable in image interpretation^[19,20].

The portion of tumor that retains iodized oil is necrotic. Pathologic specimens and the necrosis rate measured from CT image showed a good correlation between the portion of tumor that retained iodized oil and the portion of tumor necrotized. Lipiodol-negative but hypodense areas examined by X-ray proved to be necrotic or fibrotic with or without viable tumor islands. HCC with heterogeneous lipiodol uptake tended to recur at the site adjacent to the original tumors more frequently than HCC with homogeneous lipiodol uptake^[21-23]. HCC images that revealed a dense retention of lipiodol within the whole tumor or revealed no enhancement on contrast enhanced CT had a significantly higher necrotic rate. A lipiodol-negative but hypodense area with enhancement on dynamic MDCT was low-density area^[24-26]. According to the location, we divided it into three types: peripheral, one-side-located and mixed type. According to the time of enhancement of low-density area at biphasic MDCT, blood supply in low-density area was divided into four types: arterial blood supply, portal blood supply, arterial combined with portal blood supply and poor blood supply. The portal venous blood supply was mainly of tumor periphery distribution. After treatment of TACE, the portal venous blood supply to tumor periphery increased significantly, and some did have signs of enriched blood supply around the tumor^[17].

Evaluating the blood supply of low-density area with HCC after TACE has clinical significance in choosing the method and route of retreatment. When MDCT pictures revealed the patient of arterial blood supply type, repeated treatment with TACE was suggested. If it is necessary, subsegmental TACE should be performed because of its superior capability of achieving complete lipiodol accumulation. TACE showed a strong antitumor effect because of the overflow of excess iodized oil into the portal veins^[3]. Therefore, when the low-density area had two blood supply routes of arterial and portal veins, repeated treatment with TACE was also suggested. As portal venous blood supply to the tumor was affected by TACE treatment in portal blood supply group, interventional therapy via portal vein should be reasonable. Percutaneous ethanol injection and other non-vascular interventional therapy could be considered when the low-density area revealed poor blood supply^[27,28].

In short, MDCT plays important roles in evaluating the efficacy of chemoembolization. It is a practical, effective, and safe method for assessing the therapeutic effect of TACE. Evaluation of the blood supply of low-density area in MDCT is of practical significance for making retreatment plans.

Abstract

AIM: To investigate the multiple gene differential expression patterns in human ischemic liver and to produce the evidence about the hepatic ischemic safety time.

METHODS: The responses of cells to hepatic ischemia and hypoxia at hepatic ischemia were analyzed by cDNA microarray representing 4 000 different human genes containing 200 apoptotic correlative genes.

RESULTS: There were lower or normal expression levels of apoptotic correlative genes during the periods of hepatic ischemia for 0-15 min, the maintenance homostatic genes were expressed significantly higher at the same time. But at the hepatic ischemia for 30 min, the expression levels of maintenance homeostatic genes were down-regulated, the expressions of many apoptotic correlative genes and nuclear transcription factors were activated and up-regulated.

CONCLUSION: HIF-1, APAF-1, PCDC10, FBX5, DFF40, DFFA XIAP, survivin may be regarded as the signal genes to judge the degree of hepatic ischemic-hypoxic injure, and the apoptotic liver cell injury due to ischemia in different time limits. The safe limit of human hepatic warm ischemic time appears to be generally less than 30 min.

INTRODUCTION

The safety limit of human hepatic warm ischemic time is closely correlated with the recovery of hepatic function and the patient's prognosis after liver transplantation, serious hepatic injury and hepatectomy^[1-7]. Owing to the development in hepatic surgical operation techniques and perioperative period, numerous experts discovered that the safety limit of human hepatic warm ischemic time could be prolonged further. But the critical problem of what degree the safety limit should be generally controlled is drawing special attention of the whole hepatic surgery. The cell apoptosis we have found now is one

of the main cell death forms influencing visceral functions after the liver got ischemic injury^[8-12]. But because too many genes are involved in cell apoptosis, the expressions in differential ischemic safety time of the main controlling gene influencing the safety limit of human hepatic warm ischemic time remain unclear. For such a reason, by cDNA microarray, we investigated the multiple genes differential expression patterns in human ischemic liver for the purpose of producing some scientific evidence for the hepatic ischemic safety time.

MATERIALS AND METHODS

Tissue specimens

All the tissue specimens in question came from the hepatic tissues contributed by the unconscious patients dying of external brain injury whose other organic functions were normal (Table 1). Each group consisted of 5 specimens. The specimens were immediately stored in liquid N₂ after resection. All contributors had no hepatic disease, and the liver function remains normal before resection. The liver tissue construction was proved normal by pathologic examinations.

Table 1 Group division of tissue specimens

Group	Experiment group	Control group
Group 1	15 min ischemic tissue	Normal liver tissue
Group 2	30 min ischemic tissue	Normal liver tissue
Group 3	30 min ischemic tissue	15 min ischemic tissue

Chemicals and materials

TriZol and Script II reverse transcriptases were bought from American Life Technologies, Ltd. cDNA microarray containing 200 apoptotic correlative genes and biochip hybridization kit were from Shanghai Biotstar Gene chip, Ltd.

Total RNA extraction

Total RNA was extracted from human liver tissues in each group following the single step extraction (see details in the manual).

Probe preparation and hybridization

An equal volume of RNA was extracted from each group and 60 µg RNA was added into 50 µL reverse transcription system. The experiment group was labeled with Cy5-d CTP and the control group with Cy5-d CTP (see the way of labeling in the manual of the test kit). The chip was denatured and prehybridized for one time in advance. After denatured at 95 °C for 5 min, the probe mixture was added on the microarray and covered with a hyi slip. The slide was then placed in a constant temperature hybridization chamber for hybridization at 42 °C for 20 h. After hybridization, slides were washed 10 min in each of 2×SSC with 2 g/L GSDS, 0.1×SSC with 2 g/L GSDS, 0.1×SSC, then dried at room temperature. The hybridization in each group was replicated 3 times.

Fluorescent scanning and analysis

The chip was scanned by GenePix 4000B laser scanner at

2 wavelengths. The acquired image was analyzed by GenePix Pro 3.0 software. The intensity of each spot at the 2 wavelengths cut off the additional background signal represented the quantity of Cy3-dUTP and Cy5-dUTP respectively. Each ratio value of Cy3 to Cy5 was computed. The 2 overall intensities were normalized by a coefficient according to the ratio of the located 88 housekeeping genes, 43 negative control genes, 45 positive control genes and 3 blank locations. We defined two standards to screen out each differentially expressed gene. The ratio value >2 represented the level of the gene expression elevated significantly, the ratio value <0.5 represented the level of the significantly depressed gene expression. The data about the genes whose ratio value >2 or <0.5 were screened out in the comparisons of normal control group with 15 min ischemic group or 30 min ischemic group, then the variation of the ratio value was observed in the comparison of 15 min ischemic group with 30 min ischemic group and each “ ± 0.5 ” change in the ratio value was set as a “+”. All the data were input in the datasheet, and the biological functions of the target genes were analyzed.

RESULTS

Comparison of differential gene expressions between 15 min ischemic group and normal control group

Figure 1 (A and B) shows that the double-colored fluorescent labels in 15 min ischemic group and normal control group were overlapping. A total of 41 differentially expressed genes were identified by cDNA chip between the 15 min ischemic group and normal control group. Among them the ratio values of 33 genes were <0.5 , consisting of 22 genes correlated directly with cell apoptosis regulation, 9 congenic genes of stress-response protein relevant to cell apoptosis, and 3 genes correlated to metabolism regulation, 1 correlated to cell circle regulation, 1 correlated to the cell interpretation and synthesis. In the meantime, there were 8 differential expression genes whose ratio values were >2 , mainly about P43=mitochondrial elongation factor homolog (GenBank-ID: S75463), human ribosomal protein *S14* gene, complete cds (GenBank-ID: humrps 14), *H. sapiens* mRNA for squalene synthase

(GenBank-ID: hssqusyn), human sodium/potassium ATPase beta-2 subunit (atpb2) mRNA, complete cds (GenBank-ID: humatpbii), *H. sapiens* mRNA for H⁺-ATP synthase subunit b (GenBank-ID: hsatpsyn), and no gene relevant to apoptosis was highly expressed.

Comparison of differential gene expressions between 30 min ischemic group and normal control group

Figure 1 (C and D) shows that the double-colored fluorescent labels in 30 min ischemic group and normal control group were overlapping. A total of 9 differentially expressed genes were identified by cDNA chip between the 30 min ischemic group and normal control group. The ratio values of 3 genes of which were <0.5 , consisting of 2 genes correlated directly with cell apoptosis regulation (the congenic genes of survivin, AB028869 and X-linked inhibitor apoptosis protein, u45880 respectively), and 1 congenic gene (GenBank-ID: af004711) of TPKC1. In the meantime, there were 6 differential expression genes whose ratio values were >2 , of which 3 were the regulation genes correlated directly with cell apoptosis: APAF1 (GenBank-ID: NM-001160), PDCD10 (GenBank-ID: NM-007210) and an unnamed gene (GenBank-ID: AL031714), 1 was the congenic gene (GenBank-ID: AF050127) of HIF1, the functions of last 2 genes' were not clear.

Comparison of differential gene expressions between 15 min ischemic group and 30 min ischemic group

In the 200 genes, 35 genes were not expressed at the two time limits. The expressions of 167 genes in 30 min ischemic group differed from in 15 min ischemic group. One hundred and nineteen genes were expressed following the rising tendency, of which ratio values of 7 genes were $>“+++”$, 19 $>“++”$, 39 $>“+”$, and 55 genes only expressed the rising tendency but their ratio values were $\leq “+”$. There are 46 genes following the descending tendency, of which ratio values of 4 genes were $>“+++”$, 5 $>“++”$, 12 $>“+”$, and 25 genes only expressed the descending tendency but their ratio values were $\leq “+”$. In addition, 16 genes were expressed in 30 min ischemic group, but not in 15 min ischemic group, of which 11 genes were

Figure 1 Double-colored fluorescent labels and scattered diagram of signal intensity of differential gene expressions in 15 min ischemic group and normal control group. Green: Down-regulation, Signal of cy3 is stronger; Red: Up-regulation, signal of cy5 is stronger. A, C: Double-colored fluorescent labels: In 15 min ischemic group and normal control group; B, D: Scatter diagram of signal intensity of differential gene expressions in 15 min ischemia group and normal control group.

correlated directly with cell apoptosis regulation, 5 genes were expressed in 15 min ischemic group, but not in 30 min ischemic group, of which only 1 gene was correlated directly with cell apoptosis regulation, namely XIAP (GenBank-ID: u45880).

DISCUSSION

Our data suggested that the apoptosis regulation gene at the hepatic ischemia for 0-30 min presented following features.

In hepatic ischemia for 0-15 min, the apoptosis regulation gene was expressed low or normally. The differentially expressed genes whose ratio values were >2 (namely, they were expressed following the rising tendency) were mainly the maintenance harmonious genes, such as genes regulate P43=mitochondrial elongation factor homolog (GenBank-ID: S75463), Human ribosomal protein S14 gene (GenBank-ID: humrps), *H. sapiens* mRNA for squalene synthase (GenBank-ID: hssqusyn), Na^+/K^+ -ATPase activity α subunit (GenBank-ID: hsatpar) and β subunit (GenBank-ID: humatpbii), H^+ -ATPase activity (GenBank-ID: hsatpsyn). But they were not highly expressed with the congenic genes correlated directly with cell apoptosis regulation.

In hepatic ischemia for 15-30 min, the expression of apoptosis regulation genes changed greatly. One hundred and nineteen genes were expressed following the rising tendency, of which 59 genes were relevant to the apoptosis regulation. Although some anti-apoptosis genes [such as the congenic gene of *bcl-2* (GenBank-ID: AJ006288), the congenic gene of inhibitor apoptosis protein IEX-IL (GenBank-ID: AF071596)] which were expressed the low level, the majority of the higher expressed genes were the apoptotic genes, for example, the congenic gene of apoptotic protease activating factor-1 (APAF-1, GenBank-ID: NM-001160); Homo sapiens F-box protein 5, FBX5 (GenBank-ID: NM-012177); DNA fragmentation factor, 40 ku, subunit, DFF40 (GenBank-ID: AF064019); DNA fragmentation factor, 45 ku, alpha subunit, DFFA (GenBank-ID: NM-004401); p53-induced protein; PIG11 (GenBank-ID: NM-006034). Especially, APAF-1 was the only known human homologue of CED-4 and the nuclear element in the formation of apoptosis body^[13-16]. Now it is thought as the key element regulating cell apoptosis, and the ratio value of its expression in 30 min hepatic ischemia was an additional “+++” than that in 15 min hepatic ischemia. Meanwhile the ratio value of the congenic gene of PDCD10 (GenBank-ID: NM-007217) was also “++”. The significant rising of expression of the apoptotic genes showed that the unavoidable cell death after serious ischemic injury was a key expression of the serious cell injury. In 15 min hepatic ischemia, the congenic gene of the important X-linked inhibitor apoptosis protein, XIAP (GenBank-ID: u45880) changed from the normal expression to non-expression, following the obvious descending tendency. Compared with the normal group, the expression of the survivin congenic gene (GenBank-ID: AB028869) descended greatly with the ratio value <0.5 . The codogenic genes (GenBank-ID: S75463, humrps, hssqusyn, hsatpar, humatpbii, hsatpsyn and so on) relevant to the internal circumstance and the organelle functions were expressed obviously in the period of 0-15 min hepatic ischemia, but in 15-30 min period their expression descended to “+”- “++”. The congenic gene of human hypoxia-inducible factor 1 HIF-1 alpha gene (GenBank-ID: AF050127) was expressed apparently (increased to “+++”). Lots of the regulation genes of nucleus translation factors were expressed notably for example, the codogenic gene of EIF4G2 (eukaryotic translation-induction factor 4 gamma, 2 (EIF4G2) mRNA, GenBank-ID: NM-001418), NF- κ B family, TNF receptor associated factor 6 (TRAF6) responsible for the existence and death of cells (GenBank-ID: hsu78798), increased to “++”. The latter was a transmission factor

participating in IL-1 signal transmission and activating the signal transmission about apoptosis of the nuclear factor NF- κ B^[17-20].

The data suggested that in 0-15 min hepatic ischemia, the gene regulation model inside of the cells was likely to better and maintain the harmonious of the internal circumstance to keep the wholeness of cell and organ functions even by controlling ion channel and organelle functions. At the same time, although acute ischemic-hypoxic injury changed the structure and functions of cells, the expression of each kind of genes relevant to apoptosis, according to the analysis of the level of gene regulation, remained on the low level, that is to say, the occurrence of apoptosis was not a main direction yet. With the time of ischemia and hypoxia passed, when hepatic ischemia lasted for 30 min, acute ischemic-hypoxic injury perhaps would lead to the significant rising of HIF-1, and the cell gene expression model responsible for the existence or death of the cells also was changed completely. The expressions of all kinds of regulation genes maintaining cells and the internal cellular circumstance descended obviously, while NF- κ B and many genes relevant to apoptosis were activated evidently and notably expressed. Therefore, it is suggested that cell death is unavoidable when hepatic ischemia lasts for 30 min. It is true that some experts deduced that the time of the human hepatic ischemia could be prolonged beyond the safe limit according to clinical experience in the progress after liver operation. Yet when dynamic changes of gene expressions after liver suffered ischemic injury are analyzed, it is suggested that the safe limit of one time hepatic ischemia should be less than 30 min, namely, when key death genes such as *APAF-1*, *PDCD10*, *FBX5*, *DFF40*, *DFFA* are activated evidently and expressed significantly, and before the obvious descending of inhibitor apoptosis genes such as XIAP, survivin. In the meantime it is suggested that HIF-1, APAF-1, PCDC10, XIAP, survivin may be regarded as the signal gene to judge the degree of hepatic ischemic-hypoxic injury, and the apoptotic liver cell injury due to ischemia in different time limits.

Abstract

AIM: To investigate the therapeutic value of liver transplantation for advanced hepatocellular carcinoma (HCC).

METHODS: Twenty-eight patients with advanced HCC were treated by liver transplantation from August 2000 to October 2003 at Peking University Third hospital. All the patients were followed up to evaluate the result.

RESULTS: The longest follow-up duration was 3 years and 3 mo. Till the end of the follow-up period, 17 patients had already died and 11 were alive. Of those who died, 10 patients died of tumor recurrence, 4 died during the perioperative period, 2 died of variceal bleeding, and 1 died of biliary complication. According to life table method, the 1-, 2-, and 3-year survival rates were 87.5%, 52.5%, and 42.9%, respectively.

CONCLUSION: Liver transplantation provides a new treatment under the circumstance of lacking of an effective treatment for advanced HCC at present. Some patients can survive for a relatively long time free of tumor. In our country, if the patients can afford liver transplantation, advanced HCC without extrahepatic metastasis is an indication for liver transplantation at present.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a common malignant tumor in China. The methods of treatment for advanced HCC are limited, and the prognosis is so poor. Peking University Third Hospital began to carry out liver transplantation since August 2000. Some of the patients suffered from advanced HCC. In our study, the result of treatment has been found to be somewhat accepted at present.

MATERIALS AND METHODS

Materials

Twenty-eight patients with advanced HCC were treated by liver transplantation from August 2000 to October 2003 at our

hospital. Of them, twenty-six patients were male. The average age was 46.3 years, ranging from 20 to 63 years. All the patients suffered from cirrhosis caused by hepatitis B. Child-Pugh classes A, B, and C patients were 13, 8, and 7, respectively. The diagnosis was made by ultrasound, computed tomography, magnetic resonance imaging, arteriography and serum alpha-fetoprotein levels. Postoperative pathologic examination confirmed that all the patients had HCC. The patients with extrahepatic spread were excluded by ultrasound, chest film and bone scan. All the patients met the following criteria: solitary tumor ≥ 5 cm or with multiple nodules and total diameter > 8 cm; and the mean diameter of single nodule was 10.3 cm, ranging from 3 cm to 20 cm. There were 12 patients with tumor involving bilateral hepatic lobes, 5 with positive porta hepatis nodes, and 18 with portal invasion.

Methods

All the patients underwent orthotopic liver transplantation (OLT) and were taken care of by the same medical team perioperatively. The donors were healthy male who had brain death with the age of 20-40 years. The initial 11 patients did not undergo formal chemotherapy postoperatively, and only the eighth patient underwent transarterial chemoembolization preoperatively (hot lipiodol 10 mL and cisplatin 100 mg). Seventeen patients underwent the formal intravenous chemotherapy postoperatively when the hepatic function was normal. The chemotherapy regime was: administration of adriamycin 40 mg, cisplatin 60 mg, calcium folinate-SF 200 mg and 5-Fluorouracil 1 000 mg on the first day, the same doses of calcium folinate-SF and 5-Fluorouracil from the second day to the fifth day. The course of chemotherapy was 5 d once a month, and there were 6 courses altogether. All the patients were followed up and the longest duration was 3 years and 3 mo.

Statistics

The survival rate was calculated according to the life table method. Patients who died of non-tumor and who stopped the follow-up in the intervals were listed into the lost.

RESULTS

Till the end of the follow-up period, 17 patients had already died, and 11 were alive. Of those dead patients (Table 1), 10 patients died of tumor recurrence, 4 died within perioperative period, 2 died of variceal bleeding, and 1 died of biliary complication. Among the patients who survived (Table 2), there were 1, 2, 2, and 3 patients survived for 8 mo, 1, 2, and 3 years free of tumor, respectively; and there were 1 and 2 patients survived for 8 mo and 1 year with tumor-recurrence, respectively. In the first year, 8 patients were lost, 3 were dead, and the 1-year survival rate was 87.5%. In the second year, 4 patients were lost, 6 were dead, and the 2-year survival rate was 52.5%. In the third year, 3 patients were lost, 1 was dead, and the 3-year survival rate was 42.9%.

Of the patients with single tumor of more than 10 cm, there was 1 patient who survived for more than 3 years. No patients with tumors involving many hepatic lobes could survive for more than 3 years, but there were 2 patients survived for more

than 2 years. There was 1 patient with positive portal lymph node survived for more than 3 years. Of the patients with portal invasion, 2 survived for more than 3 years, and 3 survived for more than 2 years. The cases were divided according to the different standards, and their survival time can be seen in Table 3.

DISCUSSION

Among the surgical therapies of HCC, the dominant treatment is hepatic resection. A study showed that the 5-year survival rate is up to 50% after hepatic resection^[1]. But HCC always occurs in the presence of liver cirrhosis, hepatic resection is limited by the poor hepatic function and the presence of portal hypertension. In general, Child's C stage is considered an absolute contraindication for any type of resection^[1].

According to the principle of tumor surgery, replacing an allograft after total hepatectomy is an ideal curative resection of HCC^[2]. Herrero *et al.* reported that in the patients with solitary HCC nodule less than 6 cm and those with 2-3 HCC nodules less than 5 cm in diameter, 1- and 3-year recurrence free survival rates were 87% and 79%, respectively^[3]. In the study by Yao *et al.*^[2], patients with HCC meeting the following criteria: solitary tumor ≤ 6.5 cm, or ≤ 3 nodules with the largest lesion ≤ 4.5 cm and total tumor diameter ≤ 8 cm, had survival rates of 90% and 75.2%, at 1 and 5 years after OLT, respectively. So they concluded that the current criteria for OLT based on tumor size might be modestly expanded while preserving excellent survival. Since OLT for early HCC is not fit for the situation of our country as well as the economic status, and the result of hepatic resection is good in our country, OLT is not accepted by the patients except that the patients having early HCC with serious cirrhosis can not tolerate hepatic resection.

The diagnosis of early HCC is achieved in around 30% of the cases^[4]. As to the unresectable HCC, the chief therapy is a

non-surgical treatment. But it always leads to poor prognosis for it is not a curative treatment. Now the generally accepted non-surgical treatment is transarterial chemoembolization. Lo *et al.* undertook a randomized controlled trial of transarterial chemoembolization for unresectable HCC^[5]. The patients were excluded if they had 1 or more of the following criteria: poor hepatic function (presence of hepatic encephalopathy, ascites not controlled by diuretics, history of variceal bleeding within last three months, a serum total bilirubin level over 50 $\mu\text{mol/L}$, a serum total albumin level below 28 g/L, or a prothrombin time of more than 4 s over the control); extrahepatic metastasis; main portal vein thrombosis *etc*^[5]. The chemoembolization group underwent transarterial chemoembolization, and the control group received only treatment for symptoms and complications. The estimated 1-, 2- and 3-year survival rates were 57%, 31% and 26% for the chemoembolization group, and 32%, 11%, and 3% for the control group, respectively.

There is no effective therapy for the patients with advanced HCC who do not meet the chemoembolization criteria, such as poor hepatic function and/or portal thrombosis, and they have poor prognosis even if there is no extrahepatic spread when the diagnosis of HCC is made. In the initial stage of OLT, the patients with advanced HCC were also treated by OLT in abroad, and the 3-year survival rate was 20-30%^[1]. Due to the poor prognosis and the shortage of donor, OLT for advanced HCC was abandoned in foreign countries. From the year of 2000, our hospital began to perform OLT and chose advanced HCC for the initial trial just as peers at home and abroad. Till now, 28 patients with advanced HCC underwent OLT at our hospital. We can not conclude that the result is excellent through the 3-year follow-up. Many patients who underwent OLT did not meet the chemoembolization criteria, but the total survival rate was higher than that of the chemoembolization group reported by Lo *et al.* Some patients survived for a relatively long time free of tumor after OLT. Thus, liver transplantation provides a new treatment under the circumstance of lacking of an effective treatment for HCC at present, and some patients have a chance to lengthen their lives. But the expense of liver transplantation is very high. In our country, if the patients can afford liver transplantation, advanced HCC without extrahepatic metastasis is an indication for liver transplantation at present.

Abstract

AIM: To investigate the clinical features, diagnosis, treatment and prognosis of multiple primary colorectal carcinomas (MPCC).

METHODS: A retrospective analysis of 37 patients with MPCC from 1974 to 1998 was carried out.

RESULTS: The incidence of MPCC was 2.74%(37/1 348) in patients with primary colorectal carcinomas, 15 cases of them were patients with synchronous carcinomas (SC) and 22 cases were diagnosed as metachronous carcinomas (MC). Most tumors were located in the right colon and rectum. Fifty-five percent (12/22) of MC were diagnosed within 3 years after tumor resection and 41%(9/22) of MC occurred after 8 years. Radical resections were performed in all patients except for 1 case. The 5-year survival rate of SC was 72.7%(8/11) and that of MC after the first cancer and second cancer was 71.4%(15/21) and 38.9%(7/18), respectively.

CONCLUSION: The results indicate the importance of complete preoperative examination, careful intraoperative exploration and periodic postoperative surveillance. Early diagnosis and radical resection can increase survival rate of MPCC.

INTRODUCTION

Multiple primary colorectal carcinoma (MPCC) refers to two or more primary colorectal carcinomas detected in a single individual simultaneously or consecutively. It is named synchronous carcinoma (SC) and metachronous carcinoma (MC) respectively. The prognosis of colorectal carcinoma is good compared with other carcinomas of the digestive organs. Along with increasing incidence of colorectal carcinomas and prolonged survival after radical resection, patients with MPCC have increased gradually. Generally, SC does not affect prognosis if it is recognized and treated in time, but if ignored, it may turn into more advanced MC. Therefore, after colorectal cancer surgery, occurrence of metachronous carcinoma is

regarded as an serious problem^[1]. Due to influence of doctor's recognition degree, missed and error diagnosis or inaccurate treatment appears frequently. The purpose of this review was to discuss the prevalence, preoperative diagnosis, postoperative follow-up and survival, in order to strengthen the acquaintance of MPCC.

MATERIALS AND METHODS

A total of 1 348 cases of primary colorectal carcinomas were treated at the Department of Surgery, Beijing Cancer Hospital from January 1, 1974 to December 31, 1998. MPCC was diagnosed according to the following criteria proposed by Moertel^[2]. Each tumor must have a definite pathologic picture of malignancy, metastasis or recurrence from another colorectal cancer was excluded, all cancers detected at the same time or within 6 mo were defined as SC, otherwise as MC, Tumors must be distinctly separated by at least 5 cm of an intact bowel wall from each other. MC must be more than 5 cm away from the normal anastomotic site of index cancer resection. MPCC originated from familial colonic polyposis or ulcerative colitis was excluded^[2].

Tumor locations were divided into 3 groups: (1) right colon which included appendix, cecum, ascending colon, hepatic flexure, and transverse colon; (2) left colon which included splenic flexure, descending colon and sigmoid colon; (3) rectum, upper boundary of which was 15 cm from the dentate line. It was considered as lost follow-up if a patient failed to come back to the Outpatient Department or could not be contacted by letter or telephone for more than one year.

Independent *t*-test and χ^2 -test were used to compare the factors in different groups. A *P* value less than or equal to 0.05 was considered statistically significant.

RESULTS

A total of 1 348 patients with colorectal carcinoma were treated during 25 years period. Fifteen cases had 2 SCs and 22 patients had 2(20 cases) or 4(1 case) or 5(1 case) MCs, respectively (Tables 1 and 2). No significant differences were noted among the groups in age and gender. The second MC appeared in 8-240 mo (mean: 68 mo), 55%(12/22) were diagnosed within 36 mo and 41%(9/22) after 96 mo. The interval of other one patient was 45 mo. Two patients had three times of MC, their interval was 15 years (one cancer), 19 years (two cancers) and 12 years (one cancer), 17 years (three cancers) respectively.

The distribution of MC and SC is shown in Table 2. Lesions were located at the adjacent intestinal segment in 6 of SC group (43%). In MC group, 20 patients had 2 lesions, 1 had 4 lesions and the other one had 5 lesions.

The clinical presentation was variable. All the 15 patients in SC group went to see doctors because of symptoms, such as bloody stool, abdominal pain, diarrhea, anemia and abdominal mass. The time of the development symptoms was more than 1 year. Thirteen cases (87%) were diagnosed by barium enema and/or colonoscopy before operation. And 2, 9 and 2 patients were staged as Dukes B, C and D, respectively. Other 2 patients of this group were diagnosed intraoperatively. In MC group,

3 of 22 cases (13.6%) were proved by routine postoperative colonoscopy (2: Dukes A, 1: Dukes B). Twenty-one patients went to see doctor owing to symptoms, 18(86%) were diagnosed preoperatively, 2 were diagnosed intraoperatively, and 1 was diagnosed by postoperative pathology.

Operation was the primary option. In SC group, 14 cases (93%) received radical resection. Among them, 5 cases received subtotal colectomy in combination with rectoileostomy, others received radical resection or combined radical resection of adjacent loop according to the cancer locations. One received by-pass due to severe local spread. In MC group, all the 22 cases with index cancer received radical resection. All secondary or third lesions except one underwent radical resection.

The histological types of all cancers are shown in Table 2. No significant differences were noted between the second cancer and SC with index cancer. There was a significant difference between the third cancer and index cancer.

The 5-year and 10-year survival rates are shown in Table 2. There was no significant difference between SC and index cancer of MC. The 5-year survival rate of the patients with secondary cancer could reach 39% after operation.

Table 1 Age and gender of patients with MPCC

	Group SC	Group MC
Number of patients	15	22
Age(yr)		
mean±SD	47±12	48±12
Range	27-71	30-68
<i>P</i> value		>0.1
Gender		
Male	11(73%)	16(73%)
Female	4(27%)	6(27%)
<i>P</i> value		>0.1

All statistical comparisons were with index cancer of MC by independent *t*-test or χ^2 -test.

DISCUSSION

MPCC is not uncommon in clinic. The estimated incidence rates

of SC and MC were 2.0-8.1% and 0.6-10.6% respectively^[3-10]. Such a significantly different result of these series may be due to several reasons. For example, the definition varied to allow diagnosis of a second carcinoma at a range of 6 mo to 3 years after the diagnosis of the index tumor. The patient number, observation period and follow-up time all could influence the final results. Bulow *et al.*^[9] followed up 501 patients younger than 40 years old with colorectal carcinoma for up to 41 years. In the first 10 years, only 12 cases developed MC. Since then, another 32 patients had developed MC in succession. Cali *et al.*^[1] reported that the calculated incidence for MC was 0.35 percent per year and the cumulative incidence at 18 years was 6.3 percent according to a group of 5 476 patients. In another larger group of 141 945 patients with histologically confirmed primary colorectal tumors within 14 years (mean follow-up of 4.72 years), 3 402(2.4%) and 1 526(1.1%) cases were diagnosed with SC and MC respectively^[8]. In our study, the incidence of MPCC was 2.74%(37/1348). The reported data showed that the occurrence of MPCC had a rising trend^[11].

Chen *et al.*^[12] reported that there was no difference in age of patients with SC, MC and single colorectal carcinoma. Oya *et al.*^[13] found the index lesions of synchronous cases did not differ from single lesions in age, size, differentiation, and location. However the male: female ratio was higher and distant metastasis was more frequent in synchronous cases than in single cases. Welch^[14] found that patients with synchronous tumors were older than those with single colon cancers or initial metachronous lesions. Our results showed that patients with SC or MC had similar age, gender, and location.

The time intervals between the diagnosis of index and metachronous cancers varied obviously. Kiefer *et al.* showed that early metachronous cancers (within 2 years) reached 40%^[15]. But others^[8] considered the “early” MC as an overlooked SC. The interval of MC could reach 41 years after the first tumor. Welch^[14] pointed out that the median interval between metachronous tumors was 9 years. The symptom duration was shorter before discovery of the second metachronous tumors. The occurrence of the second MC was 55% within 3 years and 41% after 8 years from index cancer resection in our series. The longest was 20 years. Therefore, early follow-up examination (within 3 years) was very important.

Table 2 Location, types, and survival rate in two groups

	MC			SC
	Index cancer	2nd cancer	3rd cancer	
No. of tumors	22	22	5	30
Location				
Right colon	9(41%)	7(32%)	2(40%)	7(23%)
Left colon	7(32%)	8(36%)	2(40%)	15(50%)
Rectum	6(27%)	7(32%)	1(20%)	8(27%)
<i>P</i> value		>0.1	>0.1	>0.1
Types				
AC	20(91%)	19(86%)	3(60%)	18(64%)
Mucoid AC	2(9)	1(5)		7(25)
Canceration		1(5%)	2(40%)	3(11%)
(Adenoma/Polypus)				
Ring cell C		1(5)		
<i>P</i> value		>0.1	<0.01	>0.05
Survival Rate				
5-yr	71%(15/21)	39%(7/18)		73%(8/11)
10-yr	53%(10/19)	19%(3/16)		63%(5/8)
<i>P</i> value				>0.1

A: Adenoid; C: Carcinoma. All statistical comparisons were with index cancer of MC by independent *t*-test or χ^2 -test.

The preoperative detection of SC not only can allow an appropriate surgical strategy to be carried out but also establish a logical policy for follow-up. It is stressed that a second tumor may present in large intestine during follow-up. Barium enema and/or colonoscopy should be given to patients in time. Examinations such as B-ultrasound, CT scan, CEA, fecal occult blood and fecal occult albumin may help to improve diagnosis, especially SC preoperatively. CEA, fecal occult blood and fecal occult albumin test were also used to detect the early stage colorectal cancer during mass screening for asymptomatic or follow-up for high risk populations^[16]. However, many results were still unsatisfactory^[5,12,17]. Finan *et al.*^[5] diagnosed only 42% of 59 SC patients preoperatively. Chen *et al.*^[12] reported that 66%(31/47) of SC were omitted during preoperative barium enema (46 patients) and/or colonoscopy (7 patients). But other report^[18] showed that the sensitivity of colonoscopy reached 76.7%(56/73) for detecting SC and 82%(14/17) of missed lesions were smaller than 1 cm polyps. In our group, although preoperative diagnostic rate of SC reached 87%, but 85% were Dukes C or D. The reason why multiple lesions could not be identified preoperatively was that the occluded distal lesions made it difficult to detect the proximal lesions. Therefore, we could not be satisfactory for diagnosis of one colorectal cancer and should examine the whole large bowel carefully pre- or postoperatively.

It is important to palpate the whole colon and to check pathological specimens carefully before the end of operation so that misdiagnosis of SC can be avoided. Even now, misdiagnosis is still existed. Chen's report^[12] showed that there were still 13 patients without detection of SC by operative palpation in the 31 preoperative undiagnosed cases. Intraoperative colonoscopy should be advised if necessary. We think that this technique should not be used as a routine one and could be performed early (within 6 mo) after surgery.

It is an effective measure to follow up with barium enema or colonoscopy periodically for diagnosing MC earlier. A previous report^[9] showed that surveillance colonoscopy once every three years after surgery, together with a fecal occult blood test, would be an efficient and appropriate way to detect MC. Some nonfamilial colorectal cancers have been reported to have microsatellite instability (MSI)^[19-23]. A research^[19] indicated the incidence of MC in MSI-positive group was significantly higher than that in MSI-negative. Logical analysis showed that MSI and coexistence of adenoma were significantly independent risk factors for the occurrence of MC. Studies^[20,21] showed the analysis of MSI and testing for replication errors at microsatellite loci in tumors might be helpful in predicting the development of MC in sporadic carcinomas of the distal colon and rectum. Others^[10,24] discovered the significant risk factor for developing MC was the presence of synchronous adenoma or carcinoma at the initial operation and the subsequent development of recurring metachronous adenomas. Therefore, colorectal cancer patients with MSI-positive and coexistence of adenoma should be given more rigorous surveillance. Togashi^[25] monitored 341 colorectal cancer cases with colonoscopy about 4.6 times in 6.2 years after operation. Twenty-two MCs were detected in 19 cases (5.6%), of these 17 MCs (77%) were less than 1 cm, 14 MCs (64%) occurred within 5 years and 71%(10/14) were early stage cancers. In our study, 12 MCs (55%) were diagnosed in 3 years, 3 MCs were discovered by routine colonoscopy (Dukes A: 2 patients, Dukes B: 1 case) and 9 MCs were diagnosed after the development of symptoms (Dukes B, C, D: 3, 2, 4 respectively). These results might prove that colonoscopy was important after surgery. We suggest that regular postoperative colonoscopic examinations should be performed annually during the first 5 years, then once every 3 years.

The treatment of SC or MC is the same as single colorectal carcinoma, with removal of enough intestines and cleaning of

local lymph node. It is suggested that subtotal colectomy with rectoileostomy should be performed for patients with far apart SC, combined with multiple adenomatoid polyps or a familial hereditary history if their general condition suits for operation. Fajobi *et al.*^[7] recommended that SC in different lymph drainage areas seemed a justifiable indication for subtotal colectomy. Easson *et al.*^[26] considered multiple colon cancer was an important factor for performing subtotal colectomy. While subtotal colectomy could eliminate the need for colonoscopic surveillance, however examining the rectum is still required.

Generally speaking, MPCC develops slowly and their prognosis is acceptable. Chen^[12] reported that the 5-year survivals of patients after radical resection for MPCC did not differ from that of patients with single colorectal cancer. The incidence rate was 54%, 60%, and 62% for "single", SC, MC respectively. Other reports^[8,27] displayed similar conclusions. Adloff^[3] found patients with SC or single lesions had similar 5-year survival, even when classified by Dukes' stage. Rennert *et al.*^[8] reported that survival time of patients with the second tumor in the rectum was shorter than that of a single tumor in the same stage and site. Only the stage of the second tumor was found to influence survival time of patients with metachronous tumors. Welch's result^[14] was quite worse. The overall uncorrected 5-year survival rate of MPCC was only 21 percent. In our study, there was no significant difference between SC and index cancer of MC in the 5-year or 10-year survival rate. The 5-year survival rate could reach 39% after second cancer resection. We consider early diagnosis with complete preoperative examination; careful intraoperative exploration and periodic postoperative surveillance and radical resection can increase the survival time of patients with MPCC.

Abstract

AIM: To investigate the effects and mechanism of *d*-limonene on the growth and metastasis of gastric cancer *in vivo*.

METHODS: Metastatic model simulating human gastric cancer was established by orthotopic implantation of histologically intact human tumor tissue into gastric wall of nude mice. One percent *d*-limonene was orally administered at dose of 15 ml/kg every other day for seven weeks. Eight weeks after implantation, tumor weight, inhibition rate, apoptotic index (AI), microvessel density (MVD), vascular endothelial growth factor (VEGF), variation of ultrastructure, and the presence of metastasis were evaluated, respectively, after the mice were sacrificed.

RESULTS: The tumor weight was significantly reduced in 5-FU group (2.55 ± 0.28 g), *d*-limonene group (1.49 ± 0.09 g) and combined treatment group (1.48 ± 0.21 g) compared with the control group (2.73 ± 0.23 g, $P < 0.05$). In 5-FU group, *d*-limonene group, combined treatment group, the inhibition rates were 2.60%, 47.58% and 46.84% and 0, respectively; AI was (3.31 ± 0.33), (8.26 ± 1.21), (20.99 ± 1.84)% and (19.34 ± 2.19)%, respectively; MVD was (8.64 ± 2.81), (16.77 ± 1.39), (5.32 ± 4.26) and (5.86 ± 2.27), respectively; VEGF expression was (45.77 ± 4.79), (41.34 ± 5.41), (29.71 ± 8.92) and (28.24 ± 8.55), respectively. The incidences of peritoneal metastasis also decreased significantly in 5-FU group (77.8%), *d*-limonene group (20.0%) and combined group (22.2%) compared with control group (100%) versus 62.5%, 30% and 22.2% ($P < 0.05$). Liver metastasis was also inhibited and the incidences decreased significantly in 5-FU group, *d*-limonene group and combined group than that in control group (87.5% vs 55.5%, 20.0% and 22.2% respectively) ($P < 0.05$). The incidence of ascites in control group, 5-FU group, *d*-limonene group and combined group was 25.0%, 22.2%, 0, 0, respectively and 12.5%, 11.1% 0, 0, with respect to the metastasis rate to other organs.

CONCLUSION: *d*-limonene has antiangiogenic and proapoptotic effects on gastric cancer, thereby inhibits tumor growth and metastasis. Combination of *d*-limonene with cytotoxic agents may be more effective.

INTRODUCTION

d-limonene is a monoterpene compound. In recent years, it was used for prevention and cure of various animal tumor models induced by chemical carcinogen and was proved to have anti-cancer activities^[1-7]. Our previous study also suggested that *d*-limonene can inhibit the growth of human gastric cancer cell *in vitro* through a mechanism of inducing the apoptosis of tumor cells^[8]. To make a further understanding of the anti-cancer effects and mechanism of *d*-limonene *in vivo*, an orthotopic transplantation model of gastric cancer in nude mice was employed. The *d*-limonene emulsion was administrated to investigate its inhibition effects on the growth and metastasis of gastric cancer dynamically, which will be the theoretical basis for the clinical application of *d*-limonene.

MATERIALS AND METHODS

Materials

Experimental animals Forty male BALB/c nu/nu nude mice, purchased from Chinese Medical University, were raised under the SPF (specific pathogen free) condition for a week to adapt the surroundings before the initiation of the experiment.

Tumor tissues Gastric cancer cell line BGC-823 was obtained from Cell Research Institute (Shanghai, China). A 0.2 mL of cell suspension (2×10^6 cells) was subcutaneously injected into the anterior axilla of nude mice to form the entity of cancer. When the tumor grew to a diameter of 2-2.5 cm, the mouse was sacrificed to dissect the neoplasm and the capsule of tumor was removed and kept in saline containing 100 U/mL penicillin, 100 U/mL streptomycin (pH 7.2). Pieces of fresh tumor tissue (1 mm^3) near the margin were inoculated to another mouse by puncture method. The above procedure was repeated for 5 times and the last generation of the tumor tissue was be used for orthotopic transplantation.

Animal model Before transplantation, mice bearing tumor were killed. Then the tumor was dissected and put into saline containing penicillin (100 U/mL) and streptomycin (100 U/mL) aseptically. Pieces of intact, fish-meat-like tumor tissue of 3 mm^3 in diameter from margin were prepared after the removing of tumor capsule. Mice anesthetized by the thialisobumalnatium (40 mg/kg) injected into abdominal cavity were sterilized with caseiodine on skin of abdomen and a transverse incision was made in left upper quadrant. After the exposure of greater curvature of stomach, the serosa and muscular layer were incised. Then, tumor tissues were transplanted under serosa of stomach by means of suture and embedding. Stomach was brought into abdominal cavity; the incision in belly was sutured delaminately. The whole operation procedure followed the doctrine of aseptic manipulation.

Drugs and groups *d*-limonene with 97% purity (product

number: 183164) was purchased from Sigma Company (USA). It was prepared as 10 g/L lecithin emulsion by Dalian Medical Science Institute. Mice were randomly divided into 4 groups: control group, 5-FU group, *d*-limonene group, and *d*-limonene+5-FU group and administrated with saline (0.3 mL/d, gastric perfusion), 5-FU (30 mg/kg/d, intraabdominal injection), *D*-limonene (15 mL/kg/d, gastric perfusion), and 5-FU (30 mg/kg/d, intraabdominal injection)+ *d*-limonene (15 mL/kg/d, gastric perfusion), respectively for 7 wk. The body mass and abdominal circumstances were measured on the 7th, 14th, 21st, 28th, 35th, 42nd, 49th d after transplantation and the status of eating, drinking and defecation of mice were recorded. The dying mice were executed and necropsy was performed. In the 8th wk, all the mice were killed; the neoplasm was resected and weighted; and the occurrence of distant metastasis and ascites were examined.

Methods

The measurement of tumor weight and inhibition rate of tumor growth Mice were killed by dislocation of cervical vertebra, the tumor weight was measured and the tumor inhibition rate was calculated. inhibition rate=[(tumor weight of control group-tumor weight of treated groups)/weight of control]×100%.

The occurrence of metastasis and ascites in nude mice The metastasis of gastric cancer was examined in abdominal cavity, peritoneum and liver. Tumor specimens were fixed in neutral formaldehyde, dehydrated by dimethylbenzene and embedded in paraffin for the hematoxylin and eosin (HE) staining and immunohistochemistry. The characters and volume of ascites were recorded.

Apoptotic index (AI) TUNEL method was used to detect the apoptosis of tumor cell. The sections were fixed and embedded as usual. TUNEL test kit was purchased from Roche Company. DNase I (1 mg/mL) was used to digesting the positive control specimen for 10 min before being put into TUNEL response mixture. Only label liquor was added into the negative control response mixture. Cells with brown or yellow nuclei were assumed as apoptotic cells. the number of apoptotic cells and total cancer cells were counted under light microscope at 400×magnification in 5 fields of vision and the average values were used for the calculation of apoptosis index (AI) according to the following formula: AI=(apoptotic cells/total cancer cells) ×100%.

Microvessel density assay The polyclonal antibody for factor \square -related antigen (F \square -Rag, Santa Cruz Biotechnology, Inc, USA) was selected to detect the microvessel density in paraffin embedded tumor sections by immunohistochemical method according to the manufacturer's instruction. Result determination: Sections were screened at 40× magnification under a light microscope to identify three regions with the highest MVD. Then, blood vessels stained brown by antibody for F \square -Rag was counted at 200×magnification. For the determination of microvessels, first of all, the hemorrhage area and marginal region were eliminated. Those brown-stained endothelial cells or cell cluster that had interspaces with microvessel, cancer cells and connective tissue were regarded as a micro vessels. The average value of the three regions was regarded as MVD.

Immunohistochemical assay of VEGF Immunohistochemical staining was performed with mouse monoclonal antibody specific for human VEGF (C1, Santa Cruz Biotechnology, Inc, USA) in a dilution of 1:100 according to SP method specification. The presence of brown or yellow granules in plasma or nucleus was regarded as positive staining for VEGF protein expression. The sum of positive cells number was calculated in five fields per slide at 200×magnification under light microscope. Results were ratified by fluorescence microscope and colorful microscopic figure analysis system (OLYMPUS BX51TR, Image-Pro Plus, Analysis Software).

Statistical analysis

Tumor weight, AI, MVD and VEGF were expressed as the mean±SD. Comparison between groups was performed using analysis of variance; Differences of the metastasis in peritoneum, liver and other organs and the occurrence of ascites were examined by χ^2 test ($P<0.05$ was considered statistically significant).

RESULTS

The influence of *d*-limonene on the general condition of tumor-bearing mice

At the end of the 7th wk, two mice-bearing tumor from control group, one from 5-FU group and one from combined group died of exhaustion while none from *d*-limonene group. During the whole process of the experiment, only one mouse in 5-FU group was found with loose stools, and no passage of bloody stools was found in any groups. Compared with the control and 5-FU group in which mice were found emaciation, inactive and lassitude, mice in *d*-limonene group and combined group had better appetite and increased body mass although statistically had no difference.

Influence of *d*-limonene on orthotopic transplanted tumor weight and tumor inhibition rate

At necropsy, xenografts of gastric cancer were found in each groups of nude mice. The transplanted tumor entity was pink in color, ellipse or round in shape, with nodosity in surface and necrosis in central parts, and was confirmed as adenocarcinoma by pathological section. Compared with the control group, the tumor weight of mice in *d*-limonene group and combined group were decreased significantly ($P<0.05$). Moreover, the inhibition effects of *d*-limonene or the combined effects of *d*-limonene and 5-FU on the growth of gastric cancer were more significant than that of 5-FU (Table 1).

Effects of *d*-limonene on tumor cell morphology and ultrastructure

Morphologically, tumor cells in the control group were bigger, ellipse, with red plasma and big, deep stained nuclei. A clear imbalance ratio of nucleus to plasma was found also. No significant difference was observed between the control and 5-FU group. While in *d*-limonene group and combined group, relatively small tumor cells with vacuoles in plasma and clouding nucleus were observed in which the ratio of nucleus to plasma was relatively normal.

Table 1 Inhibition effects of *d*-limonene on growth of orthotopic transplanted gastric tumor (mean±SD)

Groups	<i>n</i>	Tumor mass (g)	Inhibition rate (%)	AI (%)	MVD (<i>n</i>)	VEGF(%)
Control	8	2.69±0.32	0	3.31±1.44	18.64±2.81	45.77±4.79
5-FU	9	2.62±0.35	2.60	8.26±1.21 ^a	16.77±1.39	41.34±5.41
<i>d</i> -limonene	10	1.41±0.58 ^{ac}	47.58 ^{ac}	20.99±2.84 ^{ac}	5.32±4.26 ^{ac}	29.71±8.92 ^{ac}
Combined	9	1.43±0.51 ^{ad}	46.84 ^{ac}	19.34±3.19 ^{ac}	5.86±2.27 ^{ac}	28.24±8.55 ^{ac}

^a $P<0.05$ vs control group; ^c $P<0.05$ vs 5-FU group.

The major morphological changes of cancer cells in D-limonene and combined group were the shrinkage of cell, the condensation of cytoplasm, the aggregation of ribosome and mitochondrion, the occurrence of nuclear fragmentation, the peripheral masses of condensed chromatin. Apoptotic bodies derived from the shedding of condensed masses were found to be degraded by surrounding phagocytes and formed vacuoles in cytoplasm. Fusiform shape, morphological irregular and karyomegaly cancer cells were observed in control and 5-FU group with tight binding between cells, imbalance ratio of nucleus to plasma and the maldistribution of chromatin. But no obviously changes in cell morphology were detected.

Effects of d-limonene on apoptosis of cancer cell

Results of TUNEL demonstrated that apoptotic cells with yellow nucleus were seen occasionally in control group and 5-FU group while piles of apoptotic cells were observed in *d*-limonene and combined group. There was a significantly difference in AI in *d*-limonene and combined group compared to the control and 5-FU group ($P < 0.05$) (Table 1, Figures 1-4).

Figure 1 Control group FVIII-RAg with SP method. ×100.

Figure 2 5-FU group FVIII-RAg with SP method. ×200.

Figure 3 *d*-limonene group FVIII-RAg with SP method. ×100.

The influence of d-limonene on MVD of orthotopic transplanted tumor

Under light microscope, the intensive brown-staining

microvessels on stomach wall was observed without integrated basement membrane in the control group. Compared with the control and 5-FU group, almost no microvessels was found in the tumor of *d*-limonene and combined group for the cancer cells were in dormancy status, and the MVD of those two groups was statistically lower than that of the control and 5-FU group (Table 1, Figures 5-8).

Inhibitory effects of *d*-limonene on metastasis of gastric cancer

The metastasis rate of gastric cancer to peritoneum (regional lymph node) was to 100% in the control group and the metastasis rates in other groups are displayed in Table 2. the metastasis to liver, peritoneum and other organs of gastric cancer and the formation of ascites were significantly inhibited in *d*-limonene and combined groups ($P < 0.05$) while no statistical inhibitory effects on the metastasis to liver and peritoneum were observed in 5-FU group ($P > 0.05$, Table 2).

Table 2 The Inhibitory effects of *d*-limonene on orthotopic transplanted gastric cancer (%)

Group	<i>n</i>	Peritoneum metastasis	Liver metastasis	Ascites	Metastasis to other organs
Control	8	8(100.0)	7(87.5)	2(25.0)	1(12.5)
5-FU	9	7(77.8)	5(55.5)	2(22.2)	1(11.1)
<i>D</i> -limonene	10	2(20.0) ^{ac}	2(20.0) ^{ac}	0 ^{ac}	0
Combined	9	3(33.3) ^{ac}	2(22.2) ^{ac}	0 ^{ac}	0

^a $P < 0.05$ vs control group; ^c $P < 0.05$ vs 5-FU group.

DISCUSSION

Gastric cancer is the most common malignant tumor in digestive system. The cure rate of gastric cancer was increased year by year with the progress of surgical technique, chemotherapy and other means. But a five-year survival rate is still wandered below 10%, especially in middle or late phase patients^[10]. Thus, to find an effective adjuvant chemotherapy drug became the focus of gastric cancer therapy besides emphasizing surgical operation.

Limonene (1-methyl-4-isopropyl-cyclohexene) is the essential component in citrus oil. *d*-limonene, the most common isomer of limonene, is a kind of monoterpene component. It has the ability of anti-oxygenation, anti-inflammation and drainage for gallstone. The anti-cancer activity of *d*-limonene was found recently. Therefore, *d*-limonene has been applied to precaution and treatment in chemical-induced animal model, such as colon cancer, breast cancer, gastric cancer, pancreatic cancer and hepatic cancer with promising results^[1-7]. Most of those studies focus in the chemoprophylaxis of tumor. Our results demonstrated that in *d*-limonene and combined group, the tumor weight of xenograft was decreased drastically, the metastasis to liver, peritoneum and the occurrence of ascites were inhibited significantly compared with the control group. Thus, an inhibition effect of *d*-limonene on the growth and metastasis of gastric cancer cells was ratified. Taking the results of TUNEL assay into consideration, we found the main mechanism underlying the inhibition effects of *d*-limonene was to induce the apoptosis of cancer cells.

At present, it is thought that a phenotype change from no-vascular period to angiogenesis stage exists during the growth

of tumor. In no-vascular period, the velocity of cancer cells apoptosis and proliferation maintain a dynamic balance and the tumor may survive for months or even years without the presence of metastasis. But the alterations of some important factors, such as heredity cause, over-expression of proangiogenic factors originated from cancer cells or down-regulation anti-angiogenic factors expressed by body tissues or cancer cells, the switch for tumor angiogenesis thereby activating and leading to vascularization of tumor. Once the tumor vascular is formed, the growth speed of tumor will be increased and the invasive growth and metastasis will be induced.

Microvessel density (MVD), is usually used to evaluate the vascularization level of tumor^[10]. A large amount of experiments and clinical research results showed that MVD had a close relationship with the prognosis of almost all malignant tumors, a higher MVD suggested the lower differentiation and the higher reoccurrence and metastasis incidence^[11]. We demonstrated that compared with control and 5-FU group, tumor MVD in *d*-limonene and combined group was decreased significantly, suggesting a inhibitive effect of *d*-limonene on tumor angiogenesis.

Although the mechanisms involved in tumor angiogenesis have not been understood exactly, the effect of VEGF on vascularization has been conformed. VEGF, a specific mitogen for vascular endothelial cells was isolated from follicular cell plasma of cattle and considered as the most important angiogenic factor of metastatic tumor^[12-14]. The expression of VEGF was found very low in normal adult tissues. Once initiated in pathologic status of tumor, the angiogenesis was induced and promoted drastically by VEGF and resulted in the increase of MVD. Among vascular growth factors, VEGF was the only one to stimulate the proliferation of tumor endothelial cell and to induce the vascularization of tumor directly^[15]. As the newly formed vessels may provide tumor with oxygen, nutrition, the growth of tumor will be invasive and uncontrollable^[16]. It was reported that the over expression of VEGF had close relationship with tumor metastasis and poor prognosis. The invasion of blood vessels and lymph nodes has been often observed in patients with enhanced VEGF expression, which will result in the rapidly malignant change of tumor, easily relapse and short survival period after surgical operation. Here we showed that relatively high level of VEGF in the tumor of control and 5-FU group, especially in the areas around vessels, while notably decreased expression of VEGF in *d*-limonene and combined group. Thus, a positive correlation of VEGF expression with increased MVD was ratified, suggesting the anti-angiogenic mechanism of *d*-limonene via down-regulation of VEGF. Moreover, we found that the anti-cancer target of 5-FU might not on the inhibition of neovascularization.

5-fluorouracil, an antimetabolite pyrimidine, has been used as traditional chemotherapeutic drug for more than 40 years. For the anti-cancer target of 5-FU lies in the inhibition of thymidylate synthetase to prevent DNA synthesis but not the interference of tumor angiogenesis^[17], no satisfied cure effect was obtained in our experiment. As to *d*-limonene, preventing tumor angiogenesis and increasing tumor cells apoptosis are the main anti-cancer mechanisms, which may diminish the incidence of drug resistance mutation for its character of physiological cell death. The effectiveness, non-toxicity, and lower drug resistance of *d*-limonene were ratified for a better eating, activity and living ability in *d*-limonene and combined groups than in control group within the 7-wk experiment. No statistical difference in body weight was observed among four groups for increased tumor weight and the formation of ascites in control and 5-FU group.

Further studies need to elucidate the apoptotic mechanisms of *d*-limonene before its clinical application.

Abstract

AIM: To evaluate the therapeutic effect of radiotherapy for esophageal cancer after expandable metallic stent placement.

METHODS: Ten cases of advanced esophageal cancer were evaluated, 7 having complete obstruction and 3 with digestive-respiratory fistula. Ten nitinol stents were placed at the site of stenosis. Patients were treated with a total dose of 1 200 cGy divided into 3 fractions of 400 cGy 4-7 d after stents placement.

RESULTS: All the 10 stents were placed successfully at one time. After radiotherapy for advanced esophageal cancer, the survival period of the cases ranged from 14 to 22 mo, with a mean survival of 17 mo. No re-stenosis occurred among all the 10 cases.

CONCLUSION: Stent placement combined with radiotherapy for esophageal cancer is helpful to prolong patients' survival and reduce occurrence of re-stenosis.

INTRODUCTION

Radiotherapy for esophageal cancer is a relatively effective treatment. However, esophageal obstruction and esophageal stenosis due to inoperable cancer, as serious complications of esophageal cancer, are directly life-threatening and contraindicatory to radiotherapy for esophageal cancer. Inserting membrane-covered esophageal stents as an effective conservative and palliative treatment to expand the stent at the stenosis site due to cancer and obstruct the digestive fistulas is a currently widely-used therapy, which can dramatically alleviate obstruction and enhance patients' quality of life by enabling oral ingestion in patients with obstruction due to late cancer^[1-4]. With radiotherapy after membrane-covered esophageal stents placement for advanced esophageal cancer, we successfully overcame the contraindication of radiotherapy for esophageal cancer and achieved a quite satisfactory short-term effect^[5,6].

MATERIALS AND METHODS

Materials

Ten cases of esophageal cancer (8 males, 2 females, aging from

58 to 85 years) were studied. Esophagoscopy examination indicated that 9 of the cases were squamous carcinoma and one was adenocarcinoma. Barium contrast radiography and meglucamine diatrizoate radiography showed that the site of stenosis due to cancer ranged from 6 to 12 cm in length, with an average length of 8 cm, and the width of the esophageal lumen at the site of stenosis was less than 2 mm, which had been hard for liquid diet to pass for more than 2 wk. Seven of the cases had complete obstruction and 3 had digestive-respiratory fistulas. Physical examination showed that 9 of them had no carcinomatous distant metastasis and 1 case had carcinomatous metastasis to unilateral lung.

Methods

Stent placement Stents to be placed were homemade or imported silicone-covered nitinol memory alloy mesh stents, 2 cm in diameter and 8, 10, 12 cm in length, respectively, and bell-mouthed at one or both ends. Patients should take gentamicin orally, 160 000 units each time, 4-5 times per day before the therapy and stop eating and drinking 2 h before the placement. In accordance with the stenosis length shown by esophageal radiography, the stent of proper length was selected, placed and released along the site of stenosis by endoesophageal stent introducer under the guidance of the peroral guide wires, leaving both ends of the stent surpassing 1-2 cm respectively. After replacement, patient was advised to drink adequate warm water, making the stent expand properly. One week after the placement, a reexamination was carried out through upper digestive tract fluoroscopy with barium to see how unobstructed the stent was and an X-ray plane film was taken to locate the stent, measure its length and width, fix reference point, set irradiation dose and draw the related dose curve.

Endoesophageal irradiation Irradiation was performed 4-7 d after the stent was properly placed. First, the balloon catheter was inserted to the site of the lesion. Second, air was pumped into the sacculi to expand it and fix it inside the stent. Third, the location of the sacculi was confirmed through fluoroscopy and spot film. And finally, irradiation was performed according to the mark of the reference point fixed through measurement with the total dose of 1 200 cGy divided into three 400 cGy doses.

RESULTS

In all the 10 cases, the stents were all placed successfully once and fixed properly. Of all the 10 stents, 7 (four 8 cm, two 10 cm and one 12 cm in length) were homemade and 3 (two 10 cm and one 8 cm in length) were imported and all could expand properly, through which contrast medium could pass smoothly after placement. Esophageal fistulas in three cases were obstructed immediately after insertion and the patients could begin to take semiliquid diet 4 h afterwards. Reexaminations were performed through radiography 4 d after insertion, and it indicated that the contrast medium could go through the stents smoothly, that the stents did not displace and the esophageal fistulas were obstructed. So, patients could take food normally without dysphagia. After stents placement, 3 cases had retrosternal

foreign body sensation and retrosternal pain, which disappeared within 4-6 d. After endoesophageal radiotherapy, the survival period of the cases ranged from 14 to 22 mo, with a mean survival period of 17 mo. Of all the 10 cases, no endogenous stenosis recurred during the survival period.

DISCUSSION

Radiotherapy for esophageal cancer after esophageal stent placement effectively solved this contraindication of endoesophageal therapy and the problem of stenosis recurrence after stent placement. Esophageal stent insertion enhanced the life quality of patients with advanced esophageal cancer in a quick and effective way in that it remarkably improved the patients' nutrition absorption and constitution by enabling them to take food orally and it completely eliminated the symptoms such as coughing while eating or drinking by effectively obstructing the digestive-respiratory fistulas, which also alleviated the patients' psychological pressure and greatly comforted them. It enlarged the indication scope of radiotherapy for esophageal cancer by turning the former contraindication into indication. The stent inserted expanded the stenosis site and made it possible for brachytherapeutic treatment and radioactive source to pass easily and eventually dramatically prolonged the patients' survival period^[7,9-18]. No stenosis recurred in the 10 cases under our treatment during their survival period, which, in contrast to the 5% stenosis reoccurrence rate in other patients under our treatment who had stents placement without radiotherapy, marked a great decrease in occurrence of re-stenosis^[8]. Radiotherapy for esophageal cancer prevented the stents from being obstructed by the overgrowth of tumor, alleviated the patients' sufferings and raised their life quality. After the stents were properly placed, radiography was performed and film was spotted, through which the width of the stents expansion was measured. According to the width after calculation, the esophagus was expanded by the stents, the diameter of the balloon catheter and the reference point were fixed, and the optimal internal irradiation dose curve was designed. A comparison of the dose curves indicated that, after the expansion of the stents, the irradiation dosage over the esophageal mucosa was decreased, with the dose gradient homogeneous and small, which prevented the esophageal mucosa from being unnecessarily harmed while effectively inhibited the overgrowth of esophageal mucosa and the surface tumor, and insured the pathological center to receive therapeutic dose of irradiation. Experiments showed that the refraction and diffraction of the irradiation ray against the metallic stents could be neglected when the radioactive source was more than 5 mm away from the metallic stents. Our results of the clinical research seem to indicate that radiotherapy for esophageal cancer after esophageal stents placement is very helpful in treatment of advanced esophageal cancer.

Abstract

AIM: To study the relationship between microvessel density (MVD), telomerase activity and biological characteristics in hepatocellular carcinoma (HCC).

METHODS: S-P immunohistochemical method and telomeric repeat amplification protocol (TRAP) were respectively used to analyze the MVD and telomerase activity in 58 HCC and adjacent normal tissues.

RESULTS: The MVD in HCC with metastasis, lower differentiation or without intact capsule was significantly higher than that in HCC with intact capsule, higher differentiation, or without metastasis. While MVD had no relationship with tumor size, hepatic virus infection and other clinical factors. Telomerase activity was related to differentiation degree, but not to tumor size or histological grade. MVD in HCC with telomerase activity was higher than that in HCC without telomerase activity.

CONCLUSION: MVD and telomerase activity may serve as diagnostic criteria of HCC in earlier stage. Meanwhile, there may be a cooperative effect between MVD and telomerase on the growth and metastasis of HCC.

INTRODUCTION

Primary hepatocellular carcinoma (HCC) is a common malignant solid tumor, which is rich of blood. It has many characteristics, such as fast infiltrating growth, metastasis in early stage, high grade malignancy, poorly therapeutic efficacy. So it is important to study the angiogenesis of HCC. At present, it has been proved that MVD can serve as a prognostic criterion for relapse, metastasis and survival rate of all kinds of carcinoma^[1-6].

Telomerase is a reverse transcriptase. It can make up telomeres that lose 50-200 bp during each DNA replication so as to retain the telomere length and stabilize the cells. The expression of telomerase activity is important to cell proliferation, senescence, immortalization and carcinogenesis^[7-9]. It is known that telomerase activity can be detected in many carcinomas, but

not in most of normal tissues^[10-16].

MVD and telomerase activity can act as specific markers for malignant tumors, and are used to analyze the biologic characteristics, infiltration, metastasis and prognosis of tumors. But the relationship between them has not been reported. In this study, S-P immunohistochemistry method and telomeric repeat amplification protocol (TRAP) were used to respectively detect MVD and telomerase activity, so as to study their relationship and other clinical factors.

MATERIALS AND METHODS

Tissue specimens

Fifty-eight HCC and adjacent normal tissues specimens were obtained from Hepatobiliary Surgery Department of Changchun Infectious Hospital from December 2000 to December 2002. They were all proved as primary HCC. These patients did not receive radiotherapy, chemotherapy, or other therapies. Of them, 35 cases had liver cirrhosis, 52 cases had chronic hepatitis, 6 cases had carcinoma emboli in portal vein, 48 cases had positive marker of HBV, 4 cases had positive anti-HCV antibody, and 4 cases had negative marker of hepatitis virus. Each specimen was divided into two parts. One was stained by immunohistochemical method, and routinely fixed in formalin, embedded in paraffin, and then cut into 4-5 μ m thick sections. The other was frozen in liquid nitrogen and used to analyze telomerase activity by TRAP.

S-P Immunohistochemical method

UltraSensitiveTM S-P kit, anti-VIII factor related antigen monoantibody (anti-FVIII RAG), and positive control were purchased from Fuzhou Maixin Biotechnology Development Company. The sections were deparaffinized in xylene and rehydrated in a serial gradient of ethanol solutions. Then S-P immunohistochemical method was used according to its manual. At last, they were restained with hematoxylin and observed. The negative control included empty control with normal rabbit IgG instead of primary antibodies or with the second antibody only. MVD was determined in triplicate in the area of the most intense vascularization (hot spot) of each tumor, and the average count was recorded.

Activity of telomerase assayed by TRAP silver staining

About 50-100 mg tissue was split. Then the supernatant was collected for analysis. The telomerase activity was detected using a TRAP kit following instructions of the manufacturer (Beijing Tiangekangning Biotech Institute). The reaction system containing 25 μ L TRAP agent, 0.2 μ L *Taq* enzyme and 1 μ L cell extract was incubated for 30 min at 25 $^{\circ}$ C, then 0.5 μ L of primer was added and PCR was conducted for 30 cycles with denaturing at 94 $^{\circ}$ C for 30 s, annealing at 60 $^{\circ}$ C for 30 s, extending at 72 $^{\circ}$ C for 30 s. Fifteen microliter PCR product was loaded onto a 90 g/L non-degenerative SDS gel, resolved through the SDS-PAGE, demonstrated by a reaction in 2 g/L silver nitrate for 15 min, and visualized by incubation in 30 g/L anhydrous sodium carbonate containing formaldehydes (1 mL/L). The activity of telomerase was indicated by the presence of a 6 bp-DNA ladder. The cell extract inactivated by incubation at 75 $^{\circ}$ C for 10 min was used as negative control.

Statistical analysis

Result were expressed as mean \pm SD. Student's *t* test and χ^2 test were used. $P<0.05$ was considered statistically significant.

RESULTS**Relationship between MVD and some clinical factors**

Observed with light microscope, venous endothelium but not lymphatic vessel endothelium was brown (Figure 1).

Table 1 shows that MVD in HCC tissues with metastasis within vein or liver was significantly higher than that in HCC without metastasis ($P<0.05$), MVD in HCC without intact capsule was higher than that in HCC with intact capsule ($P<0.05$). There was no significant difference in MVD between big (>5 cm) and small (≤ 5 cm) tumors.

Figure 1 Immunohistochemical staining with anti-FVIII RAG (S-P, original magnification: $\times 400$). A indicates the lymphatic vessel endothelium. B indicates the brown venous endothelium.

Table 1 Relationship between MVD and metastasis, capsular integrity, or size of tumor

Classification		Cases (n)	MVD(mean \pm SD)
Metastasis	+	36	39.3 \pm 9.6 ^a
	-	22	32.2 \pm 5.6
Capsular	-	38	38.8 \pm 9.3 ^a
	+	20	31.2 \pm 5.8
Integrity	>5 cm	42	37.3 \pm 8.8
Size	≤ 5 cm	16	36.9 \pm 8.7

^a $P<0.05$, vs corresponding group.

In this study, the distribution of MVD was different in various regions. MVD was higher in HCC with lower differentiation than that in HCC with higher differentiation (Table 2). MVD in

adjacent normal tissues (13.2 \pm 2.7) was mainly distributed in the area near the carcinoma tissues, especially around the pseudolobules with liver cirrhosis. It was reported that MVD in normal tissues was 11.8 \pm 0.2.

Table 2 MVD in HCC and adjacent normal liver tissues

Group	Cases (n)	MVD (mean \pm SD)
Adjacent normal tissue	58	13.2 \pm 2.7
HCC grade I	11	19.6 \pm 3.7
HCC grade II	22	29.7 \pm 6.1 ^a
HCC grade III	16	48.4 \pm 10.7 ^a
HCC grade IV	9	59.3 \pm 10.5 ^a

^a $P<0.05$ vs adjacent normal tissue.

Relationship between telomerase activity in HCC or adjacent normal tissues and some clinical factors

The results are shown in Figure 2. The positive rate of telomerase activity in HCC tissues (89.6%) was significantly higher than that in adjacent normal liver tissues (20.7%). The telomerase activity in HCC was related to differentiation grade of HCC, but was not related to HCC size, capsule integrity, number of liver nodules, metastasis, or hepatitis virus infection. While the telomerase activity in adjacent normal liver tissues was related to capsule integrity, number of liver nodules and hepatitis virus infection (Table 3).

Figure 2 Telomerase activity of HCC tissues. Lane 1: Positive control. Lanes 2, 3: HCC tissue with low differentiation with a 6-bp interval ladder pattern. Lane 4: No ladder in a adjacent normal tissues. Lanes 5, 6: HCC tissue with high differentiation with a 6-bp interval ladder pattern. Lane 7: HCC with moderate differentiation with a 6-bp interval ladder pattern.

DISCUSSION

Carcinogenesis of HCC is a multi-factor, multi-step and complex process. Angiogenesis is necessary for solid tumors larger than 1 mm×1 mm. Or else the tumor would remain at dormancy phase and would not metastasize. As soon as it entered angiogenesis stage, the potency of metastasis exhibited at once^[17-20].

MVD is an important marker of angiogenesis in tumor and is valuable in prognosis of various carcinomas. In this study, S-P immunohistochemical staining was used to analyze MVD in 58 HCC and corresponding adjacent normal tissues. FVIII in cytoplasm of various vascular endothelium cells is synthesized in endothelial cells. FVIII-RAG is specific to endothelial cells so that it could be differentiated blood vessel from lymphatic vessel. The role of vascular genesis, development and distribution in occurrence, development, infiltration, metastasis and advancement of tumors has been studied^[21]. MVD in poorly differentiated HCC with metastasis in vein or liver, intact capsule was significantly higher than that in corresponding ones. This result was consistent with others, suggesting that HCC with higher MVD may obtain more nutrition from new blood vessels, so that it can grow faster and has the ability to infiltrate and metastasize. MVD might play a key role in development of HCC. There was no close relationship between MVD and tumor size, HBV infection. Maybe HBV infection is merely a carcinogenic factor, and is not related to the growth, infiltration and metastasis of HCC.

We also detected telomerase activity in 58 HCC and adjacent normal tissues by TRAP. Similar to Nouse's research, the expression of telomerase activity in HCC was negatively related to differentiation, but was not related to tumor size or histologic grade. Telomerase activity in adjacent normal tissues with middle or big size, multi-nods, unintegral capsule, positive HBsAg was higher than that in adjacent normal tissues without them, suggesting that there is some relationship between telomerase activity in adjacent normal tissue and prognosis of HCC. Hepatitis viruses, especially HBV, have been found to be an important factor in causing HCC. HBx, encoded by HBV, could block the function of p53, and make genome unstable. With the cell division, telomerase was activated. The cells with positive telomerase activity became immortalized and further developed to carcinoma cells. Histological examination in combination with detection of telomerase activity could increase the accuracy of diagnosis in early stage and improve the judgment on its prognosis.

In addition, there was some relationship between MVD and telomerase activity. Activation of telomerase could make liver cells immortalized, and MVD could offer nutrition for their growth and stimulate metastasis. These two factors would result in carcinogenesis at last.

In a word, MVD and telomerase activity have a key role in occurrence, development, infiltration and metastasis of HCC and have notable clinical values in diagnosing and treating HCC in early stage.

Abstract

AIM: To assess the therapeutic value of endoscopic nasobiliary drainage (ENBD) and oral praziquantel for severe *Clonorchiasis sinensis* infection.

METHODS: Of the 84 *Clonorchiasis sinensis*-infected patients enrolled, 58 were treated with ENBD (as observing group, ENBD group), 26 received operations (control group, operation group). Both of the two groups were comparable in terms of patient's age, body mass index. Before and one week after treatment, the average diameters of common bile ducts were measured by ultrasound, and serum bilirubin, ALP, γ -GT and ALT were detected by biochemical methods. After ENBD or operation, the patients took praziquantel for two days.

RESULTS: Compared with the patients in operation group, ENBD patients in ENBD group had higher recovery rates of abdominal pain and fever as well as jaundice, quicker remission, smaller trauma, fewer complications and lower cost.

CONCLUSION: ENBD combined with oral praziquantel is an effective and safe method for the treatment of severe *Clonorchiasis sinensis*.

Zhi FC, Liu XM, Liu ZQ, Lin Y, Chen SJ. Treatment of severe *Clonorchiasis sinensis* by endoscopic nasobiliary drainage and oral praziquantel. *World J Gastroenterol* 2004; 10(14): 2150-2152

<http://www.wjgnet.com/1007-9327/10/2150.asp>

INTRODUCTION

Oral praziquantel is effective for the treatment of mild *Clonorchiasis sinensis*. As the parasitism of *Clonorchiasis sinensis* metacercaria can take more than 50 years in human body^[1], the therapy of *Clonorchiasis sinensis* is very difficult because of repeated infections. We have achieved effective results in treating 58 cases of severe *Clonorchiasis sinensis* infection from July 2000 to April 2003 by endoscopic nasobiliary drainage (ENBD) and oral praziquantel.

MATERIALS AND METHODS

Diagnostic criteria for severe *Clonorchiasis sinensis*

Criteria for severe *Clonorchiasis sinensis* are as follows: A

history of eating raw fish; spawn can be detected in feces or bile; obstructive jaundice or cholecystitis, biliary calculus in common bile duct, and suppurative cholangitis. All the 58 cases were in line with the above diagnostic standards.

Patients and treatments

There were 58 cases in ENBD group including 55 males and 3 females (aged from 29 to 76 with a mean age of 46.5 years). All cases had a history of eating raw fish. Among them, 36 cases had common bile duct dilatation, intrahepatic bile duct and gallbladder distention (6 of the 36 cases also had gallstones in common bile duct); 23 cases had mild dilatation in common bile duct. Nineteen cases were accompanied with fever and increased leukocyte counts. *Clonorchiasis sinensis* metacercaria were detected in feces of 39 cases. Laboratory examination results were as follows: Total bilirubin 86-280 $\mu\text{mol/L}$ with an average of 103 $\mu\text{mol/L}$, glutamic-pyruvic transaminase 60-360 U/L with an average of 98 U/L.

The 58 cases in ENBD group were treated according to the routine procedure^[2]. The instruments included duodenoscope, ducts, knives, guide wires, meshes, etc. The papilla of Vater and bile duct were examined for *Clonorchiasis sinensis* metacercaria. Then, endoscopic retrograde cholangiopancreatography (ERCP) was performed to diagnose the severity of the disease. Patients with mild inflammation without constriction were treated by nasobiliary drainage. Patients with obvious constriction were treated by nasobiliary drainage after sphincterotomy. If the common bile duct was full of *Clonorchiasis sinensis* metacercaria and purulent discharge, the ducts were first washed, and then nasobiliary drainage was performed. For the patients with biliary calculus in common bile ducts, stones were taken out by sphincterotomy followed by nasobiliary drainage. All the 58 patients took praziquantel orally 8-48 h after procedures. The dose was 3.6 g/d three times daily for 2 d.

There were 26 patients with *Clonorchiasis sinensis* infection proved by operations (operation group) including 25 males and 1 female aged 36 to 75 years with a mean age of 48.5 years. Preoperative diagnosis was as follows: Fifteen patients with cholecystitis, 5 with gallstones in common bile duct and 6 with duodenal ampulla carcinoma. Fifteen cases underwent cholecystectomy, 5 cases underwent choledocholithotomy, and 20 cases received operations for common bile duct dilatation. All the 26 cases had T-tube drainage. Laboratory examination results were as follows: Total bilirubin 76-123 $\mu\text{mol/L}$ with a mean of 94 $\mu\text{mol/L}$, glutamic-pyruvic transaminase 63-286 U/L with an average of 105 U/L.

The 26 cases were treated by exploratory laparotomy. The common bile duct was opened, and *Clonorchiasis sinensis* metacercaria and their purulent discharge were washed away with saline. Then, common bile duct was expanded with bougie. At last, T-tube was placed inside. Cholecystectomy followed by T-tube was performed for patients with cholecystolithiasis or cholecystitis. Choledocholithotomy followed by T-tube was performed for patients with gallstones in common bile ducts. All the 26 patients took praziquantel orally for 3-6 d after operation. The dose was 3.6 g/d three times daily for 2 d.

Table 1 Average diameter of common bile ducts, levels of serum total bilirubin, ALP, γ -GT and ALT one week after operation (mean \pm SD)

Group	Cases (n)	Therapy	Average diameter of common bile duct (mm)	Serum total bilirubin (μ mol/L)	ALP (U/L)	γ -GT (U/L)	ALT (U/L)
ENBD	58	Before	16 \pm 3	89 \pm 11	286 \pm 63	166 \pm 38	132 \pm 32
		After	9.6 \pm 2.2 ^b	29 \pm 9 ^b	108 \pm 23 ^b	86 \pm 22 ^b	60 \pm 12 ^b
Operation	26	Before	15.3 \pm 3.1	87 \pm 10	263 \pm 54	156 \pm 36	130 \pm 30
		After	9.5 \pm 2.1 ^d	27 \pm 8 ^d	98 \pm 25 ^d	87 \pm 22 ^d	57 \pm 11 ^d

^b P <0.01 vs markers before ENBD, ^d P <0.01 vs markers before operation.

Table 2 Therapeutic effects of two groups

Group	Cases (n)	Remission time of abdominal pain (d)	Complication (cases)	Average length of hospital stay (d)	Average cost (Yuan)
ENBD	58	1	13	9	6 503
Operation	26	6 ^b	10	20 ^b	16 300 ^b

^b P <0.01 vs ENBD group.

Observing parameters

The following parameters were measured before and one week after treatment. (1) Changes of the average diameter of common bile ducts, serum total bilirubin, ALP, γ -GT and ALT; (2) Complications, average length of hospital stay and the costs; (3) *Clonorchiasis sinensis* metacercaria in feces in follow-up patients.

Statistical analysis

All data were analysed by t test, and the significant level was set at P <0.05.

RESULTS

Therapeutic effects are shown in Tables 1 and 2. (1) ENBD group: Jaundice decreased in 72 h and disappeared in 3 wk. The average remission time of abdominal pain was 1 d after ENBD. Nineteen cases with fever returned to normal temperature 48 h after drainage. The dead polyp could be seen discharged from nasobiliary drainage 12 h after oral praziquantel. Peak time of dead polyp discharging was within 24-48 h after oral praziquantel and there was no dead polyp on the fifth day. (2) Operation group: The mean remission time of abdominal pain was 6 d after operation. Jaundice and fever began to decrease 2 d after operation. The dead polyp could be seen discharged from T-tube 12 h after oral praziquantel.

There were 8 cases with transient hyperamylasemia in ENBD group, who were cured in 48 h by fasting, anti-acid and anti-inflammation therapy. Two cases with bile duct retrograde infection after sphincterotomy accompanied with transient fever and chill were cured by anti-inflammation therapy. In all 58 cases, there was no case of bleeding and perforation, but 3 cases developed recurrent disease in 1-2 years and needed therapy again. In operation group, there were 8 cases with gallstone in common bile duct or cholangitis after operation, and 2 cases with intestinal adhesion.

Clonorchiasis sinensis metacercaria was found in feces of all the patients of the two groups 3, 6, 12, 18 and 24 mo after ENBD or operation. After oral praziquantel again, no *Clonorchiasis sinensis* metacercaria was found in feces.

DISCUSSION

Clonorchiasis sinensis is an amphixenosis parasitic disease threatening people's health. The average infectious rate was 21.1% in Pearl River Delta region, and up to 88.6% in certain

areas. Oral praziquantel is the first-line therapy drug; its effectiveness can be 98.8%^[3-5]. When *Clonorchiasis sinensis* infection is accompanied with obstructive jaundice^[6,7], obstruction remission and bile drainage should be the most important treatment target. The traditional method of obstruction remission is operation, but operation has some shortcomings, such as big trauma, high costs and recurrence. With the development of endoscopic intervention, the therapy of *Clonorchiasis sinensis* with endoscopic bile duct drainage has bright prospect^[8].

Our results showed that oral praziquantel after endoscopic nasobiliary drainage was a safe and effective way for the treatment of *Clonorchiasis sinensis* accompanied with obstructive jaundice. The two methods had equal effects (as shown in Tables 1 and 2), and no significant difference with regard to the remission time of jaundice and average diameter of common bile duct. However, endoscopic nasobiliary drainage did have some advantages, such as rapid remission of fever and abdominal pain, little trauma, rapid recovery, fewer complications, less length of hospital stay and less cost.

Sphincterotomy is required for patients with inflammatory papillary stenosis. Drainage is helpful for decreasing the restenosis after operation. Sphincterotomy is indicated in the following situations: Papilla opening is very small, stiff, and has no bile flow; it is difficult to inject contrast; contrast shows that inferior part of common bile duct is obviously narrow.

Generally, nasobiliary drainage should last 4-7 d and the bile duct should be washed by 5 g/L metronidazol 1-2 times daily. Once the drainage tube is out of place, it is not necessary to re-put drainage if there is no symptom of increasing stenosis, jaundice or fever. The causes of drainage dislocation included: Anterior extremity of nasobiliary drainage had no bents; the papilla opening was too big during sphincterotomy; some patients would pull out the nasobiliary drainage because of irritation and nausea; some patients had too much hiccupping and vomiting. Doctors should make more explanations to get patients' cooperation.

The main complication of endoscopic therapy was transient hyperamylasemia, which was associated with repeated pancreatic duct visualization during contrast imaging. This complication could be relieved by fasting, antacid and anti-inflammation therapy for 48 h. Once there was pancreatitis, the therapy was initiated for acute pancreatitis. In patients with moderate jaundice and good general condition, oral praziquantel could be taken 8 h after endoscopic drainage. Patients with

severe jaundice and severe impairment of hepatic function, should receive therapy to improve and protect hepatic function, and take oral praziquantel 2-3 d after drainage to decrease the damage to liver caused by the drugs.

On the whole, both ENBD and traditional operation are effective for the treatment of *Clonorchiasis sinensis* infection complicated with obstructive jaundice. However, ENBD has some advantages, such as rapid remission of fever and abdominal pain, little trauma, rapid recovery, fewer complications, less length of hospital stay and less cost.

Abstract

Benign nontraumatic inflammatory stricture of the common bile duct (CBD) may result in obstructive jaundice, which can be misdiagnosed as a malignant tumor of the CBD preoperatively. Two cases with strictures of the mid portion of the common bile duct presenting with obstructive jaundice are reported herein. Preoperative radiological studies prompted us to confidently make the diagnosis of cholangiocarcinoma. However, the postoperative diagnosis on histological examination of the resected lesions was chronic inflammation and fibrosis. The complications of chronic duodenal ulcer are considered as the etiology of these two disorders.

Ho CY, Chen TS, Chang FY, Lee SD. Benign nontraumatic inflammatory stricture of mid portion of common bile duct mimicking malignant tumor: Report of two cases. *World J Gastroenterol* 2004; 10(14): 2153-2155

<http://www.wjgnet.com/1007-9327/10/2153.asp>

INTRODUCTION

Malignant bile duct strictures are mainly the result of cancer of the ampulla of Vater, pancreas, or bile duct, and account for most patients presenting with obstructive jaundice secondary to extra-hepatic bile duct stricture. Benign non-traumatic inflammatory strictures of the extra-hepatic bile duct are extremely rare with the exception of primary sclerosing cholangitis^[1-3]. Most benign strictures reported in the literature are located in the hepatic hilum^[4] or distal common bile duct (CBD). Here we report two cases of benign nontraumatic inflammatory strictures of the mid portion of the CBD with painless obstructive jaundice. They were confidently diagnosed as cholangiocarcinoma by radiological studies preoperatively.

CASE REPORT

Case 1

A 70 year-old male who had a 10-year history of hypertension and type 2 diabetes mellitus was presented to our hospital. He had tea-colored urine and yellowish skin discoloration for about 2 wk. No abdominal pain or body weight loss was reported. The physical examination was unremarkable except icteric sclera. A complete blood count was within normal limits.

Serum total bilirubin/direct bilirubin (TB/DB) 5.6/2.9 mg/dL (normal 0.2-1.6/0-0.3 mg/dL), alanine aminotransferase (ALT) 127 U/L (normal 0-40 U/L), aspartate aminotransferase (AST) 78 U/L (normal 5-45 U/L), alkaline phosphatase (ALK-P) 380 U/L (normal 10-100 U/L) and gamma-glutamyl transpeptidase (γ -GT) 333 U/L (normal 8-60 U/L) were noted. Abdominal sonography showed dilatation of the intrahepatic ducts and CBD. The contrast-enhanced abdominal CT scan disclosed similar findings. A PTCD tube was inserted and antegrade cholangiograms exhibited a segmental narrowing of the CBD about 2 cm below the insertion site of the cystic duct (Figure 1A). A segmental stricture about 1.5 cm in length over the CBD but below the cystic duct level and dilatation of the intrahepatic ducts were also demonstrated in the endoscopic retrograde cholangiopancreatogram (ERCP) (Figure 1B). The pancreatogram was normal. Three sets of bile fluid cytology were negative. Tumor markers CA19-9 and CEA were not elevated. A diagnosis of cholangiocarcinoma with CBD stricture was made. At surgery, stricture of the mid portion of the CBD was found. Cholecystectomy and choledocholithotomy with T-tube drainage were performed. Histological examination of the resected CBD showed chronic inflammation and fibrosis without malignant cells. No stone was detected in the gallbladder. Unfortunately, tea-colored urine and skin itching developed 3 years later. The laboratory evaluation revealed serum TB/DB 2.9/1.5 mg/dL, AST 111 U/L, ALT 125 U/L, ALK-P 427 U/L and γ -GT 676 U/L. Serum AMA, ASMA, IgG, IgM, IgA and ANA titers were within normal range. ERCP demonstrated segmental stricture of the common hepatic duct about 4 cm in length (Figure 1C) and choledochoduodenal fistula. The pancreatogram was normal. MR cholangiogram disclosed an annular mass lesion with enhancement at the proximal CBD, which caused segmental narrowing of the common hepatic duct and dilatation of the intrahepatic ducts (Figure 1D). Bile duct tumors such as cholangiocarcinoma were considered. At surgery, a firm and fixed tumor 4 cm \times 3 cm in size at the CBD was palpated. The duodenal bulb was adhered to the tumor and a choledochoduodenal fistula was found. Segmental resection of the CBD, hepaticojejunostomy and enteroenterostomy, end-to-side, were performed. Histological examination of the resected CBD showed chronic cholangitis with focal atypical epithelium.

Case 2

A 55 year-old male without significant past medical history was admitted because of painless jaundice for 1 mo. A double-contrast barium study of the upper gastrointestinal tract 2 years earlier demonstrated chronic duodenal ulcer with bulb deformity and prepyloric constriction (Figure 2). On examination, there was only icteric sclera. A complete blood count was within normal limits. Serum TB/DB 4.2/2.5 mg/dL, ALT 404 U/L, AST 293 U/L, ALK-P 357 and γ -GT 333 U/L were noted. Abdominal sonography showed dilatation of the intrahepatic ducts and CBD. A contrast-enhanced abdominal CT scan disclosed dilatation of the intrahepatic ducts and proximal CBD associated with distention of the gallbladder. ERCP failed. The MRI revealed an annular lesion about 3.5 cm

Figure 1 Segmental strictures of CBD demonstrated in percutaneous cholangiogram, ERCP and MR cholangiogram. A: Segmental narrowing of CBD below the insertion site of cystic duct in percutaneous cholangiogram; B: Segmental stricture of CBD with dilatation of intrahepatic bile ducts demonstrated in ERCP; C: Segmental stricture of CBD demonstrated in ERCP; D: Segmental narrowing of CBD and dilatation of the intrahepatic bile ducts demonstrated in MR cholangiogram.

in length in the mid portion of the CBD (Figure 3). Three sets of bile fluid cytology were negative. Tumor markers CA19-9 and CEA were not elevated. A diagnosis of cholangiocarcinoma was made. The patient had a laparotomy for resection of the tumor. A tumor over the middle third portion of the CBD with thickened wall was found. No stone was detected in the gallbladder or CBD. Resection of the tumor and Roux-en-Y choledochojejunostomy, end-to-side, was then performed. However, the postoperative histological examination of the lesion showed only chronic inflammation with marked fibrosis.

Figure 2 Chronic duodenal disease with bulb deformity and prepyloric constriction revealed in a double-contrast barium study.

Figure 3 Annular lesion in the mid portion of CBD disclosed in MRI (coronal view).

DISCUSSION

The clinical presentation and preoperative radiological studies without tissue or cytological proof led us to the diagnosis of malignant bile duct strictures in these 2 cases. It has been agreed that any localized extra-hepatic bile duct obstruction coexisting

with intra-hepatic bile duct dilatation should be considered as malignancies such as cancer of the ampulla of Vater, pancreas, or bile duct (cholangiocarcinoma) until proven otherwise^[5]. This agreement arose because of the difficulty in obtaining a tissue diagnosis in patients with obstructive jaundice caused by a bile duct stricture. Application of improved diagnostic methods, such as thin-section spiral CT and magnetic resonance cholangiopancreatography, can potentially increase the diagnostic accuracy, but neither could reliably differentiate malignant from benign lesions^[6,7]. Preoperative histological or cytological examination by means of biopsy or brush cytology was often difficult and liable to false-negative results with low sensitivity and could carry a potential risk of needle tract metastases^[8-12]. The lack of a tissue or cytological evidence might result in some patients being inappropriately treated as malignant disease when a benign stricture was present and vice versa. In the study of Gerhards *et al.*^[4] a false-positive preoperative diagnosis of malignancy resulted in a 15% resection rate of benign lesions in patients with suspicious hilar strictures. Careful review of all preoperative information and radiological images of our 2 cases yielded the initial diagnosis of a CBD tumor, although post-operative pathological examination revealed only inflammation and fibrosis. The decision to undertake resection of the strictures in these 2 cases was therefore not an error of judgment. Obviously, resection of the lesion and obtaining a tissue diagnosis are still the most reliable way to rule out malignancy. Therefore, resection of a benign stricture mimicking a malignant stricture in the extra-hepatic bile duct cannot be avoided completely. However, the lack of clinical constitutional symptoms such as body weight loss or abdominal pain and elevated tumor markers may implicate the possible benign entity of the disorder.

Benign, single, non-traumatic inflammatory strictures of the biliary tracts were infrequently reported with the exception of primary sclerosing cholangitis^[1-3]. Indeed, many benign nontraumatic inflammatory strictures of the common bile duct have been generally considered to be a variant of primary sclerosing cholangitis although Standfield *et al.*^[13] described 12 cases of benign strictures of unknown etiology, and differentiated them from the localized form of sclerosing cholangitis. Other inflammatory conditions of the CBD which are potential etiological factors included bacteria or virus infection, parasite infestation, abdominal trauma, congenital abnormality^[14], chronic pancreatitis^[15], inflammatory pseudotumors^[16], complication of chemotherapy^[17], complication of duodenal ulcer disease^[18-20], and sclerosing therapy of bleeding duodenal ulcer^[21]. Most benign segmental strictures of the extra-hepatic bile duct reported in the literature were located at the hilum or distal CBD. Few cases in the mid CBD have been reported.

The CBD strictures of these 2 patients were less likely due to biliary duct stones because the radiological studies and operative findings did not show the existence of stones. The normal pancreatogram excluded the possibility of chronic pancreatitis as the cause of mid CBD strictures. The radiological appearance, histological examination and the extremely rare incidence in this area made the diagnosis of primary sclerosing cholangitis less likely.

According to the clinical history and surgical findings, stricture of the CBD owing to fibrous encasement by chronic inflammatory changes due to an adjacent duodenal ulcer in these 2 cases was considered. Duodenal ulcer disease is a common disorder, and its associated complications such as hemorrhage, gastric outlet obstruction and perforation, are well known. However, the biliary complications of duodenal ulcer disease, such as biliary-enteric fistula or partial obstruction of the CBD were rare and less well-known^[18-20], especially after the worldwide use of effective antisecretory agents, H₂-receptor antagonists and proton pump inhibitors.

In conclusion, benign non-traumatic inflammatory strictures affecting the common bile duct can be mistaken for malignant tumors. Their existence should be considered in the differential diagnosis of any biliary strictures. The radiological documentation of these 2 cases is of interest to draw attention to the rare complication of obstructive jaundice secondary to duodenal ulcer disease. A tissue diagnosis should be obtained whenever possible as radiology alone is often insufficient to make a firm diagnosis of malignancy in biliary strictures.

Abstract

Hepatitis E virus (HEV) is an unclassified, small, non-enveloped RNA virus, as a causative agent of acute hepatitis E that is transmitted principally via the fecal-oral route. The virus can cause large water-born epidemics of the disease and sporadic cases as well. Hepatitis E occurs predominantly in developing countries, usually affecting young adults, with a high fatality rate up to 15-20% in pregnant women. However, no effective treatment currently exists for hepatitis E, and the only cure is prevention. But so far there are no commercial vaccines for hepatitis E available in the world. Although at least four major genotypes of HEV have been identified to date, only one serotype of HEV is recognized. So there is a possibility to produce a broadly protective vaccine. Several studies for the development of an effective vaccine against hepatitis E are in progress and the best candidate at present for a hepatitis E vaccine is a recombinant HEV capsid antigen expressed in insect cells from a baculovirus vector. In this article, the recent advances of hepatitis E and the development of vaccine research for HEV including recombinant protein vaccine, DNA vaccine and the recombinant hepatitis E virus like particles (rHEV VLPs) are briefly reviewed.

Wang L, Zhuang H. Hepatitis E: An overview and recent advances in vaccine research. *World J Gastroenterol* 2004; 10(15): 2157-2162

<http://www.wjgnet.com/1007-9327/10/2157.asp>

INTRODUCTION

Hepatitis E previously known as enterically transmitted non-A, non-B hepatitis, is an infectious viral disease with clinical and epidemiological features of acute hepatitis. It is a water-born disease, transmitted primarily by contaminated water. There is also a possibility of zoonotic spread of the virus, since several non-human primates, pigs, cows, sheep, goats and rodents are susceptible to the infection^[1,2]. Hepatitis E virus (HEV) is a principal cause of acute hepatitis in adults throughout much of Asia, Middle East and Northern Africa^[3] and transmitted from person-to-person through the fecal-oral route. HEV had provisionally been classified into the *caliciviridae* family from 1988 to 1998, but now it is classified into the separate genus *Hepatitis E-like viruses*^[4-6] because the phylogenetic analysis of non-structural regions of the virus did not support the classification of HEV into the *Caliciviridae* family^[7]. Although at least four major genotypes have been

identified, only one serotype of HEV is recognized^[8-10]. HEV infection is endemic in developing countries where sanitary conditions are not well maintained. Over 50 outbreaks have been reported in Southeast and Central Asia, the Middle East, northern and western parts of Africa, and Mexico^[11-15]. Most of hepatitis E cases in developed countries have been linked to travel to endemic areas. However, recent studies revealed that hepatitis E also occurred in patients who had never been abroad^[16-18]. China is one of the high epidemic areas and there have been 11 hepatitis E epidemics reported to date. The largest one in the world occurred in Xinjiang Uighur Autonomous Region, the Northwest of China, during 1986-1988, with a total number of 119 280 cases and more than 700 deaths^[19-20]. Hepatitis E accounts for more than 50% of acute viral hepatitis in young adults of developing countries, although only 1% to 3% of non-pregnant patients progress to fatal fulminant hepatitis, the case-fatality rate can be as high as 20% among pregnant patients^[21], constituting a serious public health problem and stressing the need for development of an effective vaccine. The development of an attenuated or killed vaccine is not currently possible because of lacking an efficient cell culture system for replication of HEV^[22-27], although some cell lines have been reported for culturing and isolating HEV *in vitro*^[28,29]. Therefore, either a nucleic acid-based vaccine or a recombinant protein vaccine is needed. Compared with gene engineering vaccine for hepatitis B, the study of hepatitis E recombinant vaccine was only a recent endeavor, but some progress has been made^[30].

HEV GENOME

HEV genome consists of a linear, single-stranded, positive-sense RNA of approximately 7.5 kb containing a 3' poly (A) tail and 3' noncoding (NC) regions, and contains three overlapping open reading frames (ORFs). All three coding frames are used to express different proteins^[31-33] (Figure 1). ORF1 begins at the 5' end of the viral genome after a 27-bp non-coding sequence and extends 5 079 nt to the 3' end. ORF1 encodes a polyprotein of about 1 690 amino acids (aa) consisting of non-structural proteins that are involved in viral genome replication and viral protein processing, as its sequence contains motifs characteristic of viral methyltransferases, papain-like cysteineproteases, helicases and RNA-dependent RNA polymerases. In addition, ORF1 has two regions called Y and X domains of unknown function. The very short 5' NTR at the 5' end of the viral genome of 27-35 nucleotides is consistent with a capped genome. The ability of a monoclonal antibody to recognize 7-methylguanosine in RNA extracted from virions of different HEV genotypes suggests that HEV RNAs are capped^[34,35]. ORF3 is 369 nt long, located at the end of ORF1 and overlaps ORF1 at its 5' end by only 1 nt, and overlaps ORF2 by 328 nt. It encodes for a 123-aa protein (pORF3), which is expressed intracellularly. The studies of the biology of HEV replication have shown that pORF3 may be capable of associating with the liver cell cytoskeleton and appears to serve as a cytoskeletal anchor site, where pORF2 and RNA can bind to begin the process of viral nucleocapsid assembly^[36].

The ORF2 is located between 5 147 and 7 127 nt, consists of 1 980 nt and encodes 660 aa (71-88 kDa) most likely representing one or more structural or capsid protein(s)^[2,29-31].

However, the size of the ORF2 protein in native virions is not known^[37]. *In vitro* assays suggest that the -88 kDa of glycoprotein is co-translationally translocated across the endoplasmic reticulum and is expressed intracellularly as well as on the cell surface^[38]. ORF2 contains important epitopes that can induce neutralizing antibodies and has been the focus of vaccine development^[39]. Major epitopes appear to exist near the carboxyl ends of ORF2 and ORF3. Epitopes contained in ORF2 are more conserved (90.5%) than epitopes contained in ORF3 (73.5%) in different strains. Many different ORF2 antigens have been shown to induce antibody (Table 1). There are a number of reports suggesting that truncated ORF2 peptide of shorter length might be more antigenic than the full-length protein^[40-44]. However, in the majority of cases, it has not been shown that the resulting antibodies are neutralizing and, therefore, it is not known whether these antigens could serve as vaccine candidates. Only three ORF2 antigens (trpE-C2, Burma 62 kDa, Pakistan 55 kDa) thus far have been shown to induce antibodies that neutralize the virus^[33].

Figure 1 Genetic map of hepatitis E virus.

HEV GENOTYPE

The genome sequence of HEV seems relatively stable^[45]. The genome of strains isolated from geographically distinct locations is generally more diverse. At present, no consensus exists on genotype classification. The detected HEV strains are currently genetically characterized in laboratories on the basis of ORFs regions^[32]. Recently, some research workers have

also started to characterize HEV strains antigenetically using specific antibodies produced by the recombinant expressed capsid proteins^[46,47]. On the basis of viruses having nucleotide divergence of not more than 20% of the nucleotides in the ORF2 region^[48], the genomes of several HEV strains from different parts of the world can be grouped into at least four major genotypes^[8,31,32,49]: Genotype 1 -including the isolates from South-East Asian (Burmese, some Indian strains), North and Central Asian (strains from China, Pakistan, Kyrgyzstan, and India), and North African strains; Genotype 2 -comprising the single North American (Mexico) isolate; Genotype 3 -consisting of the US and swine isolates; and Genotype 4 -including a subset of isolates from China and most isolates from Taiwan. Genetically heterogeneous isolates from several European countries have been designated new genotypes, but probably should be grouped with the US isolates into a large, heterogeneous group^[31,50]. Two novel isolates of HEV have recently been described in Argentina. Distinct from all previously described isolates, they represent two diverse subtypes of a new genotype of HEV^[51]. Despite the diversity of HEV genotype, no evidence has been found that heterogeneity results from the genetic diversity, thus HEV seems to exist as a single serotype^[8-10].

HEV VACCINE RESEARCHES

At present, no commercially available vaccines exist for the prevention of hepatitis E. However, several studies for the development of an effective vaccine against hepatitis E are in progress^[37,52-56]. Several lines of evidence have suggested the feasibility of a HEV vaccine. First, serum antibodies to HEV develop in response to naturally acquired and experimentally induced HEV infections in cynomolgus monkeys^[57]. Second, seroepidemiology of hepatitis E suggests that people previously infected with HEV are protected during epidemics of the disease^[58]. Finally, successful passive immune prophylaxis in animals indicated that effective vaccination against hepatitis E based on humoral immunity is possible^[59]. Although different geographical isolates of HEV have been identified, only one serotype has been recognized^[8]. So it may be possible to produce a broadly protective vaccine.

ORF2-encoded protein of HEV is the most promising subunit vaccine candidate because it possesses a good antigenicity. So far, HEV ORF2 gene or its fragments have been expressed in prokaryote cells^[56,60-64], insect cells^[37,65-68], yeast cells^[69-71], animal cells^[72], and plants (tomatoes)^[30], etc., and the expression products possess immunogenicity.

Expression in prokaryote cells

It was reported recently that the smallest fragment of ORF2, which is capable of combining the neutralizing antibody of HEV, is located between 452 and 617 aa. This fragment does not only induce neutralizing antibody, but also cross react to the antibody of other genotype^[22]. It was demonstrated that the 2/3 length of C-terminal region of HEV ORF2 contains epitopes, which are recognized by both acute-phase and convalescent-phase antibody to HEV and are likely to be associated with limited immunity to the infection, but these epitopes may be masked when larger portions of ORF2 are expressed as recombinant proteins^[64]. So far, many different length of ORF2 fragments have been expressed in *E. coli*^[56,63,64], but only a few expression products have been found with significant immunoactivity. The first candidate HEV vaccine was a recombinant fusion protein including 439 amino acids (221-660 aa). It comprised tryptophan synthetase and the carboxy terminal fragment of the ORF2 protein of the Burmese strain (genotype 1) and was expressed in *E. coli*. Two cynomolgus macaques were vaccinated with the fusion protein,

and neither of them developed hepatitis following experimental challenge. The animals challenged with the heterologous HEV, the Mexican strain (genotype 2), did get infected, but did not develop hepatitis^[73]. Another study also shows that the immunization with the bacterially expressed ORF2 peptide (pE2) corresponding to 394–607 aa, may prevent HEV infection in primates experimentally transmitted with the homologous strain of HEV^[56].

Expression in insect cells

It is thought that the best candidate at present for a hepatitis E vaccine is a recombinant HEV capsid antigen expressed in insect cells from a baculovirus vector^[25]. When ORF2 of genotype 1 strain is expressed from a baculovirus vector in insect cells, the initial 72-ku protein is quickly processed to smaller proteins, possibly via a protease encoded by the baculovirus^[66]. The most abundant proteins are 56 ku and 53 ku in size, respectively. However, the only neutralization epitope identified to date was mapped to a region of the ORF2 protein of Sar-55 between amino acids 578 and 607^[74]. Therefore, the 56 ku protein (112–607 aa) but not the 53 ku protein (112–578 aa) should contain this epitope. The recombinant 56 ku protein that is more soluble than the full-length protein was an efficient immunogen when adjuvanted with alum^[53,57]. Two 400 ng doses of the vaccine were injected to rhesus monkeys intramuscularly and high antibody titers (1:10 000) were achieved. The monkeys were protected against hepatitis E following intravenous challenge with 300 000 monkey infectious doses (MID₅₀) of the homologous (Sar-55) or 100 000 MID₅₀ of a heterologous HEV (Mexican 14)^[57]. To evaluate the immunogenicity and protective efficacy of the 53 kDa protein, the same research group immunized rhesus monkeys with the 53 ku vaccine, which was derived from processing of the ORF2 protein of Sar-55 and purified from the medium of recombinant baculovirus-infected insect cells and precipitated with alum. Two doses of vaccine containing 385 ng of alum-precipitated 53 ku protein were inoculated into the monkeys intramuscularly. The immunized monkeys were challenged with a high (1000 MID₅₀) or low (100 MID₅₀) dose of homologous virus. The result showed vaccination with the 53 ku protein greatly reduced virus shedding, but did not protect against hepatitis following the high dose challenge. Virus was not detected in the vaccinated animals following the low dose challenge, suggesting that sterilizing immunity might have been achieved. This study indicated that the 53 ku protein did not function as a better vaccine than did the 56 ku protein and actually appeared to have been less effective in preventing disease^[37]. The researches have shown that almost complete vaccine-induced protection lasts for at least 6 mo and partial protection persists for at least 1 year following vaccination^[75].

Expression in yeast and other cells

Recently, yeast expression system has been successfully used for production of vaccines, for example, the recombinant hepatitis B surface antigen^[76,77]. There are some advantages of using this expression system, such as the expression products similar to the natural protein, maintaining the biological activity of the production, to produce easily in large scale and so on^[78]. In recent studies, the ORF2 of HEV (69–660 aa and 112–660 aa) was successfully expressed in *pichia pastoris* and the expression products of recombinant protein (59 ku) was purified and immunized to rhesus monkeys. High titer of anti-HEV (1:8000) was detected in the immunized monkeys^[69–71,79]. Research on using plants for expression and delivery of oral vaccine has attracted much academic attention and has become a hot spot of study since 1990 when Curtiss *et al.*^[80] first reported the expression of *Streptococcus* mutants surface protein antigen A (SpaA) in tobacco, and great progress has

been made since then^[81]. In a recent study, the ORF2 partial gene of HEV named E2 (810 bp, 349–604 aa) was constructed into plasmid pCambia1301 and yielded the reconstructed plant binary expression plasmid p1301E2^[62]. The p1301E2 was expressed in tomatoes and the recombinant antigen derived from them has normal immunoactivity. The transgenic tomatoes may hold a good promise for producing a new type of low-cost oral vaccine for hepatitis E^[30].

Subunit HEV vaccines

DNA immunization usually induces both cellular and antibody immune response. So it might provide a longer duration of protection. Therefore, it has become another focus of HEV vaccine research. Recombinant DNA vaccine is a recently developed new type of vaccine. Through directly injecting the recombinant plasmid DNA with the target gene into human or animals, the DNA will express the expected protein inside the host cells and therefore induce the immune responses to prevent and fight the disease. Recently, a new technology has been introduced for the development of subunit vaccines involving the direct injection of purified plasmid DNA containing protein coding sequences of interest and appropriate regulatory elements allowing expression in mammalian tissues. This novel technology has several potential advantages over other vaccine approaches^[82]. First, the antigens expressed in living cells are in their native form, improving processing and presentation and usually resulting in the activation of both arms of the immune system. Second, DNA can be made inexpensively, in large quantities, at high levels of purity, and is extremely stable. Third, the vector is unlikely to be, or to become, pathogenic, in contrast to live-virus vaccines, and there is little or no immune response to the vector.

In an early study, an HEV cDNA pSVL-ORF3 was constructed by inserting the full length of ORF3 fragment into prokaryotic expression vector pSVL. A total amount of 100 µg of the cDNA was injected to BALB/c mice intramuscularly and anti-HEV IgG was detected in 12 of the 16 immunized mice. However, no antibody was found in the mice injected with the empty vector. The result indicated that the recombinant HEV cDNA could induce the antibody response in mice^[83]. Later, another HEV cDNA pJHEV was constructed by inserting full length of ORF2 fragment. The HEV structural protein was expressed in Cos-7 cells under the control of a hCMV promoter. The successful construct was further tested in BALB/c mice for the induction of an ORF2 specific immune response. All the mice immunized with the cDNA were found seroconverted, but no anti-HEV responses induced in the mice of control group. Sera from the mice injected with pJHEV specifically recognized HEV ORF2 structural protein expressed in recombinant baculovirus in an enzyme-linked-immunosorbent assay (ELISA) and Western blot^[82]. Furthermore, it was also shown that the antiserum generated by the DNA vaccine could bind specifically to native HEV^[84]. Recently, a full-length HEV cDNA clone was constructed in a pSGI vector. The three ORFs were amplified separately and then reconstructed to the full-length clone. The *in vitro* transcribed RNA of the full-length cDNA clone was infective in a HepG2 tissue culture. Viral replication was detected for six passages with strand-specific PCR^[85].

The rHEV VLPs

In spite of the above vaccine candidates, recently the recombinant hepatitis E virus (rHEV) virus-like particles (VLPs) are also the focuses of vaccine research for hepatitis E. With 111 amino acids truncated at the N-terminal, when the capsid protein of HEV was expressed in the baculovirus expression system, it was spontaneously assembled into virus-like particles^[54]. Electron cryomicroscopy shows that these VLPs are formed with

60 copies of a 54 ku protein arranged in T=1 symmetry^[54, 86, 87]. As a mucosal immunogen, the VLPs have several advantages: they are composed of a single protein assembled into particles without nucleic acid, which makes them unable to replicate; they are easy to prepare and purify in large quantities, with a yield of approximately 1 mg /10⁷ insect cells; rHEV VLPs are antigenically similar to the native virions; they are highly immunogenic in experimental animals when injected parenterally; they are very stable at low pH such as in stomach; and oral delivery of rHEV VLPs could induce the same immune responses as occur in natural infection^[86, 54].

In a previous study^[87], mice were orally inoculated with purified rHEV VLPs without adjuvant. Serum IgM response was obtained within 2 wk after the first administration. Serum IgG and IgA were detected by 4 wk, and the intestinal IgA response was found at 8 wk post-immunization. Therefore, the oral immunization of rHEV VLPs is capable of inducing both systemic and intestinal antibody responses. However, since mice are not susceptible to HEV, the same group recently immunized cynomolgus monkeys orally with 10 mg of purified rHEV VLPs, serum IgM, IgG, and IgA responses were observed. All these antibody responses were obtained without adjuvants. When the monkeys were challenged with native HEV by intravenous injection, they were protected against infection or developing hepatitis. These results suggested that rHEV VLPs could be a candidate for the oral hepatitis E vaccine^[88]. Some similar experiments have been described previously^[89-91].

PRE-CLINICAL AND CLINICAL TRIALS

So many vaccine candidates for hepatitis E have been explored as described above. But so far, there is only one HEV vaccine candidate progressed to the stage of clinical trials. That is the 56 ku (expressed in insect cells from a baculovirus vector) recombinant vaccine developed at the NIH, USA^[68]. In phase I trial, the vaccine was found to be safe and immunogenic in 88 American volunteers. A further phase I evaluation was performed in Nepal, where hepatitis E is endemic. Three doses of 5 µg and 20 µg, respectively, were injected into 22 Nepalese volunteers each at zero, one and six months. No serious adverse events were observed. By the second month, 43 of 44 volunteers had seroconverted to anti-HEV. By the 7th month, the remaining volunteers also developed antibody to HEV. The study indicated that the HEV vaccine candidate was safe and immunogenic. This same lot of vaccine is currently being used in phase II/III clinical trials in Nepal^[25], where as many as 90% of the jaundice cases are caused by HEV.

In recent pre-clinical trials, the vaccine used in the experiment was from the same lot that was prepared for the above clinical trials. The results indicated that two doses of HEV vaccine as small as 1 µg were highly effective in preventing not only hepatitis but also infection following intravenous administration of 10⁴ MID₅₀ of virulent virus. However, these doses of vaccine will not be sufficient for long-term protection. Other studies have shown that a third dose of vaccine at 6 or 12 mo following the first dose will enhance immunogenicity and/or efficacy^[75, 92]. The study has also confirmed that the cross-protection against a Mexican genotype 2 isolate and extended the evidence for cross-protection to a US genotype 3 isolate of HEV. The results of this experiment have shown that the manufacture of a candidate hepatitis E vaccine can be scaled up to produce more clinical quality and that such a vaccine is highly immunogenic and effective for preventing hepatitis E in the pre-clinical trials. It is likely that protection against infection will be more effective following natural oral challenge with relatively small doses of HEV^[25].

CONCLUSIONS

Despite the achievements mentioned above, there are still many questions to be answered in future. For example, there is a study showing that acute hepatitis E can be induced by plasma transfusion from a donor with HEV viremia, which indicates the possibility of transfusion transmitted hepatitis E^[93]. Some similar studies also showed the possibility of post-transfusion hepatitis E^[94-97]. Therefore, effective measures for preventing post-transfusion hepatitis E must be taken. To achieve effective immunization, how should the HEV vaccine be given by, orally or intramuscularly? Will a monovalent vaccine protect against all HEV strains including HEV from animals and genotypes and provide a long-term immunity to hepatitis E? To facilitate vaccine development and to improve our knowledge about the mechanism of virus replication, an effective practical cell culture system should be established and demonstrated.

Abstract

AIM: To investigate clinical and pathologic data of esophageal carcinoma (EC) and cardiac carcinoma (CC) among residents in Chaoshan region of China.

METHODS: Clinical and pathologic data of 9 650 patients with EC and 4 173 patients with CC in the Chaoshan population were collected and analyzed. Moreover, Chaoshan esophageal carcinoma tissue arrays were made for high-throughput study.

RESULTS: Male to female ratio was 3:1 in patients with EC and 4.75:1 in CC. The average age of the occurrence of EC was 54.6 years, and of CC was 58.1 years. For both EC and CC, age at diagnosis was a little younger in Chaoshan region than in most other areas. The most commonly affected site of esophageal carcinoma was the middle third of esophagus (72.0%); the second was the lower third (15.3%). The main gross type of esophageal carcinoma was ulcerative type (41.50%); the medullary type was the second (39.6%). Squamous cell carcinoma accounted for the overwhelming majority of esophageal cancer (96.4%); adenocarcinoma accounted for the overwhelming majority of cardiac carcinoma (94.5%). Chaoshan esophageal carcinoma tissue arrays were easily for high-throughput study, and tissue cores with a diameter of 1.5 mm could better keep more structure for molecular expression study.

CONCLUSION: Both EC and CC are common in males. The average occurrence age of EC and CC is younger in Chaoshan than in most other regions of China. The most commonly affected site of esophageal carcinoma was the middle third of esophagus (72.0%). Squamous cell

carcinoma accounted for the overwhelming majority of esophageal cancer; adenocarcinoma accounted for the overwhelming majority of cardiac carcinoma. Tissue arrays technology is applicable for rapid molecular profiling of large numbers of cancers in a single experiment.

INTRODUCTION

Esophageal cancer (EC) ranks among the 10 most common cancers in the world, and is almost uniformly fatal. Chaoshan area is a unique littoral high-risk area of EC in China, within which Nanao island has the highest risk, the second being Jieyang county. According to the report from the Department of Public Health, Guangdong Province in 1993, the mortalities of EC in Nanao island were: $108.68 \pm 7.88/100\ 000$ in standardized Chinese population, $145.44 \pm 10.49/100\ 000$ in standardized world population, $261.16 \pm 25.01/100\ 000$ in standardized world population between the age of 35-64. The annual average incidence rates in males and females were $132.19/100\ 000$ and $69.20/100\ 000$ in Nanao island from 1987 to 1992^[1].

The predominant inhabitants of Chaoshan are offsprings of immigrants who hundreds or thousands of years ago came from the Central Plains of China, now a world well-known high risk region for EC. Chaoshan residents who have a high risk of EC and cardiac carcinoma (CC) are a relatively isolated population who have kept the old Chinese language (Chaoshan dialect) and customs. It is important to see if there is any evidence for the reducing incidence and mortality of EC and CC in Nanao island so far^[2] as the incidences of EC and CC present a downward trend in most other high risk regions. This unique society provides us an unparalleled base for the genetic and also environmental study of esophageal carcinoma. In the current study, we explored the clinical and pathologic features of EC and CC.

In addition, scholars have discovered that many genes and signaling pathways are involved in EC and CC development^[3-7]. However, genetic tumor markers have not gained in EC and CC diagnostics and prognosis prediction. Identification and evaluation of new molecular parameters are of utmost importance in cancer research. Here we present a high-throughput approach to rapidly identify relevant molecular expression changes in Chaoshan EC tissue arrays.

MATERIALS AND METHODS

Clinical data

Data about age, gender, and X-ray or pathological diagnoses of 13 823 patients with carcinoma of esophagus (9 650 cases) or

cardia (4 173 cases) were collected from the Tumor Hospital (1978-1998), First Affiliated Hospital (1989-1998), and Second Affiliated Hospital (1983-1998) of Shantou University Medical College, the Central Hospital of Shantou and the Hospital of Jieyang.

Sample collecting and EC tissues arrays construction

Seventy esophageal squamous carcinoma tissue specimens were selected from Department of Pathology, Shantou University Medical College in 2002. The specimens were fixed in 40 g/L neutrally buffered formaldehyde, embedded in paraffin. Sections of 5 μ m stained with hematoxylin and eosin were obtained to confirm the diagnosis and to identify different viable, representative areas of the specimen. From these defined areas core biopsies were taken with a precision instrument. Sixty-eight EC and para-cancerous tissue cores with a diameter of 1.5 mm from each specimen were punched and arrayed in 8×9 on a recipient paraffin block. Five- μ m sections of the EC tissue array block was cut and placed on adhesive coated slides (cooperated with Cybrdi, Dr. Li Jun).

Immunohistochemistry

The expression of Erk1/Erk2 MAPK signaling protein was analyzed using Erk1/Erk2 Mouse derived anti-activated MAP kinase monoclonal antibody (1:400, Sigma), Histostain™-SP kit and DAB visualization methods according to the manufacture's instruction (China Beijing Zhongshan Biological Technology CO., LTD.) And the expression of epidermal growth factor receptors were primarily analyzed using phosphor-EGFR (Try845) rabbit polyclonal antibodies and HRP-linked anti-rabbit IgG (Cell Signaling Technology, Inc. #2231, #7074). Four conventional normal esophageal epithelium tissues from autopsy were used as normal tissue controls. The human breast cancer tissue was used as positive control. Negative control was designed using phosphate-buffered saline (PBS) instead of primary antiserum. The detailed immunohistochemical process was carried out according to the manufacture's instructions.

Assessment of staining

The positive immunohistochemical staining of Erk1/Erk2 proteins was shown as brown signals in the nuclei; and the immunohistochemical signals of phosphor-EGFR (Tyr845) was in membrane and cytoplasm. The percentage of positive stained

cells was evaluated for each tissue sample by counting all cells at 5 high power fields of micrometric rule (5 mm×5 mm). The cases having positive cancer cells or epithelium accounting for more than 75% of all cancer cells or epithelium on the slide were defined as a score of +++, 50-74% were defined as a score of ++, 25-49% were defined as a score of +, 6-24% were defined as a score of \pm , 1-5% were defined as a score of \pm , less than 1% were defined as a score of -.

Statistical analysis

Data were stored in a computer data base (FoxPro, version 2.5 b) and analyzed using a computer (Pentium 4) spread sheet (Microsoft Excel 97) and professional statistical computer software (SPSS, version 11.0 and SAS, version 6.08). $P \leq 0.05$ was taken as significant. Immunoreactivity was classified as continuous data (undetectable levels or 0% to homogeneous staining or 100%) for all markers.

RESULTS

Gender and age

Genders of the patients were recorded in 9 635 cases. The 8 665 EC cases had age records, the youngest and the oldest were 17 years and 91 years respectively, and 3714 CC cases had age records. The male to female ratio and average age of morbidity for EC and CC in Chaoshan region are shown in Table 1. Constituent ratio of EC, CC in every age group is shown in the histogram (Figure 1).

Figure 1 The histogram of the constituent ratio for EC and CC in Chaoshan region.

Figure 2 A: Overview of Chaoshan esophageal carcinoma tissue array (tissue cores with a diameter of 1.5 mm with 68 samples); B: Esophageal para-cancerous tissue and squamous carcinoma tissue (HE staining, original magnification: ×40).

Table 1 Sex ratio, average age of morbidity for EC and CC in Chaoshan littoral region (mean±SD)

	<i>n</i>	Sex (male:female)	Age(yr)	<i>F</i>	<i>P</i>
EC	9 635	7 228:2 407(3.0:1)	54.61±10.73	103.24	<0.001
CC	4 167	3 442:725(4.75:1)	58.14±9.45		

EC:CC=2.31:1.

Pathology

The overwhelming majority of ECs were squamous cell carcinoma (96.4%); whereas CCs were composed mainly of adenocarcinomas (94.5%), and squamous cell carcinoma ranked second (4.4%). The detailed information of pathology is shown in Table 2.

Table 2 Pathology for EC and CC in Chaoshan littoral region (%)

	Site			Gross type				Histological type			
	U	M	L	UT	MT	ST	FT	SCA	ACA	UCA	O
EC	12.7	72.0	15.3	41.5	39.6	9.6	9.4	96.4	2.7	0.6	0.3
CC								4.4	94.5	0.9	0.2

Site (EC, *n*=6 384); Gross type (EC, *n*=1 193); Histological type (EC, *n*=7 272; CC, *n*=3 086); U: Upper third; M: Middle third; L: Lower third; UT: Ulcerative type; MT: Medullary type; ST: Scirrhous type; FT: Fungating type; SCA: Squamous cell carcinoma; ACA: Adenocarcinoma; UCA: Undifferentiated carcinoma; O: others.

**Figure 3** Phosphor-EGFR (Tyr845) expression on esophageal squamous carcinoma tissue (A, B, C) and esophageal para-cancerous tissue (D) (Cell Signaling Technology kit, original magnification: ×40).**Figure 4** Erk1/Erk2 expression on normal esophageal squamous tissue (A, conventional tissue section, SP×100) and esophageal squamous carcinoma tissue (B, C, D tissue arrays) (SP×200).

Table 3 Expression of Erk1/Erk2 in esophageal squamous carcinoma tissue and para-cancerous tissue (% , mean±SD)

	Normal esophageal squamous cell (n=5)	Para-cancerous tissue (n=5)	Grade I (n=19)	Grade II (n=34)	Grade III (n=9)	F	P
Activated ERK1/ERK2	5.10±1.44	76.80±0.14	76.80±0.09	75.80±0.09	69.30±0.14	2.60	0.04

There was marked difference between normal esophageal epithelium and cancer tissues or para- cancerous tissue. But there was no marked difference among para-cancerous tissues and esophageal squamous carcinoma tissues ($F=1.463$, $P=0.236$).

Chaoshan EC tissues arrays and immunohistochemistry

Sections from tissue arrays were kept structure well for pathologic and immunohistochemical research (Figure 2). The expression of phosphor-EGFR(Tyr845) in esophageal squamous carcinoma tissue are relative diversity from \pm to $++++$, but no distinct differences among esophageal squamous carcinoma tissues according to grading (Figure 3). The expression of activated ERK in esophageal squamous carcinoma tissue and para-cancerous tissue are shown in Table 3 (Figure 4).

DISCUSSION

In data from Yangquan city of Shanxi Province (502 cases)^[8], the median age of EC patients was 59.17 years, 4.56 years older than that of Chaoshan EC patients. And also data from Linxian of Henan Province (2 601 cases)^[9], the proportion of EC patients from 20 to 30 years was 0.35%, from 30 to 40 was 5.19%; whereas both of the two proportions were lower than those from our data (0.70% and 7.70% respectively). In our data from Chaoshan region, the ulcerative type (41.5%) was the most common gross type of EC, which suggests that most EC patients were in the terminal stages when they arrived at hospitals.

Both preceding evidences indicated the average age of EC occurrence was younger in Chaoshan population than those in central plains of China. Synthetically analysis of two reports from Henan Province (1 045 cases and 1 332 cases respectively)^[9,10] showed the proportion of CC patients less than 50 years old was 15.56%, which was slightly lower than that from Chaoshan CC data (17.60%). The similar phenomena were seen in other papers^[11,12]. It might indicate that the age of incidence of cardiac cancer is also younger in Chaoshan region than in most other areas. Pathological analysis of 1 572 EC patients from Henan Province indicated histological type for the overwhelming majority of EC was squamous cell carcinoma (SCC), and the proportion of SCC (95.1%) was similar to that in our data (96.44%)^[13]. In comparison of the constituent ratios of histological types for cardiac carcinoma with data respectively from the Chinese Academy of Medical Science^[14], Erlangen - Nurnberg University in Germany^[15] and our data, it homoplastically shows that adenocarcinoma accounts for the overwhelming majority of cardiac carcinoma, while the proportions of other histological types are relatively low.

Both data from Yangquan and Linxian^[16] also showed the middle third of esophagus was the most commonly affected site analogously, followed by the lower third and then the upper third, similar to our results.

Tissue array technology is applicable for rapid molecular profiling of large numbers of cancers in a single experiment. But a possible limitation of the tissue array technology is that the minute tissue samples acquired from the original tissues may not always be representative of the entire tumor, in light of the intratumor heterogeneity characteristic to most cancers. The comparisons between similarly acquired specimens from different stages of tumor progression placed on the same tissue microarray should be less problematic. If tumor arrays are used to investigate prevalence or prognostic significance of molecular changes, the critical issue is the extent to which minute tissue samples are representative of their donor tumors. The findings of this study suggest that significant results

can be obtained on tumor arrays issue cores with a diameter of 1.5 mm. Well and truly, one should consider the tumor tissue array technology as a rapid, high-throughput survey method to pinpoint the biologically most prevalent or clinically most promising genes and molecular markers for detailed studies combined with conventional tissue specimens.

The epidermal growth factor (EGF) peptide induces cellular proliferation through the epidermal growth factor receptor (EGFR), a M_r 170 000 single-pass transmembrane tyrosine kinase, which is believed to play important roles in the control of cell growth and differentiation. The EGFR activates ras and the MAP kinase pathway, ultimately causing phosphorylation of transcription factors such as c-Fos to create AP-1 and ELK-1 that contribute to proliferation. Gene amplification and overexpression of EGFR have been reported in various human tumors, including head and neck/oral cancer^[17-22].

Mitogen-activated protein kinase (MAPK) cascades have been shown to play a key role in transduction extracellular signals to cellular responses. Extracellular signal-regulated kinase (ERK) has been the best characterized MAPK and the Raf-MEK-ERK pathway represents one of the best characterized MAPK signaling pathway. The activated ERKs translocate to the nucleus and transactivate transcription factors, changing gene expression to promote growth, differentiation or mitosis^[23].

Our primary immunohistochemical study showed that phosphor-EGFR (Tyr845) and activated ERK were expressed in both para- cancerous and esophageal cancerous cells. The intensity of the expression was much higher in cancer than in normal tissue, suggesting that EGFR, Erk1/Erk2 MAPK signaling pathway might play an important role in the regulation of proliferation of esophageal cancer^[24,25].

In summary, Both EC and CC are common in males. The average age of occurrence is younger in Chaoshan than in most other regions of China. It is suggested that either genetic factors might play an important role in the pathogenesis of esophageal and cardiac cancers in Chaoshan or Chaoshan residents exposed themselves to some high risk environmental factors. Tissue microarrays technology is applicable for rapid molecular profiling of many tissue samples in a single experiment.

ACKNOWLEDGMENTS

The authors acknowledge the participation of the following members of the undergraduate scientific research group in Shantou University Medical College of China led by Professor Min Su: SM Ying, Y Ni, YS Gao, J Lin, JK Sun, BC Yuan, YF Li, XL Chen, JS X, Y F Chen, who helped us collect the case data of esophageal carcinoma and cardiac cancer. We express our special thanks to Professor Bruce AJ Ponder, Hutchison/MRC Research Centre, MRC Cancer Cell Unit and University of Cambridge, for his invaluable suggestions, Dr. John KL, for his kind assistance in the preparation of the grammatical structure of this paper.

Abstract

AIM: To determine whether cyclooxygenase-2 (COX-2) was expressed in human esophageal squamous cell carcinoma.

METHODS: Quantitative reverse transcription-polymerase chain reaction (RT-PCR), western blotting, immunohistochemistry and immunofluorescence were used to assess the expression level of COX-2 in esophageal tissue.

RESULTS: COX-2 mRNA levels were increased by >80-fold in esophageal squamous cell carcinoma when compared to adjacent noncancerous tissue. COX-2 protein was present in 21 of 30 cases of esophageal squamous cell carcinoma tissues, but was undetectable in noncancerous tissue. Immunohistochemistry was performed to directly show expression of COX-2 in tumor tissue.

CONCLUSION: These results suggest that COX-2 may be an important factor for esophageal cancer and inhibition of COX-2 may be helpful for prevention and possibly treatment of this cancer.

INTRODUCTION

Esophageal cancer is the fourth most prevalent malignancy in China. Although several factors have been implicated for the recent rise in the frequency of esophageal carcinoma, including diet, activation of *c-myc* oncogenes and inactivation of tumor suppressor genes (*p53*)^[1,2], the exact pathogenic mechanisms and promoting factors of this cancer remain to be

clarified. There is no effective strategy for treatment of this disease. Recently epidemiological studies suggest intake of nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin and indomethacin can reduce the risk of colorectal cancer^[3,4]. Based on these findings, subsequent studies have addressed the role of COX enzyme as a target of these compounds.

COX is a rate-limiting enzyme involved in the conversion of arachidonic acid to prostaglandin H₂, the precursor of several molecules including prostaglandin (PG), prostacyclin, and thromboxane. Results from recent studies have established the presence of two distinct COX enzymes, a constitutive enzyme (COX-1) and an inducible form (COX-2). They share over 60% identity at the amino acid level and have similar enzymatic activities, but both isoforms are suggested to have different biological functions^[5-9]. COX-1 is constitutively expressed in most mammalian tissues and is thought to carry out "housekeeping" functions such as cytoprotection of the gastric mucosa, regulation of renal blood flow, and control of platelet aggregation. In contrast, COX-2 mRNA and protein are undetectable in normal tissues, but can be rapidly induced by proinflammatory or mitogenic stimuli including cytokines, endotoxins, interleukins, and phorbol ester^[10-12].

Multiple lines of experimental evidence have also suggested that COX-2 is involved in carcinogenesis. For example, COX-2 is up-regulated in transformed cells^[13] and in various forms of cancer^[14-17], whereas levels of COX-1 are relatively stable. Moreover, COX-2 knockout mice develop 75% fewer chemically-induced skin papillomas than control mice. Recently, it has been shown that selective COX-2 inhibitors may significantly suppress experimentally-induced colon carcinogenesis^[18,19]. Epidemiological studies have shown that intake of aspirin was associated with up to a 90% decreased risk of developing esophageal cancer^[20,21], and in induced esophageal carcinomas, indomethacin had antitumor activity^[22,23].

Here we investigated whether COX-2 was up-regulated in esophageal squamous cell carcinomas from Chinese patients. Our data show that levels of COX-2 are markedly increased in esophageal squamous cell carcinomas, which raises the possibility that selective inhibitors of COX-2 may be useful in the prevention or treatment of this important disease.

MATERIALS AND METHODS

Samples

We examined 30 cases of esophageal squamous cell carcinoma. Both tumor tissue and surrounding normal tissue were obtained from surgical patients with esophageal squamous cell carcinoma at Tongji Hospital during operations. The age of the patients was 57±9 years (mean±SD; range, 37 to 75 years). Of the patients, 23 were men and 7 were women. A small portion from each tissue sample was immediately frozen in liquid nitrogen and stored at -80 °C. Tissue samples were fixed in 40 g/L neutral buffered formaldehyde, processed through graded ethanol solutions, and embedded in paraffin and immunostained for COX-2. A subset of paired tumor tissues and surrounding normal tissue was further examined by RT-PCR and Western blotting.

RNA extraction

Protein and total RNA were extracted using TriZol Reagent (Life Technologies, GIBCO BRL). RT-PCR kit was purchased from Takara Bio Co., Ltd. COX-2 affinity-purified polyclonal antibodies were obtained from Santa Cruz Biotechnology, Inc. Rabbit anti-goat IgG conjugated with horse-radish peroxidase (HRPO) was obtained from KPL, Inc., USA. ImmunoResearch Lab Enhanced chemiluminescence assay was purchased from PIERCE, Inc. SDS-PAGE standard was obtained from Bio-Rad, Inc.

Western blotting for detection of COX-2

Protein in the various samples were extracted and purified by TriZol Reagent, and the protein concentration was evaluated by Bradford method. A portion of protein (20 µg) extracted from each tissue sample was subjected to electrophoresis in 80 g/L polyacrylamide slab gels. After transfer to PVDF membrane and blocking with fat free milk powder, blots were probed with COX-2 antibodies (1:750), followed by incubation with HRPO-conjugated secondary antibody (rabbit anti-goat 1:800). COX-2 proteins were visualized by enhanced chemiluminescence.

Semi-quantitative RT-PCR

Total RNA was isolated and purified by TriZol Reagent, and the RNA concentration was determined. Semi-quantitative analysis of the expression of COX-2 mRNA was performed using the multiplex RT-PCR technique. In this assay, we used a housekeeping gene, glyceraldehyde-3-phosphate dehydrogenase (GAPDH), as an internal standard. A sample (1 µg) of total RNA was reverse-transcribed using the Takara Bio RT-PCR kit according to the manufacturer's protocol. PCR was performed in a 25 µL reaction mixture containing 5 µL of cDNA template, 1×PCR buffer, 1.5 mmol/L MgCl₂, 0.8 mmol/L dNTPs, 100 nmol/L of each primer for COX-2 (sense primer, 5'-CCGAGGTGTATGTATGAGTG-3'; antisense primer, 5'-AGGAGAGGTTAGAGAAGG-3') or 100 nmol/L GAPDH (sense primer, 5'-CCTTGCCTCTCAGACAATGC-3'; antisense primer, 5'-CCACGACACTCAGCAC-3') and 1 U of *Taq* DNA polymerase. The PCR primers used for detection of COX-2, and GAPDH yielded cDNA products of 314-bp and 340-bp, respectively. The conditions for PCR were one cycle of denaturing at 94 °C for 5 min, followed by 35 cycles of at 94 °C for 45 s, 56 °C for 45 s, 72 °C for 1 min with a final extension at 72 °C for 7 min. The electrophoresed PCR products were scanned by densitometry and the ratio of COX-2 to GAPDH was calculated in each sample.

Immunohistochemistry

Tissue sections (4 µm thick) were deparaffinized in xylene and rehydrated. Heat antigen retrieval was performed as described previously^[24]. Slides were then processed for immunohistochemistry. In the primary antibody reaction step, slides were incubated with the COX-2 antibody (final concentration 5 µg/mL) for 1 h at room temperature. For positive controls, sections of colon cancer expressing the COX-2 protein were included in each staining procedure. For negative controls, nonimmunized rabbit IgG or Tris-buffered saline was substituted for the primary antibody to distinguish false positive responses from nonspecific binding to IgG or the secondary antibody. In addition, preabsorbed antibody with an excess amount of immunogen abolished the staining. Staining was repeated twice to avoid possible technical errors and similar results were obtained in all cases.

Evaluation of COX-2 immunohistochemistry

All immunostained sections were coded and evaluated without

prior knowledge of the clinical or pathological parameters. In each section, five high-power fields were selected at random and a total number of at least 700 cells were evaluated. The results were expressed as the intensity of staining. The intensity of staining was judged relative to smooth muscle cells in the sample, and estimated on a scale 0-3 (0 negative; 1 weak; 2 moderate; and 3 strong). All slides were interpreted by two investigators on three different occasions. Their evaluations were similar and <10% disagreement between the investigators was noted. In case of major disagreement, the final evaluation of such sections was determined by consensus using a multihead microscope.

Immunofluorescence assay

Tissue samples were cut into 6 µm crystal-sections, and processed with COX-2 specific antibody and fluorescein labeled secondary antibodies and all the sections were observed immediately under fluorescence microscope.

Statistical analysis

Statistical analysis was performed using SAS software. Results of immunohistochemistry were analyzed by Fisher's exact test. The correlation of RT-PCR and western blotting was analyzed by logistic regression analysis. $P < 0.05$ was considered statistically significant.

RESULTS

COX-2 mRNA expression in esophageal squamous cell carcinoma by semi-quantitative RT-PCR

To examine the level of COX-2 mRNA, RT-PCR was performed to estimate the expression of COX-2 in tumor tissues relative to that in the matched normal tissues, which was expressed as COX-2/GAPDH ratio. GAPDH was used as an internal control. Semiquantitative RT-PCR indicated that COX-2 mRNA was found in 21 of 30 esophageal squamous cell carcinomas. In surrounding normal tissue of esophageal squamous cell carcinoma, COX-2 mRNA could not be detected (Figure 1). In the 21 esophageal squamous cell carcinoma tissues, the COX-2/GAPDH ratios ranged from 0.6 to 1.0, levels of COX-2 mRNA were increased by >80-fold compared to adjacent noncancerous tissue.

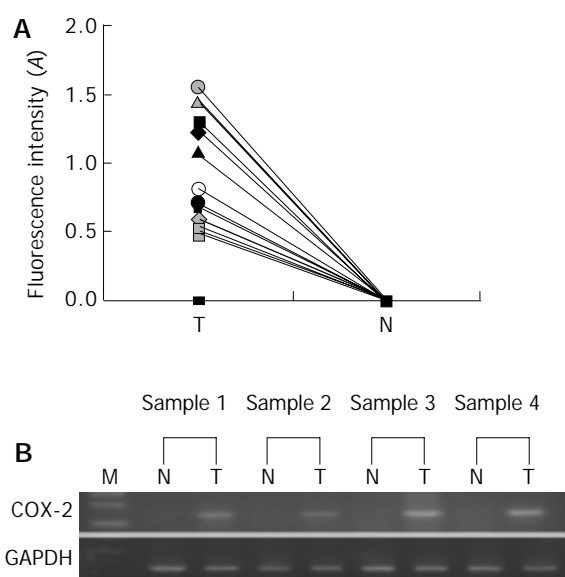

Figure 1 Semiquantitative result of RT-PCR analysis of COX-2 mRNA expression in squamous carcinoma tissues and matched normal tissues of the esophagus. A: Data are expressed as the fluorescence values of COX-2 band in tumor and nontumorous

tissue samples from 30 patients with esophageal squamous cell carcinoma. B: Representative results of semiquantitative RT-PCR, indicated COX-2 mRNA was found in esophageal squamous cell carcinoma samples (T), while in surrounding normal tissue (N), COX-2 mRNA could not be detected. The coamplified GAPDH gene served as an internal control. PCR product sizes are 314 bp for COX-2 and 340 bp for GAPDH. M indicates DNA marker. The samples in lanes 1N and 1T, 2N and 2T, 3N and 3T, 4N and 4T are paired samples from 4 patients, respectively.

Figure 2 Western blot analysis of COX-2 in squamous carcinoma tissues and matched normal tissues of the esophagus. COX-2 expressions in representative tumor (T) and nontumorous (N) are shown. A: Data are expressed as the absorbency values of COX-2 band in tumor and nontumorous tissue samples from 30 patients with esophageal squamous cell carcinoma. B: Representative result of Western blot analysis. COX-2 protein was detected in tumor tissue but was undetectable in nontumorous tissue in the same patients. β -actin was used as an internal control. The samples in lanes 1N and 1T, 2N and 2T, 3N and 3T, 4N and 4T are paired samples from 4 patients, respectively.

Western blotting

To determine whether levels of COX-2 protein were also increased in esophageal squamous cell carcinomas, western blot analysis of paired tumorous and nontumorous tissue was performed. COX-2 protein was detected in tumor tissue from 21 of 30 patients but was undetectable in nontumorous tissue in the same patients. β -actin was used as an internal control

(Figure 2). Furthermore, the results of western blot analysis paralleled those of mRNA RT-PCR analysis. There was a significant positive correlation between western blot analysis and RT-PCR analysis results ($r=0.708$, $P<0.01$) (Figure 3).

Figure 3 Correlation between western blot analysis and RT-PCR analysis results. The results showed that the expression of COX-2 in cancer tissues (western blot analysis) was highly correlated with by RT-PCR analysis (r value=0.708, $P<0.001$).

Table 1 Expression of COX-2 in esophageal squamous cell carcinomas detected by immunohistochemistry

	Intensity			
	0	1	2	3
Tumor tissue	10	2	12	6
Normal tissue	27	3	0	0

$P<0.05$

The intensity of staining was estimated on a scale 0–3. (0, negative; 1, weak; 2, moderate; and 3, strong).

COX-2 expression in esophageal squamous cell carcinoma by immunohistochemistry

Immunohistochemistry was performed to directly indicate cell specific COX-2 protein expression. In nontumorous tissue specimens, a weak COX-2 staining or no COX-2 staining was detected. In contrast, a moderate to strong expression of COX-2 was noted in many esophageal squamous cell carcinomas of the same patients. Specifically, a strong expression of COX-2 protein was present in 6 of 30 (20%) esophageal squamous cell carcinomas, moderate expression was present in 12 of 30 (40%), and weak expression was present in 2 of 30 (15%). The level of COX-2 expression in esophageal squamous cell carcinomas was significantly higher than that in surrounding normal tissue (Table 1). Expression of COX-2 was localized to tumor cells, not to surrounding stromal cells or infiltrating inflammatory cells (Figure 4).

Figure 4 Representative results of immunohistochemical analysis of COX-2 in squamous carcinoma tissues and matched normal tissues of the esophagus from the same patient (Magnification x200). In normal esophageal tissue there is no positive staining for COX-2 (A) but in esophageal squamous cell carcinoma tissue, carcinoma cells display a strong staining for COX-2, which indicate COX-2 expression specifically in cancer tissues (B).

Figure 5 Immunofluorescence analysis of COX-2 in squamous carcinoma tissues (Magnification, x400). A and B are from 2 different patients with esophageal squamous cell carcinoma, Both display a strong green fluorescence staining for COX-2 in cancer-nests.

COX-2 expression in esophageal squamous cell carcinoma by immunofluorescence

Immunofluorescence was performed to directly indicate whether COX-2 protein was expressed in esophageal cancer. COX-2 expression was detected in esophageal squamous cell carcinomas. Immunofluorescence in esophageal squamous cell carcinomas displayed a cancer-nest structure (Figure 5).

DISCUSSION

Epidemiological studies indicate that the administration of nonsteroidal anti-inflammatory drugs (NSAIDs) results in a marked reduction in adenoma size and number and, not infrequently, leads to a complete regression of colonic polyps in patients with familial adenomatous polyposis^[25-27]. NSAIDs also reduce the risk of sporadic colorectal, breast, and lung cancers^[28,29]. These effects of NSAIDs on the inhibition of carcinogenesis have also been demonstrated in animal experiments, including pancreatic tumor model induced by N-nitrosobis (2-oxopropyl) amine in hamsters^[30]. Several lines of evidence indicate that the antitumor effects of NSAIDs may be due in part to the inhibition of COX-2 activity^[19,31-33]. Indeed, in carcinomas of the colon and lung and also in gastric and esophageal carcinomas, the level of COX-2 expression is significantly increased. These findings suggest that up-regulation of this enzyme might be a common mechanism for carcinogenesis of cells of an epithelial origin. Indeed, in the present large sampled study we found that COX-2 expression was increased at both the RNA and protein levels in a large proportion of esophageal squamous cell carcinoma compared with paired normal surrounding esophageal tissues by RT-PCR and Western blot analyses. RT-PCR analyses indicated that 21 of 30 (70%) esophageal squamous cell carcinoma cases displayed increased COX-2 mRNA. Furthermore, the results of mRNA analysis paralleled those of western blot and immunohistochemistry. Thus, approximately 67% of the carcinoma samples exhibited positive staining of COX-2 protein, whereas paired normal tissues showed little or no COX-2 staining. Up to 60% of carcinoma cases showed moderate to strong COX-2 immunostaining (intensity 2 or 3). Also, immunofluorescence demonstrated the expression of COX-2 in esophageal squamous cell cancer-nests. These findings suggest that COX-2 may also be a marker for the malignant potential of esophageal squamous cell carcinoma, although this function remains to be clarified. Taken into consideration of the limited number of specimens, a conservative interpretation of the increased COX-2 mRNA and protein expression is necessary. Examination of a larger number of paired samples of tumor tissue and nonmalignant mucosa from esophageal cancer patients, as well as normal mucosa from persons without esophageal cancer in future studies will be necessary to more clearly determine the status of COX-2 in normal esophageal mucosa and in

esophageal cancer. Because COX-2 was up-regulated at the transcriptional level, which can increase COX-2 protein expression, subsequent determination of COX-2 protein synthesis and bioactivity at the protein level is important. It is also important to study the possible link between the known genetic alterations and COX-2 in esophageal cancer. However, the present results indicate COX-2 is elevated in esophageal cancer in a fashion similar to that in intestinal tumors.

COX-2 could potentially cause carcinogenesis via multiple mechanisms, and the role of COX-2 in tumor development and progression *in vivo* is not known. The most obvious possibility is that overexpression of COX-2 leads to high levels of prostaglandins (PGs) in tumor tissue. This hypothesis is supported by the finding of elevated levels of PGs in cancer tissues, compared with corresponding normal tissues^[34,35]. PGs produced by COX-2 may subsequently facilitate tumor progression by acting as differentiation and growth factors, immunosuppressors and angiogenic agents^[36-38]. Additionally, it has been shown that elevated PGE₂ levels in COX-2 overexpression cancer cells correlate with the metastatic potential of the cancer cells, and can be reduced in a dose-dependent manner by COX inhibitors^[39]. On the other hand, there is also evidence that NSAIDs might exert their antineoplastic effect by a PG-independent pathway, and the COX-2 enzyme itself may promote cancer development and progression^[40]. Thus, NSAIDs suppressed proliferative activity in colon cancer cells devoid of cyclooxygenase and PGs^[31]. Moreover, in extrahepatic tissues in which cytochrome P450 content is low, COX may be important for generation of carcinogens. For example, several classes of chemical carcinogens, e.g., dihydrodiol derivatives of polycyclic aromatic hydrocarbons, aromatic amines and heterocyclic amines, are activated to mutagenic derivatives by COX^[41]. The generation of carcinogens by COX-2 may be important, therefore, for understanding the link between cigarette smoking or consumption of grilled or fried meat and esophageal cancer^[42]. Additional studies are needed to determine which of these mechanisms are more important in esophageal squamous cell carcinoma.

Selective inhibition of COX-2 in esophageal cancer cells induces apoptotic cell death and reduces proliferative activity and these effects correlate with the inhibition of PG synthesis. Similar results have been reported^[43-45]. The significance of COX-2 likely varies between different classes of tumors. We cannot conclude from this and other published data whether the antiproliferative and proapoptotic effects of COX-2 inhibition on esophageal cancer cells are exclusively mediated through the inhibition of PG synthesis or if other mechanisms are also involved. However, our data provide a theoretical basis for evaluation of long-term intake of COX inhibitors on reduction of the incidence of esophageal cancer. Defining actual response of individual tumors to COX-2 inhibitors *in vivo*, however,

awaits further evaluation, especially since the level of COX-2 expression varies substantially between different tumors. Based on our data, a more thorough study on COX-2 expression is needed in patients with esophageal squamous cell carcinoma. Patients with a high COX-2 expression may benefit from specific or nonspecific COX-2 inhibitor medication, such as aspirin, for potential carcinogenic prevention of these cancers. Long-term intake of COX-2 inhibitors may be recommended for family members, especially with a positive family history of esophageal squamous cell carcinoma.

Taken together, our study suggests that COX-2 may play a role in esophageal squamous cell carcinoma development and/or progression and COX-2 inhibitors may be potential agents for the prevention or treatment of human invasive esophageal squamous cell carcinoma. Therefore, long-term intake of NSAIDs, such as aspirin, might reduce the risk of esophageal squamous cell carcinoma. To verify this hypothesis studies to evaluate the efficacy of COX-2 inhibitors in relevant animal models of esophageal squamous cell carcinoma are needed. In addition, studies to define the possible role of COX-2 in esophageal squamous cell carcinoma and the mechanisms by which COX-2 inhibitors exert antitumor activity are essential.

Abstract

AIM: To study the epidemiology of gastric malignancies in Jordan as a model for Middle East countries where such data is scarce.

METHODS: Pertinent epidemiological and clinicopathological data for 201 patients with gastric malignancy in north of Jordan between 1991 and 2001 were analyzed.

RESULTS: Male: female ratio was 1.8:1. The mean age was 61.2 years, and 8.5% of the patients were younger than 40 years of age. The overall age-adjusted incidence was 5.82/100 000 population/year. The age specific incidence for males raised from 1.48 in those aged 30-39 years to 72.4 in those aged 70-79 years. Adenocarcinomas, gastric lymphomas, malignant stromal tumors, and carcinoids were found in 87.5%, 8%, 2.5%, and 2% respectively. There was an average of 10.1-month delay between the initial symptoms and the diagnosis. Only 82 patients underwent "curative" gastrectomy. Among adenocarcinoma groups, Lauren intestinal type was the commonest (72.2%) and the distal third was the most common localization (48.9%). The mean follow up for patients with gastric adenocarcinoma was 25.1 mo (range 1-132 mo). The 5-year survival rates for stages I ($n=15$), II ($n=41$), III ($n=59$), and IV ($n=53$) were 67.3%, 41.3%, 5.7%, and 0% respectively ($P=0.0001$). The overall 5 year survival was 21.1%.

CONCLUSION: Despite low incidence, some epidemiological features of gastric cancer in Jordan mimic those of high-risk areas. Patients are detected and treated after a relatively long delay. No justification in favor of a possible gastric cancer screening effort in Jordan is supported by our study; rather, the need of an earlier diagnosis and subsequent better care.

INTRODUCTION

Gastric cancer (GC) is one of the most prevalent cancers and, today, is the second cause of cancer death worldwide^[1,2]. The pattern and incidence of GC vary widely between different parts of the world. Costa Rica and Japan have the first and second highest rates in the world with a death rate of 77.5 and 50.5 /100 000 population, respectively^[2,3]. In the United States 12 100 deaths from GC were expected during 2003 with a death rate of 6.8/100 000, and it was estimated that 224 00 (13 400 in men) new cases of GC were diagnosed in the same year^[4]. The risk of developing GC was relatively lower in the Middle East and North Africa compared to those of western countries^[1,5].

The epidemiology of GC has been widely studied in the Western world as well as in Japan^[6-12]. However, only few scattered reports from the developing world have been published^[13-17]. There is a lack of good descriptive data on GC from the Middle East countries, where both cancer registration and prevalence of risk factors are relatively unknown. Because of the decreasing trend that took place in the Western world as a result of possibly, socio-economic development and its consequences, it is important to gain an insight into what is happening in other parts of the world such as in the Middle East. This prompted us to report on the epidemiological and clinicopathological features of gastric malignancy in Jordan in comparison to other countries whenever possible. This could assist in the better understanding of the important risk factors, which contribute to the development of GC. This will also give a clue about whether or not screening programs are needed in our region.

MATERIALS AND METHODS

Patients

This is a retrospective study of gastric malignancy in the north of Jordan over an eleven-year period (Jan 1991 to Dec 2001). The population of Irbid province (north of Jordan) as determined in the last official census conducted in Jordan in 1994 was 745 774 out of which 385 264 (51.66%) were males. Fifty percent of the Jordanian population are below the age of 16 years^[18]. A total of 76% of the population live in cities and towns.

Initial data were obtained from the computer database at the Department of Pathology at Jordan University of Science and Technology. This is the only pathology center serving the area. Histologically confirmed primary gastric malignancy was found in 201 patients, including 176 patients with adenocarcinoma, 16 patients with primary gastric lymphoma (PGL), 5 patients with malignant gastric stromal tumors, and 4 patients with gastric carcinoids. Further information was obtained from the medical records of these patients at Princess Basma Teaching Hospital and Prince Rashed Teaching Hospital, the only two tertiary centers in Northern Jordan. All available endoscopy reports were reviewed. Patients and/or family members were contacted whenever possible.

A single pathologist reviewed all the histological slides. Gastric adenocarcinoma was classified into intestinal (IT), diffuse (DT), or mixed types according to the histological criteria

of Lauren^[19]. The site of the tumor was assessed pathologically in the resected specimens and endoscopically in the remaining cases, and was defined as that part of the stomach harboring the bulk of the tumor. Tumor staging in each patient was based on clinical information, preoperative radiological investigations, operative findings, and pathological examination. The staging was made in accordance with the TNM system endorsed by the Union Internationale Contre Le Cancer (UICC)^[20].

Vital status of patients was ascertained from death certificates or from families who were contacted.

All deaths within 30 d of surgery were considered surgical mortality. The incidence rates were adjusted to the world population. Our hospital based incidence data were matched with the Jordanian National Cancer Registry (JNCR) data only for the period 1996-2001, since the Registry was established in 1996. The survival rate was analyzed for each stage by the Kaplan-Meier method, and the survival curves were compared by the log-rank test using the Statistical Package for the Social Sciences Software Program (SPSS®, Inc., Chicago, Illinois, USA). Differences were considered statistically significant at $P < 0.05$.

RESULTS

During the study period 201 patients with primary gastric malignancy were identified, 128 (63.7%) patients were males with a male: female ratio of 1.8:1.

Sixty-five percent of the patients (131/202) were diagnosed during the second half of the study period. Analyses of the data from the JNCR, which was established in 1996, showed that all the 131 study patients diagnosed with gastric malignancy between 1st January 1996 and 31st December 2001 appeared in the registry and there were no additional patients from northern Jordan in the registry not identified by our study.

The overall age-adjusted incidence (world population) was 5.82/100 000 per year. Table 1 shows the age specific incidence

rate (ASIR) per 100 000 population by gender. The peak incidence was in the age group 60-69 years (39.8%), followed by the age group 70-79 (22.9%). Approximately 8.5% of the patients were younger than 40 years of age. The mean age for the whole group was 61.2 years (SD±12.3, range 24-91 years).

Presenting features for our patients are summarized in Table 2. Acute presentation was seen in 59 (29.4%) patients; 37 patients (18.4%) presented with upper gastrointestinal bleeding, 17 (8.5%) with gastric outlet obstruction, and in the remaining 5 (2.5%) patients perforation was the mode of presentation.

Table 2 Presenting features of patients with gastric malignancy

	Number of patients	%
Abdominal pain	144	71.6
Weight loss and/or anemia	130	64.7
Dyspepsia	98	48.8
Nausea, vomiting	96	47.8
Abdominal mass	62	30.8
Anorexia	58	28.9
Dysphagia	44	21.9
Gastrointestinal bleeding	37	18.4
Obstruction	17	8.5
Perforation	5	2.5

There was an average of 10.1-month delay (range 2-17 mo) between the initial symptoms and the diagnosis. In 119 patients this was a result of reluctance in seeking medical advice and/or delay in referring patients for endoscopy. However, in five patients the delay was caused by a false negative upper gastrointestinal endoscopy.

Table 3 shows the distribution of the different histological types according to age and sex. The histologic subtypes of the

82 patients who had gastrectomy were correctly diagnosed in pre-gastrectomy endoscopic biopsies except in 2 cases, which were diagnosed as IT adenocarcinoma and turned out to be of the DT in subsequent examinations of the resected specimens. Pathological examination of the 65 resected IT and mixed adenocarcinomas revealed that 51 of the cancers were moderately differentiated, 10 were poorly differentiated and four were well differentiated.

Table 4 shows the distribution of various histologic types of gastric adenocarcinoma according to the sites affected.

For gastric adenocarcinoma, using the TNM staging, 15 patients had stage I, 41 patients had stage II, 59 patients had stage III, and 53 patients had stage IV disease. In the remaining 8 patients, the stage could not be determined due to insufficient data (stage X).

Gastrectomy was performed for 82 patients (D1 in 63 and D2 in 19 patients). Palliative resection or bypass procedures were done for 95 patients, while 3 patients with PGL had chemotherapy only. The remaining 21 patients were too frail to be treated. No patients had D3 gastrectomy. None of the patients with adenocarcinoma was given adjuvant therapy. Postoperative morbidity occurred in 25.4%(45/177) of the patients. Eight patients died during the postoperative period giving a surgical mortality of 4.5%(8/177).

For the 176 patients with adenocarcinoma, the mean follow up until December 2002 was 25.1 mo (range 1-132 mo). At that time, vital status was available for 163 patients (92.6%). The remaining 13 patients (mean age 59.6 years; 11 males and 2 females) were lost to follow up at a mean of 28.2 mo (range 7-86 mo). The stages of the disease for these 13 patients were I, II, III, IV, and X in 1, 2, 4, 4, and 2 patients respectively.

Survival analysis included the 8 early postoperative deaths and the later non-cancer deaths. The median survival for stages II, III, and both stages IV and X was 59, 19, and 13 mo respectively. Figure 1 demonstrates the survival curves for stages I-IV using Kaplan-Meier method. The 5-year survival rates for stages I, II, III, and IV were 67.3%, 41.3%, 5.7%, and 0% respectively ($P=0.0001$). The overall 5 year survival was 21.1%.

DISCUSSION

There was consistency between our study and the data of the JNCR. The incidence was calculated and corrected for age in relation to the world population. The age-adjusted incidence of gastric malignancy in this study was 5.82/100 000 per year, which was significantly lower than those of developed countries but rather similar to most other Middle East countries^[1,2]. However, this incidence would rise sharply when the ASIR is calculated because of the specific pyramidal age distribution of our population where approximately 50% of our population are below the age of 16 years (1994 census). The ASIR for males per 100 000 population raised from 1.48 in those aged 30-39 years to 72.4 in those aged 70-79 years (Figure 2). Similarly, figures from the JNCR showed that during 1997, the ASIR raised sharply from 3.3 to 108 for the same gender and age groups^[18]. During the same year GC was the eighth commonest cancer, representing 4% of all cancer cases, and it accounted for 22% of all primary gastrointestinal tract cancers.

It is well known that the incidence of GC is decreasing globally. The apparent increase in diagnosing GC during the second half of the study period most likely reflects a better diagnostic yield after the relatively recent introduction of endoscopic services throughout the country rather than an actual increase in the incidence. Still the following two factors may play a role in this increasing trend. First, the rapid change in dietary habits Jordan is witnessing might constitute a risk factor. Vitamin C-rich fresh vegetables and fruits, starch, and natural unprocessed wheat products were the major constituents of Jordanian food. However, canned food, hot spices, pickles, and animal proteins are now dominating the Jordanian menu. It is known that the environmental risk factors for GC could be dietary in origin^[21,22]. Second, the already high prevalence of *Helicobacter pylori* in Jordan is increasing and the exposure time is also increasing with the improvement in life expectancy among Jordanians^[23,24]. It is proposed that Lauren's IT of GC is related to chronic *Helicobacter pylori* infection. Among our study group IT adenocarcinoma was the commonest histological subtype (63.2%).

Most resections were done with palliative intent. The low rate of gastrectomy with "curative" intent could be explained by the high proportion of patients with advanced GC at

presentation. However, we believe that surgical undertreatment might be a contributing factor. Our patients tended to present late as evidenced by the facts that there was a long interval between onset of symptoms and presentation, 29.4% presented acutely, and that only 40.8% (82/201) of them underwent D1 or D2 gastrectomy. This is not only due to insufficiency of current endoscopic services, but also due to the fact that many people in Jordan who have non-specific dyspeptic symptoms will seek the advice of non-physician personnel who will either prescribe herbal medicine for long term treatment or induce patches of second or third degree burns to the epigastric region using hot metals in order to ameliorate the deep seated pain! Subsequently some of these patients in whom the cause of dyspepsia is cancer will present to the hospital with late stage GC or one of its complications. In addition, the elderly people usually fail to make use of the available medical services due to inadequacy of primary health care in Jordan.

Some GC patterns in north of Jordan were similar to those reported from high-risk regions worldwide^[3,25]. In particular, the mean age was in the seventh decade, male to female ratio was 1.8:1, IT adenocarcinoma was more common than DT (4.4:1), and distal location was more frequent than proximal one (2.5:1). Since the demographic features among Jordanians are homogenous, we believe that these trends apply to whole Jordan. In contrary, in a low-risk area, such as Kenya, the DT is the commonest subtype^[26].

In our study, DT adenocarcinoma occurred in younger patients with a mean age of 51.9 years and was commoner in females with a male to female ratio of 0.45:1 (Table 3). Similar findings of diffuse tumors prevailing among young patients and women were reported from Sweden, Finland, Mexico and Taiwan^[6,8,16,17], but not from neighboring Saudi Arabia^[14,15].

Our survival rate for stages I and II is consistent with the rate reported in the Western literature^[27,28]. However, this rate was much lower for our patients with more advanced stages probably reflecting undertreatment at our institute. After the introduction of a specialized upper gastrointestinal unit at our hospital in January 2001, we have adopted a more radical approach.

In Western countries, PGL represented only 2% to 5% of gastric malignancies^[29], while it represented 8% of our series, which was similar to the 9% figure from neighboring Iraq^[30], but different from the 14-22% figure reported from Saudi Arabia^[14,15]. During the past three decades the site of PGL in the Middle East has changed^[31]. Small intestinal involvement became less common, and gastric involvement more frequent. This varying pattern seemed to be environmental in origin^[31]. Although the ratio of PGL to gastric adenocarcinoma among our patients was higher than in western series, a recent study from Jordan demonstrated that other patterns of PGL were mimicking those of the west^[32]. The stomach was the commonest site of involvement, accounting for 62% of all cases^[32].

Our rates for the gastric malignant stromal tumors and carcinoids are consistent with rates reported elsewhere^[33]. The survival rate for these patients was not calculated due to the small number of patients.

At the end of this discussion, we would like to highlight some of the shortcomings in our study. First, the incidence figures were calculated only after histological confirmation by endoscopy or surgery. In Jordan, hospital postmortem is rarely performed because of religious or social grounds. Additionally, only half of deaths are attended by medical workers personals. This means that some patients with GC were certainly not included in the incidence calculation. The limitation to histologically confirmed cases increases specificity but lowers the sensitivity in identifying cases to be included in the incidence figures. Cases admitted to hospitals with a suspicion of GC or deceased with a diagnosis of GC but without histological

confirmation were not considered in the estimation of incidence rates. Additionally as one third of our patients presented with an abdominal mass, and there was a 10-mo delay in diagnosis so the estimated incidence was lower than the real incidence because many patients did not reach the hospitals. Second, Lauren classification is known to be affected by a quite low reproducibility^[34]. Specifically, mixed cases might be classified as intestinal or as diffuse type, depending on the examined tissue areas endoscopically biopsied or from the surgical specimens.

In conclusion, the incidence of GC in Jordan is low, but increases appreciably with age. This, in addition to the fact that 50% of the Jordanian population are below the age of 16 years, shows that it does not seem justified introducing a screening program. However, general practitioners should be more liberal in referring patients for endoscopy and resist the temptation to treat dyspeptic patients with anti-ulcer therapy without an endoscopy. Open access endoscopy, greater efforts in patient education and improvement of the diagnostic technical skills may raise the chance of detecting GC early. Some patterns of GC in Jordan (age, sex, tumor location, and histological type) are similar to features from high-risk areas. Although this study clearly highlights the pertinent epidemiological and clinicopathological features of gastric malignancy in Jordan, further studies are needed to evaluate the treatment outcomes.

Abstract

AIM: To study the differential expression of proteins in normal and cancerous gastric tissues, and further identify new molecular markers for diagnosis and prognosis of gastric carcinoma, as well as develop new therapeutic targets of the disease.

METHODS: Matched pairs of tissues from 6 gastric cancer patients were analyzed for their two-dimensional electrophoresis (2DE) profiles. Soluble fraction proteins from human normal and cancerous gastric tissue were separated in the first dimension by isoelectric focusing on immobilized pH gradient (IPG, pH3-10) strips, and by 125 g/L sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) in the second dimension with silver nitrate staining. Protein differential expression was analyzed by use of image analysis software to find out candidates for gastric cancer-associated proteins.

RESULTS: Nine protein spots overexpressed in tumor tissues as compared with noncancerous regions. In the next step, 9 tumor-specific spots were cut off from Coomassie Brilliant Blue staining gels, digested in gel with L-1-tosylamide-2-phenylethyl chloromethyl ketone (TPCK)-trypsin. Protein identification was done by peptide mass fingerprinting with matrix assisted laser desorption/ionization-time of flight-mass spectrometry (MALDI-TOF-MS). In total, 5 tumor-specific protein spots corresponding to 5 different polypeptide chains were identified, including annexin V, carbonic anhydrase, prohibitin, fibrin beta and fibrinogen fragment D. Among these 5 spots, the potential significance of the differential expressions is discussed.

CONCLUSION Differential expression analysis of proteomes may be useful for the development of new molecular markers for diagnosis and prognosis of gastric carcinoma.

INTRODUCTION

Gastric cancer is a prevalent tumor worldwide. It is a multistage process involving multiple factors in aetiology and many gene-environment interactions. It is important to emphasize the heterogeneity of the histological background on which the tumor develops. Methods have been developed to identify tumor associated antigens such as molecular cloning in expression system or using a biochemical strategy based on the extraction of antigenic peptides bound to major histocompatibility complex class I molecules from tumor cells. These methods have allowed the recognition of certain human tumor antigens^[1]. Several tumor markers of gastric cancer have been identified^[2-4], including Lewis antigen, sulfomucin, CA50. However, no evidence has been obtained indicating that the detection of these markers precedes clinical diagnosis of gastric cancer. Proteomics studies of clinical tumor samples have led to the identification of cancer-specific protein markers, which provides a basis for developing new methods for early diagnosis and early detection of cancers as well as clues to understanding the molecular mechanism of cancer progression^[5]. In order to identify proteins that elicit humoral responses in gastric cancer patients, proteome-based approach was used. A number of proteins from gastric tumor tissues were separated by 2DE and identified by using mass spectrometry. It includes the systematic cataloging of protein expression on a large scale. Such studies could help elucidate the molecular mechanism of cellular events associated with cancer progression, such as cellular signaling^[6,7].

MATERIALS AND METHODS

Tissue samples and preparation^[8]

Six pairs of primary, and advanced poorly differentiated gastric adenocarcinoma tissues and corresponding adjacent noncancerous gastric tissues were obtained with informed consent from patients who underwent gastrectomy at the First Affiliated Hospital of Zhengzhou University and Beijing Cancer Hospital. Cancer samples were obtained from the "core" part of the tumor to avoid the adjacent noncancerous tissue. For each of the normal tissues, surface epithelium was selectively procured by dissection with special care for minimal contamination of nonepithelial cells, and samples were immediately snap-frozen in liquid nitrogen. They were classified histologically according to Lauren's classification after H & E staining.

Fragments of normal and malignant tissues were sharp dissected and homogenized with a homogenizer in 2 mL fresh lysis buffer [2 g/L dithiothreitol (Amersham Bioscience, USA), 200 mL/L trichloroacetic acid (Sigma, USA) and 800 g/L acetone], then placed into tubes at 4-8 °C for 8-10 h. The mixture was centrifuged at 1 000 r/min for 5 min to remove tissue and cell debris, then centrifuged in a Beckman TL-100 table top ultracentrifuge at 430 000 g in a TLA-100.2 rotor for 30 min at 4 °C. The supernatant was taken as soluble fraction. Protein was lyophilized, resuspended in isoelectric focusing gel rehydration solution {7 mol/L urea, 2 mol/L thiourea, 40 g/L 3-([3-cholamidopropyl] dimethylammonio)-1-propanesulfonate

(CHAPS), 50 mmol/L dithiothreitol, 20 g/L IPG buffer pH 3-10, L} and stored at -80 °C until use. These were used as the 2DE samples for the soluble fraction. Protein concentration of 2-DE samples was estimated according to a commercial Bradford reagent. BSA was used as standard.

2DE with IPG strips

First-dimension bioelectric focusing was carried out on Multiphor II system basically as described by the manufacturer Amersham Bioscience Inc. Samples containing up to 200 µg protein for analytical gels were diluted to up to 450 µL with dehydration solution (8 mol/L urea, 20 g/L CHAPS, 100 mol/L dithiothreitol, 5 g/L IPG buffer). Pre-cast Immobilized pH gradient (IPG) strip (24 cm, pH 3-10, linear gradient) was used for the first-dimensional separation. Strips were applied by overnight rehydration at 50 V, and for 1 h at 1 000 V. Then a gradient was applied from 1 000 to 8 000 V for 8 h to give a total of 180 000 Vh. All IEF steps were carried out at 20 °C. After the first-dimensional IEF, IPG gel strips were placed in an equilibration solution (6 mol/L urea, 200 g/L SDS, 300 g/L glycerol, 50 mol/L Tris-HCl, pH 8.8) containing 10 g/L dithiothreitol and shaken for 15 min. The gels were then transferred to the equilibration solution containing 25 g/L iodoacetamide to alkylate thiols and shaken for a further 15 min before being placed on a 125 g/L polyacrylamide gel slab. Separation in the second dimension was carried out using Tris-glycine buffer containing 1 g/L SDS, at a current setting of 5 mA/gel for the initial 0.5 h and 18 mA/gel thereafter and a temperature of 20 °C.

For silver staining, gels were immersed in ethanol: acetic acid: water (35:7:58) for 1.5 h, followed by washed twice in deionized water for 20 min. Gels were pretreated for 1 min in a solution of 0.2 g/L Na₂S₂O₃ and followed by 3 of 1-min washes in deionized water. Proteins were stained in a solution containing 2 g/L AgNO₃ and 0.075% formalin (37 g/L formaldehyde in water) for 20 min, and washed twice in deionized water for 1 min. Subsequently, gels were developed in a solution of 0.6 g/L formaldehyde, 20 g/L Na₂S₂O₃ and 0.004 g/L Na₂S₂O₃. When the desired intensity was attained, the developer was discarded and reaction stopped by 10 g/L EDTA-Na₂. For Coomassie Brilliant Blue staining of gels, gels were equilibrated in a solution containing 500 mL/L methanol, 50 mL/L acetic acid and 25 g/L Coomassie Brilliant Blue R-250. Gels were rinsed in 300 mL/L ethanol containing 70 mL/L acetic acid.

Protein patterns in the gels after silver staining were recorded as digitalized images using a high-resolution scanner. Gel image matching was done with PDQuest software.

In-gel protein digestion

Protein spots on Coomassie blue stained gel was performed essentially as described. After the completion of staining, the gel slab was washed twice with water for 10 min. The spots of interest were excised with a scalpel and put into 1.5 mL microtubes. The particles were washed twice with water and then twice with water/acetonitrile (1:1) for 15 min. The solvent volumes were about twice that of the gel. Liquid was removed, acetonitrile was added to the gel particles and the mixture was left for 2 h. After that, liquid was removed and the particles were rehydrated in 25 mmol/L NH₄HCO₃ for 5 min. Acetonitrile was added to produce a 1:1 mixture of 25 mmol/L NH₄HCO₃ / acetonitrile and the mixture was incubated for 15 min. All liquid was removed. Gel particles were dried in a vacuum centrifuge, reswelled in 10 mmol/L of dithiothreitol and 25 mmol/L of NH₄HCO₃, and incubated for 30 min at 56 °C to reduce the peptides. After chillness of tubes to room temperature and removal of the liquid, 55 mmol/L iodoacetamide in 25 mmol/L NH₄HCO₃ was added. The tubes were incubated for 30 min at room temperature in the dark to S-alkylate the peptides. Then

iodoacetamide solution was removed, the particles were washed with 25 mmol/L NH₄HCO₃ and acetonitrile, dried in a vacuum centrifuge, rehydrated in digestion buffer containing 50 mmol/L NH₄HCO₃ and 12.5 ng/µL trypsin (TPCK-treated, proteomics grade, Sigma, USA), incubated for 8-12 h at 37 °C. After digestion, 25 mmol/L NH₄HCO₃ was added, and the tube was incubated for 15 min. Acetonitrile was added and the tube was incubated for another 15 min. The supernatant was recovered, and the extraction was repeated twice with 50 g/L TFA/acetonitrile (1:1). The three extracts were pooled and dried in a vacuum centrifuge.

MALDI-TOF-MS analysis

One µL sample with 1 µL matrix solution CCA (α-cyano-4-hydroxycinnamic acid) was spotted on the target and dried. Dried spots were analyzed in an REFLEX-III (Bluker) MALDI-TOF mass spectrometer. The spectrometer was run in positive ion mode and in reflector mode with the setting: accelerating voltage, 20 kV; grid voltage, 76%; guide wire voltage, 0.01%; and a delay time of 150 ns. The low mass gate was set at 500 m/z.

Proteins were identified by peptide mass fingerprinting with the search programs Mascot (<http://www.matrixscience.com/cgi/index.pl?page=.1>). The following search parameters were applied: SWISS-PROT and NCBI were used as the protein sequence databases, a mass tolerance of 50 ppm and one incomplete cleavage were allowed; acetylation of the N-terminus, alkylation of lysine by carboxyamidomethylation were considered as possible modifications^[9].

RESULTS

Evaluation of the reproducibility

Mini 2DE gels (7 cm, pH3-10) were used to evaluate the reproducibility of the soluble protein preparations and to quantify the protein extracts for 2DE gel analysis. To ensure quality and reproducibility of results, 2DE maps (24 cm) were established from each sample based on silver staining of at least three independent gels, pairs of gels were run simultaneously with the same power supply and subjected to subsequent image analysis. Protein extracts prepared from tissues were compared in this way and found to be highly reproducible and similar amounts of total soluble protein were yielded when analyzed on the gels.

Overview analysis of the protein expression profiles of paired samples

2DE Gel separation of proteins from 6 pairs of normal and cancerous epithelial cells was procured from the same gastric carcinoma specimen respectively. A series of 2DE maps were constructed for the soluble fraction proteins of human gastric tissue. A representative 2DE gel images following silver staining of cancer tissues (Figure 1A) and normal tissues (Figure 1B) were produced in a 2DE imageMaster. Comparison of the differential protein expression between cancer and normal tissues shown in 2DE images was carried out using the AutoDetect Spots menu of PDQuest software. Figure 1A (from cancer tissues) contains a total of 356 spots, whereas Figure 1B (from normal tissues) contains a total of 382 spots. A total of 323 spots from cancer tissues could be matched to those from normal tissues. In total, we were able to identify 9 cancer-specific spots in 2DE gels. The positions of the identified proteins are shown in Figure 1A. These differences were observed in other cancerous samples. Because all of the identified spots were detectable with Coomassie Blue staining, they could be considered as abundant proteins.

Protein identification

The resulting spot identification was mapped onto the analytical

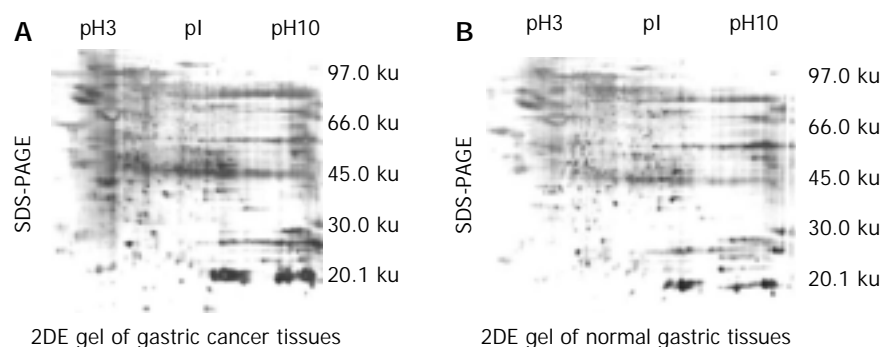

Figure 1 2DE maps of human gastric tissue from No.5 patient. A: was from gastric cancer. B: from normal gastric sample of the same patient. Proteins were separated on pH 3-10 linear IPG strip in the first dimension and 125 g/L SDS-PAGE in the second dimension, gels were silver stained. All labeled spots were tumor-specific.

gels stained by Coomassie Brilliant Blue. On the map, 9 cancer-specific spots were excised and subjected to in-gel digestion followed by peptide mass fingerprinting for protein identification. Figure 2 shows the identification of the spot No. 18 as an example. We identified proteins by peptide mass fingerprinting, MS-Fit of UCSF.

The criteria used to accept identifications included the extent of sequence coverage, the number of peptides matched, the probability score, and whether human protein appeared as the top candidates in the first pass search where no restriction was applied to the species of origin.

Figure 2 MALDI-TOF MS of tryptic digests of protein spot No. 18 resolved on 2DE gel, REFLEX III (BLUker). The data were collected on positive ion and reflector mode. Experimentally determined mass values are labeled on peptides. Spot 10 matched peptide 11; amino acid coverage, 60%; the spot was identified as carbonic anhydrase I.

The results of identification are summarized in the Appendix Table 1. For identified protein, probability based score greater than 73 was significant ($P < 0.05$). For example, in the case of annexin V, the protein score is 163. Some of these proteins, such as carbonic anhydrase I; chain B, crystal structure of fibrinogen fragment D; fibrin beta and prohibitin, have already been detected in gastric cancer tissues.

DISCUSSION

Proteome based profiling employs the measurement of protein expression pattern for the identification of individual proteins and clusters of proteins that mediate particular aspects in a physiological and pathophysiological process. The measurement of protein expression patterns of normal and disease tissues or cell populations will lead to the characterization of diagnostic and prognostic markers, and it can be further employed for the analysis of the disease stage which might also have an impact on the therapy. Thus, preferably small clusters of proteins represent the ideal diagnostic markers enabling an easier and more accurate diagnosis of diseases for better therapy^[10].

This study was based on an ongoing proteomic analysis of gastric cancer aiming at screening the protein markers in the proteome for diagnosis of gastric cancer. With the availability of high-throughput 2DE gels and initial screening by using automated procedures, identification of changes in the proteome in various tissues will be possible. The approach we described in this study has shown that high-throughput analysis will be a valuable tool. An effort is currently being made using proteome based techniques^[11]. 2DE pattern of normal and diseased tissues revealed a number of polypeptides

Table 1 Protein spots in GC searched by PeptIdent software in the SWISS-PROT database

associated with gastric cancer, which were expressed in gastric cancer tissues, but absent in normal gastric tissues. Some of them might possibly be identified and serve as diagnostic and prognostic markers in gastric cancer.

In the preparation of 2DE maps presented in this study, tissue samples from different individuals were used without pooling of samples. The total homogenate was fractionated by ultracentrifugation into soluble fraction^[12]. In order to minimize the influence of the methodology, we attempted, when possible, to make protocols for 2DE PAGE alike. Our initial analyses of six normal tissue samples indicated the overall protein pattern remained very similar across the samples.

We identified nine protein spots which were expressed in cancerous tissues but absent in normal gastric tissues. Of the 9 position identifications, spots 4, and 5 were found as multiple spots on the 2DE gels. Those included the subunits of the proteins, both of which focused in several pI positions but had the same molecular mass. It indicated that these gene products were present as isoforms with post-translation modification^[13].

Annexins are Ca^{2+} and phospholipid binding proteins forming an evolutionarily conserved multigene family. For some annexins, it appears that they participate in the regulation of membrane organization and membrane traffic and the regulation of ion (Ca^{2+}) currents across membranes or Ca^{2+} concentrations within cells. Some members of the family have been identified extracellularly where they can act as receptors for serum proteases on the endothelium as well as inhibitors of neutrophil migration and blood coagulation^[14]. Annexin V is used widely as a marker for apoptotic cells, the annexin V mutants showed defective homotypic cell adhesion and resistance to Ca^{2+} -dependent apoptotic agents without exhibiting any changes in the generation of cytosolic Ca^{2+} fluxes^[15]. Annexin V also known as calphobindindin I, has been shown to be an endogenous inhibitor of protein kinase C, a key enzyme in cellular signal transduction. The inhibition of protein kinase C by annexin V is presumed to be ultimately related to carcinogenesis and studies have demonstrated that a decrease in the production of annexin V may lead to the dysregulated protein kinase C^[16,17]. Annexin V has been found in other cancer tissues or cell lines^[18,19], but its presence in gastric cancer has not been documented.

Carbonic anhydrase (CA) is the zinc-containing metalloenzyme that catalyzes the reversible hydration of CO_2 . The role of the enzyme has been thoroughly investigated. The main functions of the enzyme are to produce HCO_3^- for the intermediate metabolism and to maintain pH, water, and ion equilibrium in the body^[20]. CAs show various levels of catalytic activity and binding to inhibitors. They have considerable diversity in tissue distribution and cellular localization, and they perform a variety of biological functions. CAI protein is associated with cell growth. It is likely expressed by rapidly proliferating tumor cells or cells that are about to enter the proliferative state, because the CA domain and other elements of the molecule take part in the regulation of cell growth in certain tumor cell types^[21].

The presence of fibrin (ogen) within the tumor stroma likely affects the progression of tumor cell growth and metastasis^[22]. The deposition of fibrin (ogen), along with other adhesive glycoproteins, into the extracellular matrix serves as a scaffold to support binding of growth factors and to promote the cellular responses of adhesion, proliferation, and migration during angiogenesis and tumor cell growth. Inappropriate synthesis and deposition of extracellular matrix constituents are linked to altered regulation of cell proliferation, leading to tumor cell growth and malignant transformation^[23,24]. Fibrin deposition occurs within the stroma of a majority of tumor types. Fibrin (ogen) content was significantly higher in malignant tumor patients than that in benign disease patients, significant

reduction was observed after treatment and became elevated again when there was recurrence or metastasis^[25]. Biggerstaff *et al.*^[26] suggested that coagulation activation and the subsequent increase in circulating fibrin may enhance platelet adhesion to circulating tumor cells and thereby facilitate metastatic spread. Assessment of fibrin (ogen) not only helps to diagnose cancers but also evaluates the therapeutic effect and prognosis^[27].

Prohibitin proteins have been implicated in cell proliferation, ageing and the maintenance of mitochondria integrity^[28], prohibitins are present in the inner mitochondrial membrane and always bound to each other. They are expressed during development and their expression levels are indicative of a role in mitochondrial metabolism^[29]. High level expression of the proteins is consistently seen in primary human tumors. The prohibitin protein has been found having various functions, including cell cycle regulation, apoptosis, assembly of mitochondrial respiratory chain enzymes and ageing. We are currently trying to identify the additional proteins whose expression is significantly altered in cancerous tissue.

This study also confirms that proteomic analysis is a powerful tool for the discovery of such molecular markers. Proteomic analysis allows the characterization of picoquantities of proteins with MS and changes in the levels inherent to the pathophysiology of any cell type, tissue, or whole organism. It is hoped that the identification of protein markers by this approach could discriminate cancerous from normal cells. As demonstrated here, proteomic analysis may be efficiently used to identify new indicators for the diagnosis and prognosis of cancer progression.

In conclusion, the differences of the proteins between normal gastric epithelial cell and malignant cells are complex. Our data only show a few of the highly expressed spots. Further basic and clinical investigation will be needed to demonstrate if these proteins could be markers for GC and to evaluate other non-constant spots in relation to the clinical condition of the patient.

ACKNOWLEDGEMENTS

The authors would like to thank Dr. Bo-Qing Li and Qing-Hua Zhou at Chinese Center for Disease Control and Prevention for their assistance in the experiments.

Abstract

AIM: To evaluate the therapeutic efficacy of three-dimensional conformal radiotherapy (3D-CRT) combined with transcatheter arterial chemoembolization (TACE) on the patients with hepatocellular carcinoma (HCC).

METHODS: Between 1998 and 2001, 94 patients with HCC received 3D-CRT combined with TACE. A total 63 patients had a Okuda stage I lesion and 31 patients had stage II. The median tumor size was 10.7 cm (range 3.0-18 cm), and liver cirrhosis was present in all the patients. There were 43 cases of class A and 51 class B. TACE was performed using lipiodol, 5-fluorouracil, cisplatin, doxorubicin hydrochloride and mitomycin, followed by gelatin sponge cubes. Fifty-nine patients received TACE only one time, while the others 2 to 3 times. 3D-CRT was started 3-4 wk after TACE. All patients were irradiated with a stereotactic body frame and received 4-8 Gy single high-dose radiation for 8-12 times at the isocenter during a period of 17-26 d (median 22 d).

RESULTS: The median follow-up was 37 mo (range 10-48 mo) after diagnosis. The response rate was 90.5%. The overall survival rate at 1-, 2-, and 3- year was 93.6%, 53.8% and 26.0% respectively, with the median survival of 25 mo. On univariate analysis, age ($P=0.026$), Child-Pugh classification for cirrhosis of liver ($P=0.010$), Okuda stage ($P=0.026$), tumor size ($P=0.000$), tumor type ($P=0.029$), albuminemia ($P=0.035$), and radiation dose ($P=0.000$) proved to be significant factors for survival. On multivariate analysis, age ($P=0.024$), radiation dose ($P=0.001$), and tumor size ($P=0.000$) were the significant factors.

CONCLUSION: 3D-CRT combined with TACE is an effective and feasible approach for HCC. Age, radiation dose and tumor size were found to be significant prognostic factors for survival of patients with HCC treated by 3D-CRT combined with TACE. Further study for HCC is needed to improve the treatment efficacy.

INTRODUCTION

Hepatocellular carcinoma (HCC) is a major health threat in Africa and China where rates of hepatitis B infection have always been high^[1]. Although early diagnosis and curative surgical resection can achieve the best prognosis, the number of patients who could undergo resection is still limited, even for those with small tumors because of the unique characteristics of this tumor, such as multifocality, early vascular invasion, and concurrent liver cirrhosis^[2]. Nonsurgical therapies, such as percutaneous ethanol injection, transcatheter arterial chemoembolization (TACE), have been tried for unresectable HCC^[3,4]. TACE has achieved improved survival; however, the antitumor effect of TACE alone has frequently been incomplete, even after repeated treatments^[5,6]. Radiotherapy used for HCC has been attempted for more than 4 decades. Early trials adopted whole liver irradiation but the radiation dose was inadequate^[7]. Because of the unsatisfactory results obtained with this low-dose whole liver irradiation, doctors have not long applied it in their treatment of HCC. The advanced technique of three-dimensional conformal radiotherapy (3D-CRT), however, has made it possible to deliver a higher dose of radiation to part of the liver accurately without a significant dose increase in the other intra-abdominal critical structures. Several studies reported that 3D-CRT could tolerate higher radiation levels with a substantial tumor response^[8-17]. Their findings indicate that 3D-CRT can be an effective component of the treatment strategy for HCC. The principle for 3D-CRT was to escalate the radiation dose in an attempt to elevate the rate of tumor response without damaging the normal liver cells. Stereotactic radiosurgery or hypofractionated radiotherapy has 80-90% local control rate, even for so-called radioresistant tumors, such as renal cell carcinoma and melanoma^[18,19]. Because of its success, small-volume radiotherapy has been applied to extracranial lesions, such as lung and liver tumors^[20,21]. Although the role of 3D-CRT in the management of HCC has been increasingly recognized, there are still several questions to be solved, one of which involves the identification of prognostic factors so as to improve the therapeutic effects of the management for HCC after 3D-CRT combined with TACE. Another is how to assess the exact effectiveness and toxicity of 3D-CRT combined with TACE. In our department, 3D-CRT combined with TACE has been actively applied for the treatment of HCC since the 1998. In this retrospective study, we aimed to analyze the effects and prognostic factors affecting survival in 94 HCC patients treated with this therapy.

MATERIALS AND METHODS

Patients

The diagnosis of HCC was based on histological features or

on radiologic findings (liver tumor CT scan, as well as hypervascular mass in hepatic angiography) and on a serum alpha-fetoprotein (AFP) level exceeding 400 ng/mL. All tumors with an AFP less than 400 ng/mL underwent a biopsy for diagnosis. The exclusion criteria included were as follows: (1) the presence of extrahepatic metastasis; (2) liver cirrhosis of Child-Pugh class C; (3) tumors occupying more than two-thirds of the liver; and (4) a score of Karnofsky performance status of less than 60.

Ninety-four patients (84 male and female) who received 3D-CRT combined with TACE in our department between August 1998 and August 2001 were enrolled in this study. The patient data are shown in Table 1. Their median age was 51.5 years (range 23–73 years). Sixty-four patients had a serum AFP level >400 ng/mL. Liver cirrhosis was present in all patients, with 43 patients of Child-Pugh class's A. Most patients had good

performance status, and 90 patients had a Karnofsky performance score (KPS) of more than 70. The Okuda stage I was in 66 patients and II in 28 patients. The tumor size was calculated according to the mean of three orthogonal diameters on CT. It was <5 cm in 7 patients, 5–10 cm in 30 patients, and >10 cm in 57 patients, with the median tumor size of 10.7 cm (range 3.0–18 cm). The massive tumor was the most frequent type, which was found in 82 patients (87.2%). Portal vein thrombosis (PVT) was present in 12 patients (12.8%). Chronic hepatitis in serum virology was present in 90 patients with type B (95.7%), and in 4 patients with type C (4.3%).

TACE procedures

TACE was performed with the infusion of a mixture of 5–20 mL of iodized oil contrast medium (Lipiodol, Huaihai Pharmaceutical Factory, Shanghai, China), 1.0 g of 5-fluorouracil (5-Fu, Xudong Haipu Pharmaceutical Inc., Shanghai, China) and 40–60 mg of cisplatin (CDDP, Qilu Pharmaceutical Factory, Jinan, China) or 30–50 mg of doxorubicin hydrochloride (Adriamycin, Main Luck Pharmaceutical Inc., Shenzhen, China), and 10 mg of mitomycin (Mytomycin-C C, Kyowa Hakko Kogyo, Tokyo, Japan), followed by 1 mm×1 mm×10 mm of gelatin sponge cubes (Gelfoam, the 3rd Pharmaceutical Factory of Nanjing, Nanjing, China) embolization. To preserve liver function as much as possible, we performed superselective TACE for the feeding arteries of each intrahepatic tumor. When there was an arterial portal shunt or main branch PVT, we performed TACE without lipiodol to prevent severe damage to the normal liver. TACE procedures were performed with a 4-wk interval, and the patients received 1 to 3 times.

Radiotherapy

Radiation treatment was given to patients placed in a supine position, with both arms raised above the head and the head in a natural position. The patients were immobilized in this position using a vacuum pillow (TN-1, TOPSLANE, Shanghai, China) with an oxygen mask (3 000–5 000 cc/min) for respiratory suppression for CT simulator (PQS 2000, Picker, USA). CT data were all transferred to a 3D-radiation treatment planning system (STP 3.0, Leibinger, Freiburg, Germany) by the network. The hepatic tumor, liver, kidneys, spinal cord, and gastroduodenal intestine of each patient were contoured and reconstructed to form a 3D representation. The radiation treatment volumes and treatment angles were designed according to the beam's-eye view technique to minimize critical organ injury. Each beam's shape was designed using a multileaf collimator or custom-made block. Three-dimensional CT-based computerized treatment planning was used to determine the best combination of coplanar and noncoplanar portals. A dose-volume histogram (DVH) was generated from the stereotactic treatment planning system for each patient. Gross tumor volume (GTV) was defined as the hepatic tumor volume, visualized by three-dimensional computation of contrast CT-defined contours. Clinical target volume (CTV) was defined as GTV plus a 0.5 cm margin. Planning target volume (PTV) was defined as CTV plus a 0.5 cm margin at medial/lateral/ventral/dorsal sides, but plus a 1.5–2 cm margin at cranial/caudal sides to account for daily setup error and respiratory organ motion. Dose inhomogeneity of PTV should be within $\pm 7\%$ of isocenter dose. Normal liver was defined as the total liver volume minus the GTV. The average volume of GTV for these 94 patients was 979 ± 623 mL. The average volume of whole liver was $1\,790 \pm 645$ mL. The number of portals used for radiation treatment ranged from 2 to 6, with a median of 5. Ultimately, the radiotherapy volume involved a portion of the liver, and whole liver radiation was always avoided. 3D-CRT was started within 3–4 wk after TACE using a 6-MV linear accelerator (CLINAC 600C/D, Varian Assoc, USA).

A dose of 4-8 Gy was applied each time and 3 times a week to deliver a total dose of 48-60 Gy. The total dose was determined by the fraction of the nontumorous liver receiving >50% of the isocenter dose. The guidelines were as follows: if <25% of the nontumorous liver received >50% of the isocenter dose, the total dose was increased to 60 Gy with 7.5 Gy each time; if 25-50%, the dose was 54 Gy with 6 Gy each time; if 50-75%, the dose was 48 Gy with 4 Gy each time; and if >75%, no treatment was given. This guideline was more strictly followed after the application of three-dimensional planning. The total radiation dose ranged from 48 to 60 Gy, and the median tumor dose was 56 Gy. During treatment, patients were monitored weekly with complete blood counts and liver function tests and AFP test.

Evaluation

The evaluation of tumor response was based on the change in mean tumor size (calculated according to the mean of three orthogonal diameters) on serial CT scans which are first started 4-6 wk after treatment completion and then performed at 1-, 3-mo interval. The evaluation of the change in tumor size was done at 3 mo after the treatment. Complete disappearance of the tumor was considered a complete response (CR), a decrease of >50% in tumor size was defined as a partial response (PR), a decrease of <50% in tumor size or no change was defined as stable disease (SD), and progression was defined as progressive disease (PD). CR and PR were considered to be responsible, whereas SD or PD not to be responsible. Acute toxicity was that occurred during treatment and 1 mo after the treatment. Subacute or chronic toxicity was defined as that occurring from 1 mo after radiotherapy.

Statistics

Statistical analysis was performed using SPSS 10.0. Overall survival was estimated from the date of diagnosis according to the Kaplan-Meier method. Log-rank statistics were used to identify the prognostic factors important for survival. Cox proportional models using enter stepwise regression were applied to all potentially significant variables for the multivariate analysis. $P < 0.05$ was considered statistically significant.

RESULTS

Tumor response

As shown in Table 2, tumor response (CR+PR) was evaluated by the change in mean tumor size on CT 3 mo after treatment completion.

Table 2 CT response of HCC to 3D-CRT combined with TACE

Response	No of patients (%)
Complete	12(12.8)
Partial	73(77.7)
Stable disease	6(6.4)
Progressive disease	3(3.1)

Figure 1 Actuarial survival of 94 patients treated with 3D-CRT combined with TACE.

Overall survival

The median follow-up was 37 mo (range 10-48 mo) after diagnosis. The overall survival rates of 1-, 2-, and 3-year were 93.6%, 53.8%, and 25.9%, respectively (median survival 25 mo, Figure 1).

Factors affecting overall survival

The results of univariate and multivariate analyses of prognosis factors for overall survival are shown in Table 3. On univariate analysis, age ($P=0.026$, Figure 2), Child-Pugh classification for cirrhosis of liver ($P=0.01$, Figure 3), Okuda stage ($P=0.008$, Figure 4), tumor size ($P=0.000$, Figure 5), tumor type ($P=0.029$, Figure 6), albuminemia ($P=0.035$, Figure 7), and radiation dose ($P=0.000$, Figure 8) were shown as significant factors. Multivariate regression identified the following independent favorable prognostic factors: younger age ($P=0.024$), high radiation dose ($P=0.001$), and small tumor size ($P=0.000$).

Toxicity

In terms of acute toxicity, alterations in the liver function test (23 patients, 24.5%) and fever (51 patients, 54.3%) were frequently found in patients during the early time after TACE. These effects were transient and most patients recovered within 1-2 wk. Hematologic toxicity involved thrombocytopenia (platelets $<50\,000/\text{mm}^3$) in 13 patients and leucopenia (white blood cells $<2\,000/\text{mm}^3$) in 2 patients. Subacute and chronic toxicity involved radiation-induced liver disease (RILD) in

12 patients, 4 of whom died from RILD, and gastroduodenal ulcer in 5 patients. The patients other than the 4 victims of RILD were treated conservatively, and no death was found related to the treatment.

Figure 8 Univariate analysis of radiation dose on survival of patients treated with 3D-CRT combined with TACE.

DISCUSSION

Although TACE has been proved to be effective in treating HCC, and selectively and repeatedly used for patients with unresectable HCC, no survival benefits have been observed in at least two randomized trials of TACE^[22,23]. TACE is not a curative method and its limitation has also been well documented. After TACE, the tumor cells remain viable, especially in and around the capsule, and tumors may recur by the blood supply from the collateral circulation or portal vein or recanalization of the originally embolized artery^[6,24,25]. In advanced HCC, it is almost impossible to achieve a measurable response with TACE^[26].

Local radiotherapy can be an effective adjunct to the palliative treatment of HCC, even with portal vein thrombosis. Some studies of local radiotherapy, however, as either combination therapy with TACE or salvage therapy following TACE, have not shown a survival benefit, despite tumor response^[4-17]. This is because HCC eradication requires at least 50 Gy of radiation^[1,2]; but 33 Gy is a sufficient dose to induce RILD for whole liver radiation. With three-dimensional radiation planning, conformal radiotherapy can minimize scattering, limit unnecessary exposure of normal tissue, and deliver higher doses (40-80 Gy) to tumors^[27,28]. Therefore, it can be a feasible approach in the treatment of HCC with high dosage of radiation.

3D-CRT has been reported by a few studies to be effective in treatment of primary and metastatic tumors of lung and liver^[20, 21], but it has not been common to be applied in the treatment of HCC. The common therapy for HCC has been reported to be a daily dose of 1.8-2 Gy, 5 fractions per week, to a total delivered dose of 40-60 Gy^[4-17]. In our study of the 94 cases of HCC, we suggested that employing 3D-CRT could be beneficially combined with TACE with the following considerations.

Firstly, the combination of 3D-CRT with TACE may remedy the limitation of each alone and has synergistic effects. Secondly, tumor shrinkage after TACE allows the use of smaller irradiation fields, which permits higher tumor doses and improves the normal liver tolerance. Thirdly, combination therapy may also serve the purpose of eliminating residual cancer cells after TACE. Furthermore, the anticancer drug retained in the tumor may have a documented radiosensitizing effect^[6,29]. The anticancer drug, when mixed with lipiodol, has been reported to maintain relatively high concentrations in tumors as long as 27 d and decrease to a trace level after 47 d^[30]. Guo *et al.*^[6] reported that TACE followed by irradiation was a promising approach for large HCC and confirmed that TACE combined with radiotherapy was more effective than TACE alone.

In discussing the factors affecting the prognosis, we are not going to deal with the commonly known ones, which were also found in our study, such as age, Child-Pugh classification for cirrhosis of liver, Okuda stage, tumor size and type, and albuminemia. Only radiation dose is to be discussed, for it is of clinical importance in exploration of a better therapeutic method for HCC. In our present study, the radiation dose started at 60 Gy in 8 fractions within 17 d in cases with <25% of the nontumorous liver receiving >50% of the isocenter dose, at 56 Gy in 9 fractions within 19 d in cases with 25-50%, and 48 Gy in 12 fractions within 26 d in cases with 50-75%. Using the linear quadratic model, the biologic effective dose (BED) was here defined to be $nd(1+d/\alpha/\beta)$ in Gray, where n is the fractionation number, d is the daily dose, and α/β ratio is assumed to be 10 for tumors. The BEDs for our 3 different dose groups were equivalent respectively to those for 87.5 Gy total doses, 72 Gy total dose and 56 Gy total dose with a daily fraction of 2 Gy. The univariate and multivariate analyses of prognosis factors for overall survival showed that radiation dose is closely related to the prognosis. It seems clear that our virtually high total doses resulted in better response rates and overall survival. In our study, the radiologically documented response rates were 90.5%, our survival rates at 1-, 2-, and 3-year were 93.6%, 53.8%, and 25.9%, respectively, and our median survival rate was 25.0 mo. Besides better survival effect, hypofractionated 3D-CRT offers advantages of a shorter treatment course than a conventional radiotherapy and higher acceptance on the part of the patients without increasing side effects.

It has been reported that if less than 25% of the normal liver is treated with radiotherapy, then there may be no upper limit on dose associated with RILD; if 33%, 67%, or the whole liver is under uniform irradiation of 90 Gy, 47 Gy, or 31 Gy, respectively, there may be 5% risk of RILD associated with the treatment^[31]. In analyzing the correlation of RILD with patient-related and treatment-related dose-volume factors, Cheng *et al.*^[15] showed that after 3D-CRT, 12 of 68 patients developed RILD which was not found to be associated with their tumor volume. Compared with the documented ones, our results showed no increased toxicity in spite of the increased dose per fraction. This indicated that 3D-CRT played a critical role in the treatment of HCC.

In conclusion, 3D-CRT hypofractionated combined with TACE is a very safe and effective treatment method in higher tumor control and similar normal-tissue toxicity to conventional radiotherapy for HCC.

Abstract

AIM: To test the efficacy of gene therapy in rat liver tumor.

METHODS: A retroviral vector GCIL12EIL2PN encoding human IL-2 (hIL-2) and mouse IL-12 (mIL-12) fused gene and its packaging cell were constructed. The packaging cell lines contained of IL-2 and/or IL-12 genes were injected intrasplenically to transfect splenocyte at different time. The therapeutic effect, immune function and toxic effect were evaluated.

RESULTS: The average survival times of the 4 groups using IL genes at days 1, 3, 5 and 7 after tumor implantation were 53.3 ± 3.7 , 49.3 ± 4.2 , 31.0 ± 2.1 and 24.3 ± 1.4 d respectively in IL-2/IL-12 fused gene group, 25.0 ± 2.5 , 23.5 ± 2.0 , 18.3 ± 2.4 and 12.0 ± 1.8 d respectively in IL-2 gene treatment group, and 39.0 ± 4.8 , 32.0 ± 3.9 , 23.0 ± 2.5 and 19.4 ± 2.1 d respectively in IL-12 gene treatment group ($P < 0.01$, $n = 10$). In the IL-12/IL-2 fused gene treatment group, 30% of rats treated at days 1 and 3 survived more than 60 d and serum mIL-12 and hIL-2 levels were still high at day 3 after treatment. Compared with IL alone, NK cell activity was strongly stimulated by IL-2/IL-12 gene. Microscopy showed that livers were infiltrated by a number of lymphocytes.

CONCLUSION: IL-2 and/or IL-12 genes injected directly into spleen increase serum IL-2 and IL-12 levels and enhance the NK cell activity, which may inhibit the liver tumor growth. The therapy of fused gene IL-2/IL-12 is of low toxicity and relatively high NK cell activity. Our data suggest that IL-2/IL-12 fused gene may be a safe and efficient gene therapy for liver tumor. The gene therapy should be administrated as early as possible.

INTRODUCTION

Gene therapy to liver cancer is limited by both number and

duration of died cancer cells being treated^[1,2]. Interleukin 2 (IL-2) and interleukin 12 (IL-12) were secreted mainly by mononuclear cell and B cell^[3], which play a prominent role in immune response to tumor. These cytokines are stimulated by antigens, for instance virus, bacteria and tumor cells. Others have shown that IL-2 and IL-12 were inhibited by colon cancer^[4] and both can up-regulated the T-cell and NK cell to kill tumor cell after administration of exogenous ILs.

The conditions under which the gene therapies of IL-2 and IL-12 are cytotoxic to liver tumor in an animal model have not been clear yet. Understanding the role and the mechanism of IL-2 and IL-12 in the induction of anti-tumor cytotoxic factors is relevant to both the long-term expression of IL and the safety of gene drug in liver tumor gene therapy.

IL-2, a glycoprotein consisted of 133 amino acids, through promotion of growth and proliferation of T cell, can induce either LAK cell or NK cell. IL-2 also induces immunocyte to produce interferon (INF) and tumor necrosis factor (TNF). Immunoreaction mediated by IL-2 increases therapeutic efficacy of colon cancer^[4,5]. Secretion of IL-2 and reaction to IL-2 are decreased in tumor patients by as yet unknown reasons. Previous report has demonstrated that metastases are related to the IL-2 level, and the tumor immune mediated by IL is decreased in favor of carcinogenesis, growth, diffusion and metastasis of tumor^[6-10].

IL-12 has p35 subunit and p40 subunit localized respectively on chromosome 3 and chromosome 5. The single subunit has no biological activity, and p35 gene and p40 gene are expressed simultaneously to have activity. IL-12 activates NK cell and LAK cell, promotes generation and differentiation of T cell and induces NK cell to express a small amount of TNF- β .

Primary liver cancer is common malignant tumors in China. The surgical treatment of the cancer is a main choice, but it is not ideal therapy because of high recurrence. Gene therapy is the new way for some diseases such as diabetes and tumors. Our previous work was to treat liver cancer with IL-12 gene alone, by which tumor growth was inhibited compared with control. Now we constructed the fused gene of IL-2/IL-12. However, little is known on liver cancer treatment with combination of IL-2/IL-12 gene therapy.

We hypothesized that the immunologic regulation to liver cancer following fused gene therapy of IL-2/IL-12 would be dependent upon the production and duration of the cytokines. The toxic effect of IL-2 and IL-12 would be dependent upon approach of drug delivery. In this study, using the model of implanted hepatoma of rats, we have shown that the liver tumors are reduced after IL-2 and/or IL-12 gene are injected into spleen and the cytokines are transferred into liver and blood circulation by porta vein.

MATERIALS AND METHODS

Construction of retrovirus vector of packaging mIL-12 gene and hIL-2 gene

Aprotinin, leupeptin, pepstatin, fetal calf serum and protein standard mixture were from Sigma. Plasmid pGCp35IRESp40 containing both p35 subunit and p40 subunit of mIL-12 gene was a gift from Professor Xin-Huan Liu. Plasmid pLIL2SN

containing hIL-2 gene was constructed by our laboratory. Cellular strains of hepatoma CBRH3 were provided kindly by Professor Hong Xie (Shanghai Institute of Biochemistry and Cell Biology, Chinese Academy of Sciences). Monotropic packaging cell PE501, amphophilic packaging cell PA317 and cell NIH3T3 were provided by our laboratory. All other chemicals were of analytical grade and obtained from Merck or Sigma.

To amplify full length *p35* and *p40* genomes, PCR fragment was generated from downstream primer of mIL-12 *p35* subunit and upstream primer of mIL-12 *p40* subunit that templated with pGCp35IRESp-40SN. The products derived from PCR were harvested after 1% agarose gel electrophoresis. According to pLIL2PN templation, hIL-2 genome was then amplified and harvested. Fragments of mIL-12 *p35* and *p40* derived from PCR were templated to amplify with downstream primer of *p35* and upstream primer of *p40* by PCR, which contain linker sequence. The mIL-12 fused gene was harvested by electrophoresis^[11,12]. The mIL-12 and hIL-2 gene fragments were connected respectively with pGEMTM-Teasy vector (Promega, USA) by T4 ligase (Boehringer Mannheim, Germany). The vector was transfected into *E. coli* TG1 competence cell and the positive clone was screened by PCR. Plasmid DNA was extracted from positive clone after partial exonuclease III digestion of PCR product, resulting in constructing GCILEXPn polyclonal sites after endonuclease (*Not* I and *Sal* I) (Promega, USA) that containing GCIL12EXPn of mIL-12 gene, GCXEIL2PN of hIL-2 gene and GCIL12EIL2PN of mIL-12 and hIL-2 fused gene.

Retrovirus packaging, identification, titer determination and expression

Reverse transcript virus was transfected into PE501 cell by electroporation. The clones were screened by G418 after 48 h. PA317 cell was infected by filtered supernatant 10-14 d late. G418 was screen after 3 d. Viral supernatants were harvested after amplifying 6 monoclonal from every groups for 2-3 wk. Stock cells were frozen at -80 °C.

Recombined reverse transcript viral vector was identified by RT-PCR. Titers of viral supernatants were determined with NIH3T3 cell. The packaging cells with highest viral titer that contain GCIL12EXPn, GCXEIL2PN and GCIL12EIL2PN were named as PA317-GCIL12EXPn, PA317-GCXEIL2PN and PA317-GCIL12EIL2PN, respectively. Protein expression of mIL-12 and hIL-2 was determined by ELISA. ELISA kits (human IL-2 DuoSet and mouse IL-2 DuoSet) were from R&D Systems.

Implanted liver cancer in rats

Male Wister rats (200-250 g bm) were obtained from Animal Center of Chinese Academy of Sciences. Animals were maintained on a standard diet. Hepatoma CBRH3 cells were injected into abdominal cavity of rat. Rats were sacrificed and tumors were removed from abdominal cavity 7-9 d late. Tumors were cut into pieces of 0.05-0.75 cm and then were implanted into rat liver for one or more locations respectively. The tumors were grown up to 0.6-1 cm in diameter after 7-10 d of implantation.

Experimental procedure

Rats were anaesthetized with diethylether. The effects of IL-2 and/or IL-12 on liver cancer were studied in a total of 75 animals for 5 groups that contained 15 rats in every group: 1. Physiological saline control: 0.8 mL 9 g/L NaCl was injected into spleen following implanted liver cancer at day 1; 2. Blank vector control: 1×10^7 packaging cells of PA317-GCXEPN was injected into spleen of rat; 3. mIL-12 gene group: 1×10^7 packaging cell PA317-GCIL12EXPn was injected into rat spleen after implanted rat liver cancer on days 1, 3, 5 and 7 thereafter; 4. hIL-12 gene group: 1×10^7 packing cell PA317-GCxeILPN was injected into

rat spleen after implanted rat liver cancer on days 1, 3, 5 and 7 respectively; 5. hIL-2 and mIL-12 fused gene group: 1×10^7 packing cell PA317-GCIL12EIL2PN was injected into rat spleen after implanted rat liver cancer on days 1, 3, 5 and 7 thereafter. In addition, when rat survived over 2 mo, rats were named long term survivors and the liver cancer tissues were implanted into liver once more in order to observe cancer growth.

CT imaging and pathology

CT imaging was observed before and after treatment. The survival time and drug toxicity were observed. To observe the tumor cell and lymphocyte infiltration, the pathologic examination was performed following 5 and 7 d of treatment. The serum IL-2 and IL-12, according to the protocol of R&D Systems, were measured on d 1 before treatment and on d 3, 7, 30 and 60 thereafter.

Analysis of NK cytotoxic activity

NK target cell YAC-1 was obtained from the American Type Culture Collection (Bethesda, MD). The cytotoxicity of spleen NK cell was analyzed as follows^[13]. A single-cell suspension of spleen cells was centrifuged at 400 r/min for 30 min. The lymphocyte layers were harvested. For the preparation of targeted cells, YAC-1 was labeled with [⁵¹Cr]Na₂CrO₄ and mixed with various numbers of spleen cell in a total volume of 200 μ L of DMEM. The experimental radioactivity released (ER) in 100 μ L samples of cell-free supernatants was determined. The amounts of radioactivity released in wells containing YAC-1 cells alone with and without 0.01% Triton X-100 were designated the total release (TR) and the spontaneous release (SR), respectively. The percentage of specific ⁵¹Cr release was calculated by $[(ER-SR)/(TR-SR)] \times 100$.

Statistical analysis

All results were expressed as the mean \pm SD of at least 10 individual measurements. A one-way analysis of variance (ANOVA) was first carried out to test for any differences in mean values between experimental and respective control group. If differences were established, the values were compared by two-tailed unpaired *t* test. The values were considered to significant difference if *P* < 0.05.

RESULTS

Identification of packing cell strain

The total RNA of packaging cell strains (PA317-GCIL12EXPn, PA317-GCXEIL2PN and PA317-GCIL12EIL2PN) was extracted. The RNA was amplified by RT-PCR and the product was harvested by electrophoresis. The sequence showed that PA317-GCXEIL2PN and PA317-GCIL12EIL2PN packaging cell strains contained the mIL-12 sequence, and PA317-GCXEIL2PN and PA317-GCIL12EIL2PN packaging cell strains contained the hIL-2 sequence. The target genes were inserted into viral genomes and the packaging cell strains were transfected by IL gene.

Determination of titer of virus and protein expression

The highest virus titer of packaging cell was 2×10^6 CFU/mL of PA317-GCIL12EXPn, 2.4×10^6 CFU/mL of PA317-GCXEIL2PN and 1.4×10^6 CFU/mL of PA317-GCIL12EIL2PN respectively. Protein expression was measured by ELISA on these 3 packaging cell strains: 1. mIL-12 fused protein: PA317-GCIL12EXPn expressed mIL-12 fused protein 150 ng/10⁶/48 h and PA317-GCIL12EIL2PN expressed mIL-2 fused protein 45.8 ng/10⁶/48 h; 2. hIL-2 protein: PA317-GCEXIL2PN expressed hIL-2 protein 7.5 ng/10⁶/48 h and PA317-GCIL12EIL2PN expressed hIL-2 protein 6.7 ng/10⁶/48 h.

Table 1 Average survival time (day) of rat ($n=0$, mean \pm SD)

Group	Injection on d 1	Injection on d 3	Injection on d 5	Injection on d 7
Physiologic saline control	10.7 \pm 1.5	-	-	-
Blank vector control	11.4 \pm 1.3	-	-	-
IL-2 gene therapy	25.0 \pm 2.5 ^b	23.5 \pm 2.0 ^b	18.3 \pm 2.4 ^b	12.0 \pm 1.8
IL-12 gene therapy	39.0 \pm 4.8 ^b	32.0 \pm 3.9 ^b	23.0 \pm 2.5 ^b	19.4 \pm 2.1 ^a
IL-12-IL-2 fused gene therapy	53.3 \pm 3.7 ^c	49.3 \pm 4.2 ^c	31.0 \pm 2.1 ^c	24.3 \pm 1.4 ^c

^a $P<0.05$ and ^b $P<0.01$ vs physiologic saline control and blank vector control; ^c $P<0.05$ vs IL-2 group or IL-12 group.

Average survival time by IL gene therapy

Table 1 shows the average survival time of rat. All rats were died within 15 d after implanting liver cancer in both physiologic saline control and blank vector control. Compared with control, the survival time of rat was prolonged significantly by treatment with IL-2 or IL-12 ($P<0.01$). The rat survival time of treatment with fused gene of IL-2/IL-12 was lengthened markedly compared with IL treatment alone ($P<0.05$). Moreover, the survival time of early treatment was much longer than that of later treatment with IL ($P<0.01$). In addition, 6 rats treated early with fused gene of IL-2/IL-12 were lived more than 60 d, but there were 3 rats treated with IL-12 that lived more than 60 d.

When the tumor was undetectable by abdominal pathologic biopsy in the rats that lived more than 60 d, the 4 rats were implanted tumor piece again. It was interested that there were no tumor growths in abdominal cavities 7 d late.

Imaging features

The liver tumor was detected by CT on day 7 after implantation in control (Figure 1). The 6 of 10 rats administrated early with IL-2/IL-12 fused gene showed that the liver tumors were reduced after 2 mo (Figure 2).

**Figure 1** CT scan of the liver cancer 7 d after implantation.**Figure 2** CT scan of the tumor treated with IL-2/IL-12 fused gene after 2 mo.

Pathologic features

A number of lymphocyte infiltrations in liver tumor were

observed significantly after 5 d of treatment with IL-2/IL-12 fused gene and 7 d of treatment with IL-2 gene or IL-12 gene (Figure 3).

**Figure 3** Pathological changes of implanted liver cancer (HE staining, original magnification: $\times 200$). There are numerous lymphocytes in tumor tissues.

Serum mIL-12 and hIL-2 levels

Compared with control, both IL-2 and IL-12 in serum were increased significantly in rats treated with IL gene on day 1 (Table 2). After the injection of IL-2/IL-12 fused gene, both IL-2 and IL-12 in serum reached the highest level on day 3, then decreased stepwise and maintained at a lower level for 2 mo (Table 3).

Table 2 Determination of serum hIL-2 or mIL-12 3 d after administration of IL gene (ng/mL)

Group	HIL-2	MIL-12
Physiologic saline control	<0.8	<0.8
Blank vector control	<0.8	<0.8
IL-2 gene therapy	19.4 \pm 1.8	<0.8
IL-12 gene therapy	<0.8	22 \pm 2.5
IL-12-IL-2fused gene therapy	18.5 \pm 2.4	20.5 \pm 2.5

Table 3 Determination of serum hIL-2 and mIL-12 on fused gene group (ng/mL)

Group	HIL-2	MIL-12
Control	<0.8	<0.8
On d 3 after therapy	18.5 \pm 2.4	20.5 \pm 2.5
On d 7 after therapy	10.2 \pm 2.5	11.5 \pm 2.5
One mo after therapy	5.3 \pm 1.2	6.2 \pm 1.4
Two mo after therapy	<0.8	<0.8

IL increases NK cell activity

IL-2 and IL-12 have been reported to increase NK cell activity. To determine if the IL-2/IL-12 fused gene could induce NK cell activation, rats were treated as described above with IL-2 and/or IL-12. The rats were sacrificed on day 7, and the spleen lymphocytes were assayed for the ability to kill ⁵¹Cr-labeled

YAC-1 target cells. There was a significant increase in NK activity after rats were injected with IL-2 or IL-12 alone ($P < 0.01$). Compared with IL alone, treatment with IL-2/IL-12 fused gene markedly enhanced NK cell activity ($P < 0.05$).

Toxicity of IL

Three rats (30%) in IL-2 group and 1 (10%) in IL-2/IL-12 group showed anorexia after administration of IL. The symptom was recovered 3-5 d later (Figure 4).

Figure 4 Activation of NK cell activity after administration of IL-2 and/or IL-12 ($n=5$). ^b $P < 0.01$ vs control; ^a $P < 0.05$ vs IL-2 group or IL-12 group.

DISCUSSION

The establishment of DNA recombination and transfection allowed us to utilize gene therapy for killing or inhibiting the tumor cells^[14]. The utility of recombinant adenoviral vectors for gene therapy is limited by the low transduction efficiency and lack of specificity for target cells^[15,16]. Spread of the virus throughout the cells maximizes the percent of cells within a cell expressing the gene of interest, and should improve the antitumor response. This may be significant for gene delivery expressing cytokines, tumor antigens or enzymes. One limitation of the transduction system is the inefficiency of the combined cytokines expression system. The initial work in this study was to construct the IL-2/IL-12 fused gene vector that was then injected into spleen, in which splenic cells, probably including liver cells, were transduced to express IL-2 and IL-12 simultaneously.

The active IL-12 is a heterogeneous dimer, which contains p35 subunit and p40 subunit, so that both subunits express simultaneously in cells if used to treat disease. Using PCR technique based on the subunit characterization of different gene sequences, we constructed the active IL-2/IL-12 fused gene and a linker sequence was incorporated into subunits of IL-12, so that the gene could correctly express protein. In present study, the IL-2 and IL-12 levels were not significantly different in serum.

The single gene therapy for the liver cancer is not ideal because it is resulted from multi-factors^[17]. Chen *et al.* suggested recently that TRAIL and chemotherapeutic agents or anticancer cytokines combination might be a novel strategy for the treatment of liver cancer. Combination of IL-2/IL-12 results in stable antitumor effect, which induces the cytotoxic T lymphocyte and NK cell^[18]. IL-2 and IL-12 have synergetic effect such as immunoregulatory^[19,20]. The antitumor immunologic effect from IL-2 and IL-12 depends on available concentration of IL-2 and IL-12. IL-2 and IL-12 also cause a long term antitumor immunologic memory^[21]. In present study, retrovirus vector containing IL-2/IL-12 genes was constructed, in which gene products of IL-2 and IL-12 were expressed simultaneously in the liver. We treated rat liver cancer with IL-2 and/or IL-12 gene. The liver cancer rats treated with IL-2 or IL-12 survived longer than those in control ($P < 0.01$). Compared with IL alone,

combination of IL-2/IL-12 gene showed a longer survival of 14-28 d in early treatment group and 5-12 d in late treatment group.

Spleen is the biggest immune organ that has a lot of immunocytes and produces antibodies and cytokines. Spleen is also the main organ of inducing immunoresponsiveness to heterologous antigen. The retrovirus packaging cell strain was injected into spleen, which expresses the high level of cytokine in order to activate immunocytes. In other hand, the retrovirus packaging cells would be transferred from spleen to liver by splenic veins and the liver cells would be infected by packaging cells resulting in enhanced anti-tumor immunity. In present study, the IL gene was injected into spleen and the blood concentration of IL was the highest on day 3. The IL concentration maintained at a level for 2 mo. Authors from Spain reported that gutless adenoviral vector encoding hIL-2 and mIL-12 was injected into animals and IL was expressed by hepatocytes. The peak concentration of IL-12 was at 10 h and it completely disappeared by 72 h. If the vectors were administrated continually, the serum IL-12 would maintain at least for 48 wk^[22,23]. The rats received the splenic gene therapy survived longer than those in control. When combination of IL-2/IL-12 gene was injected into spleen, the high concentration of IL was determined from blood until day 3 and the rats survived a longer time compared with IL therapy alone.

Moreover, early gene treatment is better than late therapy. In this study, 6 rats (30%) with combined gene therapy on early stage survived a long term and the tumor nodes in liver was not detected by CT imaging and pathologic observation, in which the IL-2 and IL-12 kept a high concentration at least for 2 mo. As same as other therapy for cancer, the IL gene therapy should administrate as early as possible. In present study, the liver cancer rats treated with IL-2 or IL-12 on day 1 survived more than 8 d or 13 d respectively compared with that treated on d 7 (Table 1). The combined IL gene therapy has the similar result.

IL-2 or IL-12 produced significant toxic reaction if they were administrated enough dosage to maintain a high blood concentration. When IL-2 or IL-12 was injected into rat liver, some rats showed acute toxic reaction such as anorexia, convulsion and bleeding shock (unpublished data). In present study, when IL genes were injected into spleen, the severe acute toxic reaction was not observed in all groups.

A mechanism of IL gene treatment may be due to enhancement of NK cell activation and production of cytokines including IL^[24]. Several investigators have shown that NK cells are a relative smaller cell population in peripheral lymphoid organs but are abundant in the liver. An initial response to tumor cell may involve the innate arm of the immune response resulting in killing of mutant cell strain by NK cell^[25,26]. The findings in this study are novel since IL-2/IL-12 fused gene expresses IL-2 and IL-12 simultaneously that result in further stimulation of NK cells. We propose that liver tumor is inhibited because of IL production, such as IL-2 and IL-12, which is stimulated by IL gene therapy.

It is interesting that serum IL-2 and IL-12 levels do not change in IL-2/IL-12 gene therapy compared with IL alone, but NK cell activity is enhanced significantly compared with IL alone. We propose that the NK cell activity is strongly stimulated by both IL-2 and IL-12 at the same time, which was caused by IL-2/IL-12 fused gene expression^[27-30].

In summary, treatment with IL-2 and/or IL-12 gene increases serum IL-2 and IL-12 levels and enhances the NK cell activity, which may inhibit the liver tumor growth. The fused gene therapy of IL-2/IL-12 is of low toxicity and relatively high NK cell activity. We suggest that IL-2/IL-12 fused gene therapy may be a safe and efficient method for the treatment of liver cancer. For IL gene therapy, early intervention is better than late one.

Abstract

AIM: To study the antitumor effect of combined gene therapy of endostatin and interleukin 12 (IL-12) with polyvinylpyrrolidone (PVP) on mouse transplanted hepatoma.

METHODS: Mouse endostatin eukaryotic plasmid (pSecES) with a mouse Igk signal sequence inside and mouse IL-12 eukaryotic plasmid (pmIL-12) were transfected into BHK-21 cells respectively. Endostatin and IL-12 were assayed by ELISA from the supernatant and used to culture endothelial cells and spleen lymphocytes individually. Proliferation of the latter was evaluated by MTT. H22 cells were inoculated into the leg muscle of mouse, which was injected intratumorally with pSecES/PVP, pmIL-12/PVP or pSecES+pmIL-12/PVP repeatedly. Tumor weight, serum endostatin and serum IL-12 were assayed. Tumor infiltrating lymphocytes, tumor microvessel density and apoptosis of tumor cells were also displayed by HE staining, CD31 staining and TUNEL.

RESULTS: Endostatin and IL-12 were secreted after transfection, which could inhibit the proliferation of endothelial cells or promote the proliferation of spleen lymphocytes. Tumor growth was highly inhibited by 91.8% after injection of pSecES+pmIL-12/PVP accompanied by higher serum endostatin and IL-12, more infiltrating lymphocytes, fewer tumor vessels and more apoptosis cells compared with injection of pSecES/PVP, pmIL-12/PVP or vector/PVP.

CONCLUSION: Mouse endostatin gene and IL-12 gene can be expressed after intratumoral injection with PVP. Angiogenesis of hepatoma can be inhibited synergistically, lymphocytes can be activated to infiltrate, and tumor cells are induced to apoptosis. Hepatoma can be highly inhibited or eradicated.

INTRODUCTION

Liver cancer is one of the most common neoplasms worldwide. In some parts of Asia and Africa the prevalence is more than 100/100 000 population^[1]. Treatments often come to failure because of its high resistance to chemotherapy or radiotherapy and the severe side-effects induced^[1]. At present the only curative options are partial hepatectomy or total hepatectomy with liver transplantation. But the chance for surgery is very limited. The effects of some other treatments such as intratumoral injection of ethanol or acetic acid, transarterial catheter embolization, and thermal destruction or microwave coagulation were also very poor due to the high incidence of tumor recurrence and hepatic failure^[1-3]. Now combined treatments including biotherapy have been regarded as the most promising methods to cure liver cancer^[4,5].

Among the biotherapies, antiangiogenic therapies have recently attracted an intense interest for their broad-spectrum action, low toxicity, and in direct endothelial targeting, the absence of drug resistance^[6]. Antiangiogenic therapy induced by endostatin could specifically inhibit endothelial proliferation and potentially inhibit angiogenesis and tumor growth accompanied by apoptosis in tumor cells^[7-9]. Repeated cycles of antiangiogenic therapy were even followed by prolonged tumor dormancy without further therapy^[10].

More and more learners have begun to realize that the occurrence of tumors is a complex course induced by multiple genes and multiple steps. Interference of single factor on tumor often can not get satisfactory results. Although primary tumors were regressed to dormant microscopic lesions after endostatin therapy, tumor cells were not eradicated at all^[7,10]. Conventional chemotherapy or radiotherapy can do little on residual tumor cells, accurate recognition and clearance of which depends on the immune system of host^[11]. IL-12 is among the most potent cytokines in stimulating antitumor immunity^[12-14], which also showed significant inhibitory activity on angiogenesis^[15].

So antiangiogenesis therapy by endostatin in combination with antitumor immunotherapy by IL-12 has become an attractive approach. On one hand synergistically antiangiogenic effect may be achieved to induce tumor dormancy. On the other hand, residual tumor cells may be also eradicated by antitumor immunotherapy induced by IL-12. Due to the problems such as bioactive protein production in large quantities, high costs and daily administration of endostatin^[10,16], and the severe side-effects of system administration of IL-12^[17,18], local gene therapy has proved to be very effective and nontoxic at the same time^[19-24]. In this study combined intratumoral gene therapy of endostatin and IL-12 was observed in treatment of mouse hepatoma.

MATERIALS AND METHODS

Plasmid and host

Mouse endostatin eukaryote expression plasmid pSecES was constructed in our laboratory (data not shown). The expression of endostatin was under the control of *cytomegalovirus* (CMV) promoter. A mouse Igk signal peptide sequence was located upstream of endostatin sequence to lead endostatin to secrete out. Mouse IL-12 eukaryote expression plasmid (pmIL-12) was

a gift from Professor David M. Mahvi in Wisconsin University, USA. Both *M*_r 35 000 light chain gene and *M*_r 40 000 heavy chain gene linked by an internal ribosome entrance site were put downstream of CMV promoter^[25]. Empty plasmid pcDNA3.1, pcDNA3.1-lacZ and *E. coli* DH5 α were from the collection of our laboratory. DH5 α bacteria containing the plasmids were grown in LB medium to mid-log phase. The plasmids were then purified with Qiagen columns (Qiagen). An analytical gel of each plasmid (cut and uncut) was done to ensure that there was no contamination with other nucleic acids. The *A*₂₆₀/*A*₂₈₀ ratios ranged from 1.8 to 2.0. Also each plasmid was confirmed to be free of endotoxin. For gene therapy, concentrated plasmid stock solution was made by lyophilizing and rehydrating with water. Then it was formulated into a solution containing 1 g/L plasmid, 50 g/L polyvinylpyrrolidone (PVP, K30, *M*_r 40 000, from Sigma), 150 mmol/L NaCl before use.

Cell culture and animals

BHK-21, human umbilical vein endothelial cell line (HUVEC) ECV304 and mouse hepatoma cell line H22 were purchased from China Center for Type Culture Collection. All the cell lines were maintained in RPMI 1640 medium (GibcoBRL) supplemented with 100 mL/L fetal bovine serum (FBS), 10⁵ U/L penicillin and 100 mg/L streptomycin. Cells were cultured at 37 with 50 mL/L CO₂. Six to 8-wk-old male BALB/c mice of specific-pathogen-free (SPF) grade (purchased from Hubei Experimental Animals Center, China) were maintained in a standard SPF animal's room. All animal studies were performed in accordance with acceptable animal use guidelines.

Secretion and activity of endostatin plasmid and IL-12 plasmid

In 6-well plate, 5×10⁵ BHK-21 cells per well were transfected with 1 μ g pSecES or 1 μ g pmIL-12, 3 μ L LipoGen (InvivoGen) in accordance with directions of the manufacturer. Forty-eight hours after transfection, 0.1 mL ECV304 cells (2×10⁷/L) cultured in RPMI 1640 additionally supplemented with 2 μ g/L recombinant human basic fibro growth factor (rhbFGF) (PeproTech, UK) was inoculated to a 96-well plate. 0.1 mL supernant of BHK-21 cells transfected with pSecES was added to ECV304 cells per well. Seventy-two hours later, 20 μ L 5 g/L MTT was added per well. After 4 h, the supernant was discarded and 150 μ L DMSO was added. Absorbency at 570 nm was assayed. Forty-eight hours after transfection, mouse spleen cells were also produced by routine protocols and cultured in RPMI 1640 medium supplemented with 100 mL/L FBS for 2 h. Then the suspending lymphocytes were adjusted to 1×10⁸/L and seeded to a 24-well plate (0.5 mL per well). Also 0.5 mL supernant of BHK-21 cells transfected with pmIL-12 was added per well. Forty-eight hours later, the proliferation was evaluated by MTT assay as above. The supernant of BHK-21 transfected with pcDNA3.1-lacZ was used as control. Also transfection rate was evaluated by X-gal staining of BHK-21 transfected with pcDNA3.1-lacZ 48 h later. All the three kinds of supernant was stored at -20 for further assay.

Combined gene therapy of endostatin and IL-12 for H22 hepatoma in vivo

In 0.1 mL PBS, 10⁵ H22 cells were inoculated i.m. into the hind limb of BALB/c mice. Then the mice were randomly divided into five groups (6 per group): PVP/NaCl (untreated), pcDNA3.1 (empty vector), pSecES, pmIL-12, pSecES+pmIL-12. Another 6 mice were not inoculated for further assay of basic serum endostatin. From the next day after inoculation, 100 μ g pSecES/PVP and/or pmIL-12/PVP, 100 μ g pcDNA3.1/PVP or 100 μ L PVP/NaCl solution was injected into the inoculation site respectively with a 26 G needle every three days. After inoculation for 21 days, tumors were removed and weighed.

Before tumor dissection, mouse blood was collected and stored at 4 overnight. Then the serum was stored at -20 for further assay after centrifugation. The data were analyzed statistically by SPSS 10.0 procedure.

Assay of mouse endostatin and IL-12 (p70) in supernant or serum

The frozen supernant of BHK-21 transfected with pSecES, pmIL-12 or pcDNA3.1-lacZ and the frozen serum were thawed to room temperature. Then mouse endostatin and IL-12 (p70) were assayed according to the directions of CytELisa mouse endostatin kit (CytImmune, USA) and mouse IL-12 (p70) ELISA kit (Shengzhen Jingmei Biotech, China).

Detection of MVD, TILs and apoptosis of H22 hepatoma

Paraffin sections (5 μ m) of tumor tissues were stained with rat anti-mouse CD31 antibody (eBioscience). Then the primary antibody was detected by biotinylated secondary rabbit anti-rat IgG and SABC immunohistochemistry kit (Wuhan Boster Biotech, China) according to directions of its manufacturer. Paraffin sections were also stained with HE to reveal tumor infiltrating lymphocytes (TILs). Apoptosis of tumors was displayed by TdT-mediated dUTP nick end labeling (TUNEL) staining with an *in situ* cell death detection kit (Boehringer Mannheim, Germany) in accordance with the guideline of its manufacturer.

Tumor microvessel density (MVD) was counted as previously described^[26,27]. The CD31 staining sections were scanned in 40× microscope and "hot spots" (area with greatest vascula) were found, from which 3 random fields of 200× microscope were selected. The average vascular number of the three fields was looked as MVD. For HE and TUNEL staining sections, 5 random nonnecrotic tissue fields in 400× microscope was selected. The average number of TILs or apoptotic cells was counted. The data were analyzed statistically by SPSS 10.0 procedure.

RESULTS

Secretion and activity of endostatin plasmid and IL-12 plasmid

β -galactosidase expression was assessed by X-gal staining 48 h post-transfection. The transfection efficiency was about 30%. No endostatin or IL-12 was detected in the supernant of BHK-21 transfected with pcDNA3.1-lacZ. Endostatin secreted by BHK-21 transfected with pSecES was 65.5±10.9 ng/10⁶ cells. When this supernant was added to ECV304 stimulated by rhbFGF, the proliferation of the latter was inhibited by 29.2% 72 h later (inhibitory efficiency=1-A of endostatin group/A of control group, *P*<0.01). Also 221.8±44.4 ng/10⁶ cells IL-12 (p70) was detected in the supernant of BHK-21 transfected with pmIL-12. It could promote mouse spleen lymphocytes to proliferate by 15.2% (proliferation efficiency=A of IL-12 group/A of control group-1, *P*<0.05). The results are displayed in Figure 1.

Antitumor effect of combined gene therapy of endostatin and IL-12 for H22 hepatoma in vivo

On the next day after inoculation, the mice received gene therapy. No skin lesions were found in the injection sites. On d 21 after inoculation, tumors were dissected and weighed. Big tumors could be found in all mice of PVP/NS group and pcDNA3.1 group. In pSecES group, all mice formed tumors, some of which were much smaller. Four mice formed tumors in pmIL-12 group and only two mice formed small tumors in pSecES+pmIL-12 group. The average tumor weight of pSecES group was much lower than that of PVP/NS group or pcDNA3.1 group (*P*<0.01) (Figure 2). The inhibitory rate was 56.4% (inhibitory efficiency=1-tumor weight of pSecES group/tumor

weight of pcDNA3.1 group). For pmIL-12 group, the inhibitory rate was 85.7%. When pSecES gene therapy and pmIL-12 gene therapy were used in combination, tumor growth was inhibited by 91.8% ($P<0.01$).

Figure 1 Proliferation of ECV304 inhibited by the supernatant of BHK-21 transfected with pSecES and proliferation of spleen lymphocytes stimulated by the supernatant of BHK-21 transfected with pmIL-12. Each bar represents A value of ECV304 or spleen lymphocytes, and mean \pm SD for 5 wells. ^a $P<0.05$ vs control, ^b $P<0.01$ vs control.

Figure 3 Increase of mice serum endostatin levels or IL-12 levels after gene therapy. A: Serum endostatin levels of mice treated with pcDNA3.1/PVP, pSecES/PVP, pSecES+pmIL-12/PVP or not inoculated with H22 cells (basic levels). Each bar represents mean \pm SD for six mice. ^a $P<0.05$ vs pcDNA3.1 group. B: Serum IL-12 levels of mice treated with pcDNA3.1/PVP, pmIL-12/PVP, pSecES+pmIL-12/PVP. Each bar represents mean \pm SD for six mice. ^a $P<0.05$ vs pcDNA3.1 group.

Figure 4 Hepatoma angiogenesis inhibited by gene therapy of endostatin and IL-12. MVD (CD31staining, 200 \times) of hepatoma treated with pSecES/PVP (7.3 ± 1.2) (B), pmIL-12/PVP (10.0 ± 1.7) (C) or pSecES+pmIL-12/PVP (3.7 ± 1.2) (D) was less than that treated with pcDNA3.1/PVP (22.7 ± 3.1 , $P<0.05$) (A).

Figure 2 Hepatoma formation and growth inhibited by gene therapy of endostatin and IL-12. Each bar represents tumor weight of mice treated with PVP/NaCl, pcDNA3.1/PVP, pSecES/PVP, pmIL-12/PVP or pSecES+pmIL-12/PVP, and mean \pm SD for six mice. $P<0.01$ by ANOVA analysis.

Serum endostatin and IL-12 levels after gene therapy

When gene therapy was finished, the serum endostatin and IL-12 levels were evaluated by ELISA. The serum endostatin level in pSecES group was 117.1 ± 12.8 $\mu\text{g/L}$, which was much higher than that in pcDNA3.1 group (87.7 ± 6.1 $\mu\text{g/L}$) or the basic level

Figure 5 Lymphocytes infiltration into hepatoma promoted by gene therapy of IL-12. TILs (HE staining, 400 \times) of hepatoma treated with pmIL-12/PVP (146.2 \pm 24.6) (B) and pSecES+pmIL-12/PVP (123.2 \pm 21.4) (C) were more than that treated with pcDNA3.1/PVP (45.2 \pm 11.8, P <0.01) (A).

Figure 6 Apoptosis of hepatoma cells induced by gene therapy of endostatin and IL-12. Apoptotic tumor cells (TUNEL, 400 \times) treated with pSecES/PVP (11.2 \pm 2.3) (B), pmIL-12/PVP (14.4 \pm 3.5) (C) or pSecES+pmIL-12/PVP (24.8 \pm 4.8) (D) were more than those treated with pcDNA3.1/PVP (1.4 \pm 1.7, P <0.05) (A).

(75.8 \pm 6.6 μ g/L) (P <0.05). Also, after pmIL-12 gene therapy, the serum IL-12 level was higher in pmIL-12 group (401.0 \pm 51.6 ng/L) than in pcDNA3.1 group (154.8 \pm 25.8 ng/L) (P <0.05) (Figure 3).

MVD, TILs and apoptosis of H22 hepatoma after gene therapy
MVD were counted after CD31 staining in tumor sections. Compared with pcDNA3.1 group, MVD of hepatoma treated with pSecES/PVP or pmIL-12/PVP were much less. And in pSecES+pmIL-12 group, MVD were less than any single gene therapy group (P <0.05) (Figure 4).

Tumor sections were stained by HE, then TILs were evaluated. After pmIL-12/PVP or pSecES+pmIL-12/PVP gene therapy, TILs in hepatoma were more than that treated with pcDNA3.1/PVP (P <0.01). The results are displayed in Figure 5.

Also, tumor apoptosis was displayed by TUNEL staining. Figure 6 shows that there were only a few apoptotic tumor cells dispersed in 400 \times random scopes in pcDNA3.1 group. But in pSecES group or pmIL-12 group, apoptotic tumor cells increased. In pSecES+pmIL-12 group, apoptotic tumor cells were much more than any group (P <0.05).

DISCUSSION

Despite the progress in early diagnosis of liver cancer, its prognosis remains poor. In average, the mean life span was less than a year after diagnosis^[1]. How to prevent or cure the recurrence of remained tumor cells after partial hepatectomy

and how to inhibit tumor infiltrating in liver cancer patients in advanced stage are urgent challenges for liver cancer therapy. Now antiangiogenic therapy and immunotherapy have been paid more and more attention and many promising conclusions have been drawn^[28-31]. But in clinical trials, few satisfactory results were obtained by single biotherapy^[17,18,32]. Whether synergistic effects of antiangiogenesis therapy in combination with immunotherapy could be achieved is worthy to be researched.

Studies showed that angiogenesis played a very important role in the course of growth and metastasis of solid tumors including liver cancer. When the tumor size was beyond 2-3 mm³, oxygen and nutrition were not enough by simple diffusion. Then new vessels must be formed for further growth^[33]. However, angiogenesis was dependent on the cooperation of pro-angiogenesis factors and anti-angiogenesis factors^[34]. Among many inhibitors, endostatin, the C terminal of collagen X VIII, which is a M_r 20 000 protein with 184 amino acids in primary structure, has the strongest antiangiogenesis and antitumor effect. It was identified from the medium of a murine hemangioendothelioma (EOMA) cell line in 1997^[7]. Researchers indicated that both natural and recombinant endostatin could markedly inhibit endothelial cell proliferation *in vitro* and angiogenesis in chick chorioallantoic membrane, but had no effect on non-endothelial cells. When endostatin was administrated subcutaneously, primary tumors were regressed to dormant microscopic lesions and metastasis was inhibited. Repeated cycles of endostatin therapy showed prolonged tumor dormancy without further therapy^[7,10]. In our previous study, subcutaneous

injection of 10 mg/(kg.d) endostatin produced by gene engineering showed a potent inhibitory effect on the formation and growth of mouse H22 hepatoma^[35]. Also the clinical trial of endostatin has been carried out^[32]. But to obtain both high quantity and high quality of endostatin was necessary for optimal therapeutic benefit^[36]. It was indicated that the activity of endostatin expressed in mammalian cells was 1 000 times than recombinant protein extracted from *E.coli*^[37]. So gene therapy of endostatin has become a very good solution and many studies suggested that gene therapy of endostatin showed a powerful inhibition on liver cancer^[21,22].

When H22 hepatoma cells, derived from Balb/c mouse liver cancer in 1940 s, were inoculated into the leg muscle of mice, solid tumors formed quickly, which were easy to touch and easy for injection. Compared with viral vectors, non-viral vectors bore some advantages such as easy to handle, high capacity for DNA sequences, low toxicity, and non-immunogenic thus permitting repeated vector administrations^[38]. So we constructed endostatin eukaryotic plasmid pSecES, inside which a mouse Igk signal peptide sequence was put upstream endostatin sequence to let endostatin secrete out. *In vitro* high-levels endostatin with inhibitory activity on the proliferation of endothelial cells could be detected from the supernatant after transfection. And *in vivo*, for lower degradation of input DNA by endosomes and/or lysosomes and higher transfection efficiency, non-toxic PVP was used to enhance gene expression according to previous reports^[39,40]. Plasmid/PVP was injected intratumorally and repeatedly for a higher local concentration. After endostatin gene therapy, mice serum endostatin levels were consistently 2-3-fold higher than basic levels. Compared with controls, tumors formed slowly with less MVD and more apoptosis cells. The average tumor weight inhibitory rate was 56.4%. It was indicated that pro-angiogenic factors such as VEGF were induced when tumor vessels formed gradually, and antiangiogenic factors such as endostatin increased for a negative regulation^[41,42]. This opinion was also confirmed by our study that serum endostatin levels in mice burdened with big tumors after vector injection were increased compared with basic levels. When more endostatin were added by gene therapy, the balance would be broken and angiogenesis was inhibited.

Immunocytokines which were important in the regulation of the immune system could overcome immune tolerance against tumor antigens, thus tumor rejection was facilitated. It was benefic for prevention of recurrence of micro tumor cells and advanced tumors which could not accept operation or chemotherapy^[11,13]. Different cytokines (IL-2, IL-4, IL-12, INF- γ , TNF- α , GM-CSF) have been used to modulate the host's immune response either *in vitro* or *in vivo*. The activation and proliferation of immunocytes and antitumor immunity were induced more or less^[13]. IL-12 is among the most potent cytokines in stimulating antitumor immunity. It is a disulfide-linked heterodimeric cytokine. IL-12 acts by inducing a TH1 type of response, activating natural killer cells and cytotoxic T lymphocytes, enhancing expression of adhesion molecules on endothelial cells, thus facilitating the traffic of lymphocytes to the tumor, and inducing a potent antiangiogenic effect. In previous researches, the antitumor effect of IL-12 was established in various *in vivo* systems^[12-14]. However, the latter was reported to cause fatal toxicity in a clinical trial^[17], which led investigators to local administration of this cytokine by gene therapy or gene gun, that proved to be very effective and nontoxic at the same time^[23,24]. In our study, active IL-12 (p70) was expressed *in vitro* and *in vivo*. Tumors did not formed in 30% mice that received IL-12 gene therapy. The formed tumors were also highly inhibited with more TILs, less MVD and more apoptotic tumor cells. Moreover, the inhibitory effect of IL-12 gene therapy on H22 hepatoma was much better than that of endostatin plasmid ($P<0.05$).

When combined gene therapy of endostatin and IL-12 was used, its antitumor effect was much better than others. Tumor formation was not observed in 66.7% mice. The average tumor weight inhibitory rate was 91.8%. But in mice that received endostatin gene therapy, no tumor regressed. The average tumor weight inhibitory rate was 56.4%. No tumor was formed in 33.3% mice after they received IL-12 gene therapy. The average tumor weight inhibitory rate was 85.7%. It was suggested that synergistic antitumor effect was achieved after combined gene therapy of endostatin and IL-12. The proposed mechanism of the combined gene therapy maybe a synergistic cooperation of an antiangiogenesis effect induced by endostatin and IL-12 in combination with an immune rejection induced by IL-12. On one hand, endostatin and IL-12, which were expressed locally in combination with increased serum levels after gene delivery mediated by plasmid with PVP, could inhibit angiogenesis of hepatoma synergistically. This was convinced by that MVD in pSecES+pmIL-12 group was much less than any single gene therapy group. But now the antiangiogenesis mechanism of endostatin and IL-12 was still not very clear. Through this way, H22 hepatoma cells came to apoptosis or necrosis due to lack of blood supply. On the other hand, more TILs (including activated CTL, NK, TH1 etc.) were observed in tumors that received IL-12 gene therapy or combined gene therapy, which maybe an indication of activated immune response on H22 hepatoma cells. Antitumor immune rejection induced by IL-12 through immunocytes or cytokines also promoted apoptosis of tumor cells. So there were much more apoptotic tumor cells in combined gene therapy group than any single one. Due to these factors, formation and growth of transplanted H22 hepatoma was prevented synergistically.

Combined gene therapies for liver cancer were also reported previously. Learners have focused on combined genes of two or three immunocytokines, or on suicide gene therapy in combination with genetic immunotherapy^[25,30,31,43]. Biotherapy in combination with chemotherapy for lymphoma was also studied^[44]. Before our reports, combined treatment with type 5 adenovirus vectors expressing murine angiostatin and IL-12 showed an antitumor effect on a murine breast cancer^[45]. Our report is the first to demonstrate the potent antitumor effect of combined gene therapy of endostatin and interleukin 12 with polyvinylpyrrolidone on hepatoma.

In conclusion, active target protein can be expressed by repeated local injections of plasmid with PVP. Through this way, a short-term course of combined gene therapy of endostatin and IL-12 can effectively prevent the formation and development of transplanted H22 hepatoma in mice. Antiangiogenic therapy in combination with immunotherapy may be used to regress or to eradicate other solid tumors.

ACKNOWLEDGEMENT

We thank Xiao-Yan Yang and Dong-Po Song for their expert technical assistance in animal experiments and Peng-Cheng Zhu for his help in histopathological analysis in this study.

Abstract

AIM: To evaluate the clinical effect of high-intensity focused ultrasound (HIFU) in the treatment of patients with liver cancer.

METHODS: HIFU treatment was performed in 100 patients with liver cancer under general anesthesia and by a targeted ultrasound. Evaluation of efficacy was made on the basis of clinical symptoms, liver function tests, AFP, MRI or CT before and after the treatment.

RESULTS: After HIFU treatment, clinical symptoms were relieved in 86.6%(71/82) of patients. The ascites disappeared in 6 patients. ALT (95 ± 44) U/L and AST (114 ± 58) U/L before HIFU treatment were reduced to normal in 83.3%(30/36) and 72.9%(35/48) patients, respectively, after the treatment. AFP was lowered by more than 50% in 65.3%(32/49) patients. After HIFU treatment, MRI or CT findings indicated coagulation necrosis and blood supply reduction or disappearance of tumor in the target region.

CONCLUSION: HIFU can efficiently treat the patients with liver cancer. It will offer a significant noninvasive therapy for local treatment of liver tumor.

INTRODUCTION

Since 1942, Lynn *et al.*^[1] firstly brought forward the conception of HIFU, i.e. high intensity focused ultrasound. Fry^[2] applied HIFU technology to experimentally treat nervous system diseases, and suggested the potential of HIFU in surgical operations. As a result, he found that ultrasound beam could form a preferable focal field at a special depth inside body, and destroy target tissue through focus pointing without damaging neighboring tissues. In 1956, Burov proposed that effect of short-time high-intensity ultrasound irradiation was better than low-intensity ultrasound. With research progress on HIFU technology, this technology has been used in clinic over the

years^[3-6]. The present study makes an assessment on clinic effect of HIFU in treating liver cancer.

MATERIALS AND METHODS

Materials

We performed HIFU treatments in 100 patients (80 male, 20 female, ranging 30-74 years with mean age of 56 years) with liver cancer from July 2001 to July 2003, totally 130 HIFU treatments, 1.30 times per patient. Patients included 62 primary liver cancers and 38 metastatic liver cancers. Sixty-eight patients were with single nodule, 22 with two nodules, 10 with three nodules. Totally 36 tumor nodules with a diameter less than 5 cm, 76 with a diameter between 5-10 cm, 30 with a diameter more than 10 cm were involved. All cases were investigated and verified by pathohistology or an obvious increase of serum AFP and positive imaging, and conformed to diagnostic standard of National Cooperation Conference and Hepatic Carcinoma Prevention and Treatment in 1997. Eighteen patients were in stage I, 48 patients in stage II, and 34 patients in stage III.

Instrument

JC type focused ultrasound tumor therapeutic system was designed by Chongqing HIFU Technology Co, Ltd. Chongqing, China. It includes two main parts, i.e. ultrasound real-time orientation monitor device and HIFU three-dimensional combination scanning therapeutic device. Under the control of a computer, it can orient to preassigned tumor target zone automatically, determine range of therapy.

The main parameters included therapy frequency 0.8 MHz, mean diameter of focal field 1.1 mm, length of focal field 9.8 mm, focus distance 135 mm, therapy power 140-240 W.

Methods

Routine examinations and preoperative preparation were conducted according to the principle of surgery. Based on the result of image and ultrasound examination, the therapeutic scheme of HIFU was constituted. HIFU treatment was performed with patient fixed properly. The tumor position and size, therapeutic layers and therapeutic range of every layer were determined by ultrasound diagnostic probe. Then the therapeutic probe treated tumor tissue of every layer from outside body, and in terms of order of layer, from spot to line, and from line to area, leading whole tumor to coagulation necrosis. During the therapeutic process, through changes of graphics of target field and echo of tissue between before and after therapy at every layer, real-time estimate of HIFU therapeutic effect by computer processing image system was carried out, and with feedback, ultrasound therapeutic dosage estimated in the therapy scheme was controlled according to changes of ultrasound photograph. The therapeutic method was divided into complete coverage and local coverage. Twenty-eight cases used complete coverage, including whole tumor focus and normal liver tissue within 2 cm away from edge of tumor, the other cases used local coverage due to reasons, such as large tumor volume, rib overlap or close-by, or involvement of liver tube or cholecyst, *etc.*

Observatory parameters

The following aspects were observed: Improvement of clinic symptoms; changes of liver function 2 d and 2 wk before and after therapy; changes of AFP 2 wk before and after therapy; changes in range and blood supply of coagulation necrosis of tumor focus, also shrink of tumor through re-examination of MRI or CT before and after therapy.

RESULTS

One hundred liver cancer patients were treated by using HIFU in this group, of which 82 exhibited clinic symptoms. Seventy-one patients were improved obviously after HIFU treatment: appetite increased, weight gained, discomfort or pain on liver region relieved. Remission rate for symptoms was 86.6% (71/82). For 6 patients who had had mild ascites, ascites disappeared after HIFU treatment. For patients with abnormal liver function

(ALT 95 ± 44 U/L, AST 114 ± 58 U/L), 2 d after HIFU treatment, liver enzymes rose slightly, but no obvious statistic difference was found compared with pre-treatment. The patients' liver enzymes fell to normal level after 2 wk, respectively, ALT 83.3% (30/36), AST 72.9% (35/48). For the patients whose AFP was increased, AFP was 50% less than original level 2 wk after HIFU treatment, in 65.3% (32/49), only one patient's AFP rose continuously after HIFU treatment, and multi-bone metastases were found by ECT examination. Self-comparison of MRI showed that T₁-weighted images and T₂-weighted images of tumor therapeutic region were high signal and low signal respectively after HIFU treatment. Enhanced MRI did not show enhanced signal, indicating that coagulation necrosis had occurred in the tumor therapeutic region, blood supply of tumor was diminished or eliminated, tumor of some patients had shrunk obviously after countercheck MRI (Figures 1-3).

Figure 1 A 42-year-old male with hepatocellular carcinoma. A: MRI T₁-weighted images before HIFU treatment showed that liver tumor of right-posterior lobe was 115 mm×100 mm×66 mm; B: MRI enhanced imaging before HIFU revealed that enhancement of mass in liver right-posterior lobe was higher than that of surrounding normal liver tissues; C: MRI T₁-weighted imaging 11 mo after HIFU revealed that liver tumor of right-posterior lobe obviously decreased in size (50 mm×55 mm×60 mm); D, E: MRI enhanced imaging (cross section and coronal section) 11 mo after HIFU revealed that liver tumor had shrunk obviously, blood supply of tumor was eliminated, the tumor therapeutic region had coagulation necrosis.

Figure 2 A 55-year-old man with metastatic hepatocarcinoma in sigmoid cancer postoperation. A: MRI images before HIFU treatment showed that liver tumor of right-posterior lobe was 40 mm×30 mm×30 mm; B: MRI images 2 wk after HIFU revealed that liver tumor of right-posterior lobe obviously decreased in size (20 mm×20 mm×15 mm).

Figure 3 A 54-year-old man with primary carcinoma of liver in right lobe. A: CT enhanced imaging before HIFU treatment revealed that enhancement of mass in liver right-posterior lobe was higher than that of surrounding normal liver tissues (AFP: 5516 $\mu\text{g/L}$); B, C: MRI enhanced imaging (cross section and coronal section) 2 mo after HIFU revealed that necrotic tissue in the therapeutic region of the tumor was not enhanced (AFP: 183 $\mu\text{g/L}$).

DISCUSSION

HIFU is a high-tech developed successfully in the 1990's, a local way of treating tumor without any damages. It utilizes the physics characteristics of ultrasound beam with assemble and penetration, to focus low energy outside body on inner tumor target field, through instantaneous high temperature effect, cavitate effect, making tumor target tissue of focal zone coagulation necrosis, without destroying surrounding tissues^[7-14].

HIFU has the following characteristics in therapy of malignant tumors. Firstly, noninvasiveness. HIFU treats inner tumor without damaging outside body. Previous research on animal angiography indicated that after treating liver tumor of Morris rat using HIFU, nourishing blood vessels which diameter was less than 200 μm of irradiation zone closed, but they were normal for blood vessels which diameter was more than 200 μm ^[15]. Secondly, accuracy. HIFU can pass through tissues and accurately damage target tissues inside organisms. The boundary between therapy zone and un-therapy zone is clear, tissue beyond target zone is hardly destroyed or without damage^[16,17]. Ultrasound Therapy Section of London Emperor Hospital, Britain found that only six cells existed between cells killed completely and cells without damage^[18]. Thirdly, real-time therapy. For whole process of therapy, it is a real-time targeting and monitoring process, real-time estimating therapeutic effect and adjusting dosage^[19]. Fourthly, suitable therapy. According to the size and shape of tumor, it determines therapy range of tumor target zone, overlays tumor target zone. Therefore, treatment of malignant tumor using HIFU has many advantages such as less pain, no damage, fewer influences on splanchnic function, faster recovery for body and no increase of tumor metastasis chance^[20], *etc.*

It is shown that in this research, 100 liver cancer patients had obvious improvement in symptoms and signs after being treated by using HIFU. Short-term effect of HIFU therapy was obvious and affirmative in liver cancer. But for liver cancer patients who had huge block or multifocal big nodules, to make tumor completely occur coagulation necrosis, to gain the purpose of "ablation" tumor integrity, we performed treatment for two or three times. Firstly, we treated deeper tumor parts, to induce coagulation necrosis of the tumor, so as to make it easy to treat remaining superficial parts next time. Conversely, if at first, it makes superficial parts occur coagulation necrosis, and then treats deep tumor tissue, because of change of the impedance dispersion and absorb coefficient of sound, the attenuation of penetrating tissue with ultrasound will aggravate. Meanwhile, focus energy in focal field can not reach ideal degree, as a result it takes more time to make tumor tissue coagulation necrosis.

If tumor locates on the edge of liver with poor blood supply, during therapy of HIFU, We estimate every therapeutic effect by using real-time ultrasound imaging to monitor the change of

gray value. If gray value is changed, it indicates that tumor tissue must occur coagulation necrosis. However, tissues with coagulation necrosis do not always exhibit changes of gray value. For tumor in deep part, during real-time monitor, most changes of gray value are not distinct or lightly increased with suffusion. Through quantitative analysis and comparison of gray value of ultrasound imaging before and after therapy, we can find that the difference of gray rank before and after therapy is obvious. This indicates that local tumor tissues have no reversible coagulation necrosis.

For liver cancer patients with abundant blood supply relatively, we should first perform transcatheter arterial chemoembolization before using HIFU, so as to make inner tumor tissue have more iodised oil deposition, which not only is convenient to ultrasound orientation, but also changes the impedance dispersion and absorb coefficient of sound of tumor zone. Accordingly, it is convenient to energy sediment of focal zone, exerts cooperative function of raising temperature, excites high temperature to get to purpose of destruct therapy at local and makes tumor tissue coagulation necrosis^[21,22].

Yang *et al.*^[15] used HIFU to treat Morris rat hepatoma implanted in the liver. Treatment was administered with a lens-focused 4-MHz transducer that created a focused beam of 550 W/cm^2 at peak intensity. One hundred and twelve rats with liver tumors were divided into two groups of 56 each. Group 1 received HIFU therapy while group 2 (the control group) did not. All rats were killed immediately or 1, 3, 7, 14, 21, 28 d after treatment. Eight rats in each group were killed at each interval for pathologic and biochemical studies. Significant inhibition of the tumor growth was seen in the HIFU-treated group, with tumor growth inhibition rates of 65.4-93.1% from on d 3 to 28 after treatment. Ultrasound-treated tumors showed direct thermal cytotoxic necrosis and fibrosis. An additional 56 ACl rats with liver tumors were divided into 4 groups of 14 each. Group 1 received doxorubicin hydrochloride intraperitoneally and HIFU therapy; group 2, HIFU therapy; group 3, doxorubicin hydrochloride; and group 4 (the control group), neither HIFU nor doxorubicin hydrochloride. Significantly improved survival rates were noted in HIFU-treated animals (groups 1 and 2) compared with those of groups 3 and 4.

Research results of home and abroad using animals showed that HIFU can safely and effectively destroy inner liver tissue or liver transplant tumor^[23-30]. Clinic results showed that HIFU can also treat liver cancer securely and effectively^[11,31,32].

HIFU is a new method with definite therapeutic effect on tumor without damage and poisonous to normal tissues. With improvement of HIFU technology, accumulation of clinic application experience and further research on mechanism of HIFU, HIFU, as a new local therapy, would be applied more extensively to treat liver cancer.

Abstract

AIM: To investigate the signal pathway of honokiol-induced apoptosis on human colorectal carcinoma RKO cells and to evaluate whether p53 and p53-related genes were involved in honokiol-treated RKO cells.

METHODS: Cell cycle distribution and subdiploid peak were analyzed with a flow cytometer and DNA fragment with electrophoresis on agarose gels. Transcriptional level of Bax, Bcl-2, Bid and Bcl-xl was accessed by RT-PCR. Western blotting was used to measure p53 protein expression and other factors related to apoptosis. Proliferation inhibition of two cell lines (RKO, SW480) with high expression of p53 and one cell line with p53 negative expression (LS180) was monitored by MTT assay.

RESULTS: Honokiol induced RKO cell apoptosis in a dose-dependent manner. The mRNA expression level and protein level of Bid were up-regulated while that of Bcl-xl was down-regulated, but no changes in Bax and Bcl-2 were observed. Western blotting showed p53 expression had no remarkable changes in honokiol-induced RKO cell apoptosis. LS180 cells treated with honokiol exhibited apparent growth inhibition like RKO cells and Sw480 cells.

CONCLUSION: Honokiol can induce RKO cells apoptosis through activating caspase cascade by p53-indepenent pathway.

INTRODUCTION

Honokiol is a major active constituent extracted from the bark of *Magnolia officianlis* (Chinese name for *Houpu*) (Figure 1). It has a variety of pharmacological effects, such as anti-inflammatory^[1], antithrombosis^[2], anti-arrhythmic^[3], antioxidant^[4] and anxiolytic effects^[5]. Recently, honokiol has been reported to exhibit a

potent cytotoxic activity by inducing cell apoptosis in some cell lines^[6-8]. Honokiol-triggered apoptotic process is accompanied with down-modulation of Bcl-XL, release of mitochondrial cytochrome C in CH27 cells^[9].

Cells undergoing apoptosis are characterized by distinct biochemical and morphological changes. Many of the biochemical and morphological events of apoptosis are a direct result of caspase-mediated cleavage of specific substrates^[10,11]. Together with caspase, Bcl-2 family is involved in inducing cell apoptosis and identified as essential components of the intracellular apoptotic signaling pathways. Cell viability versus death is determined by the relative abundance of various members of the Bcl-2 family, acting in concert with other proteins in the death pathway^[12,13].

In many tumor cells, wild-type p53 is considered to participate in apoptosis in response to DNA damage^[14]. P53 may transactivate apoptotic regulators, such as Bcl-2^[15-17] and Bax^[18,19]. Recent studies have shown that p53 plays a role in apoptosis by the mitochondrial-mediated apoptotic pathway^[20]. Activation of p53 upregulates Bax^[19] and increases the ratio of Bax:Bcl-2, releases cytochrome C and other polypeptides from the intermembrane space of mitochondria into cytoplasm. Cytochrome C activates caspase cascade^[12,13].

It is well known that a broad range of agents can induce tumor cell apoptosis through p53-regulated manner by Bax/mitochondria/caspase-9 pathway. But up to now, it is not clear that whether wild-type p53 takes part in honokiol-induced apoptosis. In this present study we examined whether wild-type p53 and p53-related gene were involved in honokiol-treated RKO cells.

MATERIALS AND METHODS

Materials

RPMI 1640 medium was obtained from Gibco BRL. Newborn bovine serum was supplied by Sijiqing Biotechnology Co. (Hangzhou, China). Monoclonal antibodies to Bax, Bcl-xl, Bid, Bcl-2, β -actin and p53 were purchased from NeoMarkers, Fremont, CA, USA. Honokiol was got from the National Institute for Pharmaceutical and Biological Products, Beijing, China. The drug was dissolved in DMSO with the stock concentration of 10 mg/mL. It was further diluted in culture medium with the final DMSO concentration <1%. 3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide (MTT) and propidium iodide (PI) were purchased from Sigma Chemical Corporation, USA.

Cell culture

Human colorectal cell lines RKO, SW480 and LS180 were provided by Cancer Institute of Zhejiang University. Three cells were maintained in RPMI 1640 medium (Gibco BRL) supplemented with 100 mL/L heat-inactivated fetal bovine serum (Si-Ji-Qing Biotechnology Co, Hangzhou, China), 100 U/mL penicillin and 100 μ g/mL streptomycin at 37 °C in a 50 mL/L CO₂ atmosphere.

Detection of DNA fragmentation

To detect DNA fragments, RKO cells were collected and lysed with lysis buffer containing 50 mmol/L Tris-HCl (pH 7.5),

20 mmol/L EDTA, and 10 g/L NP-40. Then 10 g/L SDS and RNase (5 µg/mL) were added to the supernatants, and incubated at 56 °C for 2 h, followed by incubation with proteinase K (2.5 µg/mL) at 37 °C for 2 h. After DNA was precipitated by addition of both ammonium acetate (3.3 mol/L) and ethanol (995 mL/L) dissolved in a loading buffer, DNA fragmentation was detected by electrophoresis on 15 g/L agarose gels and visualized with ethidium bromide staining.

Cell cycle analysis by FCM

Honokiol-treated RKO cells (5, 10, 15 µg/mL) and vehicle were fixed with 700 mL/L alcohol for 15 min at 4 °C, then stained with 1.0 µg/mL propidium iodide (PI, Sigma, USA). The red fluorescence of DNA-bound PI in individual cells was measured at 488 nm with a FACSCalibur (Becton Dickinson, USA) and the results were analyzed using ModFit 3.0 software. Ten thousand events were analyzed for each sample.

RT-PCR assay

RKO cells 1×10^5 were seeded on 24-well plate. After 24-h culture, cells were treated with 5, 10 µg/mL honokiol and vehicle for 48 h. Total RNA from RKO cells was extracted using Trizol (Invitrogen, USA). In RT-PCR, cDNA synthesis was performed using a RNA PCR kit (TaKaRa Biomedicals, Osaka, Japan) with the supplied oligo dT primer (Table 1). Reverse transcription was performed using a thermal program of 92 °C for 2 min, then 38 cycles of annealing for 30 s at 55 °C, extension for 90 s at 72 °C. As an internal control, semiquantitative analysis of β -actin was also amplified. This primer pair of β -actin had an optimal annealing temperature of 55 °C with 20 cycles and yielded a 350-bp PCR product. Samples were separated on 20 g/L agarose gel and visualized with ethidium bromide staining under UV light.

Western blotting

RKO cells (5×10^6) treated with 5, 10 µg/mL honokiol and vehicle respectively for 24 h were lysed by 4 g/L trypsin containing 0.2 g/L EDTA, then collected after washed twice with phosphate-buffered saline (PBS, pH 7.4). Total protein extract from RKO cells was prepared using cell lysis buffer [150 mmol/L NaCl, 0.5 mol/L Tris-HCl (pH 7.2), 0.25 mol/L EDTA (pH 8.0), 10 g/L Triton X-100, 50 mL/L glycerol, 12.5 g/L SDS]. The extract (30 µg) was electrophoresed on 12 g/L SDS-PAGE and electroblotted onto polyvinylidene difluoride membrane (PVDF, Millipore Corp., Bedford, MA) for 2 h in a buffer containing 25 mmol/L Tris-HCl (pH 8.3), 192 mmol/L glycine and 200 mL/L methanol. The blots were blocked with 50 g/L nonfat milk in TBST washing buffer for 2 h at room temperature and then incubated at 4 °C overnight with antibodies. All antibodies were diluted in TBST according to the manufacturer's instructions. After washed at room temperature with washing buffer, the blots were labeled with peroxidase-conjugated secondary antibodies.

Cell proliferation assay

RKO cells, SW480 and LS180 cells (1×10^4 in 100 µL) were seeded on 96-well plates in triplicate respectively. Following a 24-h culture at 37 °C, the medium was replaced with fresh medium containing vehicle control or various concentrations of honokiol

in a final volume of 200 µL. Cells were incubated at 37 °C for 68 h. Then 50 µL of MTT (2 mg/mL in PBS) was added to each well, incubated for an additional 4 h, the plate was centrifuged at 1 000 r/min for 10 min, then the medium was removed. The MTT formazan precipitate was dissolved in 100 µL DMSO, shaken mechanically for 10 min and then read immediately at 570 nm by a plate reader (Opsys MR, Denex Technology, USA).

Statistics

Statistical significance was determined by Student's *t*-test. A *P* value of 0.05 or less was considered significant.

RESULTS

DNA fragmentation detection in RKO cells

In honokiol-treated RKO cells, a degradation of chromosomal DNA into small internucleosomal fragments was evidenced by the formation of 180-200 bp DNA ladder on agarose gels (Figure 2), hallmark of cells undergoing apoptosis. No DNA ladders were detected in the samples isolated from control cultures. These results indicated that honokiol induced an apoptotic cell death in RKO cells

Figure 1 Chemical structure of honokiol ($C_{18}H_{18}O_2$, M_r 266.33).

Figure 2 Differences in vehicle and honokiol induced apoptotic DNA laddering of RKO cells. Lane 1: Vehicle; Lane 2: 5 µg/mL; Lane 3: 10 µg/mL.

Effect of honokiol on cell cycle phase distribution

RKO cells were exposed to the increased concentrations of honokiol (5-15 µg/mL) for 48 h, and the cell growth was analyzed using flow cytometry. In the absence of honokiol, the cell populations were at G1, S, and G2/M phases (Figure 3), accompanied with increased concentrations of honokiol by a concomitant increase of the G1 phase (Table 2). From Figure 3, we considered the peak areas of subdiploid were up at the

Table 1 Expected size of PCR amplification product with each apoptosis modulator primer pair

Apoptosis modulator	Upstream primer (5'-3')	Downstream primer (5'-3')	Size (bp)
Bax	ACCAAGAAGCTGAGCGAGTGT	ACAAACATGGTCACGGTCTGC	332
Bcl-xl	GGAGCTGGTGGTTGACTTTCT	CCGGAAGAGTTCATTCACTAC	379
Bid	GAC CCG GTG CCT CAG GA	ATG GTC ACG GTC TGC CA	586
Bcl-2	TTGTGGCCTTCTTTGAGTTCCG	TACTGCTTAGTGAACCTTTT	332
β -actin	AGGCCAACC GCGAGAAGATGACC	GAAGTCCAGGGCGACGTAGCAC	350

increased concentrations of honokiol. This observation led to a suggestion of G1 arrest. When the cells were exposed to honokiol at 10 $\mu\text{g/mL}$ and above, subdiploid peak was significantly increased and the percentage of apoptotic cells in 10 000 cells was 14.1% and 20.31% respectively (Table 2).

Figure 3 Apoptosis of RKO cells detected by FCM. A: Vehicle; B: 5 $\mu\text{g/mL}$ honokiol; C: 10 $\mu\text{g/mL}$ honokiol; D: 15 $\mu\text{g/mL}$ honokiol.

Table 2 Effect of honokiol on cell cycle distribution and apoptosis in RKO cells

Treatment ($\mu\text{g/mL}$)	Cell cycle distribution (%)			Apoptosis (%)
	G0/G1	S	G2/M	
Control	44.76	45.09	10.14	0.21
5	48.03	42.37	9.60	4.51
10	54.04	40.30	5.66	14.10 ^b
15	58.94	39.36	1.70	20.31 ^d

Cell cycle distribution was determined after 48 h of treatment in each group. The tabulated percentages were an average calculated on the results of three separate experiments. ^b $P < 0.01$, ^d $P < 0.01$ vs corresponding control group.

Semi-quantification of Bid, Bax, Bcl-2 and Bcl-xl mRNA expression

mRNA expression of apoptosis-related genes in response to different levels of honokiol was assessed. The Bcl-xl mRNA expression was significantly reduced in RKO cells exposed to honokiol, while Bid mRNA expression was remarkably up-regulated. No apparent changes of Bax and Bcl-2 were observed (Figure 4).

Effect of honokiol on expression of p53-related gene and p53

p53 and p53-related gene were found to be importantly involved in apoptosis induced by many agents. To study their role in honokiol-treated RKO, we monitored Bax, Bcl-2, Bcl-xl, Bid and p53 protein levels. Results in Figure 5 shows that no significant changes of Bax, Bcl-2 and p53 were found compared with vehicle. The level of Bcl-xl was decreased to vehicle level, while the level of Bid was increased remarkably after treated with 5 and 10 $\mu\text{g/mL}$ honokiol respectively. The protein levels were measured by quantitative Western blot analysis after normalized with β -actin content.

Inhibition of proliferation in RKO, Sw480 and LS180 cells

RKO cells had positively expressed of high wild-type p53 and SW480 cells had positive expression of high mutant p53, while LS180 had negative p53 antigen expression^[20-22]. Cells treated with various concentrations of honokiol resulted in a dose-

dependent cytotoxicity in three cells. As shown in Figure 6, honokiol-treated LS180 exhibited apparent growth inhibition like RKO cells and Sw480. Honokiol-mediated cytotoxicity occurred at the concentration of 5 $\mu\text{g/mL}$ and above. A significant decrease in cell number was seen at 10 $\mu\text{g/mL}$. The concentration leading to a 50% decrease in cell number (IC₅₀) was approximate 10.33, 12.98, 11.16 $\mu\text{g/mL}$ in RKO, SW480 and LS180 cells respectively.

Figure 4 Analysis of Bcl-2, Bax, Bid and Bcl-xl mRNA by RT-PCR. M: DNA mark; Lane 1: Vehicle; Lane 2: 5 $\mu\text{g/mL}$ honokiol; Lane 3: 10 $\mu\text{g/mL}$ honokiol.

Figure 5 Western blotting of honokiol- and vehicle-induced Bax, Bcl-2, Bcl-xl, Bid and p53 protein levels in RKO cell line. Lane 1: Vehicle; Lane 2: 5 $\mu\text{g/mL}$; Lane 3: 10 $\mu\text{g/mL}$.

Figure 6 Concentration-dependent inhibition of RKO, SW480 and LS180 cells exposed to the various concentrations of honokiol shown by MTT assay.

DISCUSSION

p53 is a crucial protein in cellular stress response. p53-dependent arrest of cells in the G1 phase of the cell cycle was an important component of the cellular response to stress^[23]. Wild-type p53 was considered to participate in apoptosis in response to DNA damage in many tumor cells^[14,24]. When cells received UV or ionizing radiation and were exposed to anticancer drugs, p53 protein was accumulated^[25,26]. The increased p53 could transactivate its downstream target genes to induce cell cycle arrest, DNA repair, and apoptosis^[27,28]. p53-dependent apoptosis was also observed *in vivo*^[29]. However, p53-independent apoptotic cascades after administration of anticancer drugs or r-irradiation have been described.

In the present study, honokiol-treated RKO cells could induce apoptosis in a concentration- dependent manner, with the ratio of G1 phase increased. The agent also caused an increase of the expression of caspase-3 and caspase-7 in a dose-dependent manner, did not cause the significant increase

of caspase-9 (data not shown). In CH27 cells it promoted to release cytochrome C and activate caspase 3^[9].

p53-dependent apoptosis was activated by the Bax/mitochondrial/caspase-9 pathway. Bcl-2 and Bax expression were regulated by p53 both *in vitro* and *in vivo*, and Bax was a direct target of p53 transcriptional activation^[30]. Bax, a proapoptotic member of the Bcl-2 family, was located in the outer membrane of mitochondria^[25]. Increased in the ratio of Bax/Bcl-2 could cause changes in the membrane potential of mitochondria, consequently, cytochrome C and other polypeptides were released from the intermembrane space of mitochondria into cytoplasm. Once released, cytochrome C could activate procaspase-9 by self-cleavage^[12,13] and then other caspases^[12].

According to previous data, honokiol led to cell G1 arrest and cytochrome C release like p53. Thus it is necessary to evaluate the mRNA and protein expression of Bax and Bcl-2. Our results showed that honokiol-induced apoptosis of RKO cells was accompanied with up-regulation of Bid and down-modulation of Bcl-xl, but did not involve the regulation of Bcl-2 or Bax protein expression. Since pro-apoptotic Bax is a p53 downstream target, the lack of change of Bax and Bcl-xl supports the view that honokiol probably does not trigger the p53/Bax-mediated apoptosis pathway. Next we examined the expression of p53 in honokiol-treated RKO cells. We found that no significant change of p53 was observed (Figure 5). Finally we analyzed honokiol-induced apoptosis of the three cells with different p53 expression. Our data showed that honokiol-treated LS180 and SW480 cells exhibited apparent growth inhibition like RKO cells.

These results suggest that honokiol-induced caspase activation and cell apoptosis are entirely controlled by the p53-independent pathway.

Abstract

AIM: Hepatitis C virus (HCV) infection is very common among end-stage kidney disease patients on hemodialysis, but its natural history is not known.

METHODS: In this study, 189 dialysis patients (case) positive for HCV antibodies who were followed up for more than 4 years were compared with twice as many sex/age matched controls with chronic hepatitis C who were diagnosed in the same month as the case and followed up for comparable periods. The longest follow-up was 23 years in dialysis cases. The disease activities were graded into "asymptomatic" if ALT was less than 40 (35 in cases) IU/L, "low activities" if ALT was 40 (35)-79 IU/L, and "high activities" if ALT was above 80 IU/L during the last or latest 4 year period.

RESULTS: All 25 dialysis cases who were followed up for more than 15 years were asymptomatic and 15 of them were negative for HCV RNA. Of the 50 controls followed up for more than 15 years, 34 had high activities, and none cleared HCV RNA. There were 60 controls who were asymptomatic, but they were all positive for HCV RNA, while 22.3% of asymptomatic dialysis cases were RNA negative. No dialysis patients with chronic hepatitis C progressed to cirrhosis, whereas the disease progressed to cirrhosis in more than one quarter of the controls. These differences were highly significant ($P < 0.0001$).

CONCLUSION: Chronic hepatitis C among hemodialysis patients is mild in disease activity, and is not progressive, perhaps due to immunological abnormalities in these patients. Hepatic C virus is frequently cleared in asymptomatic dialysis patients during a long course. A possible mechanism for viral clearance is viral particle destruction on the surface of the dialyzer membrane.

INTRODUCTION

Hepatitis C virus (HCV) infection is very common among patients on hemodialysis for chronic renal failure with global anti-HCV prevalence of up to 91%^[1], because of the frequent past blood transfusions and nosocomial infections^[2,3]. Although

at the clinical setting, dialysis patients with HCV infection seem to have a mild disease, reports on the natural history of hepatitis C in hemodialysis patients vary^[4]. Sterling *et al.*^[5] compared 50 consecutive patients with end-stage renal disease and HCV infection to HCV-positive controls. Ninety-six percent of patients on dialysis had normal alanine-aminotransferase (ALT) and low necroinflammatory score on biopsy. Despite minimal biochemical evidence of disease, some dialysis patients were more likely to have bridging hepatic fibrosis. Another cohort study^[6] showed that the crude relative risk of death comparing HCV positive to negative dialysis patients was not significant. However, adjustment for age, transplantation, and other factors raised the relative risk somewhat. Akpolat *et al.*^[7] compared liver histology between 9 dialysis patients and 37 patients with normal renal function, and found less active and progressive chronic hepatitis C in the former. They admitted that the number of patients was too small for conclusion. Thus, more information is required on the natural history of chronic HCV infection in hemodialysis patients. This study was designed to compare end-stage kidney disease patients who were positive for HCV antibodies and control patients infected with HCV but not on dialysis.

MATERIALS AND METHODS

At the end of 2001, 603 patients with renal failure were dialyzed with 221 consoles at Sanai Amalgamated Dialysis Center, Chiba, which consists of Sanai Memorial Hospital, Sanai Soga Hospital and Ichihara Dialysis Clinic. Of these 603 patients, 142 were tested positive for HCV antibodies. Many of these patients had chronic non-A, non-B hepatitis and were subsequently found to have HCV antibody positive. Dialysis patients commonly had cardiovascular, intracranial and other complications, and they died while on dialysis. At this center, about 55 patients on average died per year. As yet, none of these anti-HCV positive patients turned antibody negative during the observation period after 1991 when C100-3 antibody kit became available at the hospital. The antibody kit was subsequently changed to the 2nd and 3rd generation test. All dialysis patients underwent periodic blood tests that included ALT and aspartate-aminotransferase (AST) every 4 wk. In this study, 189 patients who were anti-HCV positive and followed up for more than 4 years to the end of 2001 constituted the study (case) subjects. Twenty-five patients were followed for more than 15 years (longest 23 years), 94 patients were followed for 10-15 years and 70 for 4-10 years (Table 1). Ten patients were treated with interferon^[8] and they were excluded. Currently 3 patients had cirrhosis, they were positive for both HBV and HCV. They were not included. The three patients had cirrhosis when dialysis was started at this hospital.

One patient with renal failure started on dialysis in 1978, 11 in 1983, 5 in 1984, 4 in 1985, 8 in 1986, 13 in 1987, 18 in 1988, 14 in 1989, 21 in 1990, 24 in 1991, 22 in 1992, 14 in 1993, 18 in 1994, 10 in 1995, and 6 in 1996. There were 137 male dialysis patients whose age ranged from 21 to 75 years, averaged 48.6 ± 11.8 years, and 52 females whose age ranged 24 to 83 years, averaged 51.7 ± 11.1 years.

The control group consisted of anti-HCV positive patients with chronic hepatitis who were diagnosed and followed up at the Liver Center of the Chiba University Hospital. The patients who were treated with interferon and had sustained virological response were excluded. At this center, approximately 1 200 HCV positive patients were followed up at an interval of 1 to 3 mo, and about 20-30 new patients were found per month. Out of these patients, two control patients for each dialysis case were chosen who were age (± 5 years) and sex matched, and found to be HCV positive in the same month and subsequently followed up for a similar period of time. All these patients were followed up for more than 4 years, and the disease activities were recorded in the last 4 years before death or in the latest 4 year period.

Diagnosis of cirrhosis was made on the basis of liver biopsy, imaging, blood chemistry and physical signs. Imaging findings suggestive of cirrhosis included ascites, liver surface irregularity, splenomegaly, enlarged left gastric vein, enlarged paraumbilical vein, obtuse liver edge, enlarged caudate lobe, excessively large left lobe compared to the right lobe, splenorenal or gastrosplenic shunt by ultrasound and CT, and esophago-gastric varices by endoscopy. The patients with past or currently elevated ALT in the absence of these features were diagnosed as having chronic hepatitis C.

Serum HCV RNA was measured using the branch DNA method and subsequently by Amplicor test (Nippon Roche, Tokyo). Viral load was measured twice at an interval of 2 or more years in dialysis patients to see the change in viral load. Beside the routine liver tests, 7S domain type IV collagen was measured as an indirect indicator of hepatic fibrosis in dialysis cases^[9,10].

The disease activities were graded into three categories: "asymptomatic" if ALT levels remained below 40 IU/L for the control group and below 35 IU/L for dialysis cases, the difference in the upper normal limit was due to normally low ALT and AST in dialysis patients^[11,12]; "low activities" if ALT fluctuated between 35 (40 in control) and 79 IU/L; and "high activities" if ALT levels exceeded 80 IU/L during the last 4 year period.

Statistical analyses were made by the χ^2 test and ANOVA.

RESULTS

The disease activities in these dialysis cases who were divided into three groups according to the length of dialysis (more than 15 years, 10-15 years and 4-10 years) are given in Table 1. All the 25 patients on dialysis for more than 15 years were asymptomatic, and only 3 of 50 controls were asymptomatic. The remainder of the controls all had disease activities. Of the 94 patients on dialysis for 10-15 years, 81 (85%) were asymptomatic and 6 (6.4%) had high activities. Whereas in the controls, only 26 (13.8%) of 188 were asymptomatic and 109 (58.0%) had high activities. Of the 70 patients on dialysis for 4-10 years, 58 (83%) were asymptomatic and 5 (7.1%) had high activities. The corresponding figures were 22.1% and 52.1%, respectively, in the controls. These differences were highly significant ($P < 0.001$). Table 1 also lists the number of patients in parentheses in whose serum HCV RNA levels were PCR negative or below the quantifiable level by Amplicor. Of the 25 long (more than 15 years) follow-up dialysis cases, RNA was negative or below the quantifiable level in 15 (60%). However, RNA was negative in only one of 14 dialysis cases with low disease activities, the remaining 13 cases were positive. All high activities cases were positive, while none of the control patients was negative for HCV RNA.

The clinical course of these 189 patients was uneventful from the point of view of liver disease. Many of these patients died from liver unrelated diseases, but the liver disease progressed to cirrhosis in none of them. The three cases of HCV positive

cirrhosis who were followed up had already had cirrhosis when they came to our hospital. All cases who were followed up for more than 15 years were asymptomatic by the end of the follow-up (Table 1). More dialysis cases who were follow-up for a shorter period of time had disease activities. Thus, chronic hepatitis C among dialysis patients seemed to slowly improve and seldom worsen. In contrast, the disease was progressive in most control patients. In the 50 control patients who were followed up for more than 15 years, the disease progressed to cirrhosis in 18 during the follow-up. In the 228 controls who were followed up for 10-15 years, cirrhosis developed in 62. In the 140 controls who were followed up for 4-10 years, 29 developed cirrhosis.

Table 1 Clinical evaluation of dialysis (case) and control patients in recent 4 years or last 4 years before liver unrelated death

Table 3 Comparison of the first and second measurements of HCV RNA at intervals longer than 2 years in dialysis patients

Change	Group		
	Asymptomatic	Low activities	High activities
Unchanged (change <50%)	44	1	2
Increased (+ >50%)	25	3	2
Decreased (- >50%)	36	5	2
Total	105	9	6

The initial serum levels of HCV RNA in 179 dialysis patients are given in Table 2. Of the 154 asymptomatic cases, the RNA

level was negative or below the quantifiable level in 53 (34.4%) and below 100 KIU/mL in 32 (20.8%), but the remaining 69 patients had RNA levels greater than 101 KIU/mL. All the 11 dialysis patients with high activities had high levels of RNA. Thus, differences among the three activity groups were significant by the χ^2 test ($P < 0.001$). Serum RNA could be measured twice at an interval of 2 years or longer in 120 patients. The change was less than 50% of the initial level (unchanged) in 44 (41.9%), increased by more than 50% in 25 (23.8%) and decreased by more than 50% in 36 (41.0%) (Table 3). Serum RNA clearly reflected the absence or presence of disease activities. Serum 7S fragment of type IV collagen was measured in 143 dialysis patients (Table 4). The values ranged from 1.8 to 12.0 $\mu\text{g/mL}$ with a mean of 5.59 ng/mL. The mean \pm SD for the asymptomatic group was 5.05 \pm 1.59 ng/mL, 6.21 \pm 1.94 ng/mL for the low activities group and 6.92 \pm 2.63 ng/mL for the high activity group. The differences were significant ($P < 0.05$) by ANOVA.

Table 4 Serum 7S fragment of type IV collagen in dialysis patients

Group	Number of patients	7S IV collagen (ng/mL)
Asymptomatic	118	5.05 \pm 1.59 ^{a,c}
Low activities	14	6.21 \pm 1.94 ^a
High activities	11	6.92 \pm 2.63 ^c
Total	143	5.59

^a $P < 0.05$, ^c $P < 0.05$ by ANOVA.

DISCUSSION

In this study, 189 dialysis patients with HCV infection were followed up for more than 4 years in comparison with 378 sex/age matched nondialysis control patients who were diagnosed as chronic hepatitis C. Disease activities were divided into three grades: asymptomatic, low activities (ALT not exceeding 80 IU/L) and high activities (ALT exceeding 80 IU/L) during the last or latest 4 year period. Of the 189 dialysis patients, 25 were followed up for more than 15 years. They all became asymptomatic after a varying period of elevated and fluctuating ALT, and 15 were HCV RNA negative. In a distinct contrast, the majority of controls who were followed up for a comparable period remained to have high activities (Table 1), and none lost HCV RNA, one quarter to one third of them progressed to cirrhosis. Serum type IV collagen 7S domain was measured in dialysis patients, and the results suggested that fibrogenetic activities increased with high disease activities. These results clearly showed that patients on hemodialysis became much better than nondialysis patients with chronic hepatitis C. No dialysis patients progressed to cirrhosis in this series.

The question is why there is such a distinct difference in the natural history of chronic hepatitis C between dialysis and nonuremic patients. It has been suggested that liver injury caused by HCV infection is mainly through immunologic processes^[13] rather than the virus that is directly cytopathic^[14]. It has been well established that patients with end-stage renal disease and on maintenance hemodialysis have severe immunologic abnormalities with reduced immune responsiveness^[15].

Some of our dialysis patients had a high viral load. RNA levels did not show direct correlation with disease activities, but more asymptomatic cases were RNA negative, and RNA levels tended to decrease in more patients when studied at an interval of 2 years or longer. There have been several studies on viral load in hemodialysis patients, but the results were not consistent. According to Umlauf *et al.*^[16], HCV viremia fluctuated with the time of undetectable RNA. Whereas in the

study of Fabrizi *et al.*^[17], HCV load was low and relatively stable. HCV RNA levels decreased in dialysis patients in another report^[18].

In 1996, we first described the phenomenon in which the number of HCV viral particles decreased after each dialysis procedure and restored to the previous level at the next dialysis^[19]. Subsequently it was found that viral particles were adsorbed onto the dialyzer membrane and destroyed^[20]. Our observations have since been confirmed. According to Furusyo *et al.*^[18], HCV RNA levels were significantly lower in 98 dialysis patients (0.4 mEq/mL) compared with 228 nonuremic patients (2.0 mEq/mL). The dialysis procedure itself might contribute to the reduction of viral load in the long run. Another possible explanation for viral load reduction in dialysis patients was coinfection with another hepatotropic virus^[21]. However, our earlier study in this dialysis center, the rates of infection with hepatitis G virus^[22] and TT virus^[23] were very low. Yokosuka *et al.*^[24] followed up 320 patients with chronic type C liver disease and found that no chronic hepatitis patients were seroconverted, seronegative conversion occurred in 2%, only in end stage cirrhotic patients with or without hepatocellular carcinoma. The difference in the temporal virus load between dialysis and non-dialysis patients was so remarkable that it required biological explanation. It is not known whether C-viruses are able to replicate in liver cells of immunologically compromised dialysis patients as in immunologically competent individuals. Hepatocytes of the dialysis patients might not have normal metabolic and synthetic capabilities under the influence of uremic state, as exemplified by very low AST and ALT levels in serum^[11,12]. Replication of viral particles within hepatocytes might be reduced for the same reason. It seems that the most plausible explanation would be the negative balance between mechanical destruction of viral particles by membrane dialysis procedure and viral replication.

Abstract

AIM: Steroids can increase hepatitis C virus (HCV) replication. After liver transplantation (LTx), steroids are commonly used for immunosuppression and acute rejection is usually treated by high steroid dosages. Steroids can worsen the outcome of recurrent HCV infection. Therefore, we evaluated the outcome of HCV infected liver recipients receiving initial steroid-free immunosuppression.

METHODS: Thirty patients undergoing LTx received initial steroid-free immunosuppression. Indication for LTx included 7 patients with HCV related cirrhosis. Initial immunosuppression consisted of tacrolimus 2×0.05 mg/kg·d po and mycophenolate mofetil (MMF) 2×15 mg/kg·d po. The tacrolimus dosage was adjusted to trough levels in the target range of 10-15 µg/L during the first 3 mo and 5-10 µg/L thereafter. Manifestations of acute rejection were verified histologically.

RESULTS: Patient and graft survival of 30 patients receiving initial steroid-free immunosuppression was 86% and 83% at 1 and 2 years. Acute rejection occurred in 8/30 patients, including 1 HCV infected recipient. All HCV-infected patients had HCV genotype II (1b). HCV seropositivity occurred within the first 4 mo after LTx. The virus load was not remarkably increased during the first year after LTx. Histologically, grafts had no severe recurrent hepatitis.

CONCLUSION: From our experience, initial steroid-free immunosuppression does not increase the risk of acute rejection in HCV infected liver recipients. Furthermore, none of the HCV infected patients developed serious chronic liver diseases. It suggests that it may be beneficial to avoid steroids in this particular group of patients after LTx.

Wietzke-Braun P, Braun F, Sattler B, Ramadori G, Ringe B. Initial steroid-free immunosuppression after liver transplantation in recipients with hepatitis c virus related cirrhosis. *World J Gastroenterol* 2004; 10(15): 2213-2217

INTRODUCTION

Liver diseases related to chronic viral hepatitis are the leading

indication for liver transplantation (LTx) worldwide^[1]. Hepatitis B virus and hepatitis C virus (HCV) infection account for the majority of liver diseases related to chronic viral hepatitis. In Europe, 8 422 patients received a liver graft for virus related cirrhosis between January 1988 to December 2000^[2]. Posttransplantation HCV infection is a relatively benign condition during the short-term follow-up and liver recipients reach survival rates similar to other indications. However, the natural history of posttransplantation HCV reinfection is variable. Almost all recipients became HCV seropositive during the first year after LTx. At 5 years posttransplantation, up to 30% of the recipients developed cirrhosis^[3,12]. The patients' immune status seems to be an important factor regarding the progression of fibrosis. The immunosuppressed liver recipients had a higher rate of fibrosis progression per year compared to patients without immunosuppression^[4].

The role of immunosuppressive treatment in the occurrence and severity of HCV reinfection has been discussed controversially^[5]. Since the first liver transplantation performed by Starzl in 1963, corticosteroids have been used traditionally for immunosuppression after organ transplantation due to the lack of other available immunosuppressive drugs^[6]. Nowadays, a variety of potent and selective immunosuppressive drugs are available, thus allowing avoidance of immunosuppressive drugs with unselective mode of action or unfavorable side effects^[7]. Corticosteroids have a well described spectrum of adverse effects including metabolic changes and an increased risk of cardio-vascular diseases. Also, corticosteroids have an unselective immunosuppressive mode of action. Furthermore, corticosteroids increased HCV replication *in vitro* and *in vivo*^[8-10]. After liver transplantation, high early HCV-RNA levels could be associated with more severe recurrence of hepatitis^[11]. Prieto *et al.* reported positive relationships between the number of rejection episodes, methylprednisolone (MP) boluses, treatment of rejection, cumulative dose of steroids and the development of HCV cirrhosis^[12]. These findings implicated that prevention of acute cellular rejection and avoidance of high-dose or maintenance steroids could be beneficial^[5], however, the experience with completely steroid-free immunosuppression after LTx is still limited.

Recently, we published a series of 30 patients receiving steroid-free immunosuppression that consisted of tacrolimus and mycophenolate mofetil (MMF)^[13]. Since the hypothesis that steroid-free immunosuppression might be particularly beneficial in HCV infected liver recipients, we analyzed this subgroup of liver recipients with regard to the risk of acute rejection, and development of serious HCV related liver disease in the graft.

MATERIALS AND METHODS

Patients

Thirty adult patients underwent LTx between June 1996 and January 1999. The detailed characteristics have been previously described^[13]. The indications for LTx included hepatitis C virus related cirrhosis in seven recipients. The HCV patients included 4 females and 3 males with a median (range) age of 58(43-62) years. HCV-RNA was seropositive prior to transplantation with a

median (range) viral load of $10^4(10^3-10^5)$ genome equivalent/mL. The serum HCV-specific RNA was detected by reverse transcription (RT)/polymerase chain reaction (PCR) as previously described by Mihm *et al.*^[14]. HCV genotype was classified as II (1b) in all seven patients according to Okamoto *et al.* and Simmonds *et al.*^[15,16]. Child-Turcotte-Pugh Score prior to LTx was Child A in 2, Child B in 2 and Child C in 3 patients. Four of the patients had a coexisting hepatocellular carcinoma.

Methods

Apart from an intravenous (IV) bolus of 500 mg MP before reperfusion of the graft, recipients received no further steroids. Tacrolimus (Prograf, Fujisawa GmbH, München, Germany) was started 6 h after reperfusion at an oral dosage of 2×0.05 mg/kg·d. Thereafter, tacrolimus dosages were adjusted to a target range of 10-15 µg/L during the first three months and 5-10 µg/L after the third month after LTx. Tacrolimus trough levels were measured by a microparticle enzyme immunoassay (Prograf-MEIA II, Abbott Laboratories, Chicago, IL, USA). MMF (Cell Cept, Hoffmann-La Roche, Grenzach-Wyhlen, Germany) was given orally starting from the first postoperative day (pod) at a body mass adjusted dosage of 2×15 mg/kg·d. Liver biopsies were performed routinely on d 7, after 6 mo, every year, and whenever clinically indicated. Acute rejection was defined as abnormal liver function tests, histological changes as graded by the Banff classification, and the necessity for therapy^[12]. Treatment of acute rejection consisted of IV-MP boluses of 500 mg over a period of 3-5 d with or without additional prednisolone tapering. Combined antiviral therapy consisting of interferon alfa and "low-dose" ribavirin was used in patients with HCV reinfection accompanied by chronic active hepatitis as described previously by Wietzke *et al.*^[17,18].

Statistical analysis

Actual survival was calculated by the Kaplan-Meier method.

RESULTS

Patient and graft survival

Twenty-two of the 30 patients receiving initial steroid-free immunosuppression have been alive after a median (range) follow-up of 1 386(44-2 037) d. Actual patient survival was 86.7% at 2 years and 73.3% at 5 years (Figure 1A). The actual patient survival of HCV-infected recipients was 85.7% at 2 years and 57.1% at 5 years, the difference was not statistically significant (Log-rank test (Cox-Mantel): $P=0.33$) (Figure 1B).

At present, four of the seven HCV infected liver recipients have been alive with a median (range) follow-up of 47(46-60)

mo after LTx. None of the deaths in the HCV patients was related to HCV reinfection. The causes of the 3 deaths were chronic graft dysfunction (CDF) on pod 164, heart failure due to preexisting toxic cardiomyopathy on pod 774, and a *de-novo* ovarian carcinoma on pod 950. One of the seven patients with HCV-related cirrhosis underwent successful retransplantation for primary nonfunction (PNF) on day 5 (Table 1).

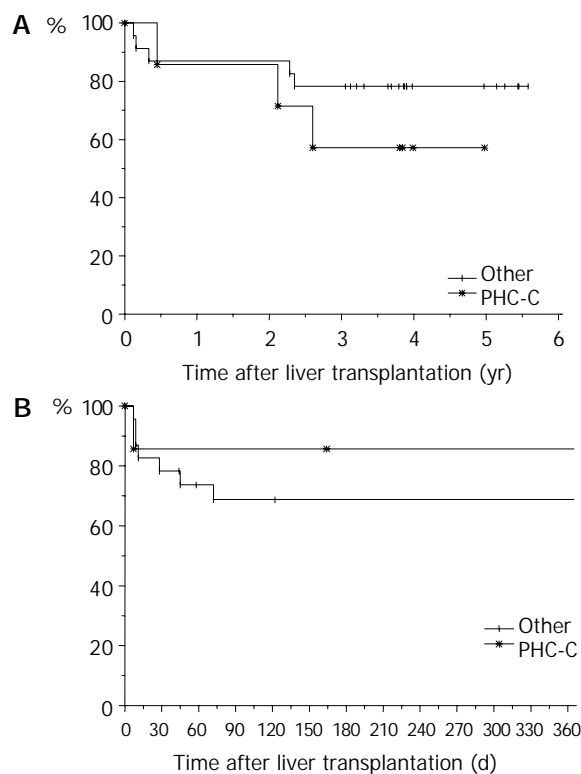

Figure 1 A: Actual patient survival according to primary indication (HCV related cirrhosis vs others) of liver recipients receiving steroid-free immunosuppression. B: Actual rejection free interval according to primary indication (HCV related cirrhosis vs others) during the first year after LTx in liver recipients receiving steroid-free initial immunosuppression.

Acute rejection episodes and immunosuppression

In total, 8 of the 30 liver recipients (26.2%) had an episode of acute rejection. The onset of acute rejection was between pod 7 and 72. The median (range) grade of acute rejection was 5.5(3-8) according to Banff classification. Low tacrolimus trough levels associated with diarrhea were observed in five of the eight recipients with acute rejection. Also, diarrhea was

Abbreviations: # (patient number), HCC (hepatocellular carcinoma), HCV (hepatitic C virus), pod (postoperative day), yr (year), mo (mo), prior (prior to LTx), AR (acute rejection), +/++/+++/- (minimal/moderate/severe/reversed), reLTx (liver retransplantation), CDF (chronic graft dysfunction).

the predominant adverse effect when tacrolimus and MMF were given simultaneously. All acute rejection episodes completely resolved after IV-MP boluses and four of the patients with rejection episodes received additional steroid taper. In the further postoperative course, there was no graft loss due to rejection and all of these patients have been alive. Only one of the eight patients with acute rejection had HCV-related cirrhosis. This patient underwent retransplantation on pod 5 for PNF. Until retransplantation, immunosuppression was temporarily discontinued and the patient suffered from diarrhea, thus tacrolimus trough levels were low.

Only 3 of the 7 HCV patients received steroids after LTx, two in conjunction with tacrolimus first and then cyclosporine (CyA), and one for acute rejection. One patient was reconverted to tacrolimus after suspicion of CDF. MMF was intermittently discontinued in all 7 patients and withdrawn in 5 patients. The cause of MMF withdrawal was diarrhea in 3 patients and conversion to CyA in 2 patients. Maintenance immunosuppression in the HCV infected recipients consisted of tacrolimus monotherapy in 3 patients, tacrolimus/MMF in 2 patients, tacrolimus/prednisolone in 1 patient, and CyA/prednisolone in 1 patient.

HCV reinfection

All 7 HCV infected patients had HCV genotype II (1b). Recurrence of HCV-RNA in serum occurred within 4 mo after LTx in all seven liver recipients with HCV-related cirrhosis. Prior to LTx the median viral load was 10^4 (10^3 – 10^5) genome equivalent/mL. During the first four months, the viral load ranged from 10^3 to 6.5×10^5 genome equivalent/mL. The virus load was not markedly increased during the first year after LTx (Figure 2). Histologically, only 1 HCV patient had suspicion of minimal portal hepatitis in the most recent biopsy that occurred 15 mo after LTx and transaminases were within normal values (Table 1). Five months after LTx, another recipient had elevated transaminases (AST 55, ALT 109 U/L), suspicion of portal hepatitis and mild fibrosis in the graft. Combination therapy with subcutaneous interferon alfa-2a 3 MU three times per week and oral ribavirin 10 mg/kg body mass in three divided doses per day was given for 6 mo. At the end of treatment, the patient had transaminases within normal values (AST 9, ALT 12 U/L), and histological improvement without fibrosis, but positive serum HCV-RNA. A third recipient developed suspicion of minimal portal hepatitis and fibrosis associated with a reduction of small bile ducts. Liver histology improved after reintroduction of MMF. Initially, this patient underwent retransplantation for PNF and acute rejection was resolved.

Figure 2 Serum virus concentration in seven HCV infected recipients during the first year after LTx. All patients received initial steroid-free immunosuppression.

DISCUSSION

Although steroids are known to increase HCV replication^[8],

they are given routinely for prophylaxis and treatment of rejection after solid organ transplantation. The potential risk of acute rejection must be faced against the benefit of steroid withdrawal. After LTx, HCV infection has been clearly identified as a risk factor for the development of early acute rejection^[19]. On the other hand, the presence, number, and treatment of acute rejections were found to be associated with the histologic recurrence of HCV infection after LTx^[20,21]. In 96 liver recipients, histologic recurrence of HCV infection occurred in 18% without acute rejection, 42% with one acute rejection episode, and 70% with more than one episode of acute rejection^[21]. In liver recipients, MP treatment for acute rejection was found to increase serum HCV RNA between 4 to 100 fold^[8]. OKT3, used for treatment of steroid-resistant rejection after LTx, was associated with more severe recurrences^[20]. The mutual relation between treatment of acute rejection and recurrence of HCV-infection after LTx sets the stage for a completely steroid-free immunosuppressive protocol.

Recently, it was clearly demonstrated that steroid-free immunosuppression after LTx was feasible and safe^[13,22–24]. The different immunosuppressive regimens consisted of CyA/azathioprine (Aza)^[23], CyA or tacrolimus monotherapy^[22], CyA/rapamycin, rapamycin monotherapy^[24], and tacrolimus/MMF^[13]. The reported rates of acute rejection were 65% for CyA and 66% for tacrolimus monotherapy^[22]. The combination of CyA/Aza resulted in 80% of acute rejection, but only 9% of acute rejections required treatment. Compared to patients receiving CyA/Aza/prednisone, the incidence and severity of rejection were similar in both groups but the dynamics of virus replication of HCV-RNA was faster among those treated with prednisone. The 2 year survival rate was 70.2% with prednisone and 78.3% without prednisone^[23]. The rate of acute rejection using rapamycin/CyA was 28% and with sirolimus monotherapy 75%^[24].

We reported that complete avoidance of corticosteroids after LTx could be performed without an increased risk of mortality, morbidity, and severe acute rejection. The rate of acute rejection with the use of tacrolimus in combination with MMF was only 26.2%^[13]. This rate of acute rejections might even be reduced, if underimmunosuppression were avoided. Low tacrolimus trough levels were observed in patients with diarrhea when tacrolimus and MMF were given simultaneously. Diarrhea could be avoided after introduction of a two hour dosing interval between tacrolimus and MMF administration^[13,25]. Therefore, the rate of acute rejections might be lower if tacrolimus and MMF are administered with a dosing interval.

In our present study, only 1 HCV patient developed acute rejection. This patient had a complicated clinical course with PNF, retransplantation, temporary discontinuation of immunosuppression, acute rejection, and received MP boluses as well as intermittent steroids until pod 255. Reinfection with HCV was noticed in all seven patients. Within 4 mo after LTx, all seven patients were HCV seropositive. Compared to the pretransplant HCV load, there was no significant increase during the first year after LTx. Also, liver histology was completely unsuspecting in 4 HCV patients. Three patients had suspicion of minimal portal hepatitis which was followed up by frequent biopsies in one patient. Another patient with supposed minimal portal hepatitis and additional mild fibrosis received combination therapy which improved transaminases and histology^[17]. Also, one patient with previous retransplantation developed portal hepatitis and fibrosis. MMF was reintroduced for reduction of small bile ducts, minimal portal hepatitis and fibrosis and resulted in histological improvement. None of the HCV infected patients developed serious chronic liver disease. However, one patient died of CDF which was related to underimmunosuppression after conversion to CyA for

suspicion of tacrolimus induced neurotoxicity. From our limited experience with the small number of patients, the avoidance of steroids did not alter the posttransplant HCV reinfection in serum and the histological alterations were mild despite all patients had HCV genotype II (1b). Feray *et al.* reported that HCV genotype II (1b) was a risk factor for recurrent hepatitis^[26,27]. However, the influence of HCV genotype II (1b) has been controversial. Gordon *et al.* reported a similar frequency of recurrent hepatitis with all HCV genotypes, but HCV genotype II (1b) was associated with a higher rate of cirrhosis^[28]. Thus, the avoidance of steroids seems to be beneficial for liver recipients with HCV genotype II (1b).

Hitherto, it remains unclear which immunosuppressive regimen is best for HCV liver recipients. MMF was discussed controversially in liver transplant recipients with HCV^[29]. In a recent prospective randomized trial comparing tacrolimus/prednisolone with tacrolimus/MMF/prednisolone in liver recipients with HCV, MMF had no impact on patient and graft survival, rejection or rate of HCV recurrence^[30]. However, MMF might reduce the frequency of acute rejection and therefore exposure to steroids^[31]. Our intention was to use a safe steroid-free immunosuppressive regimen. Tacrolimus is a potent immunosuppressive drug, but impairment of renal function might limit the use of tacrolimus especially during the early phase after LTx. Thus, we used a combination of tacrolimus and MMF which resulted in a low frequency of acute rejection^[13]. However, the combination of tacrolimus and MMF could cause diarrhea or other side effects that often required discontinuation or withdrawal of MMF. Thus, therapeutic drug monitoring of tacrolimus is an essential requirement for the combination of tacrolimus and MMF. Alternatively, anti-IL-2 receptor antibodies might have potential in steroid-free regimens. The use of anti-IL-2 receptor antibodies reduces the frequency of acute rejection after LTx, but there has been limited experience with HCV infection when anti-IL-2 receptor antibodies are given for induction of immunosuppression. Most recently, two immunosuppressive protocols using daclizumab have been reported with controversial results regarding HCV infection. Tacrolimus/MMF was compared with daclizumab/tacrolimus/MMF in a randomized open-label study and corticosteroids were eliminated 24 h after LTx in both arms. Steroids could be avoided safely after pod 1 and HCV recurrence was documented in 2 patients who did not receive daclizumab^[32]. In a group of 21 HCV infected liver recipients receiving daclizumab, MMF, and steroids for induction of immunosuppression, patients with HCV infection administered daclizumab were more likely to have an earlier onset of hepatitis, jaundice and greater histological activity compared with a well-matched HCV control group. Also, recurrent hepatitis progressed more rapidly in the daclizumab group. Nelson *et al.* concluded that daclizumab in combination with MMF might be associated with early recurrence of HCV and more rapid histological progression of disease in the early period after LTx^[33]. Also, triple and double immunosuppressive regimens had a higher rate of fibrosis and cirrhosis in HCV infected patients compared to monotherapy^[34,35]. These findings implicate that strenuous induction protocols should be avoided in HCV infected liver recipients.

As proposed by some centers, early withdrawal or avoidance of steroids in HCV infected patients could be beneficial. From our experience with the limited number of HCV infected liver recipients, initial steroid-free immunosuppression is safe, has a low risk of acute rejection without a need for high-dose steroids and high cumulative steroid dosages, which are likely to induce less severe HCV reinfection. Furthermore, none of the HCV infected patients developed serious chronic liver diseases. Therefore, it is high time to seriously reconsider the use of any steroids in liver transplantation especially for HCV-

infection patients and to prove this approach in a large randomized controlled trial.

Abstract

AIM: Hepatitis B virus (HBV) genomes in carriers from Hawaii have not been evaluated previously. The aim of the present study was to evaluate the distribution of HBV genotypes and their clinical relevance in Hawaii.

METHODS: Genotyping of HBV among 61 multi-ethnic carriers in Hawaii was performed by genetic methods. Three complete genomes and 61 core promoter/precore regions of HBV were sequenced directly.

RESULTS: HBV genotype distribution among the 61 carriers was 23.0% for genotype A, 14.7% for genotype B and 62.3% for genotype C. Genotypes A, B and C were obtained from the carriers whose ethnicities were Filipino and Caucasian, Southeast Asian, and various Asian and Micronesian, respectively. All cases of genotype B were composed of recombinant strains with genotype C in the precore plus core region named genotype Ba. HBeAg was detected more frequently in genotype C than in genotype B (68.4% vs 33.3%, $P < 0.05$) and basal core promoter (BCP) mutation (T1762/A1764) was more frequently found in genotype C than in genotype B. Twelve of the 38 genotype C strains possessed C at nucleotide (nt) position 1858 (C-1858). However there was no significant difference in clinical characteristics between C-1858 and T-1858 variants. Based on complete genome sequences, phylogenetic analysis revealed one patient of Micronesian ethnicity as having C-1858 clustered with two isolates from Polynesia with T-1858. In addition, two strains from Asian ethnicities were clustered with known isolates in carriers from Southeast Asia.

CONCLUSION: Genotypes A, B and C are predominant types among multi-ethnic HBV carriers in Hawaii, and distribution of HBV genotypes is dependent on the ethnic background of the carriers in Hawaii.

INTRODUCTION

Hepatitis B virus (HBV) is one of the major causes of chronic liver diseases including chronic hepatitis, liver cirrhosis (LC) and hepatocellular carcinoma (HCC)^[1]. HBV has been classified into 7 genotypes from A to G based on a sequence divergence of 8% or greater of the entire genome sequences^[2-5]. The genotypes of HBV have distinct geographical distributions, which have been associated with anthropologic history^[6,7].

Recently, genotypes of HBV have been reported to be an influential factor in the clinical manifestation of chronic liver disease in the host. Genotype A is associated with chronic liver disease more frequently than genotype D in Europe^[8]. Genotype C induces more severe liver disease than genotype B found in Asia^[9,10]. Furthermore, it was reported that genotype B had two subgroups^[11], and these subgroups influence the clinical manifestations of liver disease in these patients^[12].

Hawaii has a large Asian American and Pacific Islander population. Many people have emigrated from various countries in Asia and the Pacific Basin, where HBV infection is endemic. Indeed, the estimated rate of HBV carriers in Hawaii ranges from 1.7% to 3%^[13,14], higher than 0.5% of the mainland of United States. However, there has been no information on genotype distribution and sequences of HBV in multi-ethnic carriers in Hawaii.

The aim of this study was to evaluate the HBV genotypes among 61 multi-ethnic carriers in Hawaii by genetic method, and to determine the influences of HBV genotypes on the clinical characteristics.

MATERIALS AND METHODS

Patients

A total of 61 serum samples with HBsAg-positive were collected from patients with HBV infection who admitted St. Francis Medical Center in Honolulu, Hawaii between 1995 and 2000. All the patients were classified into 4 clinical groups: a symptomatic carriers (ASC) ($n=14$) who had no subjective symptoms and had consistently normal serum alanine aminotransferase (ALT) levels for at least 1 year, patients ($n=39$) with chronic liver disease and persistently elevated serum ALT levels, such as those with chronic hepatitis (CH); patients with liver cirrhosis (LC) ($n=4$), and patients with hepatocellular carcinoma (HCC) ($n=4$). A clinical diagnosis was made on the basis of serum biochemical examination, ultrasonography, computerized tomography and liver biopsy performed as required. Patients coinfectd with hepatitis C virus or human immunodeficiency virus were excluded. No patients received antiviral treatment during the follow-up period. The study protocol was approved by the Ethics Committees of the participating institutions in accordance with the 1975 Declaration in Helsinki. Informed consent was obtained from each patient prior to any study related procedures.

Genotyping of HBV

The serum samples were stored at -20 °C until assay was performed. Serum DNA was extracted from 100 µL of serum using a DNA extractor kit (Genome Science Laboratory, Fukushima, Japan). The genotypes of HBV were determined by enzyme-linked immunosorbent assay (ELISA) (HBV GENOTYPE EIA, Institute of Immunology Co., Ltd., Tokyo, Japan) with monoclonal antibodies that are type-specific to epitope in the preS2-region product^[15]. If the result of ELISA was indeterminate, the genotypes were detected by restriction fragment length polymorphism (RFLP), as previously described^[16]. Genotype B was classified into 2 subgroups, “Ba” which has a recombinant sequence of genotype C in the precore/core region, or “Bj” which does not have it, by the method reported previously^[12]. Genotype G of HBV was detected by PCR with hemi-nested primers deduced from the unique insertion of 36 nucleotides (nt) in the core gene that is specific to this genotype^[17].

Sequencing of HBV genome

Three complete genomes and 61 core promoter/precore regions of HBV were amplified by polymerase chain reaction with several primer sets, as previously described^[18]. Amplified HBV DNA fragments were sequenced directly by dideoxy sequencing using a Taq Dye Deoxy Terminator cycle sequencing kit with a fluorescent 3100 DNA sequencer (Applied Biosystems, Foster City, CA, USA). These nucleotide sequences were deposited in the DDBJ/EMBL/GenBank databases under the accession numbers AB105172- AB105174.

Molecular evolutionary analysis of HBV

The pairwise nucleotide sequences were aligned using the CLUSTAL W program^[19]. The genetic distances were calculated with the 6-parameter method, and the phylogenetic tree was constructed by the neighbor-joining method^[20] using

ODEN program (version 1.1.1)^[21]. To confirm the reliability of the phylogenetic tree, bootstrap resampling tests were performed 1 000 times. Reference sequences of HBV, shown as accession numbers, were obtained from the DDBJ/EMBL/GenBank database.

Statistical analyses

Statistical differences were evaluated using the Mann-Whitney nonparametric test, the Fisher's exact probability test and the Student's *t*-test where appropriate. Differences were considered significant for a *P*-value less than 0.05.

RESULTS

Genotypes of HBV

The distribution of HBV genotypes among 61 multi-ethnic carriers in Hawaii was 14(23.0%) for genotype A, 9(14.7%) for genotype B and 38(62.3%) for genotype C. All the 9 genotype B strains were found to be Ba that has a recombinant sequence of genotype C in precore/core region. Genotypes D, E, F and G were not found in this study.

Comparison with clinical characteristics among HBV genotypes

Clinical and serological characteristics were compared among the patients infected with genotypes A, B and C (Table 1). Patients with HBV genotype A were of Filipino (*n*=10), Caucasian (*n*=3) and Polynesian (*n*=1) ethnicities. Genotype B was found in patients of Chinese (*n*=4), Taiwanese (*n*=2), Vietnamese (*n*=2), and Hawaiian/Chinese (*n*=1) ethnicities. Genotype C was found in the patients whose ethnic backgrounds were various Asian (*n*=33), Micronesian (*n*=3), and Caucasian (*n*=2). There were no significant differences in terms of the age, gender, serum AST, ALT, ALP, γ-GTP and the clinical stages of liver disease among them. The proportion of HBeAg positive-phenotype in patients with genotypes A, B

^a*P*<0.05 between genotypes B and C. ASC: Asymptomatic carrier; CH: Chronic hepatitis; LC: Liver cirrhosis; HCC: Hepatocellular carcinoma; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; ALP: Alkaline phosphatase; γ-GTP: γ-glutamyl transpeptidase.

and C was 57.1%, 33.3% and 68.4% respectively, with a significant difference observed between genotypes B and C ($P<0.05$). HCC was found in 10.5% of patients with genotype C.

Comparison with core promoter/precore sequences

The frequency of mutation in core promoter (nt 1762/1764) and precore (nt 1858 and nt 1896) region was compared among genotypes A, B and C (Table 2). No significant differences in the frequency of the core promoter mutants were found among genotypes A, B and C (21.4%, 44.4%, and 57.9% respectively). Precore stop mutation (A-1896) was detected in genotypes B and C (33.3% and 21.1%) but not detected in genotype A. Sequence analysis of the mutation at nt 1858 in the precore region showed that all genotype B strains and 68% of genotype C strains possessed a T nucleotide (T-1858). In contrast, all genotype A strains had a C nucleotide in this region (C-1858).

HBV genotype C with C-1858 or T-1858

In order to clarify the significance of nucleotide variety (C or T) at nt 1858 in clinical and virological characteristics, 12 genotype C strains with C-1858 were compared to that of 26 strains of

genotype C with T-1858 (Table 3). All strains of both groups were obtained only from carriers whose ethnic background is Asian. HBeAg positive-phenotype was more frequent in genotype C patients with C-1858 than in those with T-1858 (83.3% vs 61.5%). The precore stop mutation (A-1896) was found in 30.8% (8/26) of those with genotype C with nucleotide T-1858, but not in those subjects with the C-1858 nucleotide. There were no significant differences in frequencies in terms of the age, gender, serum AST, ALT, ALP, γ -GTP and the clinical stages of liver disease and BCP mutation between them.

Phylogenetic analysis

To clarify the phylogenetic characterization of genotype C with C-1858, the complete genome of three HBV strains in carriers was sequenced. These subjects were from Micronesia (HI-1), Hong Kong (HI-2) and Vietnam (HI-3). Molecular evolutionary analysis was also conducted (Figure 1). Of them, one strain (HI-1) was clustered into a subgroup of genotype C with T-1858 from Polynesian with significant bootstrap values. The HI-2 and HI-3 strains were clustered into a subgroup of genotype C from Thailand and Vietnam, and separated from

Figure 1 A phylogenetic tree based on the complete genome sequences of hepatitis B virus with 27 reference strains. Isolate names of HI-1, HI-2 and HI-3 were sequenced in this study. The length of the horizontal bar indicates the number of nucleotide substitutions per site. Numbers beside the main roots are the results of bootstrap analysis.

those strains of China and Japan. Moreover, the strains from Thailand and Vietnam had separate branches, and Hawaiian strains were clustered into the branch with Vietnam strains. Interestingly, all strains from Vietnam had C-1858, and those from Thailand had T-1858.

DISCUSSION

The findings of the present study indicate that HBV genotypes A, B and C are prevalent in Hawaii, and genotype C is the major genotype. Most cases of genotype A were found in immigrants from the Philippines and countries known to be prevalent regions for genotype A^[6]. Genotype B was found only in immigrants from Asian regions where genotype B was endemic. In addition, genotype C was obtained from immigrant who came from various Asian countries, where genotype C was prevalent^[22]. These results indicate that the distribution of HBV genotypes in Hawaii is associated with their respective ethnic background.

Recently, it was reported that genotype B could be classified into the Bj (j standing for Japan) and Ba (a standing for Asia) subgroups. Ba shared a genomic sequence with genotype C in the precore/core region, which was prevalent in Asian countries. Bj was restricted to Japan, and did not have this recombination^[11]. It was shown that Ba induces more severe liver disease than Bj

due to delayed seroconversion of HBeAg^[12]. In this study, we found that genotype B, prevalent in Hawaii, was classified as Ba because they were all obtained from carriers with Asian ethnicity (excluding Japanese). In addition, the rate of positive HBeAg (33.3%) and basal core promoter (BCP) mutation (44.4%) in patients of Hawaii infected with genotype B were higher than those in Japanese patients with genotype B^[9]. This result is also consistent with a previous report.

The double mutation in the core promoter, A-to-T mutation at nt 1762 and G-to-A mutation at nt 1764, was associated with reduced synthesis of precore mRNA^[23,24]. In addition, it has been reported that the BCP mutation was associated with the progression of liver disease^[25]. In this study, although it was not significant, BCP mutation was detected more frequently in genotype C than in genotype B. This result supports our previous observation that the BCP mutation was significantly more frequent in genotype C patients than in genotype B patients^[9]. In addition, the present study demonstrated that the proportion of HBeAg positivity in genotype C was significantly higher than that in genotype B (68.4% vs 33.3%). However, our study could not show the clinical difference between genotypes B and C most likely due to the small number of patients studied. In the future, a case-controlled study in multi-ethnic carriers with larger samples is required to confirm

if genotype C could induce more severe liver disease than genotype B^[9,10].

Interestingly, we detected 12 strains of genotype C possessing C-1858 in Hawaii. HBV strain with C-1858 could prevent the A-1896 precore mutation from shutting off the synthesis of HBeAg^[26]. This C-1858 variant was frequently found in genotypes A and F^[26]. In genotype C, the C-1858 variant was observed in Southeast Asian patients, and the phylogenetic origin of genotype C with C-1858 variant has been reported from Vietnam recently. In this study, the complete genomes of 3 genotype C strains with C-1858 were sequenced. One strain obtained from a Micronesian patient with C-1858 was clustered with previously reported Polynesian strains with T-1858. This indicates that both the C-1858 and T-1858 strains of genotype C are endemic to South Pacific countries. Two other strains obtained from patients with Hong Kong and Vietnamese ethnicities were clustered with the strains of genotype C from Southeast Asian countries. This result is consistent with geographic distribution of HBV genotype^[18]. Interestingly, in this subgroup, there were 2 variants of strains, one had C-1858, prevalent in Vietnam, and the other had T-1858, prevalent in Thailand.

The clinical significance of C-1858 or T-1858 among genotype C is not well known. In this study, we compared the clinical and laboratory characteristics between C-1858 and T-1858 variant, but there were no significant differences between them. The number of patients was not enough to clarify the importance of this variation, and its significance for clinical characteristics remains unknown. Further studies would be required using larger numbers of samples.

In conclusion, genotypes A, B and C are the predominant types among multi-ethnic HBV carriers in Hawaii, and the distribution of these genotypes is dependent on the ethnic origin of the carriers in Hawaii. The influence of these genotypes on the clinical manifestations of these HBV carriers in Hawaii is not well defined due to the current small sample size. Case-controlled study with larger cohorts from our unique community is needed.

Abstract

AIM: To evaluate the inhibition effect of HCV NS5A on p53 transactivation on p21 promoter and explore its possible mechanism for influencing p53 function.

METHODS: p53 function of transactivation on p21 promoter was studied with a luciferase reporter system in which the luciferase gene is driven by p21 promoter, and the p53-DNA binding ability was observed with the use of electrophoretic mobility-shift assay (EMSA). Lipofectin mediated p53 or HCV NS5A expression vectors were used to transfect hepatoma cell lines to observe whether HCV NS5A could abrogate the binding ability of p53 to its specific DNA sequence and p53 transactivation on p21 promoter. Western blot experiment was used for detection of HCV NS5A and p53 proteins expression.

RESULTS: Relative luciferase activity driven by p21 promoter increased significantly in the presence of endogenous p53 protein. Compared to the control group, exogenous p53 protein also stimulated p21 promoter driven luciferase gene expression in a dose-dependent way. HCV NS5A protein gradually inhibited both endogenous and exogenous p53 transactivation on p21 promoter with increase of the dose of HCV NS5A expression plasmid. By the experiment of EMSA, we could find p53 binding to its specific DNA sequence and, when co-transfected with increased dose of HCV NS5A expression vector, the p53 binding affinity to its DNA gradually decreased and finally disappeared. Between the Huh 7 cells transfected with p53 expression vector alone or co-transfected with HCV NS5A expression vector, there was no difference in the p53 protein expression.

CONCLUSION: HCV NS5A inhibits p53 transactivation on p21 promoter through abrogating p53 binding affinity to its specific DNA sequence. It does not affect p53 protein expression.

INTRODUCTION

Hepatitis C virus (HCV) is recognized as a major causative agent leading to chronic hepatitis and cirrhosis^[1-3], which have a close relationship with the development of hepatocellular carcinoma (HCC)^[4,5]. HCV is a positive single-stranded RNA virus belonging to the Flaviridae family, and its genome only contains a single long open reading frame encoding a large polyprotein precursor that is thereafter processed by a combination of cellular and viral proteases into several mature proteins, including three or four structural proteins (core, E1, E2/P7) and at least 6 nonstructural proteins (NS): NS2, NS3, NS4A, NS4B, NS5A, NS5B^[6]. HCV NS5A as a nonstructural protein does not assemble into the HCV particles, but still has a lot of functions in the HCV replication and the development of chronic liver disease and hepatocellular carcinoma. Recent studies showed that HCV NS5A could interact with a number of cellular proteins including PKR, p53, Grb2 and Cdk1^[7-10], and enhance expression of some genes related to cell proliferation such as PCNA, NF- κ B, Stat-3, SRCAP and IL-8^[11-14], indicating that HCV NS5A has a critical role in promoting cell proliferation and malignant transformation. HCV NS5A prevents p53 and TNF- α mediated apoptosis^[15-17], and possibly perturbs the DNA repair when cells are treated with DNA damage agents including viruses, toxins or physical damage. HCV NS5A is important for the HCV replication. It can form a complex with an SNARE-like protein, hVAP-33 and HCV NS5B^[18] and can associate with ER and Golgi complex, and the amphipathic helix (AH) of the HCV NS5A is necessary for this membrane localization and for HCV RNA replication^[19,20]. Interaction of HCV NS5A with La protein can also maintain and benefit HCV RNA replication and HCV protein translation^[21,22]. Sequence mutation in HCV NS5A might be a reason for the responsiveness in the patient who received IFN treatment^[23-25]. The patients with wild type of interferon sensitive-determining region (ISDR) in HCV NS5A usually have a lower responsive rate to the IFN therapy, and the mechanism is that the wild type ISDR can bind PKR, which is induced by IFN and has an anti-viral activity, and can disrupt PKR function^[7,26,27]. The tumor suppressor p53 protein has been reported to possess a number of important functions. Activated p53 can transactivate a lot of target genes, maintain normal cell cycle through inducing apoptosis and repairing damaged DNA, and suppressing oncogenic transformation. In this study we explored the interaction between HCV NS5A and p53 and the mechanism by which the HCV NS5A abrogated the p53 transactivation.

MATERIALS AND METHODS

Cell lines and plasmids

P^{CMV}-NS3, P^{Wwp}-luc and P^{Wwp}-mut-luc were kind gifts from Professor Vogelstein (The Johns Hopkins University). P^{CMV}-NS3 is an eukaryotic expression vector that is constructed by cloning normal human p53 cDNA into p^{CMV} plasmid. P^{Wwp}-luc carries luciferase reporter gene driven by p21 promoter that contains the specific consensus DNA sequence binding to p53 protein. P^{Wwp}-mut-luc is approximately the same vector as P^{Wwp}-luc except for deletion mutation introduced in the p53 binding sequence

of p21 promoter. P^{CNS5A} is made in Dr. Siddiqui's laboratory (University of Colorado, USA) through inserting of HCV NS5A cDNA into P^{CMV} plasmid^[12]. The liver carcinoma cell lines Huh7 with p53 gene mutation and HepG2 with wild-type p53 gene were from ATCC(USA) and maintained in Dulbecco's Modified Eagle Medium (Life Technologies, USA) complemented with 100 mL/L fetal calf serum. The cells were transfected by the individual plasmids with Lipofectin reagent (Life Technologies, USA) when they became 60-70% confluent. Forty-eight hours after transfection, the cells were harvested for the analysis of relative luciferase activity and electrophoretic mobility shift assay (EMSA).

Relative luciferase activity assay

After 48 h of transfection, cells in the plates were washed two times with PBS, and then 750 μ L lysis buffer (0.1 mmol/L K₂HPO₄, pH 7.8, 10 mmol/L DTT, 5 g/L NP-40) was added onto plates. The plates were then placed on ice for 15 min and then cells were transferred into a clean 1.5-mL Eppendorf tube. After centrifugation at 15 000 g for 10 min, the supernatants were collected for further experiment. For relative luciferase activity assay, 0.4 mL determination buffer (0.1 mmol/L K₂HPO₄, pH 7.8, 0.15 mmol/L MgSO₄, 10 mmol/L DTT, 0.5 mmol/L ATP) and the different volumes of supernatant containing equivalent protein were put into 5-mL glass tube to observe the times of luminescence within 10 s using a luminometer (Optocomp II, MGM, USA). The experiment was repeated three times and each in triplicate.

Electrophoretic mobility-shift assay (EMSA)

In this experiment, we investigated the ability of p53 binding to the specific consensus DNA sequence, and studied if the binding could be influenced by HCV NS5A. Briefly, this experiment was done as following: (1) Labeling of DNA probe: 50 pmol chemically synthesized oligonucleotide 5' - GGACATGCCCGG GCATGTCC -3' which is the specific consensus DNA sequence to bind p53, 2 μ L γ -P³² ATP (74 000 GBq/mmol), 20 U T4 polynucleotide kinase, 2 μ L reaction buffer and incubated for 30 min at 37 °C, then 60 μ L dH₂O was added to the mixture and the labeled oligonucleotides were purified from the free γ -P³² ATP by use of Sephadex-G25. The purified P³²-labeled DNA probe was stored at -20 °C until use. (2) Nuclear protein isolation: After transfection with different plasmids for 48 h, cells were washed 3 times with PBS and scrapped down from the plates and then transferred into 1.5-mL Eppendorf tubes and washed 3 times again with PBS. Lysis buffer 30 μ L (20 mmol/L Hepes, pH 7.9, 10 mmol/L KCl, 10 mmol/L Na₃VO₄, 1 mmol/L ETDA, 100 mL/L glycerol, 1 mmol/L PMSF, 3 g/L aprotinin, 1 g/L leupeptin, 1 mmol/L DTT, 2 g/L NP-40, 20 mmol/L NaF) was added to suspend the cells. After 15 min on ice, and centrifugation at 15 000 \times g for 1 min, the supernatant was discarded and the pellet resuspended in 20 μ L nuclear extract buffer (20 mmol/L Hepes, pH 7.9, 10 mmol/L KCl, 420 mmol/L NaCl, 10 mmol/L Na₃VO₄, 1 mmol/L ETDA, 200 mL/L glycerol, 1 mmol/L PMSF, 3 g/L aprotinin, 1 g/L leupeptin, 1 mmol/L DTT, 20 mmol/L NaF). After incubation at 4 °C for 30 min. with mild agitation, and centrifugation at 15 000 g for 5 min, aliquot supernatants were collected and stored at -70 °C until use. (3) Assessment of p53 binding to DNA probe: For each reaction tube, the followings were added: 2 μ g nuclear extraction protein, 2 μ L labeled probe containing p53 binding sequence, 1.5 μ L EMSA reaction buffer (50 mmol/L NaCl, 0.5 mmol/L ETDA, 40 mL/L glycerol, 1 mmol/L MgCl₂, 1 mmol/L DTT, 10 mmol/L Tris-Cl, pH 7.5, 0.05 g/L poly (dI-dC)) and dH₂O to a total volume of 15 μ L. After incubation for 30 min on ice, 20 μ L of samples was loaded onto 60 g/L undenatured PAGE and run at 160 V for approximately 6 h. The gel was dried and autoradiographed at -70 °C for about 16 h.

Western blotting to detect p53 and HCV NS5A protein expression

Cell lysates of Huh7 cells transfected with P^{C53-NS3} or co-transfected with P^{CNS5A} were made by routine method. The same amount of total protein from the cell lysate was used to load onto 120 g/L PAGE, and then transferred onto PV (polyvinylidene difluoride) membrane. After blocked in block solution (20 mmol/L Tris-HCl, pH 7.5, 150 mmol/L NaCl, 3 g/L PVP, 5 g/L Tween 20) for 2 h, the membrane was probed by anti-HCV NS5A or anti-p53, washed and incubated with the second enzyme-labeled antibody, and then observed by using an ECL kit (Boehringer Mannheim Co., Germany).

Statistical analysis

Statistical significance of differences between the 2 groups was determined by applying Student's *t* test or two-sample *t* test. Statistical significance of differences in more than 3 groups was determined by applying one-way ANOVA. A *P* value less than 0.05 was considered significant.

RESULTS

HCV NS5A protein inhibited the transactivation of endogenous p53 on p21 promoter

Relative luciferase activities in P^{Wwp-luc}-transfected HepG2 cells (3.95×10^5) were significantly higher than that in P^{Wwp-mut-luc} group (0.60×10^5 , $t=5.92$, $P<0.01$). Compared to P^{Wwp-luc}-transfected HepG2 cells, the relative luciferase activities in the HepG2 cells co-transfected with P^{Wwp-luc} and P^{CNS5A} decreased in a P^{CNS5A} dose- dependent manner ($F=20.71$, $P<0.01$), suggesting that HCV NS5A protein can inhibit the transactivation of endogenous p53 on p21 promoter. In contrast, the relative luciferase activities of the HepG2 cells co-transfected with P^{Wwp-mut-luc} and P^{CNS5A} had little change ($F=0.76$, $P>0.05$) in comparison with P^{Wwp-mut-luc}-transfected HepG2 cells. Those results indicated that endogenous p53 has a transactivation on p21 promoter, and HCV NS5A down-regulated p21 promoter activity through inhibiting endogenous p53 activity (Table 1).

Table 1 HCV NS5A inhibits the transactivation of endogenous p53 on p21 promoter

Group	Relative luciferase activity	<i>F</i>	<i>P</i>
P ^{Wwp-luc} (1 μ g)			
+ P ^{CNS5A} (0 μ g)	3.49×10^{5b}	20.71	<0.01
+ P ^{CNS5A} (0.5 μ g)	2.69×10^5		
+ P ^{CNS5A} (1.0 μ g)	1.62×10^5		
+ P ^{CNS5A} (2.0 μ g)	0.58×10^5		
P ^{Wwp-mut-luc} (1.0 μ g)			
+ P ^{CNS5A} (0 μ g)	0.60×10^5	0.76	>0.05
+ P ^{CNS5A} (0.5 μ g)	0.65×10^5		
+ P ^{CNS5A} (1.0 μ g)	0.62×10^5		
+ P ^{CNS5A} (2.0 μ g)	0.64×10^5		

^b $t=5.92$, $P<0.01$.

HCV NS5A protein abrogated exogenous p53 transactivation on p21 promoter

The mean of relative luciferase activity in the Huh7 cells individually transfected with P^{Wwp-luc} and P^{Wwp-mut-luc} was 0.47×10^5 and 0.45×10^5 respectively and there were no statistically differences between these two groups ($t=1.16$, $P>0.05$). This might be because p53 gene in Huh7 cells has been mutated and p53 protein has lost its normal transactivation function, therefore, no matter what happened to p21 promoter (wild type or mutated), the expression of p21 promoter driven luciferase gene was not affected. When P^{Wwp-luc} or P^{Wwp-mut-luc} was co-

transfected with $P^{C53-NS3}$ into Huh7 cells, respectively, the relative luciferase activities in the $P^{wpp-luc} + P^{C53-NS3}$ group greatly increased ($\chi=5.63 \times 10^5$), but the relative luciferase activities in the $P^{wpp-mut-luc} + P^{C53-NS3}$ group only mild increased ($\chi=0.50 \times 10^5$), and a remarkable variance between the two groups existed ($t=10.12$, $P<0.01$). These results indicated that exogenous p53 should have a strong transactivation on p21 promoter. In order to see if HCV NS5A protein has any effect on the exogenous p53 transactivation, we used P^{CNS5A} , $P^{C53-NS3}$ and $P^{wpp-luc}$ to co-transfect Huh7 cells, and the result showed that the relative luciferase activities in the $P^{CNS5A}+P^{C53-NS3}+P^{wpp-luc}$ group cells decreased in a P^{CNS5A} dose-dependent way ($F=24.23$, $P<0.01$). P^{CNS5A} and $P^{wpp-luc}$ were also used to transfect Huh7 cells to find out if HCV NS5A had a direct effect on p21 promoter. The result showed that HCV NS5A did not increase or decrease the relative luciferase activity. From those experiments we proposed that HCV NS5A down-regulated p21 promoter activity by inhibiting exogenous p53 activity, and not by HCV NS5A's direct effect on p21 promoter (Tables 2, 3).

Table 2 HCV NS5A inhibits exogenous p53 transactivation on p21 promoter

Group	Relative luciferase activity	F	P
$P^{wpp-luc}$ (1 μ g)	0.47×10^{5ab}	24.23	<0.01
+ $P^{C53-NS3}$ (1 μ g)	5.63×10^{5b}		
+ P^{CNS5A} (0.5 μ g)	1.61×10^5		
+ P^{CNS5A} (1.0 μ g)	0.69×10^5		
$P^{wpp-mut-luc}$ (1 μ g)	0.45×10^{5a}	0.69	>0.05
+ $P^{C53-NS3}$ (1 μ g)	0.50×10^5		
+ P^{CNS5A} (0.5 μ g)	0.43×10^5		
+ P^{CNS5A} (1.0 μ g)	0.48×10^5		

^a $t=1.16$, $P>0.05$; ^b $t=10.12$, $P<0.01$.

+ P^{C53-NS} (1.0 μ g)	4.84×10^5		

HCV NS5A inhibited p53 protein transactivation through abrogation of p53 binding to the specific DNA

Through EMSA, the band of specific p53 and DNA probe complex was found in the nuclear lysates prepared from Huh7 cells transfected with $P^{C53-NS3}$, and verified by the appearance of the supershift after addition of the monoclonal anti-p53 (a generous gift of Dr. Harris, USA) or polyclonal anti-HCV NS5A antibody (a generous gift of Professor Rice, USA) in the EMSA mixtures. This p53-probe complex band did not occur in the nuclear lysates prepared from Huh7 cells untransfected with plasmids or only transfected with P^{CNS5A} , suggesting there is wild-type p53 protein expressed in these cells. In the next experiment, we used different doses of P^{CNS5A} and constant amount (1 μ g) of $P^{C53-NS3}$ to co-transfect Huh7 cells. The p53-probe band became gradually weakened and finally disappeared with increasing doses of P^{CNS5A} , suggesting that HCV NS5A could inhibit p53 transactivation through disruption of the binding of p53 to its specific consensus DNA (Figure 1).

HCV NS5A had no effect on p53 protein expression

p53 protein was expressed at about the same level between the Huh7 cells transfected with p53 expression vector and the Huh7

cells co-transfected with P^{CNS5A} and p53 expression vectors (Figure 2). This result indicates that HCV NS5A does not affect p53 protein expression.

Figure 1 HCVNS5A inhibits p53 binding to its specific DNA probe. Lane 1: Negative control; Lane 2: Transfected with pC53-NS3 only; Lane 3: Transfected with pCNS5A only; Lanes 4-6: Co-transfected with pC53-NS3 (1 μ g) and different dose of pCNS5A; Lanes 7-8: Transfected with pC53-NS3, and anti-p53, antiNS5A anti-bodies were added to the reaction mixture individually.

Figure 2 Western blotting for the expression of NCV NS5A and p53 proteins. Lane 1: Huh 7 cells co-transfected with $P^{C53-NS3}$ and P^{CNS5A} ; Lane 2: Huh 7 cells transfected with $P^{C53-NS3}$; Lane 3: Huh 7 cells untransfected.

DISCUSSION

HCV NS5A is a phosphoprotein that exists in two different forms of M_r 56 000 and 58 000 with modifications of serine residues, and M_r 58 000 form is produced by additional phosphorylation of the M_r 56 000 form^[28-30]. Initial studies found that HCV NS5A contains acidic and proline-rich amino acids in its carboxyl-terminal, and this structure feature resembles eukaryotic transcription activator^[31,32]. Later studies showed that the HCV NS5A with amino-terminal deleted (1-146) mutant did have a strong transcriptional activation, but the whole length HCV NS5A showed no apparent transcriptional activity^[33]. The potential transactivation of HCV NS5A has attracted great attention and become the research focus of the nonstructural proteins of HCV due to its important role in the pathogenesis of chronic liver disease and even hepatocellular carcinoma. Clinical observations suggested the responsiveness of patients to IFN treatment might be related to HCV NS5A ISDR sequence mutations^[23-25]. Several experiments from Katze's laboratory and others confirmed that HCV NS5A could repress RNA dependent protein kinase (PKR) function, by which HCV can escape the effect of IFN, and also inhibit apoptosis and promote cell proliferation^[7,26,27]. When PKR is dysfunctioned, sustained

expression of eIF-2 α in cells results in cell growth and differentiation, and induces malignant transformation and the development of tumors in nude mice. ISDR of HCV NS5A can bind the domain of PKR and prevent the PKR dimerizing which is the critical process to activate PKR function. Mapping studies found that ISDR and the adjacent C-terminal 26 amino acids can form a heterodimer with PKR. The effect of HCV NS5A on the protection of apoptosis induced by TNF- α and p53 was further identified^[16,17]. In the present study, we explored the possible effect of HCV NS5A on the transactivation of p53. Luciferase reporter gene driven by p21 promoter was used in this experiment, which showed that both endogenous and exogenous p53 protein could transactivate p21 promoter as expected. But, when HCV NS5A protein was introduced, by transfection or co-transfection with HCV NS5A expressing vector, the p21 promoter function activated by p53 was greatly depressed. This finding is in agreement with previous reports^[8,11]. To further understand the mechanism of interaction between HCV NS5A and p53, we did an EMSA experiment for p53 binding to its consensus DNA probe, to see if HCV NS5A could disturb the binding reaction. The result showed that HCV NS5A disrupted p53 binding to its DNA probe, and with the increase of dosage of HCV NS5A expressing vector transfected, inhibition of the binding seemed more remarkable. All the above results suggested HCV NS5A depressed the p53 transactivation by interrupting the binding between p53 and its specific DNA. Recent studies also evidenced that HCV NS5A could physically associate with p53 and form a complex, which might be the reason why p53 binding to its DNA was disrupted^[8,34]. Further, we wanted to know whether p53 protein expression was affected by the presence of HCV NS5A. Through western blot, we found that after co-transfection of HCV NS5A expressing vector, the level of p53 protein expression in the cells did not show any change compared to empty vector transfected cells. This result was also similarly found in another report^[11]. In summary, according to our experiments and previous reports by others, HCV NS5A represses p53 transactivation function by disrupting p53 binding to its specific DNA through HCV NS5A and p53 complex formation, not by the disturbance of the p53 protein expression. HCV NS5A can interact with many cellular factors in the host cells such as PKR, p53, Bcl2 and disrupt their functions^[7,8,26,27,34,35], which are related to the processes of apoptosis. HCV NS5A can also interact with unknown cellular factors and induce the expression of genes such as SRCAP, NF- κ B and PCNA^[11-13], which are related to the promotion of cell proliferation. HCV NS5A seems to be a very active protein interacting with host cellular proteins and taking a major part in modulating cell growth and death, as well as in the development of hepatocellular carcinoma.

ACKNOWLEDGEMENTS

We would like to thank Dr. A Siddiqui and G Waris from University of Colorado School of Medicine for their help in this study.

Abstract

AIM: To investigate the early diagnostic methods of bacterial and fungal infection in patients with chronic cholestatic hepatitis B.

METHODS: One hundred and one adult in-patients with chronic hepatitis B were studied and divided into 3 groups: direct bilirubin (DBil)/total bilirubin (TBil) 0.5, without bacterial and fungal infection (group A, $n=38$); DBil/TBil <0.5 , without bacterial and fungal infection (group B, $n=23$); DBil/TBil 0.5, with bacterial or fungal infection (group C, $n=40$). The serum biochemical index and pulse rate were analyzed.

RESULTS: Level of TBil, DBil, alkaline phosphatase (ALP) and DBil/ALP in group A increased compared with that in group B. The level of ALP in group C decreased compared with that in group A, whereas the level of TBil, DBil and DBil/ALP increased (ALP: 156 ± 43 , 199 ± 68 , respectively, $P<0.05$; TBil: 370 ± 227 , 220 ± 206 , respectively, $P<0.01$; DBil: 214 ± 143 , 146 ± 136 , respectively, $P<0.01$; DBil/ALP: 1.65 ± 1.05 , 0.78 ± 0.70 , respectively, $P<0.001$). The level of DBil and infection affected DBil/ALP. Independent of the effect of DBil, infection caused DBil/ALP to rise ($P<0.05$). The pulse rate in group A decreased compared with that in group B (63.7 ± 6.4 , 77.7 ± 11.4 , respectively, $P<0.001$), and the pulse rate in group C increased compared with that in group A (81.2 ± 12.2 , 63.7 ± 6.4 , respectively, $P<0.001$). The equation (infection = 0.218 pulse rate + 1.064 DBil/ALP - 16.361), with total accuracy of 85.5%, was obtained from stepwise logistic regression. Pulse rate (>80 /min) and DBil/ALP (>1.0) were used to screen infection. The sensitivity was 62.5% and 64.7% respectively, and the specificity was 100% and 82.8% respectively.

CONCLUSION: Bacterial and fungal infection deteriorate jaundice and increase pulse rate, decrease serum ALP and increase DBil/ALP. Pulse rate, DBil/ALP and the equation (infection = 0.218 pulse rate + 1.064 DBil/ALP - 16.361) are helpful to early diagnosis of bacterial and fungal infection in patients with chronic cholestatic hepatitis B.

INTRODUCTION

Patients with chronic hepatitis are known to be abnormally susceptible to infection as a result of multiple immunologic defects^[1-6]. The incidence of bacteremia in chronic liver disease is 5- to 7- fold higher than that found in other hospitalized patients^[7]. Infection is often associated with systemic inflammatory response syndrome and multiple organ dysfunction syndrome that is easy to develop into liver failure^[8,9]. Infection can prove fatal either directly or by precipitation of encephalopathy, gastrointestinal hemorrhage, hepatic hemodynamic derangement, portal hypertension, or renal failure^[9-17]. About 33% mortality in bacteremic patients with chronic liver disease has been noted^[18]. Considering the low positivity rate and lengthy bacterial culture, severe chronic liver disease patients with clinical diagnosis of infection should get the antibiotic treatment immediately to improve the survival opportunity before pathogen diagnosis^[19-24]. However, clinical diagnosis is made more difficult by the absence of the typical clinical feature of infection - that is, fever, leucocytosis, and localized symptoms^[9, 21]. Clinically apparent focus of infection could not be found in 20% to 60% of bacteremic patients with chronic liver disease^[9, 25, 26]. No specific site is identified in one third to one half of the infections, in which case the only clue may be deterioration of hepatic precoma or coma or renal function. The preventive antibiotic treatment is often applied to serious patients who have the liability to infection (such as the protein in ascites <10 g/L, gastrointestinal hemorrhage, and previous spontaneous bacterial peritonitis), and in the meantime it might increase the risk of drug resistance^[19, 27-30]. The early diagnostic methods of secondary bacterial and fungal infection in patients with chronic hepatitis B have not been studied. To reduce infection related mortality, the development of new methods for early diagnosis is of great significance.

MATERIALS AND METHODS

Patients

One hundred and one adult in-patients with chronic icteric hepatitis B in West China Hospital from October 2002 to March 2003 were studied and divided into three groups: direct bilirubin (DBil)/total bilirubin (TBil) 0.5, without bacterial or fungal infection (group A, $n=38$); DBil/TBil <0.5 , without bacterial or fungal infection (group B, $n=23$); DBil/TBil 0.5, with bacterial and fungal infection (group C, $n=40$).

Inclusion criteria

All patients in the study met with the following criteria: positive HBsAg or HBVDNA; TBil >17.1 mmol/L; age between 14 to 65 years. In addition, the patients in group C had the following features: leukocytes 10×10^9 /L or neutrophils 7×10^9 /L or the ratio of neutrophil $>70\%$ in blood; leukocytes in urine >5 per visual field under high power microscope; leukocytes 0.5×10^9 /L or neutrophils 0.25×10^9 /L in ascites; bacterial culture of blood, urine, phlegm or ascites was positive.

Exclusion criteria

The patient who had one of the followings was excluded from

group A and group B: infected with other pathogens rather than HBV; complicated with other diseases which had not relation with hepatitis B; recently occurring gastrointestinal hemorrhage. The patient who had one of the followings was excluded from group C: infected with other virus; complicated with other liver diseases which had not relation with hepatitis B; recently occurring gastrointestinal hemorrhage; leukocytes in urine 5 per visual field under high power microscope but normal in routine blood test in female patients who were in menstruation or in patient who had non-inflammatory nephrosis.

Investigation indexes

Blind tests for TBil, DBil, indirect bilirubin (IBil), DBil/IBil, alanine aminotransferase (ALT), aspartate aminotransferase (AST), AST/ALT, serum total protein (TP), albumin (ALB), globulin (GLOB), ALB/GLOB, γ -glutamyltransferase (GGT), alkaline phosphatase (ALP), DBil/ALP, lactate dehydrogenase (LDH), cholinesterase (ChE), serum total bile acid (TBA) and pulse rate were performed. The first liver biochemical test of group A and B after hospitalization and the first liver biochemical test of group C after confirmation of infection were done, and pulse rate of all patients were measured after 15-min bed rest.

Statistical analysis

All data were presented as mean \pm SE. Analysis of variance and covariance was used to determine whether there were significant differences among the three groups. Data with significant difference were entered into a stepwise logistic regression analysis. Statistical calculations were performed by SPSS (Version: 11.0, Chicago, USA).

RESULTS

Clinical features of infection

Fifteen percent of patients in group C showed a rise in leukocyte or neutrophil in blood, 55% of patients showed a rise in the ratio of neutrophil in blood lightly, and 12.5% of patients showed an increase in leukocyte or neutrophil in ascites. Eleven patients showed a leukocyte rise in urine (in these cases, 5 patients showed an increase in leukocyte or neutrophil in blood or in the ratio of neutrophil, 5 patients had a history of fever, 2 patients showed spontaneous bacterial peritonitis). Fifteen patients presented with the localized symptoms of infection. Sixteen patients had a history of fever (the fever was light and persisted shortly in most patients). Positivity rate of bacterial culture was 25% (3/12).

Analysis of variance

Level of TBil, DBil, ALP and DBil/ALP in group A increased significantly compared with that in group B (P <0.01, P <0.01, P <0.05, P <0.01, respectively). The level of ALP in group C decreased compared with that in group A (156 \pm 43, 199 \pm 68, respectively, P <0.05), whereas the level of TBil, DBil and DBil/ALP increased significantly (TBil: 370 \pm 227, 220 \pm 206, respectively, P <0.01; DBil: 214 \pm 143, 146 \pm 136, respectively, P <0.01; DBil/ALP: 1.65 \pm 1.05, 0.78 \pm 0.70, respectively, P <0.001). The level of IBil in group C decreased compared with that in group A (P <0.001) (Tables 1, 2).

The pulse rate in group A decreased significantly compared with that in group B (63.7 \pm 6.4, 77.7 \pm 11.4, P <0.001). The pulse rate in group C increased compared with that in group A and normal adults (81.2 \pm 12.2, 63.7 \pm 6.4, 72, P <0.001), but decreased compared with that in infectious patients without hepatitis (81.2 \pm 12.2, 90, P <0.001) (Table 2, Figure 1).

The level of ALT, AST, AST/ALT, TP, ALB, GLOB, ALB/GLOB, GGT, LDH, and ChE showed no significant difference among the three groups (data not shown).

Figure 1 Pulse rate in cholestatic patients. 1: With bacterial or fungal infection; 0: Without bacterial and fungal infection.

Figure 2 DBil/ALP and DBil in cholestatic patients. 1: With bacterial or fungal infection, 0: Without bacterial and fungal infection.

Analysis of covariance

There was linear correlation between DBil and DBil/ALP in groups A and C, and the distribution of DBil between the two groups was closely similar (Figure 2). The level of DBil and infection affected DBil/ALP (P <0.05, P <0.001, respectively).

(Table 3). Independent of the effect of DBil, infection caused DBil/ALP to rise ($P<0.05$) (Table 4).

Table 3 Tests of between-subjects effects (dependent variable: DBil/ALP)

Source	Type III sum of squares	Df	Mean square	F	P
Corrected model	50.025	2	25.012	129.672	<0.001
Infection	1.172	1	1.172	6.074	0.017
DBil	38.709	1	38.709	200.682	<0.001

Table 4 Pairwise comparisons (dependent variable: DBil/ALP)

Infection I	Infection J	Mean difference(I-J)	SE	P	95% CI
1	2	-0.293 ¹	0.119	0.017	-0.531 -0.055
2	1	0.293 ¹	0.119	0.017	0.0551 0.531

¹The mean difference is significant at the 0.05 level.

Logistic regression

The stepwise logistic regression was used to establish the best statistical model to early diagnose infection, and the equation (infection=0.218 pulse rate+1.064 DBil/ALP-16.361, $P<0.001$) was obtained. Its overall accuracy was 85.5%, and accuracy for diagnosing infection and noninfection were 85.7% and 85.3%, respectively (Table 5).

Table 5 Logistic analysis of bacterial and fungal infection

	B	SE	Wald	Df	P	Exp (B)
Pulse rate	0.218	0.059	13.468	1	<0.001	1.244
DBil/ALP	1.064	0.447	5.657	1	0.017	2.899
Constant	-16.361	4.251	14.815	1	<0.001	<0.001

Figure 3 Receiver operator characteristic curve of pulse rate and DBil/ALP.

Screening test

Because the diagnostic index of pulse rate at 80/min to screen infection was the greatest, the cut off point was selected at 80/min (Figure 3). The sensitivity (Sen), specificity (Spe), diagnostic index (DI), false positive rate (α), false negative rate (β), Youden's index (γ), crude accuracy (CA), adjusted agreement (AA), positive predictive value (PV+) and negative predictive value (PV-) were 62.5%, 100%, 1.625, 100%, 71.7%,

62.5%, 80.8%, 83.6%, 0% and 37.5%, respectively. Area under the curve (A_z)=0.889 ($P<0.001$) (Table 6). Because the diagnostic index of DBil/ALP at 1.0 was the greatest, the cut off point was selected at 1.0 (Figure 3). Sen, Spe, DI, α , β , γ , CA, AA, PV+ and PV- were 64.7%, 82.8%, 1.475, 81.5%, 66.7%, 47.5%, 73.0%, 73.9%, 17.8% and 35.3%, respectively. A_z =0.7373 ($P<0.001$) (Table 6). Pulse rate was a better index than DBil/ALP ($P<0.001$).

DISCUSSION

Bacterial and fungal infections are the common complications of chronic hepatitis, frequently aggravating hepatitis. Since the bacterium culture in chronic hepatitis patients is often negative, clinical diagnosis plays a major role. However, a large number of patients do not often present with the typical clinical features of infection. In a prospective study, fever was initially absent in 45% of cases, and leukocytosis was absent in 25% of cases^[10]. Urinary tract infection is the common type of infection and the source of bacteremia in up to 50% of patients with cirrhosis, and 20% of episodes of spontaneous bacterial peritonitis^[10-30]. However, patients with urinary tract infection often do not have localized symptoms or physical findings^[10,11]. Careful urinalysis is important to exclude infection in patients with chronic liver disease^[10]. In our study, the leukocyte or neutrophil in blood rose in 15% of infected patients, and the ratio of neutrophil rose lightly in 55% of patients. Leukocyte or neutrophil in ascites increased in 5 patients, and leukocyte in urine rose in 11 patients. Sixteen patients had a history of fever (the fever was mild and short-lasting in most patients). Only 37.5% of patients presented localized symptoms of infection. The positivity rate of bacterial culture was 25% (3/12). Therefore, early diagnosis of bacterial and fungal infection is difficult in chronic hepatitis.

The level of ALP frequently rises in cholestatic patients. However, in serious liver disease, along with the increase of serum TBil and DBil, sometimes ALP decreased. Hadjis discovered that the synthesis of ALP decreased in the case of widespread hepatocyte necrosis. As well as ALT and AST, it is a marker of disease aggravation. In our study, the level of TBil and DBil in cholestatic patients with infection increased compared with that without infection, but ALP in infection patients decreased compared with that without infection.

In order to characterize the contrary alteration of DBil and ALP in infection patients, we introduced a new index -that is the ratio of DBil to ALP. The level of DBil/ALP showed significant difference between the three groups (0.7829 ± 0.7002 , 0.1377 ± 0.0652 , 1.6468 ± 1.0500 , respectively, $P<0.01$). Analysis of covariance showed that the level of DBil and infection affected DBil/ALP, and independent of the effect of DBil, infection led to DBil/ALP increase ($P<0.05$).

To test whether DBil/ALP could be used to screen infection, a screening test was performed. Its sensitivity, specificity, positive predictive value and negative predictive value were 64.7%, 82.8%, 81.5% and 66.7%, respectively (the cut off point at 1.0). Therefore, we hypothesize that DBil/ALP can be used as an "infection index" to diagnose infection early in chronic cholestatic hepatitis B. If DBil/ALP is greater than 1.0, the probability of infection is 82.8%.

The mean pulse rate in normal adults is 72/min, but it frequently increases in infection, often above 90/min. Because the vagus's excitement increased in cholestatic patient, the

Table 6 Screening test of bacterial and fungal infection

Diagnosis	Sensitivity	Specificity	Diagnostic Index	A_z	Z	P
Pulse rat 80/min	0.625	1.000	1.625	0.889	20.372	<0.001
DBil/ALP 1.0	0.647	0.828	1.475	0.7373	4.022	<0.001

pulse rate decreased compared with that in normal adults (63.7 ± 6.4 , 72 , $P < 0.001$). Although the pulse rate in cholestatic patient increased after infection (81.2 ± 12.2 , 63.7 ± 6.4 , $P < 0.001$), it was slower compared with that in infection patients without cholestasis (81.2 ± 12.2 , 90 , $P < 0.001$). That is why alteration of pulse rate in those patients is likely to be neglected in clinic.

To test whether pulse rate could be used to screen infection, a screening test was done. Its sensitivity, specificity, positive predictive value and negative predictive value were 62.5%, 100%, 100% and 71.7%, respectively (the cut off point at 80/min). Pulse rate was better for screening infection than DBil/ALP ($P < 0.001$).

In order to establish the best statistical model to diagnose infection early, the equation (infection = $0.218 \text{ pulse rate} + 1.064 \text{ DBil/ALP} - 16.361$, $P < 0.001$) was obtained from the stepwise logistic regression. Its total accuracy, the accuracy of diagnosing infection and noninfection was 85.5%, 85.7% and 85.3%, respectively.

It is interesting that there is notable relationship between the logistic equation and screening test. Among the 18 indexes that we studied, only pulse rate and DBil/ALP could affect the logistic equation. The equation can be described approximately as "infection = $0.2 \text{ pulse rate} + \text{DBil/ALP} - 16$ ". As 0.2 multiplied by 80 is 16, if pulse rate 80/min, the equation 0 obviously. But if pulse rate < 80 /min, DBil/ALP significantly affects the equation. For severe chronic cholestatic hepatitis B, if pulse rate 80/min, perhaps the antibiotic treatment should be applied immediately before pathogen diagnosis to improve the survival opportunity. If DBil/ALP 1.0 but pulse rate < 80 /min, the equation is helpful to estimate the probability of infection. If DBil/ALP < 1.0 and pulse rate < 80 /min, the equation is useful to exclude infection. It is a sensitive, quick, simple and economical method to diagnose infection early and possibly improve the survival opportunity of severe chronic cholestatic hepatitis B.

Abstract

AIM: Several epidemiological studies have demonstrated a close association between *Helicobacter pylori* (*H Pylori*) infection and non-cardiac carcinoma of the stomach. *H pylori* infection induces active inflammation with neutrophilic infiltrations as well as production of oxygen free radicals that can cause DNA damage. The DNA damage induced by oxygen free radicals could have very harmful consequences, leading to gene modifications that are potentially mutagenic and/or carcinogenic. The aims of the present study were to assess the effect of *H pylori* infection on the expression of inducible nitric oxidative synthase (iNOS) and the production of 8-hydroxy-deoxyguanosine (8-OHdG), a sensitive marker of oxidative DNA injury in human gastric mucosa with and without tumor lesions, and to assess the possible factors affecting cell death signaling due to oxidative DNA damage.

METHODS: In this study, 40 gastric carcinoma specimens and adjacent specimens were obtained from surgical resection. We determined the level of 8-OHdG formation by HPLC-ECD, and the expression of iNOS and mechanism of cell death signaling [including nuclear factor- κ B (NF κ B), MEKK-1, Caspase 3, B Cell lymphoma leukemia-2 (Bcl-2), inhibitor of apoptosis protein (IAP) and myeloid cell leukemia-1 (Mcl-1)] by Western-blot assay.

RESULTS: The concentrations of 8-OHdG, iNOS, NF κ B, Mcl-1 and IAP were significantly higher in cancer tissues than in adjacent non-cancer tissues. In addition, significantly higher concentrations of 8-OHdG, iNOS, NF κ B, Mcl-1 and IAP were detected in patients infected with *H pylori* compared with patients who were not infected with *H pylori*. Furthermore, 8-OHdG, iNOS, NF κ B, Mcl-1 and IAP concentrations were significantly higher in stage 3 and 4 patients than in stage 1 and 2 patients.

CONCLUSION: Chronic *H pylori* infection induces iNOS expression and subsequent DNA damage as well as enhances anti-apoptosis signal transduction. This sequence of events supports the hypothesis that oxygen-free radical-mediated damage due to *H pylori* plays a pivotal role in the development of gastric carcinoma in patients with chronic gastritis.

INTRODUCTION

Helicobacter pylori (*H pylori*) infection is associated with an increased risk of both peptic ulcer and gastric cancer^[1]. Chronic gastritis induced by *H pylori* significantly increases the risk for non-cardiac gastric cancer^[2,3], and host responses that may affect the threshold for carcinogenesis include alteration of epithelial cell proliferation and apoptosis. Although the linkage between *H pylori* infection and gastric cancer is convincing, the molecular mechanism or mechanisms responsible are unclear, and both bacterial and host factors are implicated. One possible factor is that increased inflammation generates reactive oxygen and nitrogen intermediates that have been shown to damage DNA directly^[4].

Mucosal hyperproliferation has been reproducibly demonstrated in *H pylori*-infected human^[5-7] and rodent gastric tissue^[8-10], and proliferation scores normalize following successful eradication in humans^[5-7]. However, maintenance of tissue integrity requires that enhanced cell production is accompanied with increased rates of cell loss consequently, studies have also examined the effect of *H pylori* on apoptosis. In contrast to hyperproliferation, *H pylori* has been associated with increased^[11-14], unchanged^[15], or even decreased^[16] levels of apoptosis *in vivo*, and within a particular population, substantial heterogeneity exists among apoptosis scores^[11-14]. These observations suggest that increases in proliferation that are not balanced by concordant increases in apoptosis over years of colonization may heighten the retention of mutated cells, ultimately enhancing the risk for gastric malignancy in certain populations. Alteration of epithelial cell proliferation and apoptosis is a manifestation of *H pylori*-induced gastritis. However, the precise mechanisms underlying these effects remain incompletely clarified. In this study, we aimed to assess the effect *H pylori* infection on the expression of iNOS and the production of 8-OHdG, a sensitive marker of oxidative DNA injury in human gastric mucosa with and without tumor lesions, as well as the possible factors affecting cell death signaling due to oxidative DNA damage.

MATERIALS AND METHODS

Patients

In this study, 40 patients (aged 68.3 ± 11.4 years, range 39–84 years, M/F: 26/14) with non-cardiac gastric adenocarcinoma were included. Specimens from tumor site and adjacent non-tumor site were obtained from surgical resection. By TNM staging according to the criteria described by the International Union Against Cancer^[17], there were 2 cases in stage 1, 6 cases in stage 2, 8 cases in stage 3 and 24 cases in stage 4 (Table 1). *H. pylori* infection was assessed by the following three methods: histology (haematoxylin and eosin staining or Giemsa staining, rapid urease test (CLO test, Delta West Pty Ltd, Perth, Australia) and serum *H. pylori* ELISA IgG assays (Trinity Biotech USA, Jamestown, NY). A patient was considered *H. pylori* positive if one or more of the diagnostic methods applied were positive, and *H. pylori* negative if all methods were negative. There were 29 patients (72.5%) with *H. pylori* infection and 11 patients (27.5%) without *H. pylori* infection. We determined the level of 8-OHdG formation by HPLC-ECD, and the expression of iNOS and cell death signaling, including NF κ B, MEKK1, Caspase 3, Bcl-2, Mcl-1 and IAP by Western-blot assay.

DNA extraction and digestion

DNA was extracted with Dneasy tissue kit (QIAGEN) according to the protocol of Dahlhaus and Apple^[18] with minor modifications as described previously^[19]. Briefly, one volume of nuclear fraction obtained from surgical tissue was mixed with ten volumes of extraction buffer (1 mol/L NaCl, 10 mmol/L Tris-HCl, 1 mmol/L EDTA, 5 g/L SDS, pH 7.4) and one volume of chloroform:isoamylalcohol (12:1 v/v). After vigorous shaking, the aqueous phase was separated by centrifugation. This step was repeated three times before DNA was precipitated with absolute ethanol (-70°C). DNA pellet was dissolved in TE buffer (10 mmol/L Tris-HCl, 1 mmol/L EDTA, pH 7.4), and then incubated with RNase A to remove RNA. After incubation, DNA was extracted with chloroform:isoamylalcohol, and precipitated with absolute ethanol again. The DNA pellet was dissolved in 10 mmol/L Tris-HCl (pH 7.0) and hydrolyzed according to the previous procedure^[20]. Briefly, 200 μg DNA in 200 μL 10 mmol/L Tris-HCl (pH 7.0) was first denatured at 95°C for 3 min. The digestion was carried out at 37°C for 1 h with 100 units DNase I (from bovine pancreas, Sigma) in a buffer containing 10 mmol/L MgCl_2 , followed by incubation with 5 units nuclease P_1 (from penicillium citrinum, Sigma) in

100 $\mu\text{mol/L}$ ZnCl_2 for an additional hour. The mixture was incubated finally with 3 units alkaline phosphatase (from *Escherichia coli*, Sigma) at 37°C for 1 h. The incubation was terminated with acetone (HPLC grade, Merck, Germany) to precipitate proteins. After 12 000 g centrifugation for 15 min, the supernatant was dried under vacuum in a rotary evaporator (Eyela, Tokyo, Japan) and DNA was dissolved in distilled H_2O .

8-OHdG assay

8-OHdG levels were determined by HPLC/ECD consisting of a BAS PM-80 pump (Bioanalytical Systems, West Lafayette, IN, USA), a CMA-200 microautosampler (CAM/Microdialysis, Stockholm, Sweden), a BAS-4C amperometric detector (Bioanalytical Systems, West Lafayette, IN, USA), a microbore reversed-phase column (Inertsil-2, 5- μm ODS, 1.0×150 mm I.D. G.L. Sciences, Tokyo, Japan) Beckman I/O 406 interface, and Beckman system gold data analysis software (Beckman Instruments). A potential of +0.6 V was selected for the glassy carbon working electrode which corresponded to a silver/silver chloride reference electrode. The mobile phase consisted of 12.5 mmol/L citric acid, 30 mmol/L NaOH, 25 mmol/L sodium acetate, 10 mmol/L acetic acid glacial and 50 mL/L methanol (pH 5.3). The flow rate was set at 1 mL/min. Under these conditions, the retention time of 8-OHdG was 8.49 min with a significantly higher signal than background noise.

Immunoblot analysis

Cancerous and non-cancerous tissue samples were homogenized with ten volumes of homogenization buffer (50 mmol/L Tris, 5 mmol/L EDTA, 150 mmol/L sodium chloride, 10 g/L Nonidet P-401 g/L SDS, 5 g/L deoxycholic acid, 1 mmol/L sodium orthovanadate, 170 $\mu\text{g/mL}$ leupeptin, 100 $\mu\text{g/mL}$ phenylsulfonyl fluoride; pH 7.5). After 30 min of mixing at 4°C , the mixture was centrifuged at 800 r/min for 10 min, and the supernatant was collected. The protein content of the samples was determined with the Bio-Rad protein assay reagent using BSA as a standard. For Western blotting analysis, 50 μg protein from both cancerous and non-cancerous tissue samples was resolved on 100 g/L SDS-PAGE gels along with prestained protein molecular weight standards (Bio-Rad). The separated proteins were then blotted onto NC membrane (0.45 μm , Bio-Rad) and reacted with primary antibodies (against iNOS, NF κ B, MEKK1, Caspase 3, Bcl-2, Mcl-1 and IAP). After washed, the blots were incubated with peroxidase-conjugated goat anti-mouse antibody. Immunodetection was carried out using the enhanced chemiluminescence (ECL) Western blotting detection kit (Amersham Corp., UK). Relative protein expression levels were quantified by densitometric measurement of ECL reaction bands and normalized with values of tubulin. Finally, enhanced chemiluminescence (ECL) was used to detect the membrane, and then the membrane was exposed to X-ray film to observe results. All the immunoblot results were determined by Alpha Imager 2000 documentation & analysis system (Alpha Innotech Corporation).

Statistical analysis

Each parameter expressed by fold of increase of the data from cancer tissue was compared to the adjacent non-cancer tissue. The results were reported as mean \pm SE from individual magnitudes. Data were analyzed with Student's *t*-test. Statistical differences were considered significant when $P < 0.05$.

RESULTS

To assess the effect of *H. pylori* infection on each determined parameter, the results were expressed by fold of increase comparing the data of cancer tissue with those of the adjacent non-cancer tissue. The concentrations of 8-OHdG were analyzed by HPLC/ECD. There were significantly higher concentrations

Figure 1 Concentrations of 8-OHdG. A: Higher concentration of 8-OHdG in cancer tissues compared with adjacent non-cancer tissues. B: Higher concentration of 8-OHdG in cancer tissues of patients with and without *H pylori* infection. C: Significantly higher 8-OHdG concentrations in stage 3 and 4 patients ^a $P < 0.05$, N: non-cancer tissue, C: cancer tissue, Hp(-): without *H pylori* infection, Hp(+): with *H pylori* infection, 1&2: gastric cancer stages 1 and 2, 3&4: gastric cancer stages 3 and 4.

of 8-OHdG in cancer tissues than in adjacent non-cancer tissues (Figure 1). In addition, significantly higher concentrations of 8-OHdG were detected in patients infected with *H pylori* than in those without *H pylori* infection. 8-OHdG levels were also significantly higher in stage 3 and 4 patients than in stage 1 and 2 patients.

Immunoblot analysis of several factors affecting cell death signaling related to oxidative DNA damage showed increased concentrations of iNOS and NFκB in patients infected with *H pylori* compared to patients who were tested negative for *H pylori* (Figure 2A-B). Furthermore, iNOS and NFκB concentrations were significantly higher in stage 3 and 4 patients than in stage 1 and 2 patients.

Although there were some increases in the concentrations of MEKK1 and Caspase-3 in the cancer tissue (Figure 2C-D), these changes were not statistically significant. In addition, no significant increases of MEKK1 and Caspase-3 in patients infected with *H pylori* were noted. The concentrations of Caspase-3 in stage 1 and 2 patients were significantly lower than those in stage 3 and 4 patients.

Among the anti-apoptosis-related proteins, there were some increases in the concentrations of Bcl-2 in the cancer tissue (Figure 2E). However, the changes were not statistically significant. In addition, no significant increase of Bcl-2 in patients infected with *H pylori* was noted. The concentrations of Bcl-2 in stage 1 and 2 patients were significantly lower than those in stage 3 and 4 patients. Mcl-1 and IAP concentrations were significantly higher in the cancer tissues than in the adjacent non-cancer tissues (Figure 2F-G). In addition, Mcl-1 and IAP concentrations were significantly higher in *H pylori*-positive patients than in *H pylori*-negative patients. Stage 3 and 4 patients had significantly higher concentrations of Mcl-1 and IAP than stage 1 and 2 patients.

Table 2 8-oHdG, iNOS, NFκB, Mel-1 and IAP Concentrations in cancer and adjacent non-cancer tissues

	Cancer tissue	<i>H pylori</i> (+)	Stages I & II	Stages III & IV
8-OHdG	a	a	-	a
iNOS	b	b	-	b
NF-κB	a	a	-	a
MEKK1	-	-	-	-
Caspase 3	-	-	b	-
Bcl-2	-	-	b	-
Mcl-1	a	a	-	a
IAP	a	a	-	a

: increase, : decrease, -: no significant change, ^a $P < 0.05$, ^b $P < 0.01$ compared with control, by one sample *t*-test and independent *t*-test, respectively.

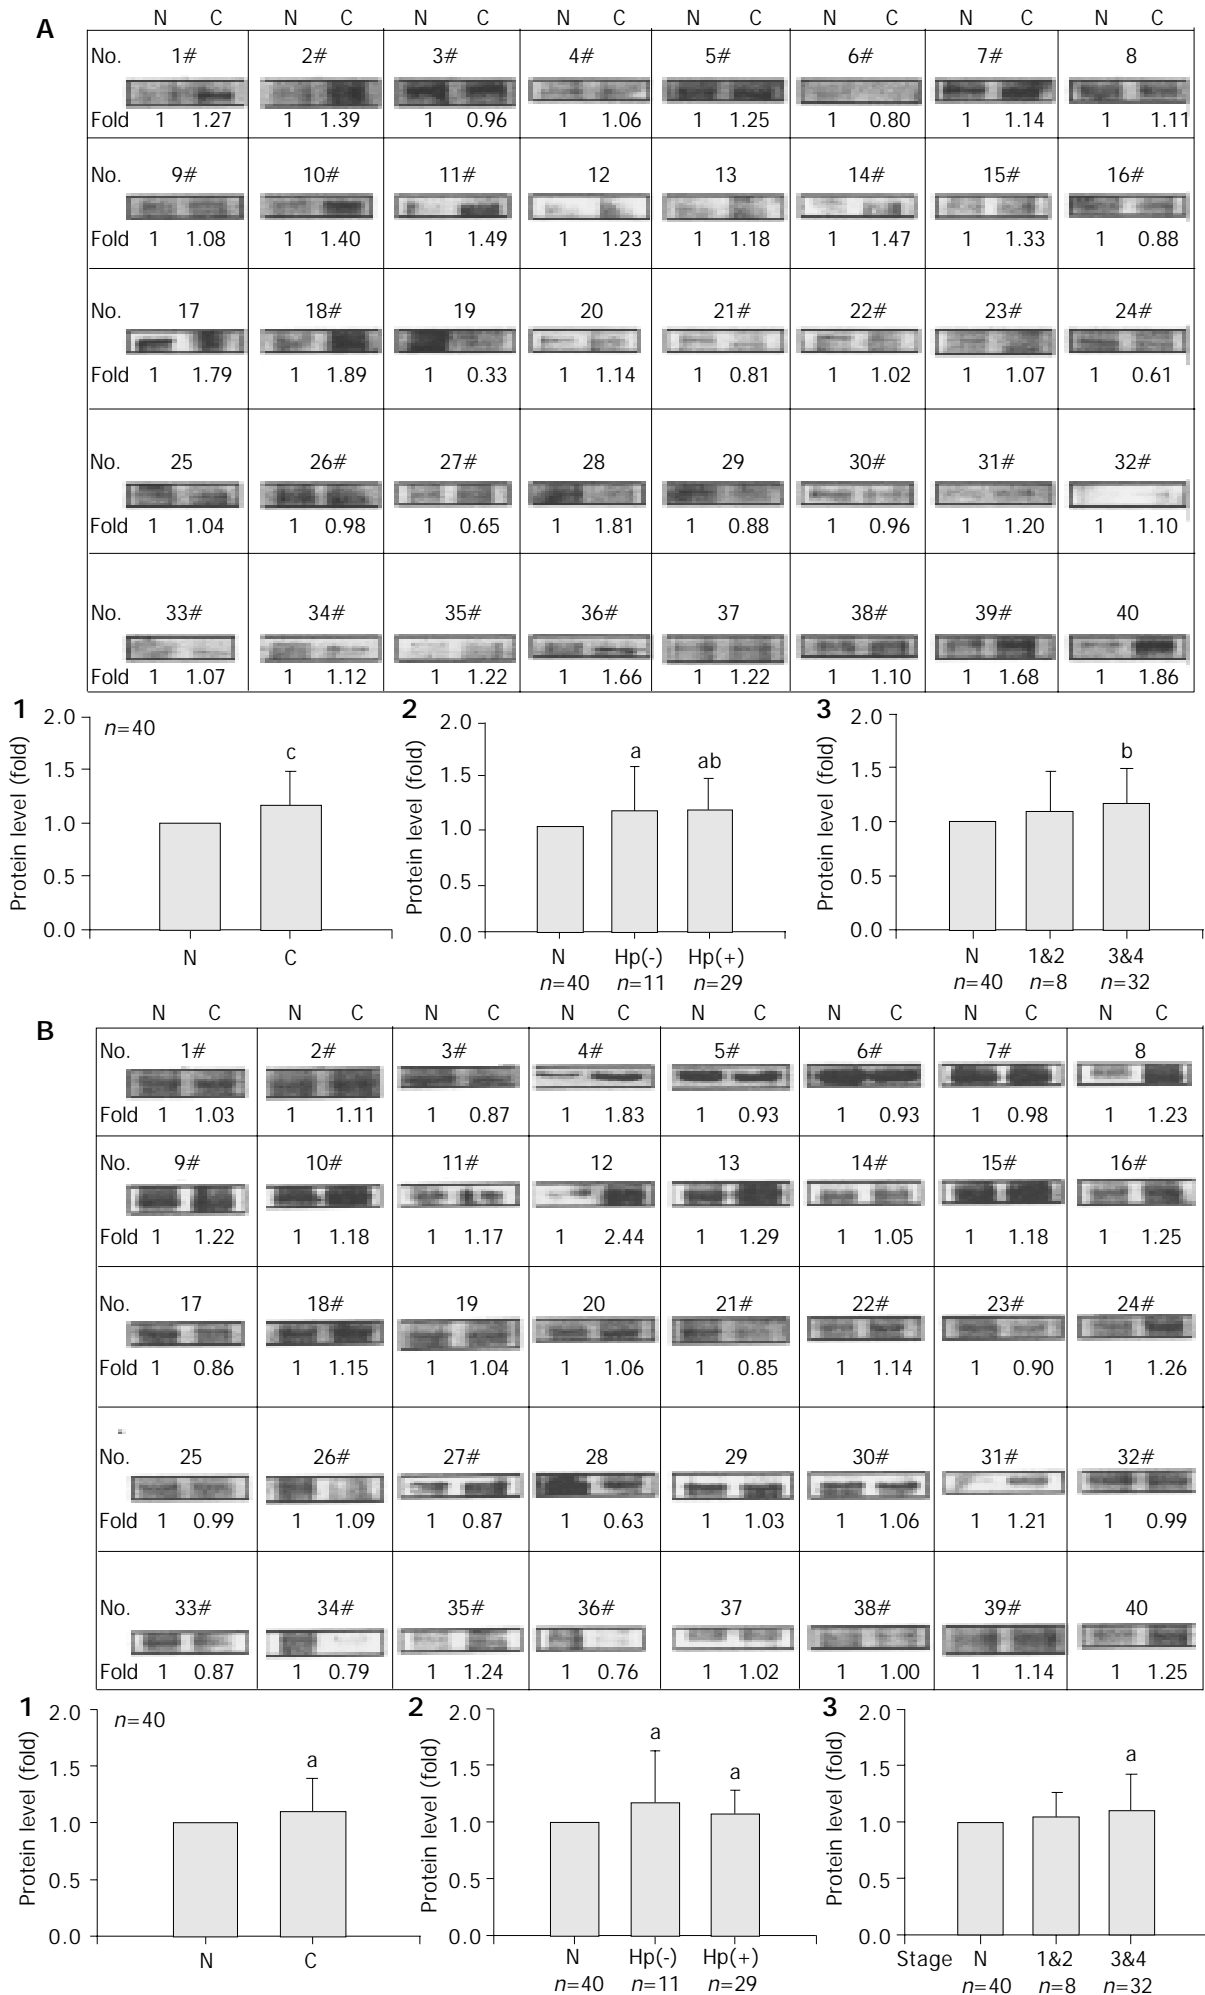

In summary, 8-OHdG, iNOS, NFκB, Mcl-1 and IAP concentrations were significantly higher in cancer tissues than in adjacent non-cancer tissues (Table 2). In addition, significantly higher concentrations of 8-OHdG, iNOS, NFκB, Mcl-1 and IAP were detected in patients infected with *H pylori* compared to patients who were not infected with *H pylori*.

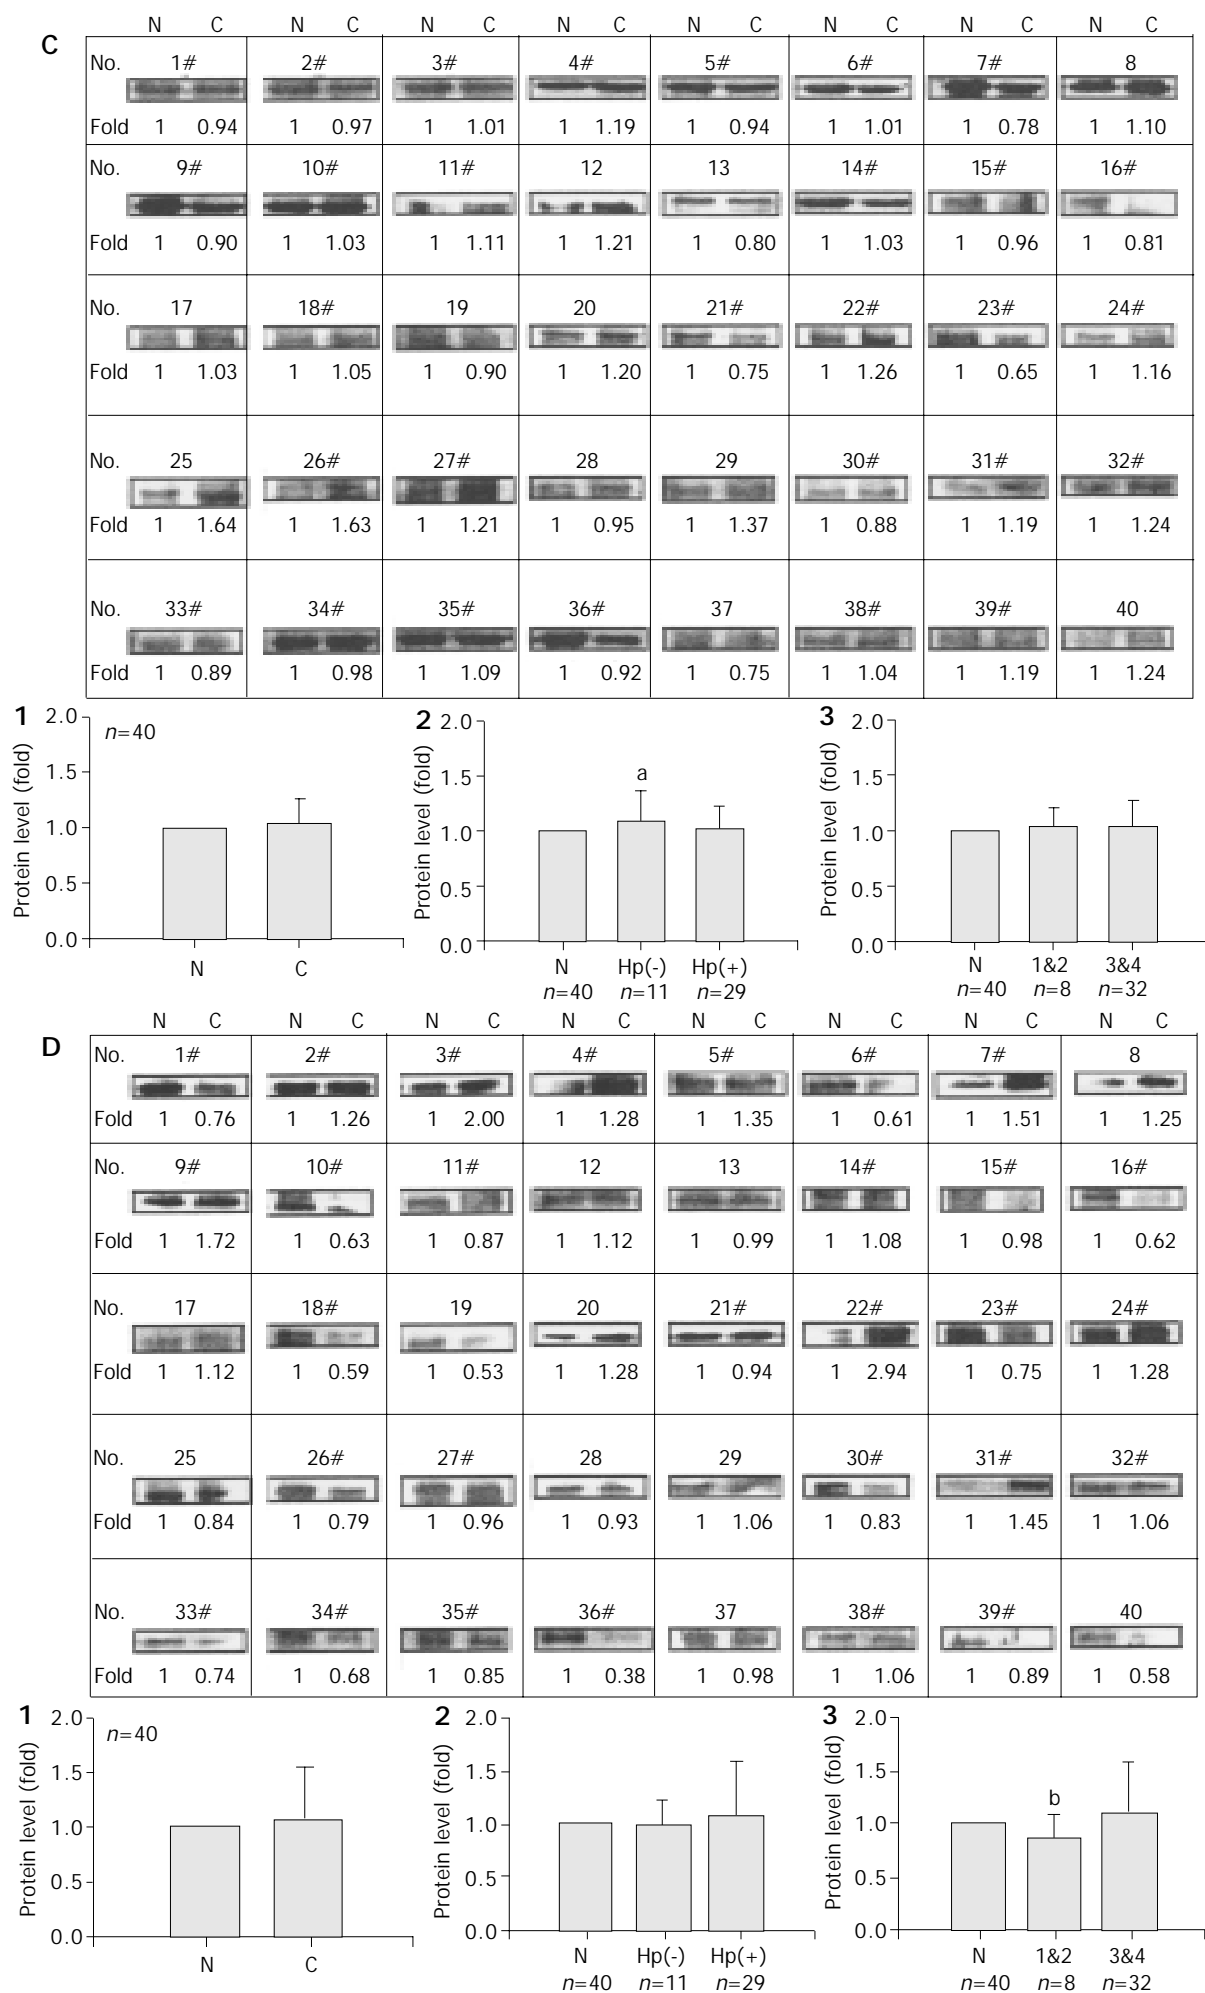

Furthermore, 8-OHdG, iNOS, NFκB, Mcl-1 and IAP concentrations were significantly higher in stage 3 and 4 patients than in stage 1 and 2 patients.

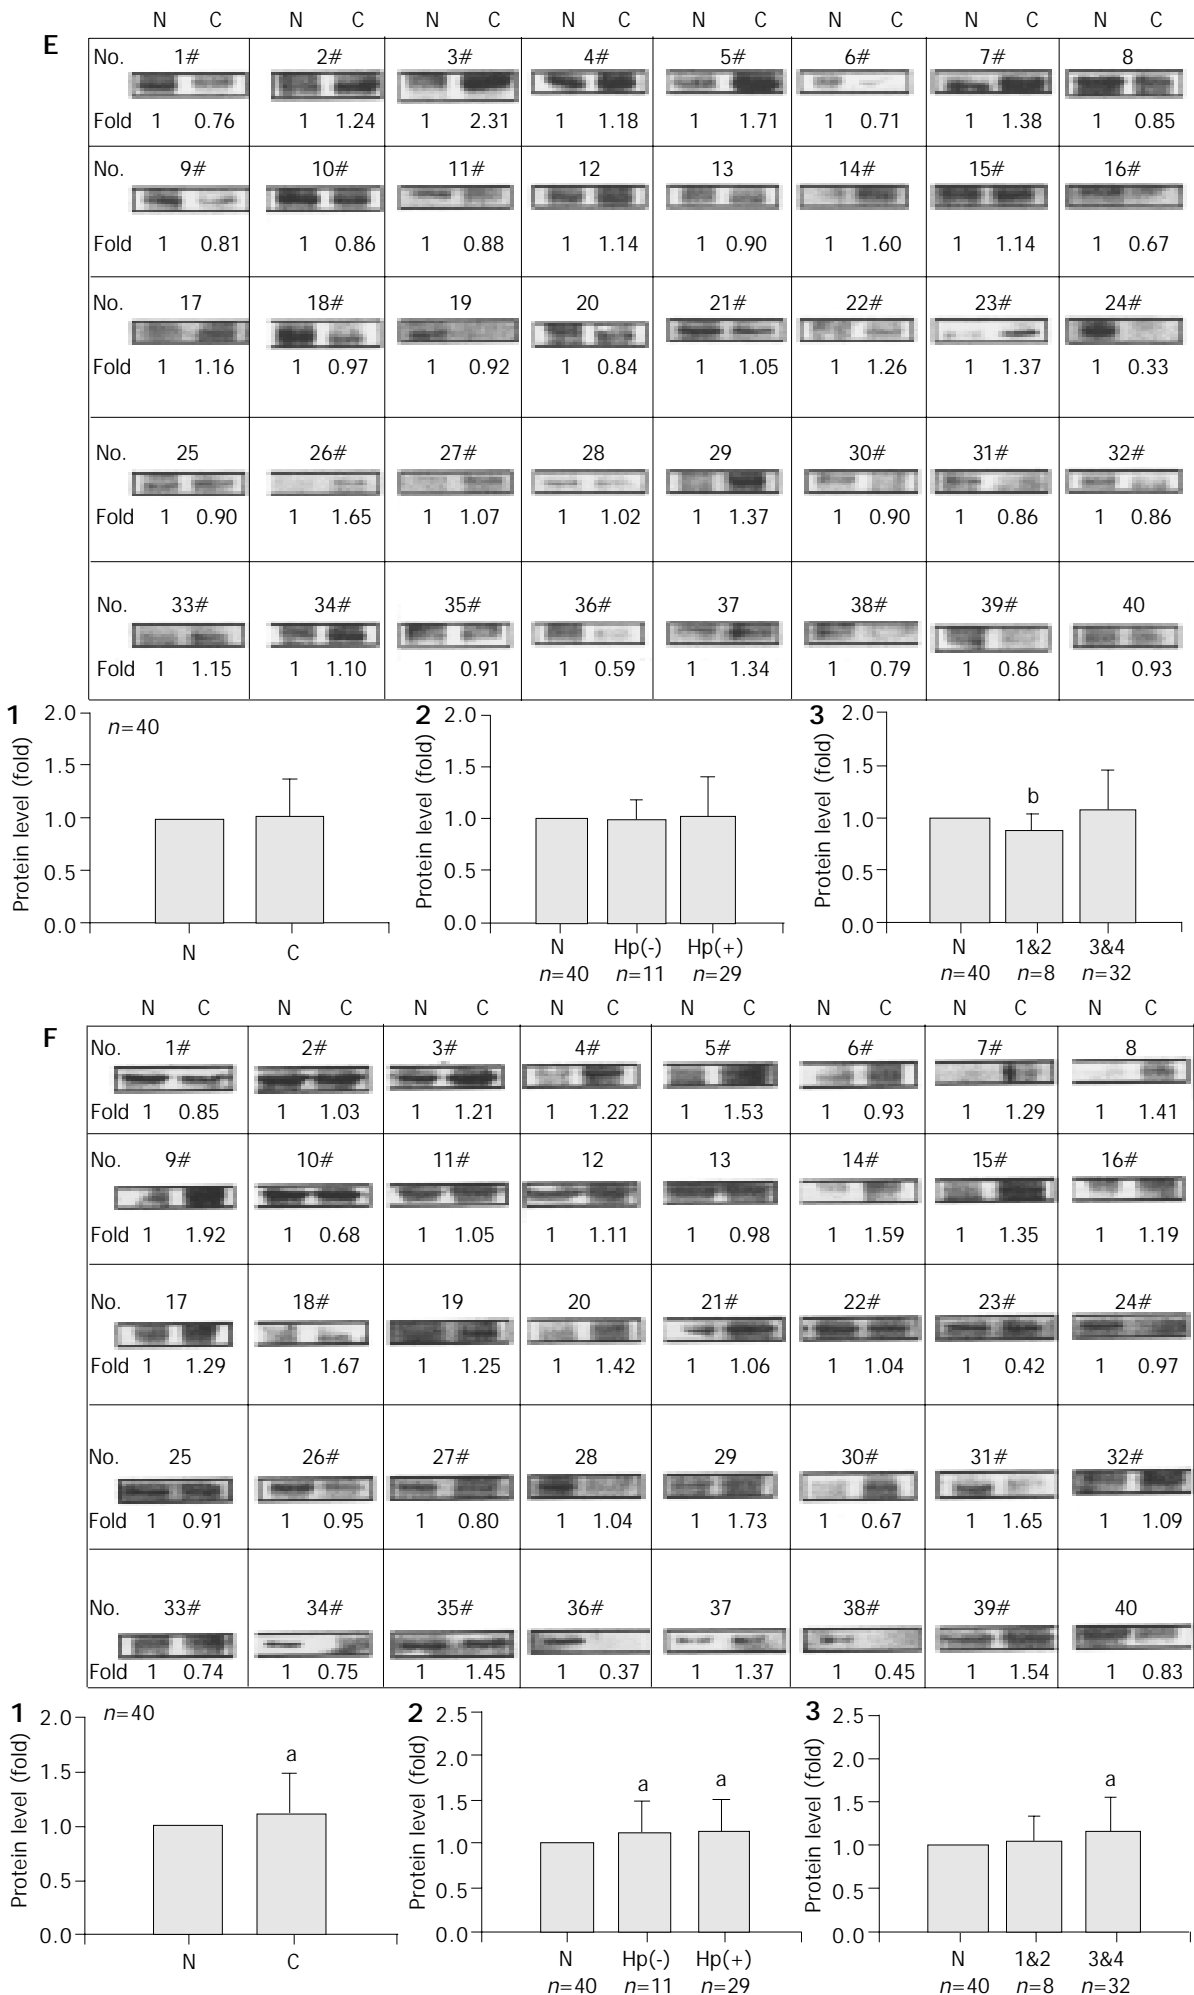

DISCUSSION

H pylori infection may influence the progression from chronic gastritis to adenocarcinoma of the distal stomach by a multifactorial, multistep process, in which chronic inflammation plays a major role. Free radical mediated oxidative DNA damage was involved in this process^[21-23]. The DNA damage provoked by oxygen free radicals can have very harmful consequences, leading to gene modifications that are potentially mutagenic and/or carcinogenic. Recently, 8-OHdG has been accepted as a sensitive marker for oxidative DNA damage in affected organs. Chronic gastritis due to *H pylori* infection is characterized by the accumulation of oxidative DNA damage measured by concentrations of 8-OHdG, indicating mutagenic and carcinogenic potential^[24]. In this study, we demonstrated an increase in the concentrations of 8-OHdG in cancer tissues. Furthermore, the increase was significantly higher in patients infected with *H pylori* as well as in patients with advanced gastric cancer. The increased level of oxidative DNA damage suggested a mechanistic link between *H pylori* infection and gastric carcinoma^[25,26].

H pylori-associated inflammation related to DNA damage is indicated by increased levels of oxidative DNA damage, increased occurrence of apoptosis, as well as increased expression of iNOS, which seemed to provide the mechanistic links between *H pylori* infection and gastric carcinogenesis^[27,28]. Upregulation of iNOS expression might contribute to the oxidative DNA damage observed during *H pylori* infection^[25]. Recent studies have shown that nitric oxide (production of iNOS) reacts rapidly with superoxide anions produced by *H pylori*-infected gastric tissues to form peroxynitrate, which could induce oxidative damage^[29]. This may increase the mutation rate in infected hyperproliferative gastric mucosa. In addition, the expressions of iNOS are closely related to tumor angiogenesis, and involved in progression of the disease as well as lymph node metastasis. Thus the expressions of iNOS might serve as indexes for evaluating staging of gastric carcinoma. In this study, we observed significantly higher increases in the concentrations of iNOS in patients infected with *H pylori* and in patients with advanced gastric cancer, compared with *H pylori*-negative patients and low stage gastric cancer patients, respectively.

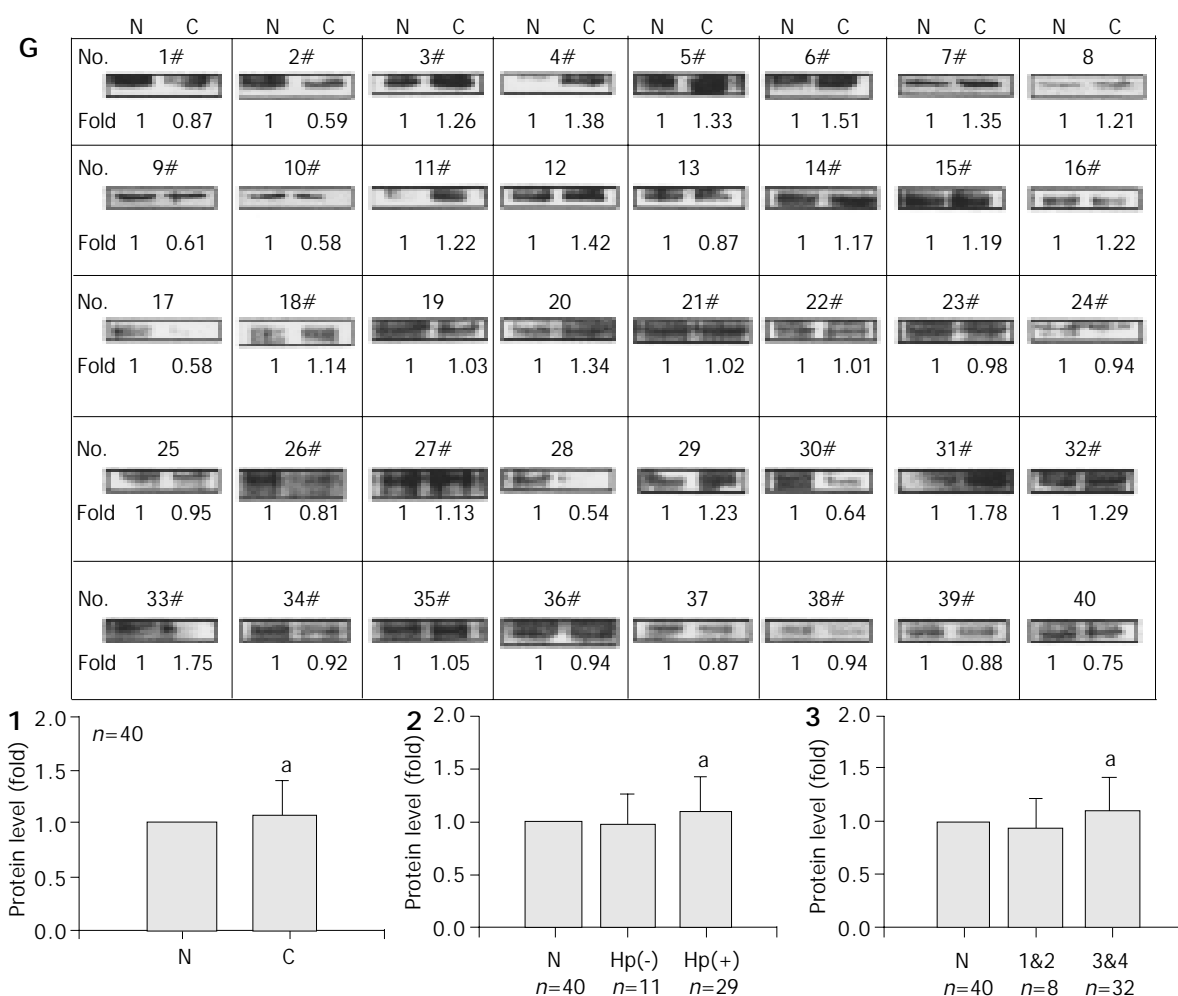

Figure 2 Immunoblot analysis of factors affecting cell death. A: Immunoblot analysis of iNOS. 1: Significantly higher concentrations of iNOS in cancer tissues compared with adjacent non-cancer tissues. 2: Significantly higher concentrations of iNOS in cancer tissues of patients with and without *H pylori* infection. 3: Significantly higher iNOS concentrations in stage 3 and 4 patients. #=*H pylori* infected, ^a*P*<0.05, ^b*P*<0.01, N: non-cancer tissue, C: cancer tissue, Hp(-): without *H pylori* infection, Hp(+): with *H pylori* infection, 1&2: gastric cancer stages 1 and 2, 3&4: gastric cancer stages 3 and 4. C: Immunoblot analysis of MEKK1. 1: Concentrations of MEKK1 in cancer tissues and adjacent non-cancer tissues. 2: Significantly higher concentrations of MEKK1 in cancer tissues of patients without *H pylori* infection. 3: No differences in MEKK1 concentrations in cancer tissues with different stages. #=*H pylori* infected, ^a*P*<0.05, N: non-cancer tissue, C: cancer tissue, Hp(-): without *H pylori* infection, Hp(+): with *H pylori* infection, 1&2: gastric cancer stages 1 and 2, 3&4: gastric cancer stages 3 and 4. D: Immunoblot analysis of Caspase 3. 1: Similar concentrations of Caspase 3 in cancer tissues and adjacent non-cancer tissues. 2: Similar concentrations of Caspase 3 in cancer tissues of patients with and without *H pylori* infection. 3: Significantly lower Caspase 3 concentrations in stage 1 and 2 patients. #=*H pylori* infected, ^b*P*<0.01, N: non-cancer tissue, C: cancer tissue, Hp(-): without *H pylori* infection, Hp(+): with *H pylori* infection, 1&2: gastric cancer stages 1 and 2, 3&4: gastric cancer stages 3 and 4. E: Immunoblot analysis of Bcl-2. 1: Similar concentrations of Bcl-2 in cancer tissues and adjacent non-cancer tissues. 2: No differences in concentrations of Bcl-2 in cancer tissues of patients with and without *H pylori* infection. 3: Significantly higher Bcl-2 concentrations in stage 1 and 2 patients. #=*H pylori* infected, ^b*P*<0.01, N: non-cancer tissue, C: cancer tissue, Hp(-): without *H pylori* infection, Hp(+): with *H pylori* infection, 1&2: gastric cancer stages 1 and 2, 3&4: gastric cancer stages 3 and 4. F: Immunoblot analysis of Mcl-1. 1: Significantly higher concentrations of Mcl-1 in cancer tissues in comparison with adjacent non-cancer tissues. 2: Significantly higher concentration of Mcl-1 in cancer tissues of patients with and without *H pylori* infection. 3: Significant higher Mcl-1 concentrations in stage 3 and 4 patients than #=*H pylori* infected, ^a*P*<0.05, N: non-cancer tissue, C: cancer tissue, Hp(-): without *H pylori* infection, Hp(+): with *H pylori* infection, 1&2: gastric cancer stages 1 and 2, 3&4: gastric cancer stages 3 and 4. G: Immunoblot analysis of IAP. 1: Significantly higher concentrations of IAP in cancer tissues compared with adjacent non-cancer tissues, 2: Significantly higher concentrations of IAP in cancer tissues with *H pylori* infection, 3: Significantly higher IAP concentrations in stage 3 and 4 patients #=*H pylori* infected, ^a*P*<0.05, N: non-cancer tissue, C: cancer tissue, Hp(-): without *H pylori* infection, Hp(+): with *H pylori* infection, 1&2: gastric cancer stages 1 and 2, 3&4: gastric cancer stages 3 and 4.

NFκB has been found to be a critical regulator of genes involved in inflammation, cell proliferation, and apoptosis^[30]. Recent studies suggested that NFκB might play a critical role in protecting cells against apoptosis^[31,32]. The magnitude of the stimulus and the cell type involved may determine whether

NFκB leads to cell survival or cell death. Maeda *et al.* reported cag PAI positive *H pylori* was capable of inducing apoptotic effects mainly through the mitochondrial pathway. Antiapoptotic effects mediated by NFκB activation were also observed by Maeda *et al.*^[33]. In this study, we revealed an

increase in the concentrations of NF κ B in cancer tissues. In addition, the increase was significantly higher in patients infected with *H pylori* as well as in patients with advanced gastric cancer compared with *H pylori*-negative patients and low stage gastric cancer patients, respectively.

Recent investigations implicated mitogen-activated protein kinases (MAPK) as additional mediators of *H pylori*-dependent NF κ B activation and IL-8 expression. Studies have demonstrated the presence of cross-talk between the MAPK and NF κ B pathways^[21-34]. MAPK cascades are signal transduction networks that target transcription factors and thus participate in a diverse array of cellular functions including cytokine production. In this study, there was an increase in the concentrations of MEKK1, a member of the MAPK signaling cascade in cancer tissues. However, the increase was not significant in all the studied patient groups.

Kanai *et al.* noted that transforming growth factor- α played an anti-apoptotic role in gastric mucosal cells by enhancing the expression of Bcl-2 family proteins via an NF κ B-dependent pathway^[35]. NF κ B is now known to upregulate transcription of several anti-apoptotic genes, including a cellular inhibitor of apoptosis, a Bcl-2 homolog, and cyclooxygenase-2, as well as pro-apoptotic genes, such as bax and p53. Tumor cells can have abnormal expression levels of factors such as Bcl-2 family proteins that slow the progression of apoptosis and elevate NF κ B-regulated transcription, which can inhibit TNF- α -induced apoptosis. However, in this study, no significant changes in the concentrations of Bcl-2 in cancer tissues or patients infected with *H pylori* were noted. Furthermore, upregulation of anti-apoptotic gene mcl-1 might play a role in interleukin-6-mediated protection of gastric cancer cells from the apoptosis induced by hydrogen peroxide^[36]. The anti-apoptotic role played by NF κ B also involves the ability of this transcriptional factor to induce expression of genes that promote cell survival, such as the genes coding for TRAF1, TRAF2, and the cellular inhibitors of apoptosis 1 and 2 (c-IAP1, c-IAP2)^[37]. In this study, we demonstrated an increase in the concentrations of IAP and Mcl-1, anti-apoptosis related proteins in cancer tissues. Furthermore, the increase was significantly higher in patients infected with *H pylori* as well as in patients with advanced gastric cancer, compared with *H pylori*-negative and non-advanced gastric patients, respectively. Therefore, enhanced antiapoptosis-related protein expression may contribute to disease progression.

Caspase3 is a member of the cell death effector (CED)-3 family, which is involved in the induction of apoptosis. Hoshi *et al.* reported Caspase 3 was involved in the development or regulation of apoptotic cell death in cell turnover of normal and neoplastic mucosa of the human stomach^[38]. These results indicate that gastric adenocarcinoma is associated with an inhibition of apoptosis and the augmentation of proliferative activity of tumor cells when compared to non-neoplastic gastric mucosa. However, in this study, there was no difference of increase in Caspase 3 between patients with or without *H pylori* infection or patients with or without advanced gastric cancer.

In conclusion, chronic *H pylori*-induced iNOS expression and subsequent DNA damage as well as signal transduction appear to make an important contribution to *H pylori*-related gastric carcinogenesis. This sequence of events found in this study supports the hypothesis that oxygen-free radical-mediated damage induced by *H pylori* plays a vital role in the development of gastric carcinoma in patients with chronic gastritis.

ACKNOWLEDGEMENT

Abstract

AIM: To determine whether *Saiko-keishi-to* (TJ-10), a Japanese herbal medicine, could protect liver injury induced by gut ischemia/reperfusion (I/R), and to investigate the role of NO.

METHODS: Male Wistar rats were exposed to 30-min gut ischemia followed by 60 min of reperfusion. Intravital microscopy was used to monitor leukocyte recruitment. Plasma tumor necrosis factor (TNF) levels and alanine aminotransferase (ALT) activities were measured. TJ-10 1 g/(kg·d) was intragastrically administered to rats for 7 d. A NO synthase inhibitor was administered.

RESULTS: In control rats, gut I/R elicited increases in the number of stationary leukocytes, and plasma TNF levels and ALT activities were mitigated by pretreatment with TJ-10. Pretreatment with the NO synthase inhibitor diminished the protective effects of TJ-10 on leukostasis in the liver, and the increase of plasma TNF levels and ALT activities. Pretreatment with TJ-10 increased plasma nitrite/nitrate levels.

CONCLUSION: TJ-10 attenuates the gut I/R-induced hepatic microvascular dysfunction and sequential hepatocellular injury via enhancement of NO production.

INTRODUCTION

Herbal medicines that have been used in China for thousands of years are now being manufactured in Japan as drugs containing ingredients of standardized quality and quantity. The clinical efficacy of these medicines has been utilized by Japanese Western-medicine practitioners for more than 20 years and is well recognized. One of the herbal medicines, *Saiko-keishi-to* (TJ-10) (Chinese name; *Chai-Hu-Gui-Zhi-Tang*), is a common drug to treat duodenal ulcer, pancreatitis, and chronic liver disease in Japan. It is an oral medicine and consists of 9 herb components: *Bupleurum* root, *Pinellia tuber*, *Scutellaria*

root, *Jujube* fruit, *Ginger rhizome*, ginseng root, cinnamon bark, peony root and *Glycyrrhiza* root. Another common herbal medicine, *Sho-saiko-to* (TJ-9), consists of 7 components of them: *Bupleurum* root, *Pinellia tuber*, *Scutellaria* root, jujube fruit, ginger rhizome, ginseng root, and *Glycyrrhiza* root. In a double-blind multicenter clinical trial, TJ-9 was reported to reduce the elevated serum activities of aspartate transaminase, alanine transaminase (ALT), and glutamyl transpeptidase in chronic active hepatitis patients^[1]. TJ-9 has been shown to improve liver function as well as the symptoms associated with chronic liver disease including digestive discomfort^[2]. Although TJ-10 has been often administered to patients with chronic liver disease as well as TJ-9, there are few epidemiological reports^[3], and little is known about mechanisms of its cytoprotective effects on liver damage. Recently, because of its major pharmaceutical effects, TJ-10 is presumed to gradually improve biological defense mechanisms. One of the components of TJ-10, *Saikosaponin*, has been reported to inhibit hepatocyte necrosis induced by galactosamine^[4], and *Saikosaponin-d* has been shown to reduce microsomal lipid peroxidation induced by NADPH and CCl₄^[5]. However, its mode of action has not been fully elucidated.

Nitric oxide (NO) has been found to be a modulator of the adhesive interactions between leukocytes, platelets, and endothelial cells^[6-9] as well as an important modulator of tissue blood flow, arterial pressure, and neurotransmission^[8], and NO-dependent cell-cell interactions have been demonstrated in tissues exposed to ischemia and reperfusion (I/R), an injury process in which leukocyte-endothelial cell adhesion plays a critical role. A role of NO in the pathobiology of I/R injury has been supported by observations that inhibition of NO biosynthesis could elicit most of the microvascular alterations observed in tissues exposed to I/R^[7,10], and NO-donating compounds have been shown to provide significant protection against the microvascular dysfunction that is normally associated with I/R^[7]. We developed a murine model of leukocyte-dependent hepatocellular dysfunction that was elicited by gut I/R^[11-13]. The model allows *in vivo* assessment of the effects of I/R on leukocyte sequestration in sinusoids of different regions of the liver lobule, leukocyte adherence in postsinusoidal venules, and the number of perfused sinusoids. Using this model, we have recently demonstrated that inhibition of both NO synthase and supplementation with exogenous NO could affect the leukocyte rolling, leukocyte adhesion, and sinusoidal perfusion elicited in the liver by gut I/R^[14-16].

Some herbal medicines have been reported to have an inducing effect on NO production by non-stimulated macrophages^[17]. We have recently reported that TJ-9 could attenuate the gut I/R-induced hepatic microvascular dysfunction and sequential hepatocellular injury via NO^[18]. However, little is known about the effect of TJ-10 on plasma NO levels and I/R injury *in vivo*. TJ-9 is contraindicated for liver cirrhosis, because of its side-effect, causing lung fibrosis. Since TJ-10 has 30% less *Saikosaponin* compared to TJ-9, it seems to be safer. Therefore, frequency and importance of TJ-10 are expected to increase in Japan. In the present study, we investigated whether TJ-10 modulated the gut I/R-induced microvascular dysfunction in the liver, and the role of NO in the responses by inhibiting NO synthase.

MATERIALS AND METHODS

Animals and surgical procedure

Male Wistar rats (200-250 g) were fed a standard rat chow for 2 wk, and TJ-10 (1 g/kg in saline) or saline alone was then administered for 7 d intragastrically through a tube. Experiments below were performed 18 h after the final dose of TJ-10 or saline. The rats were fasted for 18 h prior to each experiment, and then intraperitoneally anesthetized with pentobarbital sodium (35 mg/kg). The left carotid artery was cannulated, and a catheter was positioned in aortic arch to monitor blood pressure. The left jugular vein was cannulated for drug administration. All experiments were performed according to the criteria outlined in the National Research Council Guide.

Intravital microscopy

After laparotomy, one lobe of the liver was examined through an inverted intravital microscope (TMD-2S, Diaphoto, Nikon, Tokyo, Japan) and images were recorded with a silicon intensified target (SIT) camera (C-2400-08, Hamamatsu photonicus, Shizuoka, Japan). The liver was placed on an adjustable Plexiglas microscope stage and covered with a nonfluorescent coverslip that allowed observation of a 2 cm² segment of tissue. The liver was carefully positioned to minimize the influence of respiratory movements, and its surface was moistened and covered with cotton gauze soaked with saline. Images of microcirculation at the surface of the liver were observed through consecutive microfluorographs of hepatic microcirculation, that is, those of rhodamine-6G-labeled leukocytes in the sinusoids, were observed at 90 min after the onset of SMA occlusion and recorded on a digital video recorder. The number of stationary leukocytes was determined off-line during playback of videotape images. A leukocyte was considered to be stationary within the microcirculation (sinusoids) if it remained stationary for more than 10 s. The lobule, which had the fewest stationary leukocytes, was selected for observation at the basal condition. Stationary leukocytes were quantified in both the midzonal and pericentral regions of the liver lobule and expressed as the number per field of view (2.1×10⁵ μm²). The percentage of non-perfused sinusoids was calculated as the ratio of the number of non-perfused sinusoids to the total number of sinusoids per microscopic field.

Experimental protocols

We observed the surface of liver for 10 min before ligating the superior mesenteric artery to ensure that all parameters measured on-line were in a steady state. The superior mesenteric artery was then ligated for 0 (sham) or 30 min with a snare created from a polyethylene tube. At the end of the ischemic period, the ligation was gently removed. Leukocyte accumulation and the number of non-perfused sinusoids (NPS) were measured before ischemia, immediately following reperfusion, and every 15 min for 1 h thereafter. In one set of experiments, 7 untreated animals, and 5 TJ-10-treated animals in the control groups (sham gut I/R) and gut I/R groups were used. In another set of experiments in which TJ-10 was administered, the rats were given a NO synthase (NOS) inhibitor, N^G-monomethyl-L-arginine (L-NMMA; Sigma, St. Louis, MO) (0.5 mg/kg, i.v.) 30 min before the onset of ischemia. These experiments were performed with 5 animals in each group. In some experiments, the rats were given dexamethasone (2 mg/kg, Sigma, St. Louis, MO) with or without L-NMMA (0.5 mg/kg, i.v.) 30 min before the onset of ischemia. These experiments were performed with 5 animals in each group.

Tumor necrosis factor and endotoxin assay

Sixty min after the onset of reperfusion, blood plasma samples

for tumor necrosis factor (TNF) detection were collected from the inferior vena cava at a point proximal to the hepatic vein. Plasma TNF concentration was determined in a microtiter plate using a TNF immunoassay kit (BioSource International, Camarillo, CA) based on enzyme-linked immunosorbent assay (ELISA) as described in our previous study^[19]. Plasma endotoxin levels were measured by endospecy (an endotoxin-specific chromogen, Seikagaku Co., Tokyo, Japan) according to our previous report^[20].

Enzyme and nitrite/nitrate assay

Blood samples for enzyme activities were collected from the carotid artery 6 h after the onset of reperfusion. Serum ALT activity was determined by conventional UV methods as previously described^[21]. Blood samples for nitrite/nitrate assay were collected from the inferior vena cava 16 h after the last administration of TJ-10 (saline as control). The combined levels of nitrite and nitrate in plasma were determined by a previously reported method^[22]. Five separate experiments were performed.

Statistical analysis

The data were analyzed by standard statistical methods, i.e., ANOVA and Scheffe's (post hoc) test. All values were reported as mean±SD. *P*<0.05 was considered statistically significant.

RESULTS

Figure 1A shows the effects of TJ-10 and/or L-NMMA on the gut I/R induced leukostasis in sinusoids of the midzonal and pericentral (including the terminal hepatic venule [THV]) regions of the liver lobule (panel A), and the entire liver lobule (sinusoids + THV, panel B). In control rats, gut I/R elicited significant increases in the number of stationary leukocytes compared to basal values. Pretreatment with TJ-10 blunted the gut I/R-induced leukostasis in the midzonal (untreated+I/R: 9.6±0.6, TJ-10+I/R: 3.6±0.6, per field) and the pericentral regions (untreated+I/R: 6.0±0.7, TJ-10+I/R: 3.6±0.5, per field). L-NMMA diminished the protective effect of TJ-10 in the pericentral region (5.6±0.2, per field), but did not significantly affect the gut I/R-induced leukostasis in the midzonal region or the entire liver lobule.

Figure 1B shows the effect of TJ-10 and/or L-NMMA on the gut I/R-induced elevation of plasma TNF levels. In the control rats, gut I/R elevated the plasma TNF-α levels. Pretreatment with TJ-10, however, blunted the gut I/R-induced elevation of plasma TNF-α levels (untreated+I/R: 140.8±12.6, TJ-10+I/R: 61.7±22.5 ng/L). L-NMMA diminished the protective effects of TJ-10 (113.2±13.7 ng/L).

Figure 1C shows the effect of TJ-10 and/or L-NMMA on the gut I/R-induced elevation of serum endotoxin levels. In the control rats, gut I/R elevated the serum endotoxin levels. Pretreatment with TJ-10, however, blunted the gut I/R-induced elevation of serum endotoxin levels (untreated+I/R: 39.2±8.1, TJ-10+I/R: 11.1±3.3 ng/L). L-NMMA diminished the protective effects of TJ-10 (34.7±5.3 ng/L).

Figure 1D illustrates the effect of TJ-10 and/or L-NMMA on the gut I/R-induced elevation of plasma ALT activities. In the control rats, gut I/R elevated the plasma ALT activities. Pretreatment with TJ-10, however, blunted the gut I/R-induced elevation of plasma ALT levels (untreated+I/R: 146.6±13.0, TJ-9+I/R: 76.0±7.0 IU/L). L-NMMA diminished the protective effects of TJ-10 (123.2±11.9 IU/L).

Table 1 shows the effects of TJ-9 and TJ-10 on plasma nitrite/nitrate levels. Pretreatment with TJ-10 increased the plasma nitrite/nitrate levels as well as TJ-9.

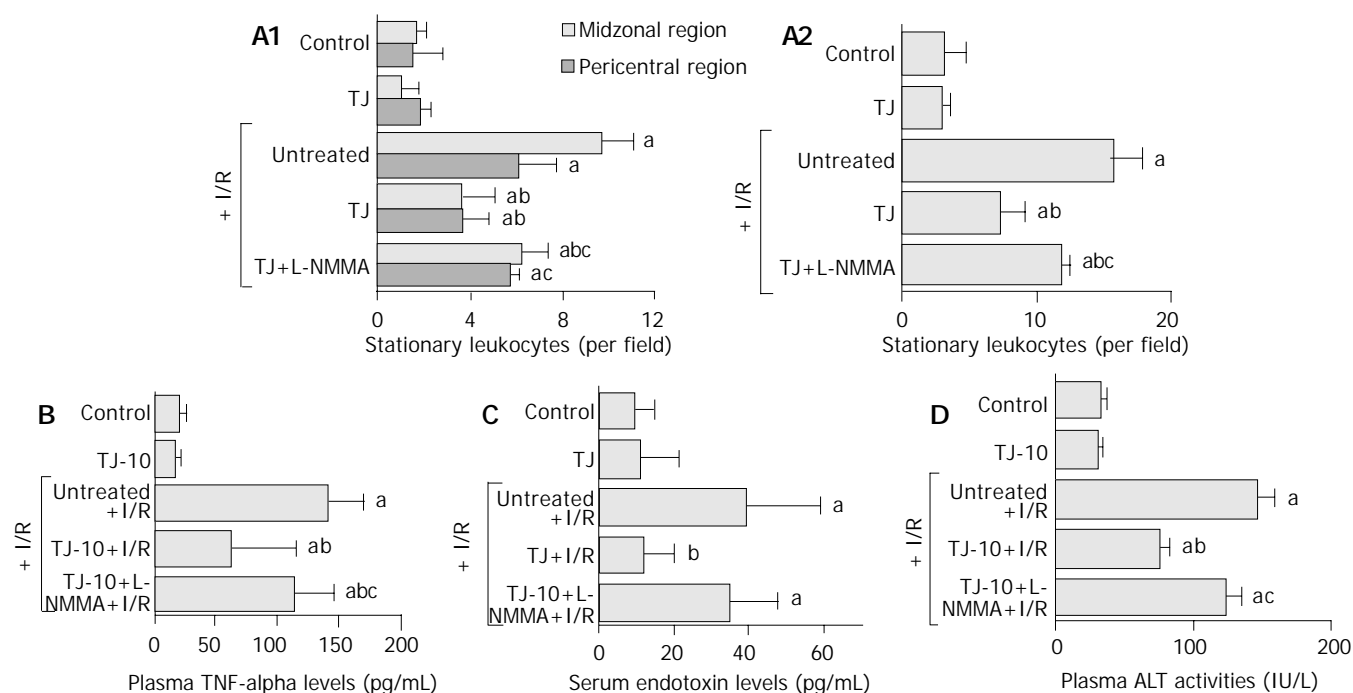

Figure 1 Effects of Saiko-keishi-to (TJ-10) and/or an NO synthase inhibitor (N^G-monomethyl-L-arginine, L-NMMA) on the number of stationary leukocytes, plasma TNF- α levels, serum endotoxin levels, and plasma ALT activities. A: In each region (the midzonal and pericentral regions) (panel A) and the entire (combined) liver lobule (panel B) after 30 min of gut ischemia and 60 min of reperfusion; B: Plasma TNF- α levels at 60 min after gut I/R; C: Serum endotoxin levels at 60 min after gut I/R; D: Plasma ALT activities at 6 h after gut I/R.

Table 1 Effects of Sho-saiko-to (TJ-9) and Saiko-keishi-to (TJ-10) on plasma nitrite/nitrate levels ($n = 5$)

Group	Plasma nitrite/nitrate levels
Control	17.1 \pm 2.9
TJ-9	35.8 \pm 4.3 ^a
TJ-10	39.0 \pm 4.0 ^a

^a $P < 0.05$ vs control.

DISCUSSION

Herbal medicines are widely used in Japan. The clinical efficacy of these medicines has been utilized by Japanese Western-medicine practitioners for more than 20 years and is well recognized. In cases of gastroenterological and hepatological diseases, they are often used for patients with chronic liver disease as well as gastrointestinal functional disorder. Although TJ-9 has been the most famous herbal medicine for chronic liver disease in Japan, TJ-10 is another common drug to treat duodenal ulcer, pancreatitis, and chronic liver disease. TJ-10 has effectiveness for more kinds of diseases rather than TJ-9. Indeed, the components of TJ-10 include all of the 7 components of TJ-9. Although TJ-10 has been often administered to patients with chronic liver disease as well as TJ-9, there were few epidemiological reports^[3], and little is known about mechanisms of the cytoprotective effects on liver damage.

Previously published work has demonstrated that reperfusion of the ischemic small intestine could elicit an acute inflammatory response both in the intestine and in distant organs, such as the liver^[11,12,23] and lung^[23,24]. In the liver, the response was characterized by leukocyte plugging of sinusoids, leukocyte adherence in postcapillary venules, a reduction in the number of perfused sinusoids, hepatocellular hypoxia, and leakage of enzymes (ALT) from hepatocytes^[11,12,23,25]. Recently, we have reported that TJ-9 could attenuate the gut I/R-induced responses in the liver^[18]. In the present study, it was demonstrated that TJ-10 had a similar effect to TJ-9 on the gut

I/R-induced responses in the liver. NO has been found to be a modulator of the adhesive interactions between leukocytes, platelets, and endothelial cells^[6-9], and NO-dependent cell-cell interactions have been demonstrated in tissues exposed to ischemia and reperfusion (I/R), an injury process in which leukocyte-endothelial cell adhesion plays a critical role. Depletion and/or inactivation of NO has been implicated as a key event in the recruitment of leukocytes in tissues exposed to I/R^[26-28]. We previously demonstrated that treatment with L-NMMA resulted in exaggerated leukostasis and cellular injury in the murine liver after gut I/R and that increased delivery/generation of NO in the liver via a NO donor attenuated the inflammatory responses and microvascular dysfunction elicited in the liver by gut I/R^[13]. These results suggest a protective effect of NO on the gut I/R-induced responses in the rat liver. The finding in the present study that L-NMMA diminished the protective effect of TJ-10 on the increase in plasma TNF- α and serum endotoxin levels, leukostasis in the liver, and plasma ALT activities, suggested that TJ-10 could prevent the gut I/R-induced cytokine production and microvascular dysfunction in the liver by elevating sinusoidal NO level. NO could modulate leukocyte- and/or platelet-endothelial cell interactions^[6,9,13,14]. Since pretreatment with TJ-10 actually increased plasma nitrite/nitrate levels in the present study, the increase in NO production by hepatocytes and macrophages after treatment with TJ-10 appeared to be involved in the cytoprotective effects of TJ-10.

In the present study, L-NMMA diminished the protective effect of TJ-10 on the increase in plasma TNF- α and serum endotoxin levels, leukostasis in the liver, and plasma ALT activities. While, in the previous study^[18], L-NMMA did not affect the protective effect of TJ-9 on the increase in leukostasis in the midzonal region, the total number of stationary leukocytes, or the plasma ALT activity. One likely interpretation is that a mechanism other than the increase in NO production mediates the protective effects of TJ-9. Steroids have been known to prevent reperfusion injury^[29]. The evidence in our previous study^[18] that L-NMMA did not affect either TJ-9- or dexamethasone-induced decrease in the gut I/R-elevated plasma

ALT activities, raises a possibility that TJ-9-increased blood corticosterone level may prevent the gut I/R-induced microvascular and hepatocellular injury. Since L-NMMA diminished the protective effect of TJ-10 on the gut I/R-induced increase in plasma ALT activities, corticosteroid effect was not involved in the prevention of gut I/R-induced hepatocellular injury by TJ-10. *Kampo* (herbal medicines) prescriptions affect as the complex. For example, though one of the components in TJ-10, cinnamon bark, which is not included in TJ-9, had a very strong anti-oxidant effect, there was no significant difference between TJ-9 and 10 in the potential for anti-oxidation^[30]. Thus, our results suggest that TJ-10 has different characteristics from TJ-9, even including all components of TJ-9.

Recently, the importance of the way of traditional diagnosis "Sho" in the use of *Kampo* prescriptions has come to be widely described even in package insert drug information pamphlets of *Kampo* prescriptions. "Sho" is judged comprehensively by a complex of subjective and objective symptoms at a certain point of illness. The process is generally complicated, but we sometimes diagnose by tonus felt on the abdomen. Namely, hypertonus is "Jitsu Sho", and hypotonus is "Kyo Sho". General fatigue, sleepiness, sleepless, appetite loss, tiredness of eyes, easily catching cold, dizziness, looking pale, and so on are symptoms of "Kyo Sho". TJ-10 suits for "Kyo Sho" rather than TJ-9. Moreover, most patients with chronic hepatitis have "Kyo Sho". TJ-10 prevents microvascular dysfunction in the liver increase in NO production. Symptoms of "Kyo Sho" described above seem to be caused by microvascular dysfunction. Taken together, TJ-10 is recommended for chronic hepatitis patients with "Kyo Sho".

Although further studies are required to clarify the mechanisms of the protective effects of TJ-10 on reperfusion injury, this study has demonstrated the protective effect of TJ-10 on reperfusion injury via NO.

Abstract

AIM: To investigate *KAI1* gene expression in the progression of human colonic carcinoma and its clinical significances.

METHODS: *KAI1* expression was detected by *in situ* hybridization and immunohistochemistry in the 4 established cell lines of colorectal carcinoma with different metastatic potentials, and in 80 specimens of colonic carcinoma, 21 colonic carcinoma specimens with lymphatic metastasis and 20 controls of normal colonic mucosa.

RESULTS: The expressions of *KAI1* in HT29 and SW480 cell lines were higher than those in LoVo and SW620. The expression of *KAI1* gene was significantly higher in colorectal carcinoma compared with normal colonic mucosa and lymphatic metastasis ($\chi^2=46.838$, $P<0.01$). The expression of *KAI1* gene had no relationship with histological grade. The *KAI1* expressions in Dukes A and B carcinoma were higher at both mRNA and protein levels compared to Dukes C carcinoma ($\chi^2=16.061$, $P<0.05$). The expression of *KAI1* in colonic carcinoma specimens with lymphatic metastasis was almost lost. The results of *in situ* hybridization were in concordance with immunohistochemistry.

CONCLUSION: *KAI1* is highly related to the metastasis of colonic carcinoma and may be a useful indicator of metastasis in colonic carcinoma.

INTRODUCTION

Colorectal carcinoma is one of the most common forms of malignancy, and metastasis is the major cause of mortality in human population. Timely and precise identification of the occurrence of metastasis and its contributive factors are very important in the enhancement of prognosis and effects of treatment. *KAI1* gene was first identified in human prostate carcinoma and mapped to human chromosome 11p11.2^[1]. It encodes 267 amino acids belonging to plasma membrane glycoprotein, which consists of 4 transmembrane domains and

1 large and 1 small extracellular domains. The extracellular domains have 3 potential N-glycosylation sites. According to its special structure, it may be predicted that the function of *KAI1* gene may come down to cell-cell adherence and cell-matrix connection^[2]. The role of *KAI1* in tumor progression may not be limited to prostatic cancer. It was reported to be important in preventing the development of metastases in a wide variety of human tumor types, including cervical^[3], breast^[4], pancreatic^[5], esophageal^[6], bladder^[7], and ovarian cancers^[8]. In the present study, the expression of *KAI1* was detected by *in situ* hybridization in 4 cell lines of colorectal carcinoma, and in paraffin-embedded normal colonic epithelium, carcinoma, and lymphatic metastasis. The purpose was to explore the relationship between *KAI1* expression and colonic carcinoma metastasis and its clinical significances.

MATERIALS AND METHODS

Cell lines and culture conditions

LoVo and HT29 cell lines were cultured in RPMI 1640 supplemented with 100 mL/L heat-inactivated fetal bovine serum (FBS) and 100 U/mL penicillin/streptomycin. SW480 and SW620 were cultured in DMEM medium supplemented with the 100 mL/L FBS. All cells were grown in 50 mL/L CO₂ humidified atmosphere at 37 °C.

Tissue specimens

A total of 80 colonic carcinoma specimens, 20 normal colonic mucosa samples and 20 lymphatic metastasis samples were obtained from Nanfang Hospital. All the samples were routinely fixed in 40 g/L formaldehyde solution, embedded in paraffin, and cut into 4 μ m thick sections. Samples were selected according to the pathological diagnosis and reviewed by a pathologist to confirm the diagnosis.

In situ hybridization (ISH) assays

The digoxigenin-labeled *KAI1*-cDNA probe for *in situ* hybridization was prepared as described in one of our previous papers^[9]. The ISH was performed according to the instruction of the enhanced sensitive ISH detection kit (purchased from Boster Biotechnology Company). Briefly, the sections were deparaffinized with xylene, dehydrated with graded ethanol and incubated in 30 mL/L H₂O₂ to block endogenous peroxidases for 30 min at room temperature. After being treated for 10 min with Triton X-100 and for 40 s with 3% pepsin, the sections were prehybridized for 3 h and hybridized overnight at 37 °C. The final concentrations of the labeled probes were 0.15 ng/ μ L. After hybridization, excess probes were removed through rinsing in 2 \times SSC (1 \times SSC is 0.15 mol/L NaCl plus 0.015 mol/L sodium citrate pH 7.0), 0.5 \times SSC, 0.2 \times SSC, respectively. The sections were incubated with an antidigoxigenin antibody conjugated biotin for 120 min at room temperature and then added strept-avidin biotin complex for 30 min. For color reaction, diaminobenzidine (DAB) was used. If the ISH signals were present, the cytoplasm would be full of brown granules. For ISH of the four colorectal carcinoma cell lines, the cells were incubated and grown on cover slip for 24 h, fixed with 950 mL/L

ethanol and washed with PBS (phosphate-buffered saline pH 7.2) 3 times, and then carried out ISH as described above. For negative controls, the digoxigenin-labeled KAI1-cDNA probe was replaced by prehybridized solution.

Immunohistochemical assays

To confirm the results of *KAI1* gene expression on *in situ* hybridization, immunohistochemical studies were performed as described previously^[9,10]. Briefly, the fixed cells and sections were subjected to immunostaining by using an ultrasensitive streptavidin-peroxidase technique (Maixin Biotechnology Company). Endogenous peroxidases were blocked by incubating with 5 mL/L H₂O₂ for 30 min at room temperature. The cells and sections were subsequently treated for 10 min with Triton X-100 and for 40 s with 30 g/L pepsin. The cells and sections were incubated for 30 min at 37 °C with normal nonimmune serum before overnight incubation at 4 °C with specific monoclonal KAI1-antibody (BD pharmingen technical company) at a dilution of 1:100. The cells and sections were then treated with biotin-conjugated second antibody before adding streptavidin-peroxidase. For color reaction, diaminobenzidine was used. If the positive signals were present, the cytoplasm and membrane were stained brown. For negative controls, the monoclonal KAI1 antibody was replaced by PBS.

Review and scoring of the section

The stained sections were reviewed and scored independently by two pathologists under Olympus microscope. The different degrees of intensity of staining were graded on a scale of 0 to 3 as follows: 0 indicated that the number of positive cells was less than 10%; 1 indicated weak positive and the number of positive cells more than 10%, but less than 30%; 2 indicated positive and the number of positive cells more than 30% but less than 50%; 3 indicated strong positive and the number of positive cells more than 50%.

Statistical analysis

Fisher's exact probability test was adopted to examine the relationship between the variables. A *P* value <0.05 was considered statistically significant.

RESULTS

KAI1 gene expression in colorectal carcinoma cell lines

HT29 and SW480 cell lines were derived from primary colorectal adenocarcinoma. SW620 and LoVo cell lines were established from metastatic colorectal carcinoma. Especially, SW620 cell line was isolated from the same case as was SW480 cell line. The expressions of KAI1 mRNA and protein in HT29 and SW480 cells were positive, whereas those in SW620 and LoVo cells were negative (Figures 1, 2).

Figure 1 *In situ* hybridization detection of expression of KAI1 mRNA in colorectal carcinoma cell lines (Original magnification: $\times 400$). A: In HT29 cells, the positive expression (brown granule) was located in cytoplasm; B: In SW480 cells, the positive expression was located in cytoplasm; C: In SW620 cells, the expression of KAI1 mRNA was negative; D: In LoVo cells, the expression of KAI1 mRNA was negative.

Figure 2 Expression of KAI1 protein detected by immunohistochemistry in colorectal carcinoma cell lines (Original magnification: $\times 400$). A: In HT29 cells, the positive expression located in cytoplasm and membrane; B: In SW480 cells, the positive expression located in cytoplasm and membrane.

Heterogeneous expression of *KAI1* mRNA in colonic carcinoma tissue

Of the 80 colonic carcinoma specimens, 56(70%) were classified as *KAI1* positive (Figure 3). There were 4 cases (20%) with positive *KAI1* mRNA expression in normal colonic mucosa and 2 cases (10%) in lymphatic metastasis. The results are shown in Table 1. The positivity ratio was significantly higher in colonic carcinoma than that in normal colonic mucosa and in lymphatic metastasis ($\chi^2=46.838$, $P<0.01$). The expression in lymphatic metastasis was almost lost.

To further investigate the relationship between the expression of *KAI1* and the clinical pathology, we sorted the colonic carcinomas based on histological grades and Dukes stages. Histological grade I means well differentiated adenocarcinoma, II means moderately differentiated and III means poorly differentiated. The results indicated that *KAI1* expression had no relationship with histological grades ($\chi^2=3.887$, $P>0.05$). The expression in Dukes A and B carcinoma was markedly higher in comparison with Dukes C carcinoma ($\chi^2=16.061$, $P<0.01$).

KAI1 protein expression analyzed by immunohistochemistry

There were 52(65%) cases with positive *KAI1* protein expressions in the colonic carcinomas (Figure 3). The positive ratios of normal colonic mucosa and lymphatic metastasis were 25% and 10%, respectively. The *KAI1* expressions in 3 groups were significantly different ($\chi^2=28.298$, $P<0.01$). Overall, the immunohistochemical results agreed well with those from the *in situ* hybridization assays.

DISCUSSION

Loss of the function of metastasis suppressor genes is an important step in the progression of a tumor type. Several candidate antimetastasis or anti-invasion genes have been studied in colorectal carcinoma, including nm23^[11], E-cadherin^[12], and CD44^[13], but inconsistent findings have been reported. For example, in separate studies, nm23 expression has been found to be directly correlated, not to be correlated, or inversely correlated with metastatic potential in colorectal cancer^[14-16]. *KAI1* has been thought to be one of such metastasis suppressor genes, because it was shown to suppress the ability of human prostatic cancer cells to metastasize when the tumor was transplanted into nude mice^[1] and because *KAI1* mRNA expression was reduced in advanced pancreatic cancer^[17] so that the pancreatic cancer cells spread to lymph nodes and distant organs. Furthermore, the transfer of the *KAI1* gene into mammary cancer cells has been shown to lead to suppression of their metastatic potential, whereas their primary tumor growth has not been affected^[18-20].

KAI1 is a member of the transmembrane-4 superfamily (TM4SF), many of which, including *KAI1*, are CD antigens present on the surface of leukocytes^[21,22]. At least three TM4SF members are implicated in metastasis, including CD9/MRP-1, CD63/ME491, and CD82/*KAI1*^[23]. *KAI1* and other TM4SF members, such as integrins and E-cadherin, have been demonstrated to bind to each other and relay extracellular signals to signal transduction pathways that are important in cellular adhesion, invasive motility, and metastasis^[24-27].

In our previous studies, we transfected the *KAI1* cDNA

Figure 3 *In situ* hybridization and immunohistochemical detection of *KAI1* mRNA and protein in colonic carcinoma (Original magnification: $\times 400$). A: *In situ* hybridization detection found that strong *KAI1* mRNA staining was located in cytoplasm (brown granule); B: Detection by immunohistochemistry showed strong *KAI1* protein staining was in cytoplasm and membrane.

Table 1 *KAI1* gene expression in normal colonic mucosa, colonic carcinoma and lymphatic metastasis *n* (%)

Tissue	KAI1/CD82 expression				Total
	0	1	2	3	
Normal colonic mucosa	16(80.0)	3(15.0)	1(5.0)	0	20
Colonic carcinoma					
Histological grade					
I	6(23.1)	2(7.7)	12(46.2)	6(23.1)	26
II	10(26.3)	12(31.6)	14(36.8)	2(5.3)	38
III	8(50.0)	6(37.5)	2(12.5)	0	16
Dukes stage					
Dukes A	1(4.3)	6(26.1)	9(39.1)	7(30.4)	23
Dukes B	3(17.6)	6(35.3)	5(29.4)	3(17.6)	17
Dukes C	20(50.0)	10(25.0)	8(20.0)	2(5.0)	40
Lymphatic metastasis	18(90.0)	2(10.0)	0	0	20

into a colorectal carcinoma cell line, LoVo, and found that the KAI1 transfectant exhibited significantly increased homotypic cell adhesion and suppressed invasion and metastasis^[9]. Our findings were consistent with those in the studies of prostatic cancer^[2] and breast cancer^[18] cells.

In this study, we first investigated KAI1 mRNA expression in 4 colorectal carcinoma cell lines and found *KAI1* gene expression was much higher in HT29 and SW480 cell lines than in SW620 and LoVo cell lines. SW480 was isolated from a high-grade primary colonic tumor, and SW620 was isolated from a metastatic lymph node from the same patient 1 year later at the time of clinical relapse. KAI1 protein expression was high in SW480 but reduced in SW620. The colonic cancer cell line derived from metastatic lesions, LoVo, hardly exhibited any expression. In our observation we found that *KAI1* gene expressions both at mRNA and protein level, were inversely correlated with the metastatic potential of some established colorectal carcinoma cell lines.

We next examined KAI1 expression in normal colonic mucosa, carcinoma and lymphatic metastasis by *in situ* hybridization. The results indicated that KAI1 gene was highly expressed in colonic carcinoma compared with normal colonic epithelium and lymphatic metastasis. We found that although the expression had no relationship with histological grades, it was significantly correlated with Dukes stages. This indicates that the KAI1 mRNA expression may be positively related with the Dukes stages. The data shown in Table 1 demonstrate that KAI1 expression increases at an earlier tumor stage of colonic carcinoma, while decreases at advanced stages, and is possibly lost in metastases. That is to say, the expression of KAI1 has a reverse correlation with metastasis in colorectal carcinoma.

How does reduced TM4SF expression cause changes of invasive ability of tumor cells? It was hypothesized that tetraspanins might be implicated in the assembly of integrin-contained signaling complexes, thus modulating the function of integrin receptors in cell migration^[24]. Some results indicated that integrin-tetraspanin protein complexes played an important role in regulating protrusive activity of the tumor cells and contributed to extracellular matrix-induced production of matrix metalloproteinase 2 (MMP-2), and as a consequence, the invasive ability of cells^[28].

KAI1 has been extensively studied for its involvement in the progression of different human cancers. The mechanism of down-regulation of KAI1 has also been analyzed, however, much debate still exists. Recent study found a putative p53 consensus-binding site within the promoter region of KAI1 and demonstrated that the loss of p53 function, which was commonly observed in many types of cancer, led to the down-regulation of the *KAI1* gene, which might result in the progression of metastasis^[29]. But other data suggested that the down-regulation of KAI1 was not associated with either mutation, allelic loss, methylation of the promoter, or p53 regulation^[30]. Our previous study also demonstrated that mutation of the KAI1 gene, methylation of CpG islands and the abnormality of p53 were not related to low expression of KAI1.

In conclusion, KAI1 expression increases in an earlier tumor stage of colonic carcinoma, decreases in advanced stages, and is possibly lost in lymphatic metastases. The loss of KAI1 expression is correlated with higher stage, a surrogate marker for metastatic potential. The down-regulation of KAI1 in Dukes C and loss in metastasis demonstrate that loss of KAI1 expression occurs in cancer progression. The selection of cells that have the ability to spread from the primary tumor to the metastasis may favor those cells that have lost KAI1 expression. Those cells would be expected to be less adhesive, more invasive, and more motile^[31], and these characteristics are necessary for metastasis.

Abstract

AIM: Recent studies in both rodents and humans indicated that bone marrow (BM)-derived stem cells were able to home to the liver after they were damaged and demonstrated plasticity in becoming hepatocytes. However, the question remains as to how these stem cells are activated and led to the liver and where the signals initiating the mechanisms of activation and differentiation of stem cells originate. The aim of this study was to investigate the influence of serum from liver-damaged rats on differentiation tendency of bone marrow-derived stem cells.

METHODS: Serum samples were collected from rats treated with a 2-acetylaminofluorene (2-AAF)/carbon tetrachloride (CCl₄) program for varying time points and then used as stimulators of cultured BM stem cells. Expression of M₂- and L-type isozymes of rat pyruvate kinase, albumin as well as integrin-β1 were then examined by reverse transcription polymerase chain reaction (RT-PCR) to estimate the differentiation state of BM stem cells.

RESULTS: Expression of M₂-type isozyme of pyruvate kinase (M₂-PK), a marker of immature hepatocytes, was detected in each group stimulated with experimental serum, but not in controls including mature hepatocytes, BM stem cells without serum stimulation, and BM stem cells stimulated with normal control serum. As a marker expressed in the development of liver, the expression signal of integrin-β1 was also detectable in each group stimulated with experimental serum. However, expression of L-type isozyme of pyruvate kinase (L-PK) and albumin, marker molecules of mature hepatocytes, was not detected in groups stimulated with experimental serum.

CONCLUSION: Under the influence of serum from rats with liver failure, BM stem cells begin to differentiate along a direction to hepatocyte lineage and to possess some features of immature hepatocytes.

INTRODUCTION

Recent studies in both rodents and humans indicated that bone marrow (BM) stem cells were able to home to the liver after they were damaged, and demonstrated plasticity in becoming hepatocytes^[1-4]. Questions remain as to how BM stem cells are activated and led to the liver and where the signals initiating the mechanisms of activation and differentiation of stem cells originate. Transfused oval cells (hepatic stem cells) that had a selective tropism for the liver in an animal model of liver-damage suggested that "signal molecules" were present in serum of this animal model and played an important role in mediating both hepatic and non-hepatic stem cell activation^[5]. However, the influence of these putative signal molecules in serum on the differentiation state of bone marrow-derived stem cells is yet unclear. The purposes of the present work were to confirm the existence of signaling molecules in serum of liver-damaged rats and to observe its effects on the differentiation of BM stem cells into hepatocytes.

MATERIALS AND METHODS

Establishment of animal model of liver-damage

Male Sprague-Dawley (SD) rats, 6-week-old, were used for the establishment of an animal model of liver-damage. The model was made by means of a 2-AAF/CCl₄ program according to Petersen^[1]. In experimental group, 2-acetylaminofluorene (2-AAF, Sigma), 2.5 g/L in earthenut oil, was administered to stomach of rats everyday for 7 d. On the 7th d of 2-AAF administration, an Ld50 dose of CCl₄ was given by intraperitoneal injection. Animal blood was taken at the time points of 2, 4, 8, 12, and 24 h after CCl₄ injection. Experimental serum was prepared on standby. The serum from normal animals was used as control.

Isolation and culture of bone marrow stromal cells

The SD rats were sacrificed by means of ether asphyxia. Bone marrow was collected from tibiae and BM cells were suspended in Dulbecco's modified Eagle's medium (DMEM) with fetal bovine serum. After centrifugation and re-suspension, the cells were seeded in a culture flask and cultured under a routine condition (37 °C, 50 mL/L CO₂). The solution of medium was changed every 4 d while the cells floating on the medium were discarded. The cells adhering to bottom of the flask (so-called BM stromal cells) were cultured sequentially for 12-14 d. After 3 population doublings, the purified cells were harvested and used in the following stimulating culture with experimental serum.

Stimulating culture of BM stromal cells with experimental serum

BM stromal cells were cultured sequentially in a specialized medium (DMEM-F12) containing 3 mL/L experimental rat serum. In the control group, the culture medium contained 3 mL/L normal rat serum instead of experimental rat serum. Cultures were grown and submerged for 12 d. The cells were harvested on the 13th culture day for ribonucleic acid (RNA) isolation.

Table 1 Primer pairs for RT-PCR

Marker genes	Primer pairs	PCR fragments
M ₂ -PK	5'ccatctaccactgacgttattcga3' / 5'tcatggtagcaggcactacacgc3'	431 bp
L-PK	5'acctctgccttctggatactgact3' / 5'tgcaagactccggttcgtatct3'	322 bp

Isolation of RNA

RNA was extracted from the cells collected from the cultures described above, according to the protocol of QIAGEN RNA easy mini kit. RNA samples were then stored at -80 °C.

Primers selection

Genes of M₂-type and L-type isozymes of rat pyruvate kinase (M₂-PK, L-PK), albumin and integrin-β1 (INT-β1) were selected as the markers representing different differentiation stages of hepatocyte lineage. The gene of glyceraldehyde-3-phosphate-dehydrogenase (GAPDH) was used as an internal control for RT-PCR reactions. Primer pairs used for RT-PCR are shown in Table 1.

RT-PCR reactions

RNA samples were first reversely transcribed into cDNA, and then used as templates in the following PCR reactions. The

reaction cocktails (containing 1 μg template cDNA, 50 μmol/L dNTPs, 400 μmol/L primers, 1×PCR buffer, 2.5 mmol/L MgCl₂, 1 U Taq-polymerase, add H₂O to 50 μL of total volume) were run on GeneAmp® PCR System 9600 (AB) with a combined program of program 1 (at 94 °C for 5 min), program 2 (at 95 °C for 1 min, at 60 °C for 1 min, at 72 °C for 1 min; 30 cycles), and program 3 (at 95 °C for 1 min, at 60 °C for 1 min, at 72 °C for 5 min). The PCR products were electrophoresed in 12 g/L agarose gel, stained with ethidium bromide, and photographed.

RESULTS

M₂-PK, as a marker of immature hepatocytes, was used to estimate the differentiation state of BM stem cells stimulated by the experimental serum. The results showed that the expression signals of M₂-PK were detected in each group

stimulated with experimental serum, but not in the control group of normal BM stem cells that had no stimulation, BM stem cells stimulated with control serum, and normal mature hepatocytes (Figure 1A). Integrin- β 1 is a marker expressed during the development of liver. In this study, its expression signals were also detectable in each group stimulated with experimental serum as those observed in the positive control of hepatocytes (Figure 1B). L-PK and albumin, as marker molecules of mature hepatocytes, were used to estimate the terminal differentiation state of BM stem cells under the influence of experimental serum. However, no signals were detected in the experimental groups, except for the positive control of hepatocytes (Figure 1C, D).

DISCUSSION

The existence of liver stem cells had been widely proved in both rodents and humans^[1-4,6-9]. By extension, liver stem cells could be divided into three groups: (1) mature hepatocytes that proliferate during normal liver tissue renewal and after less severe liver damage, (2) oval cells that are activated to proliferate when the liver damage is extensive and chronic, and (3) exogenous liver stem cells that may derived from bone marrow cells and respond to severe liver damage^[10]. However, in a narrow sense, the concept of liver stem cells is usually limited to hepatic oval cells and non-hepatic bone marrow stem cells.

A phenomenon that was often observed both in experimental animal models and in clinics was that the proliferation of liver stem cells occurred most often in conditions of severe liver damages or chronic liver diseases^[11-15]. Maybe it is the reason that stem cells were seldom detected in healthy livers. Thus it can be understood that liver-damage is an important prerequisite for activation of liver stem cells. This suggests that the signals initiating activation of hepatic or non-hepatic stem cells might originate from damaged livers. This hypothesis had been partially proved by our previous experimental work^[5]. In our previous experiments, oval cells isolated from male SD rats were transfused, through caudal vein into the circulatory system of a female rat with liver damage. Sex-determining gene *sry* that was located on Y chromosome was then examined respectively by PCR and *in situ* hybridization technique in the liver, kidney and spleen of experimental animals. The results of cell-transplant experiments showed that *sry* gene was detectable only in the liver but not in the spleen and kidney of rats with liver damages and that no signals could be detected in control animals, neither in the liver, spleen nor in the kidney. It could be also morphologically observed that some exogenous cells with *sry* marker migrated into the parenchyma of liver and settled there, suggesting that transfused oval cells had a selective tropism for damaged liver. These results also suggested that signaling molecules existed in the serum of animals with liver damage and might play a role in mediating stem cell activation.

In the present study, an animal model of liver-damage was established with a 2-AAF/CCl₄ program. In this model, the capacity of hepatocyte self-regeneration was first impaired by 2-AAF and then the liver was damaged severely by CCl₄. In this status, the damaged liver would likely produce a signal to initiate the activation of stem cells in the bone marrow. The results of the present study showed that the expression of M₂-PK, a marker of immature hepatocyte^[16-22], could be detected in each group stimulated with experimental serum, but not in any of the control groups. Integrin- β 1 is a marker expressed during the development of liver. Its expression could be detected in fetal hepatocyte as early as at 8th wk of gestation^[30]. In the present results, the expression signal of integrin- β 1 was also detectable in each group stimulated with experimental

serum. Thus, the functional state of BM-derived stem cells was changed under the influence of experimental serum, thus differentiating toward the direction of a hepatocyte lineage. Although the markers of a mature hepatocyte, L-PK and albumin were not detectable in stimulated BM stem cells, the leap from an undetermined state to a determined state was a marker of entry into the process of programmed differentiation. A variety of possibilities could account for the lack of detectable signals for L-PK and albumin in stimulated BM stem cells. Among the possibilities, one could be the deficiency in intensity and time of stimulation, while another could, by reasoning, be that the postulated "signal molecules" existing in the experimental serum were involved only in the early activation and determination of BM stem cells, while the terminal differentiation of the cells into hepatocytes might still need other signals.

The results in the present study indicated that the driving force promoting differentiation of BM stem cells to hepatocytes was certainly generated from the serum of rats treated by 2-AAF/CCl₄. It has been further testified that some "signal molecules" were existed in the circulation of rats treated by 2-AAF/CCl₄ and that they might play an important role in the initiation of activation of stem cell. It would be helpful for understanding the mechanisms of stem cell differentiation if the "signal molecules" could be further identified and isolated.

Recent studies have convincingly demonstrated that adult bone marrow contains cells capable of differentiating into hepatocyte-like cells. Nevertheless, what type of cell population are the ancestor cells for hepatocytes still remains a question. In the vast majority of reports, hematopoietic cells were considered to be capable of "transdifferentiating" into hepatocytes^[2,4,23-28]. However, Wagers (2002) deemed that there was little evidence for transdifferentiation of adult hematopoietic stem cells^[29]. The present study showed that bone marrow stromal cells demonstrated the plasticity in changing into hepatocytes. By this token, the debate about origin of liver stem cells will keep on.

Abstract

AIM: To explore the pathophysiological significance of delayed type hypersensitivity (DTH) reaction in mouse gastrointestinal tract induced by an allergen 2,4-dinitrochlorobenzene (DNCB).

METHODS: BALB/c mice were randomly divided into control and DTH₁₋₆ groups. After sensitized by DNCB smeared on the abdominal skin, the mice were challenged with DNCB by gavage or enema. The weight, stool viscosity and hematochezia were observed and accumulated as disease active index (DAI) score; the gastrointestinal motility was represented by active charcoal propulsion rate; the colon pathological score was achieved by macropathology and HE staining of section prepared for microscopy; and the leukocyte migration inhibitory factor (LMIF) activity was determined by indirect capillary assay of the absorbance (A) of migrated leukocytes.

RESULTS: Active charcoal propulsion rates of small intestine in the DNCB gavages groups were significantly higher than that in the control group ($P < 0.01$). The DAI scores and pathological score in DNCB enema groups were also higher than that in the control group ($P < 0.05$), and there were significant rises in LMIF activity in DNCB enema groups as compared with control groups ($P < 0.01$).

CONCLUSION: Mouse gastrointestinal DTH reaction could be induced by DNCB, which might facilitate the mechanism underlying the ulcerative colitis.

INTRODUCTION

The gastrointestinal tract (GI) is not only an important organ in digestion and endocrine, but also the largest peripheral

immunological organ in the body^[1]. The secretory immunoglobulin A (s-IgA) and T cell are responsible for developing mucosa vaccines and producing oral tolerance^[2,3]. Furthermore, the manifestation of T cell mediated reaction in GI tract was most often in the way of delayed-type hypersensitivity (DTH), thereby resulting in ulcerative colitis^[4,5]. 2,4-dinitrochlorobenzene (DNCB), a chemical compound of low molecular weight, could combine with tissue protein to function as a full antigen in activating T cell mediated DTH reaction, such as skin DTH^[6] and colon inflammation/ulcer^[5,7,8]. Gastrointestinal DTH (or colitis) induced by DNCB in rabbit, guinea pig and rat has been reported^[5,7,8], but that in mice has not been reported. In this study, DNCB-induced DTH in mice GI tract were found, and its pathophysiological significance was discussed.

MATERIALS AND METHODS

Animals

Healthy male BALB/c mice weighing 18-21 g (supplied by the Department of Experimental Animals, Peking University Health Science Center) were used. Animals were fed with a standard diet and allowed free access to water.

Preparation of major chemicals

DNCB solution For DNCB sensitization, 330 mg DNCB (Beijing Chemical Reagent Company, Beijing, P.R. China) was dissolved in 10 mL of acetone-olive oil (1:1) vehicle. For DNCB gavage, 300 mg DNCB was first mixed with a minimum volume of polysorbate 80, and a minimum volume of ethanol was added until the mixture was completely dissolved, followed by the addition of olive oil to achieve a final DNCB concentration of 6.6 g/L. The ratios of polysorbate 80-ethanol-olive oil in this vehicle were 6.6%, 8.8% and 84.6%, respectively. Then the 6.6% solution was diluted to 1.3 g/L and 0.3 g/L DNCB solution. For DNCB enema, DNCB was dissolved in 600 mL/L ethanol to achieve 4 g/L, 2 g/L, and 1 g/L DNCB solution, separately. All these DNCB solutions were stored at 4 °C.

Activated charcoal suspension The suspension was made according to Qi *et al.*^[9] with a little modification. A total of 6 g activated charcoal (Tianjin 6th Chemical Reagent Company, Tianjin, China) and 2 g astragalum gum (Beijing Chemical Reagent Company, China) were dissolved in 50 mL of normal saline (NS) just before intragastric use.

RPMI 1640 One milliliter of RPMI 1640 culture medium contained 100 IU penicillin and 100 µg streptomycin, and then the pH was adjusted to 6.8-7.2.

Phytohemagglutinin (PHA) A 100 mg PHA was dissolved in 10 mL incomplete RPMI1640, and then sterilized and preserved at -20 °C.

Ammonium chloride solution (erythrocyte lytic fluid) A total of 1.03 g Tris and 3.735 g NH₄Cl were dissolved in 500 mL distilled water.

Induction of DTH response in GI tract

Grouping Ninety-six BALB/c mice were randomly divided into 10 groups, including DTH₁₋₆, DTH negative (DTH₋) group and control group.

Sensitization On the first day of experiment, mouse fur on abdomen (2.5 cm diameter) was shaved. A total of 50 μ L of 33 g/L DNCB was smeared on the shaved skin once a day for 1 or 4 d. Mice in the DTH₍₋₎ and control groups were smeared with acetone-olive oil vehicle.

Gavage All the mice were fasted for 6 h before gavage. On the second day of experiment the mice in DTH₁, DTH₂ and DTH₃ groups were gavaged with 0.8 mL of 0.3 g/L, 1.3 g/L and 6.6 g/L DNCB, respectively. The DTH₍₋₎ group was gavaged 1.3 g/L DNCB and the control group was gavaged polysorbate 80-ethanol-olive oil vehicle. On the third day, 0.8 mL of activated charcoal was gavaged to each mouse. Twenty minutes later, the mice were killed by decapitation for determination of gastrointestinal motility.

Enema On the 5 th day, a silica-gel tube with 10 mm diameter was inserted into the colons of the mice, its tip being 3-3.5 cm far from the anus. The mice in DTH₄, DTH₅ and DTH₆ groups were intracolonicly administered 1 g/L, 2 g/L and 4 g/L DNCB (2 μ L/g) once a day for 4 d. DTH₍₋₎ group was administered 2 g/L DNCB and the control group was administered 600 mL/L ethanol vehicle.

Evaluation of the animals

Gastrointestinal motility After each mouse was killed, the whole small intestine was taken out, rinsed with NS quickly, and the intestinal wall was cut open longitudinally, laid and unfolded on a flat plate for estimation of the active charcoal migration distance (cm). The gastrointestinal motility was expressed by charcoal propulsion rate by using the formula: charcoal propulsion rate = migration distance of active charcoal / the distance from pylorus-duodenum junction to ileocecum $\times 100\%$.

Body mass and stool By using disease activity index (DAI) score^[10], the body mass and stool were scored as follows: Body mass: score 0-normal; score 1-1-5% lower than normal; score 2-6-10% lower than normal; score 3-11-15% lower than normal; and score 4-above 15% lower than normal. Stool viscosity: score 0-normal; score 2-fluffy; and score 4-diarrhea. Stool hemorrhage: score 0-normal; and score 2-apparent hemorrhage.

Pathological score On the 9 th d, all the mice received enema were killed by cervical dislocation. The colon was cut open longitudinally along the attachments of mesenteries and was first macropathologically observed. Then specimens were taken from inflammatory/ulcerative colon and were fixed in 40 g/L formaldehyde. Paraffin-embedded 5- μ m thick section was made for HE staining. The macropathological score and microscopy score were obtained by adopting Dr. Murano's method^[10] with slight modification as follows: Macropathological score: score 0-no cementation (colon was easily detached from other tissues) and no inflammation in colon; score 1-moderate cementation or local congestion; score 2-severe cementation with one ulcer (<1 cm); score 3- more than one ulcer (<1 cm) with inflammation; and score 4-more than one ulcer (>1 cm) with inflammation.

Microscopy: score 0-normal colon mucosa or slight congestion; score 1-mucosa hyperemia, infiltration of chronic inflammatory cells and decrease of the number of goblet cell in colon mucosa; score 2-mucosa hyperemia, infiltration of chronic inflammatory cells and local superficial erosion; and score 3-atrophic change with ulcer and serious infiltration of chronic inflammatory cells in colon mucosa.

Measurement of leukocyte migration inhibitory factor (LMIF) activity

LMIF preparation By following our previous method^[11], the spleen lymphocytes (2×10^6 /mL) of mice received enema were cultured in PHA (60 μ g/mL) for 72 h. Then the supernatant containing LMIF component was collected by centrifugation

(1 500 r/min, 15 min), followed by lyophilization. The lyophilized powder was stored at -20 °C. Working solution (LMIF solution) was prepared by dissolving the lyophilized powder in RPMI-1640 to one third of its original volume before using.

Preparation of peripheral leukocytes A suspension of indicator cells (migrated leukocytes) was prepared from the anti-coagulated whole blood of guinea pigs. Three percent gelatin of 1/3 volume of the blood was added to the blood before culturing the sample at 37 °C for 30 min. The upper layer rich in leukocytes was taken out and centrifuged (1 000 r/min) for 10 min. Then the sediment was washed twice with Hanks' solution free of Mg^{2+} and Ca^{2+} , and again centrifuged (1 000 r/min) for 10 min. Finally, the sediment was used as the indicator cell and was adjusted to a concentration of $(1.6-1.8) \times 10^7$ cells/mL RPMI 1640.

Detection of leukocyte absorbance By following our previous work^[11] with a little improvement, the leukocyte was injected into a capillary tube of 80 μ L volume. After heat-sealing one end of the tube and spinning at 1 000 r/min for 10 min, the tubes were cut at the liquid-cell interface. The portion containing the cells was placed inside each chamber of a 24-well plate filled with 210 μ L LMIF solution for culture. Twelve hours later, 200 μ L solution was taken out from each chamber and was put in an well of a 96-well plate, followed by an addition of 20 μ L methylthiazolotetrazolium, MTT) was added into each well before the plate was incubated at 37 °C for 4 h. Then the supernatant was removed, 200 μ L of DMSO was added into each well and the plate was shaken for 10 min. The absorbance (A value) of the migration cells was determined in Micro plate Reader at a wavelength of 570 nm. The average of A values of 3 wells was regarded as a mean A value. The above processes were repeated for 9 times.

Statistical analysis

Data were expressed as mean \pm SE. Analysis of variance (ANOVA) and student's *t* test were used for comparison among the groups and between paired data. $P < 0.05$ was considered to be statistically significant.

RESULTS

Gastrointestinal motility

Active charcoal propulsion rates of small intestine in the DTH₁ (0.3 g/L DNCB) and DTH₂ (1.3 g/L DNCB) groups were significantly higher than that in the control group ($P < 0.01$) and DTH₍₋₎ groups ($P < 0.05$ or $P < 0.01$), whereas there was no significant difference between the control group and DTH₍₋₎ group (Figure 1). All the mice in DTH₃ group died after the 0.66% DNCB gavage.

Figure 1 Effect of DNCB gavage on gastrointestinal motility in sensitized mice. ^b $P < 0.01$ vs control, ^c $P < 0.05$ vs DTH₍₋₎, ^d $P < 0.01$ vs DTH₍₋₎ and DTH₁ $n=8$ in control; $n=7$ in DTH₍₋₎, DTH₁ and DTH₂ groups.

Figure 2 Effect of DNCB enema on DAI score in sensitized mice. ^a $P < 0.05$ vs control. $n = 16$ in control group and DTH₄ group; $n = 11$ in DTH₅ group; $n = 17$ in DTH₆ group.

DAI score and pathological score

Diarrhea was first found in the mice 24 h after DNCB enema, and weight loss was found 3 d later. Serious weight loss and obvious diarrhea were seen in the 4 g/L DNCB group, 24% of whom died. DAI scores are shown in Figure 2.

Pathologically, the control and DTH₍₋₎ groups had normal histological structures and glands, no ulcer was found except

for occasional slight mucosa congestion (Figure 3A). In DTH₄ (1 g/L DNCB) group, there was slight colic edema, mucosa congestion, infiltration of lymphocytes and a decrease in the number of glands and goblet cells (Figure 3B). In DTH₅ (2 g/L DNCB) group, intestinal adhesion and flatulence were found. A more disturbing array of glands, local erosion, dramatic decrease in goblet cells and diffuse inflammatory cellular infiltration were found (Figure 3C). In DTH₆ (4 g/L DNCB) group, more extensive colic cementation, expansion of the proximal intestinal cavity, some white exudates, mucosa congestion, necrosis and multiple ulcers were found. Under the microscope, mucosa atrophy, decrease of glands and disturbance of tissue structure were observed (Figure 3D), moreover, erosion, hemorrhage, necrosis as well as deeper/extensive ulcers were easily seen (Figure 3E). The pathological score in each group is shown in Figure 4.

The LMIF activities and its relationship with colitis

With the increased DNCB doses in enema, which exacerbated colonic tissue damage, we could see an increase of the LMIF activity (A value decreased). The LMIF activity was significantly increased in the DTH₅ and DTH₆ groups as compared with the control group ($P < 0.01$, student's *t*-test) (Table 1). There were also significant differences in LMIF activity ($P < 0.01$) among DTH₄, DTH₅ and DTH₆ groups (ANOVA).

Figure 3 The pathological change of colon by DNCB enema in sensitized mice. A1: control 600 mL/L ethanol, normal histological structures. A2: DTH₍₋₎, only slight mucosa congestion. B: 1 g/L DNCB, hyperemia, infiltration of chronic inflammatory cells, decrease of the number of goblet cell in colon mucosa. C: 2 g/L DNCB, superficial erosion, chronic inflammation of colon mucosa. D: 4 g/L DNCB, atrophic changes of colon mucosa with chronic inflammation. E: 4 g/L DNCB, ulcer and hemorrhage in colon mucosa (HE, $\times 200$).

Figure 4 Pathological score in the mice received DNCB enema after sensitization. 4A: macropathology; 4B: microscopically observation. group 1: control (600 mL/L ethanol, $n=16$); group 2: DTH₄ (1 g/L DNCB, $n=17$); group 3: DTH₅ (2 g/L DNCB, $n=17$); and group 4: DTH₆ (4 g/L DNCB, $n=17$) ^a $P<0.05$ vs group 4A1 and 4B1, respectively.

Table 1 Effect of DNCB enema on LMIF activity in sensitized mice

Group	Skin smearing (50 μ L/mouse)	Enema (2 μ L/g bm)	A value (mean \pm SE)
Control	Acetone-olive oil	600 mL/L ethanol	0.426 \pm 0.009
DTH ₁	Acetone-olive oil	2 g/L DNCB	0.401 \pm 0.007
DTH ₄	33 g/L DNCB	1 g/L DNCB	0.383 \pm 0.038
DTH ₅	33 g/L DNCB	2 g/L DNCB	0.220 \pm 0.012 ^b
DTH ₆	33 g/L DNCB	4 g/L DNCB	0.139 \pm 0.019 ^d

^b $P<0.01$ when compared with the control and DTH₁ (student's t -test). ^d $P<0.01$ between DTH₄, DTH₅ and DTH₆ groups (ANOVA); $n=9$ in each group. A, the absorbance of migration leukocytes. The skin smearing and enema were completed daily for 4 d.

DISCUSSION

For the first time, here, we reported DTH response of mice GI tract by intra-gastrointestinal administration of DNCB. The evidence of gastrointestinal DTH response were as follows: DNCB-sensitized mouse showed increased GI motility, diarrhea, hematochezia and colitis after DNCB challenge; and the activity of LMIF released from sensitized T-lymphocyte was significantly increased after DNCB enema. The mechanism of the DTH phenomenon might be the same as that of the ear skin DTH reaction in our previous study^[6].

What is the pathophysiological significance of GI DTH reaction? Early in the 1960's, Bicks *et al.* found that inflammation and ulcer could be induced by DNCB enema in guinea pigs^[4], which he thought as being a cellular immune induced by DNCB that resulted in a DTH reaction in GI tract. Later, several other researchers explored the relations between DNCB-activated cellular immune and GI disorder, but they either indirectly inferred the possibility of GI being influenced by DTH skin tests^[12] or only focused on the pathological relation of DNCB-colitis with human ulcerative colitis (UC)^[5,7,8]. Comparing with previous DNCB-colitis in rat, guinea pig and rabbit by other researchers, our work here not only successfully created DNCB-colitis model in mouse, but also found a more convenient and more sensitive animal model for DTH study^[13]. In our study, we proved, using the specific DTH index of LMIF^[14,15], that DNCB could induce DTH in mouse GI tract, and this kind of DTH might be the essence of UC.

MIF is one of the cytokines released from sensitized T cell after subjecting the allergen again^[14,15]. According to the target cell, LMIF can be classified as LMIF and MMIF^[16]. There was a dramatic positive correlation between LMIF activity and the

gravity of DTH response^[17]. We found that the ConA-stimulated lymphocytes from mesenteric lymph node of DNCB-treated mouse showed higher LMIF activity than the control, and LMIF activity increased as DNCB concentration increased (Table 1), whereas in DTH₁ group, neither higher LMIF activity nor colon inflammation/ulcer was found, indicating a possible relations among GI DTH response, LMIF activity and UC. Secondly, we know that the main clinical manifestations of UC are diarrhea and pus hematochezia, which result from an irritated intestinal peristaltic and inflectional ulcer^[18,19]. Our results were in accordance with the clinical manifestations of UC (Figures 1–4), indicating that colitis in mouse caused by DNCB was basically similar to human UC in pathology. Finally, two representatives but separate works by Bartnik *et al.*^[20] and Murakami *et al.*^[21] support the hypothesis that the essence of UC is gastrointestinal DTH response. Bartnik *et al.* reported that patients with severe or moderate ulcerative colitis showed LMIF release, which was significantly greater than that observed in patients with other large bowel diseases^[20]; and Murakami *et al.* reported that the number of MIF expressing cells increased at the colonic mucosa in patients with ulcerative colitis, and MIF induced significant levels of IL-1 and IL-8 in monocytes and dendrite cells in UC patients, indicating a role of MIF in the induction and/or perpetuation of the inflammatory environment in UC^[21]. Comparing with all the other cytokines reported in UC^[22], we think that the distinctive (unique) significance of LMIF in UC and its pivotal role in connecting DTH with UC have been showed by Bartnik and Murakami.

To sum up, we have enough reasons to conclude that the GI DTH in mouse may provide not only experimental models of human UC, but also insight into pathogenic mechanisms of the UC, an inflammatory bowel disease (IBD) of unknown etiology.

Abstract

AIM: To study the transcriptional regulation of human telomerase reverse transcriptase (hTERT) mRNA in normal human cholangiocytes (HBECs) after hepatitis B virus X (HBx) gene transfection and to elucidate the possible mechanism of HBV infection underlying cholangiocarcinoma.

METHODS: HBECs were cultured *in vitro* and co-transfected with a eukaryotic expression vector containing the HBx coding region and a cloning vector containing coding sequences of enhanced green fluorescent protein (EGFP) using lipid-mediated gene transfer. The transfection efficiency was determined by the expression of EGFP. The expressions of hTERT mRNA and HBx protein in HBECs were detected by RT-PCR and immunocytochemical stain, respectively.

RESULTS: The transfection efficiencies were about 15% for both HBx gene expression plasmid and empty vector. No hTERT mRNA was expressed in HBECs when transfected with OPTI-MEM medium and empty vector, but a dramatic increase was observed for hTERT mRNA expression in HBECs when transfected with HBx expression vector. HBx protein was only expressed in HBECs when transfected with HBx expression vector.

CONCLUSION: HBx transfection can activate the transcriptional expression of hTERT mRNA. Cis-activation of hTERT mRNA by HBx gene is the primary mechanism underlying the proliferation, differentiation and tumorigenesis of biliary epithelia.

INTRODUCTION

Telomeres make up the ends of chromosomes of eukaryote and progressively shorten with each cell cycle. Critically short

telomeres induce cellular senescence and death^[1]. Telomere lengths become stabilized by the activation of telomerase in most tumor cells, highly proliferative cells and human somatic cells. The activation of telomerase is a crucial step in tumorigenesis and cellular senescence^[2]. The most important catalytic protein subunit of telomerase ribonucleoprotein is hTERT whose expression parallels telomerase activity^[3]. It is known that hTERT expression is regulated mainly at the transcriptional level and that the core promoter of hTERT encompasses numerous transcription factor binding sites. All these factors, which regulate hTERT promoter region individually or coordinately, comprise a complex regulation system^[4]. A recent study has shown that HBV DNA integration locates upstream to the hTERT promoter and that HBV enhancer can cis-activate the transcriptional expression of hTERT gene in hepatocarcinoma cell lines^[5]. HBx gene also activates the expression of telomerase^[6]. All these findings provide a new mechanism of HBV in liver carcinogenesis. There is a prominent expression of HBx protein in tissues of both intrahepatic^[7,8] and extrahepatic cholangiocarcinomas^[9]. So far, it is not clear whether HBV infection involves in the tumorigenesis of cholangiocarcinoma and if HBx gene can regulate the expression of telomerase gene. In order to determine the possible correlation of HBV infection and cholangiocarcinogenesis, we transferred HBx gene into human normal cholangiocytes (HBECs) and assayed the expression of hTERT mRNA by RT-PCR.

MATERIALS AND METHODS

Cell and culture

HBECs, isolated from normal human bile ducts^[10], were kindly provided by Dr. Ludwik K. Trejdosiewicz (ICRF Cancer Medical Research Unit, St James's University Hospital, Leeds, UK). HBECs were maintained as adherent monolayers in "HBEC medium" comprising a 1:1 mixture of Ham's F12 and DMEM (Gibco BRL®), supplemented with 50 g/L fetal bovine serum (Gibco BRL®), 5 ng/mL epidermal growth factor (Intergen Company), 0.4 µg/mL hydrocortisone hemisuccinate, 2 nmol/L triiodothyronine and 5 µg/mL insulin (all from Sigma) and 10 ng/mL human recombinant hepatocyte growth factor (R&D Systems,). Cells were seeded in 25 cm² tissue culture flasks and propagated at 37 °C in a humidified atmosphere of 550 mL/L CO₂ in air and monolayers passaged approximately once a week at or before confluence by incubation in trypsin-versene for approximately 5 min until the cells were shrunken. Trypsin activity was quenched by addition of fresh medium containing FBS and cells were seeded at 1/2 split ratio.

Plasmids and transfection

The plasmids pcDNA3, pCMV-X and pEGFP were the gifts from Professor Xiao-Dong Zhang (Institute for Molecular Biology, Nankai University, China). The empty pcDNA3 vector, a eukaryotic expression vector, was used as negative control. pCMV-X was constructed by inserting the entire HBx

coding region (HBV nucleotides 1 372-1 833 465 bp) into the *EcoRI/EcoRV* sites of the pCDNA3 vector^[11]. Cloning vector pEGFP carried an enhanced green fluorescent protein (EGFP) gene that was cloned between the two MCS of the pPD16.43. EGFP encoded by pEGFP could emit bright green fluorescence in eukaryotic cells. All the plasmids contained ampicillin resistance genes for propagation and selection in *E.coli*.

Transient transfection of plasmids into HBECs was performed using Lipofectamine (Gibco BRL®) according to the protocol recommended by the manufacturer. The day before transfection, cells were trypsinized and seeded in 6-well plates. On the day of transfection, cells reached 60% confluence. 2.9 µg pCDNA3 DNA or pCMV-X DNA and 0.1 µg pEGFP DNA were diluted with OPTI-MEM medium (Invitrogen) and then mixed with Lipofectamine. A total of 1 mL transfection medium was added to the cells after the cells were washed one time by OPTI-MEM medium. The cells were incubated at 37 °C in a humidified atmosphere of 50 mL/LCO₂ in air for 3 h. After 3 h incubation, the transfection medium was replaced with fresh complete medium containing serum and the cells were incubated for another 36 h. Then the cells were harvested and extracted. The expression of transfected gene was examined by immunocytochemistry. The cells transfected with OPTI-MEM medium were used as blank control and transfected with pCDNA3 vector as empty vector control, co-transfected pEGFP as a marker for transfection efficiency^[12].

RT-PCR of hTERT mRNA

Total cellular RNAs were extracted from different groups by TRIzol reagent (Gibco BRL®). A 2 µg of extracted RNA was reverse transcribed into cDNA first-strand with 200 units of Moloney murine leukemia virus reverse transcriptase (Promega) and 1 µg of oligo (dT)₁₅ primer (Promega) in a final volume of 25 µL of enzyme buffer for 60 min at 42 °C. hTERT cDNA analysis was performed by PCR amplification of a 145 bp fragment using primer pairs 5'-CGGAAGAGTGTCTG GAGCAA-3' (sense) and 5'-GGATGAAGCGGAGTCTGGA-3' (antisense) as described previously^[13]. A 320 bp fragment of GAPDH gene was amplified as an internal control. The primers for GAPDH were 5'-GGAAGCTTGTCATCAATGG 3' (sense) and 5'-CTGTGGTTCATGAGTCCTTC 3' (antisense). PCR was performed with 5 µL of cDNA first-strand in a 50 µL reaction mixture containing 2 mmol/L MgCl₂, 1 mmol/L dNTPs, 0.4 µmol/L of each primer, and 2.5 units of *Taq* DNA polymerase (Promega). The reaction mixture was heated at 94 °C for 5 min, then 33 cycles of PCR were performed. Each cycle included denaturation at 94 °C for 40 s, annealing at 60 °C for 40 s and extension at 72 °C for 90 s. A 10 µL PCR products was assessed by 1.5% agarose electrophoresis and ethidium bromide staining (0.5 µg/mL), visualized under ultraviolet light and analyzed by NIH Image software.

Immunocytochemistry

Cells in different groups were cultured on coverslips and fixed with acetone and methanol. Detection of HBx protein expression in the transfected cells was performed by the ultrasensitive immunochemistry kit (Maixin Company, Fuzhou, China) according to the manufacturer's instructions. Rabbit anti-human HBx polyclonal antibody (1:800) was provided by Dr. Wen-Liang Wang (The 4th Military Medical University, Xi'an, China).

RESULTS

Transfection efficiency

Under fluorescence microscope, EGFP can only be observed in the HBx gene transfected cell cultures and the cells of empty

vector control (Figure 1). There was no such green fluorescence in the cells of the blank control. Transfection efficiency was estimated by counting the percentage of EGFP-expressing cells in at least 3 fields of vision under fluorescence microscope. For the HBx gene transfected cell cultures and empty vector control, the transfection efficiency was about 15%.

Figure 1 Transfection efficiency evaluated by EGFP-expressing cells in the HBx gene transfected cell cultures and empty vector control. pEGFP 0.1 µg and pCMV-X (or pCDNA3) 2.9 µg were co-transfected into HBECs by Lipofectamine. Thirty-eight hours after transfection. EGFP-expressing cells were visible under fluorescence microscope in the HBx gene transfected cell cultures (A) and empty vector control (B), but not in the blank control (Under fluorescence microscope ×200).

Figure 2 Analysis of hTERT mRNA expression by RT-PCR. RT-PCR was performed on total RNA extracted from HBECs transfected with OPTI-MEN medium (1), pCMV-X (2) and pCDNA3 (3), respectively. M: DL2000 Marker.

hTERT mRNA expression

To examine the effects of HBx gene on hTERT transcription, pCMV-X expression vector was co-transfected with pEGFP into HBECs. The expression of human GAPDH RNA in all of the samples was quantitatively measured and used as an internal control. After RT-PCR analysis, a prominent level of hTERT transcript was detected in the HBx gene transfected cell cultures. In contrast, as shown in Figure 2, hTERT mRNA of HBECs in the blank control and empty vector control were undetectable. The relative expression level of hTERT mRNA was determined by measuring band intensities of both hTERT transcript and GAPDH transcript and calculating the ratio of hTERT to GAPDH. As shown in Figure 3, after transferred with HBx

gene, the HBECs exhibit more distinct hTERT mRNA expression in contrast to those transfected with blank control and empty vector.

Figure 3 Quantitative and relative changes of hTERT mRNA expression analyzed by NIH Image software. Dramatic expression of hTERT mRNA was observed in HBECs when transferred with pCMV-X vector (lane 2), but there was no hTERT mRNA expression in HBECs when transferred with OPTI-MEM medium (lane 1) and empty vector (lane 3).

HBx protein expression in HBECs

HBx protein expression in transferred HBECs was identified by immunocytochemistry. Positive signals could be observed sporadically in the HBx gene transfected cell cultures (Figure 4B). As for the HBECs in the blank control and empty vector control, there are no such observable positive signals (Figures 4A, C).

Figure 4 HBx protein expression in transferred HBECs assayed by ultrasensitive immunocytochemistry. The blank vector and OPTI-MEM transfected HBECs showed no expression of HBx protein (A, C), but pale brown positive signals scattered in pCMV-X vector transfected HBECs (B). Immunocytochemistry (S-P methods, $\times 200$).

DISCUSSION

HBECs were isolated from normal human bile duct epithelia and cultured *in vitro*. As no retroviral transduction with SV-40 large T antigen cDNA was performed, the cells were not immortalized. They were really primary culture cells and would only grow for a few passages before becoming senescent, the cells simply stopped dividing and died eventually. Though there was expression of telomerase endogenous genes (such as the telomerase RNA component gene) in this kind of finite cell lines, telomerase was inactivated as the expression of hTERT was repressed. The inhibition of hTERT expression originated from the presence of numerous transcription factors in the core promoter of hTERT. Transcriptional repressors such as p53^[14,15], Mad1^[16,17] and myeloid-specific zinc finger protein 2^[18], could specifically inhibit the transcriptional expression of hTERT mRNA in normal human somatic cells. Our results confirmed this hypothesis. When we transferred the empty vector and OPTI-MEM medium into the HBECs, we could not assay the expression of hTERT mRNA. Dramatic hTERT mRNA expression in HBECs transfected with HBx gene showed that HBx gene could cis-activate transcriptional expression of hTERT gene. An early study also showed that normal human cells could restore the telomerase activity in the presence of other oncogenic viruses^[19]. It has been reported that HBV genome was integrated into the promoter region of hTERT both in HuH-4 human hepatocellular carcinoma-derived cell line^[5] and in liver tumor tissues^[20]. The integration of HBV enhancer upstream of the hTERT promoter cis-activated hTERT gene transcription in HuH-4 cells^[5]. It is known that the up-regulation of telomerase activity could be observed in hepatocellular carcinoma cell line HepG2 after transferred with X gene^[6]. Together with our results, this was a most important demonstration of transcriptional regulation of telomerase gene through HBx gene in carcinogenesis of both human hepatocarcinomas and cholangiocarcinomas. The precise mechanism of such an action is still unknown.

It has been well known that HBx protein encoded by HBx gene, is a potential oncogenic factor and mainly acts as a transcriptional co-activator involving in multiple gene regulation and signaling pathway^[21]. Up-regulation of telomerase gene expression may be another major role of HBx at the stage of carcinogenesis^[22]. Our early study found that higher expression levels of HBx protein and mRNA could be assayed in the tissues of cholangiocarcinomas^[9,23]. Based on our present finding that HBx protein expression could be detected in HBECs transfected with HBx gene, we could suggest that HBV infection and its genome integration might involve in the pathogenesis of cholangiocarcinomas^[24]. HBx protein, which has long been studied as the major causative factor for hepatocarcinogenesis^[25,26], might still play more important role in the carcinogenesis of cholangiocarcinomas than other proteins encoded by other genes of HBV^[27]. As for the mechanism for HBx protein' carcinogenic action, we deduced there should be a binding site for HBx protein in the core promoter region of hTERT gene although this motif has not been identified. Another notion derived from our study is that HBx protein may recruit some cis-action elements (such as c-Myc^[28], AP-2^[29]) or repress other factors (like p53^[30], E2F1^[31]) in mediating the transcriptional regulation of hTERT gene. When exogenous HBx gene was transferred into HBECs, HBx protein translation was achieved in some of HBECs. It is the expression of HBx protein in the transfected cells that be responsible for cis-activation of hTERT mRNA directly or indirectly.

In summary, HBECs do not show the expression of hTERT mRNA and a dramatic high expression of hTERT mRNA can be observed in HBECs transfected with HBx gene. The cis-activation of hTERT gene by HBx is the primary mechanism

underlying proliferation, differentiation and tumorigenesis of biliary epithelia.

ACKNOWLEDGMENTS

We thank Dr. Ludwik K. Trejdosiewicz for kindly providing us HBECs and Professor Xiao-Dong Zhang for providing us three kinds of plasmids.

Abstract

AIM: To investigate the anti-coxsackievirus B₃ (CVB_{3m}) effect of the ethyl acetate extract of Tian-hua-fen on HeLa cells infected with CVB_{3m}.

METHODS: HeLa cells were infected with CVB_{3m} and the cytopathic effects (CPE) were observed through light microscope and crystal violet staining on 96-well plate and A₆₀₀ was detected using spectrophotometer. The protective effect of the extract to HeLa cells and the mechanism of the effect were also evaluated through the change of CPE and value of A₆₀₀.

RESULTS: The extract had some toxicity to HeLa cells at a higher concentration while had a marked inhibitory effect on cell pathological changes at a lower concentration. Consistent results were got through these two methods. We also investigated the mechanism of its anti-CVB_{3m} effect and the results indicated that the extract represented an inhibitory effect through all the processes of CVB_{3m} attachment, entry, biosynthesis and assemble in cells.

CONCLUSION: The results demonstrate that the ethyl acetate extract of Tian-hua-fen has a significant protective effect on HeLa cells infected with CVB_{3m} in a dose-dependent manner and this effect exists through the process of CVB_{3m} attachment, entry, biosynthesis and assemble in cells, suggesting that the ethyl acetate extract of Tian-hua-fen can be developed as an anti-virus agent.

INTRODUCTION

Tian-hua-fen is the dried root of *Trichosanthes kirilowii* Maxim or *Trichosanthes japonica* Regel. The major component of it is mass starch, various amino acids, phytohemagglutinin, saccharide, saponin and some other things^[1]. Tian-hua-fen was mentioned in Compendium of Materia Medica written by Li Shizhen in the late 14th Century as a drug to reset menstruation

and facilitating the expulsion of retained placenta. For a long time, Tian-hua-fen had been used in the powdered form in conjunction with other Chinese herbal medicines to induce abortion^[2]. Clinical applications over the years proved that Tian-hua-fen had multiple pharmacological effects, such as termination of pregnancy, anti-tumor, anti-inflammation, anti-virus and immunoregulation and so on^[3-5]. The anti-virus, especially anti-HIV-1, effect of trichosanthin (TCS) has been known to us. But to the author's knowledge research about the non-protein parts of Tian-hua-fen is rare. Coxsackievirus B is the major pathogen of viral myocarditis and now there is no effective therapeutic drug. In the process of screening anti-virus agents from Chinese medicinal herb we found that the nonprotein parts of Tian-hua-fen had a notable anti-virus effect *in vitro* and *in vivo*.

MATERIALS AND METHODS

Preparation of the ethyl acetate extract of Tian-hua-fen

A total amount of 200 g Tian-hua-fen powder (Shanghai drug store) was macerated with 2 L 750 mL/L ethanol overnight, then was boiled in water under reflux for 3 h and the boiled fluid was filtered. The filtrate was evaporated under reduced pressure to gain a residue. The residue was suspended in water and partitioned with petroleum ether, ethyl acetate and n-BuOH (Analytical pure, Shanghai chemical company Ltd) successively. The four fractions were evaporated under reduced pressure to give petroleum ether fraction (0.56 g), ethyl acetate fraction (0.82 g), n-BuOH fraction (0.85 g) and aqueous fraction (12.7 g), respectively.

Preparation of HeLa cells and titration of virus titer

HeLa cells were stored in liquid nitrogen with 100 g/L dimethyl sulphoxide (DMSO) and 900 mL/L fetal calf serum (FCS) and maintained in culture flasks in complete RPMI 1640 medium (Gibco, BRL America). Subculture was carried out every 2-3 d after it had formed a confluent monolayer. CVB_{3m} (Stored by our laboratory) was serially diluted to 10⁻¹⁰ with non-FCS RPMI1640 culture medium. On 40-well plate, 0.025 mL CVB_{3m} with variable dilution and 0.025 mL non-FCS RPMI1640 culture medium were added to each well. Finally, 0.05 mL viable HeLa cells (3×10⁵/mL) were added. Each dilution was quadrupled and normal HeLa cells co-cultured only with RPMI1640 containing 10 mL/L FCS were prepared as negative control at the same time. Then the cells were incubated at 37 °C with 50 mL/L CO₂ for 72 h. The cytopathic effects (CPE) were observed under light microscope. The titer at which cells appeared 50% CPE was designated 1 TCID₅₀ (50% tissue culture infectious doses). A 100 TCID₅₀ was used as the infectious titer in the following experiment.

Assay of the toxicity of the extract to HeLa cells

A total of 5 mg extract was dissolved in 5 μL DMSO, then 2.5 mL deionized water was added and the liquid was sterilized at 115 °C for 20 min. After cooling to 55 °C, 2.5 mL 2×RPMI 1640 culture medium (without FCS) was added to make the end concentration of the extract (1 mg/mL). The original liquid

was diluted with non-FCS RPMI 1640 culture medium serially from 1:2 to 1:1 024. A total of the 0.025 mL sample with various concentration and 0.025 mL of the same culture medium were added to each well on 96-well plate. Finally 0.05 mL viable HeLa cells ($3 \times 10^5/\text{mL}$) were added. Each concentration of the sample was quadrupled. Two controls, HeLa cells co-cultured only with RPMI1640 (containing 100 mL/L FCS) and 1 g/L DMSO respectively were prepared synchronously. Cells were incubated at 37°C with 50 mL/L CO_2 for 72 h. CPE was observed under light microscope and the concentration at which cells appeared $<50\%$ CPE (compared with that of extract-free cultures) was regarded as the lowest toxic concentration. In addition, cells were stained with 5 g/L crystal violet (Ameresco) and A_{600} was detected using spectrophotometer.

Assay of the anti-CVB_{3m} effect of the extract

The extract was diluted serially from 1:256 at which it had no toxicity to HeLa cells to 1:8 192 with non-FCS RPMI 1640 culture medium. Then 0.025 mL extract with variable concentration was added to each well of 96-well plate. Then 0.025 mL 100 TCID₅₀CVB_{3m} was overlaid. After incubation at 37°C with 50 mL/L CO_2 for 1 h, 0.05 mL viable HeLa cells ($3 \times 10^5/\text{mL}$) were added. Each concentration was quadrupled and three controls, normal HeLa cells co-cultured only with RPMI1640 (containing 100 mL/L FCS), 100 TCID₅₀CVB_{3m} and the extract (1:256 mg/mL), respectively were prepared synchronously. Cells were grown for 3 days and then CPE was observed under light microscope. Later, the cells were stained with 5 g/L crystal violet and A_{600} was measured using spectrophotometer.

Primary study on the mechanism of anti-CVB_{3m} effect of the extract^[6]

The extract was diluted with non-FCS RPMI1640 culture medium from 1:256 to 1:8 192. HeLa cells ($1.5 \times 10^4/\text{well}$) were seeded onto three 96-well plates and allowed to attach to the well bottom. When the cells were confluent the culture medium was discarded and the cells were rinsed twice with the same culture medium. The cells on three plates were treated respectively as follows: The first plate: 0.025 mL 100TCID₅₀CVB_{3m} and 0.025 mL extract of variable concentration were added to each well. After incubation at 37°C with 50 mL/L CO_2 for 1 h, the mixture was substituted with 0.1 mL non-FCS RPMI1640 culture medium; the second plate: 0.025 mL 100TCID₅₀CVB_{3m} and 0.025 mL extract of variable concentration were added. The plate was incubated at 37°C with 50 mL/L CO_2 for 1 h. Then the mixture was substituted with 0.025 mL extract of

variable concentration and 0.075 mL non-FCS RPMI1640 culture medium; the third plate: 0.025 mL 100TCID₅₀CVB_{3m} and 0.025 mL non-FCS RPMI1640 culture medium were added first. After incubation at 37°C with 50 mL/L CO_2 for 1 h the mixture was discarded and 0.025 mL extract of variable concentration and 0.075 mL non-FCS RPMI1640 culture medium were overlaid. Three controls, HeLa cells co-cultured only with RPMI1640 containing 100 mL/L FCS, 100TCID₅₀CVB_{3m} and extract (1:256 mg/mL) respectively were prepared synchronously and each extract concentration was quadrupled. At last all plates were incubated at 37°C with 50 mL/L CO_2 . When the cells treated with CVB_{3m} appeared 100% CPE, the cells were stained with 5 g/L crystal violet and A_{600} was detected using spectrophotometer.

RESULTS

Titration of CVB_{3m} titers

The incubation was terminated after 72 h and CPE was observed under light microscope. The results showed the cells in all quadrupled wells treated with CVB_{3m} at titer of 10^{-1} - 10^{-6} appeared 100% CPE. About the cells treated with CVB_{3m} at titer of 10^{-7} , the cells in two wells appeared 100% CPE while the others appeared 50% CPE. In regards to the cells co-cultured with CVB_{3m} at titer of 10^{-8} - 10^{-10} , the cells in four wells appeared no CPE completely. Then TCID₅₀ was calculated as 10^{-7} according to Reed-Muench method^[7].

Assay of toxicity of ethyl acetate extract to HeLa cells

After incubation for 72 h, CPE induced by the extract was observed under light microscope. The results showed the cells co-cultured with extract at concentration from 1:2-1:128 mg/mL appeared CPE of different degrees, while the cells co-cultured with extract at concentration from 1:256 to 1:8 192 mg/mL appeared no CPE. The 50% toxic concentration was 1:128 mg/mL according to Reed-Muench method. The value of A_{600} also indicated that the extract had no toxicity to HeLa cells from 1:256 mg/mL. The cells co-cultured with 1 g/L DMSO appeared no CPE, which showed that DMSO at this concentration had no toxicity to HeLa cells (Table 1).

Assay of the anti-CVB_{3m} effect of the extract

From 1:256 to 1:8 192 mg/mL the extract showed various protective effects to HeLa cells and the effect was decreased with the increased dilution. The protective effect was best at concentration from 1:256 to 1:1 024 mg/mL. The minimal effective inhibitory concentration (EIC) was 1:8 192. The value

Table 1 Cytotoxicity of ethyl acetate extract to HeLa cells shown in the value of A_{600}

Dilution	1:2	1:4	1:8	1:16	1:32	1:64	1:128	1:256	1:512	1:1 024
Value of A_{600}	0.20±0.029	0.22±0.030	0.32±0.022	0.29±0.069	0.38±0.043	0.59±0.035	0.69±0.075	1.30±0.069	1.23±0.061	1.29±0.056

The A_{600} value of the cells co-cultured with the extract at concentration from 1:2 to 1:128 mg/mL was lower than that of normal HeLa cells (1.32±0.034), which showed that the extract had some toxicity to HeLa cells at these concentrations. From 1:256 mg/mL the A_{600} value became close to that of normal HeLa cells, which indicated that from 1:256 mg/mL the extract had no toxicity to HeLa cells again.

Table 2 Protective effect of ethyl acetate extract on HeLa cells shown in the value of A_{600}

Dilution	1:256	1:512	1:1 024	1:2 048	1:4 096	1:8 192
Value of A_{600}	1.09±0.017	1.02±0.122	0.89±0.060	0.91±0.039	0.83±0.048	0.77±0.028

The A_{600} value of the cells co-cultured only with RPMI1640 was 1.32±0.02; the A_{600} value of the cells co-cultured only with 10^{-5} CVB_{3m} was 0.22±0.026; and the A_{600} value of the cells co-cultured only with extract at concentration of 1:256 mg/mL was 1.21±0.042. As shown in the table the value of A_{600} of the cells treated with extract is higher than that of the cells infected with CVB_{3m} while not treated with the extract ($^bP<0.01$), indicating the protective effect of the extract on HeLa cells from CVB_{3m} infection.

Table 3 Protective effect of ethyl acetate extract on HeLa cells shown in percentage (A_{600} value of cells protected with the extract/ A_{600} value of normal HeLa cells)

Dilution	1:256	1:512	1:1 024	1:2 048	1:4 096	1:8 192	10 ⁻⁵ CVB _{3m}
The ratio of A_{600}	88.56±0.032	79.46±0.008	73.07±0.057	65.57±0.023	61.83±0.038	56.1±0.015	16.7±0.027

The percentage of vital cells protected with the extract accounted for compared with normal HeLa cells decreased with the increased extract dilution, and it was preferable from concentration 1:256 mg/mL to 1:1 024 mg/mL. ^b $P<0.01$ vs group of 10⁻⁵ CVB_{3m}.

Table 4 The value of A_{600} obtained from various infective phase

Dilution/ A_{600}	1:256	1:512	1:1 024	1:2 048	1:4 096	1:8 192
First group	0.45±0.041	0.56±0.011	0.63±0.036	0.65±0.043	0.37±0.076	0.38±0.029
Second group	0.72±0.022	0.96±0.013	0.69±0.009	65.00±0.025	0.78±0.056	0.73±0.054
Third group	0.53±0.030	0.48±0.036	0.40±0.049	0.39±0.066	0.39±0.077	0.32±0.015

The A_{600} value of the cells co-cultured only with RPMI1640, cells co-cultured only with 10⁻⁵ CVB_{3m} and cells co-cultured only with extract (1:256 mg/mL) was 1.29±0.011, 0.24±0.023 and 1.20±0.029, respectively. The value of A_{600} of the cells treated with extract of variable concentration at different time of CVB_{3m} infection was higher than that of the cells infected with CVB_{3m} and not treated with the extract, which indicated the protective effect of the extract existed through all the processes of CVB_{3m} attachment, entry, biosynthesis and assemble in cells.

of A_{600} obtained using crystal violet staining showed that starting from 1:256 mg/mL, the value of A_{600} decreased with the increased dilution. There was a negative correlation between them ($r=0.8525$, $P<0.01$, Tables 2-3, Figure 1).

Figure 1 The protective effect of the extract on HeLa cells expressed in column figure. The value of A_{600} obtained using crystal violet staining decreased with the increased dilution of the extract. From 1:256 to 1:8 192 mg/mL the extract showed various protective effects on HeLa cells and the effect was decreased with the increased dilution of the extract. The protective effect was best at concentration of 1:256 to 1:1 024 mg/mL.

Primary study on the mechanism of anti-CVB_{3m} effect of the extract in vitro

In the first group, the extract was added in the process of virus adsorption. In second group, the extract was added in the process of virus adsorption and also after adsorption while in the third one, the extract was added after virus adsorption. The value of A_{600} of the three groups were obtained. Among all three groups, A_{600} obtained from the cells treated with extract from 1:256 to 1:8 192 mg/mL was higher than that treated with 100TCID₅₀ CVB_{3m}, and that of the second group was the highest. This suggested the extract exerted anti-CVB_{3m} effect through all the processes of the virus infection (Table 4).

DISCUSSION

Proliferation of virus primarily depends on the biosynthesis system of host cells because virus deficit the enzymes needed for their proliferation. Virus proliferation was similar to nucleotide replication of host cells and there is also great similarity between its products such as nucleotide and proteins

and that of host cells. So the demand for killing virus while not infecting the normal physiological function of host cells brings us great difficulty to design and synthesize effective anti-virus drug. The development of anti-virus drugs is very slow compared with that of anti-bacteria drugs in the last one hundred years since the discovery of virus. Though it is an important way to synthesize anti-virus drugs using chemical methods, it is very slow and time-consuming. In recent years, many countries are paying more and more attention to look for anti-virus agents from Chinese medicinal herbs. Tian-hua-fen is a traditional Chinese medicinal herb. It has been used in Chinese for centuries to induce mid-term abortion. And there were many records about its biological efficacy. In the 70 s, the active ingredient of Tian-hua-fen, TCS, a protein from the root tuber of the Chinese medicinal herb *Trichosanthes kirilowii* Maxim was found and purified. It is a monomeric protein with a pI (isoelectric point) of 9.4 and an apparent molecular weight of 24 kDa. There are no cysteine residues in the molecule^[8]. TCS is a member of type 1 ribosome-inactivating protein (RIP) family^[7-9]. RIP is a group of cytotoxic proteins acting on eukaryotic ribosomes. They can inactivate 60S ribosomal subunits by only hydrolyzing a single phosphodiester bond between the guanosine residue at position 4 325(G4 325) and the adenosine residue at position 4 326(A4 326) in 28S rRNA. TCS can inactivate eukaryotic ribosomes through its N-glycosidase activity by hydrolyzing the N-C glycosidic bond of adenylic acid at 4 324 site in 28S rRNA of rat liver^[10]. Thus cell protein synthesis was inhibited. Clinical application over the years showed TCS had multiple pharmacological effects. The research about TCS was once popular since McGrath *et al.*^[11,12] reported it could inhibit HIV-1 for the first time. But the severe side effect prevented its more extensive clinical application^[13]. There are some other components such as polysaccharide, phytohemagglutinin, sterol and palmitic acid and so on in Tian-hua-fen besides TCS^[14]. Polysaccharide in Tian-hua-fen had marked immunoregulation effect^[1]. The galactose-binding lectin from Tian-hua-fen stimulated the incorporation of D-[3-3H]glucose into lipids in isolated rat epididymal adipocytes^[15]. In the process of screening anti-virus agents, we found the ethyl acetate extract of Tian-hua-fen had obvious preventive effect on HeLa cells from CVB_{3m} infection. This showed the potential anti-virus effect of the ethyl acetate extract of Tian-hua-fen. In this study, Tian-hua-fen was treated with chemical reagents and then was extracted with organic reagents. Finally, four kinds of extract were obtained. The anti-CVB_{3m} effect of the four fractions was tested and the results showed

ethyl acetate fraction had the best preventive effect on HeLa cells from CVB_{3m} infection. The preventive effect decreased as the extract dilution increased. There was an obvious correlation between them. The ethyl acetate fraction was further chromatographed on silica gel column and their anti-virus effect was also tested. The results suggested that toxicity of the further extract to HeLa cells was decreased compared with the former one and there also existed a negative correlation between the preventive effect and the dilution.

Many methods have been developed for determining the antiviral activities of compounds in cell culture. For viruses that cause discernable cytopathic effects (CPE) microscopically in cells, visual scoring of CPE inhibition is performed most frequently because it is rapid, and allows a number of compounds to be evaluated using 96-well microplates^[16]. Since solely relying on visual scoring was inaccurate for assessing the cytotoxicities, the use of a dye or stain is very important. The results indicated that methods using bisbenzimidazole, crystal violet, fluorescein diacetate, MTT, neutral red, or rhodamine 6G were similar to visual scoring for determining anti-influenza virus activity in cell culture. Rapid staining (15 min) methods could be done with crystal violet and rhodamine 6G, and rhodamine 6G gave a high background in microwells containing only water (no cells or virus) which had to be subtracted^[17], whereas other methods for determining antiviral activity of test substances may be much more tedious, requiring more microplates, compound, and/or time than the above methods. These include the plaque reduction assay^[18], virus yield reduction assay^[19], determining drug effect by counting the number of infected cells stained by fluorescent antibody^[20] and [³H]TdR incorporation^[21]. For this reason, we preferred crystal violet staining in our study in order to quantitatively screen anti-virus agents.

We also did some primary study on the anti-CVB_{3m} mechanism of the extract. The extract was added before virus adsorption, during adsorption and after adsorption and then the cells were stained with crystal violet and A₆₀₀ was measured. The value of A₆₀₀ of the three groups was higher than that of the cells infected with virus. This indicated the three kinds of treatment had preventive effect on HeLa cells from CVB_{3m} infection at different levels and suggested that the extract could act through virus adsorption, penetration and synthesis in cells.

Our results showed that the ethyl acetate extract of Tian-hua-fen had marked anti-CVB_{3m} effect *in vitro*. Some questions still remained to be answered. Which component play key role in the process of anti-virus? Which has the better anti-virus effect between the crude extract and the further extract? What is the anti-virus mechanism of it? To answer these questions needs more and further research. Anyway it is sure that the ethyl acetate extract of Tian-hua-fen has marked anti-virus effect. The answers to the above questions will help to wide the range of virus that Tian-hua-fen resists and also help to make Tian-hua-fen a clinical-used drug.

Abstract

AIM: To study the effect of FR167653 on immunological liver injury (ILI) in mice.

METHODS: ILI was established by tail vein injection of 2.5 mg *Bacillus Calmette-Guerin* (BCG), and 10 d later with 10 mg lipopolysaccharide (LPS) in 0.2 mL saline (BCG plus LPS). Alanine aminotransferase (ALT), aspartate aminotransferase (AST) in sera and malondialdehyde (MDA), glutathione peroxidase (GSHpx) contents in liver homogenates were assayed by spectrophotometry. The levels of tumor necrosis factor- α (TNF- α) and nitric oxide (NO) levels in sera were determined using ELISA. Interleukin-1 (IL-1) produced by peritoneal macrophages was determined by the method of ^3H -infiltrated cell proliferation. The nuclear factor-kappa B (NF- κB) p65 in liver tissue was analyzed with reverse transcription polymerase chain reaction (RT-PCR). Liver samples collected were stained with hematoxylin and eosin.

RESULTS: FR167653 (50, 100, 150 mg/kg) could significantly decrease the serum transaminase (ALT, AST) activity and MDA content in liver homogenate, and improve reduced GSHpx level of liver homogenate. Liver histopathological examination showed FR167653 (100, 150 mg/kg) significantly reduced inflammatory cells infiltration and liver cells necrosis. FR167653 (50, 100, 150 mg/kg) significantly lowered TNF- α and NO levels in serum, and IL-1 produced by peritoneal macrophages. Moreover, expression of NF- κB mRNA in liver tissue of ILI induced by BCG plus LPS was significantly reduced by FR167653.

CONCLUSION: All results showed that FR167653 had significant inhibitory action on ILI in mice.

INTRODUCTION

It has been demonstrated that tissue inflammation plays a critical role in liver pathology via induction of cellular injury. The infiltration of mononuclear phagocytes into the liver has been shown to correlate with the severity of liver injury. Kupffer

cells (KCs) are among the first cells that respond to endotoxins, including lipopolysaccharides (LPS), and are considered to be the primary macrophages involved in the clearance of gut-derived bacteria or bacterial toxins. High portal level of LPS can lead to a pronounced secretion of proinflammatory mediators by KCs and ultimately to endotoxin-induced liver injury^[1,2]. Moreover, proinflammatory cytokines such as tumor necrosis factor- α (TNF- α) and interleukin-1 (IL-1) β have been linked to liver injury^[3-5], and shown to be early and important mediators of liver injury^[6-8]. Thus, inhibition of KCs activity and proinflammatory cytokines production would be beneficial to alleviate liver injury.

FR167653, 1-[7-(4-fluorophenyl)-1,2,3,4-tetrahydro-8-(4-pyridyl)pyrazolo[5,1-c][1,2,4]triazin-2-yl]-2-phenylethanedione sulfate monohydrate, was first discovered to be a potent dual inhibitor of IL-1 and TNF- α production in LPS-stimulated human monocytes and phytohemagglutinin-stimulated human lymphocytes^[9]. Takahashi *et al.*^[10] and Kawano *et al.*^[11] also confirmed the inhibitory effect of FR167653 on cytokine production. FR167653 ameliorated endotoxin shock in rabbits and intravascular coagulation in rats^[9,12], and also ameliorated cardiac dysfunction caused by chronic infusion of LPS in rats^[13]. Furthermore, FR167653 protected lung, liver, and heart against ischemia-reperfusion injury in dogs^[14-17], and the protection against liver ischemia-reperfusion injury was associated with inhibition of proinflammatory cytokines from KCs^[18,19]. Recent studies suggest that FR167653 inhibits IL-1 β and TNF- α production via specific inhibition of p38 MAPK activity^[12,17,20-22]. Because effective therapy has not been established for liver injury, development of an anti-inflammatory compound is urgently needed. From this viewpoint, it is worthwhile to assess the anti-inflammatory and immunomodulatory effect of FR167653. In the current study, we administered FR167653 to a murine model of *Bacillus Calmette-Guerin* (BCG) and LPS-induced liver injury and assessed histopathological changes and its effects on cytokine production.

MATERIALS AND METHODS

Animals and reagents

Male Kunming strain mice weighing 18-22 g were purchased from Animal Center of Anhui Medical University. Mice were allowed to access to food and tap water *ad libitum*, and acclimated to facilities for at least 1 wk before any treatments. 1, 1, 3, 1-tetraethoxypropane (TEP) and 5, 5'-dithiobis-(2-nitrobenzoic acid) (DTNB) were purchased from FLUKA Co., Switzerland. BCG was purchased from Institute of Shanghai Biological Products. ConA, LPS from *Escherichia coli*, and TNF- α ELISA kit were purchased from Sigma Co., St. Louis, USA. The primers of NF- κB and β -actin were synthesized by BIOASIA Biotech Co. Shanghai. FR167653 supplied by the Fujisawa Pharmaceutical Co. Ltd. (Tokyo, Japan), was dissolved to 20 mL/L with 5 g/L methylcellulose solution. To obtain the dose of 50, 100, or 150 mg/kg body mass (BM), 2.5, 5, or 7.5 $\mu\text{L/g}\cdot\text{bm}$. of 20 mL/L FR167653 solution was injected subcutaneously.

Model of BCG and LPS-induced immunological liver injury (ILI) and treatment^[23]

Each mouse was injected with 2.5 mg BCG (viable bacilli) in 0.2 mL saline via tail vein, and 10 d later with 10 mg LPS in 0.2 mL

saline. At 4, 8, and 12 h post-injection of LPS, animals received FR167653 at 50, 100, and 150 mg/kg, s.c., respectively. The control group was subcutaneously administered the same volume of 5 g/L methylcellulose solution. The mice were anesthetized with ether, then sacrificed by cervical dislocation 16 h after LPS injection and blood was collected, and centrifuged at 1 500 r/min for 10 min at room temperature. Serum was aspirated and stored at -70 °C until assayed as described below. The liver was also removed and stored at -70 °C until required.

Measurement of ALT, AST

Serum ALT, and AST were determined using commercial kits purchased from Institute of Shanghai Biological Products affiliated to the Ministry of Health.

Measurement of MDA and GSHpx in liver homogenate

Livers were thawed, weighed and homogenized with Tris-HCl buffer (5 mmol/L, containing 2 mmol/L EDTA, pH 7.4). Homogenates were centrifuged at 1 000 r/min for 10 min at room temperature and the supernatant was used immediately for the assays of MDA and GSHpx. MDA was measured by the thiobarbituric acid method according to standard techniques. The content of MDA was expressed as nmol per gram liver tissue. GSHpx was measured by the DTNB method, and its content was expressed as U per milligram protein.

Measurement of TNF- α , IL-1, and nitric oxide (NO)

Serum TNF- α and NO were measured using commercial kits produced by Sigma Co. and Beijing Biotinge-Tech Co. Ltd, and their levels were expressed as pg/mL and μ mol/L respectively. IL-1 produced by peritoneal macrophages was measured according to the method of 3 H-infiltrated cell proliferation.

RT-PCR assay for NF- κ B p65 mRNA in liver tissue

Liver tissue RNA was extracted using RNA easy kit (Invitrogen, USA). To test the efficacy of reverse transcriptase, RT-PCR was performed for β -actin mRNA. Briefly, the first strand of cDNA was synthesized by reverse transcriptase and pooled. The resulting cDNA samples were adjusted to PCR buffer conditions and run for PCR simultaneously. The primers for NF- κ B p65 were 5'-GCG GCC AAG CTT AAG ATC TGC CGA GTA AAC-3', and 5'-CGC TGC TCT AGA GAA CAC AAT GGC CAC TTG CCG-3'. The primers for β -actin were 5'-TGG AAT CCT GTG GCA TCC ATG AA-3', and 5'-TAA AAC GCA GCT CAG TAA CAG TC-3'. The amplifications of NF- κ B p65 and β -actin genes are expected to generate 198 bp and 348 bp fragments, respectively. Amplification was performed for 30 cycles, each of which consisted of 1 min of denaturation at 94 °C, 1 min of annealing at 58 °C, and 3 min of primer extension at 72 °C. Ten μ L of reaction mixture was loaded to 10 g/L agarose gel containing 0.5 μ g/mL ethidium bromide for electrophoresis, the gel was then placed under ultraviolet light for semi-quantitative detection.

Histological examination of liver specimens

Formalin-fixed liver specimens were embedded in paraffin and

stained with hematoxylin and eosin for conventional morphological evaluation.

Statistical analysis

All values were expressed as mean \pm SD. The significance of differences between groups was determined by ANOVA followed by Student's *t* test. *P* value of less than 0.05 was considered significant.

RESULTS

Effects of FR167653 on ILI induced by BCG plus LPS in mice

The levels of ALT and AST in plasma and MDA content in liver homogenate were significantly increased after the sequential injection of BCG and LPS. Meanwhile, the GSHpx level in liver homogenate was sharply decreased (Figures 1, 2). FR167653 (50, 100, 150 mg/kg, s.c.) could not only significantly decrease ALT, AST, and MDA levels, but also evidently increase GSHpx level in mice with ILI (Figures 1, 2). Liver histopathologic examination showed extensive inflammatory cells infiltration and liver cells necrosis. FR167653 (100, 150 mg/kg) significantly reduced inflammatory cells infiltration and liver cells necrosis (Figure 3).

Figure 2 Effect of FR167653 on MDA and GSHpx contents in liver homogenates of ILI mice. *n*=8, mean \pm SD, ^b*P*<0.01 vs model group; ^d*P*<0.01 vs normal group.

Table 1 Effect of FR167653 on serum TNF- α , NO and IL-1 from peritoneal macrophages in ILI mice

Group	Dose (mg/kg)	TNF- α (pg/mL)	NO (μ mol/L)	IL-1 (10 ³ /min)
Normal	-	Under detection limit	15.7 \pm 4.3	6.4 \pm 1.42
Model	-	523.1 \pm 28.6 ^d	117.8 \pm 10.7 ^d	21.5 \pm 5.04 ^d
FR167653	50	491.8 \pm 20.5 ^a	109.3 \pm 10.5	17.4 \pm 3.81
	100	404.9 \pm 18.5 ^b	95.4 \pm 8.9 ^b	14.7 \pm 3.05 ^b
	150	341.8 \pm 19.1 ^b	84.3 \pm 8.7 ^b	11.9 \pm 2.85 ^b

n=8, mean \pm SD, ^a*P*<0.05, ^b*P*<0.01 vs model group; ^d*P*<0.01 vs normal group.

Figure 3 Effect of FR167653 on liver histopathology of ILI mice. A: Normal group; B: Model group; C: Model plus FR167653 (100 mg/kg); D: Model plus FR167653 (150 mg/kg). All sections were stained with hematoxylin and eosin (200 \times).

Effects of FR167653 on TNF- α , IL-1, and NO

The levels of TNF- α and NO were elevated significantly in mice injected with BCG and then challenged with LPS. Likewise, IL-1 excreted by peritoneal macrophages was also significantly increased in the model group (Table 1). FR167653 (50, 100, 150 mg/kg) obviously counteracted the increase of TNF- α and NO levels in sera. IL-1 produced by peritoneal macrophages was also significantly inhibited by FR167653 (Table 1).

Effects of FR167653 on NF- κ B p65 expression in liver tissue

Gel electrophoresis and semi-quantitative analysis showed that FR167653 significantly reduced expression of NF- κ B mRNA in liver tissue of ILI induced by BCG plus LPS compared with model group (Figure 4).

Figure 4 Effect of FR167653 on NF- κ B mRNA in liver tissue of ILI mice. $n=3$, mean \pm SD. ^a $P<0.05$. ^b $P<0.01$ vs model group; ^d $P<0.01$ vs normal group.

DISCUSSION

It has been demonstrated that severe hepatitis could be induced

by injecting a small dose of bacterial LPS into BCG-pretreated mice^[23]. In the present study, ILI was successfully induced by BCG plus LPS. On this basis, FR167653 (50, 100, 150 mg/kg) could significantly lower the increased plasma transaminase levels and MDA contents in liver homogenate. Meanwhile, GSHpx levels were increased significantly. Histopathologic examination showed FR167653 significantly reduced inflammatory cells infiltration and liver cells necrosis.

Although several parameters of the inflammatory response contribute to liver injury^[24], one well-studied pathway is the production of TNF- α . In a number of liver injury models, elevated TNF- α levels were present and correlated with liver injury^[23,25,26]. Inhibition of TNF- α activity can decrease liver injury. The addition of soluble TNF receptors that diminished the biological effect of TNF- α could significantly decrease liver enzyme levels, improve liver histology, and reduce mortality immediately after acute carbon tetrachloride administration. Similar results were seen in chronic alcohol-induced liver disease in rats. In humans, elevated levels of TNF- α are seen in hepatitis and are associated with increased mortality^[27]. Furthermore, TNF- α might act as the first mediator of liver injury, its elevation would result in release of a number of proinflammatory mediators including IL-1, NO, IL-6, IL-8^[3,28], further deteriorating the liver injury. In the present study, TNF- α in the sera and IL-1 produced by peritoneal macrophages were significantly increased in mice with ILI compared with control. FR167653, a potent inhibitor of TNF- α and IL-1, suppressed elevated TNF- α and IL-1 levels, which was consistent with previous observations^[29]. As potent producers of inflammatory cytokines such as TNF- α and IL-1, KCs have been implicated in the pathway leading to liver injury^[30]. Whether inhibition of FR167653 on TNF- α production was associated with diminished KCs proliferation, and decreased inflammatory cells infiltration needs to be further clarified.

A growing body of evidence suggests that sustained production of NO resulting from up-regulation of inducible NOS (iNOS) after LPS challenge may cause hepatocellular injury, either directly^[31,32], or indirectly, by forming reactive nitrogen

intermediates^[33]. Menezes *et al.*^[34,35] demonstrated that a NO scavenger, NOX, decreased hepatocellular injury and improved survival after hemorrhagic shock. As reported previously, the synthesis of NO was regulated by various factors including TNF- α , IL-1, and NF- κ B. The inhibition of NF- κ B led to a decrease in the inducible isoform of NO and the transcription of TNF- α in KCs^[36-38]. Moreover, synthetic double-stranded oligodeoxynucleotides (ODN) transfer with a high affinity to NF- κ B (NF- κ B/decoy/ODN) *in vivo* effectively suppressed endotoxin-induced fatal liver injury in mice^[39]. In our study, we observed significant suppression of NF- κ B p65 mRNA in liver tissue and NO in sera of BCG plus LPS - induced ILI by FR167653. It indicated that inhibition of FR167653 on liver injury might be related with decreased NO production through inhibiting NF- κ B transcription. Recent studies suggested that p38 MAPK inhibitor, SB203580, diminished phosphorylation of the transactivation domain of the p65 subunit of NF- κ B^[40]. Moreover, the pharmacological characteristics and chemical structure of FR167653 resemble SB203580^[41,42]. Therefore, inhibition of FR167653 on liver injury was associated with reduced expression of NF- κ B via p38 MAPK, and led to down-regulation of TNF- α , IL-1, and NO.

Abstract

AIM: To clarify the effectiveness of plasma exchange by comparing the mortality and morbidity before and after the intervention of plasma exchange.

METHODS: Plasma exchange has been available as an optional therapy for hyperlipidemic pancreatitis since August 1999 in our hospital. The patients were assorted into 2 groups (group I: before August 1999 and group II: after August 1999). Group I consisted of 34 patients (before the availability of plasma exchange). Group II consisted of 60 patients (after the availability of plasma exchange). Twenty patients in group II received plasma exchange after giving their consent. The mortality and morbidity were compared between group I and group II. Furthermore, the patients with severe hyperlipidemic pancreatitis (Ranson's score ≥ 3) were analyzed separately. The mortality and morbidity were also compared between those receiving plasma exchange (group A) and those who did not receive plasma exchange (group B).

RESULTS: There was no statistical difference in the mortality, systemic and local complications between group I and group II. When the patients with severe hyperlipidemic pancreatitis were analyzed separately, there was no statistical difference between group A and group B.

CONCLUSION: Plasma exchange can not ameliorate the overall mortality or morbidity of hyperlipidemic pancreatitis. The time of plasma exchange might be the critical point. If patients with hyperlipidemic pancreatitis can receive plasma exchange as soon as possible, better result may be predicted. Further study with more cases is needed to clarify the role of plasma exchange in the treatment of hyperlipidemic pancreatitis.

INTRODUCTION

Hypertriglyceridemia (HTG) is a rare cause of pancreatitis. Hyperlipidemic pancreatitis (HLP) secondary to HTG presents

typically as an episode of acute pancreatitis or recurrent acute pancreatitis or rarely as chronic pancreatitis^[1]. The typical clinical profile of HLP is a patient with preexisting lipid abnormality along with the presence of secondary factors (such as poorly controlled diabetes mellitus, alcohol abuse, pregnancy, or a medication) that can induce HTG^[1]. It is generally accepted that a TG level more than 1 000 mg/dL is needed to precipitate an episode of acute pancreatitis^[2]. It is postulated that hydrolysis of TG by pancreatic lipase into free fatty acid is toxic to pancreatic endothelium and acinar cells^[3]. In an animal study, hyperlipidemia could intensify the course of acute edematous pancreatitis and necrotizing pancreatitis^[3].

Plasmapheresis has been claimed to reduce triglyceride level rapidly in HLP^[4-11] and is believed to halt the progression of HLP^[8-10]. Actually, experiences of plasmapheresis in HLP are limited and only sporadic cases were reported^[5-11]. There was no control study in the past concerning whether plasmapheresis could improve the mortality or morbidity of HLP. Our aim was to analyze the benefits of plasma exchange by comparing the mortality and morbidity of HLP patients with those without receiving such an intervention.

MATERIALS AND METHODS

Patient characteristics

From September 1992 to June 2003, a total of 862 patients with acute pancreatitis were reviewed and 94 patients were consistent with hyperlipidemic pancreatitis (HLP). As plasma exchange has been available as an optional therapy of HLP since August 1999 in our hospital, the patients were assorted into 2 groups (group I: before August 1999 and group II: after August 1999). Group I consisted of 34 patients (before the availability of plasmapheresis) and group II consisted of 60 patients (after the availability of plasmapheresis). Twenty of 60 patients in group II received plasma exchange after giving their consents. The Ranson's score was used for assessment of the severity of pancreatitis. Half of the patients receiving plasma exchange were severe cases (Ranson's score ≥ 3). The anatomical change of acute pancreatitis was assessed according to the Balthazar's grading. The enrolled criteria of plasma exchange in HLP were as followings: (1) overt symptoms of acute pancreatitis, (2) pancreatitis proved by CT, ultrasound or elevation of pancreatic enzymes, (3) triglyceride (TG) $>1\ 000$ mg/dL and lactescent serum, (4) exclusion of other causative conditions, such as gall stone, trauma or neoplasm, (5) patient's agreement. The mortality and morbidity between group I and group II were compared.

Furthermore, the patients with severe HLP (Ranson's score ≥ 3) were analyzed separately. We divided the patients with severe HLP (a total of 29 patients) into 2 groups. Group A received plasma exchange, while group B did not receive the intervention. The mortality and morbidity between group A and group B were also compared.

The secondary factors inducing HTG in our patients included diabetes mellitus (46 patients), alcoholic consumption (32 patients) and oral contraceptive (one patient). The median time for starting plasma exchange was 3 d after symptom onset (range, 2-6 d).

Apheresis

Plasma exchange was carried out using membrane filtration in a KM 8800 membrane plasmapheresis monitor (Kuraray, Osaka, Japan) with a Plasmacure plasma separator (Kuraray, Osaka, Japan) to separate plasma from blood. One calculated plasma volume was processed during each session of plasma exchange. One course of plasma exchange treatment consisted of one or two daily sessions based on the doctor's decision, single session in 13 patients and two sessions in 7. Heparin was used as the anticoagulant. Either a double lumen catheter in a central vein (fifteen patients) or a dialysis catheter in an antecubital vein (five patients) was used for vascular access. Replacement fluid was given with fresh frozen plasma (FFP) in 8 patients and isovolumetric 5 % albumin solution in 12 patients.

Statistical analysis

t-test and chi-square test were used for statistical analysis. $P < 0.05$ was considered statistically significant.

RESULTS

The demographic characteristics of all the patients are summarized in Table 1. The mean age and sex distribution were similar in both groups. The initial mean TG level was around 1 900 in both groups. The severity of pancreatitis was predicted by the Ranson's criteria. Severe pancreatitis (Ranson's score ≥ 3) was 20.6% in group I and 36.7% in group II ($P = 0.105$). The anatomical change of pancreatitis was assessed according to the Balthazar's grading system and 54.2% of group I and 41.3% of group II were belonged to Balthazar grade D or E ($P = 0.305$).

The mortality rate, systemic and local complications of both groups are demonstrated in the Table 2. The systemic complication was defined by the Atlanta definition^[12]: (1) pulmonary insufficiency, $\text{PaO}_2 < 8 \text{ kPa}$, (2) renal insufficiency, $\text{Cr} > 2 \text{ mg/dL}$, (3) shock, $\text{SBP} < 12 \text{ kPa}$, (4) UGI bleeding $> 500 \text{ mL/24 h}$. The local complications included abscess and pseudocyst formation. There was no significant difference between group I and group II in mortality and complications. Further comparison of individual items of systemic and local complications between the two groups revealed no statistical differences (Tables 3, 4).

Table 1 Demographic characteristics

	Group I (<i>n</i> =34)	Group II (<i>n</i> =60)	<i>P</i> value
Age (yr)	40.8 \pm 6.8	42.3 \pm 8.9	0.394
Initial TG	1 922 \pm 1 287	1 913 \pm 612	0.966
DM (%)	38(13/34)	55(33/60)	0.118
Alcohol (%)	44(15/34)	28.3 (17/60)	0.121
Ranson >3 (%)	20.6(7/34)	36.7(22/60)	0.105
Balthazar D, E (%)	54.2(13/24)	41.3(19/46)	0.305

Table 2 Comparison of mortality and morbidity between patients before and after availability of plasma exchange

	Group I (%, <i>n</i> =34)	Group II (%, <i>n</i> =60)	<i>P</i> value
Mortality (%)	5.9(2/34)	6.7(4/60)	0.881
Systemic complications (%)	17.6(6/34)	18.3(11/60)	0.934
Local complications (%)	11.8(4/34)	6.7(4/60)	0.395

When severe hyperlipidemic pancreatitis (Ranson's score ≥ 3) was analyzed separately (Table 5), the mortality rate, systemic and local complications of group A (with plasmapheresis) and group B (without plasmapheresis) were not statistically different ($P = 0.369$, 0.153, 0.454, respectively).

The mean serum concentration of TG and lipase fell significantly after plasma exchange. The serum TG level declined

from 2 019 \pm 780 mg/dL to 691 \pm 331 mg/dL (65.8% reduction) and the serum lipase level declined from 4 007 \pm 355 U/L to 447 \pm 35 U/L (88.8% reduction).

Table 3 Comparison of systemic complications between patients before and after the availability of plasma exchange

	Group I (%, <i>n</i> =34)	Group II (%, <i>n</i> =60)	<i>P</i> value
ARF	17.6(6/34)	10(6/60)	0.286
UGI bleeding	0(0/34)	8.3(5/60)	0.084
Shock	8.8(3/34)	10(6/60)	0.852
ARDS	11.8(4/34)	10(6/60)	0.790

ARF: Acute renal failure; ARDS: Acute respiratory distress syndrome.

Table 4 Comparison of local complications between patients before and after availability of plasma exchange

	Group I (%, <i>n</i> =34)	Group II (%, <i>n</i> =60)	<i>P</i> value
Abscess	17.6(6/34)	10(6/60)	0.286
Pseudocyst	0(0/34)	8.3(5/60)	0.084

Table 5 Comparison of patients with severe hyperlipidemic pancreatitis receiving plasma exchange and not receiving plasma exchange

	Group A: PE(+) (%, <i>n</i> =10)	Group B: PE(-) (%, <i>n</i> =19)	<i>P</i> value
Ranson >3			
Mortality	30(3)	15.8(3)	0.369
Systemic complications	70(7)	42.1(8)	0.153
Local complications	10(1)	21.1(4)	0.454

PE (+): With plasma exchange; PE (-): Without plasma exchange.

DISCUSSION

The association between hyperlipidemia and acute pancreatitis was first described by Speck in 1865^[1]. Studies on patients with familial HTG and their longterm follow-up have shown that extreme elevation of TG occurred during episode of acute pancreatitis^[13]. It has been generally believed that a TG level of more than 1 000 mg/dL was needed to precipitate an acute pancreatitis^[2]. The hypothesis of hyperlipidemic pancreatitis is that pancreatic damage was resulted from toxic injury to the capillary endothelium and the damage of pancreatic acinar cells was caused by free fatty acids liberated by pancreatic lipase^[3]. Conservative treatment (fasting, lipid lowering drugs, insulin or fluid restoration) might decrease TG level slowly in a time span of days to weeks^[14]. In contrast, plasmapheresis might remove excessive lipid from serum in about 2 h^[4,6]. Sporadic reports about plasmapheresis used in hyperlipidemic pancreatitis were seen in the past^[4-10]. They all concluded that plasmapheresis was helpful for treating or preventing acute hyperlipidemic pancreatitis. However, no control study to assess the value of plasmapheresis in the treatment of hyperlipidemic pancreatitis is available.

Different methods have been used in plasmapheresis. Plasma exchange is superior to double filtration in the removal of excessive TG because the membrane of plasma separator was usually blocked by the larger particles of chylomicron^[6]. We used plasma exchange with replacement of albumin or fresh frozen plasma (FFP) in the treatment of HLP in this study. FFP could supply lipoprotein lipase and apolipoprotein from the healthy donor^[13]. Lipoprotein lipase and apolipoprotein were essential for the catabolism of TG^[13].

In our study, plasma exchange could remove TG effectively

from turbid plasma in a short time (about 2 h). TG declined from $2\,019 \pm 780$ mg/dL to 691 ± 331 mg/dL (65.8% reduction). It was also postulated that plasmapheresis could remove circulating activated enzymes and inflammatory mediators^[15], but its beneficial effects in pancreatitis has not been proved^[10]. The serum lipase level declined from $4\,007 \pm 355$ U/L to 447 ± 35 U/L (88.8% reduction) after plasma exchange in our patients.

Despite the marked reduction in TG and lipase after plasma exchange, we could not achieve statistically significant improvement in the mortality and morbidity after the intervention of plasma exchange. The mortality was 5.9% before the intervention (group I) and 6.7% after the intervention (group II). The rate of systemic complications (acute renal failure, UGI bleeding, shock, or pulmonary insufficiency) was 17.6% in group I and 18.3% in group II. The rate of local complications (abscess or pseudocyst) was 11.8% in group I and 6.7% in group II. While individual items of complications were considered, there were still no statistical differences between the two groups.

When the patients with severe HLP (Ranson's score ≥ 3) were analyzed separately, the mortality rate was 30% in group A (with plasma exchange) and 15.8% in group B (without plasma exchange). The mortality in severe HLP was not decreased by plasma exchange. The rate of systemic complication was 70% in group A and 42.1% in group B ($P=0.153$). The rate of local complication was 10% in group A and 21.1% in group B ($P=0.454$). Again, plasma exchange was not able to alter the complication rate significantly.

Why could plasma exchange not improve the mortality and morbidity in HLP? We proposed that the time of plasmapheresis might be the critical point. If patients with HLP could receive plasma exchange as soon as possible, better result might be expected^[5].

In conclusion, plasma exchange fails to improve the overall mortality and morbidity of HLP in our study. Further study with more cases is needed to clarify the role of plasmapheresis in the treatment of HLP.

Abstract

AIM: In previous experiments we have demonstrated that by administering low doses of cholecystokinin-octapeptide (CCK-8), the process of regeneration following L-arginine (Arg)-induced pancreatitis is accelerated. In rats that were also diabetic (induced by streptozotocin, STZ), pancreatic regeneration was not observed. The aim of this study was to deduce whether the administration of exogenous insulin could in fact restore the hypertrophic effect of CCK-8 in diabetic-pancreatic rats.

METHODS: Male Wistar rats were used for the experiments. Diabetes mellitus was induced by administering 60 mg/kg body mass of STZ intraperitoneally (i.p.), then, on d 8, pancreatitis was induced by 200 mg/100 g body mass Arg i.p. twice at an interval of 1 h. The animals were injected subcutaneously twice daily (at 7 a.m. and 7 p.m.) with 1 µg/kg of CCK-8 and/or 2 IU mixed insulin (300 g/L short-action and 700 g/L intermediate-action insulin) for 14 d after pancreatitis induction. Following this the animals were killed and the serum amylase, glucose and insulin levels as well as the plasma glucagon levels, the pancreatic mass/body mass ratio (pm/bm), the pancreatic contents of DNA, protein, amylase, lipase and trypsinogen were measured. Pancreatic tissue samples were examined by light microscopy on paraffin-embedded sections.

RESULTS: In the diabetic-pancreatic rats treatment with insulin and CCK-8 significantly elevated pw/bm and the pancreatic contents of protein, amylase and lipase vs the rats receiving only CCK-8 treatment. CCK-8 administered in combination with insulin also elevated the number of acinar cells with mitotic activities, whereas CCK-8 alone had no effect on laboratory parameters or the mitotic activities in diabetic-pancreatic rats.

CONCLUSION: Despite the hypertrophic effect of CCK-8 being absent following acute pancreatitis in diabetic-rats, the simultaneous administration of exogenous insulin

restored this effect. Our results clearly demonstrate that insulin is necessary for the hypertrophic effect of low-doses of CCK-8 following acute pancreatitis.

INTRODUCTION

We have previously demonstrated that the administration of low doses of cholecystokinin-octapeptide (CCK-8) accelerated the processes of regeneration following L-arginine (Arg)-induced pancreatitis^[1] and this was not observed in rats that were also diabetic^[2]. The most significant difference in the regeneration was observed after two wk of CCK-8 treatment^[1]. In addition, the histologic examination revealed that the majority of hypertrophized pancreatic acinar cells were found surrounding the enlarged islets of Langerhans following CCK-8 administration. It appears that the close proximity of the islets of Langerhans functions to protect the acinar cells as well as accelerate the regenerative process during Arg-evoked pancreatic tissue damage. A reason for this may be due to the interaction of acinar and islet cells. The exocrine and endocrine pancreas possesses a multitude of complex anatomical and functional interrelations^[3]. It is well documented that intact islets of Langerhans are necessary for normal pancreatic exocrine function^[4], and so we set out to investigate whether the administration of exogenous insulin could restore the hypertrophic effect of CCK in diabetic-pancreatic rats.

MATERIALS AND METHODS

Male Wistar rats weighing 250-300 g were divided into five groups. The animals were kept at a constant room temperature of 25 °C with a 12-h light-dark cycle, and were allowed free access to water and standard laboratory chow (Biofarm, Zagyvaszántó, Hungary). Rats in group D (diabetic -control group) were injected with 60 mg/kg body mass of streptozotocin (Zanosar®, The Upjohn Company, Kalamazoo, MI) intraperitoneally (i.p.). In group DP (diabetic and pancreatic) the rats received STZ as in group D, and on d 8, pancreatitis was induced by 200 mg/100 g body mass Arg (Sigma, St. Louis, MO) i.p. twice at an interval of 1h. In group DPC, apart from being given Arg and STZ, the rats were also administered 1 µg/kg of CCK-8 (synthesized by Botond Penke, Department of Medical Chemistry University of Szeged) subcutaneously (s.c.) twice daily (at 7 a.m. and 7 p.m.). In group DPI, besides being administered Arg and STZ, the rats received 2 IU mixed insulin (300 g/L short-action and 700 g/L intermediate-action insulin, HUMULIN M3®, Lilly Hungária Kft, Hungary) s.c. twice

Table 1 Laboratory parameters changes in diabetic-pancreatic rats due to a 14 d administration of insulin and/or CCK-8

	Serum glucose	Serum insulin	pm/bm	Pancreatic DNA	Pancreatic protein	Pancreatic amylase	Pancreatic trypsinogen	pancreatic lipase
Insulin treatment				-	-		-	-
CCK-8 treatment	-	-	-	-	-	-	-	-
Insulin and CCK-8 treatment				-				-

CCK-8: cholecystokinin-octapeptide, pm/bm: pancreatic weight/body weight ratio. increased or decreased activity/ level, - no change, significantly larger increase of activity compared with the sign. All changes are given in comparison to the untreated diabetic-pancreatic rats (group DP).

daily (at 7 a.m. and 7 p.m.). In group DPCI, diabetes and pancreatitis were induced as in group DP and the rats were administered CCK-8 and mixed insulin as mentioned before. The animals were killed in the morning by exsanguination through the abdominal aorta 14 d after pancreatitis induction. The serum amylase, glucose, insulin and plasma glucagon levels, pancreatic mass/body mass ratio (pm/bm), the pancreatic contents of DNA, protein, amylase, lipase and trypsinogen were measured^[2]. Pancreatic tissue samples were examined by light microscopy on paraffin-embedded sections. Results were expressed as mean±SE. Statistical analysis was performed by using ANOVA. *P* values <0.05 were accepted as significant.

RESULTS

In diabetic groups D, DP, and DPC, the serum glucose levels (22.5±1.5 mmol/L, 29.5±0.8 mmol/L and 29.0±0.7 mmol/L respectively) were significantly elevated and the insulin levels (0.70±0.30 U/L, 0.35±0.09 U/L and 0.20±0.05 U/L, respectively) were significantly lower vs those in insulin-treated groups DPI and DPCI (14.5±2.3 mmol/L and 12.9±2.8 mmol/L; 401±38 U/L and 138±35 U/L, respectively). These results clearly indicated the presence of diabetes mellitus in the animals studied and the efficacy of insulin treatment. There were no significant differences in plasma glucagon and serum amylase levels in group D as compared with any of the other groups. In groups DPI and DPCI, pm/bm (2.98±0.21 mg/g, 3.58±0.11 mg/g, respectively) was significantly elevated vs group DP (2.09±0.26 mg/g). However, no significant differences were observed in pm/bm between group DPC and group DP (2.62±0.26 mg/g and 2.09±0.26 mg/g, respectively). In group DPCI (insulin- and CCK-8-treated diabetic-pancreatic rats), the pancreatic protein content (250±35 mg/p) was significantly elevated vs groups DP and DPC (147±10 mg/p and 148±10 mg/p, respectively). In groups DPI and DPCI (insulin-treated rats), the pancreatic amylase content (3 948±1 288 U/p, 10 502±2 935 U/p, respectively) was significantly elevated vs groups DP and DPC (158±5 U/p and 182±25 U/p, respectively). In group DPCI, pancreatic amylase content (10 502±2 935 U/p) was significantly elevated vs group DPI (3 948±1 288 U/p). No significant differences were found in the pancreatic DNA and lipase contents between group D and any other groups. In group DPCI, the pancreatic trypsinogen content was significantly elevated vs group DPI (976±132 IU/p and 592±63 IU/p, respectively). However, no significant differences were observed in the pancreatic trypsinogen content between group DPC (655±36 IU/p) and DP (776±48 IU/p). Histological examination revealed signs of chronic inflammation in diabetic-pancreatic rats, where acute inflammatory cells had been replaced by interstitial tissues, mononuclear cells and fibroblasts. Histological examination did not show any differences between groups DPC and DP. In group DPCI, a more intense mitotic activity was observed vs group DPC due to the effect of insulin (Table 1).

DISCUSSION

The intraperitoneal administration of high doses of Arg induces selective pancreatic acinar cell damage without any morphological change to the islets of Langerhans^[5]. STZ has been reported to be specifically toxic to the β-cells of the islets of Langerhans and to induce a dose-dependent and irreversible diabetes in rats without any morphological change to the exocrine pancreas^[6]. These models seemed to be suitable for studying the correlation between diabetes mellitus and pancreatitis. The role of insulin in the process of spontaneous and CCK-8-promoted pancreatic regeneration following acute pancreatitis has not yet been characterised in detail. The interesting finding which showed that periinsular acini remained intact during Arg-induced-pancreatitis as well as a lack of the hypertrophic effect of CCK in diabetic rats prompted us to continue studies on the effects of insulin in the process of pancreatic remodelling. Our hypothesis stated that insulin was necessary for the regenerative effect of CCK-8, therefore, we evoked diabetes and pancreatitis in rats as described earlier^[2] and then, in the diabetic rats insulin was administered by s.c. injections. The elevation of serum insulin level and the diminution of serum glucose level, clearly showed the efficacy of the insulin treatment. CCK-8 could only elevate pw/bw, the pancreatic contents of protein, amylase and lipase in the presence of insulin. Moreover, CCK-8 could also increase the number of acinar cells with mitotic activity when insulin was administered, but CCK-8 alone had no effect on the laboratory parameters or the mitotic activity in diabetic-pancreatic rats. Lines of evidence demonstrate that both pancreatic secretory and growth processes are (at least partially) under the control of pancreatic islet hormones. Hypoinsulinemia was known to cause pancreatic atrophy and fat infiltration of the exocrine pancreas in guinea pigs^[7]. In contrast to this, endogenous and exogenous insulin evoked an increase in pancreatic enzyme synthesis and growth^[8]. These direct (via acinar insulin receptors) and indirect (influence on CCK receptors) effects of insulin are well understood. It was also demonstrated that insulin binding to its receptors on the pancreatic acini could be correlated with the subsequent stimulation of protein synthesis^[9]. Another indirect observation was that anti-insulin serum completely blocked the CCK-8-stimulated pancreatic secretion in rats^[10]. It further suggests that endogenous insulin is necessary for the stimulatory action of CCK-8 on pancreatic exocrine secretion and growth^[10]. The present study proves our hypothesis that insulin is indeed necessary for the hypertrophic effect of CCK-8 following acute necrotizing experimental pancreatitis.

Abstract

AIM: Portopulmonary hypertension is a serious complication of chronic liver disease. Our aim was to search into the effect of terlipressin on systolic pulmonary artery pressure among cirrhotic patients.

METHODS: Twelve patients (6 males and 6 females) with liver cirrhosis were recruited in the study. Arterial blood gas samples were obtained in sitting position at rest. Contrast enhanced echocardiography and measurements of systolic pulmonary artery pressure were performed before and after the intravenous injection of 2 mg terlipressin.

RESULTS: Of 12 patients studied, the contrast enhanced echocardiography was positive in 5, and the positive findings in contrast enhanced echocardiography were reversed to normal in two after terlipressin injection. The mean systolic pulmonary artery pressure was 25.5 ± 3.6 mmHg before terlipressin injection, and was 22.5 ± 2.5 mmHg after terlipressin ($P=0.003$). The systolic pulmonary artery pressure was above 25 mmHg in seven of these 12 patients. After the terlipressin injection, systolic pulmonary artery pressure was <25 mmHg in four of these cases (58.3% vs 25%, $P=0.04$).

CONCLUSION: Terlipressin can decrease the systolic pulmonary artery pressure in patients with liver cirrhosis.

INTRODUCTION

The spectrum of pulmonary vascular disorders in liver disease and portal hypertension ranges from hepatopulmonary syndrome characterized by intrapulmonary vascular dilatations (IPVD) to pulmonary hypertension (portopulmonary hypertension), in which pulmonary vascular resistance is elevated^[1].

Hepatopulmonary syndrome (HPS) is incurable but resolves over time after liver transplantation^[2]. In patients with cirrhosis, 1% pulmonary hypertension is developed^[2,3]. Portopulmonary hypertension (PPH) is irreversible and there is no effective treatment^[4]. Mortality of liver transplantation in patients with PPH ranges from 50% to 100%^[4]. The common causes of HPS and PPH are portal hypertension and portosystemic shunting, indicating that vasoactive and angiogenetic factors originating from the liver can control pulmonary circulation^[4].

So far, observational studies have examined several drugs^[5-8]. No clearly effective medical therapies for PPH have been found. In the present study, we investigated the effects of terlipressin that was used in the treatment of variceal hemorrhage on systolic pulmonary artery pressure (SPAP) among cirrhotic patients.

MATERIALS AND METHODS

Patients

Twelve cirrhotic patients without any malignancy, heart failure, renal failure (serum creatinin >20 mg/L), chronic obstructive lung disease, pneumonia, and anemia (hemoglobin level <100 mg/L) were studied. All patients had portal hypertension. The presence of hepatic dysfunction or portal hypertension was assessed by the following: (1) clinical history of complications related to liver disease and portal hypertension (ascites, hepatic encephalopathy, esophagogastric varices, variceal bleeding and spontaneous bacterial peritonitis); (2) liver function tests (aspartate and alanine aminotransferase, alkaline phosphatase, total bilirubin, prothrombin time, and albumin); and (3) abdominal ultrasound evidences of cirrhosis and portal hypertension (small, nodular liver, hepatofugal portal venous flow, portosystemic collateral circulation, splenomegaly, and ascites). The severity of hepatic dysfunction was stratified according to the Pugh-Child's criteria.

Methods

Chest X-ray and electrocardiogram were performed for all patients. Blood samples were obtained to calculate the score of Pugh-Child in the morning of study day. Arterial blood gas samples were obtained from a single radial artery puncture while the patient was breathing room air in sitting position at rest.

Transthoracic contrast-enhanced echocardiography (CEE) was performed to investigate the intrapulmonary vascular dilations. CEE was performed after the administration of 10 mL of hand-agitated normal saline solution in the supine position via an upper extremity peripheral vein. Positive results were qualitatively defined as any visual opacification of the left heart chamber more than three cardiac cycles after appearance of microbubbles in the right ventricle^[9]. These findings suggested intrapulmonary passage of microbubbles through either dilated precapillary and capillary vessels or direct arteriovenous communications. Echocardiographic assessments were carried out with Wingmed system five 1.7 MHz electronic probe by an experienced cardiologist. Left lateral position was used during measurements. Left atrium, left ventricular diastolic and systolic dimensions were calculated with standard M-mode echocardiographic pictures in parasternal long axis view. Wall motions and wall thickness were also evaluated. Fractional

shortening was studied at level of chordae tendinae (left ventricular end diastolic dimension-left ventricular end systolic dimension/left ventricular end diastolic dimension $\times 100$). Each parameter represented the mean value of three successive measurements. Maximum flow rates with continuous wave Doppler (CW) at level of tricuspid valves were used to calculate SPAP (modified Bernoulli equation: $\Delta p = 4V^2$). SPAPs were computed by adding estimated right atrial pressure (5 mmHg) to pressure gradient calculated by modified Bernoulli equation.

CEE and measurements of SPAP were performed before and after the intravenous injection of 2 mg terlipressin (Glypressin® 1 mg flacon, ERKIM Ilac AS, Istanbul, Turkey).

All statistical calculations were done using the SPSS 11.0 software. The measurements were given as the mean values. The paired sample test, Cochran's Q test, and Friedman's test were used to determine the difference of SPAP, the frequency of CEE, and the frequency of patients whose SPAP ≥ 25 mmHg respectively before and after terlipressin injection. $P < 0.05$ was accepted as statistically significant.

RESULTS

The clinical and demographical characteristics of patients are shown in Table 1. A total of 12 patients, six males and six females were studied, with a mean age of 52 years. The mean score of Pugh-Child was 5.08, and the mean value of arterial pO_2 was 77.83 mmHg. Ascites was detected in two patients. Two patients suffered from dyspnea. In two patients, chest X ray films showed bilaterally reticulonodular densities at the basal areas.

Before the injection of terlipressin intravenously, a positive CEE was detected in 5 patients, and two of them were disappeared after the drug was injected. Three of the patients who had evident hypoxemia suffered dyspnea, and CEE was positive in these patients. After terlipressin injection, CEE was negative in two of the three patients. Arterial pO_2 was high in the rest two patients with CEE (+), after terlipressin injection CEE positivity was continued. There was not any difference before and after the drug injection according to the frequency of the positivity of CEE (5/12 vs 3/12, $P=0.15$ according to Cochran's Q test). This meaningless result might be due to the small number of patients. The SPAP value was ≥ 25 mmHg in four of five patients with positive CEE. Two patients with a negative CEE after the drug injection had the lowest SPAP value in this group, 24 mmHg and 27 mmHg respectively.

Although the value of SPAP was 25.5 ± 3.6 mmHg before the drug injection, it was decreased to 22.5 ± 2.5 mmHg after

terlipressin injection ($P=0.003$). The value of SPAP was above the level of 25 mmHg as the limit of pulmonary hypertension in seven patients. After the injection of terlipressin, it continued to be higher above this level in three patients [7/12 (58.3%) patients versus 3/12 (25%) patients]. This difference was statistically significant ($P=0.04$). CEE was positive in one of the three patients whose SPAP was >25 mmHg after terlipressin injection. The positivity of CEE disappeared after terlipressin injection in one patient who had a SPAP value lower than 25 mmHg.

DISCUSSION

The association of pulmonary hypertension with portal hypertension, also known as portopulmonary hypertension (PPH), is a complication of chronic liver disease that has been associated with high morbidity and mortality at the time of liver transplantation^[2-4]. PPH has been defined as mean pulmonary artery pressure >25 mmHg in the presence of a normal pulmonary capillary wedge pressure and portal hypertension^[2-4].

The presence of intrapulmonary vascular dilatations can be confirmed using one of the three imaging modalities: contrast-enhanced echocardiography, perfusion lung scan - technetium 99 m-labeled macroaggregated albumin scanning, and pulmonary arteriography^[9,10]. A Doppler echocardiogram is a highly sensitive and noninvasive diagnostic modality for both measuring PAP and determining IPVD. Therefore, it should be considered as the first screening method of choice^[11].

Heretofore, therapy for chronic management of PPH is lacking. Recently, continuous intravenous infusion of epoprostenol has been demonstrated to improve symptomatology and survival in the general population of patients with PPH^[5]. Anecdotal reports suggested that long-term epoprostenol therapy given by continuous infusion might be effective for patients with portopulmonary hypertension, but the efficacy of epoprostenol has not been rigorously studied in this subgroup of patients^[5-7]. Kuo *et al.*^[5] reported the use of epoprostenol in the more specific instance of PPH. Over a period of 6-14 mo, epoprostenol (10-28 ng/kg.min) therapy was associated with a 29-46% decrease in mean pulmonary artery pressure, a 22-71% decrease in pulmonary vascular resistance, and a 25-75% increase in cardiac output in a group of four patients^[5]. These results suggest that effective chronic therapy for PPH is available. In combination with inhaled nitric oxide as acute intraoperative therapy, epoprostenol infusion represented an additional therapeutic option for treatment of PPH in the liver transplant candidate^[5].

Table 1 Characteristics of patients. PBS: primary biliary cirrhosis, HBV: hepatitis B virus, HCV: hepatitis C virus, N: Normal, BB-Nod: bilateral basillary nodularity, (-): absent, (+): present, PAP: pulmonary artery pressure and, CEE: contrast enhanced echocardiography

Sex	Age (yr)	Etiology	Pugh-Child Score	pO ₂ (mmHg)	Ascites	Dyspnea	Chest X-ray	PAP-0 (mmHg)	PAP-1 (mmHg)	CEE-0	CEE-1

There are no long-term studies or guidelines on the use of pharmacotherapy in PPH. In view of the rarity of this disease, much of the traditional treatment of this disease has been empirical. Inhaled NO could decreased the pulmonary artery pressures in some patients with PPH and might have some promise for long-term treatment of this disease^[12]. Other medications have been reported to cause amelioration of pulmonary hypertension in patients with portal hypertension including beta-blockers, nitrates, calcium-channel blockers, prostacyclin and prostacyclin analogs, phosphodiesterase inhibitors (sildenafil), L-arginine, and, endothelin antagonists^[3]. In view of the decreased incidence of variceal bleeding in patients taking beta-blockers and nitrates, we encourage the use of these medications in patients with PPH. Beta-blocking agents, which are used in the treatment for portal hypertension may have deleterious effects on the setting of pulmonary hypertension because they decrease cardiac output and increase pulmonary vascular resistance. Vasodilators are usually ineffective and poorly tolerated because these patients usually have a decreased systemic vascular resistance. Most patients with porto-pulmonary hypertension do not receive anticoagulants because the risk of bleeding is deemed to be elevated, especially when esophageal varices are present.

In patients with hepatopulmonary syndrome, supplemental oxygen and liver transplantation were the usual treatments of choice^[2]. Pharmacologic approaches were limited in improving hypoxemia^[2]. Outcome following liver transplantation was variable, increased cardiopulmonary mortality occurred in patients with moderate to severe pulmonary hypertension. Although a few reports have demonstrated improvement of pulmonary hypertension after liver transplantation, this procedure was a very risky one in patients with markedly increased pulmonary artery pressures^[13]. Report about combined liver-lung transplantation might open a perspective for selected patients with porto-pulmonary hypertension^[14].

Terlipressin is a long-acting vasopressin analogue that has been proved useful in the treatment of variceal hemorrhage. Terlipressin could reduce portal pressure in cirrhotic patients mainly through intense splanchnic vasoconstriction that decreases portal venous inflow^[15]. Hepatic blood flow might also be reduced by terlipressin^[15]. The systemic haemodynamic response to terlipressin was moreover associated with the decrease in portal pressure^[16]. After administration of terlipressin, the azygos blood flow decreased significantly^[17]. In patients with cirrhosis, a single injection of 2 mg terlipressin significantly and markedly reduced portal pressure and azygos blood flow for up to 4 h^[17]. The azygos blood flow (superior porto-systemic collateral circulation) correlated strongly with portal venous flow in patients with portal hypertension^[17]. It could be expected that terlipressin could reverse the vasodilatation of dilated intrapulmonary arteries with HPS and PPH. It can also decrease SPAP by reducing the increased blood flow that may facilitate pulmonary arterial hypertension. In our study, it reduced SPAP from 25.5 ± 3.6 mmHg to 22.5 ± 2.5 mmHg and, this result was statistically meaningful. CEE that showed intrapulmonary vascular dilatation was positive in 5 patients, and it was reversed to normal in 2 patients after terlipressin injection. However, more studies are needed to decide whether this result is meaningful or not.

Chronic terlipressin therapy in combination with a multidisciplinary, well-planned evaluation and treatment plan, may be the answer to a heretofore untreatable disease. This one is a prestudy, because more and detailed studies are

required to show its efficiency. In the context of persisting uncertainty about the cause and treatment of PPH, future studies must focus on the pathophysiology of PPH, predicting reversibility after liver transplantation, and identifying other treatment options.

Abstract

AIM: To report our experience with empiric antimicrobial monotherapy (piperacillin/tazobactam, of which no data are available in such specific circumstances) in microbiologically-documented infections in patients with benign and malignant conditions of the biliary tract.

METHODS: Twenty-three patients, 10 with benign and 13 with malignant conditions affecting the biliary tree and microbiologically-documented infections were recruited and the efficacy of empirical antibiotic therapy was assessed.

RESULTS: The two groups featured similar demographic and clinical data. Overall, the infective episodes were most due to Gram negative agents, more than 60% of such episodes (mostly in malignant conditions) were preceded by invasive instrumental maneuvers. Empirical antibiotic therapy with a single agent (piperacillin/tazobactam) was effective in more than 80% of cases. No deaths were reported following infections.

CONCLUSION: An empiric therapeutic approach with piperacillin/tazobactam is highly effective in biliary tract infections due to benign or malignant conditions.

INTRODUCTION

The common causes of intra-abdominal infections are those related to the biliary tract^[1]. However, to obtain a microbiological diagnosis in biliary tract infections (BTI) is not easy, due to the difficulty of sampling bile and the low incidence of positive blood cultures. Therefore, antimicrobial therapy is often empirical^[2], and the choice of an appropriate regimen depends on the knowledge of the most common causative bacteria and the reported efficacy of antimicrobial drugs in BTI. Moreover, the paucity of randomized clinical trials for BTI treatment probably justifies the fact that there is no standardized approach to these infections^[2].

The present study was to report our experience with empirical single antibiotic treatment with piperacillin-tazobactam of BTI in patients with benign and malignant diseases of the biliary tract, since there are no specific data on this compound in the treatment of such infections.

MATERIALS AND METHODS

Twenty-three consecutive patients (15 men, 8 women, age range 22-88 years) with microbiologically documented BTI entered the study. Underlying disease and causative organisms were assessed. Empirical treatment (4.5 g t.i.d) was started immediately after obtaining samples (blood and/or bile) for microbiological cultures, and concordance with antibiogram and its efficacy were also evaluated. The treatment was judged effective when fever and clinical symptoms of infection resolved within 72 h, whereas the persistence of fever beyond 72 h from the start of treatment, the deterioration of clinical conditions or the death as a result of the primary infection was considered as failure.

RESULTS

Overall, records were obtained from 10 patients with benign and 13 patients with malignant conditions affecting the biliary tree. Table 1 shows the clinical characteristics of the two groups. In more than 60% of patients, BTI were preceded by an invasive procedure on the biliary tree, and this was less frequent in benign than in malignant conditions (50% vs 77%).

Table 1 Demographic and clinical variables of 23 patients with BTI

	Benign conditions	Malignant conditions
No (%)	10/23(43.5)	13/23(56.5)
Average duration of treatment (d)	7±1	10±1
Underlying condition (No.)	Cholelithiasis (7) Acute cholecystitis (2) Iatrogenic stenosis (1)	Cholangiocarcinoma (6) Pancreatic carcinoma (4) Gallbladder carcinoma (2) Infiltrating hepatoma (1)
Previous instrumental invasive maneuvers (No)	None (5) PTD (3) ERCP (2)	None (3) PTD (10)

Abbreviations: BTI=biliary tract infections; ERCP=endoscopic retrograde cholangio-pancreatography; PTD=percutaneous transhepatic drainage.

Table 2 Microbiological variables in 23 patients with BTI

	Benign conditions (10 patients)	Malignant conditions (13 patients)
Insulation medium (No.)	Blood (7) Bile (3)	Blood (6) Bile (7)
Polymicrobial infections	1 (4%)	7 (30%)
Isolated pathogens (No. cases)	<i>E.coli</i> (4) Enterococcus spp (3) Pseudomonas spp (3) Enterobacter spp (2) Streptococcus spp (2) Klebsiella spp (1) Candida spp (1)	Enterococcus spp (6) Staphylococcus spp (6) Candida spp (5) <i>E.coli</i> (2) Pseudomonas spp (2) Proteus spp (1) Enterobacter spp (1) Salmonella spp (1)

Table 2 shows the microbiological characteristics of the pathogens isolated in both groups. As expected, most infections were caused by Gram negative agents, and 30% of them (almost exclusively found in malignant conditions) were polymicrobial. *Candida spp* were always isolated from bile in polymicrobial infections. In 19(82.6%) patients there was no need of modifying the empiric therapeutic schedule, whereas in the remaining 4 the antibiotic regimen was modified according to the antibiogram showing resistance or insensitivity to piperacillin/tazobactam. In all patients with BTI due to benign conditions, decrease of fever and improvement of clinical conditions were observed within 3-18 h. A slower trend was observed in patients with BTI due to malignant conditions (improvement within 8-24 h), probably due to more polymicrobial infections and resistances to the empiric regimen. After the results from the antibiogram were obtained, these latter patients treated with more targeted antibiotic regimens, had the disappearance of fever and improvement of the clinical conditions. No deaths were reported attributable to BTI.

DISCUSSION

In this study, we reported our experience with an empiric antibiotic regimen in BTI, and showed that a monotherapy with piperacillin/tazobactam (that, to the best of our knowledge has still not been assessed in such circumstances) might be effective in more than 80% of cases. The organisms more commonly cultured in our patients, in both benign and malignant conditions, were Gram negative bacteria, the pathogens were more frequently associated with obstructive conditions of the biliary tree^[3,4]. Several infective episodes followed invasive instrumental procedures, especially percutaneous drainage (that also gave a discrete yield for bile culture, as previously shown for this procedure^[5]), and were mostly represented by polymicrobial infections.

A preferred therapeutic schedule for BTI, until recently, was usually a combination of a penicillin (usually ampicillin) and an aminoglycoside^[6-9]. This combination had limited anaerobic coverage, frequent resistance (to ampicillin) of Gram negative bacteria, and the risks of renal damage (aminoglycoside, significantly increased in patients with cholestasis)^[10]. However, other antibiotics (such as the ureidopenicillins) exhibited a broad spectrum of activity, that included many anaerobes, *enterococci* and *P.aeruginosa*, in addition to Gram negative bacilli^[11], so that they may result in appealing for use as single agents. Actually, it has been shown that monotherapy with a ureidopenicillin (mezlocillin, piperacillin) is equally or more effective than the traditional approach with ampicillin/aminoglycoside for treatment of BTI^[12-14], although in patients undergoing nonsurgical invasive procedure of the biliary tree and/or with suspected increased risk of *P.aeruginosa* the association of ureidopenicillin/aminoglycoside has been still

justifiable^[15,16]. On the other hand, the combination of piperacillin with the beta-lactamase inhibitor tazobactam (that displays a substantial elimination in bile^[17,18]) might be a reasonable alternative when the local resistance pattern featured a high incidence of ureidopenicillin-resistant *E.coli* or *Klebsiella spp*^[2,19], as also shown by its effectiveness as single empiric agent in high-risk, febrile neutropenic patients with cancer^[20].

Experience with quinolones for treatment of BTI was still limited^[2,21]. However, there is good evidence that monotherapy with these compounds might be as effective as combination therapy for treatment of BTI^[22-24].

To date, the combination of piperacillin/tazobactam has been demonstrated clinically- and cost-effective in both uncomplicated and complicated intraabdominal infections^[25-27], although no specific data on BTI are available. Therefore, we feel that our experience might be a useful adjunct to the therapeutic armamentarium.

In conclusion, empiric antibiotic treatment with piperacillin/tazobactam is frequently effective in BTI due to benign and malignant conditions. Of course, in such circumstances an early operative drainage of the biliary tree is always mandatory, regardless of the presence or absence of suppuration in the common bile duct^[28], to prevent relapses and septic complications.

Abstract

AIM: To evaluate the glycated hemoglobin (HbA_{1c}) determination methods and to determine fructosamine in patients with chronic hepatitis, compensated cirrhosis and in patients with chronic hepatitis treated with ribavirin.

METHODS: HbA_{1c} values were determined in 15 patients with compensated liver cirrhosis and in 20 patients with chronic hepatitis using the ion-exchange high performance liquid chromatography and the immunoassay methods. Fructosamine was determined using nitroblue tetrazolium.

RESULTS: Forty percent of patients with liver cirrhosis had HbA_{1c} results below the non-diabetic reference range by at least one HbA_{1c} method, while fructosamine results were either within the reference range or elevated. Twenty percent of patients with chronic hepatitis (hepatic fibrosis) had HbA_{1c} results below the non-diabetic reference range by at least one HbA_{1c} method. In patients with chronic hepatitis treated with ribavirin, 50% of HbA_{1c} results were below the non-diabetic reference using at least one of the HbA_{1c} methods.

CONCLUSION: Only evaluated in context with all liver function parameters as well as a red blood count including reticulocytes, HbA_{1c} results should be used in patients with advanced liver disease. HbA_{1c} and fructosamine measurements should be used with caution when evaluating long-term glucose control in patients with hepatic cirrhosis or in patients with chronic hepatitis and ribavirin treatment.

INTRODUCTION

Measurement of glycated hemoglobin (HbA_{1c}) is used for routine evaluation and management of patients with diabetes mellitus. Concentrations of HbA_{1c} provide a means of assessing

long-term glycemic status and correlate well with development of complications related to diabetes mellitus^[1,2]. The liver plays a major role in regulating glucose metabolism because it is the main source of endogenous glucose and a major site involved in insulin metabolism. Because liver disease is associated with an increased prevalence of impaired glucose tolerance and diabetes mellitus, there is a need for tools to measure its long-term glycemic control^[3]. Previous studies indicated that both HbA_{1c} and fructosamine measurement should not be used in patients with liver cirrhosis, although the reason for this was unclear^[4-6]. Shortened erythrocyte life span as in hemolytic anemia is known to cause clinically and analytically low HbA_{1c} values independent of glycemia^[7], but measurement of fructosamine, which has been used to document glycemic status over a period of 2-4 wk, should not be affected by erythrocyte life span. This study described the determination of HbA_{1c} and fructosamine as well as parameters of liver disease and anemia in patients with advanced liver disease.

MATERIALS AND METHODS

Blood samples were collected, with and without EDTA, from 15 consecutive patients with compensated liver cirrhosis and 20 patients with chronic hepatitis and fibrosis of the liver. Diagnostic liver biopsies were performed routinely in all patients during the course of treatment in the Division of Gastroenterology and Hepatology, Department of Internal Medicine, Medical University in Graz. Liver cirrhosis was histologically defined as a diffuse process characterized by fibrosis and the conversion of normal liver architecture into structurally abnormal nodules^[8,9]. Of 15 patients with compensated liver cirrhosis Child-Pugh class A (total bilirubin <2 mg/dL, serum albumin >3.5 g/dL, prothrombine time 1-4 s prolonged, no hepatic encephalopathy and no ascites), 6 were tested positive for hepatitis C, 8 had alcoholic liver disease and 1 had primary biliary cirrhosis. Of the 20 patients with chronic hepatitis and fibrosis, 19 were tested positive for hepatitis C and 1 suffered from alcoholic liver disease. Ten of these patients with chronic hepatitis C were treated with interferon- α plus the antiviral drug ribavirin that can cause reversible hemolytic anemia^[10]. None of the patients included in the study had a history of impaired glucose tolerance or diabetes mellitus.

HbA_{1c} was measured within 3 d of collection using the Hi-Auto A_{1c} HA-8140 HPLC (Menarini Diagnostics, Florence, Italy), the DCA 2000 immunoassay method (Bayer, Vienna, Austria) and the Roche Cobas Integra immunoassay method (Roche, Vienna, Austria). Each of these HbA_{1c} methods was certified by the National Glycohemoglobin Standardization Program (NGSP)^[11]. Routine hematological data were determined with a Coulter counter (Beckman, Vienna, Austria). Blood glucose was determined with a hexokinase/glucose-6-phosphate dehydrogenase colorimetric method (Gluco-Quant; Roche, Vienna, Austria) and used as mean of 4-6 measurements on separate days during the preceding 1 mo. The relationship of blood glucose and HbA_{1c} was calculated according to MBG (mmol/L)=(1.98·HbA_{1c})-4.29^[12]. Fructosamine was determined with a colorimetric test that uses nitroblue tetrazolium in alkaline solution (Unimate FRA; Roche, Vienna, Austria). Reference

ranges were provided by each manufacturer and in most cases represented the mean \pm 2SD of a population without known diabetes. All determinations were analyzed blindly and the procedures were in accordance with the declaration of Helsinki and the local ethics committee recommendations.

RESULTS

Forty percent (6/15) of the patients with liver cirrhosis had HbA_{1c} levels below the non-diabetic reference range with at least one HbA_{1c} method, while fructosamine concentrations were either within the reference range ($n=10$) or elevated ($n=5$) (Figure 1). Twenty percent (2/10) of the patients with chronic hepatitis had HbA_{1c} levels below the non-diabetic reference range with at least one HbA_{1c} method. Fructosamine concentrations of all the 10 patients with chronic hepatitis were below the non-diabetic reference range. In patients with chronic hepatitis treated with ribavirin, 50% (5/10) of HbA_{1c} levels were below the non-diabetic reference range detected by at least one of the HbA_{1c} methods (Figure 1). One patient in this group demonstrated a fructosamine concentration within the diabetic range.

Figure 1 HbA_{1c} level and fructosamine concentration in patients with liver disease. CC: Compensated cirrhosis; LF: Chronic hepatitis (liver fibrosis); IR: Chronic hepatitis with interferon and ribavirin treatment. Shaded areas represent the mean \pm 2SD reference range for each test (HbA_{1c}: 4.5-5.7%; fructosamine: 200-272 μ mol/L).

Table 1 shows the percentage of patients in each group

(cirrhosis, chronic hepatitis, chronic hepatitis with interferon and ribavirin treatment) that the levels of erythrocyte, hematocrit and hemoglobin were below the normal range, and reticulocyte counts above the normal range. Although 30-53% of the patients with cirrhosis and chronic hepatitis demonstrated moderate anemia, none had a reticulocyte count within normal. All of those with low HbA_{1c} also demonstrated anemia but some patients with anemia did not have low HbA_{1c}. Seventy to eighty percent of the patients with chronic hepatitis treated with ribavirin demonstrated moderate anemia and 30% also had high reticulocyte counts (Table 1). All of those with high reticulocyte counts, as well as some of those with anemia and normal reticulocyte counts, had below-normal HbA_{1c}. This study showed elevated reticulocytes, which might be a sign of shortened erythrocyte life span, in only 3 patients with chronic hepatitis and ribavirin treatment. In these patients HbA_{1c} was below the non-diabetic reference range on all methods. We also found HbA_{1c} values below the non-diabetic reference range in up to 40% of the patients with liver cirrhosis and in 50% of the patients with chronic hepatitis treated with ribavirin as measured by at least one of the HbA_{1c} methods. In these groups of patients the HbA_{1c} levels were negatively correlated to the percentage of reticulocytes (Pearson correlation, $r=-0.55$ to -0.79 depending on method, $P<0.05$ for all methods). There was no significant relationship between HbA_{1c} and reticulocyte count in the patients with chronic hepatitis and no ribavirin therapy.

We performed an one-sample *t*-test comparing mean blood glucose calculated of HbA_{1c} results (MBG (mmol/L) = $(1.98 \cdot \text{HbA}_{1c}) - 4.29$) and measured blood glucose as the actual value. HbA_{1c} results of the HPLC Menarini HA-8140 and the immunoassay method DCA 2000 were used to calculate a desired blood glucose value because in Pearson correlation they did not correlate with blood glucose. In patients with chronic hepatitis treated with ribavirin the one sample *t*-test for measured blood glucose and calculated blood glucose resulted in a significant difference ($t_{9\text{Menarini}}=7.68$, $P<0.05$; $t_{9\text{DCA}}=6.67$, $P<0.05$). In patients with liver cirrhosis calculated blood glucose was up to 1 mmol/L lower than measured blood glucose but a high standard deviation (Table 2) caused no statistical difference.

No correlation was found for all 3 groups between HbA_{1c} results and hepatic serum parameters as -glutamyl transferase (GGT), glutamate-oxalate transaminase (GOT) and glutamyl-pyruvic transaminase (GPT). In all 3 patient groups total protein measured in serum was within normal and albumin was normal in all patients with chronic hepatitis. Three patients with compensated cirrhosis had serum albumin below normal. There was no correlation found in all 3 patient groups between

Table 1 Percentage of patients outside the reference range for parameters of anemia

Group	Patients below normal (%) (Reference range)			Patients above normal (%) Reticulocytes (5-20%)
	Erythrocytes (4.5-5.9 T/L)	Hct (40-50%)	Hb (13-17 g/dL)	
Cirrhosis ($n=15$)	46	53	40	0
Chronic hepatitis ($n=10$)	30	30	30	0
Chronic hepatitis /ribavirin ($n=10$)	80	80	70	30

Table 2 Values of measured blood glucose (mean \pm SD) and calculated mean blood glucose values [MBG (mmol/L)=($1.98 \cdot \text{HbA}_{1c}$)-4.29]

	Measured MBG (mmol/L)	Menarini HA-8140 Calculated MBG (mmol/L)	DCA 2000 Bayer Calculated MBG (mmol/L)
Cirrhosis ($n=15$)	5.8 \pm 1.9	4.8	5.1
Chronic hepatitis ($n=10$)	5.1 \pm 0.3	5.4	5.4
Chronic hepatitis /Ribavirin ($n=10$)	5.2 \pm 0.4	4.3	4.5

MBG: Mean blood glucose.

fructosamine results and total protein or albumin. In patients with hepatic cirrhosis, mean fructosamine was within the high non-diabetic reference range. In patients with chronic hepatitis, fructosamine was close to the middle of the non-diabetic reference range. Five patients with cirrhosis and one patient with chronic hepatitis treated with ribavirin had high fructosamine levels even though they had normal blood glucose values.

DISCUSSION

The liver plays a major role in regulating glucose metabolism because it is the main source of endogenous glucose and a major site involved in insulin metabolism. The most common pathogenic agents in liver disease are alcohol abuse and infectious hepatitis that may cause disturbed erythropoiesis and decreased red cell survival. Macrocytic anemia is a common feature in liver disease but is still incompletely understood^[13]. The antiviral drug ribavirin has been widely used in combination with interferon in the treatment of chronic hepatitis C and a major side effect of ribavirin is a reversible hemolytic anemia^[10].

Glycated hemoglobin (GHb) measured as HbA_{1c} in diabetic patients, is used for evaluating long-term control of diabetes mellitus. GHb is the result of irreversible non-enzymatic glycation at one or both NH₂-terminal valines of the hemoglobin's α -chain. The extent of glycation and the relative involvement of the hemoglobin's α - and β -chains still remain unclear. Depending on the determination method used the concentration of HbA_{1c} is approximately 4-6% in healthy non-diabetic patients. Glycated hemoglobin most accurately reflects the previous 2-3 mo of glycemic control. Diabetic patients could present with abnormal liver chemistries, representing findings from benign hepatic steatosis to severe cirrhosis of the liver. Some medications to treat diabetes mellitus have an effect on liver metabolism or could even cause hepatotoxic reactions. Liver cirrhosis promotes glucose intolerance and diabetes through various mechanisms including insulin resistance and impaired insulin secretion. Sixty to 80% of patients with liver disease have glucose intolerance and 10-15% eventually develop overt diabetes.

In this study we demonstrated HbA_{1c} values below the non-diabetic reference range in up to 40% of the patients with liver cirrhosis while fructosamine results were either within the reference range or elevated in the diabetic range. However, protein metabolism was normal in our patients and although fructosamine results depend on glycation of serum proteins the results might be altered by reduced hepatic protein synthesis due to impairment of liver function. In 50% of the patients with chronic hepatitis treated with ribavirin, HbA_{1c} values were below the non-diabetic reference range as measured by at least one of the HbA_{1c} methods. In these groups of patients the HbA_{1c} results were negatively correlated to the percentage of reticulocytes that might be caused by disturbed erythropoiesis and decreased red cell survival. In patients with liver cirrhosis and chronic hepatitis treated with ribavirin, the HbA_{1c} calculated value of mean blood glucose was up to 1 mmol/L (18 mg/dL) lower than measured mean blood glucose. This underlines that impairment of liver function has influence on results of HbA_{1c} determination. Fructosamine may be a more reasonable marker for long term glucose control in patients with liver disease, but based on our findings we recommend frequent blood glucose monitoring as a measure for glucose control in patients with advanced liver disease.

We conclude that only evaluated in context with all liver function parameters as well as a red blood count including reticulocytes, HbA_{1c} should be used in patients with liver disease. Although the pathophysiologic reasons have still not

been confirmed, our data demonstrate that HbA_{1c} and fructosamine measurements should be used with caution when evaluating long-term glucose control in patients with hepatic cirrhosis or in patients with chronic hepatitis with ribavirin treatment. This interference may be due to alterations in erythrocyte lifespan and altered protein metabolism, but further investigations are needed to elucidate the exact cause of the interference in patients with liver disease.

ACKNOWLEDGEMENTS

We kindly acknowledge the determination of HbA_{1c} by the following laboratories: Institute of Chemical and Laboratory Diagnostics, Medical University Graz and Laboratory of the County Hospital in Wagna, Austria. Determination of fructosamine was performed in the Laboratory of the Department of Gynecology, Medical University Graz, Austria.

Abstract

AIM: To determine the distribution of neurons expressing c-Fos and nitric oxide synthase (NOS) in the central nerve system (CNS) following esophageal acid exposure, and to investigate the relationship between c-Fos and NOS.

METHODS: Twelve Wistar rats were randomly divided into two equal groups. Hydrochloric acid with pepsin was perfused in the lower part of the esophagus for 60 min. As a control, normal saline was used. Thirty minutes after the perfusion, the rats were killed and brains were removed and processed for c-Fos immunohistochemistry and NADPH-d histochemistry. Blood pressure (BP), heart rate (HR), and respiratory rate (RR) during the experimental procedures were recorded every 10 min.

RESULTS: There were no significant differences in BP, HR and RR between the two groups. c-Fos immunoreactivity was significantly increased in rats receiving acid plus pepsin perfusion in amygdala (AM), paraventricular nucleus (PVN), parabrachial nucleus (PBN), nucleus tractus solitarius and dorsal motor nucleus of vagus (NTS/DMV), nucleus ambiguus (NA), reticular nucleus of medulla (RNM) and area postrema (AP). NOS reactivity in this group was significantly increased in PVN, PBN, NTS/DMV, RNM and AP. c-Fos and NOS had significant correlation between PVN, PBN, NTS/DMV, RNM and AP.

CONCLUSION: Acid plus pepsin perfusion of the esophagus results in neural activation in areas of CNS, and NO is likely one of the neurotransmitters in some of these areas.

INTRODUCTION

Reflux esophagitis (RE) is a common gastrointestinal motility disorder. Esophageal reflux occurs when gastric contents move in a retrograde direction into the esophagus, and esophagitis develops by prolonged exposure to gastric contents. This happens when the lower esophageal sphincter fails to provide an adequate mechanical barrier, when the esophageal peristaltic

contractions fail to provide adequate clearance of the gastric contents, and/or when gastric contents exist for a prolonged time due to gastroparesis^[1]. Esophageal motility is controlled by a variety of factors of which the nerve system is the most important one. Locally, motility disorder caused by esophagitis is usually due to the decreased release of acetylcholine^[2,3], signal transduction failure^[4], and/or decreased intracellular Ca^{2+} ^[5]. In CNS, little has been known about the distribution of activated neurons after esophageal acid exposure^[6].

It is reported that *c-fos* is the most well characterized IEGs (immediate early genes) in neurons; the *c-fos* message is induced within minutes of stimuli and the protein is expressed within 1-3 h^[7-10]. The expression of *c-fos* in CNS is considered to be a marker of neuronal activity following an appropriate stimulus, and the site of central expression of c-Fos in response to a stimulus is used as a means of elucidating the course of the response^[11-16]. Nitric oxide (NO) acts as an intercellular messenger in CNS. As a highly diffusible and short-lived gas, NO is always studied by means of nitric oxide synthase (NOS)^[17]. Studies have shown that NOS-containing neurons are identical to those selectively stained for NADPH diaphorase^[18]. The present study was designed to determine the distribution of neurons expressing c-Fos and NOS in CNS following esophageal acid exposure, and to investigate the relationship between c-Fos and NOS.

MATERIALS AND METHODS

Animals

Twelve male Wistar rats weighing 220-260 g were housed in standard home cages under conditions of controlled illumination (12:12 h light/dark cycle), humidity, and temperature (18-26 °C) for at least 7 d prior to the experimental procedure. They were fed a standard rat diet and tap water. The animals were deprived of food but not water 12-16 h before each experiment. They were randomly divided into two equal groups. All procedures were approved by the Committee for Animal Care and Usage for Research and Education of the Peking University.

Methods

Rats were anaesthetized with an intraperitoneal injection of urethane (1.0 g/kg). After a rat reached a complete state of anesthesia, the abdominal wall and gastric wall were incised, and a drainage cannula was inserted in the gastric cardia to collect run-off solution from the esophagus. The anesthetized rat, strapped supine to an animal board, was then positioned with its head elevated at a slight angle (20-30°). A single lumen clear vinyl tube (ID 0.05 mm, A 0.8 mm) was passed by mouth into the esophagus. The tip of the cannula was located 3 cm above the esophagogastric junction. The cannula was then positioned and connected to a continuous perfusion pump (Medical Equipment Ltd. Zhejiang University, Hangzhou, China). A solution containing hydrochloric acid (HCl 0.1 mol/L) and pepsin (2 000-4 000 U/mL) (pH 1.5) was perfused continuously at a rate of 10 mL/h for 60 min. As a control, normal saline was used. Blood pressure (BP), heart rate (HR) and respiratory rate

(RR) during the experimental procedures were recorded every 10 min. After perfusion, the rat was left undisturbed for another 30 min before being deeply anesthetized with urethane (1.5 g/kg i.p.). The animal then was transcardially perfused with 9 g/L saline followed by 40 g/L paraformaldehyde in 0.1 mol/L phosphate buffer saline (PBS, pH 7.3). The brain was removed and postfixed in the same fixative overnight and cryoprotected by immersion in 200 g/L sucrose for 72 h. Coronal sections (40 μ m) of the brain were cut in a cryostat. Every fourth section was used to reveal c-Fos immunoreactivity and NADPH-diaphorase (NADPH-d) staining, and the second set of sections was used as a control for the immunohistochemical reaction.

The sections were collected and rinsed in 0.01 mol/L PBS containing 3 g/L Triton X-100 (PBST). Then they were incubated at 37 $^{\circ}$ C for 2 h in a solution containing 1 mmol/L NADPH (Biomol, London, UK), 0.5 mmol/L nitroblue tetrazolium (Biomol), Tris-HCl 50 mmol/L, and Triton X-100 2 g/L. After a rinse in PBST, sections were placed into a 50 g/L goat serum for 30 min at room temperature (RT), and incubated overnight at RT in primary antibody c-Fos (1:200, Santa Cruz Biotechnology, California, USA). After washing for 15 min with PBST, the sections were incubated in biotinylated anti-rabbit IgG (Zymed, South San Francisco, Canada) diluted 1:300 in PBST at RT for 2 h, and then incubated in peroxidase-conjugated streptavidin (1:300 dilution, Zymed) for 2 h at RT. The immunoreactivity was visualized by incubating with 0.05 mol/L Tris-HCl buffer containing 0.1 g/L 3,3'-diaminobenzidine, and 0.3 mL/L H_2O_2 for 10-20 min at RT. The stained sections were mounted on APES-coated glass slides, dehydrated and coverslipped.

Statistical analysis

BP, HR and RR recorded every 10 min during the 90-min experimental procedures were averaged per animal and then per experimental group, respectively. The distribution of c-Fos and NADPH-d positive cells was detected under a microscope (Olympus, Tokyo, Japan), and the cells were counted on LEICA Q550CW system (Leica Microsystems Imaging Solutions Ltd, Wetzlar, Germany). The numbers of cells containing c-Fos immunoreactivity and NADPH-d were counted unilaterally in specific nuclei in several sections; 5 sections for amygdala

(AM), nucleus tractus solitarius and dorsal motor nucleus of vagus (NTS/DMV), nucleus ambiguus (NA) and reticular nucleus of medulla (RNM) and 4 sections for paraventricular nucleus (PVN), supraoptic nucleus (SON), parabrachial nucleus (PBN) and area postrema (AP). The average number of c-Fos or NADPH-d positive neurons per section for each rat was calculated, respectively, by dividing the total number of c-Fos or NADPH-d positive cells obtained from all sections by the number of sections taken for each brain nucleus. Data were expressed as mean \pm SD of the respective brain areas. Statistical analyses were performed by SPSS 12.0 using the *t*-test, and a *P* value of less than 0.05 was considered statistically significant. The relationship between c-Fos and NADPH-d positive cells was performed by the correlation analysis.

RESULTS

BP, HR and RR to acid-pepsin perfusion

Esophageal acid perfusion did not change BP (18.03 ± 1.07 vs 17.26 ± 0.62 kPa, $F=2.663$, $P=0.134$), HR (275.30 ± 14.43 vs 265.00 ± 22.12 beats/min, $F=1.343$, $P=0.273$), and RR (92.00 ± 10.41 vs 94.56 ± 9.46 breathes/min, $F=0.078$, $P=0.785$) compared with control group.

c-Fos and NADPH-d staining in CNS

The c-Fos positive cell nuclei of activated cells showed the characteristic dark brown staining of oxidized DAB. In both groups of rats, c-Fos expression was observed in several brain regions. In telencephalon and diencephalon, c-Fos positive cells were mainly located in AM (Figure 1A, B), PVN (Figure 1C, D), SON and the numbers of the former two areas increased significantly in the acid-pepsin perfusion group (Table 1). Esophageal exposure to acid and pepsin also stimulated a significantly greater number of c-Fos-labeled neurons in areas of brain stem including PBN, NTS/DMV, NA (Figure 2A, D), RNM and AP (Table 1). NADPH-d activity was visualized as a vibrant blue color within perikarya, dendrites and axons. Acid-pepsin perfusion significantly increased the numbers of NADPH-d stained cells in PVN (Figure 1C, D), PBN, NTS/DMV, RNM and AP (Table 1). There were some coexistence of Fos

Figure 1 Photomicrographs showing c-Fos and NOS positive neurons in amygdala (A and B), paraventricular nucleus (C and D). A and C were taken from rats with acid-pepsin perfusion, while B and D were taken from rats with saline perfusion. (3V: the third ventricle).

Figure 2 Photomicrographs showing c-Fos and NOS positive neurons in nucleus tractus solitarius (A and B), nucleus ambiguus (C and D). A and C were taken from rats with acid-pepsin perfusion, while B and D were taken from rats with saline perfusion.

Data are expressed as mean±SD. ^a $P<0.05$, acid-pepsin perfusion vs saline perfusion. ^b $P<0.01$, acid-pepsin perfusion vs saline perfusion. c-Fos, c-Fos positive neurons; NOS, NADPH-d positive neurons.

and NADPH-d positive staining (Figure 3). The coexistence included colocalization that was visualized as blue-stained perikarya (NADPH-d activity) containing a clearly visible dark brown nucleus (c-Fos protein), and close proximity that was visualized as c-Fos positive nucleus being within

neuronal processes of NADPH-d, and that was the presence of NADPH-d positive staining within 3 μm from c-Fos-positive nucleus. Both of them have been adopted as a criterion of close proximity^[19,20]. The coexisting cells were mainly observed in PVN, SON and NTS/DMV.

Correlation between c-Fos and NADPH-d positive cells

There was a high correlation between c-Fos and NADPH-d positive cells in PVN, PBN, NTS/DMV, RNM and AP. The correlation coefficient (r) was 0.805, 0.943, 0.923, 0.947, 0.869 (all $P < 0.01$) respectively. There was no correlation between c-Fos and NADPH-d expression in AM, SON, and NA.

DISCUSSION

Acid, in combination with pepsin, was chosen to be the stimulant in this rat model of gastroesophageal reflux. This combination has been shown to cause esophagitis in experimental models^[21,22].

The nerve supply to esophagus is composed of extrinsic and intrinsic components. The extrinsic innervation is mainly through the autonomic nervous system, which is divided into sympathetic and parasympathetic components. The parasympathetic innervation of esophagus is supplied by the vagus nerves. Three types of vagal afferent fibers are classified on the basis of their sensitivity to mechanical stimulation: those responding to mucosal stroking (mucosal receptors), those responding to circular tension (tension receptors) and those responding to mucosal stroking and circular tension (tension/mucosal receptors)^[23]. Sensory afferents from the esophagus usually travel to NTS. DMV, which contains preganglionic motor neurons, has efferent fibers. The dorsal vagal complex (DVC) comprising NTS and DMV is the center of the integration of vagal control of esophagus^[24,25]. Exposing the subdiaphragmatic vagus nerves (SDV) to horseradish peroxidase (HRP), Norgren *et al.* found that retrogradely labeled neurons occurred within NA and the reticular formation caudal to NA, and DMV whereas anterograde HRP reaction product occurred in NTS and AP^[26]. Besides, connections of NTS with the medullary reticular formation and AP existed^[27]. They were reported to take part in some visceral reflexes. In the present study, c-Fos positive neurons were seen in NTS, DMV, NA, RNM, and AP. In comparison with the controls, the number was greater in the acid-pepsin group. In this context, the present results confirm those reports mentioned above. During the esophageal exposure to acid, a cascade of chemoreceptors that lie along the passage is stimulated. Some of these signals are carried by vagal afferents to NTS in brainstem. From there, visceral information is disseminated to various brain sites, where it affects regulatory functions by engaging endocrine, autonomic, and some other effector mechanisms. But how all these different pathways interconnect within subnuclei is still unknown. It has been reported that PBN is related to noxious information from the visceral organs^[14]. Esophageal acid exposure also induces high density of c-Fos expression in PBN.

A significantly increased number of c-Fos positive nuclei was observed in AM and PVN. Although many of c-Fos staining cells were seen in SON, there was no significant increase in this area in response to acid-pepsin perfusion. PVN is immediate beneath the ependyma of the third ventricle. The afferent connections of PVN are from hippocampal formation, septal nuclei, locus ceruleus, AM, and NTS. The efferent connections appear, in part, to be reciprocal to the afferent systems. The AM has reciprocal connections with locus ceruleus, substantia nigra, NTS, DMV, PBN, reticular formation, and nuclei of the hypothalamus. The present study showed that only some of those areas expressed c-Fos immunoreactivity, which suggests that those activated neurons are related to esophageal innervation. In order to exclude the potential contribution of the pressor response to the induction of c-Fos in NTS and other nuclei, BP, HR, and RR were recorded during the experimental procedures. There were no significant changes in BP, HR, and RR between the two groups.

It has been reported that NOS exists in neurons of DVC.

The premotoneurons in NTS express NOS, and NO acting in the NA takes part in the esophageal peristalsis^[28]. The present study showed that many NADPH-d positive neurons were seen in PBN, NTS/DMV, RNM, and that some were seen in NA and AP. This suggests that NO release may modulate characteristics of the activated neurons in these nuclei that are evoked by esophageal acid stimulus. It has been reported that NOS inhibitor, N-nitro-L-arginine methyl ester (L-NAME), reduces the spontaneous discharge rate of the NTS neurons *in vivo* and *in vitro*, which confirms that NO has the excitatory effect on NTS^[29]. L-NAME also reduces the c-Fos expression in DVC, suggesting that c-Fos expression is, in part, related to NO release in DVC. Little has been known about the neurotransmitters in telencephalon and diencephalon. In the present study, many NADPH-d positive cells were observed in PVN and SON, but only few were found in AM.

The present study observed the coexistence of c-Fos and NADPH-d positive staining. It is possible that the neuronal cells containing NOS are activated during esophageal acid exposure, which may cause NO release to themselves or to other brain regions in modulating the esophageal reflux.

In conclusion, acid-pepsin exposure to lower part of the esophagus stimulates the mucosal receptors, which in turn activates the neurons of NTS through vagal afferent fibers, and finally the neurons in DMV and NA to modulate the esophageal peristalsis. The possible nuclei involved in these procedures are AM, PVN, PBN, RNM, and AP. Double labeled staining of c-Fos and NADPH-d suggests that NO is one of the neurotransmitters in PVN, PBN, NTS/DMV, RNM and AP.

Abstract

AIM: To observe the effect of octreotide on apoptosis rate of human pancreatic cancer cells PC-3 after transfected with somatostatin receptor type 2 (SST2) gene.

METHODS: SST2 plasmid was transfected into PC-3 cells by liposome. Result of transfection was detected by immunocytochemical staining and Western blotting. Apoptosis rates of PC-3 cells under different dosages of octreotide were measured by MTT assay and flow cytometry (FCM).

RESULTS: Apoptosis rate caused by octreotide of transfected PC-3 cells was $7.56 \pm 1.06\%$ at the dosage of $0.20 \mu\text{g/mL}$, $9.25 \pm 1.73\%$ at the dosage of $0.40 \mu\text{g/mL}$ and $14.18 \pm 2.71\%$ at the dosage of $0.80 \mu\text{g/mL}$. Apoptosis rate caused by octreotide of non-transfected PC-3 cells was $5.76 \pm 0.75\%$ at the dosage of $0.20 \mu\text{g/mL}$, $6.69 \pm 0.80\%$ at the dosage of $0.40 \mu\text{g/mL}$ and $7.26 \pm 1.28\%$ at the dosage of $0.80 \mu\text{g/mL}$. Transfected PC-3 cells growth inhibition rate caused by octreotide was $9.36 \pm 1.34\%$ at the dosage of $0.20 \mu\text{g/mL}$, $12.03 \pm 1.44\%$ at the dosage of $0.40 \mu\text{g/mL}$ and $20.23 \pm 4.21\%$ at the dosage of $0.80 \mu\text{g/mL}$. Non-transfected PC-3 cells growth inhibition rate caused by octreotide was $6.44 \pm 0.66\%$ at the dosage of $0.20 \mu\text{g/mL}$, $7.65 \pm 0.88\%$ at the dosage of $0.40 \mu\text{g/mL}$ and $9.29 \pm 1.32\%$ at the dosage of $0.80 \mu\text{g/mL}$. We found that octreotide caused higher apoptosis rate and inhibition rate in transfected groups than in non-transfected groups ($P < 0.05$) at the tested dosages (0.20 , 0.40 and $0.80 \mu\text{g/mL}$).

CONCLUSION: Deficiency of SST2 was probably the major reason why octreotide had little effect on PC-3 cells. Transfecting SST2 gene could strengthen the ability of octreotide of killing PC-3 cells. It provided an experimental evidence for using both octreotide and transfection with SST2 gene on clinical treatment of pancreatic cancer.

<http://www.wjgnet.com/1007-9327/10/2292.asp>

INTRODUCTION

Octreotide, the artificial synthetic somatostatin analogue, which possesses the advantage of relative specificity, long lasting and small ill effect, has already been applied to clinical therapy extensively. Its anti-tumor mechanism mainly depends on the expression of somatostatin receptor, especially SST2^[1-3]. Most tumors highly express SST2, but some do not express or low express. For example, 90% human pancreatic cancer cells have lost the ability of expressing SST2, which leads to the unsatisfactory treatment effect in pancreatic cancer^[4]. We did the experiment to explore octreotide's effect on the apoptosis rate of pancreatic cancer (PC-3) cells after transfected with SST2 gene.

MATERIALS AND METHODS

Materials

PC-3 cells were a gift from China Medical University. RPMI 1640, fetal calf serum, Liposome 2000 Reagent were purchased from Gibco Co. USA. Octreotide was kindly presented by Novartis Co. Swiss. MTT, DMSO and G418 were purchased from Sigma Co. USA. Goat-anti-human SST2 monoclonal antibody was purchased from Santa Cruz Co. USA. Rabbit-anti-goat and DAB were purchased from Zhongshan Biotechnology Co. Beijing, China. ECL kit was purchased from Amersham Pharmacia Biotechnology Inc. ABC test kit was purchased from Huamei Co. China. Human SST2 plasmid was kindly presented by Junbo Hu of Maryland University, USA.

Methods

SST2 plasmid amplification and transfection We adopted colon bacillus (DH-5 α) to amplify and extract the human SST2 plasmid, which was identified by endonuclease. We cultured the PC-3 cells with RPMI 1640 supplemented with 100 mL/L fetal calf serum. When PC-3 cells were in exponential growth phase, the human SST2 plasmid was transfected into PC-3 cells mediated by Liposome 2000 reagent and screened with culture medium with 600 mg/L G418.

Immunocytochemical staining Transfective effect was detected by immunocytochemical staining. ABC test kit was adopted to stain the cells crawling on the slides with immunocytochemical staining. Goat-anti-human SST2 monoclonal antibody was diluted to 1:100. Blank groups used PBS instead of goat-anti-human antibody.

Western blotting Expression of SST2 was detected by western-blot. Transfected cells were collected and lysed with the cell-lysis to extract protein. Goat-anti-human SST2 monoclonal antibody (1:1 000) was used. The signals were developed with the ECL kit.

FCM Apoptosis rate was detected by flow cytometry. When the PC-3 cells were in exponential growth phase, octreotide at different dosages (0.05 , 0.10 , 0.20 , 0.40 , $0.80 \mu\text{g/mL}$) was added. After 24 h, culture medium was renewed and octreotide added according to the above dosages. Cells in the culture medium were collected and preserved in 700 mL/L alcohol at -20°C . Cells were collected after 48 h; the apoptosis rate was detected by flow cytometry.

MTT assay MTT assay was adopted to detect the sensitivity of PC-3 cells *in vitro* after using different dosages of octreotide. We divided them into three groups: blank groups (no cells), control groups (no drug) and octreotide groups. Octreotide treated cells were divided into five groups according to the dosages (0.05, 0.10, 0.20, 0.40, 0.80 $\mu\text{g/mL}$). Then the transfected PC-3 cells and non-transfected cells were inoculated into the 96-well culture panel, about $3 \times 10^6/\text{L}$ in each well. Each panel had 10 replicate wells. After 24-h culture, octreotide was added and then cultivated for another 48 h. The sensitivity of PC-3 cells was detected with MTT assay and inhibition rate was measured by detecting the value of the A ($\lambda=550 \text{ nm}$). Inhibition rate of PC-3 cells growth = $[(A_{\text{control group}} - A_{\text{blank group}}) - (A_{\text{experiment group}} - A_{\text{blank group}})] / (A_{\text{control group}} - A_{\text{blank group}}) \times 100\%$.

Statistical analysis

t-test and SPSS software were employed to analyze data. $P < 0.05$ indicates significant difference.

RESULTS

Expression of SST2 in transfected and non-transfected PC-3 cells

Cells crawling on the slides were stained by immunocytochemical staining. SST2 gene expressing PC-3 cells would present brown particles spreading mainly in the cytoplasm and cell membrane (Figure 1). PC-3 cells non-transfected were negative-expression (Figure 2). We proved that PC-3 cells did not express SST2. In contrast, they could express SST2 after transfected with SST2 gene. And it also proved that the transfection was effective and accorded with the requirement of our experiments.

Figure 1 SST2 expressed in the transfected PC-3 cells (10 \times 40).

Figure 2 SST2 did not express in non-transfected PC-3 cells (10 \times 40).

Western blotting of SST2 expression

Protein of transfected PC-3 cells was extracted and the expression of SST2 was detected by Western blotting. SST2 in transfected PC-3 cells was detected (Figure 3), the M_r is about

40 000. It also proved that the transfection was effective at protein level. This was the base of our next experiments.

Figure 3 SST2 could be detected in the transfected PC-3 cells.

Analysis of PC-3 cell inhibition rate by MTT assay

Inhibition rate was detected by MTT assay. Growth inhibition rate of transfected PC-3 cells caused by octreotide was $3.45 \pm 0.91\%$ at the dosage of 0.05 $\mu\text{g/mL}$, $5.18 \pm 1.21\%$ at the dosage of 0.10 $\mu\text{g/mL}$, $9.36 \pm 1.34\%$ at the dosage of 0.20 $\mu\text{g/mL}$, $12.03 \pm 1.44\%$ at the dosage of 0.40 $\mu\text{g/mL}$ and $20.23 \pm 4.21\%$ at the dosage of 0.80 $\mu\text{g/mL}$. The inhibition rate caused by octreotide for non-transfected PC-3 cells was $3.28 \pm 0.54\%$ at the dosage of 0.05 $\mu\text{g/mL}$, $4.08 \pm 0.45\%$ at the dosage of 0.10 $\mu\text{g/mL}$, $6.44 \pm 0.66\%$ at the dosage of 0.20 $\mu\text{g/mL}$, $7.65 \pm 0.88\%$ at the dosage of 0.40 $\mu\text{g/mL}$ and $9.29 \pm 1.32\%$ at the dosage of 0.80 $\mu\text{g/mL}$. After using octreotide (0.05-0.80 $\mu\text{g/mL}$) for 48 h, we found that it caused a higher inhibition rate in transfected groups than in non-transfected groups ($P < 0.05$) at different dosages (0.20, 0.40 and 0.80 $\mu\text{g/mL}$). It proved that the expression of SST2 could enhance octreotide's effect on the inhibition of PC-3 cells (Figure 4).

Figure 4 Transfected PC-3 cells growth inhibition rate under octreotide.

Flow cytometric analysis of PC-3 cell apoptosis rate

When 0.05-0.80 $\mu\text{g/mL}$ octreotide was added and incubated for 48 h, the PC-3 cells would show the typical apoptosis peak measured by flow cytometry. Moreover, the higher the drug dosage was, the higher the apoptosis rate was. Higher dosages (0.20, 0.40 and 0.80 $\mu\text{g/mL}$) of octreotide caused a greater increase of inhibition in PC-3 cells transfected groups than in non-transfected groups ($P < 0.05$) (Table 1).

Table 1 Apoptosis rate of PC-3 cells transfected and non-transfected with SST2 gene under different dosages of octreotide (mean \pm SD)

Dosage of octreotide ($\mu\text{g/mL}$)	Apoptosis rate of transfected PC-3 cells (%)	Apoptosis rate of non-transfected PC-3 cells (%)	<i>P</i>
0.05	3.65 \pm 0.66	2.77 \pm 0.33	>0.05
0.10	4.45 \pm 0.78	3.23 \pm 0.57	>0.05
0.20	7.56 \pm 1.06	5.76 \pm 0.75	<0.05
0.40	9.25 \pm 1.73	6.69 \pm 0.80	<0.05
0.80	14.18 \pm 2.71	7.26 \pm 1.28	<0.05

DISCUSSION

At present, somatostatin has been widely used in therapy of various tumors especially endocrine tumors. In a majority of cases, favorable effect has been noted. In combined treatment with classical chemotherapeutic drugs, such as 5-fluorouracil, somatostatin has synergistic action of killing tumor cells^[5]. The mechanism of somatostatin's anti-tumor effect *in vitro* lies in combining with its receptor. Somatostatin receptor belongs to a protein G coupled receptor family^[6]. According to the similarity of structure and difference in affinity to somatostatin, somatostatin receptors are classified into two categories: (1) having strong affinity to somatostatin, including SST2A, SST2B, SST3 and SST5; (2) having weak affinity to somatostatin, including SST1 and SST4^[7,8]. It is known that somatostatin receptors are extensively distributed in human central nervous system and other tissues. The category and amount of somatostatin receptor expression is different in various tumors. Somatostatin receptor, especially SST2 is usually highly expressed in many tumor tissues. SST2 may play a role in anti-tumor effect of somatostatin (It is considered as a tumor suppressing gene)^[9-11]. The mechanisms of somatostatin's anti-tumor action are as follows: (1) direct negative effect on tumor growth; (2) inhibiting the growth of tumors by interfering with synthesis of growth factors, which are produced via paracrine and autocrine of tumor cells; (3) anti-tumor effects by inhibiting excretion of somatotropin, insulin, gastrin and other hormones or depressing insulin-like growth factor-I (IGF-I), epidermal growth factor (EGF) and other growth factors; (4) interference with DNA synthesis of tumor cells; (5) suppression of angiogenesis of tumors^[12].

Substantial evidence has shown that loss or low expression of SST2 was observed in primary pancreatic cancer^[9,13-15]. Our previous research results have also shown that expression of SST2 was detected in 12.5 % of primary pancreatic cancers. These results suggest that expression of SST2 was deficient in a majority of pancreatic cancer tissues, which may be the main reason why somatostatin and somatostatin analogues were nearly inefficacious in the treatment of pancreatic cancer. But it is interesting that expression of SST2 was observed in the majority of adjacent histologically noncancerous pancreas, which was beneficial for somatostatin and somatostatin analogues to suppress fast invasion and growth of tumor cells. These results also suggest that if expression of SST2 in pancreatic cancer and adjacent histologically noncancerous pancreas was reduced; somatostatin and somatostatin analogues were nearly inefficacious in the treatment of pancreatic cancer. But if expression of SST2 in both pancreatic cancer and adjacent histologically noncancerous pancreas were observed, somatostatin and somatostatin analogues were efficacious^[11,1]. Therefore, different expression of SST2 in pancreatic cancer and adjacent histologically noncancerous pancreas is bound to result in different effects of treatment, which may be the main reason why reports of effects of somatostatin and somatostatin analogues treatment on pancreatic cancer are inconsistent at the present time. We believe that it is very important to make clear whether SST2 is expressed in pancreatic cancer and adjacent histologically noncancerous pancreas before somatostatin and somatostatin analogues are used in treatment of pancreatic cancer. We have demonstrated that transfecting SST2 gene into human pancreatic cancer cells which lack SST2 could markedly up-regulate SST2 expression, increase apoptosis rate of human pancreatic cancer cells and

enhance somatostatin analogue octreotide to inhibit growth of human pancreatic cancer cells and induce apoptosis. These results suggest that it may be an exciting molecular biological therapy for human pancreatic cancer deficiency of SST2 gene via transfection with SST2 gene and combination with somatostatin analogue.

Abstract

AIM: To assess the inhibitory effect of *Huangqi Zhechong* decoction on hepatic fibrosis in rats induced by CCl₄ plus alcohol and high fat low protein diet.

METHODS: Male SD rats were randomly divided into hepatic fibrosis model group, control group and 3 treatment groups consisting of 12 rats in each group. Except for the normal control group, all the rats were subcutaneously injected with CCl₄ at a dosage of 3 mL/kg. In 3 treated groups, either high-dose group (9 mL/kg), or medium-dose group (6 mL/kg), or low-dose group (3 mL/kg) was daily gavaged with *Huangqi Zhechong* decoction, and saline vehicle was given to model and normal control rats. Enzyme-linked immunosorbent assay (ELISA) and biochemical examinations were used to determine the changes of alanine aminotransferase (ALT), aspartate aminotransferase (AST), hyaluronic acid (HA), laminin (LN), type-III-procollagen-N-peptide (PIIIP), and type IV collagen content in serum, and hydroxyproline (Hyp) content in liver after sacrificing the rats. Pathologic changes, particularly fibrosis were examined by hematoxylin and eosin (HE) and Van Gieson staining.

RESULTS: Compared with the model control group, serum ALT, AST, HA, LN, PIIIP and type IV collagen levels dropped markedly in *Huangqi Zhechong* decoction groups, especially in the medium-dose *Huangqi Zhechong* decoction group (1 954±576 U/L vs 759±380 U/L, 2 735±786 U/L vs 1 259±829 U/L, 42.74±7.04 ng/mL vs 20.68±5.85 ng/mL, 31.62±5.84 ng/mL vs 14.87±1.45 ng/mL, 3.26±0.69 ng/mL vs 1.47±0.46 ng/mL, 77.68±20.23 ng/mL vs 25.64±4.68 ng/mL, respectively) ($P<0.05$). The Hyp content in liver tissue was also markedly decreased (26.47±11.24 mg/mgprot vs 9.89±3.74 mg/mgprot) ($P<0.01$). Moreover, the stage of the rat liver fibrosis in *Huangqi Zhechong* decoction groups was lower than that in model group, and more dramatic drop was observed in medium-dose *Huangqi Zhechong* decoction group ($P<0.01$).

CONCLUSION: *Huangqi Zhechong* decoction can inhibit hepatic fibrosis resulted from chronic liver injure, retard the development of cirrhosis, and notably ameliorate the liver

function. It may be a safe and effective therapeutic drug for patients with fibrosis.

Dang SS, Jia XL, Cheng YA, Chen YR, Liu EQ, Li ZF. Inhibitory effect of *Huangqi Zhechong* decoction on liver fibrosis in rat. *World J Gastroenterol* 2004; 10(15): 2295-2298

INTRODUCTION

Liver fibrosis is common in most chronic liver diseases regardless of the etiology^[1-8]. Although new therapeutic approaches have recently been proposed, there is no established therapy for liver fibrosis^[9]. *Huangqi Zhechong* decoction is a traditional Chinese medicine. The aim of the present study was to investigate the protective effects of *Huangqi Zhechong* decoction on liver fibrosis in rats of CCl₄-induced cirrhosis.

MATERIALS AND METHODS

Reagents

CCl₄ (Xi'an Chemical Factory) was diluted into 400 g/L in olive oil (Xi'an Chemical Factory). *Huangqi Zhechong* decoction was self-made by the Pharmaceutical Department of the Second Hospital, Xi'an Jiaotong University. The kit for Hyp was bought from Nianjing Jiancheng Biological Institute. Kits for HA, LN, PIIIP and type IV collagen were bought from Senxiong Company, Shanghai.

Animals

Sixty adult male SD rats weighing 150-200 g were provided by the Laboratory Animal Center of the College of Medicine, Xi'an Jiaotong University. The rats were randomly divided into 5 groups of 12 each: control group; model group; and 3 treatment groups. Except for the control rats, all rats were subcutaneously injected with 400 g/L CCl₄ (CCl₄:Olive oil 2:3), 3 mL/kg-b.w., at every 3 d for 6 wk, and fed with high fat low protein diet (75% pure maize plus 20% lard and 0.5% cholesterol) and 300 mL/L alcohol as drinks. In the 3 treatment groups, *Huangqi Zhechong* decoction was administered daily via gastric tube to high-dose, medium-dose and low-dose groups at a dosage of 9 mL/kg, 6 mL/kg and 3 mL/kg for 6 wk, respectively. After 6 wk, except the dead, all the rats were anesthetized with 200 g/L urethane (5 mL/kg, abdominal injection). Blood was taken from abdominal aorta, centrifuged at 4 °C, and plasma were kept at -20 °C for assays.

Pathological observations

Hepatic tissues were fixed in 40 g/L solutions of formaldehyde in 0.1% mol/L phosphate-buffered saline (pH 7.4), and embedded in paraffin. Five-micrometer thick section slides were prepared. All the sections stained with HE and standard van Gieson staining (VG) were coded and scored by blind reading. Van Gieson's method was used to detect collagen fibers^[10]. Liver condition was classified according to the standard formulated by China Medical Association in 1995^[11],

and fibrosis was graded from 0 to 4 (0: no fibrosis; 1: portal area fibrosis; 2: fibrotic septa between portal tracts; 3: fibrosis septa and structure disturbance of hepatic lobule; and 4: cirrhosis).

Statistical analysis

Results were expressed as mean±SD. Quantitative data were analyzed by using ANOVA in statistical software SPSS 11.0. A value of $P<0.05$ was considered statistically significant. Ridit test was used for statistical analysis of the qualitative data.

RESULTS

Hyp content in liver tissues

Liver Hyp level was significantly lower in rats treated with CCl_4 and *Huangqi Zhechong* decoction compared to the rats treated with CCl_4 alone ($P<0.01$). And the liver Hyp level of rat in 3 *Huangqi Zhechong* decoction treatment groups has no significant difference from control group (Table 1).

Plasma levels of ALT and AST

Plasma levels of ALT and AST in model group were higher than those in the controls ($P<0.01$), while the *Huangqi Zhechong* decoction treatment groups showed significant lower

ALT and AST levels than the model group. Furthermore, among the 3 treatment groups the medium-dose group showed the best effect and the levels of ALT and AST in serum showed no difference compared with the normal group (Table 1).

Table 1 Level of serum ALT, AST and liver Hyp

Group	<i>n</i>	ALT (U/L)	AST (U/L)	Liver Hyp (μg/mgprot)
Control	12	86.0±17.7	329±40	10.02±1.05
Model	11	1 954±576 ^d	2 735±786 ^d	26.47±11.24 ^d
High-dose group	9	989±576 ^{ad}	1 584±988 ^c	15.01±7.59 ^b
Medium-dose group	10	759±380 ^{bc}	1 259±829 ^a	9.89±3.74 ^b
Low-dose group	10	1 003±530 ^{ad}	1 650±928 ^c	10.06±2.58 ^b

^a $P<0.05$, ^b $P<0.01$ vs model group; ^c $P<0.05$, ^d $P<0.01$ vs control group.

HA, LN, PIIP and type IV collagen levels in serum

Serum levels of HA, LN, PIIP and type IV collagen in model group, compared with the controls, were all markedly increased ($P<0.01$). And compared with the model group, the serum levels of HA, LN, PIIP and type IV collagen were significant decreased in the 3 treatment groups ($P<0.01$) (Table 2).

Table 2 Serum levels of HA, LN, PIIP and type IV collagen

Group	<i>n</i>	PIIP (ng/mL)	Type IV collagen (ng/mL)	LN (ng/mL)	HA (ng/mL)
Control	12	0.34±0.67	18.47±3.43	10.07±1.74	17.96±5.86
Model	11	3.26±0.69 ^d	77.68±20.23 ^d	31.62±5.84 ^d	42.74±7.04 ^d
High-dose group	9	2.01±0.40 ^{bd}	39.14±4.97 ^{bd}	16.32±2.73 ^{bd}	21.71±5.69 ^b
Medium-dose group	10	1.47±0.46 ^{bd}	25.64±4.68 ^b	14.87±1.45 ^{bd}	20.68±5.85 ^b
Low-dose group	10	1.84±0.27 ^{bd}	29.09±2.78 ^b	17.02±2.74 ^{bd}	24.18±7.89 ^b

^a $P<0.05$, ^b $P<0.01$ vs model group; ^c $P<0.05$, ^d $P<0.01$ vs control group.

Table 3 Pathological observation of liver condition

Group	<i>n</i>	Liver condition					<i>U</i>
		0	I	II	III	IV	
Model	11	0	0	0	3	8	
High-dose group	9	0	2	3	3	1	2.98 ^a
Medium-dose group	10	0	4	4	2	0	4.01 ^b
Low-dose group	10	0	2	4	3	1	3.75 ^b

^a $P<0.05$, ^b $P<0.01$ vs model group; The value of *U* represents the Ridit value of the two groups, $U>1.96$ means $P<0.05$, $U>2.58$ means $P<0.01$.

Figure 1 Liver tissue under light microscope. A: Normal liver tissue in control group (HE staining, original magnification: ×400); B: Liver fibrosis tissue in model group, more fibrous tissue was formed in liver. A large amount of inflammatory cells soaked into the intralobular and the interlobular (van Gieson staining, original magnification: ×200); C: Liver fibrosis tissue in *Huangqi Zhechong* decoction group. The pathological change of liver was rather lighter compared with the model (van Gieson staining, original magnification: ×200).

Pathological assay

At the end of the study, the liver of control rats had no appreciable alterations (Figure 1A). In the model group, the margin of liver was uneven; more fibrous tissues formed and extended into the hepatic lobules to separate them incompletely; a large amount of inflammatory cells infiltrated in the intralobular and the interlobular regions; the liver structure was disordered with some displacement of central veins, and there were more necrotic and degenerated liver cells compared with the control (Figure 1B). While in the 3 treatment groups, especially in the medium-dose group, the pathological changes of liver was rather milder, showing less fibrous tissue proliferation and inflammatory cell infiltration in the interlobular space; the hepatic cell cords arranged radially with less displacement of central veins and less degenerated or necrosis hepatic cells, without any pseudolobule observed (Figure 1C). Compared with the model group, the liver condition of the rats was significantly improved in *Huangqi Zhechong* decoction groups (Table 3).

DISCUSSION

The incidence rate of chronic hepatopathy in China is high, which afflicts the patients by progressively developing irreversible cirrhosis^[12,13]. Hepatic fibrosis is the intermediate and crucial stage of this process, characterized by reversibility. If treated properly in this stage, cirrhosis could be successfully prevented^[14]. But it remains a problem to prevent cirrhosis or to control its progression in patients with a chronic liver disease^[15]. Great efforts have been made to find safe and effective drugs. Recent clinical and experimental observations have demonstrated that Chinese medicines might be of some preventive and therapeutic values against fibrosis^[16-18].

Of *Huangqi Zhechong* decoction, the Chinese traditional medicine, the *Astragalus* has the effects of activating blood circulation to relieve stasis, strengthening "spleen", supplementing and smoothening "qi" to eliminate fullness, reinforcement body's immunological function. It also could preserve the integrity of hepatocytes, eliminate toxic free radicals, inhibit lipid peroxidation of cytomembrane, relieve necrosis of hepatocytes, and obviously antifibrosis^[19-23]. *Thoroughfare* is mainly used to activate blood circulation, remove stasis, and dredge the liver^[24].

Huangqi Zhechong decoction has been used in clinic for many years to prevent liver fibrosis and shown good effect. However, its effect and the associated mechanisms need further experimental evidence. CCl₄ is a super-hepatotoxin, with which the CCl₃ free radical is produced during metabolic processes and acts on liver cells to covalently conjugate with the membranous unsaturated lipid to cause lipid peroxidation and necrosis of hepatocytes^[25-27]. For this reason, CCl₄ was used to induce liver fibrosis.

We started to treat the rats with *Huangqi Zhechong* decoction at the same time of subcutaneous injection with CCl₄. After 6 wk, the histological features showed that there were no appreciable alterations in control group. But pathological evaluation showed that the rats in model group almost had integrity fibrosis septum, and pseudolobular could be seen in nearly every section. While the rats received *Huangqi Zhechong* decoction had less fibrosis, the reticular fibrosis in the interlobular septum was limited remarkably, and no pseudolobular could be seen. In addition, *Huangqi Zhechong* decoction, especially the medium-dose administration could decrease the scores of hepatic fibrosis grading.

ALT and AST are indexes to describe liver functions. Most part of ALT is presented in the cytoplasm of liver cell, discharged in blood when degeneration, hyper permeability and necrosis of liver cells occur. So the increase of ALT level in serum reflects the degree of liver cell injury. Our study

showed that the *Huangqi Zhechong* decoction could decrease serum levels of ALT and AST in rats with hepatic injury caused by CCl₄. It indicates that *Huangqi Zhechong* decoction may work through protecting the liver cells.

HA, LN, PIIIP and type IV collagen are good serum markers of hepatic fibrosis. In this study, the serum contents of these 4 markers in the model group were much higher than those of the controls ($P < 0.01$). And the *Huangqi Zhechong* decoction groups had significantly low HA, LN, PIIIP and type IV collagen levels in serum than those in the controls, which indicated that *Huangqi Zhechong* decoction could successfully prevent hepatic fibrosis.

Hyp content in liver is another important index to react the hepatic fibrosis. In fibrotic liver, collagen fibers increase, which induced the rise of Hyp content in liver^[28]. So Hyp level could provide the information about the degree and variant process of cirrhosis. In this study, we observed that the liver Hyp level in the model group was much higher than that of the controls and *Huangqi Zhechong* decoction groups.

In summary, *Huangqi Zhechong* decoction may play a role in antifibrotic therapy. It can protect the liver cells and inhibit the deposition of collagen fibers in liver. It may provide a safe and effective strategy for inhibition of cirrhosis in clinic use.

Abstract

AIM: To summarize the operative experience of the transanal approach in acquired rectovestibular fistula repair.

METHODS: Ninety-six cases of acquired rectovestibular fistula in young females were analyzed retrospectively. The etiology and operative procedure were discussed. Operative essential points were, the patient was laid in prone frog position, with the knees and hips flexed at 90°; the perineum was elevated; and the anal opening was exposed. Four stay sutures were applied to the margin of the fistular orifice in the anal opening at points 3, 6, 9 and 12 o'clock. A circular incision of mucosa surrounding the stay sutures was made. The fistula was dissected from its anal opening to its vestibular opening. The wound of vestibule was sutured, and the rectoanal wound was then sutured transversely.

RESULTS: All the 96 patients recovered uneventfully from operation with a successful rate of 93.75%.

CONCLUSION: The transanal approach in the treatment of the acquired rectovestibular fistula is a simple and feasible technique.

INTRODUCTION

Acquired rectovestibular fistula in small girls is a common anorectal disease. Its etiology is still indefinite. Some of pediatric surgeons described it as a kind of congenital malformation. In China, most thought it as an acquired disease caused by the infection of crypts of *Morgagni*^[1-7]. There are two main surgical procedures that are commonly adopted, transanal and perineal approach^[8-13].

MATERIALS AND METHODS

Patients

Ninety-six patients with an average age of four years and two mo, ranging from 6 mo to 14 years, were admitted and operated. Most patients came with the complaint of passing stool or flatus through vagina. Half of them had a history of perineal inflammation at the early life of 2-3 mo. An external opening

was usually found in the vestibule, a little bit right or left to the vaginal opening, while the internal opening was always found at the mid-point of the dentate line on the anterior anorectal wall. The diameter of fistula orifice ranged from 2 to 8 mm.

Preoperative preparation

Metronidazole tablet (30 mg/kg per day, divided t.i.d) and oral garamycina (15 mg/kg per day, divided t.i.d) were given before operation for 3 d. Nothing but water by mouth was allowed for 1 d before operation day. Enema was performed at the night before operation day and on the morning of the operation day.

Operative methods

Under general anesthesia, patient was laid in prone frog position, with knees and hips flexed at 90° fixed at the caudal end of the operation table, with a soft pillow placed under the pubis. Almost half roll of sterile bandage was inserted into rectum to prevent rectal discharge. The tail of bandage might be soaked with iodophor before being sent deeply into the rectum, and it was tied by a long heavy silk, which was left outside the anal orifice in order to make the removal of the bandage easily after operation. The anal opening was widely stretched bilaterally to expose the inner opening of fistula, four stay sutures were applied to four points at 3, 6, 9 and 12 o'clock respectively. The stay sutures were pulled, and a circular incision of mucosa around the inner opening of fistula was made by Bovie. The fistula was dissected toward the outer opening in the vestibule and resected. The wound of vestibule was sutured interruptedly with 5-0 Dexon. Usually fistula was about 0.8 cm long. The levator ani muscle was approximated longitudinally to abolish the dead space anterior to the rectum. The anorectal wall was freed proximally for about 1.0 cm to make the wound closed without tension. The packing bandage in rectum was pulled out after operation.

Postoperative treatment

Nothing but water by mouth was provided for 3 d after operation, and intravenous antibiotics were given 3 to 5 d. Perianal area was kept clean and dry by warm ventilation 3 to 5 times every day for some 5 d.

RESULTS

Six cases, about 6.25% of all patients, had recurrence of fistula. However, three of them healed spontaneously 2 to 3 wk later without any specific treatment except sitz bath with 30 g/L boric acid.

DISCUSSION

Bryndorf and Madsen reported rectovestibular fistula, a fistulous tract between the bowel and the low female genital tract, in 1960^[14]. The disease is more common in Asian than in Europeans. There were two controversial opinions about its etiology, the congenital or the acquired. Chatterjee *et al.*^[1-5] described rectovestibular fistula with normal anus in females as a kind of congenital malformation, double terminal of the alimentary tract. The family history, coexisting anomalies as

anal stenosis or sacral vertebrae abnormality and the stratified squamous epithelium lining of fistular wall were the basis favouring the congenital consideration. The inflammatory changes of fistula might be secondary.

Most doctors in China believe that the development of rectovestibular fistula with normal anus in small girls was similar to the inflammatory fistula-in-ano in males^[6-8]. The inflammation started by the infection of crypts of Morgagni, perianal abscess formation followed, and finally it ruptured through the vestibule. On the other hand, some deep crypts or anal glands cystoid dilatation as well as infantile hypoergic immunity of the rectoanal mucosa make the rectum mucosa barrier imperfect^[15-17]. All these might play a role in anal fistula formation. Certainly it was not the congenital double termination of the alimentary tract. None of patients had a definite history of fistula at birth, and neither did a surgical specimen show normal histology of mucosa, submucosa and continuous smooth muscle in the fistula tract.

Ninety-six females with acquired rectovestibular fistula were treated by transanal approach in the last 10 years with a satisfactory result. The main experience may be concluded as: (1) Rectal bandage packing may prevent stool contamination during operation. (2) Fistula should be dissected completely by Bovie to make a bloodless operation field. (3) Rectum and vagina should be separated clearly. (4) Anterior rectal wall should be sutured perfectly without tension. (5) Dead space anterior to rectum should be eliminated by suturing the levator ani muscles and central body.

The favorite age for operation ought to be 3 to 5 years in order to wait for the improvement of the symptoms and also for better development of perianal structures of the child.

Recurrence of fistula, if happened, often occurred about 7 d after operation, and its symptoms included perineal inflammation, followed by passing of stool or flatus through the sutured incision. By sitz bath in 30 g/L boric acid and waiting for inflammation subsiding, half of the patients with early recurrent fistula healed spontaneously.

Diverting colostomy provides a clean operation area for anal fistula repair^[11,12], but it needs at least three operations. We believe that a careful preoperative, operative and postoperative treatment offers a satisfactory result without a diverting colostomy.

Abstract

A 62-year-old Japanese man who was positive for hepatitis B surface antigen (HBsAg) and anti-HBe antibody, underwent chemotherapy for non-Hodgkin's lymphoma (NHL). Mutations were detected in the precore region (nt1896) of HBV. Because steroid-containing regimen may cause reactivation of hepatitis B virus (HBV) and hepatitis may progress to be fulminant after its withdrawal, we administered CHO (CPA, DOX and VCR) therapy and the patient obtained complete response. However, he developed acute exacerbation of hepatitis due to HBV reactivation. Recovery was achieved with lamivudine (100 mg/d) and plasma exchange. The present case suggests that acute exacerbation of hepatitis can occur with steroid-free regimen. Because the efficacy of the prophylactic use of lamivudine has been reported and the steroid enhances curability of malignant lymphoma, the steroid containing regimen with prophylaxis of lamivudine should be evaluated further.

Shimizu D, Nomura K, Matsumoto Y, Ueda K, Yamaguchi K, Minami M, Itoh Y, Horiike S, Morita M, Taniwaki M, Okanoue T. Hepatitis B virus reactivation in a patient undergoing steroid-free chemotherapy. *World J Gastroenterol* 2004; 10(15): 2301-2302

<http://www.wjgnet.com/1007-9327/10/2301.asp>

INTRODUCTION

CHOP regimen consisting of cyclophosphamide (CPA), doxorubicin (DOX), vincristine (VCR), and prednisolone (PSL) is performed as the first line therapy for non-Hodgkin's lymphoma (NHL) because of its high response rate and less incidence of side effect. However, CHOP regimen for hepatitis B virus (HBV) carrier may cause reactivation of HBV due to prednisolone and hepatitis may progress to be fulminant after its withdrawal. On the other hand, it has already been proven

that steroid containing-regimens show higher complete response and survival rate than steroid free regimens^[1]. Thus, it is difficult to choose which chemotherapeutic regimen for NHL carrying HBV.

We described an asymptomatic HBV carrier patient with NHL who received CHO therapy. Although he achieved complete response, hepatitis acutely exacerbated. Lamivudine and plasma exchange improved hepatic failure.

CASE REPORT

A 62-year-old man complained of tonsil swelling, redness and sore throat. He was referred to our hospital in August 2003. Needle biopsy from tonsil revealed him as having NHL (diffuse large B-cell lymphoma). He was admitted to our hospital on August 21 because tonsil swelling developed rapidly. Two enlarged cervical lymph nodes were palpable and right tonsil swelled. Hematological studies showed WBC 5 600/mL, Hb 15.4 g/dL and platelet $7.2 \times 10^4/\text{mm}^3$, LDH 167 IU/L, GOT 25 IU/L, GPT 15 IU/L, ALP 392 IU/L, Ch-E 163 IU/L, T-bil 1.82 mg/dL, prothrombin time (PT) 14.7 s, IL-2 receptor 564 U/mL, indocyanine green test (ICG) 25%. Serological tests showed HBsAg (+), HBeAg (-), HBeAb (+). HBV-DNA level was 4.7 LGE/mL (TMA method). Mutant virus having mutation at precore and core promoter region was detected by enzyme-linked mini-sequence assay (Smitest HBV Pre-C ELMA, Roche Diagnostics, Tokyo, Japan) and enzyme-linked specific probe assay (Smitest HBV core promoter mutation detection kit, Genome Science Laboratory, Tokyo, Japan). Ultrasonography revealed cirrhotic pattern of liver and mild splenomegaly. Neck magnetic resonance imaging revealed swelling of right tonsil and two cervical lymph nodes. Computed tomography scanning revealed no lymph node swelling in chest and abdomen. Bone marrow aspiration revealed involvement of abnormal lymphocytes. Thus, we diagnosed he was at stage IV.

He received first course of CHO regimen on August 22. Although tonsil swelling improved, liver dysfunction gradually developed after the third course. After the fourth course, liver dysfunction got severe, as serum LDH level was 499 IU/L, GOT 650 IU/L, GPT 422 IU/L, T-bil 1.49 mg/dL, PT 25.9 s and HBV-DNA level increased 6.2 LGE/mL. We diagnosed it as acute exacerbation of HBV and started both lamivudine (100 mg/d) and plasma exchange. Liver dysfunction improved gradually. In January 2004, hematological data improved as LDH 328 IU/L, GOT 98 IU/L, GPT 54 IU/L, T-bil 3.66 mg/dL, PT 19.6 s, HBV DNA 2.8 LGE/mL. He was following good clinical course and remained complete response for NHL.

DISCUSSION

It has been reported that steroid may induce exacerbation of hepatitis after cessation of steroid therapy or during tapering of steroid. Cheng *et al.* reported that 50 NHL patients carrying HBV were randomized to receive either ACE (epirubicin, CPA and etoposide) or PACE (prednisolone+ACE). The cumulative incidence of HBV reactivation was 38% and 73%, respectively. On the other hand, it is clear that PACE chemotherapy was

more effective than ACE arm in the treatment of NHL, because CR rate was 46% and 35%, overall survival rate at 46 mo was 68% and 36%, respectively^[1]. Thus, there is no consensus regarding the best therapy for NHL with HBV.

Regarding to HBV-DNA, cases with a point mutation from G to A at nucleotide 1896 of the precore region of HBV tended to develop fulminant hepatitis with steroid containing treatment^[2-5]. Because we detected the mutant HBV in peripheral blood before chemotherapy, we performed CHO regimen and obtained CR for NHL. However, hepatitis acutely exacerbated.

Recently, several reports have shown promising results for the prophylactic use of lamivudine in cancer patients before chemotherapy^[6-8]. However, we did not administer prophylaxis of lamivudine in the present patient, because (1) he was an asymptomatic HBV-carrier, (2) lamivudine-resistant virus might appear after lamivudine treatment or acute exacerbation after discontinuation of lamivudine, and (3) in Japan, adefovir dipivoxil was not available. Theoretically, the steroid containing regimen with lamivudine prophylaxis for NHL patients carrying HBV may be the best therapy. To prove the efficacy of this therapy, further studies are required.

Abstract

Alverine citrate is a commonly used smooth muscle relaxant agent. A MEDLINE search on January 2004 revealed only 1 report implicating the hepatotoxicity of this agent. A 34-year-old woman was investigated because of the finding of elevated liver function tests on biochemical screening. Other etiologies of hepatitis were appropriately ruled out and elevated enzymes were ascribed to alverine citrate treatment. Although alverine citrate hepatotoxicity was related to an immune mechanism in the first case, several features such as absence of predictable dose-dependent toxicity of alverine citrate in a previous study and absence of hypersensitivity manifestations in our patient are suggestive of a metabolic type of idiosyncratic toxicity.

INTRODUCTION

Toxic hepatitis is a liver injury caused by drugs and chemicals. The severity varies from nonspecific changes in liver functions such as abnormalities in liver enzymes to fulminant hepatic failure and cirrhosis. Its incidence has been increased over the past several decades. Drugs have been estimated to be responsible for 15-20% of all cases of fulminant and subfulminant hepatitis in Western countries and 18% of acute liver failure in the United States^[1,2].

Alverine citrate is a smooth muscle relaxant agent, commonly used in patients with irritable bowel syndrome in association with simethicone. Hepatotoxicity of alverine citrate is extremely rare and has been reported only in 1 patient before^[3]. Herein we report a new case of alverine citrate-induced hepatotoxicity occurred in a middle-aged woman that resolved completely after discontinuation of the drug.

CASE REPORT

On July 24, 2003, a 34-year-old woman was admitted to the Outpatient Clinic of Gastroenterology Department of Yuksek Ihtisas Hospital with the chief complaint of dyspepsia lasting for 2 years. She described bloating after meals and sometimes had gastroesophageal reflux symptoms. She did not have any chronic disease states. Physical examination was completely normal. Her biochemical tests including liver enzymes (AST, ALT, ALP and GGT) were all within normal limits. Upper

gastrointestinal endoscopy was performed showing grade I esophagitis and pangastritis. On July 29, omeprazole PO 20 mg bid, liquid alginic acid (Gaviscon) PO 10 mL qid (30 min after meal and at bedtime) and meteospasmyl (a tablet containing 60 mg alverine citrate and 300 mg simethicone) PO tid (before meals) were prescribed. Till the 14th d after prescription she told that she used all of the drugs as recommended. At that time omeprazole was ceased and she continued to medical treatment with Gaviscon and meteospasmyl.

She was admitted to another hospital because of arthralgia lasting for years on August 18, 2003, but therapy was managed on an outpatient basis. Amitriptyline 25 mg PO bid was added to Gaviscon and Meteospasmyl and a gastroenterology consultation was requested because of the finding of abnormal liver function test values on biochemical screening. On August 18, serum liver enzymes were as follows: ALT: 319 IU/L, AST: 211 IU/L (N: 40 IU/L for both); ALP: 184 IU/L (N: 35-129), GGT: 116 IU/L (N: 5-40) and normal direct and indirect bilirubin levels. She began to take amitriptyline on August 23 and readmitted to our hospital on August 26. Her ALT and AST levels were 1 119 IU/L and 853 IU/L, respectively. Other biochemical tests such as, hemoglobin level, white blood cell count, platelet count, and prothrombin time were within normal limits. Hepatobiliary imaging with ultrasonography was normal. Viral markers for hepatitis including hepatitis A, B and C viruses, cytomegalovirus, Epstein-Barr virus, and herpes simplex virus were all negative. Autoantibodies (antinuclear, antimitochondrial, anti-smooth-muscle, anti-liver-kidney microsomal enzymes and anti-soluble liver antigen) were also negative. She denied taking any other medications and using alcohol or any herbal and folk remedies anytime. There were no known environmental issues that could be contributing.

Liver enzyme elevations were thought to be drug induced. Amitriptyline, Gaviscon and Meteospasmyl were all immediately discontinued on August 26. The ALT and AST values decreased to 597 IU/L and 237 IU/L 8 d after withdrawal of all drugs and became completely normal 18 d after cessation. The time course of liver function tests is presented in Table 1. Liver biopsy was not performed, and rechallenge with Meteospasmyl was not attempted because of ethical reasons. Since she had continuing mild symptoms related to gastroesophageal reflux, she continued to take Gaviscon and omeprazole without any increase in biochemical parameters.

Table 1 Time course of liver function tests

Date	AST (IU/L)	ALT (IU/L)	GGT (IU/L)	ALP (IU/L)
7/24/2003	30	32	21	162
8/18	211	319	116	184
8/26	853	1 119	-	-
9/3	237	597	-	229
10/2	22	21	35	75

Omeprazole, alginic acid, and alverine citrate were started on 7/30/2003. Omeprazole was ceased on 8/10/2003. Amitriptyline was added to alginic acid and alverine citrate on 8/23/2003 and all medications were discontinued on 8/26/2003. ALP: Alkaline phosphatase; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; GGT: γ -glutamyl transferase.

DISCUSSION

Meteospasmyl is a most widely used drug for irritable bowel syndrome. It contains 60 mg alverine citrate and 300 mg simethicone. Simethicone has been used as an antifoaming agent and considered as an inert one^[4]. It is excreted via feces without any metabolizing in the gastrointestinal system. It has been widely used in patients with gastrointestinal gas and for the improvement of visibility during radiologic examination^[5]. To our knowledge, no systemic side effect regarding simethicone was reported in the literature.

Alverine is one of the papaverine congeners. Its antispasmodic effects are mediated by processes involving smooth muscle cells, extrinsic nervous system, and calcium channels^[6]. In humans, the drug is completely absorbed by the gastrointestinal tract and mainly metabolized in the liver, with negligible amounts excreted in the urine^[3]. Side effects such as flushing on the face and neck, nausea, headache, dizziness, and allergic skin eruptions may be observed. To our knowledge, hepatotoxicity associated with alverine use was reported once in the literature. Hepatotoxicity was not reported for the other papaverine derivatives other than trimebutine^[7].

In our patient increase in liver enzymes was ascribed to alverine treatment due to several reasons. There was a temporal relationship between alverine treatment and hepatitis. Liver function tests were normal before treatment and increases appeared three weeks after the start of alverine treatment. The timeline of exposure to alverine and initial observation of increase in liver function tests were consistent with drug-induced liver disease^[8]. Liver function tests completely normalized three weeks after withdrawal of the drug. Furthermore other etiologies of hepatitis (alcohol, steatohepatitis, autoimmune hepatitis and viral hepatitis) were appropriately ruled out. Omeprazole was not thought to be responsible for our patient's hepatitis in view of her prior uses of this drug without adverse effects. Neither chemical nor clinical side effects were seen in her consequent follow-up after alginic acid and omeprazole were started again. We therefore classified our case as probable alverine-induced hepatotoxicity according to the Naranjo probability scale^[9].

Drugs cause liver injury either via intrinsic toxicity (dose-dependent or predictable) or host idiosyncrasy (dose-independent or unpredictable). Idiosyncratic hepatotoxicity may be in metabolic or immunoallergic form. Metabolic-type idiosyncratic injury develops as a result of the susceptibility of rare individuals to hepatotoxicity from a drug that is usually safe at conventional doses. In this pattern, reactions would occur among susceptible individuals who possess an isolated genetic enzymatic alteration not expressed under normal conditions, which would become clinically apparent following the

administration of certain drugs^[10]. The mechanism of alverine induced liver disease is unknown. In the first case described in the literature alverine hepatotoxicity was related to immune mechanisms due to the presence of transient hypereosinophilia, eosinophil polymorphonuclear cells in the liver inflammatory infiltrates, and antinuclear autoantibodies. In our patient autoantibodies were negative and there was no hypereosinophilia in the peripheral blood smear. Several features such as the absence of predictable dose-dependent toxicity of alverine and fever, rash, and arthralgia (hypersensitivity manifestations) in our patient were consistent with a metabolic type of idiosyncratic toxicity.

In conclusion, alverine is a smooth muscle relaxant drug. This report presents the second case of alverine-associated possible liver toxicity. Alverine citrate should be included in the list of drugs causing toxic hepatitis.

Abstract

AIM: To report the experience in successfully treating pregnant women with severe hepatitis.

METHODS: Comprehensive medical treatments were performed under strict monitoring.

RESULTS: Pregnant woman with severe hepatitis was successfully rescued.

CONCLUSION: Vital measures taken in the treatment of pregnant women with severe hepatitis include termination of the pregnancy at a proper time and control of various complications, such as disseminated intravascular coagulation (DIC), hepatorenal syndrome, hepatic encephalopathy and infection.

INTRODUCTION

Hepatitis B virus (HBV) infection is common in China^[1], and it is one of the most common causes of severe hepatitis in pregnancy, with a high mortality rate of 43-80%^[2]. In this paper, we reported a pregnant woman with severe hepatitis B infection complicated by postpartum massive hemorrhage, hepatorenal syndrome, hepatic encephalopathy, spontaneous bacterial peritonitis and infection of biliary tract. Under strict monitoring, we applied comprehensive medical treatments. Both the mother and the child were discharged in healthy condition.

CASE REPORT

A 33-year-old pregnant woman was admitted in our hospital on April 15, 2003, presenting with a 38-week pregnancy, 10-d puffiness and yellow urine, and 3-d deep jaundice. She had a history of HBsAg(+), HBeAg(+) and HBcAb(+) for about 10 years, but her liver function had been normal until she got pregnant. The last menstrual period (LMP) was 2002-7-22. The expected date of confinement (EDC) was 2003-4-29. Physical examination showed she had normal vital signs, an urgent and painful looking, clear mind, icteric sclera and xanthochromia, bulbar conjunctiva edema, normal heart and

lung on auscultation, absence of abdominal tenderness or rebound tenderness, no detection of liver or spleen and no shifting dullness on palpation, moderate edema of both legs. Obstetrical conditions were as follows: she had left occipitoanterior position (LOP) of fetus, the height of fundus was 36 cm, the abdomen circumference was 99 cm, fetal heart rate (FHR) was 120 beats/min. No dilatation of cervix was found. Laboratory findings were as follows: aspartate transaminase (AST) was 125.0 U/L, alanine transaminase (ALT) was 138.0 U/L, albumin (ALB) was 32.5 g/L; total bilirubin (TB) was 383.9 $\mu\text{mol/L}$, blood urea nitrogen (BUN) was 36.03 mmol/L, creatinine (CREAT) was 402.6 $\mu\text{mol/L}$, white blood cell count (WBC) was $21.60 \times 10^9/\text{L}$, hemoglobin (Hb) was 82 g/L, prothrombin time (PT) was 24 s, uric protein was (+++). β -ultrasonography showed her liver was in a chronic hepatitis state, and moderate ascites and a little liquid in both sides of thoracic cavity were also found. Markers of series of hepatitis virus were negative for hepatitis A, C, D and E, but positive for HBsAg (+), HBeAg (+) and HBcAb (+). Therefore she was diagnosed as pregnancy associated with hepatitis B infection and fulminant hepatic failure of pregnancy (FHFP).

After admission, the pregnant woman received supportive treatments. Later, because of "fetal distress", she received a cesarean section plus hysterectomy under general anesthesia. During the operation, we found yellow ascites of about 1 500 mL, and the same color of amniotic fluid was also found. The newborn was a mature male baby with normal vital signs, and transmitted to pediatrics department and given hepatitis B virus (HBV) specific immunoglobulin (HBIG) and HBV vaccine. After the delivery of placenta and membrane, there was no sign of uterine contraction, and massive hemorrhage occurred (about 2 000 mL). So hysterectomy was performed. The liver was obviously small, which was about the palm size and a little harder than normal.

After operation, the patient developed a clinical course of exacerbation. She developed hepatic encephalopathy of degree III, hepatorenal syndrome, spontaneous bacterial peritonitis, infection of biliary tract, secondary fungal infection, septicemia and prolonged healing of the wound. The comprehensive and well-designed rescue measures were taken and her condition was under control on June 25. After a hospitalization of 104 d, the patient and her newborn were discharged in generally good conditions.

DISCUSSION

Generally, a pregnant woman with fulminant hepatic failure refers to failure of liver function caused by viral hepatitis. Often the complications included disseminated intravascular coagulation (DIC) that presents a hemorrhage trend^[3,4], hepatic encephalopathy, hepatorenal syndrome, toxic intestinal tympanites, cerebral edema and infection of biliary tract, and so on. A pregnant woman with severe hepatitis often had hypodynamia, deep jaundice, hypocoagulability, hypoproteinemia, coma and acute renal failure. It was reported that many viruses including hepatitis virus (HAV, HBV, HCV, HDV, HEV, HGV, and so forth^[5,6]), cytomegalovirus (CMV), TTV^[7] and herpes virus^[8], could cause severe hepatitis. But HEV and HBV

infections were most frequent^[9-12]. Clinically, about 0.2-0.5% of total patients with hepatitis would develop into severe hepatitis. The prognosis of severe hepatitis during late pregnancy was so poor that it could be listed among the causes of maternity and parity mortality. In this report, the patient with a 10-year history of hepatitis had a 38-wk pregnancy. She developed severe hepatic dysfunction with hypocoagulability, hepatic encephalopathy and hepatorenal syndrome. She was positive for HBsAg, HBeAg, and HBcAb. Therefore the diagnosis of pregnancy associated with severe hepatitis and HBV infection was confirmed^[13,14]. Under strict monitoring, we took comprehensive therapeutic measures and got a successful result. The key points of rescuing the patient were as follows.

The general treatment included: (1) The patient was asked to have an absolute rest in bed with a diet low in lipid and protein^[15] and rich in fiber and vitamins. The total energy should be controlled at 1 500 kcal. Intra-gastrointestinal food could not only neutralize gastric acid, promote gastro-intestinal movement, but also reduce the incidence of toxic intestinal tympanites, endotoxemia, infection of biliary tract, peritonitis or even septicemia. (2) Protecting liver function, gastric membrane and preventing gastrointestinal hemorrhage. (3) Using antibiotics to prevent and treat infections, gamma globulin to promote immune state and neutralize endotoxins. HBIG, which can neutralize HBV and is relatively safe for gestational period, should also be used. (4) Maintaining the balance of body fluid and electrolytes and using dexamethasone for a short period of time (3-5 d) to improve the toxic symptoms and the maturity of fetal lung, thus getting ready for planned delivery.

To terminate pregnancy at a proper time, internal carotid artery centesis was performed and a tube placed to detect the central vein pressure and determine the amount of transfusion, thus preventing the incidence of cerebral edema or pulmonary edema. Before cesarean section, colocolysis and atropine were used. But sedatives such as luminal were not taken into consideration. General anesthesia instead of epidural anesthesia was to avoid epidural hematoma^[16], and during cesarean section^[17], we chose longitudinal incision. After cesarean section, we performed hysterectomy and placed an absorbable hemostatic gauze on the cervical stump to reduce hemorrhage during and after operation. We also detected the size of liver during operation to make a general evaluation of its condition of direct prognosis. We perfused the abdomen cavity with iodophors to reduce abdominal infection. We remained a gastric tube during operation to prevent intestinal tympanites and to put in medicines that could improve the movement of intestine. After operation, we remained a drainage tube in abdomen to facilitate the expulsion of ascites and to inspect whether there was continuous hemorrhage.

To prevent and cure complications, measures were taken to reduce possible motivations such as using none or as few as sedatives and narcotics, to avoid too much or too fast diuretics or relieving of ascites, to prevent constipation or mass hemorrhage or infection, to adjust intestinal environment by lactulose towards pH<7 to reduce absorption of NH₃ and endotoxin which would exacerbate the condition of hepatic encephalopathy, to take metronidazole and norfloxacin to compress intestinal bacteria which could produce NH₃, to use colocolysis to accelerate the expulsion of intestinal bacteria and endotoxin and NH₃-removing medicines, to keep normal neurotransmitter by applying L-dopa or aceglutamide, to inject hepatamine intravenously to keep amino-acid balance, to use Chinese formulated medicines such as *Angong niuhuang wan*. Heparin in low dose was used to prevent dissipation of large amount of plot and thrombin factors and to improve clotting mechanism. Thrombin factors such as fresh frozen plasma,

plot, cryoprecipitate, pro-thrombin complex, and fibrinogen were used in a great quantity. Hepatorenal syndrome was treated by restricting the infusion of fluid, correcting hypoproteinemia and hypovolemia in time. Diuretics such as furosemide, diuretics complex (furosemide + dopamine + phentolamine) or mannitol + furosemide were used.

To promote regeneration of hepatocytes, glucagon and insulin were used to trigger the synthesis of hepatocyte DNA, human albumin was used to neutralize indirect bilirubin, stimulate regeneration of hepatocytes and prevent further necrosis of hepatocytes.

Blood routine, clotting function, liver function and biochemical indices, especially ALT, AST, alkaline phosphatase (AKP), acetylcholine esterase (CHE), alpha fetoprotein (AFP) and glucose (GLU) were monitored. Intensive nursing and sterile operation were performed, regular mouth care and clean of incision and perineum were maintained. 50% glucose + insulin was used to promote wound healing.

Before labor, HBIG or anti-HBV medicines (safe for both maternity and fetus) were given to interrupt intrauterine HBV infection^[1]. The newborn was also given HBIG and HB vaccine^[18] to build up active and passive immunity.

Abstract

Ulcerative colitis (UC) is an inflammatory destructive disease of the large intestine occurred usually in the rectum and lower part of the colon as well as the entire colon. Drug therapy is not the only choice for UC treatment and medical management should be as a comprehensive whole. Azulfidine, Asacol, Pentasa, Dipentum, and Rowasa all contain 5-aminosalicylic acid (5-ASA), which is the topical anti-inflammatory ingredient. Pentasa is more commonly used in treating Crohn's ileitis because Pentasa capsules release more 5-ASA into the small intestine than Asacol tablets. Pentasa can also be used for treating mild to moderate UC. Rowasa enemas are safe and effective in treating ulcerative proctitis and proctosigmoiditis. The sulfa-free 5-ASA agents (Asacol, Pentasa, Dipentum and Rowasa) have fewer side effects than sulfa-containing Azulfidine. In UC patients with moderate to severe disease and in patients who failed to respond to 5-ASA compounds, systemic (oral) corticosteroids should be used. Systemic corticosteroids (prednisone, prednisolone, cortisone, *etc.*) are potent and fast-acting drugs for treating UC, Crohn's ileitis and ileocolitis. Systemic corticosteroids are not effective in maintaining remission in patients with UC. Serious side effects can result from prolonged corticosteroid treatment. To minimize side effects, corticosteroids should be gradually reduced as soon as the disease remission is achieved. In patients with corticosteroid-dependent or unresponsive to corticosteroid treatment, surgery or immunomodulator is considered. Immunomodulators used for treating severe UC include azathioprine/6-MP, methotrexate, and cyclosporine. Integrated traditional Chinese and Western medicine is safe and effective in maintaining remission in patients with UC.

INTRODUCTION

Ulcerative colitis (UC) is an inflammatory destructive disease of the large intestine characterized by motility and secretion

disorders. Inflammation usually occurs in the rectum and lower part of the colon, but it may affect the entire colon^[1-4]. UC rarely affects the small intestine except for the end section, called the terminal ileum. UC may also be called colitis or proctitis^[4,5].

Inflammation makes the colon empty frequently, causing diarrhea. Ulcers formed in places where the inflammation has killed the cells of colon, bleeding ulcers and pus discharge. UC is an inflammatory bowel disease (IBD) that causes inflammation in the small intestine and colon. UC can be difficult to diagnose because its symptoms are similar to other intestinal disorders and another type of IBD called Crohn's disease (CD). CD differs from UC because it causes deeper inflammation within the intestinal wall^[5-7]. Also, CD usually occurs in the small intestine, although it can also occur in the mouth, esophagus, stomach, duodenum, large intestine, appendix, and anus. UC may occur in people of any age, but most often it starts between ages 15 and 30, or less frequently between ages 50 and 70. Children and adolescents sometimes develop the disease. UC affects men and women equally and appears to run in some families.

UC CHARACTERISTICS

Of the estimated two million Americans suffer from IBD, CD is far less common than UC, but currently the incidences of each are estimated to be about equal. The incidence may vary depending on gender, age, and geography^[4-6]. Men and women have an equal risk for UC. IBD is diagnosed most often in young people between the ages of 10 and 19, but it can occur at any age. A smaller peak onset occurs between 50 and 80 years. About 2% of IBD cases appear in children below age 10. UC is most common among people of European descent. People of African descent have a lower incidence than Caucasians. Low incidence regions include Asia and South America. Ethnically, Jewish people have a higher risk. UC may disproportionately affect people of higher socioeconomic classes, but evidence for this is inconclusive.

UC shares certain characteristics^[4-8]: (1) Symptoms usually appear in young adults. (2) Symptoms can develop gradually or suddenly. (3) Both are chronic. The symptoms may flare up (relapse) after symptom-free periods (remission) or symptoms may be continuous without treatment. (4) The disease can be mild or very severe and disabling. (5) The severity of symptoms and relapse rates of both UC and DC vary with seasons, with the highest risk in winter and autumn and lowest in summer.

Factors associated with UC

Smokers have lower than average rates of UC (but higher than average rates of CD). In fact, it has been reported that some patients with UC had disorders after they gave up smoking, and many studies have stressed the association between smoking and protection against UC. This information is certainly no encouragement to smoke. Rather, patients should ask their physician about trials using nicotine replacement aids. Breast feeding also appears to be associated with lower risk of UC. Left-handed people have a significantly higher risk for both IBDs and other diseases associated with immune abnormalities. A 2001 study reported that patients with UC were more likely to have a history of depression or anxiety than those without IBD. Some researchers suggested that depression might alter the immune system and make people more susceptible to UC^[3,4].

Symptoms of UC

General symptoms Fever may occur with severe attacks, usually a low-grade. Spiking fever and chills indicate complications. Loss of appetite, weight loss and impaired growth in children are usually not evidence of mild or moderate or severe UC. Increased frequency, a feeling of incomplete evacuation, tenesmus (a painful urge for a bowel movement even if the rectum is empty) and fecal incontinence may occur in mild or severe stage. Anal ulcers and fistulae, channels that can burrow between organs, loops of intestine or between intestines and skin, may be early symptoms. Recurrent diarrhea is very common, but the onset may be very gradual and mild or silent. Feces may also contain mucus. Recurrent diarrhea is prevalent in developing countries, particularly in tropical regions^[6-8]. Blood is always present in stools, it may be readily visible or visible only using a microscope (so-called occult blood). Constipation can be a symptom of UC but not as common as diarrhea. It can occur during flare-ups, and when the inflamed rectum triggers a reflex response in the colon that causes it to retain the stool. But constipation in CD is usually a symptom of obstruction in the small intestine.

Abdominal symptoms Pain is not a prominent symptom but can vary. Vague discomfort may occur in the lower abdomen, an ache around the top of the hipbone, or cramps in the middle of the abdomen. Severe pain can occur during flare-ups. Recurrent episodes of pain in the lower right part of the abdomen or above the pubic bone often precede and are relieved by defecation. Bloating, nausea, and vomiting may also occur. Intestinal pain may also be an indication of serious conditions, such as an abscess, or a perforation of the intestinal wall.

Complications of UC Patients with UC limited to the rectum (proctitis) or colitis limited to the end of the left colon (proctosigmoiditis) usually do quite well. Short periodic treatments using oral medications or enemas may be sufficient. Serious complications are rare in these patients. In those with a more extensive disease, blood loss from the inflamed intestines can lead to anemia, and may require treatment with iron supplements or even blood transfusions. Rarely, the colon can acutely dilate to a large size when the inflammation becomes very severe. This condition is called toxic megacolon. Patients with toxic megacolon are extremely ill with fever, abdominal pain and distention, dehydration, and malnutrition. Unless the patient improves rapidly with medication, surgery is usually necessary to prevent colon rupture^[3-5,7,8].

Colon cancer is a recognized complication of chronic UC. The risk for cancer begins to rise significantly after 8 to 10 years of colitis. The risk of a patient with UC developing colon cancer is also related to the location and the extent of the disease. Patients with only ulcerative proctitis probably do not have increased colon cancer risk compared to the general population. Among patients with active pancolitis of 10 years or longer, their risk of colon cancer is 10-20 times higher than that of the general population. In patients with chronic left-sided colitis, the risk of colon cancer is increased but not as high as in patients with chronic pancolitis.

Since these cancers have a more favorable outcome when treated at an earlier stage, yearly colon examination is recommended after 8 years of a known extensive disease. During these examinations, samples of tissue (biopsies) should be taken to search for precancerous lesions in the lining cells of the colon. When precancerous lesions are found, removal of the colon may be necessary to prevent colon cancer.

Complications of UC involve other parts of the body. Ten percent of the patients can develop inflammation of the joints (arthritis). Some patients have low back pain due to arthritis of the sacroiliac joints. Rarely, patients may develop painful and red skin nodules (erythema nodosum). Yet others can have painful and red eyes (uveitis, episcleritis). Because these

particular complications are a permanent risk in vision impairment, eye pain or redness is symptoms that require a physician's evaluation. Diseases of the liver and bile ducts may associate with UC. For example, in rare patients with a condition called sclerosing cholangitis, repeated infections and inflammation in the bile ducts can lead to recurrent fever, yellowing of skin (jaundice), cirrhosis, and the need for a liver transplant.

DRUG TREATMENT

Both medications and surgery have been used to treat UC^[7-21]. However, surgery is reserved for those with severe inflammation and life-threatening complications. There is no medication that can cure UC. Patients with UC will typically experience periods of relapse (worsening of inflammation) followed by periods of remission lasting for months to years. During relapses, symptoms of abdominal pain, diarrhea, and rectal bleeding can worsen patients' quality of life. During remissions, these symptoms subside. Remissions usually occur because of treatment with medications or surgery, but occasionally they occur spontaneously.

Since UC cannot be cured by medications, the goals of treatment with medications are to induce remissions, maintain remissions, minimize side effects of treatment, and improve the quality of life. The treatment of UC with medications is similar, though not always identical, to the treatment of CD^[9-11,16-20].

Medications treating UC include anti-inflammatory agents such as 5-ASA compounds, systemic and topical corticosteroids, and immunomodulators.

Anti-inflammatory medications that decrease intestinal inflammation are analogous to arthritis medications that decrease joint inflammation (arthritis). The anti-inflammatory medications used in the treatment of UC are topical 5-ASA compounds such as sulfasalazine (Azulfidine), olsalazine (Dipentum), and mesalamine (Pentasa, Asacol, Rowasa enema) that need direct contact with the inflamed tissues in order to be effective. Systemic corticosteroids can decrease the inflammation throughout the body without direct contact with the inflamed tissue. Systemic corticosteroids have predictable side effects in long-term treatment. Immunomodulators are medications that suppress the body's immune system either by reducing the cells that are responsible for immunity, or by interfering with proteins that are important in promoting inflammation. Immunomodulators are increasingly becoming important for patients with severe UC who do not respond adequately to anti-inflammatory agents. Examples of immunomodulators include 6-mercaptopurine (6-MP), azathioprine, methotrexate, and cyclosporine.

A somewhat curious new treatment is nicotine. It has long been observed that the risk of UC appears to be higher in nonsmokers and in ex-smokers. In certain circumstances, patients could improve clinically when treated with nicotine while they failed to respond to other medications.

5-ASA compounds (azulfidine, asacol, pentasa, dipentum)

5-ASA (5-aminosalicylic acid), also called mesalamine, is chemically similar to aspirin. Aspirin (acetylsalicylic acid) has been used for many years in treating arthritis, bursitis, and tendinitis (conditions of tissue inflammation). Aspirin, however, is not effective in treating UC. On the other hand, 5-ASA is effective in treating UC if the drug can be delivered directly (topically) onto the inflamed colon lining^[17-21]. For example, Rowasa for enema is a 5-ASA solution that is effective in treating inflammation in and near the rectum (ulcerative proctitis and ulcerative proctosigmoiditis). However, the enema solution cannot reach high enough to treat inflammation in the upper colon. Therefore, for most patients with UC, 5-ASA must be taken orally. When pure 5-ASA is taken orally, however, the

stomach and upper small intestine absorb most of the drug before it reaches the colon. Therefore, to be effective as an oral agent for UC, 5-ASA has to be modified chemically to escape absorption by the stomach and upper intestines. These modified 5-ASA compounds are sulfasalazine (Azulfidine), mesalamine (Pentasa, Asacol), and olsalazine (Dipentum).

Azulfidine

Sulfasalazine (Azulfidine)^[22] has been used successfully for many years in inducing remission among patients with mild to moderate UC. Inducing remission means decreasing intestinal inflammation and relieving symptoms of abdominal pain, diarrhea, and rectal bleeding. Sulfasalazine has also been used for prolonged periods of time to maintain remissions.

Sulfasalazine consists of a 5-ASA molecule linked chemically to a sulfapyridine molecule. (Sulfapyridine is a sulfa antibiotic). Connecting the two molecules together prevents absorption by the stomach and upper intestines prior to reaching the colon. When sulfasalazine reaches the colon, bacteria in the colon will break the linkage between the two molecules. After breaking away from 5-ASA, sulfapyridine is absorbed into the body and then excreted in the urine. Most of the active 5-ASA, however, remains in the colon to treat colitis.

Most of the side effects of sulfasalazine are due to the sulfapyridine molecule. These side effects include nausea, heartburn, headache, anemia, skin rashes, and in rare instances, hepatitis and kidney inflammation. In men, sulfasalazine can reduce the sperm count which sperm count is reversible, and the count usually returns to normal after discontinuing sulfasalazine or by changing to a different 5-ASA compound.

The benefits of sulfasalazine generally are dose related. Therefore, high doses of sulfasalazine may be necessary to induce remission. Some patients cannot tolerate high doses because of nausea and stomach upset. To minimize stomach upset, sulfasalazine is generally taken after or with meals. Some patients find it easier to take Azulfidine-EN (enteric-coated form of sulfasalazine). Enteric-coating helps decrease stomach upset. The newer 5-ASA compounds do not have the sulfapyridine component and have fewer side effects than sulfasalazine.

Asacol

Asacol is a tablet consisting of 5-ASA compound, mesalamine, surrounded by an acrylic resin coating (Asacol is sulfa free)^[22,23]. The resin coating prevents 5-ASA from being absorbed as it passes through the stomach and small intestine. When the tablet reaches the terminal ileum and colon, the resin coating dissolves, thus releasing 5-ASA into the colon.

Asacol is effective in inducing remissions in patients with mild to moderate UC. It is also effective when used for prolonged periods of time to maintain remissions. The recommended dose of Asacol to induce remission is two 400-mg tablets three times daily (total of 2.4 g/d). Two tablets of Asacol twice daily (1.6 g/d) are recommended for maintaining remission. Occasionally, the maintenance dose should be higher. As Azulfidine, the benefits of Asacol are dose-related. If patients do not respond to 2.4 g/d of Asacol, the dose is frequently increased to 3.6 g/d (and sometimes even higher) to induce remission. If patients fail to respond to the higher doses of Asacol, then alternatives such as corticosteroids are recommended.

Pentasa

Pentasa is a capsule consisting of 5-ASA compound mesalamine inside controlled-release spheres. Like Asacol, it is sulfa free. As the capsule travels down the intestines, 5-ASA inside the spheres is slowly released into the intestines. Unlike Asacol, mesalamine in Pentasa is released into the small intestine as well as colon. Therefore, Pentasa can be effective in treating inflammation in the small intestine and colon. Pentasa is

currently the most logical 5-ASA compound for treating mild to moderate CD involving the small intestine. Pentasa is also used to induce remission and maintain remission among patients with mild to moderate UC^[23,24].

Olsalazine (Dipentum)

Olsalazine (Dipentum) consists of two 5-ASA molecules linked together^[24,25]. It is sulfa free. The linked 5-ASA molecules travel through the stomach and the small intestine unabsorbed. When the drug reaches the terminal ileum and the colon, normal bacteria in the intestine break the linkage and release the active drug into the colon and terminal ileum. Olsalazine has been used in treating UC and maintaining remissions. A side effect unique to olsalazine is secretory diarrhea (diarrhea resulting from excessive production of fluid in the intestines). This condition occurs in 5-10% of patients, and diarrhea sometimes can be severe.

Colazal

Colazal (balsalazide) is a capsule in which 5-ASA is linked by a chemical bond to another molecule that is inert (without effect on the intestine) and prevents 5-ASA from being absorbed^[25-29]. This drug is able to travel through the intestine unchanged until it reaches the end of the small bowel (terminal ileum) and colon. There, intestinal bacteria break apart 5-ASA and the inert molecule, releasing 5-ASA. Because intestinal bacteria are most abundant in the terminal ileum and colon, Colazal is used to treat inflammation predominantly localized to the colon. Colazal recently has been approved by FDA for use in United States of America.

More clinical trials are needed to compare the effectiveness of Colozal to other mesalamine compounds such as Asacol in treating UC. Therefore in United States of America, 5-ASA, has to be individualized^[27,28]. Colozal should be prescribed for patients who cannot tolerate or fail to respond to Asacol, also for patients with predominantly left sided colitis, since some studies seem to indicate that Colozal is effective in treating left sided colitis.

Rowasa enema

Rowasa is 5-ASA compound mesalamine in enema form and is effective in the treatment of ulcerative proctitis and ulcerative proctosigmoiditis (two conditions where active 5-ASA drugs taken as enemas can easily reach the inflamed tissues directly)^[29,30]. Each Rowasa enema contains 4 g of mesalamine in 60 mL of fluid. The enema is usually administered at bedtime, and patients are encouraged to retain the enema through the night.

The enema contains sulfite and should not be used by patients with sulfite allergy. Otherwise, Rowasa enemas are safe and well tolerated.

Rowasa also comes in suppository form for treating limited proctitis. Each suppository contains 500 mg of mesalamine and usually is administered twice daily. While some patients improve within several days after using Rowasa, the usual course of treatment is 3-6 wk. Some patients may need even longer courses of treatment for optimal benefit. In patients who do not respond to Rowasa, oral 5-ASA compounds (such as Asacol) can be added. Some studies have reported increased effectiveness in treating ulcerative proctitis and proctosigmoiditis by combining oral 5-ASA compounds with Rowasa enemas. Oral 5-ASA compounds are also used to maintain remission in ulcerative proctitis and proctosigmoiditis^[30].

Another alternative for patients who fail to respond to Rowasa or who cannot use Rowasa is cortisone enemas (Cortenema). Cortisone is a corticosteroid that is a potent anti-inflammatory agent. Oral corticosteroids are systemic drugs with serious and predictable long-term side effects. Cortenema is a topical corticosteroid that is less absorbed into the body than oral corticosteroids, and therefore, it has fewer and less side effects.

Side effects of 5-ASA compounds

Sulfa-free 5-ASA compounds have fewer side effects than sulfasalazine and also do not impair male fertility. In general, they are safe medications for long-term use and well tolerated^[23-28]. Patients allergic to aspirin should avoid 5-ASA compounds because they are chemically similar to aspirin. In a few occasions kidney inflammation has been reported due to the use of 5-ASA compounds. These compounds should be used with caution in patients with known kidney disease. It also is recommended that blood tests of kidney function are obtained before and during the treatment.

A rare instance of acute worsening of diarrhea, cramps, and abdominal pain may occur at times and may be accompanied by fever, rash, and malaise. This reaction is believed to represent an allergy to 5-ASA compounds.

Corticosteroids for UC

Corticosteroids (prednisone, prednisolone, hydrocortisone, etc.) have been used for many years in the treatment of patients with moderate to severe CD and UC or who fail to respond to optimal doses of 5-ASA compounds^[31-34]. Unlike 5-ASA compounds, corticosteroids do not require direct contact with inflamed intestinal tissues to be effective. Oral corticosteroids are potent anti-inflammatory agents. After absorption, corticosteroids exert prompt anti-inflammatory action throughout the body. Consequently, they are used in treating Crohn's enteritis, ileitis, and ileocolitis, as well as UC and Crohn's colitis. In critically ill patients, intravenous corticosteroids (such as hydrocortisone) can be given in the hospital. Corticosteroids are faster acting than 5-ASA compounds. Patients frequently experience improvement in their symptoms within days after using starting corticosteroids. Corticosteroids, however, do not appear to be useful in maintaining remissions in UC^[22-24].

Proper use of corticosteroids

Once the decision is made to use oral corticosteroids, treatment usually is initiated with prednisone, 40-60 mg daily. The majority of patients with UC respond with an improvement in symptoms. Once symptoms improve, prednisone is reduced by 5-10 mg per wk until the dose of 20 mg per day is reached. The dose then is tapered at a slower rate until prednisone ultimately is discontinued. Gradually reducing corticosteroids not only minimizes the symptoms of adrenal insufficiency, but also reduces the chances of abrupt relapse of colitis.

Many doctors use 5-ASA compounds at the same time as corticosteroids. In patients who achieve remission with systemic corticosteroids, 5-ASA compounds such as Asacol are often continued to maintain remissions^[10,17-19]. In patients whose symptoms return during reduction of the dose of corticosteroids, the dose of corticosteroids is increased slightly to control the symptoms. Once the symptoms are under control, the reduction can resume at a slower pace. Some patients become corticosteroid dependent and consistently develop symptoms of colitis whenever the corticosteroid dose is below a certain level. In patients who are corticosteroid dependent or unresponsive to corticosteroids, other anti-inflammatory medications, immunomodulator medications or surgery are considered. The management of patients who are corticosteroid dependent or patients with a severe disease which responds poorly to medications is complex. Doctors who are experienced in treating inflammatory bowel disease and in using immunomodulators should evaluate these patients.

Side effects of corticosteroids

Side effects of corticosteroids depend on the dose and duration of treatment. Short courses of prednisone, for example, usually are well tolerated with few and mild side effects. Long term high

doses of corticosteroids usually produce predictable and potentially serious side effects. Common side effects include rounding of the face (moon face), acne, increased body hair, diabetes, weight gain, high blood pressure, cataracts, glaucoma, increased susceptibility to infections, muscle weakness, depression, insomnia, mood swings, personality changes, irritability, and thinning of bones (osteoporosis) with an accompanying increased risk of compression fractures of the spine. Children on corticosteroids can experience stunted growth.

The most serious complication of long-term corticosteroid use is aseptic necrosis of the hip joints. Aseptic necrosis means death of bone tissue. It is a painful condition that can ultimately lead to the need for surgical replacement of the hips. Aseptic necrosis also has been reported in knee joints. It is unknown how corticosteroids cause aseptic necrosis. The estimated incidence of aseptic necrosis among corticosteroid users is 3-4%. Patients on corticosteroids who develop pain in hips or knees should report the pain to their doctors promptly. Early diagnosis of aseptic necrosis with cessation of corticosteroids has been reported in some patients to decrease the severity of the disease and possibly help avoid hip replacement.

Prolonged use of corticosteroids can depress the ability of adrenal glands to produce cortisol (a natural corticosteroid necessary for proper functioning of the body). Abruptly discontinuing corticosteroids can cause symptoms due to a lack of natural cortisol (a condition called adrenal insufficiency). Symptoms of adrenal insufficiency include nausea, vomiting, and even shock. Withdrawing corticosteroids too quickly can also produce symptoms of joint aches, fever, and malaise. Therefore, corticosteroids need to be gradually reduced rather than abruptly stopped. Even after corticosteroids are discontinued, the ability of adrenal glands to produce cortisol can remain depressed for months to two years. The depressed adrenal glands may not be able to produce enough cortisol to help the body handle stresses such as accidents, surgery, and infections. These patients will need treatment with corticosteroids (prednisone, hydrocortisone, etc.) during stressful situations to avoid developing adrenal insufficiency. Because corticosteroids are not useful in maintaining remission in UC and CD and because they have predictable and potentially serious side effects, these drugs should be used for the shortest possible time.

Preventing corticosteroid-induced osteoporosis

Long-term use of corticosteroids such as prednisolone or prednisone can cause osteoporosis, because corticosteroids could decrease calcium absorption from intestines and increase loss of calcium from the kidneys and bones. Increasing dietary calcium intake is important but alone cannot halt corticosteroid-induced bone loss. Management of patients on long-term corticosteroids should include adequate calcium (1 000 mg/d if premenopausal, 1 500 mg/d if postmenopausal) and vitamin D (800 U/d) intake, needs for continued corticosteroid treatment and the lowest effective dose, a bone density study to measure the extent of bone loss in patients taking corticosteroids for more than 3 mo, regular weight-bearing exercise and stopping cigarette smoking, discussion with the doctor regarding the use of alendronate (Fosamax) or risedronate (Actonel) in prevention and treatment of corticosteroid induced osteoporosis.

Immunomodulator medications

Immunomodulators are medications that weaken the body's immune system, which is composed of immune cells and cell-produced proteins. These cells and proteins serve to defend the body against harmful bacteria, viruses, fungi, and other foreign invaders. Activation of the immune system causes

inflammation within the tissues where the activation occurs. Normally, the immune system is activated only when the body is exposed to harmful invaders. In patients with CD and UC, however, the immune system is abnormally and chronically activated in the absence of any known invaders. Immunomodulators decrease tissue inflammation by reducing the population of immune cells and/or by interfering with their production of proteins that promote immune activation and inflammation. Generally, the benefits of controlling moderate to severe UC outweigh the risks of infection due to weakened immunity. Examples of immunomodulators include azathioprine (Imuran), 6-mercaptopurine (6-MP, Purinethol), cyclosporine (Sandimmune), and methotrexate^[31-37].

Azathioprine (imuran) and 6-MP (purinethol)

Azathioprine and 6-mercaptopurine (6-MP) are medications that weaken the body's immunity by reducing the population of a class of immune cells called lymphocytes^[31]. Azathioprine and 6-MP are related chemically. Specifically, azathioprine is converted into 6-MP inside the body. In high doses, these two drugs are useful in preventing rejection of transplanted organs and in treating leukemia. In low doses, they are used to treat patients with moderate to severe CD and UC. Azathioprine and 6-MP are increasingly recognized by doctors as valuable drugs in treating CD and UC. Some 70% of patients with moderate to severe disease benefit from these drugs. Because of the slow onset of action and the side effects, 6-MP and azathioprine are used mainly in the following situations^[31-34], UC and CD patients with severe diseases not responding to corticosteroids, patients experiencing undesirable corticosteroid-related side effects, patients dependent on corticosteroids and unable to discontinue them without developing relapses.

When azathioprine and 6-MP are added to corticosteroids in the treatment of UC patients who do not respond to corticosteroids alone, they may have an improved response to smaller doses, and shorter courses of corticosteroids may be used. Some patients can discontinue corticosteroids without experiencing relapses. The ability to reduce corticosteroid has earned the reputation of 6-MP and azathioprine as "steroid-sparing" medications^[32-34]. In severe UC patients with severe disease who suffer frequent relapses, 5-ASA may not be sufficient, and more potent azathioprine and 6-MP will be necessary to maintain remissions. In the doses used for treating UC and CD, the long-term side effects of azathioprine and 6-MP are less serious than long-term oral corticosteroids or repeated courses of oral corticosteroids.

Side effects of 6-MP and azathioprine

Side effects of 6-MP and azathioprine include increased vulnerability to infections, inflammation of the liver (hepatitis) and pancreas (pancreatitis), and bone marrow toxicity (interfering with the formation of cells that circulate in the blood)^[31-37].

The goal of treatment with 6-MP and azathioprine is to weaken the body's immune system in order to decrease the intensity of inflammation in intestines. However, weakening the immune system increases the vulnerability to infections. For example, in a group severe CD patients unresponsive to standard doses of azathioprine, raising the dose of azathioprine helped to control the disease, but two patients developed cytomegalovirus (CMV) infection.

Azathioprine and 6-MP-induced inflammation of the liver (hepatitis) and pancreas (pancreatitis) is rare. Pancreatitis typically causes severe abdominal pain and sometimes vomiting. Pancreatitis due to 6-MP or azathioprine occurs in 3-5% of patients, usually during the first several wk of treatment. Patients who develop pancreatitis should not receive either of these two medications again^[38,39]. Azathioprine and 6-MP also

suppress the bone marrow where red blood cells, white blood cells, and platelets are made. Actually, a slight reduction in white blood cell count during treatment is desirable since it indicates that the dose of 6-MP or azathioprine is high enough to have an effect. However, excessively low red or white blood cell counts indicate bone marrow toxicity. Therefore, patients on 6-MP and azathioprine should have periodic detection of blood counts (usually every two wk initially and then every 3 mo during maintenance) to monitor the effect of the drugs on their bone marrow. 6-MP can reduce the sperm count in men. When the partners of male patients on 6-MP conceive, there is a higher incidence of miscarriages and vaginal bleeding. There also are respiratory difficulties in the newborn. Therefore, it is recommended that whenever feasible, male patients should stop 6-MP and azathioprine for 3 mo before conception. Patients on long-term high dose azathioprine to prevent rejection of the kidney after kidney transplantation have an increased risk of lymphoma. There is no evidence at present that long-term use of azathioprine and 6-MP in low doses used in IBD increases the risk of lymphoma, leukemia or other malignancies^[6,40].

6-MP characteristics

One problem with 6-MP and azathioprine is their slow onset of action. Typically, 3 mo or a longer time is required to achieve the full benefit of these drugs. During this time, corticosteroids frequently have to be maintained at high levels to control inflammation^[33].

The reason for this slow onset of action is partly due to the way prescribed 6-MP by doctors. Typically, 6-MP is started at a dose of 50 mg/d. The blood count is then checked 2 wk later. If the white blood cell count (specifically the lymphocyte count) is not reduced, the dose is increased. This cautious, stepwise approach helps prevent severe bone marrow and liver toxicity, but delays benefit from the drug.

Studies have shown that giving higher doses of 6-MP early can speed up the benefit of 6-MP without increasing toxicity in most patients, but some patients do develop severe bone marrow toxicity. Therefore, the dose of 6-MP has to be individualized. Scientists now believe that an individual's vulnerability to 6-MP toxicity is genetically inherited. Blood tests can be performed to identify those individuals with increased vulnerability to 6-MP toxicity. In these individuals, lower initial doses can be used. Blood tests can also be performed to measure the levels of certain by-products of 6-MP^[32-34]. The levels of these by-products in the blood help doctors more quickly determine whether the dose of 6-MP is right for the patient.

6-MP maintained treatment

Patients on maintenance with 6-MP or azathioprine for years have not any important long-term side effects. Their doctors, however, should closely monitor their patients on long-term 6-MP. There are data suggesting that patients on long-term maintenance with 6-MP or azathioprine fared better than those who stopped these medications. Those who stopped 6-MP or azathioprine were more likely to experience relapses, more likely to need corticosteroids or undergo surgery^[22-24,40].

Methotrexate

Methotrexate is an immunomodulator and anti-inflammatory medication. Methotrexate has been used for many years in the treatment of severe rheumatoid arthritis and psoriasis, and is helpful in treating patients with moderate to severe CD who neither respond to 6-MP and azathioprine nor tolerate these two medications. Methotrexate may also be effective in patients with moderate to severe UC who do not respond to corticosteroids or 6-MP and azathioprine. It can be given orally or by weekly

injections under the skin or into the muscles. It is more reliably absorbed with the injections^[35-39]. One major complication of methotrexate is the development of liver cirrhosis when the medication is given over a prolonged period of time (years). The risk of liver damage is higher in patients who also abuse alcohol or have morbid (severe) obesity. Generally, periodic liver biopsies are recommended for a patient who has received a cumulative (total) methotrexate dose of 1.5 g and higher^[38-40].

Other side effects of methotrexate include low white blood cell counts and inflammation of the lungs.

Methotrexate should not be used in pregnancy.

Cyclosporine

Cyclosporine (Sandimmune) is a potent immunosuppressant used in preventing organ rejection after transplantation. It has also been used to treat patients with severe UC and CD. Because of the approval of infliximab (Remicade) for treating severe CD, cyclosporine will probably be used primarily in severe UC. Cyclosporine is useful in fulminant UC and severely ill patients who do not respond to systemic corticosteroids. Cyclosporine is available as an oral medication, but the relapse rate with oral cyclosporine is high. Therefore, cyclosporine seems most useful when administered intravenously in acute situations^[33-37].

Side effects of cyclosporine include high blood pressure, renal function impairment, and tingling sensations in the extremities. More serious side effects include anaphylactic shock and seizures.

Traditional Chinese medicine

A total of 10 218 patients with UC reported in Chinese medical literature and the cases diagnosed were analyzed according to the diagnostic criteria of Lennard-Jones from 1981 to 2000. The number of cases increased by 3.08 times over the past 10 years (2 506 patients were diagnosed from 1981 to 1990 while 7 512 patients were diagnosed from 1991 to 2000). Lesion range was described in 7 966 patients, 5 592 (70.2%) were proctosigmoiditis or proctitis, 1 792 (22.5%) left-sided colitis, 582 (7.3%) pancolitis. Among the 8 122 patients, 2 826 (34.8%) had first episode, 4 272 (52.6%) had chronic relapse, 869 (10.7%) were of chronic persistent type, 154 (1.9%) were of acute fulminant type. The course of the illness was described in 5 867 patients, 4 427 (75.5%) were less than 5 years, 910 (15.5%) between 5 and 10 years, 530 (9.1%) more than 10 years. Six hundred and sixteen patients (6.1%) had extraintestinal manifestations. The mean age at the diagnosis was 40.7 years (range 6-80 years, and the peak age 30-49 years). The male to female ratio was 1.09. Among the 270 patients diagnosed in our hospital, 36 had histories of smoking, there was no negative association between the severity of UC and smoking ($P>0.05$), 21 smokers were followed up for one year, 15 of them had given up smoking when the disease was diagnosed, and one year later, 7 patients relapsed, another 6 patients continued smoking, and one year later, 2 patients relapsed. Among the 270 UC patients diagnosed in our hospital, 4 patients (1.5%) from 2 families had a familial history of UC. Treatment was done in 6 859 patients, only 5-ASA and/or corticosteroid only in 1 276 patients (18.6%), Chinese herbs alone in 1 377 patients (20.1%), combined Chinese and Western medicine in 4 056 patients (59.1%), surgery was performed in 87 patients (1.3%), other treatments in 63 patients (0.9%). In China, the number of UC patients increased significantly in the past 10 years. Lesions were commonly located to the left side colon. The course was short with rare extraintestinal manifestations. The age of onset was relatively high. Males and females were nearly equally affected. No negative relation was found between smoking and severity of the disease. Familial relatives were rarely involved. Traditional Chinese medicine (TCM) was widely used in the treatment of UC^[33].

Langmead *et al.*^[41] reported that herbal remedies for the treatment of IBD included slippery elm, fenugreek, devil's claw, Mexican yam, tormentil and *Wei tong ning*, a traditional Chinese medicine. Reactive oxygen metabolites produced by inflamed colonic mucosa may be pathogenic. Aminosalicylates (5-ASA) are antioxidant and other such agents could be therapeutic. Luminol-enhanced chemiluminescence in a xanthine/xanthine oxidase cell-free system was used to detect superoxide scavenging by herbs and 5-ASA. Fluorimetry was used to define peroxy radical scavenging by using a phycoerythrin degradation assay. Chemiluminescence was used to detect herbal effects on generation of oxygen radicals by mucosal biopsies from patients with active UC. All materials tested scavenged peroxy dose-dependently. Oxygen radical release from biopsies was reduced after incubation in all herbs except Mexican yam. All six herbal remedies have antioxidant effects. Fenugreek is not a superoxide scavenger, while Mexican yam does not inhibit radical generation of inflamed biopsies. Slippery elm, fenugreek, devil's claw, tormentil and *Wei tong ning* are novel drugs in IBD.

A total of 118 patients with UC were treated by integration of traditional Chinese and Western medicine^[42-44]. Another 86 cases of UC were treated by simple Western drugs as controls. The therapeutic effects on both groups were observed and compared after two therapeutic courses of 40 consecutive days. As a result, 39 cases were cured, 60 cases improved and 19 cases failed, with a total effective rate of 84% in the treatment group. In the control group, 15 cases were cured, 37 cases improved and 34 cases failed, with a total effective rate of 60.5%. Statistically, the difference was very significant ($P<0.01$). It can be concluded that treatment of UC by the integrated method is superior to that by simple Western drugs^[40].

Treatment of chronic UC by traditional Chinese and Western medicine is safe and effective in maintaining remission^[41-44].

Abstract

AIM: In order to elucidate the molecular mechanism of lymphatic metastasis of hepatocarcinoma, we detected the difference of gene expression between mouse hepatocarcinoma cell lines Hca-F and Hca-P with different lymphatic metastasis potential.

METHODS: cDNA of Hca-F cells was used as a tester and cDNA of Hca-P cells was used as a driver. cDNAs highly expressed in Hca-F cells were isolated by the suppression subtractive hybridization (SSH) method. The isolated cDNA was cloned into T/A cloning vector. The ligation products were transformed into DH5 α competent cells. Individual clones were randomly selected and used for PCR amplification. Vector DNA from positive clones was isolated for sequencing.

RESULTS: There were 800 positive clones in amplified subtracted cDNA library. Random analysis of 160 clones with PCR showed that 95% of the clones contained 100-700 bp inserts. Analysis of 20 sequenced cDNA clones randomly picked from the SSH library revealed 4 known genes (mouse heat shock protein 84 ku, DNA helicase, ribosomal protein S13, ethanol induced 6 gene) and 3 expressed sequence tags (ESTs). Four cDNAs showed no homology and presumably represent novel genes.

CONCLUSION: A subtracted cDNA library of differentially expressed genes in mouse hepatocarcinoma cell lines with different lymphatic metastasis potential was successfully constructed with SSH and T/A cloning techniques. The library is efficient and lays a solid foundation for searching new lymphatic metastasis related genes. The expression of mouse heat shock protein gene, DNA helicase and other 4 novel gene may be different between mouse hepatocarcinoma cell lines with different lymphatic metastasis potential.

INTRODUCTION

Metastasis is the most lethal attribute of malignant tumors^[1].

Ninety percent of malignant tumors are carcinomas, and lymph nodes are often the first organ to develop metastasis^[2]. Lymph node metastases form a bridgehead for further metastatic spread. But its molecular mechanism remains poorly understood. A mouse hepatocarcinoma cell line named Hca-F with high lymphogenous metastatic potential and its syngeneic cell line named Hca-P^[3] with low lymphogenous metastatic potential have been isolated from hepatocarcinomas in mice. The biological phenotypes between different cells are based on the difference between their phenotypes of gene expression. In this study, we constructed a subtracted cDNA library of differentially expressed genes in these two hepatocarcinoma cell lines using the suppressive subtractive hybridization (SSH)^[4-6], which can detect the difference in gene expression between different cells.

MATERIALS AND METHODS

Animals and cell lines

Hepatocarcinoma cell lines, Hca-F and Hca-P, were obtained from our department. Twenty inbred 615-mice maintained in our laboratory were equally divided into 2 groups. Hca-F and Hca-P cells (2×10^6 cells/mouse) were respectively inoculated in 10 mice in each group. On the 28th day post inoculation, the mice were killed and their lymph nodes were collected and stained by HE and examined under microscope. Therefore, the lymph node metastasis rate was calculated.

Isolation of RNA and mRNA

Total RNA was isolated from Hca-F and Hca-P cells (10^8 cells) respectively using Trizol reagent (Gibco BRL, USA). And mRNA was isolated from total RNA using the OligotexTM mRNA kit (Qiagen, USA) according to its manufacturer's instructions. The integrity of RNA and mRNA was checked on a 1% agarose gel.

Suppression subtractive hybridization (SSH)

Analysis of differentially expressed genes in Hca-F and Hca-P cells was performed by the suppression subtractive hybridization (SSH) using the CLONTECH PCR-SelectTM cDNA subtraction kit (Clontech, USA). In brief^[7,8], 2 μ g of mRNA from Hca-F and Hca-P cells was used for double strand cDNA synthesis, and the resulting cDNA was digested with Rsa I. The digested cDNA of Hca-F cells (as a Tester) was split into two groups and ligated to either adaptor I or adaptor 2R. Subtractive hybridization was performed by annealing an excess of Hca-P cDNAs (as a Driver) with each sample of adaptor ligated tester cDNAs. The cDNAs were heat denatured and incubated at 68°C for 8 h. After the first hybridization, the two samples were mixed together and hybridized again with freshly denatured driver cDNAs for 20 h at 68°C. The two rounds of hybridization would generate a normalized population of tester specific cDNA with different adaptors on each end. After filling in the end, two rounds of PCR amplification were performed to enrich desired cDNAs containing both adaptors by exponential amplification of these products. The optimized cycles for the first and second PCR were 30 and 20, respectively, to increase representation and reduce redundancy of subtracted cDNA libraries. Secondary PCR products were used as templates for

PCR amplification of G3PDH at 20, 25, 30, 35 cycles to assure subtracted efficiency.

Cloning of subtracted cDNA libraries

Products from the secondary PCR were T-A cloned into a T vector (Takara, China). The ligation products were transformed into DH5 α competent cells. The transformed cells were plated on LB plates containing ampicillin, X-Gal and IPTG, which allowed for color selection of colonies. Randomly selected individual white clones were grown for 8 h and then used for PCR amplification of clones.

Sequencing and BLAST homology search

Twenty candidate positive clones from subtracted cDNA library were selected for sequencing. Sequencing was performed by Takara Biotech using a M13 primer. The BLAST program was used to search for the cDNA sequence homology of isolated clones in GeneBank.

RESULTS

The analysis of integrity of RNA and mRNA

The A_{260}/A_{280} of RNA and mRNA from Hca-F and Hca-P was 1.9, which showed extracted RNA and mRNA were pure. Agarose gel electrophoresis showed that RNA was not destroyed by ribonucleases (Figure 1).

Figure 1 Total RNA from Hca-F and Hca-P cells. Lane 1: RNA from Hca-F cells, Lane 2: RNA from Hca-P cells.

Rsa I digestion

The size of digested cDNA molecular was smaller than undigested in agarose gel electrophoresis, indicating that tester cDNA and driver cDNA were completely digested.

Subtracted cDNA library construction by SSH

In this study, SSH was performed to identify differentially expressed genes among cDNAs of hepatocarcinoma cell lines, Hca-F and Hca-P. One subtracted F-P cDNA library was constructed using Hca-F with high lymphogenous metastatic potential as a tester and its syngeneic cell line named Hca-P with low lymphogenous metastatic potential as a driver. The subtracted cDNA library after secondary PCR amplification looked like smears (Figure 2).

Subtraction efficiency analysis showed that the abundance of non-differentially expressed genes was effectively reduced. In no subtracted cDNA library, the PCR products of housekeeping gene G3PDH were visible after 25 cycles. However, 35 cycles were required in the subtracted cDNA library for G3PDH to be detected (Figure 3).

The subtraction cDNA library contained 800 positive (white) clones. Random analysis of 160 clones with PCR showed that 95% of positive clones contained 100-700 bp inserts (Figure 4).

Figure 2 Results of secondary PCR amplification. Lanes 1-3: Product of primary PCR amplification, Lane 4: Secondary PCR amplification product of PCR control cDNA, Lane 5: Secondary PCR amplification product of unsubtracted cDNA, Lane 6: Secondary PCR amplification product of subtracted cDNA.

Figure 3 Analysis of subtraction effect. PCR was performed on subtracted (Lanes 1-4) or unsubtracted (Lanes 5-8) secondary PCR product with G3PDH 5'-Primer and 3'-primer. Lanes 1, 5: 20 cycles, Lanes 2, 6: 25 cycles, Lanes 3, 7: 30 cycles, Lanes 4, 8: 35 cycles.

Figure 5 Sequence of clone 10-3.

Sequencing and homology search

Automatic sequencing proved that most clones were isolated no more than two times (Figures 5-7). BLAST homology search revealed that some sequences were homologous with known gene fragments and others were possibly novel genes, showing few sequence homologies with any known sequences in the GenBank. The results of homology search are shown in Table 1.

Figure 6 Gene structure of clone 10-3. Both nested primer 1 and nested primer 2R in the cDNA sequence were contained in subtracted library, indicating that only cDNA with both 2 adaptors could be amplified by PCR.

Table 1 Homologue searching of sequenced cDNA fragments from SSH library

Clone number	Size(bp)	Sequence identity
10-3	508	Mus musculus heat shock protein, 84 ku 1 (Hsp84-1)
2-2	385	Mus musculus ribosomal protein S13 (Rps13)
6-2	323	Mouse mRNA for DNA helicase
18-4	226	Mouse, similar to ethanol induced 6, clone MGG51351
11-7	363	Mouse 10 d embryo whole body cDNA, RIKEN full-length enrich library, clone 2610102k11
16-3	403	Mouse 2 d neonate thymus thymic cells cDNA RIKEN full-length library enriched library, clone E430002F13
7-1	570	Mouse chromosome 2 clone RP 24-322M5
15-7	460	Mouse chromosome 12 clone RP23-210N16
1-8	200	EST-mouse

16-8	240	Unknown

Analysis of metastasis rate of Hca-F and Hca-P cells

The lymphatic metastasis rate was 80% (8/10) and 10% (1/10), respectively, for Hca-F cells and Hca-P cells.

DISCUSSION

Cancer is the most important cause of death of humans. There is no technique that can selectively kill cancer cells. A wide range of Metastasis leads to the failure of treatment and the death of patients. Therefore, investigation of cancer metastasis, particular the mechanisms, is important in order to improve the efficacy of the treatment. Metastasis^[9] is a complex process, which is made up of several steps. However, the molecular mechanism of lymphatic metastasis remains poorly understood because of lack of lymphatic metastasis models. A mouse hepatocarcinoma cell line named Hca-F with a metastasis rate over 70% and its syngeneic cell line named Hca-P with a metastasis rate less than 30% have been separated from hepatocarcinomas in mice. The difference in their metastasis potential might be based on the difference in their phenotypes of gene expression. Many different techniques could be used to isolate differentially expressed genes, such as expressed sequencing tag (EST)^[10], serial analysis of gene expression (SAGE)^[11], subtractive hybridization, mRNA differential display (DD-RT-PCR)^[12], cDNA representative difference analysis (RDA)^[13], suppression subtractive hybridization (SSH), and cDNA microarray^[14].

The novel technique named SSH^[15-18] has become an ideal subtractive system that combines high subtraction efficiency with normalized representation of differentially expressed genes, and is based on suppression PCR that permits exponential amplification of genes differing in abundance, but suppresses the amplification of sequences of identical abundance genes in two cells at the same time. Therefore, differentially expressed genes of low abundance can be cloned, while differentially expressed genes of high abundance are not excessively isolated. It has been reported that SSH can achieve more than 1 000-fold enrichment of low abundance genes, but only requires 2 µg mRNA instead of the 5-20 µg required in other methods. This method has been successfully used to isolate significant genes in many researches^[19-23]. Von Stein *et al.* observed a 94% positive rate in their study, and suggested that confirmation of differential expression by Northern blot analysis for each clone obtained was unnecessary^[24].

In the present study, we reported the efficiency of SSH

Figure 7 Result of clone 10-3 sequencing.

technique in identifying differentially expressed genes in Hca-F and Hca-P. PCR analysis showed that the subtraction efficiency after subtractive hybridization was effectively reduced. We constructed a subtracted cDNA library between Hca-F cells and Hca-P cells. There were 800 positive clones in the amplified subtracted cDNA library. Random analysis of 160 clones with PCR showed that 95% of clones contained 100-700 bp inserts. After sequencing and BLAST homology search, these clones could be divided into three groups: known genes preciously reported to be related to metastasis and carcinogenesis, known genes never described to be related to metastasis and carcinogenesis, and unknown genes. The identification of the first group of known genes attested to the validity of this method. The library is efficient and lays a solid foundation for searching new lymphatic metastasis related genes.

The No. 10-3 clone obtained in the present study showed homology with mouse heat shock proteins (HSPs). HSPs^[25-27] have been found to be ubiquitous molecules expressed in response to stress in all living organisms. The three important roles^[28] in regard to cancer development are regulation of apoptosis, modulation of immune response and drug resistance. HSPs are cytoplasmic proteins that could act as molecular chaperones for protein molecules in various intra-cellular processes^[29,30]. They are called "heat shock proteins" since they were first discovered in cells exposed to high temperatures. HSPs were also expressed in hepatocarcinoma (HCC)^[31-34], and up-regulated in early stage of HCC compared with noncancerous liver tissue. King *et al.*^[33] reported that HSPs expressed in HCC (45/58), and its expression was stronger in HCC than in noncancerous liver tissue. HSPs were related to metastasis^[35-38]. HSP expression was found in 54 out of 86 (62.7%) gastric carcinomas and was significantly related to more than six metastatic lymph nodes^[35]. Over expression of HSPs was related to tumor configuration, lymph node metastasis, and lymphatic vessel invasion in esophageal squamous cell carcinoma^[36]. So far, there has no report concerning HSP expression and lymphatic metastasis of HCC. In the present study, we found that HSP expression was different between mouse HCC cell lines Hca-F and Hca-P, indicating that HSP expression might be related to HCC metastasis.

The No. 6-2 clone obtained showed homology with mouse helicase. It has been found that DNA helicases^[39-41], because they unwound duplex DNA, have important roles in cellular DNA events such as replication, recombination, repair and transcription. The change in helicases expression could be found in human carcinomas^[42], lymphoma^[43], leukemia and so on. Helicases were also related to metastasis^[44]. B16-F10 and B16-BL6 are B16 mouse melanoma sublines that preferentially metastasize to the lung and their metastasis potential is different. Helicases and ribosomal protein (L37) showed higher expression in B16-BL6 cells than in B16-F10 cells^[45]. There has been no report on the association between helicase up-regulation and HCC metastasis. Thus, further investigations are required to elucidate the role of helicase in HCC metastasis.

Besides, two clones obtained in the present study showed homology to mouse ribosomal protein S13 and ethanol induced 6 gene. To our knowledge, there have been no reports on their relation to metastasis. Whether ribosomal protein S13 and ethanol induced 6 gene can be considered as candidate gene of metastasis related gene remains unclear. Clone 11-7 showed homology with mouse of 10-d embryo whole body cDNA library clone 2610102k11. It is important to study the correlation between metastasis and embryo gene expression. Clone 7-1 showed homology with mouse chromosome 2 clone RP 24-322M5 and clone 15-7 showed homology with mouse chromosome 12 clones RP23-210N16. Whether there are candidate metastasis-related genes on chromosome 2 and

chromosome 12 needs further investigation. The other three clones showed homology with three EST sequence.

In addition to the known genes, four clones showed no homology with any known sequences, indicating that they were novel genes, although the full-length sequence of these new genes and their function in lymphatic metastasis remain to be determined.

In conclusion, differentially expressed genes in mouse hepatocarcinoma cell lines with different lymphatic metastasis potential can be isolated by SSH method. Comprehensive study of these genes can help understand the molecular mechanism of lymphatic metastasis.

Abstract

AIM: Cyclooxygenase-2 (COX-2) is one of the rate-limiting enzymes in metabolism of arachidonic acid, and COX-2 inhibitors demonstrate preventive effects on cancer, especially on colorectal cancer. The underlying mechanism remains unclear. The aim of this study was to illustrate the relationship between angiogenesis and COX-2 in carcinogenesis of colorectal cancer.

METHODS: One hundred and seventy patients with colorectal cancer were enrolled in our study from January 1993 to September 2001 in School of Oncology, Peking University. COX-2 and VEGF expression were detected with the immunohistochemistry (IHC) technique. IHC assays were carried out with the aid of tissue microarray (TMA) procedure. Specimens from 35 of these patients were examined with reverse transcriptase PCR (RT-PCR).

RESULTS: COX-2 and VEGF expressions were stronger in colorectal cancer than those in the corresponding normal tissues, at both protein and mRNA levels. One hundred patients were eligible for analysis after IHC assay of COX-2 and VEGF. The positive rate of VEGF was much higher in COX-2 positive group (47/85) than in COX-2 negative group ($\chi^2 = 4.181$, $P = 0.041$). The result was further verified by the result of RT-PCR ($\chi^2 = 8.517$, $P = 0.003$). Correlation coefficient was 0.409 after Spearman correlation analysis ($P = 0.015$).

CONCLUSION: COX-2 may be involved in the course of tumor angiogenesis of colorectal cancer and acts through VEGF.

INTRODUCTION

Cyclooxygenase (COX) is one of the rate-limiting enzymes in metabolism of arachidonic acid, which catalyzes arachidonic acid into a series of products such as prostaglandins and other eicosanoids. It has two isoforms, COX-1 and COX-2. COX-2 acts as superoxidants and transforms arachidonic acid into

PGG₂, and then into PGH₂. COX-2 is inducibly expressed in many human tissues by cytokines, oncogenes, and tumor promoters^[1-3]. Recent clinical epidemiological studies have demonstrated the preventive effect of COX inhibitors on cancer, especially on colorectal cancer^[4-6]. Cellular and animal experimental studies have also indicated its relevance to tumor invasion, metastasis, cell apoptosis, cell cycle, and body immunity^[7], and the role of COX-2 in the development of colorectal cancer.

Angiogenesis is among the most important characteristics of tumors and plays an important role in the course of cancer invasion and metastasis. Recent studies have confirmed the hypothesis of tumor growth, which is generally dependent on tumor angiogenesis. Any significant increase in tumor mass must be preceded by an increase in vascular supply to deliver nutrients and oxygen to the tumor^[8]. Experimental studies from Seed and Tsujii^[9,10] suggested that COX-2 might be involved in angiogenesis. Few reports on the role of COX-2 in tumor angiogenesis of colorectal cancer in clinical settings are available.

MATERIALS AND METHODS

Patients and tissues

A total of 170 patients after surgical treatment in School of Oncology, Peking University, from January 1993 to September 2001 were studied retrospectively. Specimens from these patients were prepared as tissue microarray and then underwent immunohistochemical assays. Specimens from thirty-five patients were prepared for reverse transcriptase PCR (RT-PCR), including 22 male patients and 13 female patients.

Tissue array preparation and immunohistochemical staining

Formalin-fixed and paraffin-embedded tissues were subjected to routine sectioning of 3-5 μ m thickness and HE staining. Tissue array block was completed for subsequent sectioning according to the predetermined scheme described before^[11]. Two-step immunohistochemical staining was used for COX-2 and VEGF detection. The titer of COX-2 (Cayman Chemical, USA) and VEGF (Zhongshan Biological Inc., Beijing, China) antibody were 1:200 and 1:50 respectively. Human colon adenocarcinoma with strong COX-2 staining served as a positive control, whereas PBS instead of antibody served as a negative control. Two pathologists independently reviewed slides with immunohistochemical staining. Microscopically, the slides with no staining in the negative control and the specific dark yellow staining of cytoplasm and nuclear membrane in the positive control were eligible for a further analysis. Semiquantitative scoring system was adopted according to the staining intensity: 0 for no staining, 1 for weak yellow, 2 for dark yellow, and 3 for brown staining with granular distributions. The mean score was used for statistical analysis and the threshold for positivity was 2^[11].

Specimen preparation and RT-PCR

Tumor tissues and the corresponding normal mucosae at least 10 cm away were collected 30 min after removal of the specimens. The tissues were then stored under -70 °C for RNA extraction. Total RNA was prepared from the specimens with Trizol reagent

(Gibco BRL Co.) according to the manufacturer's instructions. cDNA synthesis was carried out with 1 µg of total RNA. Sense and antisense primers of 0.5 µL were mixed with 11 µL dd H₂O, 5 µL PCR buffer, 3 µL MgCl₂ (25 mmol/L), 2 µL dNTP (10 mmol/L), 2 µL cDNA, and 0.8 µL Taq DNA polymerase for PCR. The primers for PCR were 5' TTC AAA TGA GAT TGT GGG AAA AT 3' (sense primer) and 5' AGA TCA TCT CTG CCT GAG TAT CTT 3' (antisense primer). PCR reactions were processed in a PTC 100 thermocycler under the following conditions: at 94 °C for 5 min, at 94 °C for 30 s, extension at 55 °C for 30 s, then at 72 °C for 30 s for 40 cycles, and then at 72 °C for 5 min. The RT-PCR products were then analyzed on 1.5% agarose gels. Colon cancer cell line HT-29 and β-actin served as a positive and inner control, respectively. PCR reactions without cDNA were used as blank controls.

Statistical analysis

All statistical analyses were carried out with the SPSS software, 10.0, USA. The relationship between COX-2 expression and categorical variables was compared with χ^2 test or Fisher two-sided exact test. Continuous variables were analyzed with *t* test and *P* < 0.05 was considered statistically significant. Correlation analysis was processed via the Spearman method.

RESULTS

Expression of COX-2 protein in colorectal cancer tissues

Of the 170 colorectal cancer patients, 139 were eligible for analysis after COX-2 immunohistochemical assays. Immunohistochemical assays demonstrated that COX-2 protein was located in cytoplasm and nuclear membrane. The staining was weak yellow, dark yellow, and brown at a low-power field and diffuse or granular staining at a high-power field under a microscope (Figure 1A). A weak staining of COX-2 was observed in normal tissue with a positive rate of 24.1% (7/29). COX-2 expression was much stronger in tumor cells with dark yellow or brown staining with occasional granular distributions than in normal tissues. The positive rate of COX-2 in colorectal cancer was 84.9% (118/139).

Figure 1 COX-2 and VEGF expressions in colorectal cancer tissues (IHC assay). A: Well-differentiated colonic adenocarcinoma, COX-2 immunostaining, ×100. B: Well-differentiated colonic adenocarcinoma, VEGF immunostaining, ×100.

Expression of VEGF protein in colorectal cancer tissues

For some reasons, only 100 colorectal cancer patients were eligible for further analysis after immunohistochemical assays. VEGF protein was located in cytoplasm of tumor cells and endothelial cells (Figure 1B). About 51.0% (51/100) of the tumors presented with strong VEGF staining, and the rate was much higher than that of normal tissues.

Expression of COX-2 and VEGF mRNA in colorectal cancer tissues

In consistent with the results of IHC assay, RT-PCR revealed stronger expressions of COX-2 and VEGF in tumors than in corresponding normal tissues (Figure 2). Among the 35 paired specimens of colorectal cancer tissues undergoing RT-PCR assays, 27 (77.1%) and 28 (80.0%) were positive with VEGF and COX-2, respectively, compared with 9 (25.7%) and 11 (31.4%) in normal tissues (*P* < 0.01).

Figure 2 COX-2 and VEGF expressions in colorectal cancer tissues (RT-PCR assay). N: normal T: tumor IC: internal control M: marker. The Arabic number represents the number of samples. The marker has six lanes from 100 bp to 600 bp. The left four lanes stand for the 304 bp products of COX-2 while the right two lanes are the VEGF products of 541 and 408 bp respectively. The internal control of β-actin produced a 496 bp product.

Correlation between COX-2 and VEGF expression in colorectal cancer tissues

For the reason of TMA, a total of 100 cases were eligible for IHC analysis. Among these, 47 COX-2 positive cases presented with a positive VEGF staining (55.3%). The positive rate of VEGF was much higher than that in COX-2 negative group (26.7%). The difference between two groups had a statistical significance ($\chi^2 = 4.181$, *P* = 0.041). Among the 27 cases with COX-2 mRNA expression, 25 had a strong VEGF expression while only 2 in COX-2 negative group ($\chi^2 = 8.517$, *P* = 0.003) (Table 1). COX-2 and VEGF expression demonstrated a tendency to having a positive correlation with correlation coefficient of 0.409 (*P* = 0.015).

Table 1 Expression of COX-2 and VEGF in colorectal cancer tissue (RT-PCR/IHC)¹

VEGF expression	COX-2 positive	COX-2 negative	Total
Positive	25 / 47	2 / 4	27 / 51
Negative	3 / 38	5 / 11	8 / 49
Total	28 / 85	7 / 15	35 / 100

¹Fisher double-side exact test (*P* = 0.003/0.041).

DISCUSSION

It has been documented that COX-2 plays an important role in the development of human tumors^[12-16]. COX-2 could promote the growth and invasion of tumors^[17,18] and increase invasiveness and potential of tumor metastasis^[19,20]. Recent research results indicated that COX-2 could also induce tumor angiogenesis and was correlated with hematogenous metastasis of tumors^[10,21].

Tumor angiogenesis is one of the important characteristics of tumors involving their growth and metastasis. The formation of primary or metastatic lesions and even their further development are dependent on tumor angiogenesis. Newly-formed vessels were in need of nutrition and oxygen when the tumor grew to 2-3 mm in size^[8].

It had been found many factors are involved in tumor angiogenesis including bFGF, aFGF, PGE₁, PGE₂, VEGF, TGF α , TGF β , and TNF^[22]. The most important is vessel endothelial growth factor (VEGF), a highly specific mitogen of vessel endothelial cells. The biological functions of VEGF included selective promotion of mitosis of endothelial cells, stimulation of their proliferation and angiogenesis, an increase in vessel transparency and extravasculization of plasma large molecules^[23-26]. It was reported that COX-2 might interact with VEGF^[27,28]. Therefore, the relationship of COX-2 and angiogenesis (VEGF as the marker of angiogenesis) was then investigated at protein and mRNA levels.

The positive rate of COX-2 mRNA and COX-2 protein were 80% (28/35) and 84.9% in colorectal cancer. Both were much higher than those in normal tissues ($P < 0.01$), which indicated the role of COX-2 in carcinogenesis of colorectal cancer. The expressions of COX-2 and VEGF were studied through RT-PCR and IHC assays. The result of RT-PCR showed that 25 were VEGF positive among the 28 COX-2 positive patients, and only 2 were VEGF positive in the COX-2 negative group. Correspondingly, of the 85 patients with COX-2 positive staining, 47 (55.3%) expressed VEGF while only 26.7% in the COX-2 negative group, indicating the correlation between the expressions of COX-2 and VEGF, which was further verified by the Spearman correlation analysis. Cianchi^[28] recently found a close correlation between COX-2 and VEGF as well as microvessel density (MVD) in their studies on 31 colorectal cancer patients by Western blot and Northern blot analysis, and immunohistochemical assays, which was consistent with our results.

The mechanism underlying the role of COX-2 in tumor angiogenesis has been unclear^[29]. Preliminary results showed that angiogenesis occurred when endothelial cells were cultured with cancer cells over-expressing COX-2^[10]. It could be inhibited by selective COX-2 inhibitors in endothelial cells *in vitro*^[29]. It was proved that the activity of COX-2 in interstitial cells was necessary for secretion of VEGF, proliferation of endothelial cells and new vessel formation^[30]. These experimental results suggested that such metabolic products might induce the expression of VEGF via pathways of paracrine, autocrine or intracrine, and stimulate proliferation of vessel endothelial cells and formation of tumor vessels^[29].

The regulatory effect of COX-2 on VEGF production and tumor angiogenesis suggested that COX-2 expression might be an upstream event in tumor angiogenesis^[10,29]. We also found that COX-2 expression was positively correlated with expression of VEGF, one of the most important factors for tumor angiogenesis. The expression rate of VEGF was high in patients with positive COX-2 expression (25/28) while low in COX-2 negative patients (2/7). In addition, staining intensity of COX-2 was correlated with that of VEGF. Management of the murine animal model of lung and prostate cancers with the gene knockout technique or COX-2 inhibitor resulted in not only tumor shrinkage but also inhibition of tumor angiogenesis. Endothelial cells were scattered without formation of an ordered tubular structure. The MVD of tumor and expression of VEGF were significantly decreased, further suggesting the role of COX-2 on VEGF expression and tumor angiogenesis^[31,32].

Great progresses have been made in the research of tumor angiogenesis. Trials on targeted therapy against angiogenesis have been ongoing to block or postpone tumor angiogenesis so as to cure cancer^[33,34]. More than twenty drugs are in their

phase I or II and even III clinical trials in the United States of America. Though preliminary results were promising, there is still a long way to go. Therefore, as an upper-stream event, COX-2 might be a potential target of the cancer gene therapy worthy of further research.

Abstract

AIM: To find new serum biomarkers for liver cirrhosis (LC) in chronic carriers of hepatitis B virus (HBV).

METHODS: Surface enhanced laser desorption/ionization time-of-flight (SELDI-TOF) mass spectrometry was used to discover biomarkers for differentiating HBV induced LC from non-cirrhotic cohorts. A training population of 25 patients with HBV-induced LC, 20 patients with HCC, and 25 closely age-matched healthy men, was studied.

RESULTS: Two biomarkers with M_r 7 772 and 3 933 were detected in sera of non-cirrhotic cohorts, but not in patients with HBV-induced LC. A sensitivity of 80% for all LC patients, a specificity of 81.8% for all non-cirrhotic cohorts and a positive predictive value of 75% for the study population were obtained.

CONCLUSION: These two serum biomarkers for HBV-induced LC might be used for diagnosis and assessment of disease progression.

INTRODUCTION

Liver cirrhosis (LC), the end-stage of liver fibrosis, is generally irreversible. Patients with LC caused by chronic infection of HBV are at high risks of hepatocellular carcinoma and high death rate^[1,2]. Although some serum assays are on the way to differentiate chronic HBV infection or LC from HCC, pretreatment liver biopsy has been considered as the "gold standard" for assessing the grade of liver injury and stage of liver fibrosis. Clinicians relying on liver biopsy are able to correctly diagnose the stage of fibrosis or presence of cirrhosis in 80% patients^[3]. However, liver biopsy can be associated with significant expense, manpower issues, and risk of patient

injury. As a result, we still need to identify noninvasive tests that could replace liver biopsy.

Protein profiles might reflect the pathological state of HBV infection. The relationship between protein profile and disease progression could be achieved by analyzing the complex serum proteomic patterns^[4,5]. We used a protein biochip surface-enhanced laser desorption/ionization time-of-flight (SELDI-TOF) mass spectrometry coupled with an artificial intelligence learning algorithm to differentiate HBV induced LC from non-cirrhotic cohorts. A blinded test was used to determine the sensitivity and specificity of the established pattern.

MATERIALS AND METHODS

Samples

Of the 107 serum samples selected, 40 were from patients with HBV-induced LC and 30 from patients with HCC from You'an Hospital, Beijing, China, 37 from healthy men provided by Center of Cancer Prevention and Treatment, Zhongshan University, China. All HBV infected patients with LC were examined by ELISA and were HBeAg positive in serum. The final diagnoses were pathologically confirmed and specimens were obtained before treatment. All samples were fresh and stored at -70 °C and closely age-matched.

Protein chip array analysis

Three different chip chemistries (cationic, anionic, and Cu metal binding, CIPHERGEN Biosystems, Inc, Fremont, CA) were tested to determine which provided the best serum profiles in terms of number and resolution of protein peaks. It showed that WCX2 weak cationic chip gave the best result. A total of 10 µL of each sample was diluted into 20 µL with U9 buffer (1×PBS, 9 mol/L urea, 1% CHAPS) and mixed. The mixing step was repeated several times on ice for a total of 30 min. An eight-spot WCX chip was washed with 50 mmol/L sodium acetate (pH 4.0) twice. Then sodium acetate buffer was added to U9-treated sample to make a further 1:13 dilution. The diluted serum mixture (100 µL) was applied to a protein chip array and incubated for 1 h on a shaker. After washing with the same sodium acetate buffer three times followed by a quick water rinse, 0.5 µL of saturated sinapinic acid (SPA) solution was applied onto each spot and allowed to air-dry. Then chips were performed on Protein Biological System II(c) mass spectrometer reader (PBSII, CIPHERGEN Biosystems, Inc).

Bioinformatics and biostatistics

Classification model was built up with Biomarker Pattern's Software (BPS, CIPHERGEN Biosystems, Inc). Training data set consisted of 70 serum samples (25 from patients with LC, 20 from patients with liver cancer, and 25 from healthy individuals). A classification tree was set up to divide the data set into two bins based on the intensities of peaks. At each bin a peak intensity threshold was set. If the peak intensity of a sample was lower than or equal to the threshold, this sample would go to the left-side bin. Otherwise, the sample would go to the right-side bin. The process would go on until a blind sample entered a final bin, either labeled at Con (control sample) or LC (LC serum). Peaks selected by the process to form the model

were the ones that yielded the least classification error when they were combined to use.

Data set from double-blind trials consisted of 37 serum samples (15 from patients with LC, 10 from patients with liver cancer, and 12 from healthy individuals) and was used to test the model.

Specificity and sensitivity were respectively calculated as the proportion of the number of non-cirrhotic samples correctly identified to the total number of non-cirrhotic samples. Positive predictive value gives the probability of disease if a test result is positive.

RESULTS

Evaluation of SELDI protein chip

As various chip array chemistries provided different serum protein profiles in terms of number and resolution of protein peaks, WCX2, SAX2 and IMAC3-Cu metal binding chip arrays were tested, respectively. WCX2 binding chip was observed to give the best results. To demonstrate the reproducibility of the mass spectra, 8 independently obtained spectra of a serum sample of a healthy man were performed by between-run assay. We calculated that the coefficient of variance for seven selected M/Z peaks whose relative intensities were above 25 with the highest amplitude <10%. As shown in Figure 1, serum spectra from patients and healthy men do not show large variations. Therefore, small variations between different sample groups could be used for biomarker discovery. SELDI-TOF spectra of randomly selected serum samples of patients with HBV induced LC, patients with HCC, and healthy individuals are shown in Figures 1 and 2. Two proteins of M_r 7 772 and 3 933 were down-regulated in LC or up-regulated in non-cirrhotic group (healthy/HCC).

Figure 1 SELDI-TOF mass spectra. Spectra 1-4 from HBV-induced LC patients, 5-8 from healthy men, and 9-12 from HCC patients. A biomarker of M_r 7 772 was present in non-cirrhotic group, but not in LC serum samples.

Data analysis

Peak labeling was performed with Biomarker Wizard of Ciphergen ProteinChip software 3.1.1. The peak intensities were then transferred to Biomarker Pattern's software. Totally 35 peaks from M_r 2 000 to 30 000 were selected to construct the classification model. Figure 3 shows the tree structure and sample distribution. Two peaks, M_r 7 772 and 3 933, were chosen to set up the decision tree, respectively. At Node 1, samples of M_r 7 772 with peak intensities lower than or equal to 7.514 went

to Terminal Node 1, which had 9 control samples and 21 LC samples. Otherwise, samples entered Node 2, which had 40 samples. At Node 2, samples of M_r 3 933 with peak intensities lower than or equal to 8.217 went to Terminal Node 2, which had 1 control sample and 3 LC samples. The other samples entered Terminal Node 3, which had 35 control samples and 1 LC sample. The model identified 70 samples, 36 in control and 34 in LC, and yielded a sensitivity of 96% and specificity of 77.8%. When the double-blind sample data set was used to challenge the model, the model predicted a sensitivity of 80% and specificity of 81.8%. The positive predictive value was 75%.

Figure 2 SELDI-TOF mass spectra. Spectra 1-4 from HBV-induced LC patients, 5-8 from healthy men, and 9-12 from HCC patients. A biomarker of M_r 3 933 was present in non-cirrhotic group, but not in LC serum samples.

Figure 3 Tree structure and sample distribution. The root node and descendant nodes are indicated in gray, and the terminal nodes are shown in black. Peaks with M_r 7 772 and 3 933 were chosen to set up the decision tree.

DISCUSSION

HBV infection often leads to a prolonged active viral replication, HBV DNA integration and eventually LC^[6]. About 55-85% of LC patients will develop hepatocellular carcinoma, which always has bad prognosis. It is estimated that HCC may be responsible for more than 1 million deaths annually and it is the fifth most frequent cause of cancer death worldwide^[7]. Liver biopsy has remained the gold standard for identification of patients with liver diseases. However, the differential diagnosis between HCC

and LC is sometimes difficult and new biochemical markers for HCC are required. In recent years, several non-invasive serum biomarkers have been considered to diagnose LC associated with HBV, including hyaluronic acid (HA)^[8,9], type III procollagen peptide, laminin and type IV collagen^[10].

Among the non-invasive serum biomarkers for liver fibrosis and cirrhosis, HA was reported to be the best marker for diagnosis^[11]. HA with a molecular mass of several million is present in most tissues as a component of the extracellular matrix. Elevated levels of serum HA have been reported in various diseases including liver diseases. Increases in serum HA correspond to the progression of liver diseases, including viral and non-viral diseases. Ding *et al.* demonstrated that the elevated serum HA levels were closely related to the severity of liver fibrosis, particularly in LC^[12]. In addition, Procollagen III peptide, laminin, and type IV collagen with molecular masses of 45 000, 400 000 and 67 000, respectively, are also extracellular matrix glycoproteins and have been reported to be correlated to necrosis and inflammation as well as fibrosis in patients with chronic hepatitis and LC^[13]. However, the diagnostic value, i.e. sensitivity and specificity, of these markers for patients with cirrhosis has not been satisfactory so far. Use of multiple markers led to 90% sensitivity at most in diagnosing cirrhosis, but variable specificity was about 60%^[14].

SELDI-TOF mass spectrometry is a recently described affinity-based mass spectrometric method that combines chromatography and mass spectrometry. This novel technology has been used for protein or peptide biomarker identification, biomolecular interactions and post-translational modifications. Protein chip technology has proven to be useful in the discovery of potential diagnostic markers for prostate^[15-17], bladder^[18], ovarian^[19], breast^[20-22], lung cancers^[23], and pancreatic ductal adenocarcinoma. However, using it to discover new biomarkers of HBV induced diseases has not been addressed before. To identify potential biomarkers that can detect HBV induced LC, protein profiles of serum samples from LC patients were compared with those from the non-cirrhotic controls. Biomarker Pattern's Software was used to identify two peaks differentially presented in control healthy and HCC serum samples compared with LC samples. The top-scored two peaks with M_r 7 772 and 3 933 were finally selected. These two proteins generated a sensitivity of 96% and specificity of 77.8%. It is difficult to find a good single marker associated with diseases because of the differences among patients' age, gender, diet and genes. Furthermore, double-blind test was used to determine the sensitivity and specificity of the model. A sensitivity of 80%, specificity of 81.8% and positive predictive value of 75% for the study population were obtained when comparing LC versus non-cirrhotic (HCC/healthy men) groups. The low-molecular-mass serum proteins are apparently different from known non-invasive serum biomarkers for LC in many aspects and might be acceptable for diagnosis and assessment of HBV associated LC.

Abstract

AIM: To investigate the effect of interleukin-12 *p40* gene (*IL12B*) 3'-untranslated region polymorphism on the outcome of HCV infection.

METHODS: A total of 133 patients who had been infected with HCV for 12-25 (18.2±3.8) years, were enrolled in this study. Liver biochemical tests were performed with an automated analyzer and HCV RNA was detected by fluorogenic quantitative polymerase chain reaction. B-mode ultrasound was used for liver examination. Polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) was used for the detection of *IL12B* (1188A/C) polymorphism.

RESULTS: Self-limited infection was associated with AC genotype (OR = 3.48; *P* = 0.001) and persistent infection was associated with AA genotype (OR = 0.34; *P* = 0.014) at site 1188 of *IL12B*. In patients with persistent HCV infection, no significant differences were found regarding the age, gender, duration of infection and biochemical characteristics (*P* > 0.05). According to B-mode ultrasound imaging and clinical diagnosis, patients with persistent infection were divided into groups based on the severity of infection. No significant differences were found in the frequency of IL-12 genotype (1188A/C) between different groups (*P* > 0.05).

CONCLUSION: The polymorphism of *IL12B* (1188A/C) appears to have some influence on the outcome of HCV infection.

INTRODUCTION

Hepatitis C virus (HCV) is the major cause of post-transfusion hepatitis. As is estimated by WHO, approximately 170 million people globally may have been infected with HCV^[1]. Although chronic HCV infections are often clinically silent for decades, an estimated 85% of individuals infected with HCV develop persistent infection, and these patients are likely to end up with cirrhosis and liver cancer^[1-3]. HCV infection persists despite the presence of specific humoral and cellular immune responses, and the factors leading to viral clearance or persistence are poorly understood. But some researches showed that the outcome might already be determined at an early time point following infection^[4-7]. Patients with acute HCV infection presenting a self-limited acute hepatitis develop a strong Th1 response. In contrast, patients developing a chronic infection show a predominant Th2 response, but a weak Th1 response. These findings suggest that the imbalance or skewness between responses of Th1 and Th2 cells is involved in disease progression and in the incapability to eradicate HCV^[8-10]. Interleukin 12 (IL-12) is a key cytokine presented with the initiation of immune response, which is one of the most clearly defined factors determining Th1 and Th2 differentiation^[11,12]. IL-12 might, therefore, play an important role in the pathogenesis of HCV infection by affecting the Th1/Th2 balance. Single nucleotide polymorphism (SNP) (1188A/C) was identified at position 1188 in the 3'-untranslated region (UTR) of IL-12 *p40* gene (*IL12B*) and was found to correlate with many diseases^[13-15].

In this study, we proposed that some genotypes of SNP (1188A/C) might associate with either disease outcome or the state of illness in chronic HCV infection. To test this hypothesis, we determined the frequency of genotypes at the SNP site using polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) in HCV infected patients, as well as the relationship between *IL12B* and outcome of HCV infection.

MATERIALS AND METHODS

Subjects

A total of 133 patients with confirmed diagnoses of HCV infection in Gu'an County, Hebei Province, China, who had been infected with HCV for 12-25 (18.2±3.8) years, were enrolled in this study. All the patients were investigated in January 2002. There were 61 (45.9%) male and 72 (54.1%) female patients ranging from 30 to 69 years old (mean age, 46.5±8.3 years). All subjects had no access to antiviral treatment.

Laboratory examination

Venous blood was drawn from each individual and genomic DNA was extracted from clotted blood with a protocol by using silica (Sigma, S-5631). Genotyping of SNP (1188A/C) was carried out by PCR-RFLP according to Hall *et al.*^[13]. Liver biochemistry tests including alanine aminotransferase (ALT), aspartate aminotransferase (AST), γ -glutamyltransferase (γ -GT), alkaline phosphatase (ALP), total bilirubin (TBil), direct bilirubin (DBil), total protein (Tp), albumin (ALB) and serum albumin/globulin ratio (A/G) were measured with HITACHI 7170 automatic

biochemistry analyzer. The B-mode ultrasound was performed for liver examination. HCV RNA was detected with quantitative fluorogenic PCR.

Statistical analysis

Data were expressed as mean \pm SD. Student's *t*-test, one-way analysis of variance and Chi-square tests were used for statistical analysis according to the data obtained. Logistic regression was used to assess the impact of variables on the odds of the outcome of HCV infection. Multivariate analysis of variance was used to analyze the difference of clinical characteristics among patients with persistent infection. All univariate and multivariable calculations, including odds ratios (OR), 95% confidence intervals (95% CI), and *P* values were calculated using the SPSS (version 10).

RESULTS

Of 133 cases investigated in this study, 91 (68.4%) were HCV RNA positive and 42 (31.6%) were HCV RNA negative. SNP typing of DNA samples from all the subjects is shown in Table 1. The proportions of male subjects were 31.0% in self-limited infection and 52.7% in persistent infection. Female gender was closely related to self-limited infection ($P < 0.05$). All patients were HCV infected as a consequence of plasma donation. The mean durations of infection were 17.76 and 18.44 years for patients with self-limited infection and matched patients with persistent infection, respectively. HCV genotype 1b was found in all the patients except two. In addition, the two groups were indistinguishable with respect to age, source of infection, duration of infection and HCV genotype ($P > 0.05$).

Table 1 Features of subjects enrolled in the study

Group	<i>n</i>	Gender (male/female)	Age (yr)	Duration of infection (yr)
Self-limited infection	42	13/29	45.71 \pm 7.68	17.76 \pm 3.82
Persistent infection	91	48/43	46.85 \pm 8.56	18.44 \pm 3.82

Agarose gel electrophoresis result of three genotypes of SNP (1188A/C) is shown in Figure 1. Genotype frequencies at SNP (1188A/C) are listed in Table 2. There was significant difference in genotype distribution between subjects with self-limited infection and subjects with persistent infection ($P < 0.01$). The distribution of genotype showed a good fit to Hardy-Weinberg equilibrium. At SNP (1188A/C) locus, the AC homozygous genotype was found more frequently in subjects with self-limited infection compared to those with persistent infection: 64.3% vs 34.1% (OR = 3.48; 95% CI: 1.52-8.10; $P = 0.001$). The AA genotype was more frequent in individuals with persistent infection compared to those with self-limited infection: 40.7% vs 19.0% (OR = 0.34; 95% CI: 0.12-0.87; $P = 0.014$).

Figure 1 2% agarose gel electrophoresis of restriction enzyme digested products. Lane 1: 50 bp DNA ladder; lanes 2 and 3: AC genotype; lanes 4 and 5: CC genotype; lanes 6 and 7: AA genotype.

Table 2 Genotype frequencies of 1188A/C SNP of *IL12B* in patients

Genotype	Self-limited infection (%) <i>n</i> = 42	Persistent infection (%) <i>n</i> = 91	OR	95% CI	<i>P</i>
AA	8 (19.0)	37 (40.7)	0.34	0.12-0.87	0.014
CC	7 (16.7)	23 (25.3)	0.59	0.20-1.61	0.270
AC	27 (64.3)	31 (34.1)	3.48	1.52-8.10	0.001

Comparisons of genotype distribution using chi square test showed significant difference between self-limited infection and persistent infection ($P = 0.004$).

Effects of variables on the outcome of HCV infection were investigated by means of binary logistic regression analysis (Table 3). Both genotypes of SNP (1188A/C) and gender were independently associated with the outcome of HCV infection (OR 0.43, $P = 0.001$; OR 0.41, $P = 0.029$, respectively).

Table 3 Multivariate analysis of the effects of variables on the outcome of HCV infection

Variable	<i>P</i>	Multivariate odds ratio (95% CI)
Genotype	0.001	0.43 (0.27-0.70)
Gender	0.029	0.41 (0.18-0.91)
Duration of infection	NS	-

The general features, biochemical characteristics and HCV RNA levels in patients with persistent infection grouped by the genotype of SNP (1188A/C) of *IL12B* were analyzed (Table 4). No significant differences were found in age, gender or the duration of infection between three groups. And no significant differences were found in ALT, AST, γ -GT, ALP, TBil, DBil, Tp, ALB, A/G or HCV RNA levels between three groups ($P > 0.05$). According to the result from B-mode ultrasound and clinical diagnosis, patients with persistent infection were divided into groups based on severity. No significant differences were found in genotype frequencies between different groups ($P > 0.05$). Multivariate analysis of variance was used to analyze the different biochemical characteristics between three groups, and no difference was found ($P > 0.05$) (data not shown).

Table 4 Characteristics of patients with different SNP (1188A/C) genotypes during persistent infection

Characteristics	AA <i>n</i> = 38	CC <i>n</i> = 23	AC <i>n</i> = 30
Age (yr)	46.9 \pm 8.2	46.7 \pm 9.7	46.8 \pm 8.4
Gender (male/female)	21/17	12/11	15/15
Duration of disease (yr)	18.0 \pm 3.8	18.8 \pm 4.0	18.1 \pm 3.8
ALT (U/L)	51 \pm 44	51 \pm 60	44 \pm 26
AST (U/L)	50 \pm 30	51 \pm 34	47 \pm 20
γ -GT (U/L)	24 \pm 26	35 \pm 33	28 \pm 34
ALP (U/L)	88 \pm 26	92 \pm 28	93 \pm 22
Tbil (μ mol/L)	29 \pm 11	8.95 \pm 2.59	10.1 \pm 4.2
Dbil (μ mol/L)	5.8 \pm 2.0	5.3 \pm 2.2	5.4 \pm 2.4
Tp (g/L)	75.3 \pm 3.9	72.24 \pm 5.95	75.0 \pm 5.8
ALB (g/L)	44.4 \pm 2.3	43.8 \pm 2.3	44.5 \pm 2.6
A/G	1.46 \pm 0.21	1.59 \pm 0.32	1.51 \pm 0.30
HCV RNA ¹	5.07 \pm 1.49	4.95 \pm 1.52	5.58 \pm 1.24

¹Values are expressed as log₁₀ RNA copies per mL.

DISCUSSION

For the first time, we investigated here the polymorphism of

SNP (1188A/C) of *IL12B* in patients with HCV infection and demonstrated that AA genotype decreased and AC genotype increased in self-limited infection. Although there was no significant difference in allele distribution between patients with self-limited infection and patients with persistent infection, A allele tended to be decreased and C genotype to be increased in self-limited infection. In this study, however, there was no association between genotype of SNP (1188A/C) of *IL12B* and biochemical characteristics of subjects with persistent infection. And no association was found between genotype of SNP (1188A/C) and the severity of subjects with persistent infection.

HCV infection is characterized by a broad spectrum of possible outcomes. Infection is self-limited in a fortunate minority, while the majority of patients develop persistent infection^[16,17]. Patients with acute HCV infection presenting a self-limited acute hepatitis and with eradication of the virus develop a strong Th1 response but a weak or absent Th2 response. In contrast, patients developing a chronic infection show a predominant Th2 response, but a weak Th1 response. These observations suggest that Th1 cytokine effect is essential for protection against HCV infection, while the production of Th2 cytokine seems to have an inhibiting effect on the patient's immunological system^[8,10]. IL-12 is a key regulator of the polarization of immune responses to T helper 1 or 2 categories and plays a role in autoimmune and infectious diseases^[11,12,18]. IL-12 might, therefore, have effects on the pathogenesis of HCV infection by affecting Th1/Th2 balance.

IL-12 is comprised of two disulphide-linked protein subunits designated p35 and p40, which are encoded by two different genes, *IL12A* and *IL12B*^[19,20]. IL-12 p40 expression is restricted to the production of p70 because p35 is expressed ubiquitously and constitutively at low levels. Thus, secretion of the biologically active p70 heterodimer appears to be predominantly regulated at the level of *IL12B*^[12]. IL-12 is secreted mainly by antigen-presenting cells and plays a key role in innate resistance and adaptive immunity. IL-12 acts on T cells and NK cells by enhancing generation and activity of cytotoxic lymphocytes and inducing proliferation and production of cytokines, especially IFN- γ . IL-12 is also the major cytokine responsible for differentiation of T helper 1 cells, which are potent producers of IFN- γ ^[12,19]. And IFN- γ plays important roles in the immune response to HCV infection. Some studies have been reported that the deletions of IL-12 p40 lead to serious impairment of immunity to intracellular bacteria^[21]. The SNP at position 1188 in the untranslated region of IL-12 p40 gene mapped to chromosome 5q31-33. Although SNP is located in UTR and does not alter the coding sequence, some researches showed that this SNP site was associated with immune-mediated disease^[13,22].

Many studies showed that there was close relationship between IL-12 and hepatitis C. Nelson *et al.* reported that patients with chronic HCV infection had elevated IL-12, which correlated with serum ALT and intrahepatic HCV-specific CTL activity. These data indicate that IL-12 is involved in the immunopathogenesis of chronic HCV infection, especially in cell-mediated immunity, which might be important in spontaneous or interferon mediated viral clearance^[23,24]. Another study reported the impairment in allostimulatory capacity of peripheral blood dendritic cells in HCV- infected individuals, which is likely due to low IL-12 expression and restored by endogenous IL-12^[25]. Some studies have found that IL-12 can produce lower HCV-RNA level^[26-31].

Studies on functional characteristics of this polymorphism suggest that they influence the secretion of cytokines. Morahan *et al.* reported the 3'-UTR alleles showed different levels of *IL12B* mRNA expression in cell lines. They identified EBV-transformed cell lines homozygous for each allele. Expression of *IL12B* mRNA was significantly reduced in the C/C genotype cell line in contrast to the A/A line^[32]. But Seegers *et al.* found that a TaqI polymorphism (C/C) in IL12 p40 3'-UTR correlated

with increased IL-12 p70 *in vitro*^[33]. The results were complicated and the functional characteristics of this polymorphism still need to be evaluated. Currently our group is working on the IL-12 mRNA and protein levels of three different genotypes to clarify how SNP (1188A/C) influences the course of hepatitis C.

In summary, we have reported that the frequency of A/A genotype of *IL12B* 3'-UTR SNP was decreased in self-limited HCV infection. It suggests that this SNP is associated with different outcomes of HCV infection, presumably by affecting Th1/Th2 balance. Nevertheless, since the outcome of HCV infection is a complicated polygenic trait, the interactive effects between SNP (1188A/C) of *IL12B* and other factors involved in the outcome of hepatitis C still need to be evaluated.

ACKNOWLEDGEMENT

We are very grateful to Professor Shu-Lin Liu for his critical revision of this paper.

Abstract

AIM: To investigate the relations between tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) and *Helicobacter pylori* (*H pylori*) infection in apoptosis of gastric epithelial cells and to assess the expression of TRAIL on the surface of infiltrating T-cells in *H pylori*-infected gastric mucosa.

METHODS: Human gastric epithelial cell lines and primary gastric epithelial cells were co-cultured with *H pylori* *in vitro*, then recombinant TRAIL proteins were added to the culture. Apoptosis of gastric epithelial cells was determined by a specific ELISA for cell death. Infiltrating lymphocytes were isolated from *H pylori*-infected gastric mucosa, and expression of TRAIL in T cells was analyzed by flow cytometry.

RESULTS: The apoptosis of gastric epithelial cell lines and primary human gastric epithelial cells was mildly increased by interaction with either TRAIL or *H pylori* alone. Interestingly, the apoptotic indices were markedly elevated when gastric epithelial cells were incubated with both TRAIL and *H pylori* (Control vs TRAIL and *H pylori*: 0.51 ± 0.06 vs 2.29 ± 0.27 , $P = 0.018$). A soluble TRAIL receptor (DR4-Fc) could specifically block the TRAIL-mediated apoptosis. Further studies demonstrated that infiltrating T-cells in gastric mucosa expressed TRAIL on their surfaces, and the induction of TRAIL sensitivity by *H pylori* was dependent upon direct cell contact of viable bacteria, but not CagA and VacA of *H pylori*.

CONCLUSION: *H pylori* can sensitize human gastric epithelial cells and enhance susceptibility to TRAIL-mediated apoptosis. Modulation of host cell sensitivity to apoptosis by bacterial interaction adds a new dimension to the immunopathogenesis of *H pylori* infection.

INTRODUCTION

Helicobacter pylori (*H pylori*), which infects about 50% of the world's population, is the leading cause of chronic gastritis and peptic ulcer diseases. Recent studies have shown that apoptosis of gastric epithelial cells is increased during *H pylori* infection^[1-4]. The enhanced gastric epithelial cell apoptosis in *H pylori* infection has been suggested to play an important role in the pathogenesis of chronic gastritis, peptic ulcer and gastric neoplasia. There are a number of mechanisms that may be involved, including the direct cytotoxic effects of the bacteria, as well as inflammatory responses elicited by the infection^[4-7]. Recent studies have suggested that T helper type 1 (Th1) cells are selectively increased during *H pylori* infection^[8-11]. Th1 cytokines, such as gamma interferon (IFN-) and tumor necrosis factor alpha (TNF-), can increase the release of proinflammatory cytokines, augmenting apoptosis induced by *H pylori*^[7]. *H pylori* infection could also induce gastric mucosa damage by increasing expression of Fas in gastric epithelial cells, leading to gastric epithelial cell apoptosis through Fas/FasL interaction with infiltrating T cells^[6,12]. These findings suggest a role for immune-mediated apoptosis of gastric epithelial cells during *H pylori* infection.

TRAIL, a novel TNF superfamily member with strong homology to FasL, is capable of inducing apoptosis in a variety of transformed cell lines *in vitro*^[13,14]. Recent studies indicated that TRAIL-induced apoptosis occurred through a caspase signaling cascade^[15-17]. It has been shown that T cells can kill target cells via TRAIL/TRAIL receptor interaction^[18-23], suggesting that TRAIL might serve as a cytotoxic effector molecule in activated T cells *in vivo*. In addition to its role in inducing apoptosis by binding to death receptors, TRAIL itself can stimulate T cells and augment IFN- secretion^[24]. These findings have led us to hypothesize that TRAIL/TRAIL receptor interaction was involved in the apoptosis of gastric epithelial cells in *H pylori* gastritis. We therefore designed the study to investigate the interactions between TRAIL and *H pylori* in apoptosis of human gastric epithelial cells. Additionally, we assessed the expression of TRAIL on the surface of infiltrating T-cells in *H pylori*-infected gastric mucosa.

MATERIALS AND METHODS

Bacterial strains, cell lines, and media

H pylori standard strain ATCC43504 (CagA+, VacA+) and the mutant strain ATCC51932 (CagA-, VacA-), obtained from American Type Culture Collections (ATCC) were used. *H pylori* strain NTUH-C1 (CagA+, VacA+) was isolated from a patient with duodenal ulcer in National Taiwan University Hospital. Before each experiment, *H pylori* was passaged on 5% sheep blood agar plates by incubation in an atmosphere consisting

of 5% O₂, 15% CO₂, and 80% N₂ for 2–4 d at 37 °C. Bacteria were cultured in Brucella broth (Difco Labs, Inc. Detroit, MI) supplemented with 5% FBS, vancomycin and amphotericin B under the same conditions for 30 h at 37 °C with agitation (80–100 rpm/min). Cells were then pelleted and resuspended in phosphate-buffered saline at a concentration of 10⁸ CFU/mL. Human gastric adenocarcinoma cell line AGS was obtained from ATCC and maintained in DMEM, supplemented with 10% FBS.

Generation of *cagA* or *vacA* gene knock out *H pylori* mutant strains

For generation of *H pylori* isogenic mutant strains with *cagA* or *vacA* gene defect, we introduced mutations into *cagA* or *vacA* gene in *H pylori* strain NTUH-C1. *cagA* and *vacA* genes were amplified by PCR with the following primer pairs, *cagA*: 5'-ATGACTAACGAACTATTGATCAAACA-3' and 5'-AGATTTTTGGAAACCACCTT TTGTATTA-3'; *vacA*: 5'-GCTGGGATTGGGGGAATG-3' and 5'-TTGCGCGCTA TTGGGTGG-3'. The PCR fragments were purified and then cloned on pGEM-T easy vector by a TA cloning kit (Promega, Madison, WI, USA). The cloned *cagA* or *vacA* gene was digested with *Nhe* I, after which the chloramphenicol resistant marker (CAT cassette) was ligated with recombinant *Nhe* I sites at both ends. The plasmid pGEM-T Easy Vector with *cagA* or *vacA* inserted by the CAT cassette was used for the natural transformation of *H pylori* strain NTUH-C1. The *cagA* gene or *vacA* gene isogenic knockout mutants were selected by the BHI agar plate with 40 ppm chloramphenicol and confirmed with PCR.

Expression and purification of recombinant TRAIL protein and soluble TRAIL receptor (DR4-Fc)

Recombinant TRAIL proteins were expressed in *E. coli* expression system and purified with Ni column as described^[24]. In brief, the coding portion of the extracellular domain of TRAIL (amino acid 123–314) was PCR amplified, subcloned into pRSET B vector (Invitrogen, Groningen, the Netherlands) and expressed in *E. coli* expression system. Purification of recombinant His-TRAIL fusion protein was performed by metal chelate column chromatography using Ni-NTA resin according to the manufacturer's recommendations (Qiagen, Hilden, Germany). His-TRAIL was quantified by the Bradford method and protein assay reagent (BioRad, Richmond, CA, USA). To generate soluble recombinant DR4-Fc fusion molecules, the coding sequence for the extracellular domain of human DR4 was isolated by RT-PCR using the forward primer, CGGATTTTCATGGCGCCACCACCA, and the reverse primer, GAAGATCTATTATGTCCATTGCC. The amplified product was ligated in-frame into *Bam*HI-cut pUC19-IgG1-Fc vector containing the human IgG1 Fc coding sequence. The fusion gene was then subcloned into pBacPAK9 vector (Clontech, Palo Alto, CA). DR4-Fc fusion protein was recovered from the filtered supernatants of the recombinant virus-infected Sf21 cells using protein G-sepharose beads (Pharmacia, Piscataway, NJ). The bound DR4-Fc protein was eluted with glycine buffer (pH 3) and dialyzed into PBS. The DR4-Fc is a soluble TRAIL receptor, which could bind to TRAIL and block its effect.

Culture of primary human gastric epithelial cells

The culture of human gastric epithelial cells was adapted from the methods described by Smoot *et al.*^[25]. Gastric biopsies were obtained from patients undergoing gastric endoscopy in National Taiwan University Hospital for dyspepsia with informed consents. Specimens were collected in Leibowitz's L-15 medium (Life Technologies, Grand Island, NY). Gastric cells were isolated enzymatically after mechanically mincing the tissue, into pieces less than or equal to 1 mm in size. The tissue was then pelleted by centrifugation at 1 500 rpm for five

minutes at 4 °C, the collagenase/dispase was discarded, then the tissue was washed once in 10 mL of PBS and pelleted again by centrifugation. The cells were resuspended in the cell culture medium. The gastric epithelial cells obtained above were suspended in 2 mL of Ham's F12 cell culture medium (Life Technologies, Grand Island, NY) with 10% FBS and placed into a 6-well tissue culture cluster well.

Apoptosis assay

A sensitive ELISA which detects cytoplasmic histone-associated DNA fragments was performed according to the manufacturer's protocol (Cell Death Detection ELISA^{PLUS}; Roche Mannheim Biochemicals, Mannheim Germany). Human gastric epithelial cells were cultured in a 96-well plate (10⁴ cells/well) overnight, then treated with TRAIL recombinant protein, harvested by centrifugation at 200 g. The cells were lysed by incubation with lysis buffer for 30 min, followed by centrifugation at 200 g for 10 min at room temperature. The supernatant was collected and incubated with immunoreagent pre-prepared for 2 h. After washed gently, the supernatant was pipetted into each well with a substrate solution and kept in the dark until development of the color was sufficient for photometric analysis. The reaction was determined in a spectrophotometer at 405 nm.

Effects of TRAIL and *H pylori* on apoptosis in human gastric epithelial cells

AGS cells or primary human gastric epithelial cells 5×10⁴/well were incubated with *H pylori* (ATCC strain 43504 or strain 51932) under the concentration of 4×10⁷ CFU for 12 h. Recombinant TRAIL proteins were added into the culture at the concentration of 1.0 g/mL for 4 h in the absence or presence of soluble TRAIL receptor, DR4-Fc (30 g/mL), which could block the function of TRAIL proteins. Apoptosis of gastric epithelial cells was determined by a specific ELISA as described.

Effects of lipopolysaccharide (LPS) and *Campylobacter jejuni* on induction of TRAIL sensitivity in human gastric epithelial cells

To exclude the possibility that the effect of induction of TRAIL sensitivity in AGS cells by *H pylori* was a general phenomenon in Gram-negative bacteria, possibly via interaction with LPS on cell wall, we further studied the TRAIL-mediated apoptosis in AGS cells following contact with LPS and *Campylobacter jejuni*. AGS cells were incubated with LPS from *E. coli*, *Campylobacter jejuni*, and *H pylori* (domestic strain NTUH-C1) for 12 h. Recombinant TRAIL proteins were added into the culture. Apoptosis was measured with ELISA as described.

Effects of direct cell contact of bacteria on TRAIL-mediated apoptosis of epithelial cells

AGS cells were incubated with *H pylori* (ATCC strain 43504; CagA+, VacA+) concentrated culture supernatant or with live bacteria separated by a membrane filter (Nunc Tissue Culture; Nunc, Roskilde, Denmark) under the concentration of 4×10⁷ CFU/5×10⁴ cells for 12 h. Recombinant TRAIL proteins were added into the culture. Cell death was measured with ELISA as described.

Effects of *CagA* and *VacA* on TRAIL-mediated apoptosis of epithelial cells

AGS cells (5×10⁴ cells) were incubated with a CagA-negative and VacA-negative *H pylori* mutant strain (ATCC strain 51932) as well as the *cagA* or *vacA* gene defect NTUH-C1 isogenic mutant strains for 12 h. Recombinant TRAIL proteins were then added into the culture. Apoptosis was measured with ELISA assay as described.

Expressions of TRAIL on surface of T-lymphocytes in gastric mucosa

For isolation of gastric infiltrating lymphocytes from endoscopic biopsy specimens, the collected tissues were immediately placed in ice-cold RPMI 1640 complete medium (GIBCO BRL, Gaithersburg, MD, USA) containing 10% fetal calf serum (FCS) supplemented with penicillin (50 IU/mL), streptomycin (50 mg/mL), L-glutamine (2 mmol/L) and sodium pyruvate (1 mmol/L). The tissues were washed, diced into 1 mm³ pieces and treated with collagenase (Type I, 5 g/mL; Sigma Co. St. Louis, MO) and heparin (5 U/mL) in RPMI 1640 complete medium at 37 °C for 60 min. After the samples were washed twice with RPMI 1640 medium, mononuclear cells were collected and then stained with anti-CD3 and anti-TRAIL mAb. The expression of TRAIL on the surface of T cells was detected by flow cytometry according to our previous study^[24].

Statistical analysis

The values of apoptosis assay were presented as mean±SD. The results were compared by Student's *t* test. A *P* value less than 0.05 was regarded as statistically significant.

RESULTS

Effects of TRAIL and *H pylori* on apoptosis in human gastric epithelial cell line

Figure 1 shows the effects of *H pylori* and TRAIL on apoptosis in AGS cells. The apoptosis of AGS cells was slightly increased by TRAIL proteins or *H pylori* alone. Interestingly, the apoptotic index was dramatically increased when AGS cells were incubated with both TRAIL and *H pylori* (*P*<0.01 as compared with control medium, TRAIL or *H pylori* alone). Further studies disclosed that TRAIL-induced apoptosis in AGS cells was increased by *H pylori* in a dose-dependent manner (data not shown).

Figure 1 Effects of TRAIL and *H pylori* on apoptosis in human gastric epithelial cell line AGS (^b*P*<0.01 when compared with medium control, TRAIL or *H pylori* alone).

Figure 2 AGS cells incubated with heat killed, paraformaldehyde-fixed (PA-fixed) or live *H pylori* (ATCC strain 43504) under the concentration of 4×10⁷ CFU/5×10⁴ cells for 12 h. Open bar: without TRAIL; filled bar: with TRAIL (^b*P*<0.01).

Figure 2 shows that the TRAIL-induced apoptosis depended on viable *H pylori* because exposure of the host cells to heat-killed *H pylori* and paraformaldehyde-fixed *H pylori* did not induce sensitivity to TRAIL-mediated apoptosis.

Impacts of TRAIL and *H pylori* on apoptosis in primary human gastric epithelial cells

We further isolated and cultured primary human gastric epithelial cells from 23 different human cases (*H pylori*-positive: 12 cases; *H pylori*-negative: 11 cases) to investigate the effects of *H pylori* and TRAIL on apoptosis. The apoptosis of primary human gastric epithelial cells was mildly elevated by either TRAIL or *H pylori* alone (Table 1). However, the apoptotic indices were markedly elevated when the primary gastric epithelial cells were incubated with both *H pylori* and TRAIL. The apoptosis induced by *H pylori* and TRAIL was specifically blocked by adding soluble TRAIL receptor, DR4-Fc, indicating that the cell death was resulted from interaction between TRAIL and TRAIL receptor on the cell surface. Figure 3 shows the representative responses of four cases. All the gastric epithelial cells tested were sensitive to TRAIL after interaction with *H pylori* *in vitro*.

Table 1 Effects of TRAIL and *H pylori* on apoptosis in primary human gastric epithelial cells

	Apoptotic index ¹ (n=23)	<i>P</i> value ²

HP+TRAIL+DR4	0.816±0.129	0.216

¹mean±SD; ²Compared with medium alone samples.

Figure 3 Enhancement of TRAIL-mediated apoptosis by *H pylori* in primary human gastric epithelial cells.

Effects of LPS and *Campylobacter jejuni* on induction of TRAIL sensitivity in human gastric epithelial cells

To exclude the possibility that the effect of induction of TRAIL sensitivity by *H pylori* was a general phenomenon in Gram-negative bacteria, possible via interaction with lipopolysaccharide (LPS) on cell walls, we further studied the induction of sensitivity to TRAIL-mediated apoptosis in AGS cells after interaction with LPS from *E. coli* and with *Campylobacter jejuni*, a Gram-negative bacterial pathogen in gastrointestinal tract. The results in Figure 4 demonstrate that *H pylori* enhanced TRAIL-mediated apoptosis in AGS cells. However, neither LPS from *E. coli* nor *Campylobacter jejuni* was able to induce TRAIL-sensitivity. Moreover, similar to ATCC strains, domestic *H pylori* strain NTUH-C1 was also capable of inducing TRAIL-sensitivity in AGS cells (Figure 4). These results indicated the ability to sensitize human gastric epithelial cells to TRAIL-induced apoptosis was *H pylori*-specific and not a general phenomenon in Gram-negative bacteria.

Figure 4 Induction of TRAIL sensitivity specific for *H pylori* in human gastric epithelial cells (^b*P*<0.01 when compared with *H pylori* alone without adding TRAIL samples).

Effects of direct cell contact of bacteria on TRAIL-mediated apoptosis of gastric epithelial cells

To investigate the effects of direct bacteria-epithelial cell contact in induction of TRAIL sensitivity by *H pylori*, AGS cells and bacteria were separated by a membrane filter (Nunc Tissue Culture; Nunc, Roskilde, Denmark). Figure 5 shows the effects of direct cell contact of bacteria on TRAIL-mediated apoptosis in human gastric epithelial cells. The enhancement of TRAIL sensitivity by *H pylori* was abrogated when AGS cells were separated by the filter without direct bacteria-cell contact or co-cultured with concentrated *H pylori* culture supernatant without viable bacteria, indicating that direct contact with viable bacteria was required for induction of TRAIL sensitivity by *H pylori*.

Figure 5 Enhancement of direct bacteria-cell contact dependent TRAIL sensitivity by *H pylori* (^b*P*<0.01).

Effects of *cagA* and *vacA* on TRAIL-mediated apoptosis of epithelial cells

To exclude the possibility that the death of gastric epithelial

cells induced by TRAIL was related with *vacA* cytotoxin of *H pylori*, and to elucidate the role of *cagA* gene products in onset of the apoptotic process, we examined the abilities to enhance TRAIL-mediated apoptosis in *H pylori* mutant strain, ATCC 51932, which is deficient of cytotoxin *vacA* and *cagA*, and *H pylori* NTUH-C1 *cagA*, *vacA* gene knock out isogenic mutant strains. Figure 6 shows the effects of *CagA*-negative and *VacA*-negative *H pylori* strains on TRAIL-mediated apoptosis in gastric epithelial cells. *H pylori* strain 51932 significantly enhanced sensitivity to TRAIL-mediated apoptosis in gastric epithelial cell lines in a dose-dependent manner. *cagA* or *vacA* gene knock out NTUH-C1 mutant strain was also capable of inducing TRAIL sensitivity in gastric epithelial cells. Taken together, these results suggested that *vacA* and *cagA* proteins of *H pylori* were not required for induction of TRAIL-sensitivity in human gastric epithelial cells.

Expression of TRAIL on surface of T-lymphocytes in gastric mucosa

To confirm the expression of TRAIL in gastric infiltrating lymphocytes, gastric biopsy specimens were collected from subjects and examined by flow cytometry. Figure 7 demonstrates the expression of TRAIL on surface of T-lymphocytes isolated from gastric mucosa. Flow cytometry confirmed the presence of TRAIL on the surface of gastric infiltrating T-lymphocytes.

Figure 7 Expression of TRAIL on surface of T cells isolated from gastric mucosa.

DISCUSSION

In this study, we investigated the effects of *H pylori* and TRAIL on apoptosis in human gastric epithelial cells. The apoptosis of primary human gastric epithelial cells was mildly increased after incubated with either *H pylori* or TRAIL alone. Interestingly, the apoptotic indices of gastric epithelial cells were markedly increased when the primary gastric epithelial cells were incubated with both TRAIL and *H pylori*. The

Figure 6 Effects of *vacA* and *cagA* on induction of TRAIL sensitivity by *H pylori*. A: AGS cells (5×10^4 cells) were incubated with a different concentration of *H pylori* (ATCC strain 51932) for 12 h. B: AGS cells were incubated with *H pylori* NTUH-C1 and its *cagA*, *vacA* gene knock out mutant strains (*cagA* KO, *vacA* KO) in the concentration of 4×10^7 CFU/ 5×10^4 cells for 12 h (^b*P*<0.01 when compared with *H pylori* alone without adding TRAIL samples).

induction of TRAIL-mediated apoptosis by *H pylori* was specifically blocked by adding soluble TRAIL receptor, DR4-Fc. The results implicated that *H pylori* could directly trigger apoptosis in gastric epithelial cells as previously described^[26-28]. Additionally, the microorganism was also capable of enhancing TRAIL sensitivity in gastric epithelial cells. Most of the apoptosis in gastric epithelial cells after exposure to both *H pylori* and TRAIL was resulted from interaction between TRAIL and TRAIL receptor on the surface of gastric epithelial cells, but not due to direct cytotoxicity induced by *H pylori*.

To confirm the expression of TRAIL in infiltrating T-lymphocytes of gastric mucosa, we isolated the gastric infiltrating lymphocytes from gastric biopsy specimens of *H pylori*-infected subjects. Our data confirmed that TRAIL was expressed on the surface of gastric infiltrating T-cells. This important finding further supports the hypothesis that TRAIL/TRAIL-R interaction is involved in epithelial cell damage during *H pylori* infection. Furthermore, it implicates that infiltrating T-cells in gastric mucosa may play a crucial role in the sequential changes of *H pylori*-related chronic gastritis.

In this study, we also demonstrated that neither *Campylobacter jejuni* nor LPS from *E. coli* was able to induce TRAIL-sensitivity in AGS cells. In contrast, *H pylori* standard strain ATCC43504 (CagA+, VacA+), mutant strain ATCC51932 (CagA-, VacA-) and our domestic strain NTUH-C1 (CagA+, VacA+) were capable of inducing TRAIL-sensitivity in AGS cells. The results indicate the ability to enhance TRAIL sensitivity of gastric epithelial cells is specific for *H pylori* and not a general phenomenon of Gram-negative Bacteria.

It has been demonstrated recently that *H pylori* could directly trigger cell death by cytotoxins after interaction with gastric epithelial cells^[26,27,29]. Other reports have shown that *H pylori* could secrete *cagA* into gastric epithelial cells by Type IV secretion, thus inducing intracellular protein phosphorylation in host cells^[30-33]. To elucidate the role of *cagA* gene products and *vacA* in TRAIL-mediated apoptosis, we examined the ability to induce TRAIL of a CagA-negative and *vacA*-negative *H pylori* mutant strain, ATCC 51932 as well as *cagA*, *vacA* gene knock out mutants of NTUH-C1 strain. All the *H pylori* wild type and mutant strains significantly enhanced sensitivity to TRAIL-mediated apoptosis in gastric epithelial cell lines. These findings suggest that expression of *cagA* and *vacA* is not mandatory for induction of TRAIL-sensitivity in gastric epithelial cells.

To investigate the effects of direct bacteria-epithelial cell contact in induction of TRAIL sensitivity by *H pylori*, AGS cells were separated by the filter without direct bacteria-cell contact or co-cultured with concentrated *H pylori* culture supernatant without viable bacteria. The enhanced TRAIL sensitivity was only observed when AGS cells were co-cultured with viable *H pylori*, but not with bacteria culture supernatant or with viable bacteria separated by a permeable membrane, indicating that direct contact with viable bacteria is necessary for induction of TRAIL sensitivity of gastric epithelial cells.

We demonstrated here that human gastric epithelial cells sensitized to *H pylori* conferred susceptibility to TRAIL-mediated apoptosis. Although the induction of TRAIL sensitivity by *H pylori* in gastric epithelial cells was independent of *H pylori* virulent factors CagA and VacA, the degree of apoptosis was linked to the presence of *H pylori* and the associated inflammatory response. Therefore, the degree of mucosal damage was also determined by the inflammatory response induced by *H pylori* within gastric epithelium. Our results suggest a role for immune-mediated apoptosis of gastric epithelial cells by infiltrating T cells during *Helicobacter* infection.

In conclusion, *H pylori* enhance susceptibility of gastric epithelial cells to TRAIL-mediated apoptosis. The induction of TRAIL sensitivity by *H pylori* is dependent upon direct contact

of viable bacteria with gastric epithelial cells, but independent of expression of *H pylori* virulent factors *vacA* and *cagA*. Gastric infiltrating T-lymphocytes can express TRAIL on their cell surfaces. Modulation of host cell apoptosis by bacterial interaction adds a new dimension to the immune pathogenesis in chronic *Helicobacter* infection.

Abstract

AIM: To construct and select antigen epitopes of vacuolating cytotoxin A (VacA) for nontoxic VacA vaccine against *Helicobacter pylori* (*H pylori*) infection.

METHODS: Eleven VacA epitopes were predicted according to VacA antigenic bioinformatics. Three candidates of VacA epitope were constructed through different combined epitopes. The candidate was linked with *E. coli* heat-labile enterotoxin B (LTB) by a linker of 7 amino acids, and cloned into plasmid pQE-60 in which fusion LTB-VacA epitope was efficiently expressed. To test the antigenicity of the candidate, 6 BALB/c mice were treated with the fusion LTB-VacA epitope through intraperitoneal injection. To explore the ability of inhibiting the toxicity of VacA, antiserum against the candidate was used to counteract VacA that induced HeLa cells to produce cell vacuoles *in vitro*.

RESULTS: Serum IgG against the candidate was induced in the BALB/c mice. *In vitro*, the three antisera against the candidate efficiently counteracted the toxicity of VacA, and decreased the number of cell vacuoles by 14.17%, 20.20% and 30.41% respectively.

CONCLUSION: Two of the three candidates, LZ-VacA1 and LZ-VacA2, can be used to further study the mechanism of vacuolating toxicity of VacA, and to construct nontoxic VacA vaccine against *H pylori* infection.

INTRODUCTION

Pathogenic strains of *Helicobacter pylori* (*H pylori*) release a M_r 95 000 protein toxin in the growth medium. Growing evidence indicates that VacA is a major virulence factor in *H pylori* long-term infection leading to gastroduodenal ulcers^[1-5]. This toxin induces formation of vacuoles in the cytosol of cells, therefore it has been named vacuolating toxin^[6-11]. VacA is thus considered as a therapeutic vaccine for individuals infected with *H pylori*. The VacA gene encodes a protoxin approximately M_r 140 000, which belongs to the family of secreted proteins. During the process of VacA secretion, a M_r 95 000 mature toxin is exported.

A large oligomeric complex appear as 'flower' with M_r 900 000 which is composed of 6-7 VacA monomers^[12-15]. When exposed to the acidic situation, the oligomeric complexes were assembled into monomers and the toxicity of VacA was enhanced^[16-18]. After VacA exerted its effect on the cells for 90 min, vacuoles were formed^[19]. The vacuoles induced by VacA were acidic. Intracellular vacuolation is believed to induce cell damage and eventually apoptosis, which might lead to release of necrotic factors *in vivo* and therefore contribute to the establishment of a chronic inflammatory response. Because vacuolating cytotoxin A is difficult to express, purify and construct the combined vaccine, we studied the antigen epitopes to reduce the toxin.

MATERIALS AND METHODS

E. coli JM109, pFS2.2 and HeLa cell were preserved in our laboratory; pQE-60 was a gift of professor Hou-Chu Zhu, Beijing Institute of Biotechnology, Beijing, China; *H pylori* Sydney strain (*HP SSI*), was a gift of professor Min-Hu Chen, Sun Yat-sen University, Guangzhou, China.

*Bam*H I, *Eco*R V, *Nco* I, *Hind* III, Pyrobest Taq DNA polymerase and T₄ DNA ligase were purchased from TaKaRa Biotechnology corporations.

Isopropyl β -D-thiogalactoside (IPTG), Freund's adjuvant and sheep anti-mouse IgG-HRP were purchased from Sigma corporations, RPMI 1640 and newborn calf serum were purchased from Hyclone corporations.

BALB/c female mice: 6-8 wk old, SPF.

Bioinformatic analysis and design for candidates of VacA antigen epitope

According to the protein characteristics of hydrophilicity, hydrophobicity, secondary structure, accessibility, flexibility and antigenicity, 9 VacA antigen epitopes in the amino acid site of 34-810 were predicted by the antigen-analyzing software GOLDKEY (Table 1).

Table 1 Site and amino acid sequences of predicted VacA epitopes

Site of amino acid	Amino acid sequences of predicted epitopes
35-46	AEEANKTPDKPD
61-66	PHKEYD
146-154	KDSADRTTR
297-317	GYKDKPKDKPSNTTQNNANN
335-338	NSAQ
446-450	TDTKN
566-568	SGE
734-737	NNNR
746-748	TDD
766-768	DNY
799-806	TPTENGGN

Three candidates of VacA antigen epitope were designed by combining part of 9 predicted epitopes. The candidate LZ-VacA1 was composed of amino acids 35-36 and 146-154, LZ-VacA2 included amino acids 297-317, and LZ-VacA3 contained

aminoacids 61-66, 446-450, 734-737, 746-748, 766-768, and 799-806. The gene sequence of candidate epitope was fused with a 7-amino acid linker (YPQDPSS). The nucleotide acid and amino acid sequences of three candidate epitopes were as following.

The sequence of LZ-VacA1 was:

```
TAC CCT 5'---CAG GAT CCG TCT TCC gcc gaa gaa gcc
Y P Q D P S S A E E A
aat aaa acc cca gat aaa ccc gat aag gat agt gct gat
N K T P D K P D K D S A D
cgc acc acg aga GAT---3'

Synthesis of DNA sequence of candidate epitopes and insertion of plasmid pFS2.2

Two splicing sequences were designed according to the nucleotide acid sequences of the candidate epitope and linker. These sequences were synthesized artificially and spliced by PCR reaction. PCR reaction solution containing 5 µL 10× PCR buffer, 0.25 µL pyrobest Taq polymerase (5 U/µL), 1 µL P1 and P2 primer (50 ng/µL), 4 µL dNTP, H₂O to 50 µL. Five PCR cycles were performed, each at 95 °C for 30 s, at 60 °C for 30 s, at 72 °C for 15 s.

LZ-VacA1 primer sequence was P1: 5'--cag gat cgc tet tcc gcc gaa gaa gcc aat aaa acc cca gat aaa ccc gat aag--3', P2: 5'--atc tct cgt ggt cgc atc agc act atc ctt atc ggg ttt atc tgg gg--3'.

LZ-VacA2 primer sequence was P1: 5'--cag gat cgc tet tcc ggt tat aag gat aaa cct aag gat aaa cct agt aac acc--3', P2: 5'--atc gtt att att agc att att ttg cgt ggt gtt act agg ttt atc c--3'.

LZ-VacA3 primer sequence was, P1: 5'--cag gat cgc tet tcc cct cac aag gaa tac gac acg gat acc aaa aac aac aat aac cgc act gat--3', P2: 5'--atc att gcc acc att ctc agt agg ggt gta att gtc gtc atc agt cgc gtt att gtt gt--3'.

The DNA sequences of the candidate epitope and plasmid pFS2.2 containing LTB, were digested with restriction endonucleases *Bam*HI and *Eco*RV, and ligated with T₄ ligase. The recombinant plasmid, which included LTB-VacA gene was transformed to JM109. The positive clones were screened and named them as pLZ-SV1, pLZ-SV2 and pLZ-SV3, respectively.

Construction of expression vector and purification of LTB-VacA protein

To improve the efficiency of expression, two primers with the cloning sites *Nco*I and *Hind*III were designed to construct plasmid pQE-60 with LTB-VacA gene. The recombinant plasmid was transformed to JM109. The positive clones were screened and named them as pLZ-QV1, pLZ-QV2 and pLZ-QV3 respectively.

The primers was

P1 5'---cagccatggGTGAATAAAGTAAAATG---3'

*Nco*I

P2 5'---ggcaagccttGCTCGGTACTAATTAATTAG---3'

*Hind*III

The strain with recombinant plasmid was cultured in the Luria-Bertani broth for 3 h, induced by IPTG for 4 h, and then harvested. The targeted protein of LTB-VacA was an inclusion body by SDS-PAGE test. The inclusion body was denatured with 6 mol/L guanidine hydrochloride, and nutured with dialysis. LTB-VacA infused protein was purified through the anti-LTB antibody affinity chromatography.

Immunization

Twenty-four female BALB/c mice were randomly and averagely divided into control (LTB), LTB-VacA1, LTB-VacA2 and LTB-VacA3 groups. The mice of each group were immunized through intraperitoneal injection of 200 µL (100 µg protein) LTB, LTB-VacA1, LTB-VacA2 or LTB-VacA3 on days 0, 14 and 28. On days 7, 21 and 35, blood of each mouse was collected and antibody titer was determined.

Cell Vacuolization test

VacA was purified from *H. pylori* strain SS1 culture supernatant with ammonia sulfate precipitation. The preliminary experiment was performed to show the amount of *H. pylori* strain SS1 culture supernatant was added when cell vacuoles were formed. HeLa cells were cultured as monolayers in flasks in RPMI 1640 containing NCS under 50 mL/L CO₂ at 37 °C. Twenty-four hours before experiment, the cells were released with trypsin/EDTA and seeded in 96-well plates in 10³/well. After the VacA protein was incubated with antibody to LTB-VacA1, 2, 3 and LTB for 4 h at 37 °C, we added the fixture and VacA protein onto the cell surface for 6 h. Then we calculated the total cell number and cell number of vacuolization.

Statistical analysis

Data are presented as mean±SD. Analysis of variance with a two-tailed students *t*-test was used to identify significant differences. *P*<0.05 was considered statistically significant.

RESULTS

Construction of recombinant plasmid

Recombinant plasmids pLZ-VacA1, 2, 3 encoded the infused gene of LTB and VacA1, 2, 3. It was shown from the digestion map of restriction endonucleases *Nco*I and *Hind*III, the infused gene was successfully cloned to pQE-60 (Figure 1). LTB-VacA1 had the nucleotide acid number of 465 bp (LTB387+LZ-VacA1 78). LTB-VacA2 had the nucleotide acid number of 465 bp (LTB387+LZ-VacA2 78). LTB-VacA3 had the nucleotide acid number of 489 bp (LTB387+LZ-VacA3 102). The amino acids of three LTB-VacA were deduced from the nucleotide acid sequences. LTB-VacA1 and LTB-VacA2 had 155 amino acids, and the *M_r* was about 17 000. LTB-VacA3 had 163 amino acids, and the molecular weight was about 17 900. The sequences of the three genes were correct by sequencing analyses.

Expression and purification of infused protein

The LTB-VacA1, 2, 3 proteins were expressed in the JM109 strain. In the SDS-PAGE, the three proteins were 14.13%, 15.51% and 14.79% of the total protein respectively. After purification with anti-LTB antibody affinity chromatography, the percentage of three proteins in the total proteins was improved to 69.26%, 70.18% and 75.35% respectively (Figure 2).

Serum antibody levels in infused protein

Intraperitoneal immunization with the infused protein and Freund's adjuvant resulted in a marked elevation of serum IgG antibody in all the 6 mice after three immunizations (Figure 3).

Figure 3 IgG against VacA induced by different LTB-VacA.

Seven days after the first immunization, the level of antibody was lower. The titer of the antibody was about 1:100. Seven days after the second immunization, the titer of the antibody had no remarkable changes. But 14 d after the third immunization, the titer of the anti-LTB-VacA1 antibody, the titer of the anti-LTB-VacA2 antibody and the titer of the anti-LTB-VacA3 antibody was increased to 1:800, 1:1 000 and 1:600 respectively. The biggest value of positive and negative in the three antibodies was 3.8, 4.2 and 3.2.

HeLa cell vacuolization

The preliminary experimental results showed when we added 10, 30, 40, 80 and 100 μ L culture supernatant, the cell vacuolization was produced. Because the space of wells in flasks well was limited, 100 μ L VacA protein was added into the culture medium. The ratio of cell vacuolization after we added 100 μ L protein was 49.52% (Figure 4).

The control serum, anti-VacA1 serum, anti-VacA2 serum and anti-VacA3 serum were incubated with 100 μ L VacA antigen for 4 h. Then we added the mixture and VacA protein in the flasks wells for 6 h. The result showed the control serum and 100 μ L VacA antigen could not reduce the ratio of cell vacuolization, but anti-VacA1 serum, anti-VacA2 serum, anti-VacA3 serum could decrease the ratio of cell vacuolization. The change rate of cell vacuolization is 30.41%, 20.20% and 14.17% respectively (Table 2).

Table 2 Inhibition of anti-LTB-VacA antibody on VacA toxin

Group	HeLa cells with vacuoles in total cells (%)	Change rate (%)
VacA toxin	49.52 \pm 2.77	0
Anti-LTB antibody (Control)	47.51 \pm 1.31	-4.05 \pm 1.61
Anti-LTB-VacA1 antibody	34.47 \pm 1.97	-30.41 \pm 2.41 ^b
Anti-LTB-VacA2 antibody	39.52 \pm 1.69	-20.20 \pm 2.07 ^b
Anti-LTB-VacA3 antibody	42.51 \pm 1.84	-14.17 \pm 2.27 ^a

^a $P < 0.05$, ^b $P < 0.01$ vs control.

DISCUSSION

Many methods could predict the epitopes of protein known as the primary structure, for example hydrophilicity scheme^[20], accessibility scheme^[21], antigenicity scheme^[22], flexibility scheme^[23,24] and secondary structure scheme^[17]. The antigenic epitopes are correlated with the characteristics, number, sequence of amino acid and protein conformation. Because the different prediction methods emphasize different biological information of antigens, several methods are considered in practice. In this study we chose the GOLDKEY software developed by the Experimental Group led by professor Jia-Jin Wu to analyse the characteristics of VacA protein including hydrophilicity, hydrophobicity, secondary structure, accessibility, flexibility and antigenicity. This software could predict the linear B epitope. At last we got 11 VacA candidate epitopes.

Due to the small molecular weight and the weakness of antigenicity of the antigen epitopes, the carrier or adjuvant must be linked to the epitopes^[25,26]. Several epitopes were joined in series and at last got 3 VacA candidate epitopes. LTB is an excellent protein adjuvant to facilitate the organism to produce the antibody epitopes, so we chose LTB to link the 3 epitopes.

Figure 4 Microscopy of large vacuoles induced by VacA in HeLa cells. A: Normal HeLa cells; B: Vacuolated HeLa cells (Original magnification: $\times 400$).

The experiment of Schodel enucleate that plasmid pFS2.2 was a carrier in which *LTB* gene could express soluble LTB and carry outer polypeptides. The experiment of Zhang showed that 21-bp nucleotide acids between LTB and the epitopes could enhance the antigenicity of the epitopes. In our study, 7 peptides were used as a linker to join LTB with the epitopes.

At the beginning, LTB-VacA was cloned into plasmid pFS2.2, but the gene could not express these proteins, and then the genes were cloned into plasmid pET22b (+) again. There was a signal peptide in plasmid pET22b (+) in which the gene could express the soluble protein and secrete the protein into periplasm. The soluble proteins would be purified through the anti-LTB antibody affinity chromatography. Contrary to our wishes, the proteins in pFS2.2 were not expressed as expected. Finally, infused proteins were cloned into plasmid pQE-60 and expressed in JM109, but the expressed proteins were inclusion bodies. The inclusion bodies were denatured with guanidine hydrochloride and nutured with dialysis, and LTB-VacA was purified through the anti-LTB antibody affinity chromatography.

Protein vacuolating toxin A is the only known virulence factor of *H. pylori*. Ninety minutes after VacA activation, the acidic vacuoles were induced in cells. Scientific researches showed that VacA was integrated with receptors in membranes to form an anionic channel. This channel could change the permeation characteristics of the membranes, so that the cells were damaged would undergo apoptosis. In this study, all the 3 antigen epitopes of VacA could induce antibody in mice. Although the antibody could inhibit the vacuolation of Hela cells at a certain extent, they did not inhibit the vacuoles entirely. There are two reasons for this result. First, these epitopes were a part of the neutralized epitopes of VacA, antibody to these epitopes combined with VacA did not destroy the toxicity of VacA, only suppressed the toxin partly. Second, the titer of the antibody was not enough to neutralize the toxin of VacA. Next we are going to settle the problem. First, these epitopes will be joined in series for several copies so that the titer of the antibody will be improved to inhibit the toxin of VacA. Second, we will construct deficient mutations to farther verify the neutralized epitopes of VacA.

Abstract

AIM: Activated pancreatic stellate cells (PSCs) are implicated in the pathogenesis of pancreatic inflammation and fibrosis, where oxidative stress is thought to play a key role. 4-hydroxy-2,3-nonenal (HNE) is generated endogenously during the process of lipid peroxidation, and has been accepted as a mediator of oxidative stress. The aim of this study was to clarify the effects of HNE on the activation of signal transduction pathways and cellular functions in PSCs.

METHODS: PSCs were isolated from the pancreas of male Wistar rats after perfusion with collagenase P, and used in their culture-activated, myofibroblast-like phenotype unless otherwise stated. PSCs were treated with physiologically relevant and non-cytotoxic concentrations (up to 5 μ mol/L) of HNE. Activation of transcription factors was examined by electrophoretic mobility shift assay and luciferase assay. Activation of mitogen-activated protein (MAP) kinases was assessed by Western blotting using anti-phosphospecific antibodies. Cell proliferation was assessed by measuring the incorporation of 5-bromo-2'-deoxyuridine. Production of type I collagen and monocyte chemoattractant protein-1 was determined by enzyme-linked immunosorbent assay. The effect of HNE on the transformation of freshly isolated PSCs in culture was also assessed.

RESULTS: HNE activated activator protein-1, but not nuclear factor κ B. In addition, HNE activated three classes of MAP kinases: extracellular signal-regulated kinase, c-Jun N-terminal kinase, and p38 MAP kinase. HNE increased type I collagen production through the activation of p38 MAP kinase and c-Jun N-terminal kinase. HNE did not alter the proliferation, or monocyte chemoattractant protein-1 production. HNE did not initiate the transformation of freshly isolated PSCs to myofibroblast-like phenotype.

CONCLUSION: Specific activation of these signal transduction pathways and altered cell functions such as collagen production by HNE may play a role in the pathogenesis of pancreatic disorders.

INTRODUCTION

In 1998, star-shaped cells in the pancreas, namely pancreatic stellate cells (PSCs), were identified and characterized^[1,2]. They are morphologically similar to the hepatic stellate cells that play a central role in inflammation and fibrogenesis of the liver^[3]. In normal pancreas, stellate cells are quiescent and can be identified by the presence of vitamin A-containing lipid droplets in the cytoplasm. In response to pancreatic injury or inflammation, they are transformed ("activated") from their quiescent phenotype into highly proliferative myofibroblast-like cells which express the cytoskeletal protein α -smooth muscle actin (α -SMA), and produce type I collagen and other extracellular matrix components. Many of the morphological and metabolic changes associated with the activation of PSCs in animal models of fibrosis also occur when these cells are grown in serum-containing medium in culture on plastic. There is accumulating evidence that PSCs, like hepatic stellate cells, are responsible for the development of pancreatic fibrosis^[1,2,4]. It has also been suggested that PSCs may participate in the pathogenesis of acute pancreatitis^[4,5]. In view of their importance in pancreatic fibrosis and inflammation, it is of particular importance to elucidate the molecular mechanisms underlying their activation. The activation of signaling pathways such as p38 mitogen-activated protein (MAP) kinase^[6] and Rho-Rho kinase pathway^[7] is likely to play a central role in PSC activation. However, the precise intracellular signaling pathways in PSCs are largely unknown.

The role of oxidative stress in the development of acute and chronic pancreatitis has been clarified^[8,9]. Reactive oxygen species and aldehydic end-products of lipid peroxidation, such as 4-hydroxy-2,3-nonenal (HNE), could act as mediators affecting signal transduction pathways, proliferation, and functional responses of target cells^[10-12]. HNE is a specific and stable end product of lipid peroxidation. It could be produced in response to oxidative insults^[13], and has been regarded to be responsible for many of the effects during oxidative stress *in vivo*^[13,14]. It reacts with DNA and proteins, generating various forms of adducts (cysteine, lysine, and histidine residues) that are capable of inducing cellular stress responses such as cell signaling and apoptosis^[14]. It has been shown that alcoholic chronic pancreatitis is characterized by the co-localization of evident lipid peroxidation, as assessed by immunoreactivity of HNE inside acinar cells, and the deposition of collagen type I in the fibrous septa and fibrotic stroma surrounding the pancreatic acini^[15]. The stronger HNE immunoreactivity at the periphery of acini raised the possibility that HNE might affect the cell functions of PSCs, but the effects of HNE on the signaling pathways and the regulation of cell functions in PSCs are unknown. We here report that HNE at physiologically relevant and non-cytotoxic concentrations activated activator protein-1 (AP-1) and three classes of MAP kinases in PSCs. In addition, HNE increased type I collagen production from PSCs. Specific

activation of these signal transduction pathways and altered cell functions such as collagen production by HNE may play a role in the pathogenesis of pancreatic disorders.

MATERIALS AND METHODS

Materials

3-(4, 5-dimethylthiazole-2-yl)-2, 5-diphenyltetrazolium bromide (MTT) was obtained from Dojindo (Kumamoto, Japan). Poly (dI.dC)-poly (dI.dC) and [γ - 32 P] ATP were purchased from Amersham Biosciences UK, Ltd. (Buckinghamshire, England). Collagenase P and recombinant human interleukin (IL)-1 β were from Roche Applied Science (Mannheim, Germany). Double-stranded oligonucleotide probes for AP-1 and nuclear factor κ B (NF- κ B) were purchased from Promega (Madison WI). Rat recombinant platelet-derived growth factor (PDGF)-BB was from R&D Systems (Minneapolis, MN). Rabbit antibodies against phosphospecific MAP kinases, total MAP kinases, and inhibitor of NF- κ B (IkB- α) were purchased from Cell Signaling Technologies (Beverly, MA). Rabbit antibody against glyceraldehyde-3-phosphate dehydrogenase (G3PDH) was from Trevigen (Gaithersburg, MD). HNE, SB203580, SP600125, and U0126 were from Calbiochem (La Jolla, CA). All other reagents were from Sigma-Aldrich (St. Louis, MO) unless specifically described.

Cell culture

All animal procedures were performed in accordance with the National Institutes of Health Animal Care and Use Guidelines. Rat PSCs were prepared from the pancreas tissues of male Wistar rats (Japan SLC Inc., Hamamatsu, Japan) weighing 200–250 g as previously described using the Nycodenz solution (Nycomed Pharma, Oslo, Norway) after perfusion with 0.3 g/L collagenase P^[16]. The cells were resuspended in Ham's F-12 containing 100 mL/L heat-inactivated fetal bovine serum (ICN Biomedicals, Aurora, OH), penicillin sodium, and streptomycin sulfate. Cell purity was always more than 90% as assessed by a typical star-like configuration and by detecting vitamin A autofluorescence. All experiments were performed using cells between passages two and five except for those using freshly isolated PSCs. Unless otherwise stated, we incubated PSCs in serum-free medium for 24 h before the addition of experimental reagents.

Cell viability assay

Cell viability was assessed by the MTT assay as previously described^[17]. After treatment with HNE for 24 h, MTT solution was added to the cells at a final concentration of 500 μ g/mL and the incubation continued at 37 °C for 4 h. After the incubation period, the medium was aspirated and the formazan product was solubilized with dimethylsulfoxide. Cell viability was determined by the differences in absorbance at wavelengths of 570 nm and 690 nm.

Intracellular peroxide production assay

Intracellular peroxide production was examined as previously described^[14]. Briefly, cells were incubated with 2',7'-dichlorofluorescein diacetate (DCF-DA) at 50 μ mol/L for 30 min at 37 °C, and then treated with experimental reagents for an additional 30 min at 37 °C. After chilled on ice, cells were washed with ice-cold PBS, scraped from the plate, and resuspended at 1×10^6 cells/mL in PBS containing 10 mmol/L EDTA. The fluorescence intensities of 2', 7'-dichlorofluorescein formed by the reaction of DCF-DA with peroxides of more than 10 000 viable cells from each sample were analyzed by FACSCaliber flow cytometer (Becton Dickinson Co. Ltd., Tokyo, Japan) with excitation and emission settings of 488 and 525 nm, respectively. Prior to data collection, propidium iodide was added to the

sample to gate out dead cells. Experiments were repeated at least twice with similar results. The data are expressed as one representative histogram.

Cell proliferation assay

Serum-starved PSCs (approximately 80% density) were treated with HNE at the indicated concentrations in the absence or presence of PDGF-BB (25 ng/mL). Cell proliferation was assessed using a commercial kit (Cell proliferation ELISA, BrdU; Roche Applied Science) according to the manufacturer's instruction. This is colorimetric immunoassay based on the measurement of 5-bromo-2'-deoxyuridine (BrdU) incorporation during DNA synthesis^[18]. After 24-hour-incubation with experimental reagents, cells were labeled with BrdU for 3 h at 37 °C, fixed, and incubated with peroxidase-conjugated anti-BrdU antibody. Then the peroxidase substrate 3,3',5,5'-tetramethylbenzidine was added, and BrdU incorporation was quantitated by differences in absorbance at wavelength 370 nm and 492 nm.

Nuclear extracts preparation and electrophoretic mobility shift assay

Nuclear extracts were prepared and electrophoretic mobility shift assay was performed as previously described^[19]. Double-stranded oligonucleotide probes for AP-1 (5'-CGCTTGATGAGT CAGCCGGA-3') and NF- κ B (5'-AGTTGAGGGGACTT TCCCAGGC-3') were endlabeled with [γ - 32 P]ATP. Nuclear extracts (approximately 5 μ g) were incubated with the labeled oligonucleotide probe for 20 min at 22 °C, and electrophoresed through a 40 g/L polyacrylamide gel. Gels were dried, and autoradiographed at -80 °C overnight. A 100-fold excess of unlabeled oligonucleotide was incubated with nuclear extracts for 10 min prior to the addition of the radiolabeled probe in the competition experiments.

Luciferase assay

Luciferase assays were performed as previously described^[20] using luciferase expression vectors containing two consensus AP-1 binding sites (TGACTCA), or two consensus NF- κ B binding sites (GGGACTTTCC), which were kindly provided by Dr. Naofumi Mukaida (Kanazawa University, Japan). Approximately 1×10^6 PSCs were transfected with 2 μ g of each luciferase expression vector, along with 40 ng of pRL-TK vector (Promega) as an internal control, using the FuGENE6 reagent (Roche Applied Science). After 24 h, the transfected cells were treated with HNE at 1 μ mol/L for an additional 24 h. At the end of the incubation, cell lysates were prepared using Pica Gene kit (Toyo Ink Co., Tokyo, Japan), and the light intensities were measured using a model Lumat LB9507 Luminescence Reader (EG&G Berthold, Bad Wildbad, Germany).

Western blot analysis

Activation of MAP kinases was examined by Western blot analysis using anti-phosphospecific MAP kinase antibodies as previously described^[21]. Cells were treated with HNE, and lysed in sodium dodecyl sulfate buffer (62.5 mmol/L Tris-HCl at pH 6.8, 20 g/L sodium dodecyl sulfate, 100 mL/L glycerol, 50 mmol/L dithiothreitol, 1 g/L bromophenol blue) for 15 min on ice. The samples were then sonicated for 2 s, heated for 5 min, and centrifuged at 12 000 g for 5 min to remove insoluble cell debris. Whole cell extracts (approximately 100 μ g) were fractionated on a 100 g/L sodium dodecyl sulfate-polyacrylamide gel. They were transferred to a nitrocellulose membrane (Bio-Rad, Hercules, CA), and the membrane was incubated overnight at 4 °C with rabbit antibodies against phosphorylated MAP kinases (extracellular signal-regulated kinase (ERK)1/2, c-Jun N-terminal kinase (JNK), or p38 MAP kinase). After incubation with peroxidase-conjugated goat anti-rabbit secondary

antibody for 1 h, proteins were visualized by using an ECL kit (Amersham Biosciences UK, Ltd.). Levels of total MAP kinases, I κ B- α , α -SMA, and G3PDH were examined in a similar manner.

Enzyme-linked immunosorbent assay

After a 24-h incubation, cell culture supernatants were harvested and stored at -80 °C until the measurement. Monocyte chemoattractant protein-1 (MCP-1) levels in the culture supernatants were measured by enzyme-linked immunosorbent assay (Pierce Biotechnology, Rockford, IL) according to the manufacturer's instructions.

Collagen assay

PSCs were incubated with HNE in serum-free medium for 48 h. Type I collagen released into the culture supernatant was quantified by enzyme-linked immunosorbent assay, as previously described^[22]. Briefly, immunoassay plates (Becton Dickinson, Franklin Lakes, NJ) were coated with diluted samples overnight at 4 °C. After blocking with 50 g/L dry milk in PBS, plates were incubated with goat anti-rat type I collagen antibody (SouthernBiotech, Birmingham, AL). After washing of the plate, rabbit anti-goat IgG antibody conjugated with alkaline phosphatase was added, and incubated. Finally, P-nitrophenylphosphate was added as a substrate, and the collagen levels were determined by differences in absorbance at wavelength 405 min 690 nm. Rat tail collagen type I was used as a standard. The collagen levels in each sample were normalized to the cellular DNA content, which was determined by a fluorometric assay, according to the method of Brunk *et al.*^[23]. The results are expressed as a percentage of the untreated control.

Activating effect of HNE on PSCs in culture

Freshly isolated PSCs were incubated with HNE (at 1 μ mol/L) in serum-free medium or 50 mL/L fetal bovine serum-containing medium. After 7-d incubation, morphological changes characteristic of PSC activation were assessed after staining with glial acidic fibrillary protein (GFAP) as previously described^[24] using a streptavidin-biotin-peroxidase complex detection kit (Histofine Kit; Nichirei, Tokyo, Japan). Briefly, cells were fixed with 100 mL/L methanol for 5 min at -20 °C, and then endogenous peroxidase activity was blocked by incubation in methanol with 3 mL/L hydrogen peroxide for 5 min. After immersion in normal goat serum for 1 h, the slides were incubated with rabbit anti-GFAP antibody at a dilution of 1:100 overnight at 4 °C. The slides were incubated with biotinylated goat anti-rabbit antibody for 45 min, followed by peroxidase-conjugated streptavidin for 30 min. Finally, color was developed by incubating the slides for several minutes with diaminobenzidine (Dojindo, Kumamoto, Japan). In addition, total cellular proteins (approximately 25 μ g) were prepared, and the levels of α -SMA and G3PDH were determined by Western blotting.

Statistical analysis

The results were expressed as mean \pm SD. Luminograms and autoradiograms are representative of at least three experiments. Differences between experimental groups were evaluated by the two-tailed unpaired Student's *t* test. A *P*-value less than 0.05 was considered statistically significant.

RESULTS

HNE was cytotoxic at high concentrations

Because HNE has been shown to be cytotoxic at high concentrations in several types of cells^[25], we first examined the effect of HNE on the cell viability of PSCs. PSCs were incubated with increasing concentrations of HNE for 24 h, and the cell viability was assessed by MTT assay. HNE up to 5 μ mol/L

did not alter the cell viability, but above 5 μ mol/L, HNE was cytotoxic (Figure 1). The results were also confirmed by trypan blue dye exclusion test (data not shown). Based on these results, we used HNE up to 5 μ mol/L in the subsequent experiments.

Figure 1 PSCs were incubated with HNE at the indicated concentrations in serum-free medium for 24 h. Cell viability was determined by the MTT assay, and the absorbance at 570 min 690 nm ("A.") of the sample is given. Data are shown as mean \pm SD (*n* = 6). ^a*P* < 0.05 vs control, ^b*P* < 0.01 vs control.

HNE was a potential inducer of oxidative stress

We examined the production of pro-oxidants using a peroxide-sensitive fluorescent probe, DCF-DA. This chemical is freely permeable to cells. Once inside the cells, it is hydrolyzed to DCF and trapped intracellularly. In the presence of peroxides, especially hydrogen peroxide, DCF is oxidized to fluorescent 2',7'-dichlorofluorescein, which can then be readily detected by flow cytometry^[14]. Treatment with HNE (at 5 μ mol/L) increased the peroxide-activated fluorescence intensity, indicating that HNE was a potential inducer of intracellular oxidative stress in PSCs (Figure 2).

Figure 2 PSCs were incubated with DCF-DA (at 50 μ mol/L) for 30 min and then treated with HNE (at 1 or 5 μ mol/L) for 30 min. The fluorescence intensity of more than 10 000 cells was analyzed using a flow cytometer.

HNE increased AP-1, but not NF- κ B binding activity

We next examined the effects of HNE on the activation of the transcription factors NF- κ B and AP-1. These transcription factors are important regulators of gene expression in response to many stimuli including proinflammatory cytokines and growth factors^[26,27]. PSCs were incubated with HNE, or IL-1 β for 1 h. Nuclear extracts were prepared, and the specific binding activities of AP-1 and NF- κ B were examined by electrophoretic mobility shift assay. HNE, as well as IL-1 β , increased the AP-1 binding activity (Figure 3A). The specificity of AP-1-specific DNA binding activity was demonstrated by the addition of a 100-fold molar excess of unlabeled AP-1 oligonucleotide, but not by unrelated NF- κ B oligonucleotide in competition assays (data not shown). In contrast, NF- κ B binding activity was induced by IL-1 β , but not by HNE (Figure 3B).

Figure 3 PSCs were treated with IL-1 β (at 2 ng/mL, lane 2) or HNE (at 5 μ mol/L, lane 4) in serum-free medium for 1 h. Nuclear extracts were prepared and subjected to electrophoretic mobility shift assay using AP-1 (panel A) or NF- κ B (panel B) oligonucleotide probes. Arrows denote specific inducible complexes competitive with cold double-stranded oligonucleotide probes (lane 3). Lane 1: control (serum-free medium only). \square : free probe.

HNE increased AP-1, but not NF- κ B dependent transcriptional activity

To confirm that AP-1 activation observed by electrophoretic mobility shift assay was functional, the effect of HNE on AP-1 dependent transcriptional activity was examined. PSCs were transiently transfected with NF- κ B- or AP-1-luciferase gene reporter constructs and assayed for the luciferase activity. As shown in Figure 4, HNE increased AP-1-dependent, but not NF- κ B-dependent luciferase activity. Phosphorylation and degradation of the inhibitory protein I κ B- α , and subsequent dissociation of this protein from NF- κ B were thought to be necessary for the activation^[26]. We also examined the effect of HNE on the degradation of I κ B- α by Western blotting. IL-1 β , but not HNE, induced transient degradation of I κ B- α , further supporting that HNE did not activate NF- κ B (Figure 4B).

Figure 4 HNE increased AP-1, but not NF- κ B, -dependent transcriptional activity. A: PSCs were transfected with the luciferase vectors (2 X AP-1 or 2 X NF- κ B) along with pRL-TK vector as an internal control. After 24 h, the transfected cells were treated with IL-1 β (at 2 ng/mL) or HNE (at 1 μ mol/L). After another 24-h incubation, intracellular luciferase activities were determined. The data represent mean \pm SD, calculated from three independent experiments as fold induction compared with the activity observed in control (serum-free medium only, "Con"). ^b P < 0.01 vs control. RLU: relative light

units. B: PSCs were treated with IL-1 β (at 2 ng/mL) or HNE (at 1 μ mol/L) in serum-free medium for the indicated times. Total cell lysates were prepared, and the level of I κ B- α was determined by Western blotting.

HNE activated MAP kinases

Induction of the expression of AP-1 components c-Fos and c-Jun by a variety of stimuli such as growth factors and cytokines is mediated by the activation of three distinct MAP kinases: ERK1/2, JNK, and p38 MAP kinase^[27,28]. Activation of these kinases occurs through phosphorylation^[27,28]. We determined the activation of these MAP kinases in HNE-treated cells by Western blotting using anti-phosphospecific MAP kinase antibodies. These antibodies recognize only phosphorylated forms of MAP kinases, thus allowing the assessment of activation of these kinases. HNE activated these three classes of MAP kinases in a time-dependent manner with peaking around 5 to 15 min (Figure 5).

Figure 5 PSCs were treated with HNE (at 1 μ mol/L) for the indicated times. Total cell lysates (approximately 100 μ g) were prepared, and the levels of activated, phosphorylated MAP kinases were determined by Western blotting using anti-phosphospecific antibodies. Levels of total MAP kinases were also determined.

Figure 6 PSCs were treated with HNE (at 0, 1, or 5 μ mol/L) in the absence or presence of PDGF (at 25 ng/mL) in serum-free medium. After 24-h incubation, cells were labeled with BrdU for 3 h. Cells were fixed, and incubated with peroxidase-conjugated anti-BrdU antibody. Then the peroxidase substrate 3,3', 5,5'-tetramethylbenzidine was added, and BrdU incorporation was quantitated by differences in absorbance at wavelength 370 nm 492 nm ("A.", optical density). Data are shown as mean \pm SD (n = 6). ^b P < 0.01 versus control (serum-free medium only), N.S.: not significant.

HNE did not alter basal and PDGF-BB-induced proliferation

We then examined the effects of HNE on basal and PDGF-induced proliferation. As previously reported^[16], PDGF-BB significantly increased proliferation. HNE did not affect either

basal or PDGF-BB-induced proliferation of PSCs (Figure 6).

HNE did not induce MCP-1 production

Activated PSCs acquired the proinflammatory phenotype; they might modulate the recruitment and activation of inflammatory cells through the expression of MCP-1^[29]. IL-1 β induced MCP-1 production, but HNE did not (Figure 7).

Figure 7 PSCs were treated with IL-1 β (2 ng/mL, "IL") or HNE (at 1 or 5 μ mol/L) in serum-free medium. After 24 h, culture supernatant was harvested, and the MCP-1 level was determined by enzyme-linked immunosorbent assay. Data shown are expressed as mean \pm SD ($n = 6$). ^b $P < 0.01$ versus control ("Con", serum-free medium only).

HNE increased type I collagen production

It has been shown that culture-activated PSCs express α -SMA and produce type I collagen. Indeed, α -SMA expression has been accepted as a marker of PSC activation^[1], and *in situ* hybridization techniques showed that α -SMA-positive cells were the principal source of collagen in the fibrotic pancreas^[4]. HNE increased the production of type I collagen (Figure 8). Our previous finding that ethanol and acetaldehyde induced collagen production through p38 MAP kinase^[30] prompted us to examine the role of MAP kinases in HNE-induced type I collagen production. Thus we employed specific inhibitors to block these pathways. A selective p38 MAP kinase inhibitor SB203580^[31], and a JNK inhibitor SP600125^[32] decreased type I collagen production. In contrast, U0126, a specific inhibitor of MAP kinase kinase activation and consequent ERK1/2 activation^[33], did not affect the collagen production. These results suggested that HNE induced type I collagen production through the activation of p38 MAP kinase and JNK, but not ERK pathway.

Figure 8 PSCs were treated with HNE (at 1 μ mol/L, lane 2) in the absence or presence of SB203580 (at 25 mmol/L, lane 3), SP600125 (at 10 μ mol/L, lane 4), or U0126 (at 5 μ mol/L, lane 5). After 48-h incubation, type I collagen released into the culture supernatant was quantified by enzyme-linked immunosorbent assay. The collagen levels in each sample were normalized to the cellular DNA content. The results are expressed as a percentage of the untreated control ("Con"). Data are shown as

mean \pm SD ($n = 6$). ^b $P < 0.01$ vs control (serum-free medium only, lane 1). ^d $P < 0.01$ vs HNE only (lane 2).

HNE did not initiate the transformation of freshly isolated PSCs to activated phenotype

Finally, we examined whether HNE initiated the transformation of PSCs from quiescent to myofibroblast-like phenotype in culture. Freshly isolated PSCs were incubated with HNE in serum-free medium or 50 mL/L serum-containing medium for 7 d. Morphological changes characteristic of PSC activation were assessed after staining with GFAP. After 7 d, PSCs cultured with 50 mL/L serum showed transformation into cells with a myofibroblast-like phenotype (Figure 9A). In contrast, PSCs treated with HNE were small and circular, with lipid droplets presenting in many cells and slender dendritic processes (Figure 9B), as PSCs treated with serum-free medium only (Figure 9C). In agreement with the morphological changes, significant expression of α -SMA was observed on d 7 in serum-treated PSCs, whereas HNE did not induce α -SMA expression.

Figure 9 A,B,C: Freshly isolated PSCs were incubated with 50 mL/L serum (panel A), HNE (at 1 μ mol/L, panel B), or serum-free medium (panel C) for 7 d. Morphological changes characteristic of PSC activation were assessed after staining with GFAP. Original magnification: $\times 10$ objective. D: Total cell lysates (approximately 25 μ g) were prepared from cells treated with serum-free medium ("Cont"), 50 mL/L serum ("FBS"), or HNE (at 1 μ mol/L) for 7 d, and the levels of α -SMA and G3PDH were determined by Western blotting.

DISCUSSION

It has been established that oxidative stress plays a critical role in the pathogenesis of both acute and chronic pancreatitis^[8,9]. HNE, an aldehydic end product of lipid peroxidation, is believed to be largely responsible for pathological effects observed during oxidative stress^[13]. The major effects of HNE produced during oxidative stress are believed to be damage to cellular components such as glutathione and proteins. However, recent studies have revealed that HNE at non-cytotoxic levels could potentially activate a stress response mechanism^[14]. In this study, we have shown for the first time that HNE, at non-cytotoxic concentrations, activated AP-1, but not NF- κ B, in PSCs. This selective pattern of activation was distinct from that elicited by IL-1 β and tumor necrosis factor- α , which also activated NF- κ B^[5]. In addition, HNE activated three classes of MAP kinases (ERK1/2, JNK, and p38 MAP kinase). HNE-induced type I collagen production was inhibited by SB203580, a p38 MAP kinase inhibitor, and by SP600125, a JNK inhibitor, suggesting

a role of p38 MAP kinase and JNK in the type I collagen production. The concentrations of HNE used in this study (up to 5 $\mu\text{mol/L}$) could be easily reached *in vivo* in conditions of mild to moderate oxidative stress, and were considered to be physiologically relevant^[13].

It has been shown that ethanol increased HNE protein adduct accumulation in the pancreas of rats^[34]. During pancreatic injury *in vivo*, PSCs might be exposed to HNE via two pathways: (1) exogenous exposure as a result of the generation of HNE by surrounding cells (e.g. acinar cells and inflammatory cells) or (2) endogenous exposure as a result of the generation of HNE within the cells. Casini *et al.*^[15] have shown that stronger HNE immunoreactivity was observed at the periphery of acini in chronic alcoholic pancreatitis. Under such a circumstance, it is likely that PSCs exogenously expose to HNE. Our present study is exclusively concerned with the effect of exogenously-delivered HNE on cell biology, and it remains to be clarified how results of this study correlated with the potential effect of HNE formed endogenously in the cell. It is likely that PSCs were exposed to endogenous HNE during ethanol consumption, because PSCs, in addition to pancreatic acinar cells^[35], had the capacity to metabolize ethanol to acetaldehyde via alcohol dehydrogenase-mediated oxidation of ethanol^[36].

Activated PSCs acquire the proinflammatory phenotype; they may modulate the recruitment and activation of inflammatory cells. We have reported that activated PSCs expressed MCP-1^[29] in response to IL-1 β and tumor necrosis factor- α *in vitro*. Indeed, MCP-1 expression by activated PSCs was shown to be increased in fibrous tissue sections from patients with chronic pancreatitis^[37]. In this study, HNE failed to induce NF- κ B activation and consequent MCP-1 production. The failure of HNE to induce MCP-1 expression is not surprising because the activation of NF- κ B has been shown to play a central role in MCP-1 expression in PSCs^[29]. This is in contrast to human endothelial cells where the AP-1 proteins c-Fos and c-Jun directly induce MCP-1 expression independently of the NF- κ B pathway^[38]. The effects of HNE on the activation of NF- κ B and AP-1 appeared to depend on the types of cells. In a similar manner to PSCs, HNE activated AP-1, but not NF- κ B, in murine and human macrophages^[39] and human hepatic stellate cells^[40]. On the other hand, HNE did not activate AP-1, but did attenuate IL-1 β - and phorbol ester-induced NF- κ B activation in human monocytic THP-1 cells^[41]. The inhibition of NF- κ B activation was mediated through the inhibition of I κ B phosphorylation and subsequent proteolysis^[41]. Recent reviews^[42,43] have emphasized that redox-dependent activation of NF- κ B was cell and stimulus specific as opposed to the concept that oxidative stress was a common mediator of diverse NF- κ B activators. Li and Karin^[42] reported that when a redox-regulated effect on NF- κ B was observed, it appeared to occur downstream from the I κ B kinase, at the level of ubiquitination and/or degradation of I κ B.

In this study, HNE activated three classes of MAP kinases in PSCs. This is in agreement with the previous study showing that HNE activated these three classes of MAP kinases in rat liver epithelial RL34 cells^[14]. In human hepatic stellate cells, Parola *et al.*^[40] reported that HNE formed adducts with the p46 and p54 isoforms of JNK, leading to the nuclear translocation and activation of these signaling molecules, and, in turn, the induction of the transcription factors c-jun and AP-1. Unlike human hepatic stellate cells, we showed that HNE induced phosphorylation of p46 and p54 JNK in rat PSCs. On the other hand, we have shown that activation of ERK played a central role in PDGF-BB-induced proliferation of PSCs^[16]. In spite of the ability to activate ERK, HNE failed to alter the proliferation regardless of the presence or absence of PDGF-BB, suggesting that activation of ERK is required but not sufficient for the proliferation of PSCs. This is in agreement with the concept

that activation of ERK, although necessary, may not be sufficient to justify the mitogenic properties of an agonist^[44].

We here showed that HNE did not initiate the transformation of quiescent PSCs. This is in disagreement with the previous reports showing that ethanol and acetaldehyde activated quiescent PSCs through the generation of oxidative stress^[36]. However, it should be noted that previous studies examining the effects of oxidative stress on the activation of hepatic stellate cells have reported conflicting results. Lee *et al.*^[45] reported that quiescent hepatic stellate cells were activated upon exposure to the pro-oxidant compound ascorbate/ferrous sulfate or the lipid peroxidation product malondialdehyde. Maher *et al.*^[46] reported that stimulatory effects of malondialdehyde only occurred after hepatic stellate cells had been preactivated by culture on plastic. Olynyk *et al.*^[47] reported that malondialdehyde and HNE decreased α -SMA expression in hepatic stellate cells at d 3 when compared to controls not incubated with the compounds. Previous studies have suggested that cytokines and growth factors such as transforming growth factor- β 1 and tumor necrosis factor- α induced the transformation of quiescent PSCs^[48,49]. These mediators were released or produced from inflammatory cells, platelets, and pancreatic acinar cells, during the course of pancreatitis^[48,49], leading to the activation of PSCs. Once activated, PSCs were sensitive to HNE, and showed profibrogenic responses, thus playing a role in the pathogenesis of pancreatic fibrosis.

In agreement with the previous study in human hepatic stellate cells^[40], HNE increased type I collagen production in PSCs. Lee *et al.*^[45] reported that oxidative stress-induced collagen synthesis in hepatic stellate cells was associated with induction of transcription factors NF- κ B and c-myc^[45]. In rat PSCs, the role of NF- κ B was unlikely because HNE failed to activate NF- κ B. Although the molecular mechanisms by which HNE increased type I collagen production in hepatic stellate cells were not further pursued, we have shown that HNE-induced type I collagen production was mediated by the activation of JNK and p38 MAP kinase. Along this line, it has been reported that malondialdehyde increased α 2(I) collagen gene activity through JNK activation in hepatic stellate cells^[50]. It should be noted that the biological action of HNE may result in multiple effects within the complex network of events occurring in the process of fibrosis following reiterated pancreatic injury, with the resulting overall biological effects being influenced by the actual HNE concentration, the target cell or cells available, and the presence of growth factors and other mediators in the microenvironment. Nevertheless, our findings that HNE induced type I collagen production suggest possible links between oxidant stress, aldehyde-adduct formation, and pancreatic fibrosis. Very recently, it has been reported that HNE acted as a potent pro-fibrogenic stimulus in the expression of genes involved in extracellular matrix deposition in activated hepatic stellate cells^[51]. Indeed, we have found that HNE increased the transcriptional activity of prolyl 4-hydroxylase (α), a key enzyme that catalyzes the formation of 4-hydroxyproline (Satoh *et al.* manuscript in preparation). Elucidation of the functions of PSCs would provide better understanding and rational approaches for the control of pancreatic inflammation and fibrosis.

ACKNOWLEDGEMENT

The authors thank Dr. Naofumi Mukaida for the luciferase vectors.

Abstract

AIM: To predict wild human heme oxygenase-1 (whHO-1) and hHO-1 His25Ala mutant (Δ hHO-1) structures, to clone and express them and analyze their activities.

METHODS: Swiss-PdbViewer and Antheprot 5.0 were used for the prediction of structure diversity and physical-chemical changes between wild and mutant hHO-1. hHO-1 His25Ala mutant cDNA was constructed by site-directed mutagenesis in two plasmids of *E. coli* DH5 α . Expression products were purified by ammonium sulphate precipitation and Q-Sepharose Fast Flow column chromatography, and their activities were measured.

RESULTS: rHO-1 had the structure of a helical fold with the heme sandwiched between heme-heme oxygenase-1 helices. Bond angle, dihedral angle and chemical bond in the active pocket changed after Ala25 was replaced by His25, but Ala25 was still contacting the surface and the electrostatic potential of the active pocket was negative. The mutated enzyme kept binding activity to heme. Two vectors pBHO-1 and pBHO-1(M) were constructed and expressed. Ammonium sulphate precipitation and column chromatography yielded 3.6-fold and 30-fold higher purities of whHO-1, respectively. The activity of Δ hHO-1 was reduced 91.21% after mutation compared with whHO-1.

CONCLUSION: Proximal His25 ligand is crucial for normal hHO-1 catalytic activity. Δ hHO-1 is deactivated by mutation but keeps the same binding site as whHO-1. Δ hHO-1 might be a potential inhibitor of whHO-1 for preventing neonatal hyperbilirubinemia.

INTRODUCTION

Heme oxygenase (HO) is responsible for the physiological breakdown of heme into equimolar amounts of biliverdin, carbon monoxide, and iron. Three isoforms (HO-1, HO-2, and HO-3) have been identified. HO-1 is ubiquitous, its mRNA levels and activity can be increased several-fold by heme, other metalloporphyrins, transition metals, and stress-inducing stimuli. In contrast, HO-2 is present chiefly in brain and testes and is virtually uninducible. HO-3 has very low activity; its physiological functions probably include heme binding. The HO system has been strongly highlighted for its potential significance in maintaining cellular homeostasis. Nevertheless the physiological correlations of the three isoforms and their reciprocal interrelation have been poorly understood^[1-4].

HO-1 regulates the levels of serum bilirubin as the rate-limiting enzyme in heme degradation pathway. Recent reports showed that HO-1 was identified as an ubiquitous stress protein and it had important physiological roles. Overexpression of HO-1 gene resulted in protection from cytokine-induced oxidative stress^[5], inflammation^[6-9], apoptosis^[10-17] and proliferation^[18-25].

It has been reported that histidine (His) residues at positions 25, 84, 119 and 132 in HO-1 sequence are conserved in rat, human, mouse and chicken. These histidines may be important for heme-binding^[26]. His25 and His132 mutants were reported for the proximal heme iron ligand in rat heme oxygenase-1 (rHO-1)^[27]. The unambiguous spectroscopic demonstration that His25 is the proximal iron ligand leaves the role of His132 uncertain. His 25 is essential for heme degradation activity of the enzyme. The research on human HO-1 (hHO-1) structure has been shown that hHO-1 embodies a novel protein fold that consists primarily of α -helices, and the heme is held between two of these helices^[28].

It is unclear whether hHO-1 mutant has the same characteristics and displays catalytic inactivity but binding heme as Ala replacing His 25. In this study, the characteristics of wild hHO-1 (whHO-1) and its mutant were predicted by bio-informatics method. On the basis of the results, the truncated hHO-1 cDNA mutant was constructed by site-directed mutagenesis. Two expression plasmids, pBHO-1 and pBHO-1 (M) containing whHO-1 and hHO-1 His25Ala mutant (Δ hHO-1), respectively, were constructed and expressed in *E. coli*, and then isolated, purified and analyzed of their activities analysis.

MATERIALS AND METHODS

Materials

Swiss-PdbViewer and Antheprot 5.0 were from GlaxoSmithKline R&D and the Swiss Institute of Bioinformatics and CBI, BeiJin University respectively. Plasmid pBHO-1 was provided by Lightning and Ortiz de Montellano (Department of Pharmaceutical Chemistry, University of California). Mutation primer was synthesized by Boya Company. Anti-HO-1 antibody, RNase and DNase were purchased from Sigma. Restriction endonucleases were from Haojia Company, Q-Sepharose Fast Flow Anion exchange column was from Amersham Pharmacia. pBS II KS+/-, pGEM3Z and *E. coli* strain DH5 α were stored in author's laboratory.

Methods

Structure analysis of hHO-1 and its mutant Swiss-PdbViewer and Antheprot 5.0 were used to analyze the structure diversity and physical-chemical changes between whHO-1 and Δ hHO-1. Then the prime structure was refined by energy minimization. Gromos96 was used as force field. The molecular surfaces and electrostatic potential were calculated. The rationality of the resulted model was validated by Ramachandran plot.

Construction of Δ hHO-1 expression vector pBHO-1 (M) *EcoRI/SalI* digested fragment of pBHO-1, which is from expression vector containing the truncated hHO-1 cDNA (804 bp), was cloned into the *EcoRI/SalI* sites of plasmid pBSKS II to construct plasmid pBSHO-1. hHO-1 His25Ala mutant cDNA could be amplified by PCR using pBSHO-1 as template. The mutation primer (5'-GACAGCATGCCCCAGGATTTGTCAGAGGCCCTGAAGGAGGCCACCAAGGAGGTGGCCACCC-3') and reverse primer (5'-AACAGCTATGACCATG-3') were chosen, which have changed the His 25 codon CAC into Ala codon GCC. The reaction conditions were: at 94 °C for 5 min, followed by 94 °C for 1 min, at 55 °C for 1 min, 72 °C for 2 min, with amplification repeated for 30 cycles, and finally at 72 °C for 10 min. The mutant cDNA was gel-purified and digested with *SphI/SalI* and then cloned into *SphI/SalI* sites of plasmid pGEM3Z. hHO-1 His25Ala mutant cDNA was screened by restriction digestion and confirmed by sequencing in pGEM3ZHO-1(M). Verified hHO-1 mutant cDNA was obtained from *SphI/SalI* digested fragment of pGEM3ZHO-1 (M) and then cloned into pBHO-1, thus the expression vector containing Δ hHO-1 was designated as pBHO-1 (M) (Figure 1).

Figure 1 Construction of expression vector pBHO-1(M).

Expression and purification of whHO-1 and Δ hHO-1 A total of 5.0 mL inoculum was set up from plates with fresh colonies of transformed *E. coli* DH5 α and incubated at 37 °C for 12-16 h. From the fresh cultures 400 μ L was used to inoculate into 40 mL cultures of the same media. The cells were grown at 37 °C until A_{600} reached 0.3-0.5, then added with 0.5 mmol/L IPTG for 18 h. The expression products were harvested and analyzed with sodium dodecyl sulfate-polyacrylamide gel (SDS-PAGE) and Western blotting at the time points of 7, 9 and 11 h, respectively, after addition of IPTG. Then 500 mL inoculum in medium was incubated under same condition. The harvested cells were centrifuged at 6 000 r/min for 20 min at 4 °C, washed once in PBS, and then centrifuged at 6 000 r/min for 10 min at 4 °C. The cells were lysed in 50 mmol/L Tris buffer (pH 8.0) containing 1 mmol/L dithiothreitol, 1 mmol/L EDTA, 1 mmol/L phenylmethanesulfonyl fluoride (PMSF) and sonicated for 10 min. Then the cells were centrifuged at 13 000 r/min for 1 h at 4 °C. The supernatant was collected and ammonium sulfate was added to a final concentration of 30%, and the solution was stirred for 60 min. Following centrifugation (13 000 r/min for 20 min), ammonium sulfate concentration was raised to 60% of saturation. The pellets precipitated by ammonium sulfate were collected and resuspended in 0.1 mol/L potassium phosphate (pH 7.4) and then dialyzed against 1 g/L NH_4HCO_3 for 4 h ($\times 4$ -times). Protein 130 mg was applied to a Q-Sepharose Fast Flow anion column and eluted with a step gradient of 50 mmol/L Tris-HCl (pH 7.4) (buffer A) containing 0-0.5 mol/L NaCl (buffer B). The fractions containing hHO-1 protein were pooled together and applied to Q-Sepharose Fast Flow anion column again. The protein was eluted with a step gradient of 50 mmol/L Tris-HCl (pH 8.4) (buffer C) containing 0-0.5 mol/L NaCl (buffer B). The gradient was increased linearly from 0-100% buffer B. Fractions containing hHO-1 protein were pooled and dialyzed against 1 g/L NH_4HCO_3 for 4 h ($\times 4$ -times).

Western blotting Blot analysis was carried out as previously described^[29]. Microsomal protein samples were fractionated by SDS-PAGE under denaturing conditions. The separated proteins were electrophoretically transferred to a nitrocellulose membrane. Western blotting was carried out using monoclonal antibody to hHO-1 and the immunoreactive bands were visualized by staining (1 mol/L Tris-HCl pH 9.5, 1 mol/L MgCl_2 , 0.1 mg/mL nitro-blue tetrazolium, 0.1 mg/mL 5-bromo-4-chloro-3-indolylphosphate-toluidine salt).

Analysis of whHO-1 and Δ hHO-1 activities Protein samples were incubated with heme (50 μ mol/L), rat liver cytosol (5 mg/mL), MgCl_2 (2 mmol/L), glucose-6-phosphate dehydrogenase (1 unit), glucose-6-phosphate (2 mmol/L), and NADPH (0.8 mmol/L) in 0.5 mL of 0.1 mol/L potassium phosphate buffer (pH 7.4), for 60 min at 37 °C. Reaction was stopped by putting the tubes on ice, and reaction solution was extracted with chloroform. The rate of bilirubin formation was monitored at 464 nm by a spectrophotometer and then calculated using an extinction coefficient of 40.0 mmol/(L.cm)^[29].

RESULTS

Whole structure comparison between whHO-1 and Δ hHO-1

In heme-heme oxygenase-1 complex, heme is sandwiched in whHO-1. When Ala 25 replaces His 25, the complex structure does not change. In the heme-binding pocket, Ala 25 loses contacting with heme as His 25 does. The molecular surface has a catalytic reaction pocket, which includes Thr 21, His 25, Ala 28, Glu 29, Gly 139, Asp140, Gly 143. After binding heme, His 25 still lies on the surface but Gly139, Asp140 and Gly143 are covered by heme. When Ala 25 replaces His 25, Ala 25 still lies in the surface (Figure 2). In activity domain, the bond angle, dihedral angle and chemical bond appear differently after Ala 25 replacing His 25 (Table 1, Figure 3).

Figure 2 Prime simulated structure of whHO-1 and Δ hHO-1. Red: heme; Black: His 25 and Ala 25. Ala 25 loses contacting with heme as His 25 does in the heme-binding pocket.

Figure 3 Changes of bond angle, dihedral angle and chemical bond.

Figure 4 Molecular surfaces and electrostatic potential of whHO-1 and Δ hHO-1. The electrostatic potential of active pocket is -1.800 .

Table 1 Bond angle, dihedral angle and the distance between atoms of Δ hHO-1

		Prime simulation	Optimized simulation
Bond angle	C24-N-CA	119.12	121.79
	CA-C-N26	115.92	115.12
Distance between atoms	CB-FE	5.55	5.58
	CA-FE	6.28	6.26
Dihedral angle	ω	175.40	175.61
	ϕ	-40.78	-34.45
	ψ	-60.70	-62.89

Though Ala 25 replaces His 25, the molecular surfaces and electrostatic potential changed little (Figure 4). The electrostatic potential of active pocket was still negative. The mutagenesis had no apparent effect on molecular surface. Ramachandran plot showed that dihedral angles ϕ (-33.98) and ψ (-64.46) were in rational range.

Antheprot 5.0 analysis also showed that there was no alteration in the secondary structure between whHO-1 and Δ hHO-1. Garnier, Gibrat, DPM and homology predicted the same results. Physical-chemical characteristics showed somewhat alteration. Hydrophobicity increased, while hydrophilicity decreased. There was no change in antigenicity, helical membranous regions and solvent accessibility.

Construction of pBHO-1(M) containing Δ hHO-1

hHO-1 cDNA was site mutated at His 25 (to Ala) by PCR with pBSHO-1 as the template. The 866-bp PCR product showed that nucleotide 3-773 sequences encoded hHO-1 domain from 25-265 AA. The mutant cDNA was cloned into the *SphI/SalI* sites of plasmid pGEM3Z for constructing plasmid pGEM3ZHO-1 (M). hHO-1 His25Ala mutant cDNA was confirmed by sequencing in pGEM3ZHO-1 (M). The verified hHO-1 mutant cDNA from the *SphI/SalI* digested fragment of pGEM3ZHO-1 (M) was cloned into pBHO-1, thus the expression vector containing Δ hHO-1 was designated as pBHO-1 (M) (Figure 1). Both whHO-1 and Δ hHO-1 cDNAs equally encoded the proteins containing 265 amino acids with a M_r 30 500.

Expression and identification of whHO-1 and Δ hHO-1 in *E. coli* DH5 α

E. coli DH5 α was transformed by pBHO-1 and pBHO-1 (M), respectively, and treated with 0.5 mmol/L IPTG for 18 h at 37 °C. Equal quantities of cells transformed with different expression vectors were lysed by protein electrophoresis buffer. Untransformed *E. coli* sample was used as the negative control. As shown in Figure 5, *E. coli* DH5 α transformed pBHO-1 or pBHO-1 (M) highly expressed whHO-1 and Δ hHO-1 with a M_r 30 500. Meanwhile, *E. coli* DH5 α not treated with IPTG also expressed whHO-1 and Δ hHO-1, but its expression yield

was significantly lower than that of transformed cells. Analysis of cell lysates showed that whHO-1 and Δ hHO-1 were mainly present in the supernatants.

Figure 5 Western blotting of whHO-1 and Δ hHO-1 expressed in DH5 α . Lanes 1, 2: Expression products of pBHO-1 and pBHO-1(M) in DH5 α induced with IPTG; lane 3: Control; lanes 4, 5: Expression products of pBHO-1 and pBHO-1(M) in DH5 α not treated with IPTG; lane 6: Marker.

Purification of whHO-1 and Δ hHO-1

The protein with a M_r 30 500 was purified by 30–60% ammonium sulphate precipitation and analyzed by SDS-PAGE.

After precipitated with ammonium sulphate, whHO-1 sample was applied to Q-Sepharose Fast Flow anion column (pH 7.4). The first peak containing whHO-1 (No. 1–3 tubes) was collected (Figure 6A) and loaded on Q-Sepharose Fast Flow anion column (pH 8.4) again. whHO-1 was shown to be eluted in the second peak (No. 49–63 tubes) (Figure 6B). All samples were analyzed by SDS-PAGE and Western blotting in order to identify the separation efficiency. The activity of whHO-1 after purification was 30-fold higher than that in the initial lysates (Table 2).

Figure 6 Q-Sepharose Fast Flow column chromatography. A: pH 7.4 buffer; B: pH 8.4 buffer.

Precipitated Δ hHO-1 was further purified in the same way as described above. One purified protein's M_r was 30 500. The purified whHO-1 and Δ hHO-1 are shown on SDS-PAGE (Figure 7).

Table 2 whHO-1 activities after different purification

	Supernatant of DH5 α lysates	30–60% (NH ₄) ₂ SO ₄	Q-Sepharose fast flow
whHO-1 activity (U·mg ⁻¹ ·h ⁻¹)	0.5	1.8	15
Purification fold	1.0	3.6	30

Figure 7 SDS-PAGE analysis of purified whHO-1 and Δ hHO-1. Lane 1: Marker; lane 2: whHO-1; lane 3: Δ hHO-1.

DISCUSSION

An understanding of the structure and function of hHO-1 is of importance in the context of human diseases, but due to limited accessibility and difficulties associated with their purification from microsomal membranes, little direct information has been available until the expression of rHO-1 in *E. coli* was achieved. The protein thus obtained is soluble, easily purified, and fully active. Encouraged by this result, the research on HO-1 including hHO-1 has been thriving.

hHO-1 is anchored to the endoplasmic reticulum membrane via a stretch of hydrophobic residues at the C-terminus. While full-length hHO-1 consists of 288 residues, a truncated version with residues 1–265 has been expressed as a soluble active enzyme in *E. coli*. This recombinant enzyme precipitated from ammonium sulfate solution but without a high purity for studies^[30].

In the present studies, we acquired the structures of hHO-1 with residues 1–265 and its mutant using Swiss-PdbViewer. Due to the high similarity between hHO-1 and its mutant, the hHO-1 structure was used as template. Through homology modeling, template selection and target-template alignment, a molecular backbone and side chains were built in one step. Results demonstrated that the refined model, as well as the entire assay, was valid. Predictions of the structure showed that hHO-1 and its mutant had similar electrostatic potential suggesting that they have similar affinity to heme in electrostatic potential. Ala is a hydrophobic amino acid without chemical activity, and its side chain is short. So it has no interference with binding through steric hindrance.

Rat His25Ala HO-1 provides a new approach to construct hHO-1 mutant. hHO-1 mutants were prepared in which residue His25 was replaced by Ala using site-directed mutagenesis to understand the role of hHO-1 His25 in keeping the activity of this enzyme. In this study, the synthesized forward primer was applied in which His25 codon was replaced by the Ala codon. This cDNA was cloned into the expression vector pBHO-1, then pBHO-1 and pBHO-1(M) were transformed into *E. coli*, which were used to express whHO-1 and Δ hHO-1. Although the endogenous protein expression of *E. coli* could disturb the measurement of whHO-1 and its mutants by SDS-PAGE, hHO-1 and its mutant expression could be detected by anti-HO-1 antibody in Western blotting.

Our study shows that precipitation with ammonium sulfate can enrich whHO-1 and Δ hHO-1 in the lysates. Compared with the whHO-1 activity, Δ hHO-1 activity was reduced by

91.21%. It suggests that His25 is crucial for the catalytic activity of hHO-1, the proximal His25 ligand is critically required for normal hHO-1 catalysis. The results are similar to previous reports^[31-35].

hHO-1 has anti-inflammatory^[6-9], antiapoptotic^[10-17], and antiproliferative^[18-25] effects, and salutary effects on neonatal hyperbilirubinemia^[36]. The results show a valid way to control the concentration of bilirubin in human, since hHO-1 is the rate-limiting enzyme in the catabolic reaction of heme, which ultimately produces bilirubin in human body. High-level bilirubin in newborns, patients with the Crigler-Najjar type I syndrome and certain hepatic disorders can result in hyperbilirubinemia, especially in patients whose bilirubin is impaired for developmental or genetic reasons. Currently clinical methods are only to eliminate formed bilirubin. There is no effective way to inhibit bilirubin production, and Δ hHO-1 would be a potential inhibitor for bilirubin production.

Abstract

AIM: To investigate the effects of the SNPs (rs411021, rs436045, rs427811, rs385039 and rs809912) on gene expression and further identify the susceptibility genes of type 2 diabetes.

METHODS: Ten allele fragments (49 bp each) were synthesized according to the 5 SNPs mentioned above. These fragments were cloned into luciferase reporter gene vector and then transfected into HepG2 cells. The activity of the luciferase was assayed. Effects of the SNPs on RNA splicing were analyzed by bioinformatics.

RESULTS: rs427811T allele and rs809912G allele enhanced the activity of the reporter gene expression. None of the 5 SNPs affected RNA splicing.

CONCLUSION: SNPs in protein kinase *Cz* (*PKCZ*) gene probably play a role in the susceptibility to type 2 diabetes by affecting the expression level of the relevant genes.

INTRODUCTION

Type 2 diabetes is a highly heterogeneous chronic disease characterized by metabolic disorder of blood glucose, its onset involves a number of susceptibility genes. Since 1996, locating and cloning the predisposing genes of type 2 diabetes, as well as the functional investigation, has become one of the hot spots worldwide in type 2 diabetes research. Based on genomic screening technology, it was reported firstly among Western population in succession that type 2 diabetes susceptibility

genes located on different chromosomes^[1-23]. The susceptibility genes were localized on chromosome 9 in Chinese population^[24]. According to the case-control analysis in the region of 1p36.33-1p36.23, our research group found that one SNP locus, rs436045 in protein kinase *Cz* (*PKCZ*) gene, was linked to type 2 diabetes in Chinese population, and the haplotype block has been identified. While analyzing the haplotype which consists of the 5 SNPs (rs411021, rs436045, rs427811, rs385039, rs809912), we noticed that, in the case group, the haplotype CGTAG showed a significantly higher frequency than that in control group, whereas the frequency of haplotype TAGGA decreased significantly ($P < 0.01$, OR = 1.625), it implied that the changes of those haplotypes related to the onset of type 2 diabetes in Chinese^[25]. However, it is still unclear whether haplotypes play a role during the episode of the disease.

To determine the biological function of those haplotypes, we investigated their influence on gene expression by bioinformatics approach and reporter gene activity determination system, which would provide a basis for further research.

In the previous work, we found that the 5 SNPs at the introns of *PKCZ* gene located in the same haplotype block in case group, and the haplotype they formed was clearly associated with type 2 diabetes mellitus. In order to determine the susceptibility loci associated with type 2 diabetes, we performed functional analysis on 5 SNPs.

MATERIALS AND METHODS

Identification of SNPs in the coding region of *PKCZ* gene

Coding region (from exon 4 to exon 13 or from rs1878745 to rs262642) of *PKCZ* gene was investigated for SNPs (cSNP) by sequencing. Ten unrelated type 2 diabetic patients and 10 control subjects from Han population in China were enrolled in a case-control study. Primers were designed by Primer 3.0 program (http://zeno.well.ox.ac.uk:8080/gitbin/primer3_www.cgi) and each PCR product was limited within about 500 base pairs. The sequencing results from ABI377 sequencer were analyzed through PhredPhrap/consed program to identify functional SNPs.

Analysis of the effect of 5 intron SNPs on mRNA splicing

The distance from the SNP to the splicing point in exon was determined based on the published genome sequence. According to this information, we preliminarily estimated whether the SNP site influences gene splicing.

Search of the information on PKC family member

The location and sequence of other PKC family members were obtained by means of bioinformatics. Then, different spliceosomes from other family members residing in the sequence of *PKCZ* were analyzed.

Analysis of the introns where 5 SNPs located

Each SNP and the intron sequence around the loci were compared with the data in cDNA database (www.sanbi.ac.za) to reveal the sequence homology. The open reading frames in this sequence were analyzed, and then the amino acid was

blast using the (www.ncbi.nlm.nih.gov) protein database in search of the sequence homology.

Effects of SNPs on gene expression by transient transfection

Ten alleles corresponding to the 5 SNPs in *PKCZ* gene were cloned into pGL3-promoter vector in the direction from 5' to 3' (Table 1). Meanwhile, HepG2 cells were cultured with DMEM (Gibco, LOS angeles, USA) containing 100 mL/L fetal bovine serum. Then, the cells (1.5×10^5 - 2×10^6) were transfected with pGL3-promoter vector (1 uL) or recombinant vector with Lipofectamine transfection reagent (Promega, madison, USA). The transfection rate was assayed by using pRL-SV40 DNA (100 ng, Promega, madison, USA) as an internal control. Forty-eight hours post transfection, the luciferase activity was determined by the Dual-Luciferase® Reporter Assay System using pRL-SV40 as an internal control.

RESULTS

SNPs in the coding region of *PKCZ* gene

While seeking for functional SNPs by sequencing the exons around the 13 intron SNPs discovered in the previous work, we found no new ones except for the rs1878745 corresponding to NCBI database. It suggested that the disease loci probably did not exist in the coding region.

Influence of positive SNP on the *PKCZ* gene expression

To locate the disease SNP, we investigated the effect of the 5 positive SNPs (rs411021, rs436045, rs427811, rs385039, and rs809912) lying in the same haplotype block on *PKCZ* gene expression. The influence of the 5 SNPs over RNA splicing was evaluated since all the 5 SNPs lay in the introns. The distance of the SNPs from the upstream and downstream of the splicing site are respectively as the following: rs411021 (3 535 bp, 5 283 bp), rs436045 (4 770 bp, 4 048 bp), rs427811 (8 729 bp, 89 bp), rs385039 (1 629 bp, 57 bp), and rs809912 (>2 kb, 2 057 bp). Those are comparatively long distant to 5' splice donor site, 3' receptor site and the internal vertex, suggesting that they have little association with pre-mRNA splicing. In addition, we estimated if differential splicing occurs between *PKCZ* gene and other PKC family members. Although there are at least 11 family

members besides *PKCZ*, none of them locate on chromosome 1, which negates the 'differential splicing supposition'. The location of introns where 5 SNPs located was analyzed. As a first step, we compared the intron sequence around the loci of each of the 5 SNPs with the data in cDNA database (www.sanbi.ac.za) in order to reveal the sequence homology. Result showed that the introns had no coding function because neither cDNA sequence homology nor protein sequence homology by ORF analysis was found. But this result needs to be further confirmed by Northern blotting. And finally, the effects of the SNPs on gene expression were investigated. Transfected HepG2 cell containing pGL3-promoter reporter gene vector was used to detect the activity of the reporter gene that could reflect indirectly whether the fragment inserted affected gene expression. Statistical analysis showed a significant difference between the two SNPs of rs4278111 and rs809912. In rs4278111, the reporter gene activity of T allele was 1.5 times that of the G allele, while in rs809912, in G allele it was 1.7 times that of A allele (Table 2). Therefore, these two SNPs will probably affect the expression level of *PKCZ* gene.

Table 2 Transcriptional regulatory activity of each construct of *PKCZ* in HepG2 cells

Construct	Relative luciferase activity	P

DISCUSSION

PKCZ is a member of serine/threonine protein kinase family, belonging to atypical PKC, and independent of both calcium and diacylglycerol (DAG)^[26]. It is insensitive to PKC inhibitors and cannot be activated by phorbol ester. *PKCZ* protein is thought to function downstream of phosphatidylinositol 3-kinase (PI 3-kinase) in insulin signaling pathway and plays a role in promoting the translocation and activation of GluT4 from the cytosol to membranes which will accelerate the glucose transport in skeletal muscle and adipocytes^[27-30]. In addition, *PKCZ* can induce negative feedback to the signaling pathway through phosphorylating IRS-1^[31,32]. Insulin-stimulated glucose transport is defective in type 2 diabetes mellitus, and this defect can be ameliorated via correcting PRKC-zeta/lambda activation defect^[33], suggesting that the transport deficiency is at least partly associated with the activation defect of *PKCZ*. Our previous research showed that *PKCZ* is related to susceptibility to type 2 diabetes mellitus in Chinese population. If so, whether genetic polymorphism of *PKCZ* gene will influence the pathways associated with blood glucose regulation by affecting its gene expression, and increase the susceptibility to this disease ultimately? Based on bioinformatics research and reporter gene activity determination system, our data provide first evidence that intron SNP loci in *PKCZ* gene affect gene expression. Horikawa^[34] has reported that gene expression was under the influence of the 3 intron SNPs in *CAPN10* gene, the

susceptibility gene of type 2 diabetes in Mexican American. Such kind of result was also reported by other groups, for example, an SNP in *COL1N1* gene can change the binding site of transcription factor Sp1 thereby influencing the gene expression, resulting in the decline of bone density as well as osteoporosis^[35].

In our experiment, we found the two alleles (rs427811T and rs809912G) that had a relatively high frequency in type 2 diabetic patients could improve the reporter gene expression, apparently in conflict with our predicted result. This phenomenon might be explained by the hypothesis that *PKCZ* gene was involved in other signaling pathways and its relation to the disease was more complicated than we had estimated. Till now, there have been no reports that *PKCZ* gene expression is changed in the tissues of type 2 diabetic patients. But PED/PEA-15, a substrate of PKC, was reported to increase *PKCZ* gene expression in the patient's tissues^[36], which inhibited insulin stimulated glucose transportation. Thus, the high expression of PED/PEA-15 gene probably plays a role in insulin resistance of type 2 diabetes. Our next goals are to determine whether *PKCZ* interacts with PED/PEA-15 in insulin signaling pathway, and whether PED/PEA-15 or its analogue is involved in the inhibition of the insulin stimulated glucose transport via another signal pathway.

Abstract

AIM: To induce the tolerance of rat liver allograft by dendritic cells (DCs) modified with NF- κ B decoy oligodeoxynucleotides (ODNs).

METHODS: Bone marrow (BM)-derived DCs from SD rats were propagated in the presence of GM-CSF or GM-CSF+IL-4 to obtain immature DCs or mature DCs. GM-CSF+IL-4-propagated DCs were treated with double-strand NF- κ B decoy ODNs containing two NF- κ B binding sites or scrambled ODNs to ascertain whether NF- κ B decoy ODNs might prevent DC maturation. GM-CSF-propagated DCs, GM-CSF+NF- κ B decoy ODNs or scrambled ODNs-propagated DCs were treated with LPS for 18 h to determine whether NF- κ B decoy ODNs could prevent LPS-induced IL-12 production in DCs. NF- κ B binding activities, costimulatory molecule (CD40, CD80, CD86) surface expression, IL-12 protein expression and allostimulatory capacity of DCs were measured with electrophoretic mobility shift assay (EMSA), flow cytometry, Western blotting, and mixed lymphocyte reaction (MLR), respectively. GM-CSF-propagated DCs, GM-CSF+IL-4-propagated DCs, and GM-CSF+NF- κ B decoy ODNs or scrambled ODNs-propagated DCs were injected intravenously into recipient LEW rats 7 d prior to liver transplantation and immediately after liver transplantation. Histological grading of liver graft rejection was determined 7 d after liver transplantation. Expression of IL-2, IL-4 and IFN- γ mRNA in liver graft and in recipient spleen was analyzed by semiquantitative RT-PCR. Apoptosis of liver allograft-infiltrating cells was measured with TUNEL staining.

RESULTS: GM-CSF-propagated DCs, GM-CSF+NF- κ B decoy ODNs-propagated DCs and GM-CSF+ scrambled ODNs-propagated DCs exhibited features of immature DCs, with similar low level of costimulatory molecule (CD40, CD80, CD86) surface expression, absence of NF- κ B activation, and few allostimulatory activities. GM-CSF+IL-4-propagated DCs displayed features of mature DCs, with high levels of costimulatory molecule (CD40, CD80, CD86) surface expression, marked NF- κ B activation, and significant allostimulatory activity. NF- κ B decoy ODNs completely abrogated IL-4-induced DC maturation and allostimulatory activity as well as LPS-induced NF- κ B activation and IL-12

protein expression in DCs. GM-CSF+NF- κ B decoy ODNs-propagated DCs promoted apoptosis of liver allograft-infiltrating cells within portal areas, and significantly decreased the expression of IL-2 and IFN- γ mRNA but markedly elevated IL-4 mRNA expression both in liver allograft and in recipient spleen, and consequently suppressed liver allograft rejection, and promoted liver allograft survival.

CONCLUSION: NF- κ B decoy ODNs-modified DCs can prolong liver allograft survival by promoting apoptosis of graft-infiltrating cells within portal areas as well as down-regulating IL-2 and IFN- γ mRNA and up-regulating IL-4 mRNA expression both in liver graft and in recipient spleen.

INTRODUCTION

Dendritic cells (DC) play a critical role in the initiation and regulation of immune response and are instrumental in the induction and maintenance of tolerance^[1-7]. The function of DCs is regulated by their state of maturation. Immature DCs resident in nonlymphoid tissues such as normal liver are deficient at antigen capture and progressing^[8,9], whereas mature DCs, resident in secondary lymphoid tissues, are potent antigen-presenting cells (APC), which can induce naive T-cell activation and proliferation^[9-13]. The ability of DCs to initiate immune responses is determined by their surface expression of major histocompatibility complex (MHC) gene products and costimulatory molecules (CD40, CD80, CD86), and the secretion of the immune regulator, interleukin (IL)-12^[9-18]. Immature DCs that express surface MHC class II, but deficient in surface costimulatory molecules and few expressions of IL-12, can induce T-cell anergy^[8,19,20], and inhibit immune reactivity^[21,22].

Immature donor-derived DCs that are deficient in surface costimulatory molecules freshly isolated from commonly transplanted organs, can induce alloAg-specific T cell anergy *in vitro*^[23]. These DCs prolong survival of fully allogeneic grafts in rodents, in some cases, indefinitely^[24,25]. In addition, pharmacologic inhibition of DC maturation in nonhuman primates is associated with the induction of organ transplant tolerance^[26]. Moreover, immature human DCs have been shown to induce T regulatory cells *in vitro*^[27] and to promote Ag-specific T cell tolerance in healthy volunteers^[28]. Thus, DCs offer potential both for therapy of allograft rejection and promotion of transplant tolerance.

The inherent ability of DCs to traffic exquisitely to T cell areas of secondary lymphoid tissues^[8,29] and to regulate immune responses makes them attractive targets for manipulation with genes encoding immunosuppressive molecules, such as IL-4, IL-10, CTLA4Ig, Fas ligand (CD95L), or transforming growth factor (TGF)- β 1, that suppress T cell response by various

mechanisms. A potential obstacle to the successful use of genetically engineered DCs for therapeutic immunosuppression is their maturation/activation *in vivo* following interactions with proinflammatory factors that may overcome the desired effect of transgene products. Recent studies showed that both DC maturation and immunostimulatory ability depended on NF- κ B-dependent gene transcription^[29-34], inhibition of NF- κ B activation could suppress DC maturation/activation induced by IL-4 or LPS stimulation^[29,34,35], and DCs treated with NF- κ B decoy oligodeoxynucleotides (ODNs) containing specific NF- κ B binding sites could induce tolerance of cardiac allograft^[29,34].

Although genetically engineered DCs have been used in tolerance induction of cardiac allograft, there are few evidences that genetically engineered DCs can be used to induce tolerance of liver allograft. In the present study, whether NF- κ B decoy ODNs-treated DCs could prolong liver allograft survival in rats was studied.

MATERIALS AND METHODS

NF- κ B decoy ODNs

Double-stranded NF- κ B decoy ODNs or scrambled ODNs (as a control for NF- κ B decoy ODNs) were generated using equimolar amounts of single-stranded sense and antisense phosphorothioate-modified oligonucleotide containing two NF- κ B binding sites (sense sequence 5'-AGGGACTTTCCGCTG-GGGACTTTCC-3', NF- κ B binding sites bold lines and underlined)^[34] and scrambled oligonucleotide (sense sequence 5'-TTGCCGTACCTGACTTAGCC-3')^[36]. Sense and antisense strands of each oligonucleotide were mixed in the presence of 150 mmol/L PBS, heated to 100 °C, and allowed to cool to room temperature to obtain double-stranded DNA.

Propagation of bone marrow-derived DC populations

Bone marrow cells harvested from femurs of normal SD rats were cultured in 24-well plates (2×10^6 per well) in 2 mL of RPMI 1640 complete medium supplemented with antibiotics, 10 mL/L fetal calf serum (FCS) and 4.0 ng/mL recombinant rat GM-CSF to obtain immature DCs. In addition to GM-CSF, 10 ng/mL recombinant rat IL-4 was added to cultures to obtain mature DCs. To select plates, 10 μ mol/L NF- κ B decoy or scrambled ODNs was added at the initiation of culture of DCs^[34] to test the ability of NF- κ B decoy ODNs to inhibit IL-4-induced DC maturation. Cytokine-enriched medium was refreshed every 2 d, after gentle swirling of the plates, half of the old medium was aspirated and an equivalent volume of fresh, cytokine-supplemented medium was added. Thus, nonadherent granulocytes were depleted without dislodging clusters of developing DC attached loosely to a monolayer of plastic-adherent macrophages. Nonadherent cells released spontaneously from the clusters were harvested after 7 d. In certain experiments, after propagation for 7 d, GM-CSF-propagated DCs, GM-CSF+ NF- κ B decoy ODNs - propagated DCs and GM-CSF + scrambled ODNs - propagated DCs were cultured with 10 μ g/mL LPS for 18 h to test the ability of NF- κ B decoy ODNs to prevent LPS-induced IL-12 production in DCs.

Phenotypical features of DCs

Expression of cell surface molecules was quantitated by flow cytometry as described in our previous study. Aliquots of 2×10^5 DCs propagated for 7 d *in vitro* were incubated with the following primary mouse anti-rat mAbs against CD40, CD80, CD86, or rat IgG as an isotype control for 60 min on ice [1 μ g/mL diluted in PBS/(10 mL/L FCS)]. Cells were washed with PBS/(10 mL/L FCS) and labeled with FITC-conjugated goat anti-mouse IgG, diluted 1/50 in PBS/(10 mL/L FCS) for 30 min on ice. At the end of this incubation, the cells were washed, propidium iodide/PBS were added, and the cells were subsequently analyzed by a FACS -

4 200 flow cytometer.

DCs allostimulatory capacity

One-way mixed leukocyte reactions (MLR) were performed in 96-well, round-bottomed microculture plates. Graded doses of γ -irradiated (20Gy) allogeneic (SD) stimulator cells (DCs) were added to 2×10^5 nylon wool-eluted LEW rat splenic T cells (responders) and maintained in complete medium for 72 h in 50 mL/L CO₂ in air at 37 °C. [³H]thymidine (1 μ Ci/well) was added for the last 18 h of culture. Cells were harvested onto glass fiber mats using an automatic system, and [³H]thymidine incorporation was determined by a liquid scintillation counter. Results were expressed as mean \pm SD.

Isolation of nuclear proteins

Nuclear proteins were isolated from DC extract by placing the sample in 0.9 mL of ice-cold hypotonic buffer [10 mmol/L HEPES (pH 7.9), 10 mmol/L KCl, 0.1 mmol/L EDTA, 0.1 mmol/L ethylene glycol tetraacetic acid, 1 mmol/L DTT, protease inhibitors (aprotinin, pepstatin, and leupeptin, 10 mg/mol/L each)]. Homogenates were incubated on ice for 20 min, vortexed for 20 s after adding 50 μ L of 100 g/L Nonidet P-40, and then centrifuged for 1 min at 4 °C in an Eppendorf centrifuge. Supernatants were decanted, nuclear pellets after a single wash with hypotonic buffer without Nonidet-P40 were suspended in an ice-cold hypertonic buffer [20 mmol/L HEPES (pH 7.9), 0.4 mol/L NaCl, 1 mmol/L EDTA, 1 mol/L DTT, protease inhibitors], incubated on ice for 30 min at 4 °C, mixed frequently, and centrifuged for 15 min at 4 °C. Supernatants were collected as nuclear extracts and stored at -70 °C. Concentrations of total proteins in the samples were determined according to the method of Bradford.

Electrophoretic mobility shift assay (EMSA) for NF- κ B activation of DCs

NF- κ B binding activity was performed in a 10- μ L binding reaction mixture containing 1 \times binding buffer [50 mg/L of double-stranded poly (dI-dC), 10 mmol/L Tris-HCl (pH 7.5), 50 mmol/L NaCl, 0.5 mmol/L EDTA, 0.5 mmol/L DTT, 1 mmol/L MgCl₂, and 100 mL/L glycerol], 5 μ g of nuclear protein, and 35 fmol of double-stranded NF- κ B consensus oligonucleotide (5'-AGT TGAGGGGACTTT CCCAGGC-3') that was endly labeled with γ -³²P (111 TBq/mmol at 370 GBq⁻¹) using T4 polynucleotide kinase. The binding reaction mixture was incubated at room temperature for 20 min and analyzed by electrophoresis on 70 g/L nondenaturing polyacrylamide gels. After electrophoresis, the gels were dried by a gel-drier and exposed to Kodak X-ray films at -70 °C.

Western blotting for IL-12 protein expression in DCs stimulated with LPS

GM-CSF-propagated DCs, GM-CSF+ NF- κ B decoy ODNs-propagated DCs and GM-CSF + scrambled ODNs-propagated DCs were cultured with 10 μ g/mL LPS for 18 h. DCs were starved in serum-free medium for 4 h at 37 °C. These cells were washed twice with cold PBS, resuspended in 100 μ L lysis buffer (1 mL/L Nonidet P-40, 20 mmol/L Tris-HCl, pH 8.0, 137 mmol/L NaCl, 100 mL/L glycerol, 2 mmol/L EDTA, 10 μ g/mL leupeptin, 10 μ g/mL aprotinin, 1 mmol/L PMSF, and 1 mmol/L sodium orthovanadate), and total cell lysates were obtained. Homogenates were centrifuged at 10 000 g for 10 min at 4 °C. Cell lysates (20 μ g) were electrophoresed on SDS-PAGE gels, and transferred to PVDC membranes for Western blot analysis. Briefly, PVDC membranes were incubated in a blocking buffer for 1 h at room temperature, then incubated for 2 h with Abs against IL-12 p35 and IL-12 p40 and IL-12 p70. Membranes were washed and incubated for 1 h with HRP-labeled horse anti-goat or goat anti-rabbit IgG. Immunoreactive bands were visualized by ECL detection reagents. The binding bands were quantified by a

scanning the densitometer of a bio-image analysis system. The results were expressed as a relative optical density.

Liver transplantation

Sixty male LEW rats and sixty male SD rats weighing 250–300 g were used in all experiments. Allogeneic liver transplantation model was established using a combination of SD rats with LEW rats. All operations were performed under ether anesthesia in sterile conditions. Orthotopic liver transplantation was performed according to the method described in our previous study. Normal saline (group A), 1×10^7 GM-CSF-propagated DCs (group B), 1×10^7 GM-CSF+IL-4-propagated DCs (group C), and 1×10^7 GM-CSF+ NF- κ B decoy ODNs or scrambled ODNs-propagated DCs (group D or group E) were injected intravenously through the penile vein into recipient LEW rats 7 d prior to liver transplantation and immediately after liver transplantation, respectively. Liver graft tissues and recipient spleen samples ($n = 8$) were harvested 7 d after liver transplantation and immediately frozen in liquid nitrogen and kept at -80°C until use. Part of the liver graft tissues was sectioned and preserved in 40 g/L formaldehyde.

Histology

Part of liver tissues was sectioned and preserved in 40 g/L formaldehyde, embedded in paraffin, and stained with hematoxylin and eosin. Histological grading of rejection was determined according to the criteria described by Williams.

Apoptosis of liver graft-infiltrating cells (GIC)

Apoptotic cells in tissue sections were detected with the *in situ* cell death detection kit. Liver graft tissue sections were dewaxed and rehydrated according to standard protocols. Tissue sections were incubated with proteinase K (20 $\mu\text{g}/\text{mL}$ in 10 mmol/L Tris/HCl, pH 7.4–8.0) for 15 to 30 min at $21\text{--}37^\circ\text{C}$. Endogenous peroxidase activity was quenched with blocking solution (3 mL/LH₂O₂ in methanol) for 30 min at room temperature before exposure to TUNEL reaction mixture at 37°C for 60 min. After washed in stop wash buffer, peroxidase (POD) was added to react for 30 min at 37°C . DAB-substrate was used for color development, and the sections were counterstained with Harris' hematoxylin. TUNEL staining was mounted under glass coverslip and analysed under a light microscope.

Semiquantitative RT-PCR assay for expression of IL-2, IL-4 and IFN- γ mRNA in liver graft and spleen

IL-2, IL-4 and IFN- γ mRNA expression was determined by semiquantitative RT-PCR amplification in contrast with house-keeping gene β -actin, respectively. Total RNA from 10 mg liver allograft and recipient spleen tissue was extracted using TripureTM reagent. First-strand cDNA was transcribed from 1 μg RNA using AMV and an Oligo(dT)₁₅ primer. PCR was performed in a 25 μL reaction system containing 10 μL cDNA, 2 μL 10 mmol/L dNTP, 2.5 μL 10 \times buffer, 2.5 μL 25 mmol/L MgCl₂, 2 μL specific primer, 5 μL water and 1 μL Taq (35 cycles: at 95°C for 60 s, at 59°C for 90 s, and at 72°C for 10 s). Primers^[37–39] used in PCR reactions were as follows: IL-2, 5' primer 5'-CAT GTA CAGCA TGCAGCTCGCATCC-3', 3' primer 5'-CCACCACAGTTGCTG GCTCATCATC-3', to give a 410-bp PCR product; IL-4, 5' primer 5'-TGATGGGTCTCAGCCCCACCTTGC-3', 3' primer 5'-CTT TCAGTGTGTGAGCGTGGACTC-3', to give a 378-bp PCR product; IFN- γ , 5' primer 5'-AAGACAACCAGGCCATCAGCA-3', 3' primer 5'-AGCCACAGTGTGAGTTCAGTC-3', to give a 547-bp product; β -actin, 5' primer 5'-ATGCCATCC TGCGT CTGGACCTGGC-3', 3' primer 5'-AGCATTGCGGTGCAC GATGGAGGG-3', to give a 607-bp product. PCR products of each sample were subjected to electrophoresis in a 15 g/L agarose gel containing 0.5 mg/L ethidium bromide. Densitometrical

analysis using NIH image software was performed for semiquantification of PCR products, and mRNA expression was evaluated by the band-intensity ratio of IL-2, IL-4 and IFN- γ to β -actin, and presented as percent of β -actin (%).

Statistical analysis

Statistic analysis of data was performed using the *t*-test and rank sum test, $P < 0.05$ was considered statistically significant.

RESULTS

NF- κ B decoy ODNs inhibited IL-4 or LPS - induced NF- κ B activation in DCs

To confirm whether NF- κ B decoy ODNs might specifically bind to NF- κ B, analysis of NF- κ B activity was performed with nuclear extracts obtained from GM-CSF-propagated DCs, GM-CSF+IL-4-propagated DCs, GM-CSF+LPS-propagated DCs, GM-CSF+IL-4+ODNs-propagated DCs and GM-CSF+LPS+ODNs-propagated DCs by EMSA. As shown in Figure 1, EMSA analysis showed no NF- κ B activation in GM-CSF-propagated DCs but significant NF- κ B activation in IL-4 or LPS-stimulated DCs. NF- κ B decoy ODNs completely inhibited IL-4 or LPS-induced NF- κ B activation in DCs, whereas scrambled ODNs had little effect on inhibition of IL-4 or LPS-induced NF- κ B activation in DCs.

Figure 1 Inhibition of IL-4 or LPS-induced NF- κ B activation in DCs by NF- κ B decoy ODNs. Nuclear proteins of GM-CSF DCs, GM-CSF + IL-4 DCs, GM-CSF+IL-4 + NF- κ B decoy ODNs DCs, GM-CSF+IL-4 + scrambled ODNs DCs, GM-CSF + LPS DCs, GM-CSF+LPS+ NF- κ B decoy ODNs DCs and GM-CSF+LPS+ scrambled ODNs DCs were measured by EMSA (lanes 1–7).

NF- κ B decoy ODNs inhibited IL-4 - induced costimulatory molecule surface expression in DCs

Functional maturation of DCs was associated with up-regulation of costimulatory molecules (CD40, CD80, and CD86). To test the ability to inhibit DC maturation, NF- κ B decoy ODNs or scrambled ODNs were added at the initiation of culture of GM-CSF+IL-4-stimulated SD rat BM-derived DCs. After culture for 7 d, surface expression of CD40, CD80, and CD86 was analyzed by flow cytometry. Figure 2 shows the effects of ODNs on phenotype of the cultured DCs in the presence of GM-CSF+IL-4. Flow cytometric analysis showed GM-CSF-propagated DCs exhibited immature phenotypical features with very low levels of CD40, CD80 and CD86 surface expression, GM-CSF+IL-4-propagated DCs displayed mature phenotypical features with high level of CD40, CD80, and CD86 surface expression. NF- κ B decoy ODNs prevented IL-4-induced DCs maturation, and maintained DCs in the immature state, with low levels of surface costimulatory molecule expression. Whereas the scrambled ODNs could not prevent IL-4-induced DCs maturation, and maintained DCs in the mature state, with similar high levels of surface costimulatory molecule expression compared with GM-CSF+IL-4-propagated DCs (data not shown).

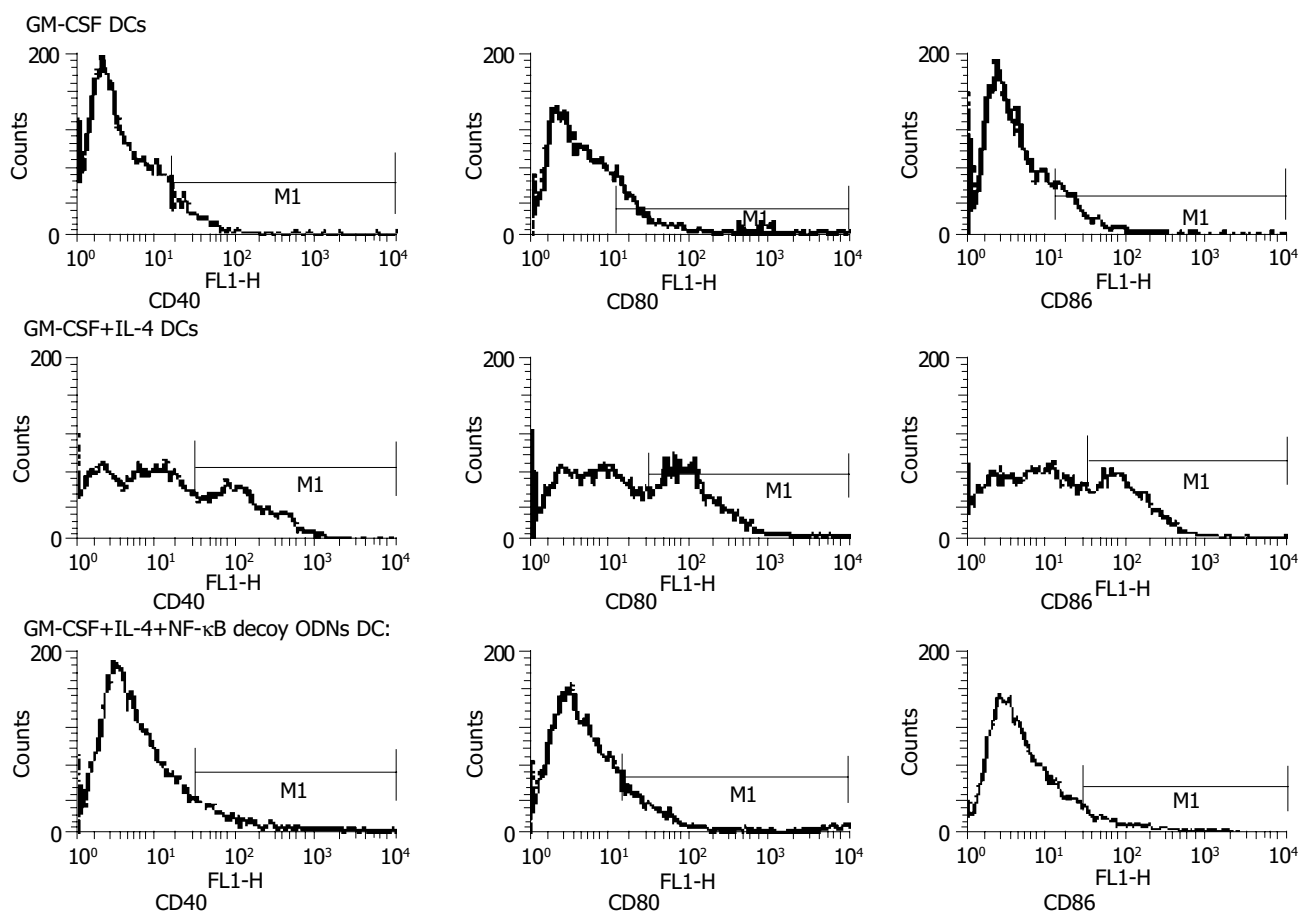

Figure 2 Suppression of IL-4-induced costimulatory molecule expression in DCs by NF- κ B decoy ODNs.

Figure 3 Suppression of IL-12 protein expression in LPS-stimulated DCs by NF- κ B decoy ODNs. Protein extracts from GM-CSF DCs, GM-CSF+LPS DCs, GM-CSF+LPS+Nf- κ B decoy ODNs DCs and GM-CSF+LPS+scrambled ODNs DCs were measured by Western blot (lane 1-4).

NF- κ B decoy ODNs abrogated LPS-induced IL-12 protein expression in DCs

Previous studies showed that IL-12 protein expression was significantly up-regulated in mature DCs^[10,17,19,40]. To further confirm whether NF- κ B decoy ODNs might prevent DC maturation, LPS-induced IL-12 protein (p35, p40 and p70) expression in DCs was measured. As shown in Figure 3, very low level of IL-12 protein was detected in GM-CSF DCs, and markedly high level of IL-12 protein was detected in LPS-stimulated DCs ($P < 0.001$). NF- κ B decoy ODNs completely abrogated the LPS-induced production of IL-12 protein in DCs, whereas scrambled ODNs had almost no effect on down-regulation of LPS-induced IL-12 protein expression in DCs.

DCs allostimulatory capacity was inhibited by NF- κ B decoy ODNs

The effect of NF- κ B decoy ODNs on DCs immunostimulatory activity was evaluated by *in vitro* MLR. Graded number of γ -irradiated DCs (SD) was cultivated for 72 h with a fixed number of allogeneic (LEW) splenic T cells in MLR. The results of a representative experiment are shown in Figure 4. In comparison with IL-4 stimulated mature DCs or IL-4+scrambled ODNs-propagated DCs, which were potent inducers of DNA synthesis and consistent with their mature surface phenotype, IL-4+Nf- κ B

decoy ODNs-propagated DCs induced only a minimal T cell proliferation. The poor stimulatory capacity of IL-4+Nf- κ B decoy ODNs DCs remained unchanged after a longer incubation with allogeneic T cells (4- or 5-d MLR, data not shown). The results suggested that allostimulatory capacity of DCs was inhibited by NF- κ B decoy ODNs.

Figure 4 Suppression of allostimulatory function of IL-4-stimulated DCs by NF- κ B decoy ODNs. ^b $P < 0.001$ vs IL-4+Nf- κ B decoy ODNs-propagated DCs.

NF- κ B decoy ODNs-treated DCs prolonged donor-specific liver allograft survival

To examine the effect of NF- κ B decoy ODNs-treated DCs on liver allograft survival *in vivo*, 1×10^7 unmodified immature bone marrow-derived DCs from SD rats (GM-CSF DCs), GM-CSF+IL-4-propagated mature DCs, and GM-CSF+NF- κ B decoy ODNs or scrambled ODNs-propagated immature DCs were injected intravenously through the penile vein into recipient LEW rats 7 d prior to liver transplantation and immediately after liver transplantation, respectively. Table 1 and Figure 5 show the effect of DCs on liver allograft rejection and recipient survival. GM-CSF+IL-4-propagated mature DCs accelerated the liver allograft rejection and shortened the survival time of recipient animals. Immature donor DCs (GM-CSF or GM-CSF+scrambled ODNs-propagated DCs) significantly suppressed liver allograft rejection and prolonged graft survival compared with untreated controls. In comparison with GM-CSF or GM-CSF+scrambled ODNs-propagated DCs, NF- κ B decoy ODNs-treated DCs exerted a marked effect on liver allograft rejection and recipient survival, and significantly suppressed the liver allograft rejection and prolonged survival time of recipient animals.

Table 1 Rejection stages of liver allografts

Rejection stages	Group A (n)	Group B (n)	Group C (n)	Group D (n)	Group E (n)
0	0	1	0	6	2
1	2	6	0	2	6
2	6	1	2	0	0
3	0	0	6	0	0

Group B vs group A, $u = 2.475$, $P < 0.05$; Group C vs group A, $u = 2.951$, $P < 0.01$; Group D vs group A, $u = 3.298$, $P < 0.01$; Group D vs group B, $u = 2.416$, $P < 0.05$; Group E vs group A, $u = 0.901$, $P > 0.05$.

NF- κ B decoy ODNs-treated DCs promoted apoptosis of liver allograft-infiltrating cells in portals

Although the precise mechanisms remain unclear, spontaneous acceptance of liver grafts in mice has been associated with high levels of apoptosis in GIC population^[41]. In contrast, FL liver allografts that were rejected acutely showed reduced apoptotic activity in GIC within portal areas and enhanced apoptosis of hepatocytes^[42]. These data suggested a critical immunoregulatory role of apoptosis in determining the outcome of hepatic allografts. To determine whether the prolongation of

liver allografts survival induced by NF- κ B decoy ODNs-treated DCs was associated with enhanced apoptosis of GIC, apoptotic activity in the graft was examined by TUNEL staining with immunohistochemistry analysis. *In situ* TUNEL staining of liver graft sections revealed that a certain level of apoptosis of GIC was induced by immature DCs (GM-CSF or GM-CSF+scrambled ODNs-propagated DCs), and mature DCs appeared to protect GIC from apoptosis. The greatest degree of apoptosis of GIC within portal areas of liver grafts was induced by NF- κ B decoy ODNs-treated DCs (Figure 6). These data strongly suggested that augmentation of apoptosis of activated GIC within portal areas of liver grafts might be critical in promoting the tolerance of liver allografts.

Figure 5 Prolongation of survival of liver allograft recipient by NF- κ B decoy ODNs-treated DCs. ^b $P < 0.001$ vs group A, ^d $P < 0.001$ vs group A, ⁱ $P < 0.001$ vs group C, ^h $P < 0.001$ vs group A, ^j $P < 0.001$ vs group B, ^l $P < 0.001$ vs group B, ^a $P > 0.05$ vs group B.

Figure 6 Augmentation of apoptosis of liver allograft-infiltrating cells in portals, by NF- κ B decoy ODNs-treated DCs ($\times 400$).

Figure 7 Suppression of IL-2 and IFN- γ mRNA expression and up-regulation of IL-4 mRNA expression both in liver graft and in recipient spleen by NF- κ B decoy ODNs-modified DCs.

NF- κ B decoy ODNs-treated DCs suppressed IL-2 and IFN- γ mRNA but elevated IL-4 mRNA expression both in liver graft and in recipient spleen

To determine the relationship of specific cytokine production to the outcome of liver transplantation, cytokine mRNA expression in liver graft and recipient spleen 7 d after liver transplantation was examined by RT-PCR assay. IL-2, IL-4 and IFN- γ mRNA were readily detected both in liver graft and in recipient spleen 7 d after liver transplantation in animals from group A. Administration of immature DCs (group B and group E) partially down-regulated IL-2 mRNA and INF- γ mRNA expression and partially up-regulated IL-4 mRNA expression in liver graft and recipient spleen. Administration of IL-4 stimulated mature DCs (Group C) significantly up-regulated expression of IL-2 and IFN- γ mRNA but markedly down-regulated IL-4 mRNA expression in liver graft and recipient spleen ($P < 0.001$ vs group A, B, D, E. Statistic data not shown). However, administration of NF- κ B decoy ODNs-modified DCs (group D) significantly suppressed expression of IL-2 and IFN- γ mRNA and significantly elevated expression of IL-4 mRNA both in liver grafts and in recipient spleen ($P < 0.001$ vs group A, B, C, E. Statistic data not shown). Taken together, these results suggested that prolongation of liver allograft survival induced by NF- κ B decoy ODNs-modified DCs might be associated with down-regulation of IL-2 and IFN- γ production and up-regulation of IL-4 production in liver graft and recipient lymphoid tissue.

DISCUSSION

It is accepted that both donor and recipient DCs mediate the rejection of graft in organ transplantation. Thus, conversion of these two sets of DCs to specifically inactivate recipient alloreactive T cells should allow the long-term acceptance of graft in the absence of continuous immunosuppression. In the present study, we showed that stably immature DCs modified with NF- κ B decoy ODNs markedly suppressed the rejection of liver allograft and prolonged liver allograft survival.

The ability of DCs to traffic to T cell areas of secondary lymphoid tissues and subsequently direct immune responses makes them ideal candidates for cell-based therapies of allograft rejection. Several studies showed that immature donor DCs, deficient in surface costimulatory molecules, could induce T-cell hyporesponsiveness^[20-22] and prolong graft survival in unmodified hosts^[43,44].

Several strategies have been used to arrest the maturation of DCs and to potentiate their tolerogenicity. While some have shown their promising, all have significant disadvantages. CsA could inhibit DC function, but its effect was weak and temporary, easily to be overcome by cytokines such as IL-4^[45]. CsA may inhibit DC maturation *in vivo*, but also interferes with signal transduction through the T cell receptor complex, thus impairing the development of antigen-specific tolerance. Indeed, CsA interferes with T cell maturation and selection and can lead to generation of autoreactive T cells. Additionally, CsA is associated with significant toxicity. Antibodies to fusion proteins specific for cell-surface molecules (anti-CD40, CTLA4Ig) could prevent DC costimulation of T cells^[46]. However, antibodies and fusion proteins have a limited half-life. Late up-regulation of DC costimulatory molecules upon encountering the host microenvironment requires treatment of multiple antibodies. Expression of immunosuppressive gene products such as IL-10, TGF- β and CTLA4-Ig by DCs could result in further inhibition of alloimmune responses *in vitro*^[20,29,47,48]. However, adenoviral vectors used to efficiently deliver transgene expression could simultaneously activate DCs^[20,29]. Thus, transgene expression was overcome by the vigorous upregulation of costimulatory molecules on the transfected DC surface. Antisense oligodeoxynucleotides to molecules such as ICAM-1

could prolong kidney and heart allograft survival^[49]. However, effects were not donor specific, nor did grafts survive indefinitely. To date, strategies using genetically DCs alone in experimental organ transplantation have failed to induce tolerance. In the setting of transplantation, proinflammatory cytokines and other factors were capable of promoting DC maturation around within recipient tissues. Thus, late maturation and inherent T cell stimulatory potential of genetically engineered DCs may overcome the effects of localized immunosuppressive transgene expression. However, our and other data indicated that preconditioning donor DCs *in vitro* with ODN to block NF- κ B nuclear translocation were sufficient to stably suppress the up-regulation of costimulatory molecules and IL-12 production in response to potent activating stimuli, such as LPS and IL-4.

NF- κ B is an important transcriptional regulator of the immune response in a variety of cell types, but its precise function in DCs has not been extensively evaluated. Nonetheless, interference with its actions, either by CsA or using ODN decoy approach, could result in significant suppression of immune function at the level of cytokine production, effector function, and costimulation capacity.

Although long-term allograft survival has been achieved after infusion of costimulatory molecule-deficient DCs in a few specific mouse strain combinations, the ability of immature DCs to prolong allograft survival in most models is still not satisfactory.

In this study, by targeting the NF- κ B pathway in DCs with short NF- κ B decoy ODNs, DCs were maintained in an immature phenotype associated with significantly reduced allostimulatory capacity *in vitro*. More importantly, with administration of NF- κ B decoy ODNs-treated donor DCs, significant suppression of liver allograft rejection and marked prolongation of recipient survival were achieved in the absence of immunosuppression. *In vivo*, only the effect of NF- κ B decoy ODNs-treated donor DCs on liver allograft survival was maximal, although some suppression of liver allograft rejection and survival prolongation were observed in recipients injected with immature DCs without NF- κ B decoy ODNs modification.

The mechanisms by which NF- κ B decoy ODNs-treated DCs prolong survival of liver allografts are unclear. We found *in vitro* and *in vivo* evidence that stably immature NF- κ B decoy ODNs-treated DCs could suppress T cell allostimulatory ability, promote apoptosis of graft-infiltrating cells, and inhibit Th1 immunostimulatory cytokines such as IL-2 and IFN- γ mRNA expression and increase Th2 cytokine (IL-4) mRNA expression both in liver graft and in recipient spleen. Apoptosis of alloreactive T cells appears to be an important mechanism underlying the survival prolongation of organ graft, apoptosis of immunoreactive T cells within the graft and host secondary lymphoid tissue plays a pivotal role in determining the balance between liver transplant tolerance and rejection. Previous studies showed that blockade of costimulation by donor-derived DCs markedly promoted apoptosis of alloreactive T cells in host lymphoid tissue and prolonged organ graft survival^[50,51]. However, prevention of apoptosis of alloreactive T cells could block the induction of peripheral transplant tolerance^[42,52]. In the present study, *in situ* TUNEL staining of liver grafts from NF- κ B decoy ODNs-modified DCs-treated recipients showed the greatest degree of apoptosis of lymphocytes within portal areas of liver grafts. The result strongly suggested that the enhanced apoptosis of liver allograft-infiltrating lymphocytes might be an important mechanism for survival prolongation of liver allograft induced by NF- κ B decoy ODNs-treated DCs.

Another important mechanism by which NF- κ B decoy ODNs-treated DCs prolong survival of liver allografts may be the alteration of immunoregulatory cytokines (such as IL-2, IL-4 and IFN- γ) mRNA expression both in liver graft and in recipient spleen. In the present study, high level expression of IL-2, IL-4 and IFN- γ mRNA was observed in grafts and recipient spleen

of untreated recipient animals, which was consistent with immune activation. Administration of immature DCs (GM-CSF DCs or GM-CSF + scrambled ODNs DCs) partially down-regulated IL-2 mRNA and IFN- γ mRNA expression and partially up-regulated IL-4 mRNA expression both in liver graft and in recipient spleen. NF- κ B decoy ODNs-treated DCs appeared to skew cytokine expression toward Th2 cytokines (IL-4), and significantly suppressed Th1 cytokines (INF- γ and IL-2) mRNA expression both in liver graft and in recipient spleen. The suppressed expression of IFN- γ and IL-2 mRNA both in liver graft and in spleen might be associated with the enhanced apoptosis of T cells and the skewing toward Th2. Although there is evidence that IL-10 could exacerbate organ allograft rejection and its neutralization could modestly prolong transplant survival^[53,54], the predominant expression of Th2 cytokines, such as IL-4 and IL-10, was implicated in long term survival of the allograft in general. In contrast to Th2 cytokines, expression of Th1 cytokines, especially IFN- γ , in graft models has been shown to be associated with acute rejection^[29,50,55]. Thus, significantly decreased expression of Th1 cytokines such as IL-2 and IFN- γ mRNA, as well as the relatively high level of IL-4 mRNA both in liver allograft and in recipient spleen may be an important mechanism underlying the tolerance of liver allograft induced by NF- κ B decoy ODNs-treated DCs.

Abstract

AIM: To assess the grey scale enhancement of a new lipid-coated ultrasound contrast agent in solid abdominal organs as liver and kidney.

METHODS: Size distribution and concentration of the lipid-coated contrast microbubbles were analyzed by a Coulter counter. Two-dimensional (2D) second harmonic imaging of the hepatic parenchyma, the inferior vena cava and the right kidney of the rabbits were acquired before and after contrast agent injection. Images were further quantified by histogram in Adobe Photoshop 6.0. Time-intensity curves of hepatic parenchyma, inferior vena cava and renal cortex were generated from the original grey scale.

RESULTS: The 2D images of hepatic parenchyma and cortex of the kidney were greatly enhanced after injection and the peak time could last more than 50 min.

CONCLUSION: This new lipid ultrasound contrast agent could significantly enhance the grey scale imaging of the hepatic parenchyma and the renal cortex for more than 50 min.

INTRODUCTION

New ultrasound contrast consisting of perfluorocarbon microbubbles could enhance grey scale images of parenchymal organs. It provided a new method in diagnosis^[1-10]. The development of new ultrasound contrast agent (UCA) has become one of the most promising fields in ultrasound medicine. So far, several UCAs, like Optison^[11,12] and Definity^[13], have been approved for treatment and become commercially available; many others are still in clinical trials^[14-16]. Based on the chemical components of bubble film, UCAs could be divided into four different types: Surfactants^[17-19], human albumin^[20,21], polymer^[22] and lipids^[23-25]. The lipids are superior to the others in many aspects: no risk of blood transmitted infection, excellent stability and some tissue-specific targeting, like the reticuloendothelial

system. This study was aimed to investigate the effectiveness, reproducibility of a new lipid contrast agent in the enhancement of abdominal parenchymal organs. All the protocols were approved by IRB (Internal Review Board) of Xinqiao Hospital.

MATERIALS AND METHODS

Preparation and analysis of lipid-coated microbubble agent

Liposome, which consists of two kinds of phospholipids and polyethylene glycol, was prepared by lyophilization. Then the lipids were rehydrated with certain media, like glucose and deionized water. The resultant suspension was sonicated by an ultrasound sonicator (YJ 92-II Xinzhi Corp. Hang-zhou, Zhejiang Province). The perfluoropropane was introduced into the suspension during sonication, then it was kept still, until it was separated into two layers, the upper layer was still in white colloid whereas the lower layer was slowly defecated. Then the upper layer of the agent was extracted and analyzed. To acquire size distribution data of the new contrast agent, the milky microbubbles suspension was analyzed by Sysmex KX-21 (Sysmex Corporation, Japan). The surface electric potential and pH of UCA were measured by Zeta 3 000 (Malvern Ltd., United Kingdom).

Animal models

Ten healthy rabbits, weighing 2.0-2.2 kg, were enrolled in this study. The body hair at experimental region was removed for liver and renal scan. Rabbits were anesthetized by intramuscular injection of "Xu Mian Xing" (mainly consisted of haloperidol and made by Changchun University of Agriculture and Prologue) at the dose of 0.15 mL/kg bm, and the intravenous infusion was set up through ear veins. Lipid contrast agent was injected at 0.01 mL/kg bm, and followed by 1 mL saline flush.

Settings of ultrasound equipment

A Siemens Sequoia 512 (Siemens Acuson Co., Mountain View, California) ultrasound system was used in this study. The second harmonic imaging of 6L3 probe at 3.0/6.0 MHz was used. The mechanic index and output power were set at 0.11 and -24 dB, respectively. All the other parameters, like gain, depth, TGC, compress and focus, were kept constant during experiment. Experimental images were digitally recorded. Overall, baseline and 60 min contrast images were acquired. All images were transformed from original DICOM files into JPEG format by Viewpro (Acuson Co.). Grey scale was calculated by histogram in Adobe Photoshop 6.0 (Adobe Co.). Sample area used in the histogram had 1 088 pixels in an ellipse. Time-density curve was generated based on the mean pixel grey scale of hepatic parenchyma and renal cortex.

Pathological examination

All animals were sacrificed by intravenous injection of 10% potassium chloride. The liver, kidney and lung tissues were autopsied and fixed in 40 g/L formaldehyde for H&E stain. All tissue slides were reviewed by pathologists.

Statistical analysis

The grey scale data acquired from liver, inferior vena cava and

renal cortex were expressed as mean \pm SD. Pre- and post-contrast of liver's and kidney's grey scale data were compared by paired two-tailed Student's *t* test in SPSS 8.0 program. *P* critical value less than 0.05 was considered to be statistically significant.

RESULTS

Contrast agent

The visual appearance of the newly made liposome contrast agent was an opaque milky suspension, and it was slowly delaminated. The microbubble concentration was $(7-8) \times 10^9/\text{mL}$, and the size distribution was 2 to 10 μm . About 90% of the microbubbles were less than 8 μm (Figure 1). The surface electric potential was -71.2 mV and the pH was 6.42.

Figure 1 Microbubbles in 400-fold diluted saline (original magnification: $\times 100$).

Figure 2 Ultrasound images of liver parenchyma and inferior vena cava (IVC) before and after the injection of microbubbles. A: before injection; B: 30 s after injection; C: 1 min after injection; D: 2 min after injection.

Grey scale enhancement of liver and kidney

The images of both hepatic parenchyma and renal cortex were visually significantly enhanced after intravenous injection of the contrast agent (Figures 2-5). Time-intensity curves of both liver and cortex were elevated and kept at a high level. The grey scale of liver parenchyma (61.2 ± 3.1) 30 s after contrast injection was significantly higher than that of baseline image (38.0 ± 3.0 , $P < 0.05$). At the time point of 180 s after injection, the grey scale of liver parenchyma reached 83.2 ± 1.8 which was significantly

higher than baseline ($P < 0.01$). And 54 min after the injection, the liver enhancement remained at 57.8 ± 1.4 . One hour after contrast injection, the grey scale dropped to 45.2 ± 1.0 , which had no statistical significance. Similar results were observed in the contrast enhancement of renal cortex, and the grey scales were 18.1 ± 3.8 at baseline, 48.8 ± 3.3 ($P < 0.01$) 10 s after injection, 27.4 ± 4.1 ($P < 0.01$) 56 min after injection, 26.1 ± 3.9 60 min after injection ($P < 0.05$). These results confirmed that this lipid microbubbles contrast agent could effectively enhance hepatic parenchyma and renal cortex at a relatively long time.

Figure 3 Ultrasound images of liver parenchyma and inferior vena cava (IVC) before and after the injection of microbubbles. A: 15 min after injection; B: 25 min after injection; C: 30 min after the injection; D: 40 min after the injection.

Figure 4 Ultrasound images of renal cortex before and after the injection of microbubbles. A: before injection; B: 30 s after injection; C: 1 min after injection; D: 2 min after injection.

Figure 5 Ultrasound images of the renal cortex after injection of microbubbles. A: 5 min after injection; B: 10 min after injection; C: 30 min after injection; D: 40 min after injection.

At inferior vena cava (IVC), the time-intensity curve was different from that of hepatic parenchyma and renal cortex. The grey scale of IVC significantly rose to 52.5 ± 2.9 20 s after contrast injection which was higher compared with baseline (5.8 ± 1.6). The significant enhancement lasted only 120 s after injection, then diminished gradually and disappeared at 240 s after contrast injection. IVC contrast intensity dropped back to baseline 27 min after injection (17.0 ± 5.2).

Pathological results

All tissues from liver, lung, and kidney were normal in histology, and there was no sign of air embolism or infarction spot.

DISCUSSION

Lipid-coated microbubbles were mainly composed of several biocompatible phospholipids that had excellent stability and non-bioactive components. The lipids had been widely used in the preparation of ultrasound contrast agent, liposome and other drugs. In this study, a new ultrasound contrast agent based on lipids was prepared and showed excellent stability in the enhancement of hepatic parenchyma and renal cortex at a minimal dose of 0.01 mL/kg bm. Grey scale enhancement could last more than 50 min from both visual assessment and quantitative statistical analysis. This enhancement was longer than some previous reports, which were about 5–15 min^[19,25,26]. Also, the time-intensity curves of hepatic parenchyma and renal cortex were quite different from that of inferior vena cava. These microbubbles tended to be stable in parenchyma, rather than in circulation, as the time-density curve from IVC showed a 200-s wash-in and wash-out enhancement.

According to some reports^[27,28] and our experiment^[29], we assumed that the prolonged enhancement was due to the uptake of microbubbles by the reticuloendothelial system in liver. But this could not explain the prolonged enhancement in the kidney, which is not rich of reticuloendothelial system. There might be some other reasons. Since the peak contrast intensities of liver parenchyma and cortex appeared much later than that of inferior vena cava, they were 12 min, 6 min and 30 s,

respectively, it indicated that after the peak contrast in circulation there was another peak contrast in solid organs, and it was presumed to be the accumulation of microbubbles in hepatic sinusoids or capillary bed in cortex. As we know, hepatic parenchyma is consisted of hepatic sinusoids and renal cortex is mostly consisted of glomeruli. They are both rich in capillaries. Meanwhile, the blood flow in hepatic sinusoids and glomeruli is much slower than that in inferior vena cava. So, the microbubbles could easily be accumulated in capillary bed, which resulted in the prolonged enhancement of liver and kidney.

As IVC grey scale at 27 min postinjection was lower than that before injection, the hepatic parenchyma might block ultrasound transmission to IVC by condensed bubble's attenuation, and this could produce visually lower IVC echo.

In this study, the new lipids ultrasound contrast agent was long-term stable in enhancement of liver parenchyma and renal cortex. The mean size of the microbubbles was less than 8 μ m, which was smaller than that of red blood cell, and thereby it was safe for intravenous injection. Pathologically, all the tissues from liver, lung, and kidney were normal in histology, and there were no signs of air embolism or infarction spot.

In comparison with other lipid-coated microbubbles^[30], this contrast agent had a higher bubble concentration and a longer stability in parenchymal organs. The reason for this might attribute to the reconstituted membrane of the microbubbles. Polyethylene glycol could protect phagocytosis from Kupffer cell, and it could exist in hepatic sinusoid longer. Tween 80, a kind of surfactant, which has never been used in other lipid microbubbles contrast agent, may increase the bubbles or microbubbles concentration.

Although this new lipid-based contrast agent exhibited a prolonged enhancement, the true reason has not been clarified. Further studies are needed to investigate the mechanism of long-lasting enhancement.

Abstract

AIM: To investigate the intestinal barrier function damage induced by trauma and infection in rats.

METHODS: Experimental models of surgical trauma and infection were established in rats. Adult Sprague-Dawley rats were divided into 4 groups: control group ($n = 8$), EN group ($n = 10$), PN group ($n = 9$) and Sep group ($n = 8$). The rats in PN and Sep groups were made into PN models that received isonitrogenous, isocaloric and isovolumic TPN solution during the 7-d period. Rats in EN and Sep groups received laparotomy and cervical catheterization on day 1 and received lipopolysaccharide injection intraperitoneally on d 7. On the 7th day all the animals were gavaged with lactulose and mannitol to test the intestinal permeability. Twenty-four hours later samples were collected and examined.

RESULTS: The inflammatory responses became gradually aggravated from EN group to Sep group. The mucosal structure of small intestine was markedly impaired in PN and Sep groups. There was a low response in IgA level in Sep group when compared with that of EN group. Lipopolysaccharide injection also increased the nitric oxide levels in the plasma of the rats. The intestinal permeability and bacterial translocation increased significantly in Sep group compared with that of control group.

CONCLUSION: One wk of parenteral nutrition causes an atrophy of the intestinal mucosa and results in a moderate inflammatory reaction in the rats. Endotoxemia aggravates the inflammatory responses that caused by laparotomy plus TPN, increases the production of nitric oxide in the body, and damages the intestinal barrier function.

INTRODUCTION

Severe infection is still the main cause of death in critical illnesses such as severe trauma, burns and in massive use of immunosuppressive medicines. The endotoxin produced by G⁻ bacilli is the important factor for the impairment of tissues and cells of the body. It could damage the systemic immunity, impair the intestinal barrier function, increase the mucosal permeability, and hence cause enterogenous infection, a phenomenon known as bacteria translocation^[1,2]. The impairments aggravate the

primary infection, which might cause multiple organ dysfunction syndrome (MODS), and even death. The alterations in pathophysiology and immunology when endotoxemia occurs, are very important for us to evaluate the impaired gut barrier function.

In routine clinical practice, some patients would complicate with infections after operation and trauma. Most of them can be cured, but a few of these infections would last for a longer time. Based on the consideration of the latter being a phenomenon of bacterial translocation as a result of the damage of intestinal barrier function, we conducted this animal experiment so as to investigate if there were gut barrier damage and bacterial translocation in such instances.

MATERIALS AND METHODS

Experimental animals and grouping

Adult, healthy male Sprague-Dawley rats, with body mass of 150-180 g (supplied by Shanghai Experimental Animal Center, Chinese Academy of Sciences) were used. The rats were fed for over 1 wk in our laboratory for adaptation and then put into metabolic cages for 5-7 d. The temperature in the animal rooms was 17-21°C with proper humidity (about 60%) and illumination of 12 h/d (6:00-18:00). During the adaptation period all the rats were fed with regular rat chow and tap water *ad libitum*. When the rat's body mass reached 200-300 g, 33 rats were chosen randomly and divided into 4 groups: (1) control group ($n = 8$), which were fed rat chow and tap water freely; (2) EN group ($n = 10$), in which a central venous catheter was inserted into animals' superior vena cava through right jugular vein under anaesthesia, and connected to the swivel apparatus. The rats also received laparotomy and were fed the chow freely; (3) PN group ($n = 9$), which were infused with a whole nutrients solution through a central venous catheter, and with drinking water *ad libitum*; (4) Sep group ($n = 8$) in which an exploratory laparotomy and central venous catheterization served as the trauma. After this, TPN was their sole nutrition source plus drinking water *ad lib*. On the 7th day 5 mg/kg of lipopolysaccharide was injected intraperitoneally for EN and SEP groups. PN and Sep Groups received isonitrogenous, isocaloric and isovolumic TPN solution during the 7-d period. All the protocols and procedures were approved by our University Committee of Animal Experiment Administration.

Intravenous nutrients and other relevant chemicals

TPN ingredients About 11.4% compound amino acids injection (Novamin), 20% medium-long chain fat emulsion (Lipovenoes MCT), multivitamin mixture (Soluvit, Vitalipid) and a trace element mixture (Addamel) were purchased from Sino-Sweden and Fresenius Pharmaceutical Corp. LTD.

Chemicals and reagents Lipopolysaccharide (LPS, from *E. coli*, 055: B5) was purchased from Sigma Co.; NO Test Kit was purchased from Promega Co., USA. Immunohistochemistry (T cell subgroups measurement) reagents were purchased from Serotec Ltd., Germany and IgA, Bethyl Co., USA.

Experimental model

Operation procedures Under anaesthesia with 100 mg/kg of ketamin injected into the animals intraperitoneally, the TPN model was established and a rotary transfusion apparatus was

used for TPN infusion^[3]. For surgical trauma, after shaving the hair on the abdomen, an incision (about 4 cm in length) was made and the whole abdominal cavity was explored and examined for about 5 min from the epigastrium to the pelvic cavity. The incision was sutured in double layers with silk suture No. 1. The operation was done under aseptic conditions.

TPN solution The rats were put in the metabolic cages after surgical recovery. Each rat received 230 kcal/kg body mass of calories and 1.42 g nitrogen/kg each day in 50 mL of TPN solution. The ratio of glucose to lipid in this solution is 2:1, and nonprotein calorie to nitrogen (kcal/g), 137:1. Multivitamins, electrolytes, trace elements and 500 units of heparin were also included in the TPN solution. All the nutrient solutions were prepared under aseptic conditions daily and the infusion was done with an injecting micropump continuously and uniformly during 24 h each day. TPN infusion was started immediately after recovery from the laparotomy. On the first and last days of the experiment, each rat was given half of the total calories without any changes of other TPN ingredients.

Induction of endotoxemia On the 7th d of the experiment, 5 mg/kg of LPS in 5 mL of sterile distilled water was injected into the animals' peritoneal cavity to cause a sepsis state.

Lactulose/mannitol solution gavage On the 7th d of the experiment, 66 mg of lactulose and 50 mg of mannitol dissolved in 2 mL of normal saline were gavaged. Twenty-four hour urine was collected, the volume recorded and 0.2 mL of mercury salicylosulfide added. Then 5 mL of the urine specimen was stored at -20 °C until measurement.

Sample preparation and measurements

Twenty-four hours after gavaging with lactulose and mannitol and injecting endotoxin, 100 mg/kg of ketamine was injected intraperitoneally as an anesthetic. After the laparotomy was done, tissue and blood samples were collected and gross and laboratory examinations were performed.

Bacteriological test Blood 0.5 mL from the portal vein was drawn for culture. One gram of anterior lobe liver tissue and about 0.2-0.5 g mesenteric lymph nodes were excised. Each sample was put in a tissue homogenizer and 1.5 mL of normal saline was added before they were homogenized. The specimens were sent to a microbiological laboratory for aerobic culture and bacterial identification by morphological and bacteriological analyzer.

Bacterial culture (1) 10 μ L homogenates of the lymph nodes and liver were separately taken and put on blood agar plates. Another 10 μ L lymph nodes and liver homogenates were mixed with 10 mL saline for a dilution and the diluted samples were inoculated also on blood agar plates. (2) 0.5 mL of portal vein blood was inoculated into 4.5 mL of common broth for bacterial enrichment 16-18 h, then 20 μ L of the enrichment solution was inoculated on blood agar plates. (3) The cultured media were put in a CO₂ incubator at 35 °C for 24-48 h. If there was no bacterial growth, they would be regarded as negative; but if there was growth, it would be further identified.

Identification of bacteria First, Gram-stained smears were made to determine whether they were cocci or bacilli and G⁺ or G⁻. Second, identifications were made using bacteriological analyzer of Vitek-32 (Bio Merieux Vitek, Inc., USA). Gram-positive cocci were tested with GPI card, Gram-negative bacilli, with GNI card, and fungi, YBC card.

Preparation of small intestine specimens The whole small intestine below the Treitz ligament was excised and immediately placed on ice cold of 9 g/L saline. The intestine was opened longitudinally and the contents of the intestine were washed out with icy saline. Two cm of proximal jejunum and distal ileum were cut and put into a 40 g/L neutral formaldehyde solution promptly and sent to be examined histologically. About 5 cm intestine segments from the upper, middle and lower sections

were resected and then the surfaces of the mucosa were dried with cotton swabs. The mucous membrane of the icy specimens was scraped, weighed and divided into two equal parts. They were immediately put into liquid nitrogen and then stored at -70 °C.

Histological examination of the intestinal mucosa Specimens were embedded in paraffin, 4 μ m sections were cut and stained with H.E., analyzed with an HPIAS-1000 Multimedia Color Analysis System. Three low power (10 \times 10) fields in each section were observed. The lengths of 5 villi, the depth of 5 crypts and the thickness of the mucosa at 5 sites were analyzed. The average value was calculated and documented. All the calculation was done double-blindly by two experienced pathologists.

Immunohistochemical analysis of T cell subpopulation^[4]

Specimens were embedded in paraffin, 4 μ m sections were cut and stained with H.E., T cell subsets were examined by immunohistochemical SP method. The total T lymphocyte and its positive stained subpopulations (CD3, CD4, CD8) were counted in 10 whole villi in each section. The ratios and rates were then calculated. All the calculation was done double-blindly by two experienced pathologists.

Blood sampling Three milliliter blood from the right cardiac ventricle was drawn and 1 250 u heparin added. The blood was centrifuged and the serum stored at -70 °C. Then the animals were sacrificed by exsanguination.

Lactulose/mannitol test The lactulose and mannitol concentrations in the preserved urine sample were measured by a high-performance liquid chromatograph (Waters Co., USA). The ion-exchange column used was purchased from Transgenomic Co., USA. The ratio between the two sugars was then calculated. The test was to measure the amount of excreted dual sugars in urine of 24 h. Because these two kinds of saccharide nearly neither metabolize nor synthesize in the body, amounts of the two sugars being excreted from urine reflect the "leaking" degree of the intestine, or permeable extent of the intestine. The molecular weight of these two saccharides is different. The test error can be reduced when using two sugars of different molecular weight than using one only for the test. If the ratio of the two sugars' percentage in tested group was significantly bigger than that of normal control group, it could be concluded that the intestinal permeability in tested animals increased.

Determination of IgA The frozen samples of blood plasma and mucosa of the small intestine were melted to room temperature and 1 mL normal saline was then added to the melted 100 mg of mucosa before the homogenates were made, and then the concentration of IgA in their supernatants after centrifugation below 4 °C was measured. The results were shown as IgA μ g/mL of blood plasma and IgA μ g/g of small intestine mucosa.

Determination of NO The frozen samples of blood plasma and mucosa of the small intestine were melted to room temperature and concentration of NO in them was measured with the enzymatic method (Griess Reaction)^[5]. The results were shown as NO μ mol/L of blood plasma and NO μ mol/g of small intestine mucosa.

Statistical analysis

All the values were expressed as the mean \pm SE. One-way ANOVA was used to check the differences between groups. Chi-square test was used to check the differences of bacterial translocation rates between groups. When *P* was less than 0.05, the difference was considered statistically significant. The degree of correlation was described using Pearson correlation coefficient. Software SPSS10.0 was used in all statistical tests.

RESULTS

General animal manifestation

All the rats except those in the normal group appeared to have

symptoms in different degrees, such as lethargy, idleness, ruffling of hair, stop drinking and grossly concentrated urine. Some rats appeared very slow in their responses to sound stimulations and also had diarrhea. Their eyes appeared glazed with crusting exudates. These symptoms were prominent during the 5 to 15 h following LPS injection. There was no statistical difference in mortality within 24 h after LPS injection between EN and Sep groups.

Complete blood cell count

The total number of leukocytes and the number of neutrophils in PN group $[(14.97 \pm 2.704) \times 10^9/L$ and $(6.82 \pm 2.254) \times 10^9/L]$ was more than those of control group $[(7.59 \pm 0.379) \times 10^9/L$ and $(2.34 \pm 0.568) \times 10^9/L]$. On the contrary, Sep group rats showed a low response in cell count $[(8.9 \pm 0.82) \times 10^9$ and $(4.35 \pm 0.92) \times 10^9/L]$. Platelet count in groups of EN, PN and Sep $[(586.5 \pm 65.03) \times 10^9$, $(483.33 \pm 94.62) \times 10^9$ and $(277.5 \pm 44.87) \times 10^9/L$ respectively] decreased markedly as compared with that of control group $[(928.7 \pm 33.89) \times 10^9/L]$.

Body weight

At the beginning of the experiment there was no difference in the body mass of the animals. At the end of the experiment, the body mass increase was 32.38 ± 3.39 g in the control group. The body mass of other three groups decreased; it was 33.88 ± 3.19 g of loss in Sep group, the greatest among them.

Morphology and morphometry of small intestinal mucous membrane

The degree of damage of the villi and crypts and the thinning of the mucous membrane in jejunum and ileum were most significant in Sep group among the animals (Figures 1, 2).

Concentrations of NO in blood plasma and small intestinal mucosa

Concentrations of NO in blood plasma increased significantly after LPS injection (groups EN and SEP), whereas it was not evident in mucous membrane of small intestine (Table 1).

Figure 2 Morphometry for structure of small intestine mucosa (mean \pm SE). ^b $P < 0.001$ vs EN, PN and Sep groups; ^d $P < 0.001$ vs PN and Sep groups; ^f $P < 0.01$ vs Sep group; ^h $P < 0.005$ vs PN and Sep groups; ^j $P < 0.001$ vs Sep group; ^l $P < 0.02$ vs Sep group; ⁿ $P < 0.01$ vs EN group; ^l $P < 0.001$ vs PN and Sep groups.

IgA levels in plasma and small intestinal mucosa

IgA level was highest in blood plasma and intestinal mucosa in EN group among the animals (Table 2).

CD3 lymphocyte and CD4/CD8 ratio

There was no difference in CD3 population among the groups

Figure 1 Alterations in architecture of small intestinal mucosa. (HE staining, original magnification: $\times 100$). A: Normal mucous membrane of jejunum in control rats. B: Normal mucous membrane of ileum in control rats. C: Histological changes of jejunal mucosa of group T1 rats. The villi become sparser than those in control. The height and shape of villi are normal on the whole. D: Histological changes of ileal mucosa in PN group rats. The section shows a severe atrophy in mucosal structure. The villi become shorter, blunt and swollen. E: Histological changes of jejunal mucosa of Sep group. The villi are sparse and shorter than those of control group.

but CD4/CD8 ratio in EN and PN groups was higher than that of control group. There was no significant difference in ratio of CD4 to CD8 between Sep group and control group.

Table 1 Concentrations of NO in blood plasma and in intestinal mucosa

Group	n	BP(μmol/L)	SIM(μmol/g) ¹
Control	8	38.63±8.75 ^b	39.19±2.68
EN	10	103.39±10.18	67.19±6.67
PN	9	63.06±23.33 ^a	66.90±6.25
Sep	8	113.33±30.47	53.10±2.16

Values are expressed as mean±SE; BP, blood plasma; SIM, mucous membrane of small intestine; ^b*P*<0.01 vs EN group and Sep group; ^a*P*<0.05 vs Sep group; ¹There was no statistical significance in NO levels in mucous membrane of small intestine among groups; *r* = 0.485, *P* = 0.515, there was no correlation of NO concentration in mucous membrane with that in blood plasma.

Table 2 IgA levels in blood plasma and small intestinal mucosa

Group	n	Blood plasma IgA (μg/mL)	Mucosa tissue IgA (μg/g)
Con	8	146.73±18.03 ^a	507.48±59.18 ^a
EN	10	260.37±38.54 ^b	733.51±81.42 ^b
PN	9	133.94±21.47	489.38±14.27
Sep	8	194.52±39.31	511.89±52.33

Data are expressed as mean±SE; ^a*P*<0.05 vs EN group; ^b*P*<0.01 vs PN group; *r* = 0.998, *P* = 0.002, *P*<0.003, there was a positive correlation in IgA level in blood plasma with that in intestinal mucosa.

Lactulose/mannitol (L/M) test

The L/M ratio showed a significant increment in all rats except those in control group animals (Table 3).

Table 3 Dual sugar (lactulose/mannitol) test

Group	n	Rate of lactulose	Rate of mannitol	Ratio of L/M
Control	8	0.0097±0.0027	0.0202±0.0026	0.4789±0.1001
EN	10	0.0213±0.0035	0.0283±0.0020	0.7981±0.1559
PN	9	0.0981±0.0374	0.0723±0.0285	1.4494±0.2670
Sep	8	0.1466±0.0572	0.0361±0.0089	4.0088±0.8893 ^b

Data are expressed as mean±SE. Rate of lactulose (or mannitol): denotes the rate of lactulose (mannitol) amount excreted in urine with that gavaged; Ratio of L/M denotes the ratio of the above two rates. ^b*P*<0.01 vs control, EN and PN groups.

Table 4 Examination of bacterial translocation

Group	n	MLN	Liver	PVB	RBT	Log ₁₀ TB±SD
Control	8	3/8	0/8	0/8	12.5% (3/24)	0.5414±0.288
EN	10	4/10	2/10	3/10	30.0% (9/30)	1.6444±0.349
PN	9	5/9	4/9	4/9	48.15% (13/27) ^b	2.3279±0.433 ^b
Sep	8	6/8	7/8	7/8	83.33% (20/24) ^d	3.2815±0.483 ^d

Values are expressed as mean±SE; MLN: Mesenteric lymph node; PVB: Portal venous blood; RBT: Rate of bacterial translocation; TB: Translocated bacteria; 3/8: Numerator represents the positive samples of bacteria culture; denominator represents the number of animals enrolled. ^b*P*<0.01 vs Control; ^d*P*<0.01 vs control, EN and PN groups; *r*=0.979, *P*=0.021, *P*<0.03, there was a positive correlation of rate of bacterial translocation with the value of Log₁₀ translocated bacteria.

Bacterial identification and bacterial translocation

The results of bacterial culture were labeled as positive when the CFU found per gram of tissue (or mL of blood) was more than or equaled to 10³[6]. In Sep group the rate of bacterial translocation was the highest. The logarithm of the number of translocated bacteria correlated positively with the rate of bacterial translocation (Table 4). The bacteria translocated, in order of frequency, were proteus, *E. coli*, enterococcus and other Gram-negative bacteria. One or two, even three bacterial groups were usually recovered from the same organ when translocation was present.

DISCUSSION

Recent studies have shown that the gastrointestinal tract is not only an organ for nutrient digestion and absorption, but also an organ for systemic immunity and at the same time performs a barrier function. It prevents bacteria and endotoxin in the lumen of the GI tract from entering the blood circulation (bacterial/endotoxin translocation). At the time when body and/or organ tissues are injured by trauma, burns, infection, ischemia/reperfusion and surgical operation strikes, the intestinal barrier malfunction occurs and enterogenous infection ensues. Thus, it aggravates the original illness and makes it persistent, causing multiple organ dysfunction syndrome (MODS) and even death^[1, 2, 6-9]. Based on these, Wilmore named the GI tract as "a central organ after surgical stress"^[3].

Most infections that take place in abdominal surgery are commonly caused by G⁻ bacilli or polyinfection, which brings harm to body through endotoxin. Endotoxin (LPS) plays a very important role during stress. *In vivo* and *in vitro* studies in animals and humans indicated that LPS could cause damage to the intestinal barrier function and cause bacterial translocation^[1, 3, 6]. The aim of the experiment was to mimic the clinical cases above. In the experiment, we had laparotomy plus parenteral nutrition as trauma. Sick manifestations emerged after a few days' parenteral nutrition. One wk parenteral nutrition was obviously an inflammatory stimulus to rats. Laparotomy was a minor injury, whereas it was an intermediate degree of impairment when administering laparotomy plus 1-wk parenteral nutrition to rats. Clinical manifestations in rats confirmed the point of view. We injected lipopolysaccharide to rats intraperitoneally after 1-wk parenteral nutrition so as to mimic infested clinical situations after trauma. There were two main harmful stimuli, parenteral nutrition and LPS injection, included in our experiment. We have had another two control groups, the group of parenteral nutrition (PN) and the group of LPS injection with enteral feeding (EN) except the normal control one so as to investigate and compare the damage degree of different injury stimuli to gut barrier.

Investigations have reported the relation of TPN with bacterial translocation. Qin and his colleagues^[10] discovered that parenteral feeding in a 7-d period in experimental pancreatitis of dogs caused a significant damage of intestinal mucosa and bacterial translocation (BT) when compared with that of given isonitrogenous and isocaloric enteral feeding. Similar results were reported by other scholars^[11, 12]. A study even revealed that 2-d TPN resulted in BT in SD rats^[13]. In their investigation patients underwent thoracic esophagectomy, Takagi *et al.* presented that in patients receiving TPN from 1 wk before operation to 2 wk after operation, serum levels of IL-6, IL-10 and endotoxin were higher than that of receiving isonitrogenous and isocaloric TEN. The result suggested that TPN could increase the endotoxin translocation from the bowel^[14].

Our investigation achieved similar results and showed that feeding rats with TPN for 1 wk led to a remarkable atrophy of the intestinal mucous membrane; hence an increase in intestinal permeability and bacterial translocation ensued. The rats were

in a state of systemic inflammatory response, which was shown by clinical manifestations of the animals and analysis of their blood cells. It is known that the cause of increment in intestinal permeability in animals fed with TPN is mainly the atrophy of the intestinal mucous membrane^[15,16]. Parenteral nutrition could meet the needs of other organs and tissues of the body, but not that of the intestinal mucosa. Seventy percent of the nutrients that intestinal epithelia need is absorbed directly from the intestinal lumen by mucosa cells^[17]. Enteral feeding could prevent the intestinal mucous membrane from atrophy and avoid increment of intestinal permeability^[10-12]. Likewise, it could also prevent gut associated lymphatic tissue (GALT) from atrophy, which could increase the intestinal mucosal immunity^[16,17]. It could be seen from our investigation that the damage of intestinal mucous membrane in EN rats was greatly attenuated. Enteral feeding led to a better immune reaction in these rats than others. The increase of gut permeability was avoided and the rate of bacterial translocation alleviated. It was shown from the analysis of complete blood cell count in the rats that the total number of leukocytes and the number of neutrophils increased following the stimulus of TPN in PN group, whereas there was a low reaction in Sep group, which suffered from more severe stress injury than PN group. The falling of platelet count may be related to a greater depletion of platelets that was caused by an intravascular coagulation due to the systemic inflammatory reaction^[1,18].

A series of symptoms appeared after injecting LPS into laparotomised TPN-rats in our experiment: lethargy, idleness, ruffling of hair, stopping drinking and grossly concentrated urine *etc.* Some rats appeared to have very low reactions to sound and other stimulations and also had diarrhea. Some eyes appeared glazed with crusting exudates. These symptoms were prominent during the 5 to 15 h following LPS injection, and the manifestations were alleviated gradually thereafter. These were in accordance with other reports^[1,3,6,18-20]. No statistical difference was found in the mortality within 24 h after LPS injection between the two groups (there were 1 and 3 deaths for EN and Sep groups respectively).

The animals in Sep group responded acutely after being injected with LPS intraperitoneally. LPS aggravated the impairment of the intestinal mucosal barrier and bacterial translocation that was caused by TPN. The aggravation of impairment of the mucosal barrier function might be related to nitric oxide (NO), which was shown by an increased NO level in blood plasma after LPS injection. Some scholars considered that high output of NO after surgical stress could damage the oxygenation metabolism in mitochondria of the intestinal epithelia^[3,21].

The increment of intestinal permeability caused by endotoxin is very complicated. It may relate to many inflammatory mediators such as cytokines, vasoactive amines and oxygen free radicals^[22,23]. Among them, NO, one of the main oxygen free radicals in the body, is an important inflammatory mediator causing impairment of the intestinal barrier^[3,18,24]. Generally, the body could only secrete small amounts of NO under the effects of constructive NO synthase (cNOS) and endothelial NO synthase (eNOS). This low level of NO has protective effects on the body^[20], whereas a higher concentration of NO being produced under the effect of inducible NO synthase (iNOS) when the body suffered from harmful stimulations, would impair the functions of cells and tissues of the body, including the intestinal barrier function. It was concluded from a great number of studies that a lower NO level was beneficial and a higher NO level was harmful to the body^[3,23,25], and using NO inhibitor when stress occurred could reduce the damage of gut barrier^[26,27]. The results from our investigation were in accordance with this hypothesis.

The intestinal immunity is very important in maintaining

intestinal barrier function. It is known that the digestive tract is the largest immune organ in the human body. About 80% of humoral immunity and 50% of cellular immunity locate in the digestive tract^[25,28]. Intestinal mucosal IgA is the first defense line of the intestinal barrier. It has an important function in preventing bacterial adherence and translocation from intestinal lumens^[21]. The IgA secretion in our EN group increased after LPS stimulation, but it had a low reaction in PN group when compared with that of EN group. The ratio of CD4 to CD8 in mucous membrane of small intestine in Sep group was lower than that in groups EN and PN, reflecting a low cellular immune response. This is in accordance with other reports that LPS could stimulate the increment of suppressive T lymphocytes^[22]. IgA level in blood plasma is positively correlated with that in the intestinal mucosa, and this accords with a previous report^[29]. Our results indicated that the increase of bacterial translocation was not only caused by an increased intestinal permeability, but also by an impairment of the whole intestinal barrier function^[16,30]. The kinds and groups of translocated bacteria and the phenomenon that there were 1 to 3 kinds of translocated bacteria in the same organ found in our experiment were in accordance with other reports^[3,31].

In summary, one week of parenteral nutrition caused an extreme atrophy of intestinal mucosa and an impairment of intestinal barrier function in SD rats. LPS aggravated this damage and also damaged the systemic immunity of the animals. The aggravation was related to the increased NO produced by the stimulation of LPS.

ACKNOWLEDGEMENT

We would like to thank Professor Hai-Feng Shao and Professor Gen-Bao Xu for their technical guidance and advice; we are grateful to the staff of the Animal Laboratory and the Institute of General Surgery of Nanjing University Medical School for their generous support and assistance to our study.

Abstract

AIM: To determine the efficacy and safety of DA-9601 on erosive gastritis versus cetraxate as a standard drug by gastrointestinal endoscopy.

METHODS: Five hundred and twelve patients with erosive gastritis were divided into three groups. The groups received 180 mg or 360 mg of DA-9601, or 600 mg of cetraxate (Neuer™) t.i.d. for 2 wk, respectively. Endoscopic observations were performed before and 2 wk after the treatment, and the cure and improvement rates were investigated.

RESULTS: Of the 512 intention-to-treat (ITT) population, 457 patients comprised the per protocol (PP) analysis. Endoscopic cure rate was significantly higher in the DA-9601 group than in the cetraxate group in both the PP (56%, 58% vs 36%; DA-9601 180 mg, 360 mg and cetraxate, respectively) and ITT (52%, 51% vs 35%) populations. Two DA-9601 groups (180 and 360 mg) had significantly higher endoscopic improvement rates than the cetraxate group in both the PP (67%, 65% vs 46%) and ITT (63%, 58% vs 45%) populations. The percentage of symptom relief over the 2 wk was found not significantly different between groups. During the study, both DA-9601 and cetraxate produced no treatment-associated adverse events.

CONCLUSION: From these results, it appears that DA-9601 has excellent efficacy on erosive gastritis. This study also confirms the safety profile of DA-9601.

INTRODUCTION

Gastritis is a heterogeneous pathological condition, and is one of the most frequent reasons for medical consultation in Asian

countries, including Korea and Japan. However, in Western countries, these conditions are diagnosed as non-ulcer dyspepsia (NUD), which affects approximately one in five Americans^[1-4]. Gastritis, the “precursor” lesion to mucosal ulceration is both an important clinical entity and an important cause of abdominal pain in children^[5]. Inflammation of the gastric mucosa is the end result of an imbalance between mucosal defensive and aggressive factors (i.e., disturbances in gastric acidity and the mucus-bicarbonate barrier), and recently a great deal of attention has been focused on gastric hormones, specifically gastrin, and pepsinogens I and II^[6,7].

Gastritis can be classified into acute or chronic forms based upon Sydney System, and chronic gastritis can be subclassified as nonatrophic, atrophic, and special types^[8,9]. Using this Sydney pathologic classification as a guide, Chen *et al.*^[10] reported a simplified classification for gastritis based on practical radiologic evaluation, including erosive gastritis (acute and chronic), *Helicobacter pylori* (*H. pylori*) gastritis, chronic nonspecific gastritis, hyperplastic gastritis, and miscellaneous types (including granulomatous, phlegmonous, eosinophilic, corrosive, other infectious types and rare types).

At present, the exact pathophysiology of this syndrome is poorly understood. However, current evidence suggests that *H. pylori* infection, changes in lifestyles, eating behaviors, and nonsteroidal anti-inflammatory drug (NSAID) ingestion are causative factors in the pathogenesis of gastric mucosal injury in humans^[11]. *H. pylori* is known to be a particularly important pathogen in gastric and duodenal inflammation by producing excessive mucosal-reactive oxygen species (ROS), which damage the cell membrane and deplete gastric antioxidants^[12].

The current rationale for drug treatment in gastritis is similar to other gastrointestinal disorders (eg., non-ulcer dyspepsia), and depends mainly on symptomatic relief using gastroprotective agents (e.g., rebamipide, teprenone, ecabet sodium, sofalcone, cetraxate, *etc.*), H₂ receptor antagonists (e.g., cimetidine, ranitidine, famotidine, *etc.*), and antacids^[13]. However, despite many efforts, the pharmacological treatment of patients with gastritis usually achieves only partial symptomatic relief in the majority of cases.

DA-9601 (Stillen™), a phytopharmaceutical derived from *Artemisia asiatica*, has been reported to possess antioxidative and cytoprotective actions in various models of gastric mucosal damage^[14-16]. Though the mode of action of DA-9601 has not been fully elucidated, this new antioxidative drug scavenges superoxide and hydroxyl radicals, possesses potent anti-inflammatory activities, regenerates mucosal epithelial cells, and enhances the cytoprotective cytokines^[17-19].

The present study was designed to assess the therapeutic effects and safety of DA-9601 on gastritis. Cetraxate, which has been shown to have therapeutic effects on gastritis was selected as the standard drug for comparative purposes.

MATERIALS AND METHODS

Patients

The patients examined in this study consisted of 550 erosive gastritis patients who were diagnosed endoscopically between

August 2000 and December 2001. All patients gave their written consent to this study. Out of 550 initially enrolled patients, 512 completed the study. Those 512 patients were subsequently randomized, of whom 326 were allocated to DA-9601 (186 had 180 mg and 140 had 360 mg daily) and 186 to cetraxate 600 mg. The exclusion criteria were: a history of peptic ulcer disease and reflux esophagitis; the presence of a malignant tumor in the digestive tract; the use of drugs capable of interfering with digestive mucosal integrity, gastric secretion or gastrointestinal motility, including H₂ receptor antagonists, NSAIDs, muscarinic antagonists, gastroprotective agents (within the previous 14 d); thrombotic patients (cerebral thrombosis, myocardial infarction, thrombophlebitis, *etc.*); consumption coagulopathy patients; a history of hypersensitivity to drugs (rash, fever, itching, *etc.*); the presence of major hematological, renal, cardiac, pulmonary, or hepatic abnormalities.

Methods

The study was performed as a randomized, double-blind, placebo-controlled, multicenter trial. Subjects were recruited at the following five Korean centers; Inje University of Medicine (Busan), Ulsan University of Medicine (Seoul), Chonnam University of Medicine (Gwangju), Catholic University of Medicine (Seoul), and Ajou University of Medicine (Suwon). Gastrointestinal endoscopies were performed in all patients before starting therapy, and 2 wk later. Patients diagnosed with erosive gastritis were included and divided into 3 groups following initial symptom assessment, and either treated with DA-9601 180 or 360 mg, or cetraxate 600 mg t.i.d. for 2 wk. After completing the therapy, endoscopic examinations were conducted according to the following grades: score 1, no erosions; score 2 (mild), erosion number between 1 and 2; score 3 (moderate), erosion number between 3 and 5; score 4 (severe), erosion number more than 6, for the evaluation of cure rate and improvement rate (Table 1). In addition, all patients completed a standardized subjective assessment questionnaire, according to Table 2. Safety surveillance was done at the end of therapy, based on responses to a complaint questionnaire, results of physical examinations and laboratory tests. Blood samples were obtained at the end of therapy to determine concentrations of GPT, GOT, and bilirubin. Complaint questionnaires were recorded for the appreciable harmful or unpleasant reactions experienced by a patient as a result of drug therapy.

Table 1 Evaluation of efficacy based on endoscopic observations

Score	Number of erosions
1 (none)	0
2 (mild)	1–2
3 (moderate)	3–5
4 (severe)	6 <

Table 2 Evaluation of efficacy in individual symptom

Score	Criteria
1 (none)	No symptom
2 (weak)	Symptoms occurred once a week
3 (moderate)	The symptoms did not affect their life and occurred more than twice a week
4 (strong)	The symptoms affected their everyday life and occurred daily

Statistics analysis

Endoscopic efficacy was analyzed on an intention-to-treat (ITT) and per protocol (PP) basis. Both subjective and objective

criteria were analyzed using Duncan's multiple test. Comparisons between treatment groups were performed using the chi-square test. Data were considered to be significant when $P < 0.05$.

RESULTS

A total of 512 patients completed the trial. Baseline characteristics of the study populations are detailed in Table 3, which shows that the study groups were comparable with respect to demographics and disease-specific characteristics.

Table 3 Base-line characteristics of the patients (n, %)

Table 4 Number of patients for ITT and PP assays

	Number of patients		
	DA-9601 180 mg	DA-9601 360 mg	Cetraxate 600 mg
ITT analysis	186	140	186
PP analysis	171	120	166

Efficacy evaluation

The ITT population was composed of 512 patients (186 in the DA-9601 180 mg group, 140 in the DA-9601 360 mg group, and 186 in the cetraxate 600 mg group) (Table 4). Endoscopic cure rates in DA-9601 180 mg, 360 mg, and cetraxate 600 mg groups were 52.2%, 51.4%, and 35%, respectively (Figure 1). A significant difference was found between the DA-9601 and cetraxate groups ($P < 0.05$), however, no difference in cure rates was found between the DA-9601 groups.

Figure 1 Estimated cure rates of erosive gastritis by intention-to-treat (ITT) analysis among patients treated with DA-9601 (180 mg or 360 mg, t.i.d.) or cetraxate (600 mg, t.i.d.) for 2 wk. * $P < 0.05$ vs 600 mg of cetraxate.

Figure 2 Estimated cure rates of erosive gastritis by per protocol (PP) analysis among patients treated with DA-9601 (180 mg or 360 mg, t.i.d.) or cetraxate (600 mg, t.i.d.) for 2 wk. ^a $P < 0.05$ vs 600 mg of cetraxate.

The PP assay population comprised 457 patients (171 in the DA-9601 180 mg group, 120 in the DA-9601 360 mg group, and 166 in the cetraxate 600 mg group) (Table 4). The estimated cure rates of erosive gastritis by PP analysis in DA-9601 180 mg, 360 mg, and cetraxate 600 mg groups were 55.6% (95/171), 57.5% (69/120), and 35.5% (59/166), respectively (Figure 2). The cure rates between the DA-9601 and cetraxate groups ($P < 0.05$) were significantly different, however, no difference was found between the DA-9601 groups.

Estimated improvement rates by ITT analysis of erosive gastritis patients treated with cetraxate (600 mg) and DA-9601 (180 or 360 mg) showed statistically significant differences ($P < 0.05$); however, no difference was observed between the DA-9601 treated populations (Figure 3). The improvement rates of those treated with DA-9601 180 mg, 360 mg and cetraxate 600 mg were 63.4% (118/186), 57.9% (81/140), and 44.6% (83/186), respectively.

The estimated improvement rates by PP analysis for erosive gastritis treated with DA-9601 or cetraxate were statistically different ($P < 0.05$) (Figure 4). However, no difference was found between the DA-9601 treated groups. The estimated improvement rates were 67.3% (115/171), 65.0% (78/120), and 46.4% (77/166) in the DA-9601 180 mg, DA-9601 360 mg, cetraxate 600 mg treated groups.

Figure 3 Estimated improvement rates of erosive gastritis by intention-to-treat (ITT) analysis among patients treated with DA-9601 (180 mg or 360 mg, t.i.d.) or cetraxate (600 mg, t.i.d.) for 2 wk. ^a $P < 0.05$ vs 600 mg of cetraxate.

Symptom relief rates

The symptom relief rates determined by the ITT and PP methods showed no statistically significant difference between the study populations. The overall degrees of symptom reduction by the ITT method in the DA-9601 180 mg, 360 mg, and cetraxate 600 mg groups were 77.4% (144/186), 75.0% (105/140), and 73.1% (136/186), respectively (Figure 5), and by PP analysis these were 81.3% (139/171), 81.7% (98/120), and 76.5% (127/166).

Figure 4 Estimated improvement rates of erosive gastritis by per protocol (PP) analysis among patients treated with DA-9601 (180 mg or 360 mg, t.i.d.) or cetraxate (600 mg, t.i.d.) for 2 wk. ^a $P < 0.05$ vs. 600 mg of cetraxate.

Figure 5 Overall reduction rates of symptoms among patients treated with cetraxate (600 mg, t.i.d.) or DA-9601 (180 mg and 360 mg, t.i.d.) for 2 wk.

Safety

Serious adverse reactions were not encountered during this study. Of the 186 cetraxate 600 mg treated patients, the incidence of adverse effects was 7.5% (11 cases); including heartburn, abdominal pain, acid reflux, headache, itching, skin redness, facial edema, etc. Mild adverse events were observed in 14 of 186 patients treated with DA-9601 180 mg (Table 5). In the case of DA-9601 360 mg group, no notable change was observed.

either in subjective assessment questionnaire or in clinical examination at the end of the study as compared to DA-9601 180 mg or cetraxate groups. No statistically significant difference was observed between the cetraxate and DA-9601 treated groups.

DISCUSSION

Although gastritis is the most common complication in the digestive tract, the definition of gastritis is not consensual due to differences in diagnostic criteria. It has been postulated that gastritis contributes to the natural history of ulcer development due to the decreased protection offered by the mucosal barrier lining the stomach, and increased epithelial cell exposure to hydrochloric acid.

The aim of this study was to demonstrate the efficacy and safety of DA-9601 versus cetraxate, a widely used anti-ulcer drug, for the treatment of erosive gastritis. Cetraxate, which has a mucosal protective effect, was first introduced in 1976 as an anti-ulcer drug^[20]. It is widely used clinically in Japan and other Asian countries. The mode of action of cetraxate is ascribed to an increased gastric mucosal blood flow through enhanced nitric oxide synthase activity, and the prevention of a decrease in the mucosal prostaglandin content^[21]. The results of the present randomized, double-blind, placebo-controlled, multicenter study demonstrate that orally administrated DA-9601 is both effective and well-tolerated in the treatment of erosive gastritis of various etiologies.

Adverse reactions were seen in 7.5% (14/186) of the patients in DA-9601 180 mg treated group and in 5.9% (11/186) of patients in the cetraxate 600 mg treated group. In both groups, the main adverse reactions were vomiting, abdominal pain, headache, skin rash, itching, and sGPT elevation. However, in DA-9601 360 mg treated group, no obvious adverse reactions were observed (0%, 0/140). Therefore, we concluded that there was no drug treatment related adverse reaction based on the lack of dose-response relationship. In the previous four-wk oral toxicity study of DA-9601 in rats at doses of 120, 500, and 2 000 mg/kg.d, no treatment related alternations, including changes in blood biochemistry were observed^[22]. In animal experiments, DA-9601 prevented acetaminophen, and CCl₄-induced hepatic GSH depletion and CCl₄-induced increased hepatic MDA (a parameter of lipid peroxidation) in a dose-dependent manner^[23,24]. In addition, sGPT and sGOT levels showed a tendency to fall to below the normal range in DA-9601 treated patients (unpublished data).

Conclusively, the present study indicates that DA-9601 has an excellent efficacy and safety profile. Therefore, we believe that DA-9601 is a highly attractive option for the treatment of erosive gastritis, in which a balance between aggressive and defensive factors plays a significant role.

Abstract

AIM: Gallbladder and gastrointestinal motility defects exist in gallstones patients and to a lesser extent in pigment gallstone patients. To investigate the role of gallbladder and gastrointestinal motility disorders in pigment gallstone formation in β -thalassemia major.

METHODS: Twenty-three patients with β -thalassemia major (16 females; age range 18-37 years) and 70 controls (47 females, age range 18-40 years) were studied for gallbladder and gastric emptying (functional ultrasonography), orocecal transit (OCTT, H_2 -breath test), autonomic dysfunction (sweat-spot, cardiorespiratory reflex tests), bowel habits, gastrointestinal symptoms and quality of life (all with questionnaires). Gallbladder content (ultrasonography) was examined before and during 8-12 mo follow-up.

RESULTS: Gallstones and/or biliary sludge were found in 13 (56%) patients. β -thalassemia major patients had increased fasting (38.0 ± 4.8 mL vs 20.3 ± 0.7 mL, $P = 0.0001$) and residual (7.9 ± 1.3 mL vs 5.1 ± 0.3 mL, $P = 0.002$) volume and slightly slower emptying (24.9 ± 1.7 min vs 20.1 ± 0.7 min, $P = 0.04$) of the gallbladder, together with longer OCTT (132.2 ± 7.8 min vs 99.7 ± 2.3 min, $P = 0.00003$) than controls. No differences in gastric emptying and bowel habits were found. Also, patients had higher dyspepsia (score: 6.7 ± 1.2 vs 4.9 ± 0.2 , $P = 0.027$), greater appetite ($P = 0.000004$) and lower health perception ($P = 0.00002$) than controls. Autonomic dysfunction was diagnosed in 52% of patients (positive tests: 76.2% and 66.7% for parasympathetic and sympathetic involvement, respectively). Patients developing sludge during follow-up (38%, 2 with prior stones) had increased fasting and residual gallbladder volume.

CONCLUSION: Adult β -thalassemia major patients have gallbladder dysmotility associated with delayed small intestinal transit and autonomic dysfunction. These

abnormalities apparently contribute together with haemolytic hyperbilirubinemia to the pathogenesis of pigment gallstones/sludge in β -thalassemia major.

INTRODUCTION

Patients with cholesterol gallstones have impaired gallbladder emptying^[1] and may show dyspeptic symptoms with functional defects of both upper and lower gastrointestinal tract^[2-4]. Recently, we reported that gallbladder emptying was also defective in patients with black pigment stones and such defect was less severe than in patients with cholesterol stones^[2].

β -thalassemia is one of the most widespread single-gene disorders with 3-6% of the world's population carrying the gene. The disease represents a major public health problem in the Mediterranean area, the Middle East, the India subcontinent and the Far East^[5]. Increased production of bilirubin from chronic hemolysis is a prerequisite for formation of pigment gallstones^[6,7], and black pigment gallstones often accompany thalassemia major^[6]. However, despite similar biochemical and clinical features, many β -thalassemia major patients with marked hemolysis did not develop gallstones. One might hypothesize that gallbladder stasis and functional gastrointestinal disorders could contribute to gallstone pathogenesis in β -thalassemia major. In the present study, we investigated for the first time the role of gallbladder and gastrointestinal motility in adult β -thalassemia major patients in relation to gallstone/sludge formation. Autonomic neuropathy and gastrointestinal symptoms were also evaluated.

MATERIALS AND METHODS

Subjects

β -thalassemia major patients ($n = 23$) Age 26 ± 1 years (mean \pm SE, range 18-37 years), body mass index (BMI) of 21.4 ± 0.6 kg/m². Sixteen were women. Patients attended regular review from October 2001 until June 2003 at the Referral Center of the University Hospital of Bari. All the patients were homozygous for a mutation β^0 or β^+ or double heterozygous for a mutation β^0 or β^+ . The genetic characteristics of the patients seen in Bari have been previously reported^[8]. As β -thalassemia major requires regular blood transfusions and chelating therapy to alleviate the harmful accumulation of iron, all patients were on a program consisting of one or two monthly blood transfusion of packed red blood cells and desferrioxamine given as 40-60 mg/(kg·d) subcutaneously overnight using syringe pumps. The program

lasted for 5 nights per week. Mean length of desferrioxamine treatment was 19.2 ± 0.6 years. All patients had various stages of liver involvement, as confirmed by ultrasonography (e.g. liver steatosis, hyperechoic parenchyma) and/or liver biopsy (ranging from active/chronic siderotic and fibrotic hepatitis to definite liver cirrhosis, $n = 1$). The analysis of organ involvement confirmed that splenomegaly, hypothyroidism, and heart disease were the most frequent conditions with a prevalence of 39%, 35% and 18%, respectively. Hypogonadism was present in 35% of the patients. Type I insulin-dependent diabetes and a positive oral glucose tolerance test were present in 9% and 22% of the patients, respectively.

Healthy subjects ($n = 70$) Age 28 ± 1 years (range 18–40 years), BMI 22.0 ± 0.3 kg/m². Forty-seven were women. They were recruited from local staff members, students, and family practices. None of the healthy subjects complained of gastrointestinal symptoms or had previous gastrointestinal diseases or surgery. All had a negative abdominal ultrasound.

No significant difference existed in age, BMI and gender distribution between the patients and the normal controls. As expected^[9], patients had shorter stature than their matched controls (males: 168 ± 2 cm vs 178 ± 7 cm, $P = 0.0006$ and females: 158 ± 0.01 cm vs 167 ± 6 cm, $P = 0.00005$). All subjects gave their informed consent and the study was approved by the University of Bari Human Subjects Committee.

Study design

After the outpatient clinic evaluation consisting of history, physical examination, and serum analyses, subjects were scheduled for the motility studies and tests for autonomic neuropathy. A clinical and ultrasonographic follow-up was planned within the next 8–12 mo. Ultrasonography was chosen because it was a non-invasive and validated technique allowing to study both gallbladder^[11,10] and gastric^[11–16] emptying, simultaneously^[17]. We also developed a novel, one-day test for studying the upper gastrointestinal motility by simultaneous assessment of gallbladder, stomach, and small bowel transit^[18].

Gallbladder and gastric emptying

The gallbladder was studied for content, wall, shape, and motility with standardized methodology^[17]. Gallstones were diagnosed by the presence of mobile high-level echoes with acoustic shadows in the gallbladder, and sludge by the presence of mildly echogenic intraluminal sediment in the

absence of acoustic shadows^[19]. All gallstone patients had a small gallstone burden (i.e. less or equal to 20% of fasting gallbladder volume)^[20] and a thin gallbladder wall (i.e. less than 3 mm in the fasting state) delimiting a regularly pear-shaped organ^[17]. Gallbladder motility was assessed by monitoring gallbladder volumes before and at 5–15 min intervals over 2 h after ingestion of a liquid test meal.

Gastric emptying was assessed by monitoring antral areas at the same time points as for the gallbladder^[11,13]. The equipment consisted of an Esaote AUC50 equipped with a 3.5 MHz convex probe. The test meal consisted of 200 mL liquid formula containing fat 11.6 g (35%), protein 12 g (16%) and carbohydrate 36.8 g (49%) with a total of 300 kcal, 1 270 kJ, 445 mOsm/L (Nutridrink®, Nutricia S.p.A., Lainate Milano, Italy).

Orocecal transit time

Orocecal transit time was measured at the time when ultrasonographic studies were performed by the hydrogen breath test with a portable, previously validated device (EC60-Gastrolyzer, Bedfont, USA)^[18,21]. The substrate consisted of 10 g lactulose (Duphalac Dry®, Solvay Pharma, Belgium) which was added directly to the standard liquid test meal. The accuracy of the detector was ± 2 p.p.m. A rise of 10 p.p.m. above baseline on two consecutive measurements was considered as orocecal transit time and expressed in minute^[22].

Autonomic neuropathy

Symptoms and signs of autonomic dysfunction were evaluated by taking the clinical history according to Rangari *et al.*^[23]. The questionnaire was scored as “normal”, “mild” and “severe” for the presence of orthostatic hypotension, gastric symptoms, bowel disorders, sweating disorders, bladder dysfunction and in males, impotence. A combination of tests including the Sweat-spot-test (SST)^[22,24,25] and cardiorespiratory reflex tests^[26], were employed as sensitive methods to assess the presence of autonomic neuropathy^[27]. The SST was used to investigate the involvement of cholinergic sympathetic fibers by analyzing sweat abnormalities on the dorsum of the foot. An example of positive and negative test is shown in Figure 1.

A portable device was used to measure the “beat-to-beat” modifications of the R-R interval using skin electrodes connected to Cardionomic® (Lifescan, Italy). Lying-to-standing and standing-to-lying tests were used for sympathetic involvement. Valsalva maneuver, deep-breathing, cough test, and postural hypotension test were used for parasympathetic

Figure 1 Sweat spot test (SST) for assessment of sympathetic autonomic nervous system^[22,24,25]. The skin is coated with iodine and a fine emulsion of starch in arachis oil. Sweat is stimulated by intra-dermal injection of 0.1 mL acetylcholine (the red dot indicates the point of injection). Denervated glands do not respond to the acetylcholine injection. A colorimetric reaction between starch and iodine is triggered by the sweat from stimulated glands, so that each pore appears as a small black dot after 2–5 min. A digital photo is taken and transferred to a magnifying software to measure the number and distribution of dots appearing in a standard squared grid of 529 mm² divided into 64 squared subareas. A normal SST implied a score 12 dots/subarea and/or <8% of abnormal subareas (each square of the grid having less than 6 dots) according to Ryder^[24] and to our group^[25]. Only patients with both indices (SST score and % abnormal subareas) outside normal limits were considered to have a positive test. A: Normal and even distribution of sweating glands seen as black dots; B: Defective response in a β -thalassemia major patient with sympathetic autonomic neuropathy.

involvement. The results of each test were scored as normal, borderline or abnormal, according to age-controlled values. The overall results for autonomic neuropathy were therefore normal (all tests normal), early involvement (one abnormal test or two borderline abnormal), definite involvement (two or more abnormal tests)^[23].

Questionnaires

On the same day of the motility studies, subjects were asked to complete the following questionnaires under the supervision of one operator.

Bristol stool scale form^[28] This is a semi-quantitative score to assess the quality of bowel movements. The weekly frequency of evacuations over a time span of one mo was also assessed.

Dyspepsia score^[29] This is a semi-quantitative score from four symptoms such as epigastric pain, burning, belching/burping, postprandial fullness. Maximum score was equal to 48 with the upper normal limit equal to 8 and estimated from the mean \pm 2SD of healthy control values.

Visual analogue scales (VAS) of upper gastrointestinal perception^[18,30] These are self-assessed 100 mm horizontal lines of upper gastrointestinal perception monitoring appetite, satiety, nausea, abdominal fullness and upper abdominal (epigastric) pain or discomfort. Scores in mm were obtained at baseline (*i.e.* time 0) and at 15, 30, 45, 60, 90 and 120 min postprandially.

Rome criteria for biliary pain^[31] Patients with gallstones or sludge were considered "symptomatic" with a history of one or more episodes of colicky pain during the last 12 mo.

Health survey SF-36^[18,32,33] This is a short form of questionnaires assessing health-related quality of life (HRQOL). The SF36 includes 36 items which measure eight multi-item variables: general health, physical function, role physical, role emotional, social function, mental health, body pain, and vitality. Healthy subjects in this setting had a HRQOL profile remarkably similar to that derived from subjects across different cultures in USA and UK^[34].

Statistical analysis

Results are expressed as mean \pm SE. Demographic data, as well as baseline characteristics were checked for normal distribution (Kolmogorov-Smirnov goodness of fit test). Statistical significance in contingency tables was evaluated using χ^2 -test or Fisher's exact test when appropriate. Comparison of continuous variables among groups was performed with unpaired Student's *t*-test or Mann-Whitney rank sum test when appropriate. Comparison between multiple groups was assessed using one-way analysis of variance (ANOVA) or the Kruskal-Wallis non parametric ANOVA on ranks. *Post-hoc* multiple pair wise comparisons were calculated with the Fisher's LSD test. Linear regression analysis was performed by the method of least square and Pearson's coefficient. A multivariate analysis was constructed to study the effect on appetite of motility variables. The variables showing significant correlations in univariate analysis were included in a stepwise multiple regression analysis. All statistical calculations were performed with the NCSS2004 software (Kaysville, UT, USA). Statistical tests were conducted as a two-sided alpha level of 0.05^[35,36].

RESULTS

Gallbladder sludge and stones were found in 13 (56%) patients, all asymptomatic for previous episodes of biliary pain. Sludge was detected in 6 (26%) patients, while gallstones were observed in 7 (30%) patients, solitary and small in size (5-9 mm). The other 10 patients (44%) were gallstone/sludge-free.

Routine biochemical analysis

There was no difference in laboratory biochemistry among the

three subgroups of thalassemia patients, according to gallbladder content (Table 1). There was a statistically significant relationship between levels of ferritin and AST and ALT in the serum ($0.73 < r < 0.77$; $P > 0.00002$, $P < 0.00007$).

Table 1 Laboratory biochemistry in β -thalassemia major patients with gallstones, biliary sludge and gallstone-free

	Gallstones	Sludge	Gallstone/ sludge-free	P
No. of subjects	7	6	10	
Total bilirubin (mg/dL)	2.3 \pm 0.4	1.4 \pm 0.4	1.8 \pm 0.3	NS
AST (U/L)	50.9 \pm 11.5	32.8 \pm 12.5	44.9 \pm 9.7	NS
ALT (U/L)	76.7 \pm 17.7	42.7 \pm 19.1	59.8 \pm 14.8	NS
Ferritin (mg/dL)	1 922 \pm 445	1 165 \pm 481	1 900 \pm 372	NS
Hb (g/dL)	9.3 \pm 0.1	9.5 \pm 0.2	9.5 \pm 0.1	NS
Iron (mg/dL)	186.8 \pm 16.8	189.6 \pm 8.4	156.5 \pm 16.8	NS
Total proteins (g/dL)	7.8 \pm 0.2	7.9 \pm 0.2	7.4 \pm 0.2	NS
GGT (U/L)	34.4 \pm 5.6	18.3 \pm 6.0	19.4 \pm 4.7	NS
Alk. Phosphatase (U/L)	1.15 \pm 0.2	0.98 \pm 0.2	0.9 \pm 0.2	NS
LDH (U/L)	331.3 \pm 46.7	293.7 \pm 36.7	310.7 \pm 28.4	NS
Cholesterol (mg/dL)	98.3 \pm 10.2	129.4 \pm 12.1	96.9 \pm 9.0	NS
Tryglicerides (mg/dL)	114.9 \pm 23.5	71.6 \pm 27.9	84.4 \pm 22.0	NS

Data are expressed as mean \pm SE; NS: Not significant; AST: Aspartate transaminase; ALT: Alanine transaminase; GGT: Gamma-glutamyl transpeptidase; LDH: Lactate dehydrogenase.

Ultrasonographic studies

The study of gallbladder emptying showed that β -thalassemia major patients had increased fasting gallbladder volume (38.0 \pm 4.8 mL vs 20.3 \pm 0.7 mL, $P = 0.0001$), and residual volume (7.9 \pm 1.3 mL vs 5.1 \pm 0.3 mL, $P = 0.002$), decreased percent residual volume (20.3 \pm 1.5% vs 24.6 \pm 1.0%, $P = 0.03$) and slightly slower emptying (24.9 \pm 1.7 min vs 20.1 \pm 0.7 min, $P = 0.04$) than controls, as also suggested by the analysis of the gallbladder emptying curves (Figure 2).

Although all subgroups compared to controls had a significantly greater fasting gallbladder volume, only patients with biliary sludge and normal gallbladder had increased residual volume and delayed emptying. Indeed, relative gallbladder contraction (percent residual volume) was increased in patients with gallstones. β -thalassemia patients and controls showed comparable fasting and postprandial indices of gastric emptying (Table 2).

Orocecal transit time

Mean OCTT was longer in β -thalassemia patients than in controls (132.2 \pm 7.8 min vs 99.7 \pm 2.3 min, $P = 0.00003$) (Figure 3). Seven patients (30.4%) but none of controls had OCTT above the upper normal value of 140 min (*i.e.* mean \pm 2SD) derived from the control group ($P = 0.000026$, χ^2 -test). Similar results were found among different subgroups (Table 2).

Autonomic neuropathy

Twenty-one patients agreed to undergo the tests. Symptoms and signs of autonomic dysfunction were found in 11 patients (52%), which were mild in all but 2 cases (asymptomatic). Early or definitive parasympathetic and sympathetic involvement was present in 76.2% and 66.7% of cases, respectively. Early involvement was more frequent in the cases of parasympathetic AN system than those of sympathetic AN system (81.3% vs 28.6%, $P = 0.00037$). Overall, there were 3 (14%), 5 (24%), and 13 (62%) patients with normal tests, early involvement (mainly parasympathetic), and definitive involvement (both parasympathetic and sympathetic), respectively. All 5 patients with type I insulin-dependent diabetes or impaired oral glucose tolerance test and all 7 patients with thyroid involvement had

Figure 2 Time-course of fasting and postprandial gallbladder volumes in 23 β -thalassaemia major patients and 70 controls and expressed as mL (panel A) or percent fasting gallbladder volume (panel B). Symbols indicate means, while vertical lines indicate SEM. Patients had impaired gallbladder emptying, with significantly increased fasting and postprandial volumes at each time point (panel A), in spite of similar contraction (panel B), compared to controls.

Table 2 Dyspeptic symptoms, bowel habits and gastrointestinal motility indices (gallbladder, stomach, small bowel) in β -thalassaemia major patients with or without gallstone/sludge and in controls

	Gallstones	Sludge	GS/sludge-free	Controls	P
No. of subjects	7	6	10	70	
Dyspepsia (Buckley score)	5.0 \pm 1.0	6.8 \pm 2.2	7.8 \pm 2.5 ^a	4.9 \pm 0.2	0.046
Bowel habits (Bristol score)	3.5 \pm 0.21	3.4 \pm 0.6	3.8 \pm 0.2	3.5 \pm 0.07	NS
Stomach					
Fasting antral area (cm ²)	2.8 \pm 0.2	2.9 \pm 0.2	3.4 \pm 0.3	3.2 \pm 0.1	NS
Postprandial maximal area (cm ²)	10.4 \pm 0.2	10.7 \pm 0.5	10.9 \pm 0.4	11.5 \pm 0.2	NS
Postprandial minimal area (%)	0.9 \pm 0.5	0.3 \pm 0.3	0.4 \pm 0.7	2.1 \pm 0.4	NS
Postprandial minimal (cm ²)	2.9 \pm 0.2	3.0 \pm 0.2	3.3 \pm 0.2	3.4 \pm 0.1	NS
Half-emptying time (min)	28 \pm 2	31 \pm 2	28 \pm 2	27 \pm 1	NS
Gallbladder					
Fasting volume (mL)	30.1 \pm 3.8 ^a	42.9 \pm 10.3 ^a	40.6 \pm 8.9 ^a	20.3 \pm 0.7	0.000001
Postprandial residual volume (mL)	4.4 \pm 0.9	10.0 \pm 2.7 ^{ac}	9.1 \pm 2.3 ^{ac}	5.1 \pm 0.3	0.00030
Postprandial residual volume (%)	14.7 \pm 1.6 ^a	23.0 \pm 2.7	22.6 \pm 2.4	24.6 \pm 1.0	0.023
Half-emptying time (min)	21 \pm 1	27 \pm 5 ^a	26 \pm 2 ^a	20 \pm 1	0.009
Small bowel					
Orocecal transit Time (min)	128.6 \pm 13.4 ^a	30.0 \pm 15.0 ^a	136.0 \pm 13.6 ^a	99.7 \pm 2.3	0.000002

Data are expressed as mean \pm SE; GS: Gallstones; ^a P <0.05 vs controls; ^c P <0.05 vs gallstones (ANOVA and Fisher's LSD multiple-comparison test); NS: Not significant.

evidence of autonomic neuropathy. Neither age nor mean duration of desferrioxamine therapy was significantly different in patients with or without autonomic neuropathy (data not shown). Patients with autonomic neuropathy compared with those without it ($n=3$, scant number might imply a type 2 error), showed a trend towards longer OCTT (132 \pm 9 min vs 117 \pm 3 min, $P=0.06$), increased fasting volume (39.5 \pm 5.7 mL vs 19.7 \pm 4.3 mL, $P=0.07$) and decreased contraction (residual volume 8.6 \pm 1.6 vs 3.2 \pm 0.7 mL, $P=0.044$).

Figure 3 Orocecal transit time (OCTT) by lactulose H₂-breath test in β -thalassaemia major patients and controls. Patients had significantly longer OCTT than controls. Data are expressed as

individual points and means (bars).

Questionnaires

Overall, bowel habits were comparable in controls and patients (overall: 3.5 \pm 0.01 vs 3.6 \pm 0.2, respectively), while the score for dyspepsia was slightly higher (and statistically significant) in patients than in controls (6.7 \pm 1.2 vs 4.9 \pm 0.2, $P=0.027$) (Table 2).

The results of VAS for satiety and appetite (as postprandial AUC) showed that the two feelings were strongly and negatively correlated in both patients ($r=-0.87$, $P<0.0001$, $n=23$) and controls ($r=-0.03$, $P<0.0001$, $n=70$). Profiles for both appetite and satiety, however, were different in patients and controls. Fasting and postprandial appetite scores were invariably greater in patients than in controls. In particular, VAS for appetite was increased at baseline and showed a rapid decrease followed by a rapid and marked postprandial increase, compared to controls (Figure 4). Whereas univariate analysis suggested an inverse relation between appetite and OCTT, gallbladder contraction (as residual volume in percent) and gallbladder half emptying time, multiple regression analysis identified gallbladder half-emptying time as the only predictor ($P<0.002$) of time-related changes of appetite perception in patients. The relationship is shown in Figure 5.

There was no difference in nausea, fullness and abdominal pain between patients and controls either at baseline or postprandially (data not shown).

Figure 4 Time-course of visual analogue scale (VAS) for appetite and satiety in β -thalassemia major patients and controls. Data are mean \pm SE. On the X-axis time “0” is before ingestion of test meal. Asterisks indicate significant differences of controls vs patients ($0.0001 < P < 0.001$, at various time-points and overall ANOVA).

Figure 5 Correlation between appetite sensation (area under curve during 120 min of visual analogues scale) and speed of gallbladder emptying (half-emptying time) in β -thalassemia major patients.

Quality of life

Patients showed a significant deterioration in general health and a lower score than controls (51.7 ± 4 vs 73.1 ± 2 , $P = 0.00002$, ANOVA). All other domains were similar between the two groups.

Follow-up

The follow-up was completed after 8–12 mo in 16 out of 23 (69.6%) patients (2 patients were lost at follow-up because one died and the other moved to a different city). All patients remained asymptomatic for biliary symptoms. Gallbladder ultrasound was utilized to identify three subgroups of patients according to gallbladder content: (1) patients with a still anechoic gallbladder bile ($n = 5$), (2) patients who developed biliary sludge alone ($n = 4$) and (3) patients with prior sludge/gallstones who had unchanged gallbladder content ($n = 5$) or had stones and developed additional sludge ($n = 2$) during follow-up.

Table 3 Prior gallbladder motility indices in β -thalassemia major patients according to ultrasonographic appearance of the gallbladder during 8–12 mo follow-up

	Still anechoic	Developed sludge	Prior sludge/gallstones
No. of subjects	5	4	7
Fasting volume (mL), basal	29.2 ± 7.3	60 ± 17^a	29.2 ± 4.2
Residual volume (mL), basal	5.5 ± 1.4	14.7 ± 4.6^a	4.9 ± 0.9
Fasting volume at follow-up (mL)	30.9 ± 6.5	72.8 ± 20.1^{ac}	36.7 ± 5.1

Data are expressed as mean \pm SE; $^aP < 0.017$ vs still anechoic group; $^cP < 0.05$ vs prior sludge/gallstones group (ANOVA and Fisher's LSD multiple comparison test).

Variations in individual fasting gallbladder volumes for each subgroup are depicted in Figure 6. Major changes were evident in patients developing biliary sludge (panel A), also when gallbladder volume was expressed as percent increase (panel B). Interestingly, maximum percent increase in fasting gallbladder volume was observed in 2 patients (89% and 130%) who developed sludge in a gallbladder which previously contained only stones and showed normal fasting volume (*i.e.* <cut-off value of 32 mL). These two patients had clinical evidence of diabetes mellitus (and autonomic neuropathy) and hypothyroidism.

Furthermore, patients who developed sludge during follow-up had also significant changes in postprandial gallbladder volume (Table 3), with a trend towards decreased gallbladder contraction (residual volume: $25.6 \pm 4.7\%$ vs $19.5 \pm 2.8\%$ vs $17.9 \pm 3.0\%$), and longer transit time (OCTT: 150 ± 15.8 vs 108 ± 9.7 vs 126 ± 12.9 min) when compared with the other two subgroups.

Figure 6 Variations in individual fasting gallbladder volumes for each subgroup in β -thalassemia major patients. A: Major changes in patients who developed biliary sludge: asterisks indicate significant differences, compared to the other two groups of patients ($^aP < 0.05$ vs prior sludge/gallstones group and $^cP < 0.017$ vs still anechoic group). B: Percent increased fasting gallbladder volume in the three groups of patients. The last bar represents those gallbladders with stones that developed additional sludge ($n = 2$).

DISCUSSION

The present study examined the role of gallbladder and gastrointestinal motility in a well characterized group of adult β -thalassemia major patients in their 3rd decade of life, in relation with the presence of gallstones/biliary sludge. The results suggested the coexistence of impaired gallbladder motility, delayed small intestinal transit, and high prevalence of autonomic neuropathy in β -thalassemia major patients. These abnormalities might contribute, together with haemolytic hyperbilirubinemia to the pathogenesis of gallstones/sludge in β -thalassemia major.

As for other hemolytic disorders including sickle hemoglobinopathy^[37], both hyperbilirubinemia and bilirubin overload/precipitation in bile were definite predisposing factors for pigment gallstone in β -thalassemia major patients during chronic hemolysis^[6]. Indeed, in this study gallstones and/or biliary sludge were found in 56% of β -thalassemia major patients at entry, increasing to over 80% during follow-up (8-12 mo). A previous study^[7] in young patients reported a prevalence of 11.8% and 29.4% for gallstones and sludge, respectively. However, the mean age of β -thalassemia major patients in the present series was 26 years, while it was 12 years in the above mentioned study.

Several pathways might be involved in the pathogenesis of sludge and pigment stones in β -thalassemia. Glucuronidation of excess bilirubin was a predisposing factor in chronic haemolytic diseases^[38]. After injection of desferrioxamine, both fecal and urinary excretion were observed and there was formation of iron-desferrioxamine complex^[39] which might potentially interfere with the gallbladder microenvironment, already enriched in calcium bilirubinate. Moreover, increased secretion of glycoproteins by epithelial cells was seen after iron-induced stimulation in the guinea pig gallbladder^[40], and this might also take place in β -thalassemia major patients who developed sludge. However, since not all β -thalassemia patients with hemolytic hyperbilirubinemia had gallstones, other pathogenetic mechanisms underlying gallstone formation in β -thalassemia major may play a role.

The present study for the first time suggested that bile stasis and intestinal dysmotility might be key factors in the pathogenesis of pigment gallstones in β -thalassemia major. Pigment stones were common in patients with cirrhosis^[41,42], chronic hemolysis^[37,43,44], ileal Crohn's disease^[45], and conditions associated with impaired gallbladder kinetics^[37,44,46-48]. A recent study by our group found a certain degree of impaired motorfunction of the gallbladder also in non-hemolytic pigment stone patients^[1]. Compared with controls, there was about 100% increase of fasting gallbladder volume across 3 β -thalassemia major subgroups: *i.e.* patients with stones, sludge and stone-sludge free. Increased fasting gallbladder volume seems to be common in hemolytic conditions leading to pigment stones. Everson *et al.* found a volume of about 27 mL in adolescents and young adults with sickle hemoglobinopathy^[37]. Nevertheless, we found that adult "symptomatic" pigment (non hemolytic) stone patients had a fasting volume comparable to controls^[2]. In general, fasting gallbladder volume increased with body size^[49] and obesity^[49,50]. In this respect, the finding of increased fasting gallbladder volume was even more striking if one considered that β -thalassemia major patients had reduced growth with short stature, compared with matched controls^[9]. The increment in fasting gallbladder volume in β -thalassemia major, therefore, represents a true phenomenon and seems to point to defective interprandial (fasting) gallbladder motility. It has been found that fluctuations in fasting gallbladder volume (leading to 20-30% contraction) are normally synchronized with the intestinal migrating motor complex (MMC) and release of the intestinal hormone motilin^[51]. Patients with cholesterol gallstones had frequently increased fasting gallbladder volume^[1] with abnormal MMC and motilin release pattern. Interdigestive gallbladder emptying was reduced, contributing to gallstone formation^[52,53].

A similar derangement of fasting gallbladder motility might also develop in β -thalassemia major patients, and contribute to stasis and sludge/stone formation. A mechanical effect on fasting volume due to the physical presence of gallstones in the gallbladder lumen in β -thalassemia major was unlikely since fasting volume was larger in patients with sludge than in those with stones and also greater in patients without gallstone/sludge than in controls. Also, patients were all asymptomatic for biliary colicky pain (excluding an impacted stone within the cystic duct and/or acute cholecystitis). Our data indicate that postprandial gallbladder motility in β -thalassemia major patients is deranged. Not only fasting, but also residual volume was increased and emptying speed was somewhat slower (although still in the normal range) in sludge or gallstone/sludge-free patients, compared to both patients with gallstones and controls. The large residual gallbladder volume might be the consequence of a greater starting fasting volume^[1,50,54-58]. By contrast, we found that "crude" contraction was preserved (*i.e.* similar or even smaller percent residual volume than in controls, Table 2). Thus, findings in the present study mimicked those seen in sickle hemoglobinopathy^[37], with a smaller contraction index characteristic of β -thalassemia major patients (without mentioning gallbladder emptying speed). Differences in patients' characteristics, age and study protocol might partly account for the discrepancies across studies. Why in our study those patients with gallstones had better gallbladder contraction than controls, remains to be elucidated. Prospective observations are needed to see if, at *equilibrium* (*i.e.* after stone have formed), the gallbladder adapts to a smaller fasting volume and therefore better contraction (smaller residual volume). According to Laplace's law, in fact, the smaller the radius of a given shape (*i.e.* the gallbladder), the smaller the wall tension (from smooth muscle contraction) required to withstand a given internal fluid pressure^[59]. It is highly unlikely that release of endogenous cholecystokinin was deranged in this series of pigment gallstone patients, as seen during total parenteral nutrition^[60]. Whereas in cholesterol gallstone patients excess biliary cholesterol might alter cholecystokinin smooth muscle receptors^[61,62], resulting in secondary impaired gallbladder motility. This possibility has been ruled out in β -thalassemia major patients. In fact, biliary cholesterol saturation did not increase in pigment stone patients and gallbladder smooth muscle contractility *in vitro* was normal^[63].

We also found that OCTT was slightly delayed in β -thalassemia major patients, evidently across all subgroups. A clear explanation of the finding is not readily available, but a condition secondary to bacterial overgrowth or delayed colonic transit was highly unlikely, since there was no evidence of bacterial translocation with H₂-breath test and all patients had normal weekly bowel habits and a stool scale form. Small bowel dysmotility might accompany abnormal intestinal migrating motor complexes, as seen in a subgroup of patients with irritable bowel^[64] and functional dyspepsia^[65]. Also, intestinal mucosal changes have been described in β -thalassemia major patients^[66] and might influence some motility patterns in the small bowel. Others have found that small bowel inflammation and/or malabsorption are not more frequent in β -thalassemia major patients^[67]. Patients with ileal disease, bypass, or resection were at increased risk for developing pigment gallstones, so were patients with ileal Crohn's disease. Increased bilirubin levels in bile of patients with Crohn disease were caused by lack of functional ileum^[45]. One might speculate that delayed OCTT in β -thalassemia major patients might lead to increase of enterohepatic cycling of bilirubin^[68], therefore predisposing to pigment gallstone formation.

Autonomic neuropathy might be associated with gastrointestinal dysmotility. As expected, all β -thalassemia major patients with diabetes or abnormal oral glucose tolerance test had impaired tests for autonomic neuropathy (*i.e.* 23% of all patients).

Surprisingly abnormal tests of sympathetic and parasympathetic system were found in 86% of the patients. Potential causes for autonomic neuropathy in β -thalassemia major patients were the coexistence of diabetes mellitus, neurotoxicity of desferrioxamine and iron overload (or both)^[69,70] (for example, visual and auditory neurotoxicity were found in 1 patient of this series). The presence of hemolysis might also contribute to neuropathy, as abnormal autonomic cardiovascular response was described in patients with sickle cell anemia^[71]. Last but not least, the presence of autonomic dysfunction was also a feature in patients with different types and stages of chronic liver disease,^[72] and this might also be the case in chronic liver disease of β -thalassemia major patients. Further studies are needed to clarify if the presence of autonomic dysfunction is a useful tool for the prediction of prognosis and outcome of patients with β -thalassemia major.

Positive tests for autonomic neuropathy tended to relate to abnormal gallbladder and small bowel motility. Interestingly, we found delayed OCTT with increased bowel movements in chronic alcoholic patients during abstinence, was associated with dysfunction of autonomic nervous system. A form of subclinical autonomic neuropathy might predispose to a diffuse disorder of smooth muscle, suggesting the multi-organic involvement of the gastrointestinal tract. In the determination of altered OCTT a possible role for dysfunction of autonomic nervous system has been suggested in other series of patients^[22] and might deserve further investigations also in β -thalassemia major patients.

In conclusion, the present study shows for the first time that in β -thalassemia major patients in the 3rd decade of life, increased volume and deranged motility of the gallbladder are associated with delayed small intestinal transit and mild dyspeptic symptoms. Such functional abnormalities apparently contribute together with haemolytic hyperbilirubinemia to the pathogenesis of gallstones/sludge in β -thalassemia major.

Abstract

Human intestinal capillariasis is a rare parasitosis that was first recognized in the Philippines in the 1960 s. Parasitosis is a life threatening disease and has been reported from Thailand, Japan, South of Taiwan (Kaoh-Siung), Korea, Iran, Egypt, Italy and Spain. Its clinical symptoms are characterized by chronic diarrhea, abdominal pain, borborygmus, marked weight loss, protein and electrolyte loss and cachexia. Capillariasis may be fatal if early treatment is not given. We reported 14 cases living in rural areas of Taiwan. Three cases had histories of travelling to Thailand. They might have been infected in Thailand while stayed there. Two cases had the diet of raw freshwater fish before. Three cases received emergency laparotomy due to peritonitis and two cases were found of enteritis cystica profunda. According to the route of transmission, freshwater and brackish-water fish may act as the intermediate host of the parasite. The most simple and convenient method of diagnosing capillariasis is stool examination. Two cases were diagnosed by histology. Mebendazole or albendazole 200 mg orally twice a day for 20-30 d is the treatment of choice. All the patients were cured, and relapses were not observed within 12 mo.

INTRODUCTION

Capillaria species parasitize many classes of vertebrates, although only 4 species described have been found in humans, namely *Capillaria philippinensis*, *Capillaria plica*, *Capillaria aerophila*, and *Capillaria hepatica*^[1]. *C. philippinensis* is a tiny nematode that was first described in the 1960 s as the causative agent of severe diarrheal syndromes in humans. In 1962, the first case of human intestinal capillariasis occurred in a previously healthy young man from Luzon (Philippines) who subsequently died. At autopsy, a large number of worms, later

described as *C. philippinensis*, were found in the large and small intestines^[2]. The disease was first reported by Chitwood *et al.* in 1964^[3]. During the Philippine epidemic from 1967 to 1968, more than 1300 persons acquired the illness and 90 patients with parasitologically confirmed infections died^[4]. In late 1978 and early 1979, another small outbreak was identified in northeastern Mindanao, the Philippines, and about 50 persons acquired the infection^[4]. Sporadic cases continued to appear in northern Luzon as well as in other areas where epidemics had occurred. The disease is also endemic in Thailand, and was first reported in 1973^[5]. Sporadic cases have also been found in Iran^[6], Egypt^[7,8], Taiwan^[9], Japan^[10,11], Indonesia^[12], Korea^[13], Spain (probably acquired in Colombia)^[14] and Italy (acquired in Indonesia)^[15], indicating that this infection is widespread. Because the infection can result in a severe disease with a high mortality when untreated, early diagnosis is very important. Here we described 14 cases of human intestinal capillariasis found in Taiwan from 1983 to 2001.

MATERIALS AND METHODS

Since 1983, 14 cases have been diagnosed as intestinal capillariasis in Taiwan, all with the symptoms of chronic diarrhea, abdominal pain, borborygmus and marked weight loss. All patients were hospitalized for examination and treatment. Their diagnosis was confirmed by eggs and/or larvae and/or adult *C. philippinensis* found in the feces of 5 patients. Two cases were recognized by a pathologist by histology of jejunum or ileum (Figures 1, 2) with negative stool examination. Bacterial cultures of stool specimens were negative in all patients. The stool specimens were examined by formalin-ether concentration method. *C. philippinensis* eggs were peanut-shaped with flattened bipolar plugs, 20×40 mm in size (Figure 3).

Figure 1 *C. philippinensis* worms embedded in intestinal mucosa (arrow). Hematoxylin and eosin, ×200.

RESULTS

Fourteen cases, nine males and five females, were 36 to 76 years old when they were diagnosed as intestinal capillariasis (Tables 1, 2). Three lived in Kaohsiung County and eleven in Taitung County. Seven of them were aborigines and two were brother and sister. Two of them had histories of travelling to Thailand. Two patients had history of eating raw or insufficiently cooked fresh-water fish. Four of 14 patients had mixed infection with *Clonorchis sinensis* or *Strongyloides stercoralis* whose eggs were also found in the feces.

Figure 2 Multiple longitudinal sections of *C. philippinensis* on mucosal surface and lumen. The longitudinal sections shows a row of stichocytes (arrow). Hematoxylin and eosin, $\times 200$.

Three cases received emergency laparotomy due to peritonitis and two of them were found to have jejunitis cystica profunda. Small bowel series and colonoscopic study revealed mild dilatation and thickened mucosa of jejunum and ileum, which suggested malabsorption. Laboratory findings revealed anemia, malabsorption of fats and carbohydrates and low serum levels of potassium, sodium, calcium and total protein. Mebendazole 200 mg twice a day for 20 d was given to 12 patients, while albendazole was given to the other two patients. All of them were cured and relapses were not observed within 12 mo following chemotherapy and supportive treatment.

Figure 3 Peanut-shaped eggs of *C. philippinensis* in feces with flattened bipolar plugs. $\times 160$.

DISCUSSION

Capillaria species parasitize many classes of vertebrates, although only 4 species have been found in humans, namely *C. philippinensis*, *C. plica*, *C. aerophila*, and *C. hepatica*^[1]. *C. philippinensis* is a tiny nematode first described in the 1960s as a pathogen inducing severe diarrheal syndromes in humans. In 1962, the first reported case of human intestinal capillariasis occurred in a previously healthy young man from Luzon in the Philippines, who subsequently died. At autopsy, a large number of worms were found in the large and small intestines^[2]. Chitwood *et al.* described this case in 1964^[3]. There was an epidemic of

the disease in the Philippines from 1967 to 1968, more than 1 300 persons acquired the illness, and 90 patients with parasitologically confirmed infection died^[4]. In late 1978 and early 1979, another small outbreak was identified in northeastern Mindanao, Philippines, with about 50 persons infected^[4]. Sporadic cases continued to appear in northern Luzon and also in other areas where epidemics had occurred. The disease is endemic in Thailand, where it was first reported in 1973^[5]. Sporadic cases have also been found in Iran^[6], Egypt^[7,8], Taiwan^[9], Japan^[10,11], Indonesia^[12], Korea^[13], Spain (probably acquired in Colombia)^[14], and Italy (acquired in Indonesia)^[12]. The parasite thus appears to be widespread. Because infection may result in severe disease with a high mortality when untreated, early diagnosis is very important. Infection with *C. philippinensis* should be considered in the differential diagnosis of malabsorption syndrome^[15]. There was often a delay in diagnosis, averaging 4 mo and even longer in Taiwan, especially in non-endemic areas^[16]. The delay was over a year in our cases.

It has been found that *Capillaria* species are closely related to *Trichuris* and *Trichinella* species^[1], and the eggs of *Trichuris trichiura* and *C. philippinensis* are similar in appearance, although they can be differentiated by experienced observers^[17]. Some individuals could be infected with both parasites, which further confuse the picture. In fact, 10 of the 11 patients described by Whaler *et al.*^[18] were infected with both *T. trichiura* and *C. philippinensis*. An inexperienced observer might confuse the eggs of *Capillaria* with those of *T. trichiura*^[1], although a correct parasitologic diagnosis could be made by finding characteristic peanut-shaped eggs with flattened bipolar plugs^[2].

The source of *C. philippinensis* infection in our two patients was unclear, particularly as they had no travel history. In Thailand and the Philippines, the infection has been attributed to eating raw or insufficiently cooked fish harboring the larvae^[2,19]. Hakka Chinese in Taiwan like to eat raw, freshwater fish, so they might be expected to have a significant incidence of infection if freshwater fish in Taiwan commonly host *C. philippinensis*. This is not the case, however. Our two patients lived in the southeastern part of Taiwan, closest to Luzon, so it was possible that the fish imported from the Philippines were the source of infection. Fish in markets in Taitung County, southeastern Taiwan, have been examined for *C. philippinensis* infection, but the results were negative. Recent findings suggested that fishing-eating birds might be the natural definitive hosts^[20], including *Bulbulcus ibis*, *Nycticorax nycticorax*, and *Ixobrychus sinensis*, all of which have been found in Taiwan^[21]. Therefore, the possibility of human infection acquired in Taiwan by direct or indirect ingestion of fresh-water fish with a larval stage of the parasite cannot be discounted.

Enteritis cystic profunda is a disorder with mucin-filled cystic spaces lined by non-neoplastic columnar epithelium in the wall of small intestine, predominantly the submucosa. The histology has been found to simulate mucinous carcinoma^[22]. It has also been shown to occur in the esophagus^[23] and stomach^[24,25]. The irregular distribution of the glands and cysts with normal-appearing glandular epithelium containing mucus and Paneth's cells were features suggestive of its benign nature^[26].

Albendazole was presently considered the drug of choice for the treatment of human intestinal capillariasis because it was effective against eggs, larvae, and adult worms^[1,26]. However, for a major infection, mebendazole (200 mg orally twice a day for 20 d) was recommended as the treatment of choice. Attempts to reduce the standard schedule of mebendazole treatment (400 mg daily for 3 wk) have failed in Thailand. Our patients responded well to a standard course of mebendazole and had no evidence of relapse.

Convenient international travel and commercial globalization

have facilitated the wide dissemination of infectious diseases, whether they are carried by human hosts or non-human vectors. Intestinal capillariasis needs to be considered in the differential diagnosis of patients with chronic diarrhea, borborygmus, abdominal pain, and marked weight loss.

Abstract

AIM: To investigate whether the non-invasive real-time Indocyanine green (ICG) clearance is a sensitive index of liver viability in patients before, during, and after liver transplantation.

METHODS: Thirteen patients were studied, two before, three during, and eight following liver transplantation, with two patients suffering acute rejection. The conventional invasive ICG clearance test and ICG pulse spectrophotometry non-invasive real-time ICG clearance test were performed simultaneously. Using linear regression analysis we tested the correlation between these two methods. The transplantation condition of these patients and serum total bilirubin (T. Bil), alanine aminotransferase (ALT), and platelet count were also evaluated.

RESULTS: The correlation between these two methods was excellent ($r^2=0.977$).

CONCLUSION: ICG pulse spectrophotometry clearance is a quick, non-invasive, and reliable liver function test in transplantation patients.

Hsieh CB, Chen CJ, Chen TW, Yu JC, Shen KL, Chang TM, Liu YC. Accuracy of indocyanine green pulse spectrophotometry clearance test for liver function prediction in transplanted patients. *World J Gastroenterol* 2004; 10(16): 2394-2396 <http://www.wjgnet.com/1007-9327/10/2394.asp>

INTRODUCTION

Monitoring of liver function is important in patients undergoing liver transplantation. Exact liver function and the extent of the remaining liver function at end-stage liver disease can indicate the appropriate timing of liver transplantation^[1-3]. During liver transplantation, immediate liver function evaluation can resolve primary non-functioning of the liver and technical complications^[4]. Moreover, post-transplantation early liver function evaluation can detect delayed graft malfunction or acute/chronic graft rejection.

Indocyanine green (ICG) is a synthetic dye that has been used for many years to measure hepatic blood flow and as a test of liver function^[5]. It was also used by Makuuchi and his colleagues, based on their experience, as a guide for selecting

the type of resection to be performed^[6,7]. During liver transplantation, ICG clearance rate has been used for evaluation of the recipient liver^[3,8], the donor liver^[9,10] and the post-transplant liver graft^[3]. Conventional ICG clearance is determined by measuring the rate of elimination using 3 mL venous samples at 0, 5, 10, 15, and 20 min after administering ICG. This invasive technique produces patient discomfort through repeated peripheral venous sampling at exact time intervals. Pulse spectrophotometry is an infrared-based non-invasive technique originally developed for monitoring tissue oxygenation. It has been previously used for the measurement of hepatic ICG concentration by Shinohara *et al.*^[11]. In a recent case report, infrared spectrophotometry was sufficiently sensitive to measure the ICG clearance in surgical patients^[12].

Even though the ICG clearance test has been used worldwide to predict liver function, there are some limitations for end-stage liver disease in patients with hyperbilirubinemia, intrahepatic shunt or capillarization^[13].

ICG pulse spectrophotometry (LiMON) has not been tested in transplanted patients previously.

The aim of this study was to determine the accuracy of ICG spectrophotometry, compared with the conventional invasive method, in predicting liver function in waiting and transplanted patients.

MATERIALS AND METHODS

Thirteen patients who underwent liver transplantation and follow-up at the Tri-Service General Hospital were evaluated in the current study. Eleven male patients were transplanted for chronic liver disease of various etiologies (1 hepatitis C, 2 hepatitis B, and 8 hepatitis B with hepatoma) and 2 patients with end-stage liver disease awaiting transplantation. Patients 7 and 11 were studied in acute rejection during follow up (d36 and 90) and proved by liver biopsy. Patients 3, 4 and 13 were studied immediately post-liver transplantation (within 24, 27 and 12 h) (Table 1).

Invasive ICG measurement

An intravenous (IV) bolus of 0.5 mg/kg ICG was injected rapidly through a central venous catheter or large peripheral venous line, and samples were obtained from another peripheral venous line at 0, 5, 10, 15, 20 min thereafter and kept in an EDTA-treated tube at room temperature until centrifuged at 3 000 r/min for 10 min. Absorbance was measured by a Perkin Elmer spectrophotometer at 805 nm. Direct ICG retention rate at 15 min (ICG_{15D}) and the elimination rate constant (ICG(K)_D) values were calculated using a commercial computer program (V-500 Spectra Manager, Jasco, Japan).

ICG pulse spectrophotometry

Pulse-dye densitometry (LiMON, Stahigruburring, Munich, Germany) was used to measure the blood ICG concentration non-invasively in real time. This apparatus makes such measurements possible by continuously monitoring the optical absorption at 805 nm and 890 nm, via an optical probe attached to the patient's finger. During the first 5-10 min after

ESLD: End-stage liver disease on waiting list; During-OLT: immediately after liver transplantation within seven days; Post-OLT: > one month after liver transplantation in stable condition; Acute rejection: proved by liver biopsy; the number in brackets means the case number.

ICG was injected, blood ICG concentrations were monitored at every pulse interval via pulse spectrophotometry. The elimination rate constant ICG(K)_E was calculated automatically by the time course of blood ICG concentration. The estimated ICG₁₅ retention rate (ICG_{15E}) was obtained via pulse spectrophotometry computer analysis during the first 5-10 min. As the usual measurement time of the Limon is between 5 and 10 min, the (ICG_{15E}) is simply calculated from the ICG plasma disappearance rate^[14].

Statistical analysis

Linear regression analysis was used to test the correlation. Statistical significance was considered at $P < 0.05$. The statistic software was S-Plus®2000 for Windows (CANdiensten, Amsterdam, The Netherlands).

Figure 1 Correlation between the ICG_{15E} and ICG_{15D}. The correlation is excellent, $r^2 = 0.977$.

RESULTS

The correlation between ICG_{15D}, ICG_{15E}, ICG(K)_D, ICG(K)_E values for ICG₁₅ and ICG(K) by these two methods was excellent ($r^2 = 0.977, 0.855$) (Figures 1, 2). Two patients had poor liver function, elevated T. Bil, and higher ICG₁₅ retention rates, and were on the waiting list for transplantation. Three patients who had good liver function immediately post-liver transplantation showed elevated T. Bil, and lower ICG₁₅ retention rates. Two patients who were in acute rejection had poor liver function with elevated ALT and higher ICG₁₅ retention rates. Five patients, who were in a stable condition with good liver function post-liver transplantation, had low T. Bil. and better ICG₁₅ retention rates.

Figure 2 Correlation between ICG (K)_E and ICG (K)_D. The correlation is excellent, $r^2 = 0.855$.

DISCUSSION

ICG is a water-soluble tricarbo-cyanine dye that is extracted by

hepatic parenchyma cells and excreted almost entirely into bile. Hepatic clearance of ICG occurs by two major processes: by uptake across the sinusoidal plasma membrane with a high extraction ratio; and by removal from the hepatocytes via cytoplasmic transport and exclusive biliary excretion with neither intrahepatic conjugation nor enterohepatic circulation^[15]. The concentration in the plasma can be measured by spectrophotometry and its rate of elimination has been widely used as a measure of liver blood flow and liver function^[16]. Most of the studies assessing liver function before hepatectomy and the postoperative outcome were carried out using the ICG clearance test^[17].

Pulse spectrophotometry has been developed in recent years to enable the blood ICG concentration to be measured easily, less invasively, and continuously. The previous method for measuring the ICG concentration by spectrophotometry did not show sufficient accuracy. The new approach, based on pulse spectrophotometry, is able to continuously measure the arterial ICG concentration because of its ability to detect the pulse wave, greatly improving its accuracy.

Pulse spectrophotometry measurements of ICG concentration with each pulse could provide information on ICG liver uptake and excretion. From the concentration, a time curve of the ICG uptake and excretion rates were calculated under different experimental conditions. The experimental study by El-Desoky *et al.*^[5] showed the sensitivity of measurement of ICG uptake and excretion rates in hepatic artery occlusion, portal vein occlusion, ischemia-reperfusion injury, hepatic microcirculation, colchicines treatment, and bile duct ligation.

Assessment of liver function remains difficult in transplanted patients because of etiological complexity. The differential diagnosis includes primary non-function of the graft, rejection, virus re-infection, drug intoxication, and thrombosis of hepatic blood vessels. After liver transplantation, liver function tests are often difficult to interpret and non-specific. The diagnosis at present relies on a combination of biochemical, hemodynamic, clinical markers, and occasionally liver biopsy. However, serial observations up to 72 h are required. Measurement of ICG clearance appears to be a simple and safe test to assess early liver graft function. The development of non-invasive pulse spectrophotometry has enabled bedside assessment of the elimination of ICG with immediate results, therefore increasing its clinical usefulness.

A study by Jalan *et al.* showed the ICG measured at 24 h after liver transplantation accurately reflected graft function and predicted graft survival and outcome. In other studies, ICG excretion was a sensitive index of ischemia/reperfusion injury during the early stages post-liver transplantation^[17].

The traditional ICG clearance test is invasive and labor-dependent. The whole procedure requires more than 30 min at the bedside for loading dosage and venous puncture. Failure may occur as a result of the patient's underlying disease and medication such as gout, arthritis, and anti-TB drugs. Technical failure may be due to blood hemolysis or laboratory errors. The real-time pulse spectrophotometry ICG clearance test is non-invasive and machine-dependent. Technical failure may be due to detecting probe malpositioning, and patient movement.

In this study, we have chosen two ICG clearance test methods to measure end-stage liver disease, immediately post-liver transplantation or in acute rejection patients. In patients with hyperbilirubinemia, before and after successful liver transplantation, the ICG₁₅ clearance test may be very useful in

evaluating the new liver's function. ICG pulse spectrophotometry appears to be a sensitive and specific test to predict graft function in ischemia/reperfusion and acute rejection patients. The correlations between ICG(K) and ICG₁₅ using these two methods were excellent.

In conclusion, in this study, the correlation between conventional and pulse spectrophotometry ICG clearance tests is excellent in transplanted patients. The ICG pulse spectrophotometry clearance test is a quick, non-invasive, easy, inexpensive, and reliable liver function test in transplantation patients.

Abstract

AIM: Subclinical hepatic encephalopathy (SHE) is a common complication of liver diseases. The aim of this study was to find out the normal value of psychometric test and to investigate the prevalence of SHE in Chinese patients with stabilized hepatic cirrhosis.

METHODS: Four hundred and nine consecutive cirrhotic patients without overt clinical encephalopathy were screened for SHE by using number connection test part A (NCT-A) and symbol digit test (SDT). SHE was defined as presence of at least one abnormal psychometric test. The age-corrected normal values were defined as the mean \pm 2 times standard deviation (2SD), and developed in 356 healthy persons as normal controls. Four hundred and sixteen patients with chronic viral hepatitis were tested as negative controls to assess the diagnostic validity of this test battery.

RESULTS: There was no significant difference in NCT scores and SDT quotients between healthy controls and chronic hepatitis group ($P>0.05$). In all age subgroups, the NCT and SDT measurements of cirrhotic patients differed significantly from those of the controls ($P<0.05$). When mean \pm 2SD of SDT and NCT measurements from healthy control group was set as the normal range, 119 cirrhotic patients (29.1%) were found to have abnormal NCT-A and SDT tests, 53 (13.0%) were abnormal only in SDT and 36 (8.8%) only in NCT-A. Taken together, SHE was diagnosed in 208 (50.9%) cirrhotic patients by this test battery. The prevalence of SHE increased from 39.9% and 55.2% in Child-Pugh's grade A and B groups to 71.8% in Child-Pugh's grade C group ($P<0.05$). After the adjustment of age and residential areas required from the tests, no correlation was found in the rate of SHE and causes of cirrhosis, education level and smoking habit.

CONCLUSION: Psychometric tests are simple and reliable indicators for screening SHE among Chinese cirrhotic patients. By using a NCT and SDT battery, SHE could be found in 50.9% of cirrhotic patients without overt clinical encephalopathy. The prevalence of SHE is significantly correlated with the severity of liver functions.

INTRODUCTION

Subclinical hepatic encephalopathy (SHE) has been defined as a condition in which patients with cirrhosis regardless of its etiology, demonstrates neuro-psychiatric and neuro-physiological defects, yet, having a normal mental and neurological status through global clinical examination^[1-3]. SHE could have some disadvantageous influence on patients' daily life, and could be a preceding stage of manifested hepatic encephalopathy (HE) clinically. The prevalence of SHE was reported to vary from 10% to 84%, depending on the diagnostic techniques used and patients selected for the studies^[1-10]. Many diagnostic techniques including psychometric test, electro-encephalogram, evoked potentials (EP), have been used to detect SHE. Among these tests, only psychometric test can be administered easily in epidemiological studies. In a variety of psychometric tests listed in the medical literature, SDT and NCT part A (NCT-A) were reported to have the advantages of simplicity and reliability^[1,11-15]. The combination of these two tests was commonly applied in epidemiological studies. We evaluated a battery of SDT and NCT tests in a pilot study in Chinese patients with good results^[16]. Therefore, it was selected in this big sample size study. By definition, SHE can only be found in cirrhotic patients. In this study, besides the healthy control group for the establishment of normal values of SDT and NCT, we also set up a chronic hepatitis group as negative control to assess the reliability of SDT and NCT test battery. In recent years, studies on the prevalence of SHE have been greatly increased in Western literature, but those from Chinese patients have not been fully documented. The aim of the present study was to establish the normal value of psychometric tests for Chinese people, to determine the prevalence of SHE in stable cirrhotic patients in China by using this test battery, and to explore the features of SHE in these patients.

MATERIALS AND METHODS

Subjects

Four hundred and nine consecutive cirrhotic patients attending the Department of Gastroenterology of Guangzhou Municipal First People's Hospital for screening of SHE from June 1, 1998 to March 31, 2002 were included in the study. Inclusion criteria were: no neurological or mental diseases, no attack of HE in the past or present, no use of sedative or other psychotropic drugs two wk prior to the tests. The following patients were excluded. Those who had portosystemic shunt operation, those who had alcohol consuming more than 150 g daily within 1 wk prior to the study, those who had gastrointestinal bleeding 4 wk previously, those whose hemoglobin level was less than 90 g/L, those who had dehydration or electrolyte imbalance, those whose body temperature was higher than 37.5 °C, those who had severe cardiac or pulmonary or renal or cerebrovascular

diseases or diabetes mellitus, and those who were illiterates.

Diagnosis of cirrhosis was made according to the criteria revised in 1990 National Symposium on Cirrhosis in China^[17]. In this study, 10 patients had liver biopsy. The Child-Pugh's scores were used to assess the severity of liver disease. Special attention was paid to the exclusion of stage 1 HE. The symptoms in this stage included abnormal behavior (exaggeration of normal behavior, euphoria or depression), sleeping disorders (hypersomnia, insomnia or inversion of sleeping pattern), neuromuscular activity (muscular incoordination, impaired handwriting) and changes in mental function (declined alertness or memory, subtle disorientation or impaired calculation). The etiology of the 409 cirrhotic patients consisted of chronic hepatitis B in 322 (78.7%), chronic hepatitis C in 28 (6.9%), and chronic alcoholics in 59 (14.4%). According to the Child-Pugh's grading of liver function, 188 (46.0%) were grade A, 143 (35.0%) grade B and 78 (19.0%) grade C. Two hundred and fourteen patients (52.3%) had no ascites, 72 (17.6%) had mild ascities and 123 (30.1%) had severe ascities. One hundred and sixty-nine patients (41.3%) had normal levels of serum albumin, 102 (24.9%) had mild hypoalbuminemia (30-35 g/L) and 138 (38.8%) had severe hypoalbuminemia (<30 g/L). One hundred and twenty-three patients (30.1%) had normal prothrombin time (PT), 152 (37.2%) had mildly prolonged PT (14-18 s) and 134 (32.7%) severely prolonged PT (>18 seconds). Under endoscopic examination, 28 patients (6.8%) had severe esophageal varices, 152 (37.2%) had mild varices and 229 (56.0%) had no varices.

Normal values of the psychometric tests were obtained from 356 consecutive healthy subjects undergoing routine physical check-up in the hospital between June 1 and July 1, 1998. All of them had no physical and psychological disorders, no neurological or mental diseases and no history of sedatives or alcohol consumption. The negative control group consisted of 416 consecutive outpatients with chronic viral hepatitis in Division of Infectious Diseases of our hospital in the same period. The diagnostic criteria were in accordance with the Chinese National Standards of Viral Hepatitis^[18]. Among the 416 cases, 384 (92.3%) had hepatitis B, 32 (7.7%) hepatitis C.

The study was approved by the Ethics Committee of the First Municipal People's Hospital of Guangzhou, Guangzhou Medical College, with written consent from each patient and subject.

Questionnaire

Questionnaire was given to each subject. It included the following items, namely age, sex, smoking habit (smoking cigarette daily, yes/no), alcohol (drinking alcohol daily, yes/no), education (<6 years, 6-12 years, >12 years), residential area (urban/rural), occupation, history of liver diseases, concomitant illness.

Psychometric assessment

Symbol digit test (SDT) was in Chinese version of Wechsler adult intelligence scale revised (WAIS-RC) by Gong^[19]. The individuals were given a list of digits from 1 to 9 associated with symbols and asked to fill in blanks with symbols that corresponded to each number. An initial demonstration was performed to familiarize the subjects with the test. The test scores were the total number of correctly sequential matched symbols to the number within a 90-seconds interval. The score was only 0.5, if the symbol was placed upside down. According to age, the total score of each subject was transformed to a quotient from an equivalent form, the subjects were divided into two groups according to their residential areas, either rural or urban area.

In the number connection test (NCT) part A, the subjects were asked to connect the numbers printed on the paper

consecutively from 1 to 25 as quickly as possible^[20]. After explanation to the subjects, demonstrative tests were given to ensure a correct understanding and then the test was carried on. The test scores included the time required for the test and for correcting the errors.

These two psychometric tests were performed by the patients and subjects with help from medical staffs without awareness of the diagnosis.

Statistical analysis

Student's *t* test and Chi-square test were used to assess the differences among the groups. Multivariate logistic analysis was used to evaluate the influence of the variables in the prevalence. $P < 0.05$ was considered statistically significant. Normal cut-off values of SDT and NCT were set at the mean \pm 2SD from the normal control arm, with a low value indicating a poor performance in SDT test and a higher score indicating a poor performance in NCT test. The diagnosis of SHE was made when one or both SDT and NCT appeared abnormal.

RESULTS

The demographic data of three arms are shown in Table 1. There was no significant difference ($P > 0.05$) among all variables from the three arms. The results of SDT and NCT in different age subgroups from the three arms are shown in Table 2 and Table 3. In both tests, no significant difference was found between healthy controls and chronic hepatitis arms ($P > 0.05$). However, the results in the cirrhotic arm differed significantly from those of the two control arms ($P < 0.05$). This finding supported that the Chinese version of SDT and NCT tests could clearly distinguish the neuro-psychiatric defects in SHE. The values of SDT and NCT tests from the healthy control arm could be good parameters for the establishment of normal values of these two tests.

Table 1 Demography in 3 groups

	Control <i>n</i> = 356	Hepatitis <i>n</i> = 416	Cirrhosis <i>n</i> = 409
Age (yr)	44.4 \pm 12.7	36.8 \pm 18.6	53.4 \pm 11.9
Male/female	207/149	330/86	248/161
Education (yr)			
>6	69 (19.4)	69 (16.9)	82 (20.0)
6-12	168 (47.2)	215 (51.7)	190 (46.5)
> 12	119 (33.4)	132 (31.7)	137 (33.5)
Smoking	65 (18.3)	99 (23.8)	88 (21.5)
Alcohol	39 (10.9)	48 (11.5)	123 (30.1)

The influence of the variables on the results of SDT and NCT is shown in Table 4. No significant difference was found in sex, smoking and alcohol drinking habits, and the etiology of cirrhosis ($P > 0.05$), but the difference was related to age, education and Child-Pugh's grade ($P < 0.05$). However, after adjustment of age and residential areas required for SDT and NCT tests, Child-Pugh's grade was the only risk factor of SHE ($P < 0.05$).

The relationships between Child-Pugh's grade and SDT/NCT are shown in Table 5. Although the rate of SHE between Child's grades A and B of liver disease was not significantly different ($P > 0.05$), significance was found between grades A and C, and grades B and C ($P < 0.05$). One hundred and nineteen patients (29.1%) were abnormal in both NCT and SDT, 53 (13.0%) abnormal in SDT only and 36 (8.8%) in NCT-A only. Taken together, the two-test battery gave the diagnostic rate of SHE in 50.9% of 208 patients.

DISCUSSION

The reasons why we selected SDT and NCT part A out of a variety of psychometric tests from the medical literature in this study are as follows. (1) NCT and SDT were simple, inexpensive and sensitive tests and have been well used in many SHE studies on its prevalence, prognosis and treatment^[1-15]. NCT part A alone has been shown to be sufficient in detection of SHE in the majority of patients^[3,12]. (2) The patients with SHE exhibited selective deficits in reactivity and fine motor skills, with preservation of general intelligence, memory and language speaking. Therefore, it was reasonable to select WAIS performance subtests such as SDT^[11,12]. (3) Both SDT and NCT were easy to perform and reproduce in minutes at the outpatient clinics. Moreover more complicated tests would increase the patients' fatigue and mental burden and affect their performance efficiency^[11]. In order to evaluate the reliability of SDT/NCT test battery, two control groups were set up. Normal data of each age subgroup in the two tests were obtained from healthy subjects and then assessed with the data from chronic hepatitis negative control and cirrhosis positive control. The corresponding scores of the tests from healthy and chronic hepatitis control groups were very close. By using the normal range drawn from healthy subjects, the total abnormal rate of SDT and NCT in chronic hepatitis group was 5.5% and 7.2% respectively, near marginally statistical range. The results supported that SDT and NCT test battery was a sensitive and specific method for detection of SHE.

Whether or not the patients with alcoholic cirrhosis have a higher prevalence of SHE is still controversial. The higher prevalence of SHE in patients with alcoholic cirrhosis was mostly reported from the studies using EP or electroencephalogram^[21], suggesting a diffuse neurological disturbance in alcoholic cirrhotic patients. In China, most cirrhotic patients were caused by chronic hepatitis B. No significant difference in various etiologies was found among the subgroups in this investigation, probably due to the application of psychometric measures only. Some reports supposed that the elder and educational levels might influence the results of psychometric tests^[22,23]. No significant correlation was found between the different subgroups in age and education in the present study, since we used age-related normal values to correct the findings.

The selected subjects in this study reflected the real spectrum of cirrhotic patients in Guangzhou. The detected SHE prevalence was 50.9%, with its rate increased from 39.4% in Child-Pugh's grade A to 54.5% and 71.9% in grades B and C. These results agreed well with the data reported from Western literature. The patients with worse liver functions assessed by Child-Pugh's grade had a higher rate of SHE. Child-Pugh's scores were based on patients' symptoms (HE and ascites) and laboratory tests (serum levels of albumin, bilirubin, prothrombin). Patients with HE were excluded from this study. We also observed that the patients who had more or severer symptoms and poorer laboratory parameters of cirrhosis whether or not including in Child-Pugh's grade might tend to develop SHE.

Patients with SHE appeared to have no clinical symptoms. However, they might be at risk when they performed complex

motor activities as operating a heavy machinery or driving an automobile^[24]. They might have abnormal behaviors such as altered sleeping pattern and impaired cognitive function^[25,26]. Patients with SHE were vulnerable to HE^[27-29]. However, medical treatment and dietary management in these patients could improve the psychometric tests^[28-30]. Early diagnosis and treatment of SHE seem extremely important in China, because of the big population and high prevalence of liver diseases in this country. A high prevalence of SHE in cirrhotic patients should lead us to pay attention to these important findings frequently encountered in our medical practice.

Abstract

AIM: To establish nested-PCR methods for the detection of SENV-D and SENV-H and to investigate the epidemiology of SEN virus in China.

METHODS: According to published gene sequences, primers from the conserved region were designed. Then, 135 samples from healthy voluntary blood donors and 242 samples from patients with various forms of liver disease were detected by nested-PCR of SENV-D/H. Some PCR products were cloned and sequenced.

RESULTS: By sequencing, the specificity of genotype-specific PCR was confirmed. SENV-D/H DNA was detected in 31% of the blood donors, which was higher than those in America and Italy (2%), and in Japan and Taiwan (15-20%). The prevalence of SENV-D/H viremia was significantly higher in patients with hepatitis B and hepatitis C than in blood donors (59-85% vs 31%, $P < 0.05$). The prevalence among patients with non-A-E hepatitis was significantly higher than among blood donors (68% vs 31%, $P < 0.01$), and equivalent to that among patients with hepatitis B and C.

CONCLUSION: Nested-PCR with genotype-specific primers could serve as a useful SENV screening assay. SENV has the same transmission modes as HBV and HCV. The high prevalence in patients with non-A-E hepatitis may attribute to the transmission modes, and SENV may not serve as the causative agents.

INTRODUCTION

Recently, a novel DNA virus designated SEN virus (SENV) was discovered in the serum of a human immunodeficiency virus type 1 (HIV-1)-infected patient^[1]. Phylogenetic analysis^[2] showed 8 strains (A-H) of SENV. To date, the ninth genotype (SENV-I) has been identified^[3]. Among them, 2 SENV strains

(SENV-D and SENV-H) were significantly associated with transfusion-associated non-A-E hepatitis^[4]. SENV-D and SENV-H were also detected more frequently in patients with chronic liver disease and hepatocellular carcinoma (HCC) than in healthy adults^[5,6]. However, the association of SENV infection with liver cell damage is far from clear, and further studies are needed to investigate the clinical relevance of SENV infection worldwide.

The purpose of this study was to develop a nested polymerase chain reaction (nPCR) method for the detection of SENV-D and SENV-H DNA in serum and elucidate its specificity. The presence of SENV-D and SENV-H viremia in patients with various forms of liver diseases and the possible role of SENV infection in non-A-E hepatitis were investigated.

MATERIALS AND METHODS

Patients

A total of 377 serum samples from March 1999 to April 2003 were studied in Xijing Hospital. They were divided into 5 groups as follows: 135 blood donors; 55 patients with acute hepatitis A virus (HAV); 126 with chronic hepatitis B; 20 with chronic hepatitis C; 41 with non-A-E hepatitis defined as negative control for known serologic markers, including I gM anti-HAV, I gM antibody to hepatitis B core antigen (anti-HBc), hepatitis B surface antigen (HBsAg), and antibodies to HCV, HDV and HEV.

Detection of SENV DNA

Viral DNA was extracted from 100 µL serum with the QIAamp blood kit (Qiagen) and resuspended in 20 µL elution buffer. PCR mixture of 20 µL contained 0.4 µmol/L sense primer SENV-P2 (5' -CC[C/G]AAA CTG TTT GAAG GAC [C/A]A-3') (designed by ourselves), 0.4 µmol/L antisense primer Lucky2AS (5' -CCT CGG TT[G/T] [C/G]AA A[G/T]G T[C/T]T GAT AGT-3')^[1], 200 µmol/L of each dNTP, 2 µL DNA sample, and 1 U *Taq* DNA polymerase. The reactions consisted of preheating at 94 °C for 3 min, 30 cycles of denaturation at 94 °C for 1 min, annealing at 50 °C for 1 min, extension at 72 °C for 40 s, and final incubation at 72 °C for 5 min. The second PCR step was carried out with a 20 µL PCR reaction mixture containing 2 µL of the first-step amplification product, the same PCR buffer used for the first PCR step, 0.4 µmol/L sense primer D10s (5' -GTA ACT TTG CGG TCA ACT GCC-3')^[1] and antisense primer Lucky2AS for SENV-D; 0.4 µmol/L sense primer C5s (5' -GGT GCCCCT [A/T] GT [C/T]AG TTG GCG GTT-3') (designed by ourselves) and antisense primer Lucky2AS for SENV-H, 200 µmol/L of each dNTP, and 1 U *Taq* DNA polymerase. PCR consisted of preheating at 94 °C for 1 min, annealing at 58 °C for 1 min, extension at 72 °C for 40 s, and final incubation at 72 °C for 5 min.

Determination of SENV genotypes

Amplicons containing polyA tails and producing visible bands on agarose gel were excised from the gel and ligated to the pGEM vector. DNA extracted from transformed *Escherichia Coli* was sequenced. The sequences excluding primer sequences were aligned with Cluster W to all SENV genotypes, representative of TTV (TA278) and TLMV isolates. The genotype of SENV was determined by the phylogenetic trees.

Table 1 Prevalence of SENV infection in different hepatitis groups in China

Disease	<i>n</i>	Single SENV-D	Single SENV-H	Combined SENV-D/-H	Total <i>n</i> (%)
Acute hepatitis A	55	2 (3.6)	12 (21)	6 (11)	20 (36)
Chronic hepatitis B	126	17 (13)	16 (12)	41 (32)	74 (59) ^b
Chronic hepatitis C	20	4 (20)	4 (20)	9 (45)	17 (85) ^b

^b*P*<0.01 vs Blood donors.**Statistical analysis**

Data were analyzed by χ^2 test with Yates' correction or Fisher's exact test; *P*<0.05 was considered to be statistically significant.

RESULTS**Genotype-specific PCR with specific primers**

PCR products were detected by 20 g/L agarose gel. The results showed that there was a 230-bp band in the gel (Figure 1). The PCR products were inserted into pGEM-T vectors and sequenced. A phylogenetic tree of the SENV-D sequences (Figure 2A) from 8 blood donors (B7, B11, B13, B14, B28, B29, B31 and B33) and 7 patients with non-A-E hepatitis (N4, N9, N10, NC, NF, NG and NK) was constructed. To determine a root of the phylogenetic tree, TLMV was used as an out-group. SENV-D DNA sequences from study subjects clustered in a monophyletic group with the SENV-D prototype sequences. A phylogenetic tree of the SENV-H sequences (Figure 2B) from 7 blood donors (B1, B4, B11, B12, B28, B29 and B30) and 5 patients with non-A-E hepatitis (N4, N8, N10, NA and NF) was constructed. SENV-H DNA sequences from study subjects clustered in a monophyletic group with the SENV-H prototype sequences with the exception of 2 outliers (B1 and B28), which had closer homology to SENV-C.

The specificity of genotype-specific PCR was confirmed by sequencing. Here, all 15 patients diagnosed as SENV-D by the genotype-specific PCR had homology to SENV-D (Figure 2A), while 10 of 12 patients (83%) diagnosed as SENV-H by the genotype-specific PCR had homology to SENV-H, the other 2 had homology to SENV-C which was of the same genotype as SENV-H (Figure 2B).

**Figure 1** Electrophoresis of PCR products. Lane 1: Negative control; lane 2: Positive control; lanes 3, 4: SENV-D; lane 5: Marker DL2000; lanes 6, 7: SENV-H.**SENV prevalence in patients with liver diseases and in blood donors**

SENV-D and/or SENV-H (SENV-D/H) DNAs were positive in 31% of healthy Chinese adults. SENV viremia was identified in 20 (36%) of 55 patients with acute or chronic hepatitis A, in 74 (59%) of 126 patients with chronic hepatitis B, in 17 (85%) of 20 patients with chronic hepatitis C, in 28 (68%) of 41 patients with acute or chronic non-A-E hepatitis. Compared with healthy blood donors, SENV infection was found more frequently in patients with hepatitis B, hepatitis C and non-A-E hepatitis

(59-85% vs 31%, *P*<0.01, Table 1). However, the prevalence was comparable among patients with acute hepatitis A and healthy adults (31% vs 36%). The prevalence of SENV-H was 2-fold higher than that of SENV-D in patients with acute hepatitis A. Mixed SENV-D/H infection was common (Table 1).

DISCUSSION

Viral hepatitis is a worldwide disease^[7] and imperils human health gravely. To date, 5 hepatitis viruses from HAV to HEV^[8], which account for 8% to 90% hepatitis cases, have been discovered. But we could not find any hepatitis viruses in the left 10% to 20% cases that have typical viral hepatitis manifestations. Scientists speculated that the virus TTV was correlated with non-A-E hepatitis. Chinese scholars studied infection rate of TTV in different populations and its pathogenicity in liver^[9-12], and found that TTV had no pathogenicity^[13-15]. Afterwards, Primi *et al.*^[11] found that SENV and TTV had similar structure. SENV has homogeneity of 55% at nucleotide level with TTV, but they only have homogeneity of 37% at amino acid level^[2]. SENV appears to belong to a family of small, circular, non-enveloped, single-stranded DNA viruses that have been designated as circoviruses^[16,17]. Phylogenetic analysis of SENV has shown the existence of 8 different variants (A-H). Among them, only SENV-D and SENV-H have higher prevalence ratios, and they are found in 2% of blood donors and >50% of persons with transfusion-associated non-A-E hepatitis in Italy and the United States. Although a strong association of SENV-D/H with transfusion-associated non-A-E hepatitis has been reported, whether SENV-D/H serves as a causative agent of post-transfusion hepatitis remains unknown^[18-20].

The results of our present study indicate that nPCR amplified with genotype-specific primers could serve as a useful SENV screening assay. Moreover, because all components of the assay are readily available (specific antibodies are not required), viral testing can be performed in most laboratories that perform PCR. Our recent study indicated that 31% of healthy Chinese adults were positive for SENV-D/H DNA, a rate comparable to that of blood donors in Japan (10-20%)^[5,21] and Taiwan (14-20%)^[6] (age-specific prevalence), but higher than that of blood donors in the United States and Italy (2%)^[22,23]. Co-infection with SENV has been frequently observed in 22-67% of patients with chronic hepatitis B^[5,6] and 20-76% of patients with chronic hepatitis C^[4-6,24,25]. Our study showed that the prevalence of SENV-D/H infection in patients with chronic hepatitis B and C were 59% and 85% respectively, implying that HCV, HBV and SENV may share common modes of transmission. Our study also indicated that compared with blood donors (31%), SENV-D/H infection was more frequent in patients with non-A-E hepatitis (68%), but comparable to those in patients with chronic hepatitis C and B (85% and 59%, respectively). These results can not support a causal role for SENV-D/H in the development of non-A-E hepatitis. Otherwise, we also documented that the prevalence of SENV-H was comparable to that of SENV-D in different subjects, such as blood donors, patients with chronic

Figure 2 Phylogenetic tree of SENV by neighbor-joining method. A: The tree constructed on basis of 1 prototype TTV isolate (TA278), 1 TTV variant, 8 SEN virus isolates (A-H) and 15 SENV-D Chinese isolates. B: The tree constructed on basis of 1 prototype TTV isolate (TA278), 1 TTV variant, 8 SEN virus isolates (A-H) and 12 SENV-H Chinese isolates.

hepatitis B or C, and patients with non-A-E hepatitis, but among patients with acute hepatitis A, SENV-H was more prevalent than SENV-D ($P < 0.05$). This phenomenon awaits further prospective studies.

In summary, the results of this study suggest that SENV has the same transmission modes as HBV and HCV^[26]. The high prevalence in patients with non-A-E hepatitis may attribute to the transmission modes, and SENV may not serve as the causative agents. At present, SENV and the larger group of human circoviruses have no established pathogenicity, but

they may have disease associations that have not been identified, or they may serve as commensal organisms that have some beneficial role in maintaining homeostasis in the host. They are worthy of more attention, even in the absence of confirmed disease associations.

Abstract

AIM: To investigate the expressions of E-cadherin and calretinin in exfoliated cells of serous effusions and evaluate their values in distinguishing malignant effusions from benign ones.

METHODS: Fresh serous effusion specimens were centrifuged and exfoliated cells were collected. Cells were then processed with a standardized procedure, including paraformaldehyde fixation, BSA-PBS solution washing and smears preparation. E-cadherin and calretinin were detected by immunocytochemistry (ICC).

RESULTS: In the exfoliated cells of serous effusions, most of carcinoma cells only expressed E-cadherin, and most of mesothelial cells only expressed calretinin, and benign cells (lymphocytes and granulocytes) did not express either of them. For E-cadherin, 85.7% (30/35) of malignant effusions and 8.1% (3/37) of benign fluids were ICC-positive ($P < 0.001$). The sensitivity of E-cadherin ICC in the diagnosis of malignant effusions was 85.7%, specificity 91.9%, and diagnostic rate 88.9%. For calretinin, 94.6% (35/37) of benign effusions and 11.4% (4/35) of malignant effusions were ICC-positive ($P < 0.001$). The sensitivity of calretinin ICC in the diagnosis of benign effusions was 94.6%, specificity 88.6%, and diagnostic rate 91.7%. For diagnosis of benign and malignant effusions by combining E-cadherin ICC and calretinin ICC, the specificities were up to 100% and 97.1%, respectively.

CONCLUSION: E-cadherin ICC and calretinin ICC are sensitive and specific in differential diagnosis of benign and malignant serous effusion specimens and specificities are evidently improved when both markers are combined.

INTRODUCTION

Serous effusions are common in clinical practice and some cases

are caused by metastasis of malignant tumors (malignant effusions). Distinguishing malignant from benign tumors is very important, but sometimes very difficult^[1]. Some studies have shown that immunocytochemistry (ICC) of exfoliated cells is valuable in differentiating malignant effusions from benign ones^[2-6]. However, the diagnostic value of a single marker was limited, and a panel of markers were more useful^[7,8]. Recently, several studies have shown that E-cadherin, an epithelial adhesion molecule, was a useful marker for identifying the carcinoma cells in effusions^[9,10], and calretinin, a calcium-binding protein, was a useful marker for identifying the mesothelial cells^[11,12]. It is well known that the differentiation between cancer cells and reactive mesothelial cells is the main problem in cytological diagnosis of effusions. In the present study, both E-cadherin and calretinin were used as markers in immunocytochemical staining of exfoliated cells in serous effusions, and their diagnostic values were evaluated.

MATERIALS AND METHODS

Patients and specimens

Seventy-two patients with serous effusions were enrolled in this study (35 male, 37 female, age 14-77 years with an average of 51.8 years). All patients were from the First Affiliated Hospital of Jiangxi Medical College from 2001 to 2002. Effusion specimens were collected and divided into two groups, benign and malignant, according to cytological results. Of these specimens, there were 45 pleural effusions, 24 peritoneal effusions, and 3 malignant pericardial effusions. In the 23 cases of benign pleural effusions, there were 13 cases of tuberculous pleuritis, 2 cases of liver cirrhosis, 1 pulmonary tuberculosis, 1 chyle pleural effusion, and 6 unknown causes. In the 22 cases of malignant pleural effusion, there were 11 cases of lung cancer, 1 submaxillary gland cancer, 1 gastric cancer, 1 primary liver cancer, and 8 cases of unknown origin. In the 14 cases of benign peritoneal effusions, there were 8 cases of liver cirrhosis, 3 tuberculous peritonitis, 1 hepatitis B, 1 Budd-Chiari syndrome, 1 unknown cause. In the 10 cases of malignant peritoneal effusions, there were 4 cases of ovarian cancer, 2 primary liver cancers, 1 gastric cancer, 1 colonic cancer, 1 duodenal papilla cancer, and 1 unknown origin. Three cases of malignant pericardial effusions included 1 case of lung cancer, 1 metastatic squamous cancer and 1 unknown origin.

Specimen processing

About 100 mL fresh effusion was centrifuged at 2 000 r/min for 10 min, and cell pellets were collected. When the effusion was bloody, erythrocytes were destroyed with isotonic ammonium chloride solution (NH_4Cl 4.5 g, KHCO_3 0.5 g, EDTA 0.0186 g, solved in 400 mL distilled water, then distilled water add to a total volume of 500 mL). Same volume of the solution was added to dissolve the cell pellets, which were stirred for 5 min at room temperature, centrifuged at 2 000 r/min for 10 min, and the supernatants removed. Two cell smears were prepared for cytological diagnosis. The remaining cells were processed with a "standardized" procedure^[13]: fixed in 40 g/L paraformaldehyde-PBS solution, washed in 10 g/L BSA-PBS solution, the cell concentration was adjusted to $2 \times 10^6/\text{mL}$, and finally several

cell smears were prepared. The smears were air-dried and stored in a freezer (-85 °C).

Immunocytochemistry and evaluation

Reagents for immunocytochemical staining were provided by Beijing Zhongshan Biotechnology Co. Ltd. Mouse anti-human E-cadherin monoclonal antibody (1:100 dilution) or rabbit anti-human calretinin polyclonal antibody (1:50 dilution) was used as the primary antibody. Biotinylated goat anti-mouse/rabbit IgG was used as the second antibody. The reaction products were visualized by using the streptavidin-horseradish peroxidase and diaminobenzidine. The smears were counterstained with hematoxylin. PBS was used instead of the primary antibodies as negative control.

In E-cadherin ICC, positive cells were stained at cytomembrane, especially in the areas surrounding the cells. In calretinin ICC, whole cells were stained with a “fried eggs” staining pattern. One hundred cells (carcinoma and/or non-carcinoma) were counted under a high power microscope, and the percentage of positive cells was calculated. ICC-positive cells $\geq 80\%$ were defined as strong expression (+++), 20-79% as moderate expression (++), 6-19% as weak expression (+), 0-5% as negative expression (-). Specimens with expressions (+)-(++) were regarded as ICC-positive, and expression (-) as ICC-negative.

Statistical analysis

Qualitative data were analysed with chi-square test, and rank data were tested with rank sum test. Diagnostic values of ICC results were calculated in contrast to that of the cytological results. Diagnostic values of the combination of E-cadherin and calretinin ICC results were calculated in series ways.

RESULTS

E-cadherin expression of exfoliated cells in serous effusions

E-cadherin expression in carcinoma cells was usually strong, with obvious staining at cytomembrane and sometimes in cytoplasm (Figure 1). The areas surrounding the cells had densely stained lines in the clusters of carcinoma cells, but single carcinoma cell was weakly stained. Mesothelial cells were stained occasionally, and no lymphocytes and granulocytes were stained. Thirty of 35 malignant effusion specimens were ICC-positive for E-cadherin (85.7%), and most of them were strong (93.3% was +++). Only 3 of 37 benign effusions were ICC-positive for E-cadherin (8.1%), in which a few mesothelial cells were weakly stained in cytoplasm. The differences in positivity rates and expression intensities between two groups were significant ($P < 0.001$ -0.0001) (Table 1).

Figure 1 Immunocytochemistry of E-cadherin in the cells from a malignant ascites specimen. Carcinoma cells were mainly stained at cell membranes. Inflammatory cells without staining were as control (Original magnification, $\times 400$).

Table 1 E-cadherin expression in exfoliated cells of serous effusions

Effusion group	n	Positivity (%)	Expression intensity			
			-	+	++	+++
Malignant	35	30 (85.7)	5	2	21	7
Benign	37	3 (8.1)	34	1	2	0

$\chi^2 = 43.633$, $P < 0.001$ between the two groups, $H = 42.744$, $P < 0.0001$ between the two groups.

Calretinin expression of exfoliated cells in serous effusions

Calretinin expression in mesothelial cells was usually high, stained in whole cells (Figure 2). The typical cells looked like “fried eggs”. Carcinoma cells were occasionally stained weakly, and no lymphocytes and granulocytes were stained. Thirty-five of 37 benign effusions were ICC-positive for calretinin (94.6%), and all of them were strong positive (+++). Only 4 of 35 malignant effusion specimens were ICC-positive for calretinin (11.4%), with a few carcinoma cells stained weakly. Differences of positivity rates and expression intensities between the two groups were significant ($P < 0.001$ -0.0001) (Table 2).

Figure 2 Immunocytochemistry of calretinin in the cells from a malignant ascites specimen. Mesothelial cells were stained strongly and some of them like “fried eggs”. Carcinoma cells and inflammatory cells without staining were as control (Original magnification, $\times 400$).

Table 2 Calretinin expression in exfoliated cells of serous effusions

Effusion group	n	Positivity (%)	Expression intensity			
			-	+	++	+++
Malignant	35	4 (11.4)	31	1	3	0
Benign	37	35 (94.6)	2	0	0	35

$\chi^2 = 50.109$, $P < 0.001$ between the two groups, $H = 59.576$, $P < 0.0001$ between the two groups.

Table 3 Diagnostic values of E-cadherin or/and calretinin ICC for serous effusions

Index	Malignant effusion (%)		Benign effusion (%)	
	E-cadherin	E(+) + C(-)	Calretinin	E(-) + C(+)
Sensitivity	85.7	77.1	94.6	86.5
Specificity	91.9	100	88.6	97.1
PV+	90.9	100	89.7	97.0
PV-	87.2	82.2	93.9	87.2
DAR	88.9	88.9	91.7	91.7

E (+)/E (-): E-cadherin (+)/(-); C (+)/C (-): Calretinin (+)/(-); PV+: ICC-positive predictive value; PV-: ICC-negative predictive value; DAR: Accordance rate.

Diagnostic values of E-cadherin ICC or/and calretinin ICC for serous effusions

The diagnostic values (sensitivity, specificity) of both E-cadherin ICC and calretinin ICC for malignant effusions were $\geq 90\%$. Combination analysis of E-cadherin ICC and calretinin ICC could improve the specificities (up to 97.1-100%), while the sensitivities maintained at an acceptable level (Table 3).

DISCUSSION

Serous effusions are common clinical syndromes and can be simply divided into benign and malignant. Differentiation between two kinds of effusions is very important for diagnosis, treatment and prognostic evaluation. The cytological examination is a simple and reliable method for the diagnosis of malignant effusions, but its sensitivity is only 40-60%^[14], even lower in clinical practice. Cytological examinations are based on the cellular morphology, which may raise difficulties in distinguishing carcinoma cells from reactive mesothelial cells. Sometimes, carcinoma cells without typical morphological changes or enough number could not be diagnosed cytologically. How to identify the metastatic carcinoma cells and differentiate them from reactive mesothelial cells is key to diagnosing malignant effusions^[15]. In the past decade, immunocytochemistry seemed to be a valuable tool in solving the problem, with a complementary value for cytological diagnosis of malignant effusions^[16].

The cadherin family consists of more than 16 kinds of molecules that make up a group of phylogenetically and structurally related molecules, with M_r 120 000^[17]. E-cadherin, one member of a family of intracellular calcium-dependent adhesion molecules, is a transmembrane protein expressed in epithelial cells. Its extracellular amino terminal binds to the same structure of neighboring homotypic cells when calcium ion exists, mediating the epithelial cell-cell adhesion. Theoretically, only the exfoliated cells originating from epithelial tissues can express E-cadherin, so detection of E-cadherin expression is helpful for determining cells from epithelia. Because no epithelial cells were in benign effusions, the appearance of epithelial cells in effusions means a metastasis of carcinoma developed from epithelia. Our results showed that E-cadherin ICC of the exfoliated cells were valuable for the diagnosis of malignant effusions, with a sensitivity, specificity, positive predictive value, negative predictive value, and diagnostic rate near or over 90% respectively, similar to other studies^[1,18]. However, when epithelial cells transformed into malignant cells, E-cadherin expression might decrease to some extent^[19,20]. That is the reason why a few carcinoma cells showed weak or negative E-cadherin expression in effusions.

Calretinin is a calcium adhesion protein with M_r 29 000 and mainly expresses in nerve system. Lately, it was found that calretinin selectively expressed in mesotheliomas^[21,22], with powerful ability to differentiate mesothelial cells from other cells in effusions^[1,5,11,22]. Our results showed that calretinin expression in mesothelial cells was evident, but not in non-mesothelial cells, therefore it is useful in determining the cells from mesothelium, with a sensitivity, specificity, positive predictive value, negative predictive value, and diagnostic rate all near or over 90%. The "fried eggs" staining pattern made calretinin ICC more valuable in differentiating mesothelial cells from carcinoma cells^[1].

E-cadherin is an epithelial cell marker, and calretinin is a mesothelial cell marker. Our results showed that the combination of both markers significantly increased their differential diagnostic value with specificities up to 97.1% in serous effusions and 100% in benign and malignant effusions.

Abstract

AIM: The significance of hepatitis C virus (HCV) serum titers has been examined in several clinical situations. There is much evidence that patients with a lower viral load have better response rates to anti-viral therapy compared to those with higher levels. Moreover, a direct association has been observed between serum titers of HCV and transmission rates of the virus. The aim of the present study was to determine if there was any correlation between HCV viral load and the severity of liver disease.

METHODS: Fifty patients with HCV infection were included in the study. These comprised of 34 subjects with a history of alcohol use and 16 non-alcoholics. Quantitative serum HCV RNA assay was carried out using the branched DNA (bDNA) technique. Linear regression analysis was performed between serum viral titers and liver tests. In addition, for the purpose of comparison, the subjects were divided into two groups: those with low viral titers (≤ 50 genome mEq/mL) and high titers (> 50 mEq/mL).

RESULTS: All subjects were men, with a mean \pm SD age of 47 ± 7.8 years. The mean HCV RNA level in the blood was $76.3\times 10^5 \pm 109.1$ genome equivalents/mL. There was no correlation between HCV RNA levels and age of the patients ($r = 0.181$), and the history or amount (g/d) of alcohol consumption ($r = 0.07$). Furthermore, no correlation was observed between serum HCV RNA levels and the severity of liver disease as judged by the values of serum albumin ($r = 0.175$), bilirubin ($r = 0.217$), ALT ($r = 0.06$) and AST ($r = 0.004$) levels. Similarly, no significant difference was observed between patients with low viral titers and high titers with respect to any of the parameters.

CONCLUSION: Our results indicate that the severity of liver disease is independent of serum levels of hepatitis C virus. These findings are important since they have a direct impact on the current debate regarding the role of direct cytopathic effect of hepatitis C virus versus immune-mediated injury in the pathogenesis of HCV-related liver damage.

INTRODUCTION

Hepatitis C virus (HCV) is a bloodborne pathogen that is

endemic in most parts of the world, with an estimated overall prevalence of nearly 3%^[1]. Approximately 80% patients with hepatitis C virus develop chronic infection, and progression to cirrhosis occurs in nearly 20% of these subjects^[2]. Moreover, patients with HCV-related cirrhosis are at an increased risk of developing hepatocellular carcinoma, which is estimated to occur at the rate of 1.5% to 4% per year^[2]. In most individuals, liver disease progresses slowly over several decades, but the rate of progression is highly variable^[3-5]. Whereas some patients develop cirrhosis and end-stage liver disease within one to two years of exposure, others may die of old age or an entirely unrelated cause^[6]. Although it is mostly unclear why some patients progress more rapidly than others, several factors have been identified as having a role in disease severity. HCV patients co-infected with hepatitis B virus (HBV) have an increased risk of developing cirrhosis and decompensated liver disease^[7] as well as hepatocellular carcinoma^[8]. Several researches have noted more severe clinical and histological abnormalities in HCV infected chronic alcoholics compared to non-alcoholics with HCV infection^[9-12]. Other factors associated with a more rapid course of liver disease include age at acquisition of HCV infection, gender of the patient and presence of immunodeficiency states^[5,6].

Several studies have assessed the correlation between serum HCV titers and different clinical and laboratory parameters. Perinatal transmission of HCV from mothers to infants has been found to be related to maternal HCV titers. The risk of HCV transmission was found to be significantly higher (36%) among infants born to women with HCV RNA titers of at least 10^6 per mL compared to none if the titers were $< 10^6$ per mL^[13]. HCV titers have been found to be associated with responses to anti-viral treatment. Patients with a baseline HCV viral load of $\leq 2\times 10^6$ copies per mL have significantly better responses to anti-viral therapy compared to those with higher viral titers^[14]. Patients with HCV genotype 1 have been found in some studies to have higher viral loads than those with HCV genotype 2^[15,16], although other studies have failed to observe such an association^[17-19]. Previous attempts to assess the effect of viral titers on the severity of liver disease have produced conflicting results and the present study was designed to examine this issue in more detail.

MATERIALS AND METHODS

Patients with chronic hepatitis C virus infection diagnosed on the basis of a positive recombinant immunoblot assay (Riba) were included in the study. All patients were negative for other causes of chronic liver disease including hepatitis B virus infection. Patients were interviewed with respect to alcohol use, and in those with a positive history an assessment was made of the duration of alcohol abuse and amount of daily consumption. Physical findings and results of laboratory tests were recorded. All patients were treatment-naïve and were tested before the administration of anti-viral therapy.

Quantitative HCV analysis

Quantitative assay of hepatitis C virus levels was performed by the branched-chain DNA (bDNA) technique (Quantiplex

HCV-RNA; Chiron Corporation, Emeryville, USA). The bDNA assay incorporates a series of steps involving viral nucleic acid hybridizations to obtain signal amplification. This technique is unlike the polymerase chain reaction (PCR)-based assays in which the viral genome is amplified. The results of viral RNA titers in clinical samples are expressed as viral or genome milliequivalents per mL (mEq/mL). When the study was first initiated, only the initial version of the bDNA assay (Quantiplex 1.0), which had a lower limit of detection of 350 000 viral mEq/mL, was available commercially. Subsequently, the Chiron Corporation upgraded the technique and the latest version of the assay (Quantiplex 2.0) was employed which has a lower limit of detection of 200 000 viral mEq/mL.

Statistical analysis

Descriptive statistical analyses were performed, and the results are presented as mean±SD. Comparison of quantitative measurements between groups was performed using Wilcoxon Rank Sum Test. The Students' *t*-test was used to assess changes in HCV RNA levels in the same individual. Linear regression analysis was employed to examine the presence of any correlation between serum HCV RNA levels and different laboratory and clinical parameters including the amount of daily alcohol consumption.

RESULTS

A total of 50 patients were included in the study. These comprised of 34 patients with a history of alcohol use and 16 non-alcoholics. All subjects were men, with a mean±SD age of 47±7.8 years. The mean HCV-RNA level in the blood was $76.3 \times 10^5 \pm 109.1$ genome equivalents/mL. There was no correlation between HCV RNA levels and the age of the patients ($r = 0.181$), a history of alcohol use or the amount (g/day) of alcohol consumption ($r = 0.07$). Furthermore, no correlation was observed between HCV RNA levels and the severity of liver disease as judged by the values of serum albumin ($r = 0.175$), bilirubin ($r = 0.217$), ALT ($r = 0.06$) and AST ($r = 0.004$) levels.

To further assess the effects of viral titers on the severity of liver disease, the study subjects were arbitrarily divided into two groups: patients with low viral titers (≤ 50 genome mEq/mL) and those with high titers (> 50 mEq/mL). The results are shown in Table 1. Again, no difference was observed between the two groups with respect to any of the parameters examined.

Table 1 Comparison of patients with low and high hepatitis C virus serum titers

Parameter	Low HCV RNA level (≤ 50 genome mEq/L) <i>n</i> = 28	High HCV RNA level (> 50 genome mEq/L) <i>n</i> = 22	<i>P</i> value
Age (yr)	48±8.8	45±6	0.35
Alcohol use (g/d)	221±110	274±170	0.27
ALT (U/mL)	77±56	75±41	0.76
AST (U/L)	79±58	93±100	0.96
Albumin (g %)	3.70±0.76	3.90±0.43	0.44
Bilirubin (mg %)	1.35±1.2	0.88±0.32	0.55

Results are expressed as mean±SD.

DISCUSSION

Several factors have been incriminated in predicting the rate of progression of HCV-related chronic liver disease. These include age at acquisition of HCV infection, gender of the patient, alcohol abuse and co-infection with HBV and HIV infections^[5-12]. Studies assessing the relationship between serum viral titers and the severity of biochemical and histological abnormalities

have produced conflicting results. Some found no correlation between HCV viral loads, and serum ALT values and the extent of histological damage^[16,17,19-21]. On the other hand, Kato *et al.* observed significantly higher HCV RNA titers in patients with chronic active hepatitis and cirrhosis compared to those with milder histological abnormalities such as chronic persistent hepatitis^[22]. Similarly, Fanning *et al.* in a study on Irish women who acquired their HCV infection through the administration of contaminated anti-D immunoglobulin, obtained a significant correlation between serum HCV viral loads and the degree of hepatic inflammation in liver biopsy specimens^[23].

In the present study, we further assessed the association between serum HCV RNA titers and several clinical and laboratory factors. Linear regression analysis showed a complete lack of correlation between the viral loads and age at presentation of the patients and the extent of alcohol consumption. Moreover, none of the laboratory tests showed any correlation with HCV viral count. For the purposes of statistical analysis, we subdivided the patients into those with low (≤ 50 genome mEq/L) and high (> 50 genome mEq/L) viral loads. Again, there was no correlation between any of the clinical and laboratory parameters and HCV viral loads (Table 1).

Our results indicate that the severity of liver disease is independent of serum levels of hepatitis C virus. The precise mechanism by which hepatitis C virus damages the liver remains poorly understood. Until recently, a direct cytopathic effect of the virus was considered as the primary form of liver injury caused by the virus. It has been suggested that the degree of liver damage is the result of a complicated interaction between the virus and immune response of the host^[24]. Immune mediated liver damage is believed to be initiated by HCV-specific T cells and is enhanced by HCV-induced HLA-A, B and C and intracellular adhesion molecules^[25,26]. The results of the present study are important since they argue against a direct cytopathic effect of HCV and support the hypothesis that the pathogenesis of HCV-related liver damage is immune-mediated.

Abstract

AIM: Hypertrophied anal papillae and fibrous anal polyps are not given due importance in the proctology practice. They are mostly ignored being considered as normal structures. The present study was aimed to demonstrate that hypertrophied anal papillae and fibrous anal polyps could cause symptoms to the patients and that they should be removed in treatment of patients with chronic fissure in anus.

METHODS: Two groups of patients were studied. A hundred patients were studied in group A in which the associated fibrous polyp or papillae were removed by radio frequency surgical device after a lateral subcutaneous sphincterotomy for relieving the sphincter spasm. Another group of a hundred patients who also had papillae or fibrous polyps, were treated by lateral sphincterotomy alone. They were followed up for one year.

RESULTS: Eighty-nine percent patients from group A expressed their satisfaction with the treatment in comparison to only 64% from group B who underwent sphincterotomy alone with the papillae or anal polyps left untreated. Group A patients showed a marked reduction with regard to pain and irritation during defecation ($P = 0.0011$), pricking or foreign body sensation in the anus ($P = 0.0006$) and pruritus or wetness around the anal verge ($P = 0.0008$).

CONCLUSION: Hypertrophied anal papillae and fibrous anal polyps should be removed during treatment of chronic anal fissure. This would add to effectiveness and completeness of the procedure.

INTRODUCTION

Hypertrophied anal papillae are essentially skin tags that project up from the dentate line, or the junction between the skin and the epithelial lining of the anus^[1]. They are often found as part of the classic triad of a chronic fissure, namely the fissure itself, hypertrophied papilla above and a skin tag below^[2,3]. They are also found in isolation, maybe firm and palpable on a digital examination of the anus. In this situation, they must be differentiated from polyps, hemorrhoids, or other growths. Endoscopically they could be differentiated from an adenomatous

polyp by their white appearance and their origin from the lower (squamous) aspect of the dentate line in the anal canal. They are usually a symptomatic but occasionally grow large enough to be felt by the patient or are likely to prolapse. Hypertrophied anal papilla should be included in the differential diagnosis of a smooth mass located near the anal verge, especially in a patient with a history of chronic anal irritation or infection^[2].

With passage of time, papillae continue to grow in size. A papilla is liable to acquire considerable fibrous thickening over a period of time when it gets a rounded expanded tip, which is known as a fibrous polyp. This is due to piling up and consolidation of chronic inflammatory tissues at the proximal part of the fissure at the dentate line. As many as 16% of the patients having chronic fissure in anus recorded the presence of papillae that turned into fibrous polyps^[4]. These papillae are presumed to be caused by edema and low-grade infection.

A fibrosed-hypertrophied papilla is also frequently found at the upper part of a chronic anal fissure or guarding the internal opening of fistula in anus. In the later case however, the symptoms may completely dominate and distort the clinical findings. Dilated veins, white areas, and a large hypertrophied anal papilla are often found in prolapsing types of hemorrhoids^[5].

In the past, these structures were not given any importance and were left untreated. Those patients, in whom, the fissure in anus was treated but the concomitant papillae or polyps were left untouched, continued to complain of pruritus, wetness, or an intermittent pricking sensation in the anus. Those with fibrous polyps felt incompletely treated due to a feeling of *something* projecting from the anus. Even a case of giant hypertrophied anal papilla complicated with a massive anal bleeding and prolapse was reported^[6].

This study was aimed to assess the impact and utility of attending to these two conditions concurrently while dealing with cases of fissure in ano.

MATERIALS AND METHODS

This study was carried out at Gupta Nursing Home, Nagpur, India, between July 2000 and December 2001.

Two hundred patients suffering from chronic fissure in ano associated with hypertrophied anal papillae or fibrous polyps were selected for the study. All these patients had primarily reported symptoms and complaints of chronic anal fissure. The papillae and polyps were diagnosed preoperatively by using a pediatric anoscope to avoid discomfort during examination. The number of papillae ranged from two to four. However, the fibrous polyp was found to be single in all those patients who were having this pathology.

Only those patients who came for a follow-up after 12 mo of the procedure were included in the study.

Exclusion criteria

Patients having fissure in ano with sentinel tags or hemorrhoids and those who had not signed the informed consent were not included in the study.

The patients were divided into two groups viz: group A and B.

Group A consisted of one hundred patients in whom the anal papillae, anal polyp, or both were treated by radio frequency

procedure along with the fissure. Another hundred patients (group B) were treated only for the fissure and the papillae or polyps were left untreated. The randomization was done by a sealed envelope, which was opened by the operation room nurse upon patient's arrival for the procedure.

An informed consent was obtained from all patients under study. The study was approved by the local ethical committee and was done in accordance with the Declaration of Helsinki. No special pre-operative preparation was carried out. All the patients received a dose of laxative on the prior night. The patient description is given in Table 1.

Table 1 Patient demographic data

Patient characteristics	Group A	Group B
No. of patients	100	100
Mean age yr	37	39
Male: Female	64:36	66:34
Hypertrophied papillae (No. of patients)	100	100
Fibrous anal polyp (No. of patients)	11	8

Statistical analysis

Unpaired Student's *t* test was used to measure postoperative parameters. The level of statistical significance between groups was set at 5 per cent.

Procedures

The procedure was carried out under a short general anesthesia with a muscle relaxant. A lateral subcutaneous sphincterotomy was performed to relieve the sphincter spasm. This was followed by insertion of the anoscope with a proximal illumination. The anal canal was cleaned off the collection. The papillae or polyps were located and were dealt with through a radio frequency surgical technique.

Radio frequency surgery aims at cutting or coagulation of tissues by using a high frequency alternate current. The radiofrequency device performs a simultaneous function of cutting and coagulating of the tissues. The effect of cutting, known as high frequency section, is executed without pressuring or crushing the tissue cells. This is due to the result of heat produced by the tissues' resistance to the passage of the high frequency wave set to motion by the equipment. The heat makes the intracellular water boil, thereby increasing the inner pressure of the cell to the point of breaking it from inside to outside (explosion). This phenomenon is called cellular volatilization^[7].

In this procedure, we used the radio frequency generator known as Ellman Dual Frequency 4MHz by Ellman International, Hewlett, N.Y. This instrument produces an electromagnetic wave of a very high frequency that reaches 4 megahertz. The unit is supplied with a handle to which different interchangeable electrodes could be attached to suit the exact requirement^[8]. In our study, we used the ball electrode for coagulation and a round loop electrode for shaving off the desired tissues.

The papillae were directly coagulated with a ball electrode with the radio frequency unit kept on coagulation mode, which resulted in shrinkage and disappearance of the papillae in no time.

For the fibrous anal polyp, we initially coagulated its base circumferentially by a ball electrode and then shaved off the mass by using the round loop electrode. The minor bleeding encountered in some cases was coagulated by touching the bleeding points with the ball electrode. The whole procedure took around 7-10 min to complete.

The patients were prescribed analgesics for one wk and a stool softener for a period of 1 mo.

The first follow up was made after 30 d. The fissures were healed and there was no sphincter spasm in any of the patients from either group. During examination of patients from group A, anoscopies showed total absence of the papillae. Patients who were treated for fibrous polyps did have some amount of edema and mild elevation at the site of destruction. However, patients had fewer complaints of pruritus, pricking, heaviness and a sense of incomplete evacuation as compared to patients from group B.

Follow up on completion of 12 mo of treatment

An independent observer blinded to the procedures made the observations during the follow up. He noted down all the symptoms in a prescribed format specially prepared for the study. The findings are given in Table 2.

RESULTS

The patients from group A who were treated by sphincterotomy followed by radio frequency surgical procedures for removal of hypertrophied anal papillae or fibrous polyps felt far more comfortable as compared to patients in group B who were subjected only to sphincterotomy for treatment of fissure and in whom, as per the prevailing practice, the papillae or anal polyps were left untouched. The other visible advantages experienced by the patients in group A were: a relief of pain and irritation during defecation, absence of pricking or foreign body sensation in the anus and disappearance of pruritus or wetness around the anal verge.

Table 2 One-yr follow-up findings of patients with removal or no removal of hypertrophied anal papillae and fibrous anal polyps (Student's unpaired *t* test)

Findings based on complaints of	Group A	Group B	P
Pruritus ani	7 (7%)	32 (32%)	0.0008
Anal pain and irritation	5 (5%)	26 (26%)	0.0011
Discharge per anus	2 (2%)	34 (36%)	0.0005
Sense of incomplete evacuation	5 (5%)	22 (22%)	0.0008
Crawling sensation in anus	8 (8%)	48 (48%)	0.0002
Pricking or foreign body sensation in anus	3 (3%)	32 (32%)	0.0006
Prolapsed per rectum	Nil	4 (4%)	N
Sepsis in the wound	1 (1%)	8 (8%)	0.0044
Recurrence of papillae or polyps	Nil	Not applicable	N
Recurrence of fissure	Nil	Nil	N
Overall satisfaction from the procedures	89%	64%	0.0004

N, not studied.

DISCUSSION

Anal papillae were found in almost 50-60% patients examined by us in regular practice. Usually, they were small, caused no symptoms, and could be regarded as normal structures^[9]. However, if it is a case of hypertrophy and the papillae start projecting in the anal canal, it not only requires attention but calls for a suitable treatment also. In such cases, there are chances of increase in the mucus leak resulting in increased anal moisture. These are liable to get traumatized and inflamed during the passage of stool. In addition, on being converted into a fibrous polyp, they tend to project at the anal orifice during defecation, often requiring to be digitally replaced. These polyps are considered as one of the differential diagnoses of rectal prolapse^[10]. The patients also reported symptoms like pruritus^[11], a foreign body sensation, pricking, a nagging sense of incomplete evacuation and heaviness in the anal region.

As a routine practice, these pathologies were not given any importance^[12]. There is very brief reference to this entity in the standard textbooks and other references. Secondary goals of fissure surgery sometimes required the removal of hypertrophied papilla and skin tag as well as the removal of inflammatory and fibrotic tissues surrounding the fissure^[13]. Customarily, in the symptomatic papillae or polyps, their removal by crushing of the bases, excision after ligation or electrocautization has been suggested. All these procedures are time consuming and are associated with complications at times. The use of radio frequency devices to deal with these pathologies has been found to be a quick, easy and significant complication free procedure^[14]. The device can ablate the papillae instantly, while the fibrous polyps can be excised after coagulation of the bases and thereafter the pedicles. In the present study, we have specifically excluded those patients of chronic fissure in ano who had sentinel tags or piles, as they were known to cause few of the similar symptoms that were associated with hypertrophied papillae or fibrous anal polyps.

Hypertrophied anal papillae and fibrous anal polyps are important anal pathologies associated with chronic anal fissure and are responsible for symptoms like pruritus, a pricking sensation, heaviness, etc. Their removal should be made an essential part of treatment of chronic fissures in ano. Persistence of these structures leaves behind a sense of incomplete treatment and thereby reducing the overall satisfaction on the

part of the patient. radio frequency procedures have been found useful in successfully eradicating these concomitant pathologies of chronic fissure in ano. This procedure should be given a fair chance to prove its utility and long-term efficacy.

Abstract

AIM: It is reasonable to assume that microchimerism could also be involved in the induction of primary biliary cirrhosis (PBC). However, previous reports investigated only fetus-microchimerism in women patients. Maternal microchimerism has not been investigated until now. The current study aimed to clear either maternal microchimerism was involved in the pathogenesis of PBC or not.

METHODS: We used fluorescence *in situ* hybridization on paraffin-embedded tissue (We called "Tissue-FISH".) to determine whether maternal cells infiltrated in male patients who were diagnosed as having PBC. Tissue-FISH was performed by using both X and Y specific probes on the biopsy liver sample of 3 male PBC patients.

RESULTS: Infiltrating lymphocytes demonstrated both X and Y signals in all 3 male patients.

CONCLUSION: Maternal microchimerism does not play a significant role in PBC. PBC may not relate to fetus and maternal microchimerism.

INTRODUCTION

Molecular biological techniques have shown that fetal cells can be detected in maternal peripheral blood in most pregnancies^[1-3]. On this observation, the radical hypothesis of autoimmune disease, proposed in 1996, may be caused by fetal cells that are retained after pregnancies^[4]. In systemic sclerosis, it was reported that fetal antimaternal graft-versus-host reactions might be involved in the pathogenesis of systemic sclerosis in some women^[5,6]. Thus, the hypothesis that microchimerism might cause the primary biliary cirrhosis (PBC) is very fascinating^[7], because it may explain clinical similarities between PBC and chronic graft-versus-host disease (GVHD) in liver after bone marrow transplantation. Some previous reports hypothesized that fetal microchimerism may also play a role in the pathogenesis of PBC^[8-11]. However, they concluded that fetal microchimerism was not important in the development of PBC.

Although there is a possibility that PBC may be developed by maternal microchimerism, not fetal microchimerism in female patients, maternal microchimerism has not been considered until now. Thus, we produced one hypothesis that maternal microchimerism might cause PBC.

To test the hypothesis, we investigated 3 male PBC patients by fluorescence *in situ* hybridization (FISH) on paraffin-embedded tissues.

MATERIALS AND METHODS

Patients

Three male patients with PBC were studied after giving informed consent. They were diagnosed at Kyoto Prefectural University of Medicine by liver biopsy and the positivity of serum antimitochondrial antibody (AMA). All patients were compatible with the feature of PBC. None of these patients had scleroderma. They had no experience of blood transfusion.

Methods

We reported tissue-FISH method previously^[12-14]. Sections from paraffin-embedded tissues were placed on silane-coated glass slides. The slides were deparaffinized immediately in 2 rinses of 1 000 g/L xylene for 10 min each. Each slide was rehydrated in an ethanol series for 5 min. The slides were then treated with 0.2 mol/L HCl for 20 min, followed by 2×SSC (0.3 mol/L sodium chloride and 0.03 mol/L sodium citrate) for 20 min at 80 °C, treated with 0.05 mg/mL proteinase K in TEN (0.05 mol/L Tris-HCl, pH 7.8, 0.01 mol/L EDTA, and 0.01 mol/L sodium chloride) for 10 min at 37 °C, and placed in 40 g/L formaldehyde in PBS for 10 min. Both FISH probes and target DNA were denatured simultaneously for 10 min at 90 °C, and the slides were incubated overnight at 42 °C, placed in 2×SSC for 10 min at 42 °C, washed twice in 2×SSC/500 g/L formaldehyde formamide for 5 min each at 42 °C, washed 2×SSC for 5 min at 42 °C, and counterstained in 2×SSC/0.03 µg/mL DAPI.

RESULTS

It was easy to recognize the architecture of liver tissues by

fluorescence microscope BX40-RF (Olympus, Tokyo, Japan). The lymphocytes aggregated at the portal zone (Figure 1). We assessed only non-overlapping nuclei having XY or XX signals. Almost infiltrating lymphocytes at septa revealed the XY chromosome pattern (Figure 2). The frequency of nuclei having XY in 3 patients is 96%, 98%, and 97%, respectively. ($P < 0.01$).

Figure 1 Aggregated lymphocytes at the portal zone.

Figure 2 Infiltrating lymphocytes revealed XY chromosome pattern (X; Green, Y; Orange).

DISCUSSION

The hypothesis that fetal microchimerism causing PBC is fascinating. However, this hypothesis does not explain why some cases with PBC were fetal microchimerism negative and why even males and nulliparous women were suffering from PBC. On the other hand, the hypothesis that maternal microchimerism causes PBC is more fascinating, because it resolves the above questions. Every one has the risk of maternal microchimerism, because it has been already established that maternal cells persist for a long-term in immunocompetent offsprings^[15]. However, this hypothesis could not be resolved by polymerase chain reaction (PCR), because PCR can only detect the Y-chromosome specific DNA.

To clear whether infiltrating lymphocytes derived from either maternal or fetal cells in male PBC patients, we performed tissue-FISH. Tissue-FISH is able to distinguish infiltrating lymphocytes from hepatocytes, because this method preserves the architecture of liver tissues and the shapes of cells. Tissue-FISH revealed that almost infiltrating lymphocytes were male cells in the liver sample of male patients. These results showed that maternal

microchimerism did not play an important role in introducing and maintaining primary biliary cirrhosis.

In conclusion, we were unable to provide the evidence of maternal microchimerism in PBC patients. Although PBC shows the similar histological features with GVHD, PBC may be different from GVHD in etiology.

Abstract

AIM: Gastrointestinal stromal tumor (GIST) is a rare type of cancer. Computed tomography (CT) is an imaging modality of choice for diagnosing GIST. The aim of this retrospective study was to review the CT imaging features of 17 GIST patients.

METHODS: From 1995 to 2003, there were 47 patients with pathologically proven GISTs at our hospital. Of these, 17 patients underwent preoperative CT. We collected and analyzed these CT images. The CT imaging features included tumor diameter, number and location, tumor margin, location of metastasis, hounsfield units of tumor and effect of contrasts. In addition, we also recorded the surgical findings, including complications, tumor size and location for comparative analysis.

RESULTS: The results showed that 12 (70%) tumors were located in the stomach and five (30%) were located in the jejunum mesentery. GISTs were extraluminal in 12 (70%) patients. The tumor margins of 13 (76%) tumors were well defined and irregular in four (24%). The effect of contrast enhancement on GIST CT imaging was homogenous enhancement in 13 (76%) and heterogeneous enhancement in four (24%). The hounsfield units (HU) were 30.41 ± 5.01 for precontrast images and postcontrast hounsfield units were 51.80 ± 9.24 .

CONCLUSION: The stomach was the commonest site of GIST occurrence among our patients. The CT features of GIST were well-defined tumor margins, homogenous enhancement on postcontrast CT images.

Lee CM, Chen HC, Leung TK, Chen YY. Gastrointestinal stromal tumor: Computed tomographic features. *World J Gastroenterol* 2004; 10(16): 2417-2418
<http://www.wjgnet.com/1007-9327/10/2417.asp>

INTRODUCTION

The term gastrointestinal stromal tumor (GIST) has traditionally been used as a descriptive term for soft tissue tumors of the gastrointestinal tract. Although their exact incidence is still somewhat unclear, it is now estimated that between 5 000 and 10 000 people each year develop GISTs in the world; men and women are equally affected^[1]. GISTs were previously thought to be smooth muscle neoplasms, and most were classified as leiomyosarcoma. With the advent of immunohistochemistry and electron microscopy, it has become apparent that GIST may have myogenic features (smooth muscle GIST), neural

attributes (gastrointestinal autonomic nerve tumor), characteristics of both muscle and nerve (mixed GIST) or may lack differentiation (GIST not otherwise specified)^[2]. GISTs are often discovered incidentally at surgery and should be completely excised. The increasing use of computed tomography (CT) and endoscopy of the upper gastrointestinal tract is a non-or minimally invasive means for the detection of asymptomatic GISTs^[3].

In this retrospective study, we analyzed our experience with 17 patients with GISTs who were presurgically investigated by using CT and described the anatomic distribution and imaging features of GIST.

MATERIALS AND METHODS

Patients' data

From 1995 to 2003, there were 47 patients with pathologically proven GISTs at Taipei Medical University Hospital (TMUH) and Wan Fang Hospital (WFH). Of these, 17 (8 males, 9 females, with ages ranging from 33 to 91 years, mean age: 64 years) underwent preoperative CT. We collected and analyzed these CT images.

The abdominopelvic CT scans (HiSpeed CT/I; GE Medical Systems, Milwaukee, WI, USA) were typically obtained after oral administration of 1 000 mL 40 g/L iohalamate meglumine (Mallinckrodt, USA) and intravenous administration of 100 mL (350 mg/mL) iohexol (Nycoveien, Norway) at a flow rate of 2 mL/s, with a section thickness of 10 mm and a pitch of 1.5. The CT imaging features included tumor diameter, number and location, tumor margin (well defined, irregular or clearly invasive), location of metastasis, hounsfield units of tumor and effect of contrast. These characteristics were reviewed blindly by three radiology diplomates. In addition, we also recorded the surgical findings, including complications, tumor size and location for comparison.

RESULTS

The CT imaging findings showed that 14 (82%) patients had one tumor and 3 (18%) patients had two tumors. GIST size ranged from 2 to 19 cm (5.4 ± 1.8 cm). Tumors were located in the stomach in 12 (70%) patients and 5 (30%) patients had tumor located in the jejunal mesentery. GISTs were extraluminal in 12 (70%) patients and intraluminal in 5 (30%). GISTs caused intraluminal bowel obstruction in two patients.

The mean precontrast hounsfield units were 30.41 ± 5.01 and the mean postcontrast hounsfield units were 51.80 ± 9.24 . The effect of contrast enhancement on GIST CT imaging was slight enhancement (Figure 1). Thirteen (76%) showed homogenous enhancement and 4 (24%) showed heterogeneous enhancement.

Tumors were well defined in 13 (76%) patients and irregular in 4 (24%) patients. There was no clearly invasive or vascular encasement of tumors among our patients. Three (18%) patients had metastasis, two to the liver and one to the lung. Twelve patients underwent follow-up CT (range of follow-up period from date of diagnosis, 2-40 mo, mean, 22 mo). No patients relapsed.

Operative findings showed that 14 (82%) patients had one tumor and 3 (18%) patients had two tumors. The smallest GIST was 2 cm×2 cm×1.8 cm and the largest was 19 cm×16 cm×8.5 cm in size. The commonest complications among our patients were gastrointestinal tract chronic inflammation, diarrhea and wound

infection. In addition, 17 patients all underwent lymphadenectomies but no metastasis to the lymph nodes was found.

Figure 1 Precontrast and postcontrast CT scans of tumor. A: A precontrast CT scan shows a well-defined intragastric tumor with slightly lower density than the liver. The hounsfield units are 38.77. B: A postcontrast CT scan shows homogenous enhancement of the tumor, with a hounsfield unit of 57.58.

DISCUSSION

The distribution of 725 malignant smooth muscle tumors of the gastrointestinal tract was 47.3% in the stomach, 35.4% in the small intestine, 4.6% in the colon and 7.4% in the rectum, according to Skandalak and Gray^[4]. In the report by Akwari *et al.*^[5], 68.3% of GISTs were in the stomach, 25.4% were in the small intestine, 2.6% were in the colon and 3.7% were in the rectum. According to a previous study^[6], GIST can also occur in the omental and mesenteric tissues, the duodenum and other sites of the gastrointestinal tract. In our study, 12 (70%) patients had tumors located in stomach and five (30%) patients had tumors located in the jejunal mesentery, a distribution more similar to that reported by Akwari *et al.*^[5].

According to our results, the precontrast hounsfield units of the tumors were 30.41 ± 5.01 and the postcontrast hounsfield units were 51.80 ± 9.24 . The postcontrast hounsfield units were 70% higher than the precontrast hounsfield units. Suster^[7] reported hounsfield units of 33.2 ± 1.25 on precontrast imaging and 55.32 ± 5.22 on postcontrast imaging, with 68% enhancement. Ludwig^[8] reported hounsfield units of 34.21 ± 1.33 on precontrast imaging and 56.29 ± 3.12 on postcontrast imaging, with 67% enhancement. We believe that precontrast hounsfield units of 30 to 35 and postcontrast hounsfield units of 50 to 60 are indicative of GISTs on CT.

We analyzed the correlation of contrast type and tumor size. Of the 17 patients, 4 (24%) had heterogeneous contrast enhancement and 13 (76%) had homogenous contrast enhancement. The mean tumor diameter of the heterogeneous tumors was 11.6 ± 2.1 cm and that of the homogenous tumors was 3.8 ± 1.3 cm. We found that large tumor sizes appeared to be related to heterogeneous enhancement. Our result is similar to that of Conlon *et al.*^[9]. In addition, we found tumors in 13 (76%)

of our patients were well-defined, and in Lee's study^[10], more than two-thirds of patients also had well-defined GISTs. Thus, well-defined tumors appear to be a feature of GISTs on CT imaging.

Licht *et al.*^[11] proposed that the relationship between multiple tumors and metastasis needed further investigation. In our study, we had three patients with multiple tumors and also had three patients with metastases. Only one patient with liver metastasis had multiple tumors; the other two patients with metastasis had only single tumor. Our data appear to indicate that there is no evident correlation between multiple tumors and metastasis. Additionally, 3 (18%) of our patients had metastasis compared to other studies^[12,13] in which 20% to 35% of patients had metastasis, but this difference was not statistically significant. Fong *et al.*^[13] reported that the metastasis percentage was related to the degree of lymph node involvement. Based on our surgical findings, all the patients who had metastasis had no lymph node involvement. Thus, our results differed from those reported by Fong.

In conclusion, the stomach was the commonest site of GIST tumor location among our patients, with a mean tumor diameter of 5.4 ± 1.8 cm. The CT features of GISTs included well-defined tumor margins and predominantly homogenous contrast enhancement, with precontrast hounsfield units of 30 to 35 and postcontrast hounsfield units of 50 to 60. According to the percentage presented above, we also found a "4 seventy rule" in our GIST images review: 70% tumors were located in the stomach, 70% tumors were extraluminal, 76% tumor margins were well defined, 76% GIST CT imaging were homogenous enhancement. In addition, metastasis was not related to the degree of lymph node involvement or tumor number in our study.

Abstract

AIM: To evaluate the effect of parenteral and enteral nutrition combined with octreotide on pancreatic exocrine secretion of the patients with pancreatic fistula.

METHODS: Pancreatic juice, drained directly from the pancreatic fistula, was collected, and the volume, protein, amylase, HCO_3^- , K^+ , Na^+ and Cl^- were determined on d 1, 4 and 7 before and after 7-d treatment with octreotide, respectively.

RESULTS: No differences in exocrine pancreatic secretion were observed during the enteral and parenteral nutrition period ($t = 2.03$, $P > 0.05$); there were significant decreases in pancreatic juice secretion volume, protein, amylase, HCO_3^- , K^+ , Na^+ and Cl^- after parenteral and enteral nutrition combined with octreotide compared with octreotide pretreatment ($t = 4.14$, $P < 0.05$).

CONCLUSION: There is no stimulatory effect on the pancreatic secretion by intrajejunal nutrition and parenteral nutrition. Octreotide is effective on the reduction of pancreatic fistula output.

INTRODUCTION

Since the 1960 s, parenteral nutrition (PN) has been the dominant mode for administering postoperative nutritional support. PN and enteral nutrition (EN) have been successfully used to treat varied severe diseases^[1,2]. But in patients who are recovering from pancreatitis or who have a pancreatic fistula, efforts should be made to avoid stimulation of pancreatic secretion. More recent experimental studies and clinical findings about small intestinal motility and absorption, the development of needle-catheter jejunostomy, and the appearance of new diets have given impetus to the use of enteral feeding for early postoperative nutritional support and the use of octreotide to inhibit pancreatic fistula^[3-5]. During application of enteral feeding, the question arises. How the pancreatic secretion was influenced by EN

administered into the second jejunal loop? Can the more expensive and less physiological PN be replaced by this method^[2]? Since the exocrine function of the pancreas is stimulated by the vagus nerve and the release of gastrointestinal hormones in response to food, there might be no significant increase in the exocrine activity of the pancreas. Animal experiments supported this supposition^[6,7]; however, perfusion of distal jejunum with essential amino acids in human and infusion of carbohydrate into the ileum in human and dog enhanced pancreatic enzyme secretion. The present study was to evaluate the effect of parenteral and EN combined with octreotide on pancreatic secretion of the patients with pancreatic fistula by determining the levels of pancreatic secretion, amylase and electrolytes.

MATERIALS AND METHODS

Patients and groups

Seventeen patients (12 male and 5 female; mean age 43 years, range 27 to 71 years) with pancreatic fistula after abdominal injury or operation from July 1997 to March 2003 were recruited and randomly divided into PN group ($n = 9$) and EN group ($n = 8$). It included pancreatic fistula after pancreas injury in 8 cases, pancreatic body and tail tumor resection in 5 cases, pancreatoduodenectomy in 4 cases.

Parenteral nutritional support

Nine cases with pancreatic fistula 3-5 d postoperatively were supported by PN for 2 wk. In the first wk, they received only PN. In the second week they received PN and octreotide. The target of nutritional therapy was to provide 20-25 kcal/(kg·d) non-protein diet and 0.12-0.15 g protein/(kg·d), the ratio of calories to nitrogen was (100-120):1. PN was given through continuous infusion (14 h/d) of a mixture of 200 mL/L Intralipid or 200 mL/L Lipofundin (B.Braun), 500 g/L glucose and 70 g/L Vamin and branched-chain amino acid. Seizure energy index of glucose to fat emulsion was 1:1. Multivitamins and electrolytes were also administered into total PN (TPN) solutions. Insulin was supplemented into PN at a ratio of glucose vs insulin 6:1. Six patients received TPN through right subclavian vein, 3 cases through right jugular vein. TPN was infused initially at a rate of 40 mL/h and was increased by 20 mL/h every 4 h. Antibiotics were infused by another peripheral vein. The liver and renal function, bicarbonate, serum glucose, fat metabolism were measured every other day. Human albumin, plasma and fresh blood were infused according to the patient's condition. Octreotide 0.3 mg/500 mL saline was infused continuously for 8 h in the second wk and 0.1 mg octreotide was injected subcutaneously at 8:00 pm per day for 7 d.

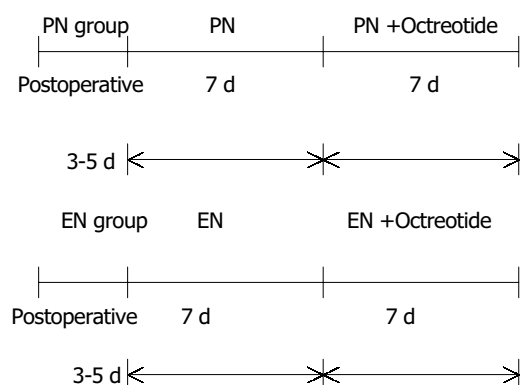

EN

Eight cases with pancreatic fistula were administered EN 3-5 d postoperatively. Nutrison (Nutricia) was used. Enteral feeding included 2 cases of nasoduodenal tube feeding, 4 cases of jejunectomy, and 2 cases of endoscopically placed nasojejunal tube. The jejunum through jejunostomy catheter was infused 250 mL Nutrison and 500 mL 9 g/L saline during days 1-3; Nutrison 500-1 000 mL and 500 mL milk or vegetable soup were infused for 10-14 d. The infusion rate was controlled by a

microcomputer-pump (Nutricia). During EN, inadequate calories and nitrogen were supplemented by partial PN. Octreotide 0.3 mg/500 mL saline was continuously infused for 8 h in the second week, 0.1 mg octreotide was injected subcutaneously at 8:00 pm per day for 7 d.

Observation samples

Pancreatic juice was collected on ice from the fistula during PN or EN and on d 1, 4, 7 before and after using octreotide, respectively. Samples were stored at -20 until amylase and protein content of the fractions were measured by established methods. Experimental procedures are shown as below.

Statistical analysis

Data were collected by two persons blinded to the patients and presented as mean±SD. Statistical significance was evaluated using *t* test by SPSS 10.0 statistical-software, and a *P* value less than 0.05 was considered significant.

RESULTS

Effect of PN and/or EN on pancreatic juice, protein and amylase secretion

Though pancreatic juice, protein and amylase in EN group were slightly increased as compared with PN group, there were no significant changes between the two groups at the first wk (*P*>0.05). During the second wk, the pancreatic juice, protein, amylase decreased markedly from 79.6 mL/d to 60.8 mL/d, 31 mg/L to 22.8 mg/L and 4 220 U/L to 3 270 U/L, respectively, and there was a significant statistical difference as compared with

that of pre-using octreotide in PN group (*P*<0.05). During EN combined with octreotide, the pancreatic juice, protein, amylase secretion decreased significantly from 87.9 mL/d to 65.3 mL/d, 36 mg/L to 29.1 mg/L, and 4 440 U/L to 3 670 U/L, respectively, and there is a statistical difference as compared with that of pre-using octreotide (*P*<0.05); but there was no statistical difference between two groups after using octreotide (*P*>0.05).

Effect of PN and/or EN combined with octreotide on HCO₃⁻, K⁺, Na⁺, Cl⁻ secretion in pancreatic juice

During the first wk, there were no differences in HCO₃⁻, K⁺, Na⁺ and Cl⁻ secretion in pancreatic juice between the two groups. After PN combined with octreotide, HCO₃⁻, K⁺, Na⁺, and Cl⁻ secretion decreased markedly, from 71 mmol/d to 45 mmol/d, 30 mmol/L to 21 mmol/L, 130 mmol/L to 87 mmol/L, and 60 mmol/L to 45 mmol/L, respectively, and there was a statistical difference as compared with that of pre-using octreotide, respectively (*P*<0.05). During EN supporting, there were no differences in HCO₃⁻, K⁺, Na⁺ and Cl⁻ secretion in pancreatic juice as compared with PN. During the second wk, HCO₃⁻, K⁺, Na⁺, and Cl⁻ secretion in EN group decreased significantly, from 79 mmol/d to 52 mmol/d, 35 mmol/L to 25 mmol/L, 135 mmol/L to 94 mmol/L, and 74 mmol/L to 54 mmol/L, respectively, there was a statistical difference as compared with that of pre-using octreotide (*P*<0.05); but there was no statistical difference between two groups after using octreotide (*P*>0.05).

DISCUSSION

As many as 50-70% of patients underwent enterocutaneous pancreatic fistulas after operation^[5]. High-output fistulas (more than 200 mL daily) result in significant loss of fluid, alteration in acid-base status and malnutrition. In addition, digestive enzymes, often of extreme pH, can cause inflammation and soft tissue or skin destruction along the fistula tract. These increase the risk of infection and hemorrhage, prolonging the time required for spontaneous fistula closure and increase postoperative mortality rates. Conservative management of enterocutaneous pancreatic fistula, including TPN, skin care and infection control, succeeds in a spontaneous closure rate of 24-73%^[5-10]. However, such treatment is often of long duration (2-3 mo) and high cost, and is associated with considerable morbidity. In cases in which maximal medical treatment has failed, re-operation for fistula closure is required.

Oct: Octreotide; ^a*P*<0.05 vs PN group; ^c*P*<0.05 vs EN group.

In theory, reduction of fistula output should promote the chances of spontaneous closure. This is usually achieved by restriction of oral intake, sometimes supplemented with nasogastric suction in order to relieve the burden of gut and pancreas. Pharmacological attempts to decrease intestinal secretions involve using drugs such as somatostatin, loperamide, atropine or pirenzepine, and H_2 blockers such as omeprazole. Although the effectiveness of such treatments has yet to be confirmed^[7]. In clinics, PN or EN is usually considered, and they may play an important role in the spontaneous closure of pancreatic fistula, but there is some controversy over their effectiveness and safety.

Effect of PN on pancreatic exocrine secretion

TPN with complete gut rest has been proposed as adjuvant therapy in the treatment of severe acute pancreatitis, to meet metabolic demands and relieve pancreas. A decrease in volume of pancreatic secretion and, in particular, its enzymatic content would likely have a beneficial effect on patient's clinical course. That TPN decreases pancreatic activity is supported by several animal studies. Hamilton *et al.* documented a marked decrease in pancreatic secretions of the normal dog pancreas stimulated maximally by secretion and pancreozymin with the institution of TPN. The volume of pancreatic secretion decreased by 50% and amylase secretion decreased by 71%, but there was a slight increase in bicarbonate excretion. Adler, in 1975, demonstrated that intravenous administration of hypertonic solutions including 50% dextrose resulted in a 24% decrease in pancreatic secretion and a 69% decrease in biliary secretion in a maximally secretin- and pancreozymin-stimulated dog model. PN for patients with pancreatitis has, in general, shown no adverse or beneficial effects on the course of pancreatitis but has provided adequate nutritional support.

The use of intravenous lipid formulations in patients with pancreatic fistula remains controversial despite the evidence that they are not harmful. Kelly and Nahrwold^[11] compared the exocrine pancreatic secretory response to intravenous saline and PN in dogs with chronic gastric fistula and found that the latter produced a small but significant increase in the mean volume of pancreatic juice (2.4 vs 1.8 mL per 15 min; $P < 0.05$) with a slight increase in mean protein and bicarbonate secretions. These differences are minimal compared with the changes found in dogs receiving an intraduodenal infusion of an enteral diet. Hamiloon reported that PN could ameliorate stimulation to the pancreas. The output of the pancreatic juice decreased by 50%, that of amylase by 71% and that of glucose slightly increased. Another canine with chronic pancreatic fistula and stomach ectomy received fat emulsion infusion. Meanwhile, the canine received stimulation of secretin. The results showed that pancreatic juice, protein enzyme, total protein and HCO_3^- did not change during infusion of fat emulsion^[12]. Patients with pancreatic fistula postoperative of gastrectomy received PN by administration of 640 mL or 840 mL 100 g/L Liposym for 8 d, the pancreatic juice, protein and HCO_3^- did not increase^[13]. Klein *et al.*^[14] believed that the effects of different PN contents on the pancreatic juice, HCO_3^- and amylase secretion were different. Intralipid could increase pancreatic juice from 33 mL/h to 39 mL/h, HCO_3^- from 44.5 mmol/L to 54.5 mmol/L, amylase from 25 000 U/L to 32 000 U/L. They held that fat emulsion should be used to supplement essential fatty acid. In the present study, 250 mL 200 mL/L Intralipid or 200 mL/L Lipofundin per day was used as fat energy sources for 2 wk. The results showed that pancreatic juice, protein, amylase, HCO_3^- , K^+ , Na^+ and Cl^- secretion did not change. It suggested that PN could not stimulate pancreatic secretion, and supplemental fat emulsion was safety.

Effect of EN on pancreatic secretion

The presence of food in the stomach and duodenum elicits

gastropancreatic and duodenopancreatic reflexes that result in stimulation of pancreatic exocrine secretion. However, these effects are not pronounced when nutrients are delivered directly into jejunum.

A study^[15] in dogs showed that intragastric delivery of nutrients caused an increase in the volume, and protein and bicarbonate content of pancreatic secretions compared with those in saline-infused controls. Intraduodenal feeding increased the volume of pancreatic secretions but did not affect protein or bicarbonate secretion. Other studies^[16] in dogs also showed that the intraduodenal administration of elemental diets or pure amino acid solutions significantly increased pancreatic secretions, suggesting that the amino acid content of elemental diets is responsible for the stimulatory effects. In contrast, intrajejunal delivery of nutrients was not associated with a significant change in the volume, or protein or bicarbonate content of pancreatic secretions compared with controls. These authors also found in one human subject that avoidance of cephalic, gastric, and duodenal stimuli by jejunal tube feeding of acids did not result in pancreatic stimulation. Another canine study^[17], in which an elemental diet was fed into the proximal jejunum, demonstrated a brisk pancreatic secretory response. However, the pancreatic juice collected was watery and low in enzyme. They concluded that bypassing the stomach minimized acid secretion, which played an important role in keeping the pancreas at rest. Bodoky *et al.*^[18] randomized 12 patients undergoing pylorus-preserving pancreaticoduodenectomy for chronic pancreatitis to receive EN via a needle catheter feeding jejunostomy (7 patients) or PN (5 patients). A catheter placed during operation in the pancreatic duct was used to collect pancreatic secretions. The authors believed that the disease was mainly in the pancreatic head and that the function of the pancreatic remnant was nearly normal. They did not find any difference in the volume of pancreatic secretions or the content of bicarbonate, protein, chymotrypsin or amylase between the two groups.

In the present study, 8 patients received EN for 2 wk, during which the volume of pancreatic juice, protein, amylase and bicarbonate in EN group had a small but not significant increase as compared with PN group. Although there is a paucity of human studies on the effects of oral feeding and EN on pancreatic secretion, one might reasonably conclude from available evidence from human and canine studies that oral, intragastric and intraduodenal feeding produce a significant stimulation of pancreatic secretions. In contrast, intrajejunal feeding has much fewer stimulatory effects and is therefore the route of choice for enteral feeding in pancreatic diseases.

Effect of octreotide on pancreatic juice exocrine secretion

Discovered in 1972, somatostatin is a naturally occurring tetradecapeptide with a wide spectrum of inhibitory biological actions. Within the gastrointestinal tract, somatostatin has been found in the pancreas, stomach, intestinal mucosa and mesenteric neurons. Because of its inhibitory actions, it has been used in the management of upper gastrointestinal haemorrhage, secretory diarrhoea, dumping syndrome and peptide-secreting tumors. Since the mid-1980 s, somatostatin has been advocated as an adjuvant therapy in the conservative treatment of patients with enterocutaneous pancreatic fistula^[19,20]. However, its short half-life (1.1–3.0 min) mandates continuous administration. Long-acting somatostatin analogues, such as octreotide acetate and lanreotide, have been developed. Octreotide has a biological half-life of 90–120 min and can be administered subcutaneously two or three times per day. Compared with somatostatin, it not only significantly reduces the secretions of the pancreas and stomach, but also has a more selective range of targets. Both somatostatin and octreotide have been described as effective treatments for

enteric fistulas in adults, with few severe short-term side-effects (mostly diarrhoea, flushing and abdominal pain). These preparations have, therefore, the potential benefit of cutting the cost of treatment and reducing the discomfort of patients by shortening the length of hospital stay. Since 1990, several groups have described favourable results using somatostatin or octreotide for the "conservative" management of enterocutaneous pancreatic fistula. Administration of such drugs has been reported to result in rapid and significant reduction of fistula output (often within 24 h of treatment) and acceleration of fistula closure (from as early as day 2)^[21-25].

Martineau *et al.*^[4] reviewed the role of octreotide for the management of established enterocutaneous pancreatic fistulas by summarizing the results of 4 randomized trials and 8 case series. They concluded that octreotide significantly decreased enterocutaneous pancreatic fistula output, but did not significantly improve the rate of spontaneous fistula closure. Furthermore, octreotide did not seem to reduce the output, or hasten the time or rate of closure, in fistula of recent onset (less than 8 d). Recently, Berberat *et al.*^[8] reviewed six randomized controlled trials and one open randomized trial, and assessed the efficacy of octreotide on preventing postoperative complications in patients underwent major pancreatic operations. They concluded that prophylactic use of octreotide could significantly reduce the complication rate. Sitges-Serra^[9] reported that 20 cases with pancreatic fistula received octreotide 10 µg/8 h for 20 d ($n = 13$). The output of pancreatic juice decreased from 725 mL/24 h to 151 mL/24 h, the rate of spontaneous fistula closure was 78%. Another group ($n = 7$) used octreotide 100 µg/8 h for 7 d. The output of pancreatic juice increased from 218 mL/24 h to 436 mL/24 h. Torres^[26] reported 33 patients with pancreatic fistula received octreotide 75-100 µg/8 h for 10 d, and then stopped. It resulted in increase of pancreatic juice secretion from 228 mL/24 h to 498 mL/24 h. After 6 h, octreotide was used again. Output of pancreatic juice decreased from 828 mL/24 h to 247 mL/24 h, the rate of spontaneous fistula closure was 79%. The time of spontaneous fistula closure of octreotide group was 2-10 d shorter than that of control group. In the present study, the patients with pancreatic fistula received octreotide combined with PN and EN, the secretion of pancreatic juice, protein and amylase was decreased, and secretion of HCO_3^- , K^+ , Na^+ and Cl^- was inhibited. These results showed that octreotide can inhibit pancreatic juice, amylase secrete, and maybe beneficial to pancreatic fistula self-repair.

We conclude that administration of nutrient solutions into second jejunal loop does not overstimulate the exocrine function of pancreas, while it produces equivalent results to parenteral administration of nutrients. The enteral feeding combined with octreotide could be effective and safe to reduce pancreatic fistula output.

Abstract

AIM: To examine the association of daily alcohol intake, types of alcoholic beverage consumed, drinking patterns and obesity with alcoholic liver disease in China.

METHODS: By random cluster sampling and a 3-year follow-up study, 1 270 alcohol drinkers were recruited from different occupations in the urban and suburban areas of Xi'an City. They were examined by specialists and inquired for information on: Medical history and family medical history, alcohol intake, types of alcoholic beverage consumed, drinking patterns by detailed dietary questionnaires. Routine blood tests and ultrasonography were done.

RESULTS: Multivariate analysis showed that: (1) The risk threshold for developing alcoholic liver disease was ingestion of more than 20 g alcohol per day, keeping on drinking for over 5 years in men. The highest OR was at the daily alcohol consumption ≥ 160 g, the occurrence rate of ALD amounted to 18.7% ($P < 0.01$). No ALD occurred when ingestion of alcohol was less than 20 g per day. (2) 87.9% of all drank only at mealtimes. The cumulative risk of developing ALD was significantly higher in those individuals who regularly drank alcohol without food than in those who drank only at mealtimes, especially for those who regularly drank hard liquors only and multiple drinks ($P < 0.05$). (3) The alcohol consumption in those with BMI ≥ 25 was lower than in those with BMI < 25 , but the risk increased to 11.5%, significantly higher than that of general population, 6.5% ($P < 0.01$). (4) Abstinence and weight reduction could benefit the liver function recovery.

CONCLUSION: In the Chinese population the ethanol risk threshold for developing ALD is 20 g per day, and this risk increases with increased daily intake. Drinking 20 g of ethanol per day and for less than 5 years are safe from ALD. Drinking alcohol outside mealtimes and drinking hard liquors only and multiple different alcohol beverages both increase the risk of developing ALD. Obesity also increases the risk. Abstinence and weight reduction will directly affect the prognosis of ALD. Doctor's strong advice might influence the prognosis indirectly.

INTRODUCTION

Alcoholic liver disease (ALD) is a major health and economic problem in the Western world^[1-5]. Over 14 million Americans are alcohol abusers or alcohol dependent. The problem in China is not as serious as that in Western world. But in recent years, along with the improved living standard and increased alcohol consumption, the morbidity of ALD has risen quickly. Among drinkers, the morbidity has reached 6.1%^[6]. Therefore, ALD has become an increasingly serious disease risk in health care. However, not all drinkers are ALD patients, and there is different susceptibility to damage by alcohol in individuals^[5]. As a common problem, some of its risk factors have been reported in Western countries, but recent analyses have confirmed that geographic and racial variations are evident. In China, however, there is no such study to confirm the main risk factors of ALD, such as cumulative alcohol intake, drinking patterns, types of alcoholic beverage ingested and obesity. In the present study, we aimed to analyze these factors according to random cluster sampling data and a 3-year follow-up study.

MATERIALS AND METHODS

Subjects

We recruited 1 270 drinkers from different occupations in the urban and suburban areas of Xi'an City by random cluster sampling. Every participant was examined by medical staff and received detailed inquiry at his or her home. The medical staff members were trained before the beginning of the study in order to be able to administer the questionnaire uniformly. The questions included: (1) An extensive medical history, including previous diagnosis of chronic liver disease and family medical history. (2) Evaluation of alcohol intake, including detailed questions on the use of alcoholic beverages, types of alcoholic beverage consumed, drinking patterns, the duration of use and the time of drinking (at mealtimes or without food). All the questions were also validated by cross-checking with family members. (3) A detailed physical examination, the body mass index (BMI) and ultrasonography were also performed and recorded. (4) Blood samples were taken to check serum alanine aminotransferase (ALT), serum aspartate aminotransferase (AST), γ -glutamyl transferase (GGT), hepatitis B (HBsAg) and anti-hepatitis C virus (anti-HCV). (5) Three years later, all the patients were investigated again, including detailed inquiry about their relevant diseases and alcohol intake in the past 3 years. Meanwhile, the BMI, ultrasonography and blood samples were taken again.

Diagnosis

The diagnosis of ALD was confirmed according to the published data^[6].

Statistical analysis

Statistical analysis was performed with SPSS 10.0 statistical

package. A logistic-regression model was used in the multivariate modeling of associations. All the factors for which the *P* value of univariate and discriminant analysis was less than 0.05 were entered in the model. Odds ratios (ORs) and 95% confidence intervals (CI) were also calculated.

RESULTS

Study population

Of the 1 270 drinkers, 83 were ALD patients including 72 cases of alcoholic fatty liver, 6 cases of alcoholic hepatitis, and 4 cases of alcoholic cirrhosis. Only one woman was excluded from the study. None of the patients took any medicine in latest 3 mo. Anti-HCV and HBsAg were all negative. Three years later, 66 of 82 ALD subjects were reinvestigated, constituting 80.5% of all. Of the 66 ALD, 19 subjects had BMI ≥ 25 and 47 subjects had BMI less than 25.

Daily alcohol consumption and ALD

Analysis of the data showed that the risk of having ALD was significant with a daily alcohol intake higher than 20 g (Table 1) and the mean duration of drinking longer than 5 years. Above this threshold, the OR for ALD increased proportionally with daily alcohol consumption. The highest OR (10.7, $P < 0.01$) occurred when daily consumption exceeded 160 g. At this highest level of alcohol intake, the percentage of subjects with ALD was 18.7%, significantly higher than that of the lowest level of alcohol intake of less than 20 g/d. Among these subjects whose daily alcohol consumption was less than 20 g and the duration of drinking was less than 5 years, no ALD occurred. So we can assume that daily intake of 20 g alcohol for 5 years is the risk threshold. With longer duration of drinking (more than 10-15 years), a few cases occurred even though the daily intake was less than 20 g, but the morbidity was very low, only 2.2%.

Table 1 Average daily alcohol intake and duration of drinking

Alcohol intake	<i>n</i>	<5 yr	$\geq 5-9$ yr	$\geq 10-14$ yr	$\geq 15-19$ yr	≥ 20 yr	Total	OR (95% CI)

Table 3 Relationship between BMI and ALD

BMI	<i>n</i>	ALD	Years	Daily intake (g)	OR	<i>P</i>
≥ 25	203	24	13.5 \pm 6.2	26.4 \pm 13.7	5.6 (3.02-6.21)	< 0.01
< 25	1 067	58	16.3 \pm 5.8	35.7 \pm 18.1		

Drinking habits and ALD

In our population, beer or wine drinkers were 41.1%, and their alcohol daily intake was less than others. Rural people tended to drink hard liquors. Multiple drinkers were 20.2%, 87.9% of the drinkers consumed alcohol only at mealtimes, the daily alcohol intake was significantly lower than that of alcohol consumed at any time (with and without food) ($P < 0.05$). Daily alcohol intake of only hard liquors, also without food was significantly higher than that of all other categories of drinkers, the morbidity of ALD was also the highest, 2.7 times that of drinkers who drank only wine or beer at mealtimes (Table 2).

Obesity and ALD

Among the 1 270 drinkers, 203 had BMI more than 25. Although their average daily alcohol intake was lower than those with BMI less than 25, the ALD morbidity was 11.5%, more than twice that of normal body mass, significantly higher than the average 6.5%. There were no significant differences in drinking habits between the two groups. Multivariate analysis of the data showed that obesity was a risk factor for ALD, (OR: 5.6, $P < 0.01$). The difference was significant (Table 3).

Retrospective results

A 3-year follow-up indicated that among 19 cases with BMI ≥ 25 , only 3 cases had a body mass of 20% higher than before, and an increased BMI. Their serum ALT and AST were more than twice the upper normal level. The ultrasonography of the liver also indicated typical alcoholic fatty liver. In 9 of the 19 cases with a significant loss of body weight, their BMI also reduced to below 25. The ultrasonography of liver in several cases also became nearly normal. ALT and AST level was below the upper normal level. Of the remaining 7 subjects, their BMI was the same as before, the "liver function" became nearly normal. Ultrasonography findings became normal in 2 of 7 cases, and

remained the same in the other 5. All these 19 subjects except 3 who drank a little occasionally have already abstained.

Among 47 cases with BMI<25, their body mass did not change significantly. Eleven of them who kept on drinking had ALT and AST more than twice the upper normal level. The ultrasonography of liver revealed no improvement. Of the remaining who abstained from drinking, more than 85% of them had nearly normal "liver function", and better ultrasonographic findings. The percentage of "liver function" recovery was significantly higher than those who went on drinking ($P<0.01$).

DISCUSSION

Alcohol abuse has been claimed as one important factor leading to chronic liver diseases, as known in other diseases^[7-12]. The natural history of alcoholic liver disease ranges from asymptomatic indolent to end stage liver disease. Most patients lack specific clinical features^[13,14]. Diagnosis of alcoholic fatty liver and alcoholic steatohepatitis, like non-alcoholic fatty liver, without confirmatory laboratory tests, may involve the history of drinking, ultrasonography and liver biopsy^[15-18].

ALD is not only associated with genetic factors, but also involves other factors such as sex, body weight, BMI, the type and pattern of alcoholic beverage consumed, the habit of drinking hard liquors and of consuming alcohol without food, the duration of drinking^[19-21]. Yet, as to the risk threshold, in terms of daily alcohol intake and years of duration that can induce alcohol liver damage, there is no uniformed conclusion: with the wide range between 30 g/d and 80 g/d^[13]. Great differences between Western and Eastern countries exist: geographic variations must be present^[22,23], especially in China.

Our data suggested that the risk threshold of daily alcohol intake was 20 g; the duration was 5 years for Chinese men. Below the threshold, drinking seldom induced liver damage. If the daily intake exceeded 40 g and the duration was longer than 5 years, the liver damage occurred more frequently. However, with a daily intake higher than 160 g, in some cases the prevalence of alcoholic liver disease was only 18.7%. It means there is significantly different susceptibility among different individuals^[24]. It is commonly believed that prevalence of ALD in general population is up to about 15%, and rises with increased alcoholic intake. Our result was a little higher than that, maybe because our subjects were all men. In China, women drinkers are few, and their alcohol consumption is low, so few women develop ALD. There was only one woman case in our data. In spite of that, we believe that there is a great hepatic susceptibility to damage by alcohol in women.

The types of alcoholic beverage and the different drinking and dietary habits are closely related with ALD. Yet, a dose-effect relation between alcohol intake and alcohol-induced hepatic and other organ functional impairment has been demonstrated.

We were able to demonstrate for the first time in China that the habit of drinking hard liquors without food and the consumption of multiple types of drinks were risk factors of alcohol-induced liver damage. Those who drank only wine and beer were at lower risk for ALD. Fortunately, 90% of the Chinese drink wine or alcohol at mealtimes with food. Drinking without food might differentially affect the intragastric metabolism of ethanol by decreasing gastric alcohol dehydrogenase and hepatic glutathione and by accelerating gastric emptying, as it occurs in rats.

Recent studies confirm that the prevalence of alcohol-induced liver disease in obesity is high and serious. Obesity may be a co-risk factor for ALD and accelerate liver damage^[25,26]. It is reported that if the body weight is 20% above normal, the risk for ALD will be twice as great as in normal weight one. This is similar to our result. Among those obese patients whose

weight was above normal for more than 10 years, the risk for ALD was 2.5-3 times higher. At the same time, the liver damage increases with the increased BMI^[27,28]. However, the mechanism is not clear.

All of the patients in this study whose Anti-HCV and HBsAg were negative and with no recent medication history were "pure" ALD. Multivariate analysis showed that each factor was independent of the other variables.

Besides abstaining, which directly affects the prognosis of ALD^[29], BMI can also affect the progress of ALD^[30]. For the overweight cases, weight loss is an important treatment^[31]. Our data have another indication that "education" is also very important for changing patients' lifestyle^[32]. Because all the subjects with BMI \geq 25 had been told that alcohol and overweight would cause bad prognosis of ALD and strongly recommended complete alcohol abstinence and weight reduction, none of these cases went on drinking heavily. On the other hand, among the men with BMI<25, some did not take the risk of drinking seriously, nearly 15% of them went on drinking during the 3 years, resulting in progress of their ALD.

From the present data we can conclude that the minimum alcohol intake and the duration of years associated with a significant increase in the prevalence of alcohol-related liver disease was 20 g per day and 5 years for men. This risk increases in a dose-related pattern. However, the most striking result is that not only the quantity of alcohol consumed, but also the patterns of drinking are an important determinant of the risk of having ALD. Drinking only hard liquors or multiple types of alcoholic beverages without food, independent of the amount, is associated with an increased prevalence of alcohol-related liver disease. Obesity is also an independent risk factor for ALD. Abstinence and weight loss directly affect the prognosis of ALD. Therefore, we suggest reducing alcohol intake, avoiding drinking outside of mealtimes and consuming only wine or beer, especially for obese people.

Abstract

AIM: To characterize the receptor binding affinity and cytotoxicity of insulin-methotrexate (MTX) for the potential utilization of insulin as carriers for carcinoma target drugs.

METHODS: MTX was covalently linked to insulin. Insulin-MTX conjugate was purified by Sephadex G-25 column and analyzed by high performance liquid chromatography. Hepatocellular carcinoma cell membrane fractions were isolated by sucrose density gradient centrifugation. Competitive displacement of ^{125}I -insulin with insulin and insulin-MTX binding to insulin receptors were carried out. Cyto-reductive effect of insulin-MTX on human hepatoma BEL7402 cells and human hepatocyte cell line HL7702 was evaluated using the MTT assay.

RESULTS: Insulin-MTX competed as effectively as insulin with ^{125}I -insulin for insulin receptors. The values of Kd for insulin-MTX and insulin were 93.82 ± 19.32 nmol/L and 5.01 ± 1.24 nmol/L, respectively. The value of Kd for insulin-MTX was significantly increased in comparison with insulin ($t=7.2532$, $n=4$, $P<0.005$). Insulin-MTX inhibited the growth of human hepatoma cells (BEL7402) almost as potently as MTX. The inhibitory effect reached a peak on the 5th day when the growth of cells was inhibited by 79% at a concentration of 5.0 $\mu\text{g/mL}$ insulin-MTX. Treatment with 5.0 $\mu\text{g/mL}$ of MTX and 5.0 $\mu\text{g/mL}$ of insulin-MTX merely resulted in inhibition of HL7702 cells by 31.5% and 7.8% on the 5th day.

CONCLUSION: Insulin-MTX specifically recognizes insulin receptors and inhibits the growth of BEL7402 cells. These results suggest that insulin can be used as a carrier in receptor mediated carcinoma-targeting therapy.

INTRODUCTION

Methotrexate (MTX), a folic acid analog, is a widely used

antimetabolite in cancer chemotherapy. It inhibits dihydrofolate reductase, an enzyme necessary for purine and pyrimidine synthesis. However, MTX also acts on other rapidly dividing cells such as trophoblast cells, which comprise the implantation site of early gestation. Other toxic effects include depression of the bone marrow and damage to the epithelium of the gastrointestinal tract. Selective targeting of therapeutic and diagnostic agents may improve MTX's efficacy and reduce its adverse effects. Existing methods for selective targeting are usually based upon chemical conjugation of agents to cell-specific targeting molecules (e.g. ligands, antibodies).

Receptor mediated endocytosis may provide a pathway by which exogenous molecules are transported into the interior of target cells. In recent years a number of receptors have been used for DNA delivery via receptor-mediated endocytosis, including asialoglycoprotein^[1-4], transferrin^[5-7], epidermal growth factor (EGF) peptides^[8-10], as well as insulin receptor^[11-13]. It has been shown that expression of insulin receptor is increased on a variety of malignant tumor cells^[14-17]. Insulin can be internalized into nuclei of cells possessing insulin receptors^[18-21]. These facts indicate that insulin may be an attractive candidate carrier for anticancer drugs in target therapy of carcinomas.

To reduce side effects and increase safety, we planned to deliver MTX via insulin receptor-mediated endocytosis. In the present study, we conjugated MTX to insulin and characterized the binding activity and cytotoxicity of insulin-MTX complex. Our results suggest that insulin is a suitable candidate carrier for anticancer drugs.

MATERIALS AND METHODS

Radioiodination of insulin

Porcine insulin was radioiodinated using the Ch-T method and purified by polyacrylamide gel electrophoresis. Radiochemical purity of the ^{125}I -insulin was measured by thin layer chromatogram (TLC).

The radiochemical purity of ^{125}I -insulin was 98% and remained over 95% 14 d after stored at -20°C .

Preparation of insulin-MTX

Insulin-MTX was synthesized by the Department of Pharmacy, Sichuan University. Briefly, MTX (50 mg), EDC (100 mg) and HOBt (50 mg) were dissolved in 3 mL of phosphate-buffered saline (pH = 8.9) and mixed with 1 mL of phosphate-buffered saline (pH = 8.9) containing 25 mg of insulin. The mixture was stirred at 4°C for 48 h. The precipitation was removed by filtration and pH of the solvent was adjusted to 5.5 with 0.5 mol/L HCL. The reaction mixture was kept at 4°C overnight. Thereafter, the solution was filtered through a 0.25 μm membrane (Millipore, Germany) and the filtrate was evaporated under vacuum. The products were purified over a 3 cm \times 45 cm Sephadex G-25 column eluted with 2% ammonium carbonate, and fractions which had the maximal absorbance at 276 nm were collected.

Isolated insulin-MTX was analyzed by analytical HPLC (Beckman) with a 4 mm \times 200 mm ODS column. The mobile phase was 270 mL/L acetonitrile and 730 mL/L 0.1 mol/L NaH_2PO_4 (pH = 0.3) at a flow rate of 0.5 mL/min.

SDS-polyacrylamide gel electrophoresis (SDS-PAGE) was performed in 150 g/L polyacrylamide gel to calculate the molecular weight of insulin-MTX.

Preparation of cell membrane

Hepatocellular carcinoma specimens were obtained from six patients during surgery whose diagnoses were confirmed by histopathology and immediately frozen at -70°C . Cell membrane fractions were prepared according to established techniques. Tissues were cut into pieces, put into Tris-HCL buffer (pH 7.5) and homogenized. The cell membrane fractions purified by centrifugation in a discontinuity sucrose density gradient were stored at -70°C . The protein concentration was determined according to Lowry method.

Receptor binding assay

The conditions of the assay system were modified according to the method reported earlier. In saturation experiments, the cell membrane fractions (80 μg protein) were incubated with increasing concentrations (5×10^3 – 5×10^5 cpm) of ^{125}I -insulin in the absence (total binding) or presence of the same unlabeled insulin (4.3 nmol/L, nonspecific binding). In competition experiment, the cell membrane fractions (80 μg protein) were incubated with 5 nmol/L ^{125}I -insulin in the absence (total binding) and presence of increasing concentrations (10^{-12} – 10^{-7} mol/L) of the unlabeled insulin or insulin-MTX. After incubation for 20 h at 4°C , free ligands were removed by centrifugation at 2000 r/min for 10 min after addition of 0.1 mL of 3 g/L bovine γ -globulin and 0.8 mL of 15.8% PEG. Radioactivity of the membrane pellets was determined in a gamma counter for 1 min as the total binding. Specific bindings were obtained by subtracting nonspecific bindings from total bindings.

Cell culture

Human hepatoma BEL7402 cells and human hepatocyte HL7702 cells were grown at 37°C in a humidified incubator with 50 mL/L CO_2 atmosphere in RPMI1640 (GIBCO BRL) medium containing 100 mL/L of decompemented FBS, penicillin (100 U/mL) and streptomycin (100 U/mL).

Cell treatment and MTT assay

BEL7402 cells and HL7702 cells were seeded at a density of 10^4 cells per well into 96-well plates. After overnight growth, the medium was removed and RPMI containing different concentrations of insulin-MTX or MTX was added. At given time points, 20 μL of MTT (50 mg/mL) was added to each well. After incubation for 4 h at 37°C in a humidified 50 mL/L CO_2 atmosphere, the medium was removed and 0.2 mL of DMSO was added. Then, the absorbency at 570 nm was read.

Data calculation and statistical analysis

Binding data were calculated with receptor binding analysis software. Values were presented as mean \pm SD. Statistical

comparisons between the means were made with paired *t*-test at a confidence level of 95%.

RESULTS

Analysis of insulin-MTX

The recovery of insulin-MTX was around 71.5%. HPLC assay indicated that isolated insulin-MTX (retention time 12.08 min) yield was approximately 94% (Figure 1). The rest contained insulin (8.81 min) and MTX (4.16 min).

The calculated molecular weight of insulin-MTX was 6779 u according to its relative position to the molecular mass marker in SDS-PAGE pattern.

Receptor binding

The binding of insulin receptors to unlabelled insulin and the insulin-MTX conjugate derivative were determined by their ability to compete with free radioactively labelled insulin for receptor sites on cell membranes of hepatocellular carcinoma. We first established the normal binding characteristics of ^{125}I -insulin to cell membranes. Binding took place rapidly in the first 2 h, then slowed down and reached its maximum at approximately 18 h. For all subsequent binding experiments, the incubation time was 20 h at 4°C . As the concentration of ^{125}I -insulin increased, the binding mounted up and plateaued rapidly.

Similar to insulin, the conjugate competed for the binding sites with ^{125}I -insulin on the insulin receptor in a dose-dependent manner (Figure 2). Binding of ^{125}I -insulin (5 nmol/L) was reduced to 50% in the presence of 5.01 ± 1.24 nmol/L of unlabelled insulin or 93.82 ± 19.32 nmol/L of insulin-MTX, respectively. In contrast, MTX did not compete for binding (data not shown).

Figure 2 Competitive binding curves of ^{125}I -insulin against insulin-MTX or insulin. The concentration of ^{125}I -insulin was 5 nmol/L. The binding assay was described in the MATERIALS AND METHODS.

Inhibition of insulin-MTX complex on cell proliferation

Dose-response curves of insulin-MTX and MTX on BEL7402 and HL7702 cells are shown in Figure 3. Viability was expressed as a percentage of control by dividing the absorbance of each treated well by the average of untreated control. BEL7402 cells

Figure 1 HPLC analysis of insulin and insulin-MTX. The condition was described in MATERIALS AND METHODS. Retention time of insulin was 8.81 min. Retention time of insulin-MTX was 12.16 min. A: HPLC analysis of insulin. B: HPLC analysis of insulin-MTX.

Figure 3 Concentrations of MTX and insulin-MTX in BEL7402 and HL7702 cells. BEL7402 cells and HL7702 cells having cultured overnight were exposed to insulin-MTX or MTX at the indicated concentration for 24 h, 48 h, 72 h, 96 h, 120 h and 144 h respectively. Cell viability was assessed using MTT assay. Viability was expressed as a percentage of control by dividing the absorbance of each treated well by the average of the untreated control. A: Viability of BEL7402 cells treated with insulin-MTX (mean \pm SD, $n = 3$), B: Viability of BEL7402 cells treated with MTX (mean \pm SD, $n = 3$), C: Viability of HL7702 cells treated with insulin-MTX (mean \pm SD, $n = 3$), D: Viability of HL7702 cells treated with MTX (mean \pm SD, $n = 3$).

were sensitive to both insulin-MTX and MTX. Cyto-reductive effect of MTX and insulin-MTX on BEL7402 cells was concentration-dependent. As early as 24 h, 5.0 μ g/mL of insulin-MTX inhibited BEL7402 cell growth by 34.3%, which was relatively lower as compared with 40.6% by 5.0 μ g/mL of MTX. The effect reached its peak on the 5th d, and BEL7402 cells were inhibited by 79% at a concentration of 5.0 μ g/mL insulin-MTX and 82.1% at 5.0 μ g/mL MTX, respectively. In contrast, treatment with 5.0 μ g/mL of MTX and 5.0 μ g/mL of insulin-MTX merely resulted in the inhibition of HL7702 cells by 31.5% and 7.8% on the 5th d.

DISCUSSION

The molecule of insulin has sufficient hydroxys and carboxyls that can be used for conjugation with other small molecules. Exploration of the efficiency and specificity of cell entry offered by insulin receptor mediated endocytosis has been proposed previously^[22,23]. Here we demonstrated that cross-linking MTX to insulin produced a soluble molecule capable of both specific recognition of the insulin receptors and inhibition of growth of tumor cells, thereby providing a possible tool for target transporting anticancer drugs. The use of insulin as a carrier might offer two advantages. First, most of insulin-MTX could go to tumor cells which overexpress insulin receptors, thus rapidly dividing normal tissues would not be damaged by the drug. Second, tumor cells could develop MTX-resistance frequently via various mechanisms. One of them was due to decreased membrane transport^[24-28]. The use of insulin as a carrier might offer an increased MTX transportation into drug-resistant tumor cells.

Since laboratory iodination of insulin with 125 I could incur oxidation damage and brings about indiscriminate labelling of tyrosine residues leading to decreased biological activity including aberrant receptor binding, polyacrylamide gel electrophoresis was used to purify monoiodo [125 I-Tyr^{A14}] insulin, which was fully active in receptor binding assays^[29]. Receptor binding analysis showed that insulin-MTX could specifically bind to insulin receptors on human hepatocellular carcinoma.

The increased K_d indicated a decreased affinity for receptors, indicating that linking MTX to insulin molecule did interfere with the affinity of insulin-receptor binding. High affinity is one of the most important criteria of tumor-target agents. Decrease in affinity of insulin-MTX for insulin receptors may result from conjugation of MTX with A13 and B17 positions of insulin molecules. These positions are located in the hexamer-forming surface and on the opposite side of the classical binding site, and constitute a second domain of the molecule important for receptor binding^[30]. Further studies to improve the affinity of insulin-MTX by modifying the method of conjugation would be needed.

Insulin receptor was considered to play a role in the regulation of hepatocellular carcinoma^[31] and there have been reports showing increased insulin receptors expressed on these cells^[29,32]. Therefore human hepatoma BEL7402 cell line was selected to measure the cyto-reductive effect of insulin-MTX. Our studies showed that BEL7402 cells were sensitive to both insulin-MTX and MTX. However, the molecular weight of insulin-MTX complex was far greater than that of MTX. It was observed that 0.375 nmoL (1.5×10^{-6} mol/L \times 0.25 mL) of MTX conjugated to insulin inhibited the growth of BEL7402 cells as effectively as 2.5 nmoL (1×10^{-5} mol/L \times 0.25 mL) of MTX. HL7702 cells appeared to be less sensitive to both insulin-MTX and MTX, especially to insulin-MTX, when compared with BEL7402 cells. Treatment with 5.0 μ g/mL of insulin-MTX resulted in about 10-fold higher toxicity on BEL7402 cells than on HL7702 cells. This may result from the elevated proliferation and the increased expression of insulin receptors of BEL7402 cells. These results indicated that conjugation of insulin could enhance the cytotoxicity of MTX to hepatocarcinoma cells.

Our results showed that the new construct could bind specifically to insulin receptors, but its effect on glucose metabolism depended on the residues with which MTX molecule interacted. An unparalleled relationship of receptor binding and glucose uptake was observed in other insulin analogues and mutants^[33,34]. Therefore, it is necessary to test the biological activity of insulin-MTX in glucose metabolism in order to understand its effects on plasma glucose levels. In our study,

SDS-polyacrylamide agarose gel electrophoresis showed the molecular weight of insulin-MTX was 6 779 u, which equaled the mass of one molecule of insulin ($M_r = 5\,800$) and two molecules of MTX ($M_r = 454.5$). The ratio of insulin molarity to the MTX was estimated to be 1:2. On the basis of this molar ratio, only 20–200 μmol insulin is required to obtain a high plasma concentration (10–100 $\mu\text{mol/L}$). Besides, the dose may be reduced because of the targeting ability of insulin-MTX. Even if the conjugates have partial bioactivity in glucose uptake, there is little probability that administration of such a low dose in therapy would result in adverse effects of glucopenia.

In the present study, we demonstrated that insulin-MTX complex could specifically bind to insulin receptors and efficiently inhibit the growth of human hepatoma BEL7402 cells, although the affinity needs to be improved. Receptor-mediated endocytosis has a tremendous potential for delivery of carcinoma target drugs because of the overexpression of insulin receptors on carcinoma tissues.

Abstract

AIM: To explore the etiology, pathogenesis, diagnosis, and treatment of postsurgical gastroparesis syndrome (PGS) after pancreatic cancer cryotherapy (PCC) or pancreaticoduodenectomy (PD), and to analyze the correlation between the multiple factors and PGS caused by the operations.

METHODS: Clinical data of 210 patients undergoing PD and 46 undergoing PCC were analyzed retrospectively.

RESULTS: There were 31 (67%, 31/46) patients suffering PGS in PCC group, including 29 with pancreatic head and uncinate tumors and 2 with pancreatic body and tail tumors. Ten patients (4.8%, 10/210) developed PGS in PD group, which had a significantly lower incidence of PGS than PCC group ($\chi^2 = 145$, $P < 0.001$). In PCC group, 9 patients with PGS were managed with non-operative treatment (drugs, diet, nasogastric suction, etc.), and one received reoperation at the 16th day, but the symptoms were not relieved. In PD group, all the patients with PGS were managed with non-operative treatment. The PGS in patients undergoing PCC had close association with PCC, tumor location, but not with age, gender, obstructive jaundice, hypoproteinemia, preoperative gastric outlet obstruction and the type and number of gastric biliary tract operations. The mechanisms of PGS caused by PD were similar to those of PGS following gastrectomy. The damage to interstitial cells of Cajal might play a role in the pathogenesis of PGS after PCC, for which multiple factors were possibly responsible, including ischemic and neural injury to the antropyloric muscle and the duodenum after freezing of the pancreaticoduodenal regions or reduced circulating levels of motilin.

CONCLUSION: PGS after PCC or PD is induced by multiple factors and the exact mechanisms, which might differ between these two operations, remain unknown. Radiography of the upper gastrointestinal tract and gastroscopy are main diagnostic modalities for PGS. Non-operative treatments are effective for PGS, and reoperation should be avoided in patients with PGS caused by PCC.

INTRODUCTION

Postsurgical gastroparesis syndrome (PGS) is a complex disorder characterized by postprandial nausea, vomiting, and gastric atony in the absence of mechanical gastric outlet obstruction. Patients frequently suffer marked weight loss and malnutrition that require hospitalization and prolonged parenteral nutrition (PN). These symptoms can be disabling and often fail to be alleviated by drug therapy, for which gastric reoperations usually prove unsuccessful. An identified cause for PGS has not been available, nor is its mechanism quite clarified. PGS after gastrectomy or pancreatoduodenectomy (PD) has been reported in a number of literatures^[1-5]. Based on the results of clinical investigations^[6-9], cryosurgery targeting at the pancreaticoduodenal region was considered safe and effective for unresectable pancreatic cancer. However, PGS caused by cryotherapy for pancreatic cancer (PCC), to our knowledge, has not been reported. As a unique complication of PCC, gastric stasis occurs in the early postoperative period in most of cases receiving PCC (67%), resulting in long-term loss of a large amount of gastric juice and delayed recovery of oral food intake, and occasionally, excessive gastric juice loss leads to body fluid deficit and metabolic alkalosis. To define the factors contributing to the development of PGS following PD or PCC, we performed this study to retrospectively examine the clinical data of 210 patients undergoing PD and 46 undergoing PCC.

MATERIALS AND METHODS

Subjects

From January 1990 to June 2003, 210 patients (147 male and 63 female patients, aged 35 to 75 years with a mean of 53.6 years) received PD in our hospital for pancreatic cancer or periampullary adenocarcinoma. None of the patients were preoperatively identified to have mechanical gastric outlet obstruction, but 95 had obstructive jaundice and 15 had hypoproteinemia.

During the period between January 1995 to March 2003, another 46 patients (including 31 male and 15 female patients, aged between 39 and 78 years with a mean of 54 years) underwent PCC for unresectable advanced pancreatic cancer, located in the pancreatic head in 21 cases, in the uncinate process in 15 cases, and in the pancreatic body and tail in 10 cases. All the tumors were identified by preoperative helical computed tomography (CT) scan and by intraoperative exploration, including 31 tumors with local involvement and 15 metastatic tumors. Preoperatively, 34 patients were identified to have obstructive jaundice and 6 had hypoproteinemia. All the patients, excluding the 8 with preoperative duodenal obstruction, were free of preoperative mechanical gastric outlet obstruction. Gastrojejunostomy was performed in 37 cases, and cholecystojejunostomy or choledochojejunostomy done in 32 cases during PCC for relief or prevention of the common bile duct and gastric outlet obstruction. Four patients also had concurrent splanchicectomy with ethanol.

Endoscopy or radiography was employed to identify and exclude cases of mechanical gastric outlet obstruction, and also to detect such problems of anastomotic stricture, efferent

limb obstruction, and jejuno gastric intussusception *etc.*, as well as food retention after a 4- to 8-h fast, for validating the diagnosis of gastroparesis.

Diagnostic criteria for PGS

At present, consensus has not been reached on the criteria for diagnosis of PGS. Stanciu^[10] suggested using gastric scintigraphy with ⁹⁹Tc-labeled low-fat meal as the gold standard for diagnosing delayed gastric emptying, which utilized gamma camera imaging of the abdomen following the ingestion of a radiolabeled meal, performed at regular intervals of 2 to 4 h to quantify the meal emptying in terms of percentages. Typically, meal emptying of over 50% within 2 h was considered normal, whereas delayed gastric emptying was indicated if gastric retention greater than 10% at 4 h. In this study, we formulated practical diagnostic criteria for PGS after consultation of the previous documentations in the literature^[5-7,10], as the following: (1) Absence of mechanical gastric outlet obstruction identified by one or more medical examination modalities; (2) A volume of gastric juice aspirate exceeding 800 mL/d that sustained for more than 10 d; (3) No abnormalities in water, electrolytes, or acid-alkali balance. (4) Absence of underlying diseases causing gastroparesis, such as diabetes, chorionitis, hypothyrosis, *etc.* (5) No history of using such agents as morphine, atropine, *etc.* that affected contraction function of the smooth muscle.

Surgical procedures

In PD group, the organs resected during PD included the gallbladder, common bile duct, head of the pancreas, the entire duodenum, with also subtotal gastrectomy. Proximal jejunum of 10 to 15 cm was also resected. The alimentary and biliary tracts were reconstructed with methods of Child or Whipple.

In patients of PCC group that defied surgical resection of the tumor, cryoprobes were deployed directly into the tumor for freezing to -196 °C twice, lasting for 10-15 min (using LCS 2000 cryogenic surgical system), with the common bile duct, stomach, and jejunum protected by dry cotton pads. Subsequent gastroenteroanastomosis, cholecystojejunostomy, or choledochojejunostomy were performed to reconstruct the alimentary and biliary tracts, according to the findings by intraoperative exploration. Care was taken to avoid freezing of the duodenal wall or causing other iatrogenic injuries such as damage to the biliary system or gastroduodenal artery. Jejunostomy was performed in some cases highly suspected of gastroparesis after PCC for postoperative enteral nutrition (EN) support.

Statistical analysis

The incidence of PGS in the two groups was compared and multiple factors were analyzed using χ^2 test. A *P* value less than 0.05 was considered statistically significant.

RESULTS

No serious complications took place in the PCC group, nor did operative death or complications occur in relation to the anastomosis. None of the patients developed fistula or pancreatitis. There was only transient elevation of amylase following the operation and the liver function and blood sugar remained normal. In PD group, in contrast, 4 patients developed serious complications after PD, including leakage at the pancreatojejunostomy in 2, bleeding at the anastomosis in 2 cases, stenosis of the anastomosis in 1 and stress peptic ulcer in 1 case. The mortality rate of PD in the perioperative period was 1.5%.

Ten of the 210 patients in PD group presented PGS within 5-10 d postoperatively. PGS developed in 31 of the 46 patients in PCC group, occurring within 5-7 d after the operation, including 29 patients with pancreatic head and uncinate tumors

and 2 with pancreatic body and tail tumors. In PD group, 14 patients with PGS received non-operative treatment such as medication, diet therapy, and nasogastric suction *etc.*, and 1 patient underwent reoperation on postoperative day 16, which, however, failed to relieve the symptoms. All patients with PGS in PCC group received non-operative treatment. Altogether 41 patients developed PGS in the two groups according to our diagnostic criteria, 15 of these cases were identified 4-7 d after withdrawal of the nasogastric tube and 10 were found to have a gradually increasing volume of gastric juice aspirate to 800 mL/d till 3-7 d after operation. Twenty of the 40 patients developed PGS 2-3 d after intake of liquid or semiliquid diet. Furthermore, the volume of gastric juice suction exceeded 2 000 mL/d in 4 cases following PCC and persisted for ten or more days (Table 1).

PGS following cryosurgery was closely associated with PCC, tumor location, but not with age, gender, obstructive jaundice, hypoproteinemia, preoperative gastric outlet obstruction or the type and number of gastric biliary tract operations (Table 2). PGS following PD was related with age, hypoproteinemia, preoperative gastric outlet obstruction and the type and number of gastric operations performed. Patients undergoing PCC were more likely to develop PGS than those undergoing PD (67% vs 4.8%, $\chi^2 = 145$, $P < 0.001$).

DISCUSSION

Many debates over the etiology and pathophysiology of PGS remain unresolved. Clinically, the frequency of this complication varies in close association with the type and number of gastric operations performed. Donahue *et al.*^[11] reported a 26% incidence of chronic morbidity in patients after truncal vagotomy and antrectomy compared with a 5% incidence after highly selective vagotomy. There also appears to be a greater incidence of PGS associated with antrectomy and Roux-en-Y reconstruction compared with more conventional Billroth I and Billroth II reconstructions. Therefore, the main factor contributing to PGS is denervation and the consequent atony of the gastric remnant rather than disruption of the pacemaker activity in the Roux limb.

The exact mechanisms responsible for PGS after gastric surgery remain unclear but are likely to be multifactorial. The loss of gastric parasympathetic control resulted from vagotomy contributes to PGS via several mechanisms. In the proximal stomach, loss of vagal control leads to accelerated emptying of liquids by disrupting the late-stage tonic contractions responsible for relaxation and accommodation of the gastric fundus. In the distal stomach, vagotomy weakens antral peristaltic contraction responsible for breakdown of chyme. When coupled with the observed decrease in intestinal secretion of prokinetic hormones seen after truncal vagotomy, this leads to delayed emptying of solid substances. Also, the loss of vagal suppression of the ectopic intestinal pacemakers may cause dissociation of the antral pressure waves from the duodenal waves. The consequent disruption of wave sequence prolongs the lag phase of solid food digestion during which food is broken down into small particles by retropulsion and further delays the digestive process^[12,13].

Recently, it has been recognized that interstitial cells of Cajal generate electrical pacemaker activity and mediate motor neurotransmission in the stomach. The interstitial cells of Cajal are located in the muscular wall of the gastric corpus and antrum. Gastric dysrhythmias (tachygastrias and bradygastrias) are disturbances of the normal gastric pacemaker potentials and are associated with such symptoms as nausea, epigastric fullness, bloating and delayed gastric emptying. Ordog *et al.*^[14] suggest that damage to interstitial cells of Cajal may play a key role in the pathogenesis of diabetic gastropathy. Meanwhile, Zarate *et al.*^[15] reported that histological and immunohistochemical

study of the resected specimen showed hypoganglionosis, neuronal dysplasia, and marked reduction in both myenteric and intramuscular interstitial cells of Cajal in patients with idiopathic gastroparesis.

Certainly, PGS after gastric surgery also can be due to

muscular, neural, or humoral abnormalities. Hypothyroidism and diabetes^[4] have been identified as contributing factors to gastroparesis in some patients. In patients without an identified cause, the gastroparesis is labeled as idiopathic. The mechanisms of PGS following PD is similar to that after gastrectomy.

The results of our observations suggest no significant direct relation of PGS following PCC with the types of gastric operations or the loss of gastric parasympathetic control, nor was it related to the patients' age or presence of hypoproteinemia or preoperative gastric outlet obstruction (Table 2), which, however, might be the factors contributing to PGS after gastrectomy or PD^[1-5]. We therefore suggest that the mechanism of PGS after PCC may differ, at least partially, from that underlying the PGS following gastrectomy or PD.

Patients with tumors located in the pancreatic head and uncinate process are at higher risk to develop PGS following PCC than those with tumors in the pancreatic body and tail (Table 2). The interstitial cells of Cajal in the muscular wall of the gastric corpus and antrum are exposed to likely damage during the freezing of the pancreatoduodenal area, which offers a possible explanation for the pathogenesis of PGS after PCC.

Pylorus-preserving pancreatoduodenectomy (PPPD) frequently results in gastric stasis^[12,16], which occurs in 20% to 50% of the patients during the early postoperative period. As the duodenum has proved to be important in the initiation and consolidation of phase III activity of the migrating motor complex (MMC) of the stomach, its removal severely undermines the gastric phase III, hence gastric stasis may occur. On the basis of their findings that patients undergoing PPPD had slower recovery of gastric phase III and lower plasma motilin concentrations than those undergoing duodenum-preserving pancreatic head resection, Matsunaga *et al.*^[16] concluded that PGS after PPPD might be attributed, at least in part, to delayed recovery of gastric phase III activity due to lowered concentrations of plasma motilin after resection of the duodenum. However, resection of the pancreas does not seem to affect gastrointestinal motility. Malfertheiner and Sarr^[17] reported that even a total pancreatectomy failed to obviously affect the motor activity of the entire upper gastrointestinal tract in dogs.

We found in this study that PGS developed in 67% of all patients after PCC through multifactorial mechanisms, which could be at least partially in common with those underlying the PGS resulted from PPPD. The possible factors responsible for PGS after PCC include ischemic and neural injury to the antropyloric muscles and the duodenum after freezing of the pancreatoduodenal area (but not to direct freezing of the duodenal pacemaker) and reduced circulating levels of motilin originally produced by the enterochromaffin cells in the duodenum and proximal jejunum. The peak plasma motilin concentration occurs in line with phase III activity of the interdigestive MMC in the stomach and duodenum. The phase III starts in the gastroduodenal region and migrates downward along the small intestine, hence its nickname the "housekeeper". The housekeeper function of phase III may be important to empty the gastric juice in the postoperative period after PCC. As the duodenum plays a role in the initiation and consolidation of gastric phase III, the injury of the duodenum by freezing -and thus the interruption of gastric phase III- may be one of the several possible causes of PGS after PCC. But still, the above hypotheses currently have to remain hypothetical, and the exact mechanisms of PGS caused by PCC must await

further investigation.

Patients with PGS have non-specific symptoms of early satiety, postprandial bloating, nausea, and vomiting, and the volume of gastric juice suction in most of them can increase gradually during early postoperative period. The diagnosis of PGS is often difficult to confirm. In the absence of identifiable anatomic problems such as anastomotic stricture, efferent limb obstruction, or jejuno gastric intussusception, other causes of gastric dystonia must be carefully examined. Hypothyroidism has been identified as a contributing factor to gastroparesis in some patients. Gastroparesis can also occur in patients with diabetes^[18,19]. Several complementary diagnostic modalities may be used to confirm the diagnosis of PGS. Fiberoptic endoscopy or radiography of the upper gastrointestinal tract should be performed routinely to exclude anatomical causes of gastric outlet obstruction. Radionuclide GESs can also be necessary, for clinical evaluation and conventional radiographic studies are often unreliable. If endoscopy and radionuclide scintigraphy are inconclusive, a small bowel contrast study should be performed to rule out possible mechanical lesions and/or generalized gut hypomotility. Although not routinely available^[20], electromyography of the gastrointestinal tract may provide valuable assistance in the diagnosis of patients with complex motility disturbances.

As the treatment of gastroparesis is far from ideal, nonconventional approaches and nonstandard medications might be of use. Traditional medical therapy consists of behavioral and diet modification, nasogastric tube suction and the use of prokinetic drugs such as bethanecol, metoclopramide, erythromycin and the more recent cisapride^[10]. Dietary measures and prokinetic drugs may help relieve the symptoms in most patients, while some patients with severe nausea and vomiting require antiemetic medications. A few patients fail medical therapy and continue to have debilitating symptoms of gastroparesis, who may benefit from a venting gastrostomy^[18] or jejunostomy performed surgically, endoscopically, or fluoroscopically^[20]. Near-completion gastrectomy (NCG) has proved useful in small series of patients^[21], but data on long-term follow-up has been lacking. Gastric electrical stimulation can be of value in the management of gastroparesis^[22-24], in which the patients with PGS received continuous high-frequency/low-energy gastric electrical stimulation via electrodes deposited in the muscular wall of the antrum and connected to a neurostimulator in an abdominal wall pocket. This method produced entrainment of the intrinsic slow wave and promoted contractions in phase III with the normal slow wave. This is why a suitable stimulation to the stomach during gastroscopic examination is also helpful for the remission of PGS^[3-5]. In this study, 5 patients received gastroscopic examination and the symptoms were markedly relieved. Ten patients with PGS were treated with acupuncture, and the effects were satisfactory.

According to our experience, all patients of PGS caused by PD or PCC need to undergo a long period of nasogastric suction till the clinical symptom relief or recovery occurs. The patients may experience epigastric fullness, nausea, or even vomiting, if

the nasogastric tube is withdrawn too early. Therefore, almost all of the patients with PGS in this study received the gastric juice suction over an average period of 2.2 wk, with the longest exceeding 8 wk. Because of long-term absence of food intake, these patients required nutritional support with a feeding jejunostomy tube or underwent a period of parenteral nutrition. The jejunostomy tube, as we believe, is safe, economic and practical for nutrition support in such patients, because their small intestinal peristaltic contractions and absorption function were normal in spite of PGS. Clinically, almost all of the patients had a concurrent jejunostomy during cryosurgery, considering the likeliness of these patients to develop delayed gastric emptying and for administration of postoperative enteral nutrition support. We consider that the non-operative treatments are effective for PGS after PCC or PD, and gastric reoperations should be avoided.

Abstract

AIM: To design and establish a method of multiplex PCR normalization for simultaneously detecting HBV and HCV.

METHODS: Two pairs of primers with a 20 bp joint sequence were used to amplify the target genes of HBV and HCV by two rounds of amplification. After the two rounds of amplification all the products had the joint sequence. Then the joint sequence was used as primers to finish the last amplification. Finally multiplex PCR was normalized to a single PCR system to eliminate multiplex factor interference. Four kinds of nucleic acid extraction methods were compared and screened. A multiplex PCR normalization method was established and optimized by orthogonal design of 6 key factors. Then twenty serum samples were detected to evaluate the validity and authenticity of this method.

RESULTS: The sensitivity, specificity, diagnostic index and efficiency were 83.3%, 70%, 153.3% and 72.2%, respectively for both HBsAg and anti-HCV positive patients, and were 78.6%, 80%, 258.6% and 79.2%, respectively for HBsAg positive patients, and were 75%, 90%, 165% and 83.3%, respectively for anti-HCV positive patients.

CONCLUSION: The multiplex PCR normalization method shows a broad prospect in simultaneous amplification of multiple genes of different sources. It is practical, correct and authentic, and can be used to prevent and control HBV and HCV.

INTRODUCTION

Multiplex PCR uses several pairs of primers that target different genes to simultaneously amplify several different target sequences at a high speed and with a high efficiency. As many amplification factors may interact and produce non-specific amplification, its clinical use is limited. According to the characteristics of a small fragment that did not complement to

the genes of PCR primers, we established a multiplex PCR normalization method (This method has been patented in the Chinese Patent Agency). By creating a primary reaction that was appropriate to all target templates, the multiplex was normalized to a single target PCR. This method could overcome the difficulties in establishing and optimizing the multiplex reaction system. In this article the practicality and effectiveness of multiplex PCR were validated by simultaneous detection of HBV and HCV.

MATERIALS AND METHODS

Specimen collection

Twenty-eight serum samples were collected from Jinan Central Hospital and Jinan Infectious Disease Hospital. The samples were all validated by ELISA method, in which 14 cases were HBsAg (+), 8 were anti-HCV (+), and 6 were positive for both HBsAg and anti-HCV. Ten cases were negative for both HBsAg and anti-HCV and used as control.

Reagents and instruments

HBV PCR kits and HCV PCR kits were purchased from Institutes of Liver Diseases, Peking University Medical College. dNTPs, AMV, proteinase K, isothiocyanate guanidine and Triton X-100 were products of TAKARA. PCR Amplification Minicycler™ was from MJ Research, USA. Innotech Imager™ 2200 was from Alpha Innotech Incorporation.

Extraction of virus nucleic acids

Method 1^[1]: Proteinase K (10 mg/mL) was added to 150 µL serum and incubated at 50 °C for 2 h. RNA and DNA were extracted with phenol-chloroform at pH4.0 and 8.0 respectively, and then nucleic acids were precipitated with Isopropyl alcohol. The final pellets were dissolved in 10 µL RNase free water and stored at -70 °C.

Method 2^[2]: 200 µL guanidine isothiocyanate and 20 µL glass powder were added to 200 µL serum and incubated at ambient temperature for 90 min and centrifuged at 12 000 g. The supernatant was removed and the pellet was washed and dissolved in reverse transcription buffer PCR detection.

Method 3^[3]: 90 µL lytic buffer (120 g GUSCN, 100 mL 0.1 mol/L Tris-HCl, pH6.4), 0.2 mol/L EDTA (20 µL, pH8.0) and glass powder were added to 50 µL serum and incubated at room temperature for 10 min, mixed and centrifuged at 12 000 g for 15 s, washed 2 times with washing solution (120 g GUSCN, 100 mL 0.1 mol/L Tris-HCl, pH 6.4, 2.6 g Triton ×100), and further washed with 700 mL/L ethanol and acetone. Then acetone was removed and dried at 56 °C for 10 min and TE buffer was added to the pellets and incubate at 56 °C for 2 min and then centrifuged for 2 min. The supernatant was transferred to another tube for further amplification.

Method 4^[4]: 200 µL lytic buffer [6 mol/L guanidine hydrochloride, 10 mmol/L Tris-HCl (pH 7.5), 200 g/L Triton X-100 (pH 4.4)], and 10 mmol/L urea, were added to 200 µL serum, proteinase K 40 µL, glass powder 10 µg, and incubated in 72 °C water bath for 10 min, then 100 µL Isopropyl alcohol was added and centrifuged at 8 000 r/min for 1 min. The supernatant was removed, and washed with 100 µL washing solution [20 mmol/L NaCl, 20 mmol/L Tris-HCl (pH7.5) and 1 000 mL/L ethanol] and

centrifuged at 8 000 r/min for 1 min. The supernatant was removed and washed and centrifuged at 8 000 r/min for 1 min and 13 000 g for 10 s, dried and dissolved in 50 μ L RNase free water.

Primer design

The primers for the first round of PCR: HBV reverse primer: 5'-GAT GAT GGG ATG GGA ATA CA-3' (position: 2 566-2 586 of P gene), HBV RT primer: 5'-GCT GGT TCA CAT TGT GAG GGG AGT CTA GAC TCG TGG TGG A-3' with the former 20 bp as the joint sequence, and the latter 20 bp in the position of the overlap of genome P region and Pre-S region (position 2 921-2 941). There was a 395 bp between R and RT primers. HCV reverse primer: 5'-ATC ACT CCC CTG TGA GGA A-3' which was located between 47-65 bp. RT-PCR primer: 5'-GCT GGT TCA CAT TGT GAG GGC TAC GAG ACC TCC CGG GGC A-3'. The former 20 bp was the joint sequence, the latter 20 bp was in 313-332 of HBV genome. The product between R and RT primers was a 315 bp fragment. The second round primers: N primer sequence was 5'-GCT GGT TCA CAT TGT GAG GG TAG AGG ACA AAC GGG CAA CA-3', the former 20 bp was the joint sequence, and the latter 20 bp was in 2 703-2 723 of HBV genome. RT-PCR primer was the same as that of the first round, the amplification product was a 278 bp fragment between N and RT. The HCV N primer was 5'-GCT GGT TCA CAT TGT GAG GGG GAG GCC AT AGT GGT CTG-3', the former 20 bp was the joint sequence, and the latter 20 bp was located between 132-151 of HCV. RT primers were the same as the first round of amplification and the product was a 241 bp fragment. After two rounds of amplification, the third round was amplified with the common primers T: 5'-GCT GGT TCA CAT TGT GAG GG-3'. The primers were synthesized by phosphoamidite method with 391 DNA synthesizer. The synthesized primers were purified with OPC column^[5].

Quality evaluation parameters of designed diagnostic assay

Sensitivity indicated the percent of positive cases by the diagnostic assay in the patient group. It was calculated according to the following formula.

$$\text{Sensitivity} = \frac{\text{True positivity}}{\text{True positive} + \text{false negative}} \times 100\%$$

The sensitivity should be 100% for a perfect diagnostic assay.

Specificity indicated the percent of negative cases determined by the diagnostic assay in control group. It was calculated according to the following equation.

$$\text{Specificity} = \frac{\text{True negativity}}{\text{False positivity} + \text{true negativity}} \times 100\%$$

The specificity should be 100% for a perfect diagnostic assay.

Diagnostic index was a combined parameter to evaluate the sensitivity and specificity. It was the sum of sensitivity and specificity. The perfect diagnostic index should be 200%, and

it should not be lower than 100%.

Agreement rate indicated the ability of a diagnostic assay to correctly discern the patients and control cases. It was calculated by the following method. The perfect agreement rate of a diagnostic assay should be 100%.

$$\text{Agreement rate} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{FP} + \text{TN} + \text{FN}} \times 100\%$$

(TP: true positivity; TN: true negativity; FP: false positivity; FN: false negativity).

Positive predictive value (PPV) indicated the percent of patients in the positive results of diagnostic assay. It was calculated according to the following equation.

$$\text{PPV} = \frac{\text{TP}}{\text{TP} + \text{FP}} \times 100\%$$

Negative predictive value (NPV) indicated the percent of non-patients in the negative results of diagnostic assay. It was calculated according to the following equation.

$$\text{NPV} = \frac{\text{TN}}{\text{FN} + \text{TN}} \times 100\%$$

(NPV: negative predictive value; TN: true negativity; FN: false negativity; TN: true negativity).

RESULTS

Screening extraction methods for HBV DNA from HBsAg positive serum

Four methods were used to extract HBV DNA from HBsAg positive sera of patients. The results of amplification were compared to that of ELISA (Table 1).

The positive amplification rates were 20%, 60%, 85% and 95% for methods 1 to 4 respectively.

Screening the extracting methods of HCV RNA from anti-HCV positive serum

Fifteen anti-HCV positive sera were extracted with the four methods and the results were compared with ELISA (Table 2).

The positive amplification rates were 6%, 6%, 30% and 95% for methods 1 to 4, respectively compared to the ELISA.

Establishment of simultaneous extraction method of HBV DNA and HCV RNA

Six samples positive for both HBsAg and anti-HCV were extracted and amplified, the simultaneous extraction positive rate was 100% for HBV and 83% for HCV, respectively.

Establishment of RT and first round of amplification method

Orthogonal method was used to select the six common factors

affecting the amplification, which were the concentrations of dNTPs, Mg^{2+} , Taq polymerase, AMV and primers (including HBV and HCV). Five levels were designed for each factor. The pattern of orthogonal was L 25^[5,6]. The PCR reaction was as follows: HBV, 8 μ L HCV template, 5 μ L 10 \times buffer, 40 U RNase inhibitor, and other components and finally ddH₂O was added to make the total volume 50 μ L. Twenty-five kinds of amplification system were available. After paraffin oil was added, reactions were performed at 50 °C for 30 min, at 95 °C for 2 min, and 30 cycles at 95 °C for 30 s, at 55 °C for 30 s, at 72 °C for 1 min. Then 10 μ L amplification product was identified by 15 g/L agarose electrophoresis. The results showed under the condition of protocol 13, that both HBV and HCV targets were successfully amplified, therefore protocol 13 was chosen as the first round protocol. The amplification program was at 50 °C for 30 min, at 95 °C for 2 min, and at 95 °C for 30 s, at 55 °C for 30 s and at 72 °C for 1 min for a total of 30 cycles.

Screening of the second round of amplification reaction condition

According to the orthogonal method and experience, 6 protocols were designed. The reaction condition was at 95 °C for 30 s, at 55 °C for 30 s, and at 72 °C for 45 s for a total of 10 cycles. The results showed that the two target bands of HBV and HCV were successfully separated in protocol 1. Therefore the protocol 1 was chosen as the final optimal protocol.

Screening of the third round of amplification reaction

According to the results of the above two rounds of amplification, 7 protocols were designed for the third round of amplification. All the amplification reactions were done at 95 °C for 30 s, at 55 °C for 30 s, at 72 °C for 1 min for a total of 30 cycles. The results showed that the HBV and HCV target bands were discerned more obviously under the condition of protocol 2, which was therefore determined as the optimal protocol.

Comparison of normalized PCR detection results with ELISA method

Twenty-eight samples were detected with both normalized PCR method and ELISA method. In the 14 samples positive for HBsAg, the results of the six antibody-positive amplifications are shown in Figure 1. The concordance of PCR with ELISA was 78.8%. Eight anti-HCV positive samples detected with multiplex PCR had a coincidence rate of 75% compared with ELISA method. When it was used to detect samples positive for both HBsAg and anti-HCV, the coincidence rate was 83.3%. Ten control cases negative for both HBsAg and anti-HCV were also detected with normalized PCR, of which 2 were positive for HBV and 1 for HCV.

Quality evaluation of simultaneous PCR detection of HBV and HCV

Fourteen patients with HBV infection were detected with normalized PCR method. The results showed that the true positivity was 11 and the false negativity was 3 (Table 3).

Figure 1 Normalized PCR amplification for patients with both HBsAg and anti-HCV antibodies. M represents X174-hae III marker. Lanes 1 to 6 represent amplification results of six patients who were positive for HBsAg and anti-HCV. Only lane 2 is negative for HCV.

Of the eight HCV patients detected with normalized method, 6 were positive and 2 were negative. Six patients with both HBV and HCV infection were also detected, of which 5 were positive and 1 was negative (Figure 1 and Table 4). Ten patients without HBsAg and anti-HCV infection were also detected with our method, of which 8 were negative for HBV and 2 were positive for HBV (false positivity), 9 were negative for HCV and 1 positive for HCV (false positivity) (Tables 3, 4).

Evaluation of validity and diagnostic power of normalized PCR for detecting HBV DNA

The sensitivity of this method for the detection of HBV DNA was 78.6% (11/14). The specificity was 80% (8/10). The diagnostic index was 158.6% (78.6% plus 80%) and the agreement rate was 79.2%. The positive predictive value was 84.6% (11/13). The negative predictive value was 72.7% (8/11) (Table 3).

Positive	5	8	13
Negative	1	2	3
Total	6	10	16

DISCUSSION

Virus particles of HBV and HCV are rare in blood and HCV RNA is easily to degrade, therefore selecting protein denaturing agents to quickly dissolve the membrane protein is very important in the process of simultaneous extraction of HBV and HCV nucleic acids. Our results showed that method 4 was the most effective among the four extraction methods. The effective extraction rate was 95% for both HBsAg and anti-HCV positive serum. In method 4, hydrochloride guanine was a potent protein denaturant, it could dissolve the protein and destruct its secondary structure and cell structure, and made it possible to separate nucleotide protein from nucleic acids. Urea and Triton X-100 are non-detergents and could dissolve cell membrane and precipitate the protein. Proteinase K could further degrade protein. Glass powder had absorptive effect on nucleic acids and therefore could absorb nucleic acids on its surface. Isopropyl alcohol could precipitate nucleic acids and finally the low ion potential solution could elute nucleic acids from the glass powder. This method was confirmed to be effective and authentic, suitable for the separation of virus RNA and DNA. In practice, it was a simple, fast, stable and reproducible method.

Theoretically, there is no limit on the number of target sequences simultaneously amplified by multiplex PCR. But the stringency of specific conditions restricted the number of target sequences amplified. In order to overcome these limits, we established a multiplex normalized amplification method. First a nested PCR amplification was performed with 2 pairs of primers with a joint sequence. Then a normalized amplification was done with joint primers. The effects of competition of primers were the lowest, so that the multiplex PCR became a single target PCR. These measurements could overcome the difficulties in establishing and optimizing the conditions of multiplex PCR. The success of this method has shed some lights on the development of PCR techniques. We used the orthogonal method for the design of experiment^[6], and divided the key factors of PCR reaction such as primer concentration, dNTPs, Taq polymerase, AMV and magnesium chloride concentration into different grades, and a factor table was set up. This included all possible arrangements and combination of factors. The results showed that the coordination of proportion of the 6 factors was very important. If the proportion of HBV and HCV primers was not appropriate, and sometimes one of the amplifications was superior to another and only one band could

be identified by electrophoresis.

ELISA is a method to detect antibody for the purpose of diagnosis of virus infection. The antibody was only detected 1 to 2 wk after infection, which reflected the immune response of the host, but could not explain the virus replication. PCR method could directly detect the virus nucleic acids. It could reflect the state of virus replication. When the virus was cleaned up, only the antibody was positive, the nucleic acids could not be detected. That is why the detection rate of PCR was lower when ELISA was used as a golden standard. In this study, 1/8 of the anti-HCV patients were negative for HCV RNA, and 1/6 patients were positive for both HBsAg and HCV, which were undetectable by our method. This is partly because the patients were in the state of convalescence, and the virus was already cleaned up or was false positive for ELISA due to hyperimmunoglobulinemia, rheumatoid factor and superoxide dismutase. The detection of HCV RNA in non-hepatitis patients could be explained by the fact that the patients might be in the early stage of acute hepatitis, and the antibody had not been produced yet. A close follow-up is needed for the early diagnosis and treatment after the possibility of false positive is excluded.

Currently, the super-infection rate of HBV and HCV was very high, and it was 13.64% to 27.27% reported by Xu^[7]. It is important to establish methods that can simultaneously detect combined virus infection. Konomi *et al.*^[8] reported a multiplex polymerase chain reaction (PCR) method for simultaneous detection of hepatitis B, C, and G viral genomes. The levels of concordance with the data obtained by conventional single PCR method were 100% for single infection, 98-100% for double infection, and 92% for triple infection. Meng Q and his colleagues^[9] established an automatic multiplex system for simultaneously screening hepatitis B virus (HBV), hepatitis C virus (HCV), and human immunodeficiency virus type 1 (HIV-1) in blood donations. The detection limits (95% confidence interval) were 22 to 60 copies/mL for HBV, 61 to 112 IU/mL for HCV, and 33 to 66 copies/mL for HIV-1, using a specimen input volume of 0.2 mL. The AMPLINAT MPX assay could detect a broad range of genotypes or subtypes for all three viruses and had a specificity of 99.6% for all three viruses with sero-negative specimens. In an evaluation of sero-conversion panels, the AMPLINAT MPX assay detected HBV infection an average of 24 d before the detection of HBsAg by enzyme immunoassay. HCV RNA was detected an average of 31 d before HCV antibody appeared. HIV-1 RNA was detected an average of 14 d before HIV-1 antibody and an average of 9 d before p24 antigen. A Chinese group has designed a visual gene-detecting technique using nanoparticle-supported gene probes. With the aid of gold nanoparticle-supported 3'-end-mercapto-derivatized oligonucleotide serving as a detection probe, and 5'-end -amino-derivatized oligonucleotide immobilized on glass surface acting as a capturing probe, target DNA was detected visually by sandwich hybridization based on highly sensitive "nano-amplification" and silver staining. Different genotypes of hepatitis B and C viruses in serum samples from infected patients were detected using home made HBV, HCV, and HBV/HCV gene chips by the gold/silver nanoparticle staining amplification method. The present visual gene-detecting technique might avoid limitations of the reported methods due to its high sensitivity, good specificity, simplicity, speed, and cheapness^[10].

Multiplex PCR assay has been used for the simultaneous detection of many different genes of pathogens including genes related with antibiotic resistance genes in *Staphylococcus aureus*^[11]. A multiplex reverse transcriptase polymerase chain reaction (RT-PCR) was also applied for the simultaneous detection of hepatitis A virus (HAV), poliovirus (PV) and simian rotavirus (RV-SA11), and compared with specific primers for

each genome sequence. Three amplified DNA products representing HAV (192 bp), PV (394 bp) and RV (278 bp) were identified when positive controls were used^[12]. A multiplex RT-PCR method was described for the simultaneous detection of all four viruses in combination with a plant mRNA specific internal control which could be used as an indicator of the effectiveness of the extraction and RT-PCR. The upper detection limit for the four viruses was at an extract dilution of 1/200^[13]. A multiplex semi-nested PCR was developed for the simultaneous detection and differentiation among porcine circovirus 1 (PCV1), PCV2, and porcine parvovirus (PPV) from boar semen. Primers of PCV1, PCV2 and PPV were specific and did not react with other viruses respectively. Twenty (20.4%) and 42 (42.9%) out of 98 whole semen samples were found to be positive for PCV and PPV using conventional multiplex and semi-nested PCR respectively^[14]. Multiplex method for HBV/HCV/HIV-1 has been used for screening 6 805 010 units of serologically negative donation and 112 HBV DNA-positives, 25 HCV RNA positives and 4 HIV-1 RNA positives were screened out and prevented transfusion of the positive blood^[15,16].

The sensitivity of our multiplex normalized PCR method was 78.6%, 75% and 83.3% for the detection of HBVDNA, HCV RNA, and super-infection of HBV and HCV respectively. The specificity was 80%, 90% and 70%, respectively. These are good enough for a diagnostic assay. It can detect both DNA and RNA simultaneously and can be completed in one day. It is not only suitable for clinical diagnosis, but also suitable for the screening of HBV and HCV from blood donors to prevent the transmission of these diseases. It can also be used for an epidemiological study. In these respects it needs to be further studied in a large-scale population.

Abstract

AIM: To evaluate the role of miniprobe ultrasonography under colonoscope in the diagnosis of submucosal tumor of the large intestine, and to determine its imaging characteristics.

METHODS: Thirty-five patients with submucosal tumors of the large intestine underwent miniprobe ultrasonography under colonoscope. The diagnostic results of miniprobe ultrasonography were compared with pathological findings of specimens by biopsy and surgical resection.

RESULTS: Lipomas were visualized as hyperechoic homogeneous masses located in the submucosa with a distinct border. Leiomyomas were visualized as hypoechoic homogeneous mass originated from the muscularis propria. Leiomyosarcomas were shown with inhomogeneous echo and irregular border. Carcinoids were presented as submucosal hypoechoic masses with homogenous echo and distinct border. Lymphangiomas were shown as submucosal hypoechoic masses with cystic septal structures. Malignant lymphomas displayed as hypoechoic masses from mucosa to muscularis propria, while pneumatosis cystoides intestinalis originated from submucosa with a special sonic shadow. One large leiomyoma was misdiagnosed as leiomyosarcoma.

CONCLUSION: Endoscopic miniprobe ultrasonography can provide precise information about the size, layer of origin, border of submucosal tumor of the large intestine and has a high accuracy in the diagnosis of submucosal tumor of the large intestine. Pre-operative miniprobe ultrasonography under colonoscope may play an important role in the choice of therapy for submucosal tumor of the large intestine.

INTRODUCTION

Due to the development of colonoscope and CT, the reported number of submucosal tumor (SMT) of the large intestine has been increased. SMT of the large intestine includes lipoma,

lymphangioma, leiomyoma, carcinoid, metastatic tumor, *etc.* Previous diagnosis depended mainly on barium enema and colonoscope, but none of them could make clear the histological features of SMT, and it was also difficult to differentiate SMT from extramural compression. In the 1980 s, the development of endoscopic ultrasonography (EUS) significantly improved the accuracy of diagnosis of the digestive tract diseases^[1]. EUS can provide detailed information about gastrointestinal wall structure and adjacent organs. EUS is highly accurate in the visualization of submucosal lesions and their sonographic layer of origin within gastrointestinal wall. Concerning SMT of the digestive tract, several studies have been published mainly in upper digestive tract^[2-4], but there have been few studies on SMT of the lower digestive tract. The aim of this study was to assess the value of EUS in the diagnosis of SMT of the large intestine and determine their imaging characteristics.

MATERIALS AND METHODS

Patients

EUS was performed in 35 patients with elevated lesions which had normal mucosal vision under colonoscope between January 2001 and November 2003. The patient group comprised 19 men and 16 women with a mean age of 54.6 years (range, 32-72 years). The diameter of lesions ranged 0.5-4.2 cm. Of the 35 lesions, 28 were confirmed histologically by endoscopic biopsy and surgical resection, and the histological findings were compared with ultrasonographic imagings. The other 7 patients were observed without resection. The lesion that caused extramural compression of intestinal wall was excluded from this study, which could easily be confused with SMT clinically.

Instruments

A ultrasonic miniprobe (Olympus UM-2R, 12MHz; UM-3R, 20 MHz, Tokyo, Japan) was introduced under electronic colonoscope (Olympus CF-Q240, Tokyo, Japan), as well as an endoscopic ultrasonography system (Olympus EU-M30, Tokyo, Japan). The video image was recorded by ultrasonography image recorder (Sony UP-890, Tokyo, Japan).

Operative procedures

Patients undergoing EUS were prepared with the same method as for conventional colonoscopy. Five mg midazolam was administered intramuscularly and 10 mg scopolamine butylbromide was injected intravenously for sedation before the procedure. When an elevated lesion with normal mucosa was observed endoscopically, the tip of the colonoscope was placed at the distal end of the lesion. The lumen was filled with 100-200 mL water to achieve acoustic coupling between the transducer and the intestinal wall. Subsequently, the miniprobe was introduced through the working channel of the colonoscope and advanced beyond the lesion. The lesion was assessed by real-time ultrasonography while the miniprobe was moved over the lesion region^[4].

The layer of origin of SMT was determined according to the continuity between the lesion and adjacent normal colonic wall. The nature of SMT was assessed by its size, layer of origin, border characteristic and internal echogenicity.

Statistical analysis

Values were presented as mean \pm SD. Analysis of variance with *t* test was used for statistical analysis. $P\leq 0.05$ was considered statistically significant.

RESULTS

EUS was performed successfully in all 35 patients. The normal wall of the large intestine was displayed in 5 layers (Figure 1). The first 2 layers represented the mucosa (m). The third layer stood for the submucosa (sm). The muscularis propria (mp) was depicted by the 4th layer. Adventitia or serosa (sa) was sometimes displayed as the 5th layer. As the lower part of rectum below the peritoneal reflection had no serosa, the pericolic fat and the mural outer layer constituted the hyperechoic layer. SMT was mostly visualized as hyperechoic, hypoechoic, anechoic lesions within the colorectal wall (Figure 1). The EUS characteristics of SMT are summarized in Table 1.

Lipomas, the most common SMT of the large intestine (accounting for 1/3 in our study), were visualized as hyperechoic homogeneous masses located in the third layer (sm) with a distinct border. Leiomyomas were visualized as hypoechoic homogeneous mass originated from the 4th layer (mp). Two

Figure 1 EUS imagines of normal wall and SMT of the large intestine. A: The normal wall was displayed in 5 layers; B: Lipoma imagine showed a hyperechoic homogeneous mass located in the third layer; C: Leiomyoma imagine showed a hypoechoic homogeneous mass originated from the 4th layer; D: Rectal carcinoid imagine showed a submucosal hypoechoic mass with a homogenous echo.

leiomyosarcomas with a mean diameter of 38 mm, inhomogeneous and irregular border were confirmed histologically by surgical resection. One large leiomyoma was misdiagnosed as leiomyosarcoma. Carcinoid was presented as a submucosal hypoechoic mass with a homogenous echo and distinct border. All 3 carcinoids were located in rectus, of which 2 were less than 10 mm in diameter, submucosal continuity was not disrupted, and were resected under colonoscope. Another one was resected by surgery because of large diameter (1.8 cm) and disrupted submucosal continuity. Lymphangiomas were shown with EUS as submucosal anechoic masses with cystic septal structures. Malignant lymphoma displayed as hypoechoic mass from mucosa to mp depending on stage of the disease, while pneumatosis cystoides intestinalis, not real tumor, originated from sm with a special sonic shadow behind mass.

DISCUSSION

Barium enema and colonoscopy are the main widely used examinations in the diagnosis of submucosal lesions of the large intestine. Takada *et al.*^[3] classified colonic SMT into five types on the basis of barium enema studies. Typical endoscopic feature of the colonic SMT is an elevated lesion with normal mucosa, and each has its own endoscopic morphologic features. However, it is difficult to determine the real size, layer of the origin and histologic nature of SMT with these procedures alone. In addition, lesions smaller than 10 mm cannot be detected.

Under these circumstances, the development of EUS has provided a brand new dimension in the diagnosis of colorectal lesions^[5-11]. EUS can image the entire structure of the colonic wall which corresponds to the histologic layer structure. Normal colonic wall is presented as five-layered structure. By placing high frequency miniprobe on the elevated spot, the layer of the origin of SMT is generally determined by demonstrating continuity between the tumor and the colonic wall. Extraluminal compression is easily differentiated from SMT by EUS. Our study found lipoma, lymphangioma and carcinoid were originated from the third layer (sm). Myogenic tumors were found to be originated from the fourth layer (mp). According to literature, some myogenic tumors were from muscularis mucosa^[12].

The size of SMT can be measured with EUS. The biggest SMT we detected in this study was 4.2 cm in diameter. Because of the high frequency employed in this study, it was difficult for miniprobe to observe big lesions. In general, the lower the frequency employed, the better the depth of US penetration and the clearer the image. Therefore, 20 MHz is suitable for clear images of superficial lesions. On the other hand, 12 MHz and 7.5 MHz are more suitable for the evaluation of the big lesions and contiguous tissues. The smallest SMT we detected was 5 mm in diameter, while Sun *et al.*^[13] reported that the smallest size detectable was 2 mm in diameter histologically.

The nature of SMT can be determined by the internal echogenicity. In this study, all lipomas were hyperechoic

Table 1 EUS characteristics of SMT of the large intestine

Diagnosis (No. of patients)	EUS findings					
	Size (mm)	Shape	Border	Layer of origin	Echogenicity	Internal echo
Lipoma (n = 12)	15 \pm 3.1	Round	Regular	Third	Hyperechoic	Homogeneous
Leiomyoma (n = 8)	17 \pm 4.3	Round	Regular	Fourth	Hypoechoic	Homogeneous
Lymphangioma (n = 6)	14 \pm 2.3	Round	Regular	Third	Anechoic	Multilocular
Leiomyosarcoma (n = 2)	38 \pm 2.8	Round Lobulated	Regular	Fourth	Hypoechoic	Inhomogeneous
Carcinoid (n = 3)	14 \pm 4.2	Round	Regular	Third	Hypoechoic	Homogeneous
Malignant lymphoma (n = 2)		Irregular	Irregular	Second to fourth	Hypoechoic	Inhomogeneous

^a $P < 0.05$ vs leiomyoma.

homogeneous and lymphangiomas were anechoic with cystic septal structures^[14]. The other SMTs were mostly visualized as hypoechoic masses. Therefore, the former findings are strongly suggestive of lipomas and lymphangiomas.

Leiomyosarcoma of the large intestine is extremely rare, only accounting for 0.1% of colonic malignancy^[12]. With regard to differential diagnosis of leiomyomas and leiomyosarcomas, it is suggested to distinguish according to the size and the internal ultrasonic characteristics of the tumor in literature. For the lesion which has the diameter <30 mm, homogenous resonance and clear borderline, the benign is considered. In contrast, if the lesion has a diameter >30 mm, inhomogeneous resonance and irregular border, it may be diagnosed as malignant. But one case in our study with a diameter of 3.2 cm was eventually diagnosed as leiomyoma by pathology. Endoscopic ultrasonography guided fine needle aspiration (FNA) can further help to diagnose the submucosal masses^[15].

EUS is useful in determining the therapy for SMT of the large intestine^[16]. Lipoma and lymphangioma are easy to be diagnosed by EUS, and these lesions can be removed endoscopically or observed without resection. Although leiomyoma and leiomyosarcoma are difficult to differentiate, leiomyosarcoma should be strongly suspected, and surgery should be considered when the tumor is over 30 mm in diameter and has an inhomogeneous internal echo. Although myogenic tumor diagnosed by EUS is an indication for surgery at our department, patients are followed up by EUS according to a strict protocol when the size of tumor is smaller than 20 mm and the patient declines surgery.

In conclusion, EUS can provide precise information about the size, layer of origin, and echogenicity of the SMT of the large intestine. It is useful in the diagnosis of SMT of the large intestine and can have an important role in the choice of therapy.

Abstract

AIM: Gastrointestinal autonomic nerve tumors are uncommon stromal tumors of the intestinal tract. Their histological appearance is similar to that of other gastrointestinal stromal tumors. We report two cases and performed an analysis of the literature by comparing our findings with the available case reports in the medical literature.

METHODS: Two patients were admitted with abdominal tumor masses. One occurred in the stomach with large multiple liver metastases and the second originated in Meckel's diverticulum. The latter site has never been reported previously. Both patients underwent surgery. In one patient gastrectomy, right liver resection and colon transversum resection were performed to achieve aggressive tumor debulking. In the other patient the tumor bearing diverticulum was removed.

RESULTS: Postoperative recovery of both patients was uneventful. Histological examination, immunohistochemical analysis and electron microscopy revealed the diagnosis of a gastrointestinal autonomic nerve tumor. The patient with the tumor in Meckel's diverticulum died 6 mo after surgery because of pneumonia. The patient with liver metastases have been alive 13 years after initial tumor diagnosis and 7 years after surgery with no evidence of tumor progression. In light of our results, we performed a thorough comparison with available literature reports.

CONCLUSION: Radical surgical resection of gastrointestinal autonomic nerve tumors seems to be the only available curative approach to date, and long term survival is possible even in large metastasized tumors.

INTRODUCTION

Gastrointestinal autonomic nerve tumors (GANTs) were first described by Herrera *et al.* in 1984. The authors used the term plexosarcoma to describe this entity^[1]. In the last decade several investigators have recognized the distinct characteristics of this type of tumor^[2-6]. It consists of a subgroup of gastrointestinal stromal tumors (GISTs) with a specific ultrastructural appearance, suggesting that it originates from neurons of the

enteric plexus. Histologically, GANTs are usually low-grade spindle-cell neoplasms but cannot be definitely distinguished from stromal tumors or other neurogenic tumors by histological or immunohistochemical features. To date, the diagnosis of GIST is strongly suggested by immunostaining for the transmembrane tyrosine kinase receptor CD117 and c-kit gene mutations^[7,8]. Partly based on these findings GISTs have been defined as tumors of the interstitial cells of Cajal^[9]. Because GANTs also often showed CD117 staining some authors considered GISTs to be identical to GANTs^[10]. Eyden *et al.* have recently studied 82 gastrointestinal stromal tumors in terms of their cellular differentiation by using electron microscopy. They demonstrated that electron microscopy was needed to establish the diagnosis of GANTs and to exclude other gastrointestinal stromal tumors^[6]. We performed an analysis of the literature to compare our patients with the published data. The literature search yielded more than 120 published cases of GANTs, including the two cases presented in this report^[1-6,11-38].

CASE REPORT

Case 1

This female patient was 22-year-old when she first noted fatigue, loss of appetite and epigastric discomfort in 1990. On physical examination she had a palpable epigastric mass. Upper gastrointestinal series and computed tomography (CT) suggested that the mass was a large gastric tumor. Endoscopy revealed several large masses protruding into the stomach without erosion of the overlying mucosa. Laparotomy showed that the entire stomach was infiltrated with nodular masses. In addition, the liver demonstrated multiple nodules. Intraoperatively obtained frozen sections revealed a leiomyosarcoma. Due to the poor prognosis of the disease and the extensive tumor burden the surgeon decided not to remove any tumor mass. The patient was discharged without any further treatment. Histological features and immunohistochemical characteristics were determined and found to be analogous to the results obtained six years later. Ultrastructural examination was not performed. At the time this case was diagnosed, only 10 GANTs had been documented in the literature.

Six years later the patient was still alive and was admitted to our hospital after an extensive weight loss (she weighed 38 kg at the time of admission). The patient complained of progressive abdominal discomfort and dyspnea. On physical examination the abdominal wall was extremely distended by a large palpable epigastric mass. Diagnostic studies including CT scan confirmed the known abdominal tumor. On the CT image the liver foci were partly solid and partly liquid (Figure 1).

Again, a laparotomy was performed. The intraoperative findings were similar to those obtained 6 years earlier. By then, the gastric tumor invaded the transverse mesocolon. Maximum debulking was achieved by total gastrectomy, transverse colon resection and right hepatectomy, leaving only small tumor deposits in the left liver. The resected gastric tumor mass measured approximately 40 cm×25 cm×20 cm in aggregate and the liver foci covered 25 cm×12 cm×12 cm (Figures 2, 3). After an uneventful recovery the patient was discharged after 3 wk and returned to work 5 wk later. CT series obtained 3, 6 and 12 mo after the operation showed no measurable expansion of the remaining foci in the left liver. A CT scan performed 24 mo

after the operation revealed spontaneous partial regression of the metastatic liver foci. Seven years after surgery, the patient was still in excellent clinical condition and free of discomfort. In addition, the patient delivered a healthy boy in 1997.

Figure 1 Preoperative CT-scan of diseased liver and stomach.

Figure 2 Stomach with infiltrating nodular masses.

Figure 3 Right liver containing multiple metastatic nodules.

Microscopically, the resected gastric tumor chiefly consisted of plump spindle cells with distinct nuclear pleomorphism. In some areas 15 mitotic figures per 10 high power fields were identified. Immunohistochemical studies showed positive staining with antibodies to neuron specific enolase (NSE) and vimentin. There was also a weak focal staining for S 100 and HISL-19. No detectable staining for chromogranin A, 1 A 4, HHF 35, EMA, MNF 116, CAM 5.2, JC 70a and CD117 was observed. Just a small part of the tumor mass showed positive staining with an antibody to CD 34. Microscopically, the resected metastatic liver tumor also mainly consisted of plump spindle cells. In contrast to the original tumor mass, immunohistochemical studies showed 100 percent positive staining for CD 34 but negative staining for CD 117. CD 117 staining was performed a few weeks ago in order to take into account newest drug developments like tyrosine kinase inhibitors as a potential treatment option. Approximately 80% of the sampled tumors were necrotic. Ultrastructural examination showed neuron-like cells with long cytoplasmatic processes and dense core neurosecretory granules. Thus, the diagnosis of a gastrointestinal autonomic nerve tumor (GANT) was made.

Case 2

A 68-year-old man was admitted to the hospital with a one month history of fever and weight loss of 4 kg. No abnormal findings were registered on physical examination. Computerized tomography showed a decaying liver tumor. The Mendel-Mantoux reaction was highly positive. Therefore the liver focus was considered to be tuberculous. Tuberculostatic triple-drug therapy was administered for 6 mo. After 12 mo, a CT scan of the abdomen and upper gastrointestinal series showed a normal liver with no pathological signs. An additional new finding was suggestive of a tumor of the ileum. Laparotomy revealed neoplastic nodular masses (9 cm×6 cm) originating from Meckel's diverticulum. The tumor was resected along with an ileal segment. The patient had an uneventful recovery and was discharged 10 d postoperatively. Light microscopy revealed that the tumor was composed of interlacing fascicles of plump, pleomorphic spindle cells, partly showing a storiform and epithelioid pattern. Less than one mitotic figure per 10 high-power fields was identified. Immunohistochemical stainings for vimentin, S-100 and neuron specific enolase (NSE) were positive, whereas staining for Lu 5, CAM 5.2, MNF 116, EMA, desmin, chromogranin, 1A4, Q-BENT10, JC70A, HMB-45, PGM1, HHF35 and CD117 was negative.

Ultrastructural examination showed neuron-like cells with long branching cytoplasmatic processes. Dense-core granules were scarce. No basal lamina, dense bodies, or pinocytotic vesicles were found.

Six months later the patient died of a severe pneumonia. A post-mortem examination showed no intestinal abnormalities or recurrence of disease.

DISCUSSION

Gastrointestinal autonomic nerve tumors represent a rare distinct subcategory of gastrointestinal stromal tumors. First described by Herrera *et al.* in 1984 as plexosarcoma supposedly originating from the enteric autonomic plexus, more than 120 cases including our own have been documented in the literature^[1-6,11-38]. These tumors were found in patients of a wide age range (10 to 85 years) with a median age of 58 years. Seventy-nine per cent of patients were older than 50 years. The tumors were found slightly more often in males (62 males vs 58 females). The reported clinical signs and symptoms are shown in Table 1. In the majority of cases, the primary site of the tumor was the stomach, duodenum, jejunum and ileum, but the esophagus^[21,22], rectum^[26, 34], bladder^[30] or colon^[31] have also been reported in some cases (Table 2).

Table 1 Clinical symptoms of 78 reported GAN tumors

Clinical symptoms	No. of patients	Percent of patients
Abdominal pain	32	41
Meaena	19	24
Abdominal mass	10	13
Weight loss	10	13
Vomiting	9	12
Fatigue	7	9
Fever	5	6
Anemia	4	5
Obstructive jaundice	2	2
No clinical symptoms	5	6

On imaging studies, the tumor often presents as a large and lobulated solid mass, with areas of necrosis. It is locally invasive. Radiological techniques did not permit a distinction between GANTs and other gastrointestinal stromal tumors^[28,33].

The greatest dimension of the tumor was determined in 81

cases, and ranged from 1.5 cm to 40 cm (median 10.4 cm). Eighty per cent was larger than 5 cm and 37% had one dimension larger than 10 cm. The bulky tumor masses were predominantly cystic and necrotic. In two cases an abscess was present in the tumor^[17,29]. Some of these GANTs were observed in patients with Carney's triad (3 cases)^[16,17], neurofibromatosis (3 cases)^[15,20,25], and adrenal ganglioneuroma (1 case)^[20].

Table 2 Anatomic sites of the primary tumors (*n* = 120)

Location	No. of patients	Percent of patients
Stomach	45	37.5
Jejunum	26	22.0
Ileum	21	17.5
Duodenum	12	10.0
Retroperitoneum	4	3.3
Mesentery	3	2.5
Esophagus	2	1.6
Peritoneum	2	1.6
Rectum	2	1.6
Colon	1	0.8
Bladder	1	0.8
Omentum	1	0.8

The tumors were usually intramuscular-intramural, well demarcated, but not encapsulated, unilocalized or multilocalized masses of variable consistency, with or without haemorrhage and necrosis.

Histologically, the reported tumors showed a variety of patterns, none of which was specifically diagnostic. Most lesions were spindle cell tumors with features resembling either smooth muscle tumors or neurogenic tumors. Epithelioid cells were also detected, usually as a minor population. The cellular arrangement was either whorled, patternless, fascicular, palisaded or storiform. Generally, the tumor cells had an eosinophilic cytoplasm. Pleomorphism was not significant and mitosis ranged from 1 to 23/10 high-power fields.

Results of immunohistochemical studies demonstrated that the tumor was most often reactive to vimentin and other markers of nerve tissues such as neuron-specific enolase (NSE), synaptophysin, S-100 protein, neurofilament, and chromogranin A (Table 3). These proteins are normally expressed by neurons from the autonomic enteric nerve plexus, supporting a histogenesis of GANTs from enteric autonomic plexuses of Meissner or Auerbach. The muscle marker desmin and muscle-specific actin could not be demonstrated, although focal alpha-SMA positivity was seen in 7 reported cases^[24,27]. Except for one study (2 cases) focal staining for cytokeratins (CAM5.2) was found to be negative^[26]. GANTs usually lacked smooth muscle cell features^[1,2,11].

Table 3 Summary of immunohistochemical findings of 120 cases

Antigens	No. of cases studied	No. positive cases	Percent of positivity
Vimentin	103	95	92
Neuron-specific Enolase	117	105	90
Chromogranin A	92	10	11
Synaptophysin	105	33	31
S-100 protein	117	44	38
Neurofilaments	87	14	16
Vasoactive intestinal peptide	25	5	20

Over the last two years GANTs were also tested for CD117 and almost all of them were positive^[10].

Ultrastructural studies of all the reported cases revealed features suggestive of myenteric plexus in origin. The diagnostic ultrastructural features included the presence of long, closely opposed cell processes containing intermediate filaments, dense-core neurosecretory granules, microtubules, and synapse-like structures with variable numbers of neurosecretory granules and small vesicles. The essential ultrastructural criteria applied for the diagnosis of GANT in all reported cases included neurosecretory granules and intermediate filaments. It should be noted that five reported GANTs showed weak signs of smooth-muscle morphology. Therefore, the presence of smooth muscle cell features might also suggest GANT^[6].

The primary therapy in almost all reported cases was surgical resection or debulking, in 2 cases preceded by radiotherapy, and in nine cases preceded by chemotherapy. Three patients received chemotherapy alone. There was no evidence of clinical response using chemotherapy or radiation. As demonstrated in our report, aggressive tumor debulking without any further treatment could also be considered suitable in terms of prolonged survival and quality of life.

According to published reports, 8 patients out of 67 (12%) had metastases at clinical presentation and 18 patients (27%) developed metastases during follow up (Table 4). The estimated survival curve of the clinically documented cases (*n* = 67) is shown in Figure 4.

Table 4 Metastases of reported GANT cases (*n* = 67)

Metastases at clinical presentation			Metastases in clinical follow up		
Location	No. of patients	%	Location	No. of patients	%
Liver	7	10	Liver	6	9
			Retroperitoneal	4	6
Lymph node	2	3	Local recurrence	5	7
			Omentum	3	4
Omentum	2	3	Mesentery	2	3
			Peritoneum	2	3

Figure 4 Estimated Kaplan-Meier survival curve of 67 reported patients.

Gastrointestinal autonomic nerve tumors occurred with an estimated frequency of 1% of all malignant gastrointestinal tumors and up to 25% of gastrointestinal stromal tumors^[6]. In retrospective studies of collected pathological specimens, several investigators found that light microscopic studies yielded ambiguous results and ultrastructural examination was required in order to establish an accurate diagnosis of gastrointestinal autonomic nerve tumor^[6,20,26].

Based on these observations we believe that GANTs are probably more common than previously thought. The rarity of GANT may therefore be a consequence of the unavailability of routine electron microscopic analysis. The exact biological behavior of GANTs is not fully elucidated because of the limited

number of reported cases, but it appears that, despite their low grade malignant histological appearance, most GANTs had an uncertain and a poor prognosis in case of metastases. With respect to one of our patients long term survival was possible even with metastatic diseases. Preliminary data indicated no significant correlation between treatment, tumor site and clinical outcomes^[2,15].

Some authors suggested that GANTs should be regarded as a type of GISTs because of their mostly identical c-kit mutations^[10,39]. Others argued that this common feature might not justify considering GIST and GANT as the same entity because of the neuronal nature of GANT^[6]. The recent observation that most GANTs were CD117 positive could have an important clinical impact, since tyrosine kinase inhibitors have yielded good responses in other CD117 positive tumor entities. To date there are no reports on the use of tyrosine kinase inhibitors in CD 117 positive GANTs, but promising data for c-kit positive GISTs which were successfully treated with tyrosine kinase inhibitors have recently been published^[39].

Radical surgical resection appears to be the most promising and solely curative treatment regimen for gastrointestinal autonomic nerve tumors. However, as demonstrated in case 1, patients with metastases might also survive for a long time. Some studies in the literature report had similar findings. We therefore suggest that even in cases of large tumor masses, non-curative, aggressive surgical tumor debulking is potentially useful to improve the patient's quality of life. For metastatic CD117 positive tumors tyrosine kinase inhibitors might be an appropriate palliative treatment approach. As demonstrated in case 2, GAN tumors could also involve unusual anatomic sites like Meckel's diverticulum.

To gain more information about this distinct type of GISTs, careful ultrastructural and immunohistochemical studies of all GIST cases would be beneficial. We are aware that ultrastructural examination is not available at every clinical pathology unit. However, we propose that pathologists harvest small specimens of the tumor for analysis at specialized institutions. An accurate histological diagnosis seems to be essential in order to ensure that all patients receive adequate and timely treatment and furthermore to learn more about this tumor and its biological behavior especially with respect to newly developed drugs like tyrosine kinase inhibitors. To date there is no difference in the surgical treatment of GANTs and GISTs. But there is some evidence that these tumors are from different origins and may therefore exhibit distinct biological behaviors. However, due to the limited number of reported GANTs further investigations would be necessary to fully characterize these tumors with respect to future treatment decisions.

ACKNOWLEDGMENT

Abstract

Granular cell tumor (GCT) is uncommon in the colon and rectum. Here we report a case of GCT in the transverse colon. A 48-year-old male patient underwent a screening colonoscopy. A yellowish sessile lesion, about 4 mm in diameter, was found in the transverse colon. An endoscopic snare resection was performed without complication. Histological examination revealed the tumor consisted of plump neoplastic cells with abundant granular eosinophilic cytoplasm containing acidophilic periodic acid Schiff-positive, diastase-resistant granules. Immunohistochemical analysis showed the tumor cells expressed S-100 protein and neuron-specific enolase. Thus, the resected tumor was diagnosed as a GCT. Since GCTs are usually benign, endoscopic resection constitutes an easy and safe treatment. Colonoscopists should consider the possibility of GCT in the differential diagnosis of submucosal tumors of the colon.

INTRODUCTION

Granular cell tumor (GCT) is relatively rare soft tissue tumor that can be located anywhere in the body. It commonly occurs in oral cavities and subcutaneous tissues, but is uncommon in

the colon and rectum^[1,2]. In the gastrointestinal tract, the most common site for GCT is the esophagus, followed by the duodenum, anus and stomach^[3,4]. This usually benign tumor appears as a submucosal nodule, measuring less than 2 cm in diameter, and is often found incidentally during colorectal examinations^[2-6]. Here we report a case of a 48-year-old man diagnosed with a GCT arising in the transverse colon and treated by endoscopic resection.

CASE REPORT

A 48-year-old man was admitted for a screening colonoscopy. He had been healthy without specific complaints, family or past medical history. At the time of colonoscopy, a yellowish, hemispheric nodule 4 mm in diameter, was found in the transverse colon. It was a firm nodule covered by intact mucosa (Figure 1). The patient underwent an endoscopic snare resection, was observed for 30 min, and then discharged. There was no immediate or delayed complication.

Figure 1 A hemispheric, yellowish submucosal tumor with intact mucosa, about 4 mm in diameter in transverse colon revealed by endoscopy.

Histological examination of the resected tissue revealed a submucosal tumor composed of solid masses of plump histiocyte-like tumor cells with abundant granular eosinophilic cytoplasm containing acidophilic periodic acid Schiff (PAS)-positive, diastase-resistant granules (Figure 2). Immunohistochemical analysis showed the tumor cells

7	The present case		M/48	T-colon	0.4×0.3	Polypectomy

expressed S-100 protein and neuron-specific enolase (NSE) (Figure 3), but were negative for desmin and cytokeratin. The resected tumor was diagnosed as a GCT occurring in the transverse colon.

**Figure 3** Diffuse and strong expression of S-100 protein in tumor shown by immunohistochemical examination (Original magnification: ×100).

DISCUSSION

GCT, first described by Abrikossoff in 1926^[7], may arise virtually anywhere in the body, but was seldomly found in the gastrointestinal tract^[1,2]. In most cases, gastrointestinal GCTs were found incidentally during endoscopy, and appeared as small, round submucosal nodules covered by normal mucosa^[1-5,8-10]. GCTs have also been detected in the muscle layer of the gastrointestinal tract and in subserosal areas, although such findings were uncommon^[2,4,11].

Endo *et al.*^[10] reported 33 cases of colorectal GCT in Japan, and Rossi *et al.*^[8] reported 55 patients diagnosed with GCTs of the colon. To date, 7 cases of colonic GCT have been reported in Korean literature (Table 1). This excludes two cases of perianal GCT which may have arisen from perianal skin rather than anal mucosa. Except for one rectal case, all 6 colonic GCTs reported in Korea were located in the proximal colon - ascending colon, transverse colon and cecum including the appendix. The male-to-female ratio was 1:1.3 and the mean age was 41.0±6.5 years (range 31-49 years). Bowel resection was the treatment administered for the 2 cases diagnosed before 1985, while endoscopic removal of the tumor was performed in the later cases. Advances in endoscopic diagnosis and resection probably led to the alteration in treatment approach for the latter cases.

GCT could seldomly be diagnosed based on macroscopic and endoscopic examination due to both its small size and its shape resembling a diminutive polyp^[1]. Recently, endoscopic ultrasound has been frequently used for determining the depth of tumor invasion in the gastrointestinal wall, and is also useful for evaluating gastrointestinal submucosal tumors^[9,10,18]. However, in the present case, it was difficult to suspect GCT because the endoscopic features of the tumor resembled those of a small sessile polyp. We performed one-stage endoscopic

snare polypectomy during screening colonoscopy.

The final diagnosis of GCT depends on pathological findings. The histological markers for GCT are: (1) plump histiocyte-like, bland-looking neoplastic cells with abundant granular eosinophilic cytoplasm containing acidophilic, PAS-positive, diastase-resistant granules; (2) small, uniform nuclei, in which mitotic figures are absent; (3) neural markers, including S-100 protein or NSE expressed uniformly^[6,11,22]. In the present patient, the histological findings on the resected specimen were typical of a GCT.

Although GCTs are usually benign, some malignant GCT cases have been reported. Malignancy has been found to correlate with tumor size, more than 60% of metastatic GCTs were larger than 4 cm in diameter^[6,11,23]. However, in most colonic GCTs, the tumor size was less than 2 cm and the tumor was well separated from the muscularis propria. Since this tumor is considered to be usually benign, endoscopic removal has been the most appropriate choice of treatment for colonic GCT^[2,8,10,24].

In conclusion, we report a case of GCT in the transverse colon. The tumor was removed by endoscopic resection and the patient was discharged without complication. GCTs of the colon can be found incidentally during colonoscopy, and endoscopic removal of the tumor is the safest and most feasible treatment. Colonoscopists should consider the possibility of GCT in the differential diagnosis of submucosal tumors of the colon.

Abstract

We report a case of a 61-year-old man who presented with fatigue, abdominal pain and hepatomegaly. Computed tomography (CT) of the abdomen showed hepatomegaly and multiple hepatic lesions highly suggestive of metastatic diseases. Due to the endoscopic finding of colon ulcer, colon cancer with liver metastases was suspected. Biochemically a slight increase of transaminases, alkaline phosphatase and gammaglutamyl transpeptidase were present; α -fetoprotein, carcinoembryogenic antigen and carbohydrate 19-9 antigen serum levels were normal. Laboratory and instrumental investigations, including colon and liver biopsies revealed no signs of malignancy. In the light of spontaneous improvement of symptoms and CT findings, his personal history was reevaluated revealing direct contact with pigs and their tissues. Diagnosis of leptospirosis was considered and confirmed by detection of an elevated titer of antibodies to leptospira. After two mo, biochemical data, CT and colonoscopy were totally normal.

INTRODUCTION

Leptospirosis is a zoonosis caused by spirochetes of the genus *Leptospira*. Humans are infected only occasionally by direct contact with infected animals or through contaminated water and soil. The clinical presentation ranges from occult infection to Weil's disease with fatal complications as hepatorenal failure. It remains underdiagnosed largely due to the broad spectrum of symptoms and signs.

CASE REPORT

A 61 year-old male farmer, non-smoker without a history of alcohol abuse or cancer, was admitted to a local hospital due to fatigue and pain in the right upper abdominal quadrant with discovery of enlarged liver over the past three days. Ultrasonography (US) showed many hypoechoic lesions scattered in all hepatic

segments. A computed tomography (CT) scan of the abdomen showed substitution of the whole liver by multiple low-density lesions with mild ring enhancement highly suggestive of metastatic disease (Figure 1) and retroperitoneal small (< 1 cm) lymph nodes. Upper gastrointestinal endoscopy was negative and colonoscopy disclosed an ulcer of the transverse colon which histologically revealed edema and necro-inflammatory damage without signs of malignancy.

Figure 1 Contrast-enhanced abdominal CT scan (portal phase): multiple lesions appearing hypodense compared with normal liver parenchyma and showing mild ring enhancement.

Ultrasound guided liver biopsy of one of the lesions taken 10 d after admission excluded malignancy and was consistent with mild portal hepatitis and cholestasis. Laboratory tests showed alanine aminotransferase (ALT) 130 IU/l (normal < 40), aspartate aminotransferase (AST) 76 IU/l (normal < 37), alkaline phosphatase (ALP) 359 MU/mL (normal < 280), gammaglutamyl transpeptidase (γ -GT) 252 MU/mL (normal < 50). Normal serum levels of α -fetoprotein, carcinoembryogenic antigen (CEA) and carbohydrate 19-9 antigen (CA 19-9) were present. The patient refused further investigations and was discharged with the suspicion of misdiagnosed neoplastic disease. Four wk later, on admission to our Unit, the patient was in good general condition and denied a weight loss and gastrointestinal symptoms. Physical examination revealed only a mild indolent hepatomegaly. Laboratory investigations showed only ALP 443 MU/mL and γ -GT 77 MU/mL. Ultrasonography and abdominal CT scan (Figure 2) revealed a dramatic decrease both in number and volume of the hepatic lesions with unmodified vascularization pattern. Chest X-ray was unremarkable. Colonoscopy revealed an ulcer of the right colon (Figure 3) characterized under histological profile by edema and necro-inflammatory cells. Viral, autoimmune and metabolic liver diseases were excluded by appropriate tests as well as metastatic tumors, primary hepatoma, pyogenic liver abscess, parasitic liver and colon lesions and colon cancer. Due to spontaneous improvement of symptoms and CT findings, his personal history was reevaluated. A direct contact with pigs and their tissues three days before the onset of symptoms was reported (the patient, living in rural areas, butchered a domestic pig). On specific request, transient hematuria before admittance was reported. The hypothesis of leptospirosis was considered and confirmed by the positive result of indirect immunofluorescence on cultured leptospires (*Leptospira interrogans* serovar icterohaemorrhagiae), which showed a high titer of antibodies

to leptospira (titer 1:1024). No cross-reaction with other spirochetes (*Treponema* and *Borrelia*) was seen. In two wk' time biochemical alterations were almost subsided. Despite spontaneous recovery, treatment with tetracyclines was started and the patient was dismissed. Two mo later US, CT and colonoscopy were totally normal and after a 2-year follow-up the patient has been fine.

Figure 2 Contrast-enhanced abdominal CT scan (portal phase): after 46 d both number and volume of hepatic lesions were considerably decreased.

Figure 3 Endoscopic view of right colon showing an ulcerated lesion without signs of bleeding. A series of biopsies of the ulcer revealed only necro-inflammatory cells.

DISCUSSION

Leptospirosis is a worldwide zoonotic infection that commonly occurs in tropical and subtropical regions and in both urban and rural contexts. Human disease is acquired by contact with urine or tissues of an infected animal or through contaminated water and soil, whereas human-to-human transmission is rare. Diagnosis of leptospirosis is based either on isolation of the organism from the patient or on seroconversion. Antibodies generally do not appear until the second week of illness. The pathogenesis of leptospirosis is incompletely understood but it is well known that all forms of leptospires can damage small blood vessels, lead to vasculitis and spread to all organs^[1]. The clinical presentation ranges from occult infection to Weil's disease with fatal complications as hepatorenal failure. The severity of disease reflects the severity of the underlying vasculitis. As a result of its protean clinical manifestations and non-specific presentations, leptospirosis has been underdiagnosed and frequently misdiagnosed as other diseases such as influenza, viral hepatitis, encephalitis, pneumonitis and acute renal failure^[1-3]. The great majority of cases, as in this patient, were of mild severity (anicteric leptospirosis) and resolution coincided with the appearance of antibodies. Icteric leptospirosis, occurring between 5 and 10 % of patients, was a severe disease and often very rapidly progressive with multi-organ failure^[4,5]. Treatment of leptospirosis depends on the severity of infection. Anicteric leptospirosis often requires

hospital admission and close observation. Streptomycin, penicillins, cephem and tetracyclines are all effective anti-leptospiral antibiotics^[4,5]. Radiological abnormalities, in particular pulmonary localization on high resolution CT (nodular densities, ground glass opacities, areas of consolidation) possibly related to haemorrhage, have been described in severe forms^[6-8]. Although hepatomegaly is usual, CT evidence of multiple hepatic lesions, to our knowledge, has not yet been described in patients with leptospirosis. The histopathology of the liver in the course of leptospirosis was characterized by intrahepatic cholestasis, centrilobular necrosis with hypertrophy and hyperplasia of Kupffer cells but the architecture of parenchyma was not significantly disrupted and severe hepatic necrosis was not usual^[4]. The presence of multiple hypoattenuated nodules in the liver was the most interesting feature of this case. The differential diagnosis of this CT appearance included hypovascular metastases, abscess, especially by angioinvasive organisms or lymphoma. However, the absence of a mass effect on the surrounding hepatic structures would be helpful in suggesting the possibility of an abscess correlated with damage of small blood vessels. The pathologic basis for this hypoattenuation may be correlated with a coagulative necrosis of the hepatic tissues caused by vasculitis of the hepatic vessels.

Gastrointestinal involvement with haemorrhage has been reported, mainly in the severe form of leptospirosis^[2]. Interestingly, in this patient a colon ulcer was found at two different sites without any symptoms and signs of bleeding. The endoscopic and histological patterns of these colon lesions were consistent with ischemic colitis. Vascular disease of diverse etiologies and in particular vasculitis could be a cause of ischemic colitis^[9].

In this patient, according to our experience, liver lesions were correlated with the endoscopic findings of colon ulcer therefore primary colon cancer with liver metastases was suspected initially. On the other hand, the CT pattern when seen in the appropriate clinical setting reduced the diagnostic suppositions of infectious disease.

In conclusion, this case, initially misdiagnosed as colon cancer with liver metastases, confirms clinical polymorphism of leptospirosis and high lights the role of a good knowledge of personal history and epidemiological data in the diagnosis of leptospirosis, especially in areas of relatively low endemicity as in western countries, where domestic animal contact is prominent sources of infection. This report also suggests that a diagnosis of leptospirosis should be considered in patients with laboratory and CT findings of liver involvement and a relevant history.

Abstract

Acute esophageal necrosis (AEN) or "black esophagus" is a clinical condition found at endoscopy. It is a rare entity the exact etiology of which remains unknown. We describe a case of 'black esophagus', first of its kind, in the setting of liver cirrhosis and hepatic encephalopathy.

Khan AM, Hundal R, Ramaswamy V, Korsten M, Dhuper S. Acute esophageal necrosis and liver pathology, a rare combination. *World J Gastroenterol* 2004; 10(16): 2457-2458
<http://www.wjgnet.com/1007-9327/10/2457.asp>

INTRODUCTION

Endoscopic discovery of a 'black esophagus' or 'acute esophageal necrosis' (AEN) that is unrelated to ingestion of caustic or corrosive agents is quite exceptional. It has been described only a few times in the past. Lacey *et al.* in 1991 reported 25 cases^[1]. A similar report by Benoit *et al.*^[2] in 1999 cited 27 cases after an extensive review of the literature. Since then there have been sporadic case reports. It is difficult to estimate its true incidence as we think this disease is largely underreported. The exact etiology of 'black esophagus' still remains unknown. We describe a case of 'black esophagus', first of its kind, in the setting of liver cirrhosis and hepatic encephalopathy.

CASE REPORT

A 59-year-old hispanic male with a known past medical history of hypertension, chronic alcohol abuse, liver cirrhosis, chronic pancreatitis and depression was admitted to the psychiatry service for aggressive behaviours, depression and suicidal ideation. On d 2, he was transferred to the medical floor after evaluation for a change in mental status with confusion, disorientation and impulsive behaviours.

A detailed history was elicited on further interrogation. Patient was known to have hypertension for 10 years for which he required monopropranolol, metoprolol and clonidine. The history also revealed alcohol abuse for 45 years, still an active abuser, alcoholic liver cirrhosis diagnosed for 4 years and negative hepatitis B and C serologies. He had multiple previous admissions for hepatic encephalopathy and earlier in the same year underwent chemotherapy for a biopsy proven hepatocellular carcinoma. He denied smoking and illicit drug abuse.

On examination the patient was drowsy but arousable, responding to verbal commands, oriented to 'place and person', but not 'time'. He was afebrile and hemo-dynamically stable. General physical examination was normal. Cardiac, pulmonary, abdominal and neurological examinations did not show any abnormalities. Rectal examination was normal with a negative

guaiac test.

Laboratory data on admission were: WBC 5.1 n/L with 48% granulocytes, hemoglobin (H)/ hematocrit (Hct) of 10.3/ 31, MCV of 80.3 fl, RDW of 15.4%, platelets of 174 /n.

Na 141 mEq, K 4.5 mEq, Cl 108 mEq, CO₂ 26.1 mEq, BUN 32 mg/dL, Creatinine 2.1 mg, Gluc 134 mg, Total bili 0.6 (0.3 direct), albumin 2.8 gm, proteins 6.7 gm, alkaline phosph 217 U/L, SGOT 50 U/L, SGPT 39 U/L, LD 225 U/L, PT 11.4, aPTT 27.6 s and INR 1.05 s, Ammonia 139.8 um.

Ethanol on admission was 56.2, serum Osm 312, normal TSH, syphilis(-), ferritin 593, TIBC 168, total iron 58 and iron saturation 35%, B12/folate 226/22.7. CT scan of the head was negative for bleed/metastasis or any mass. CT scan of the abdomen revealed a few scattered diverticuli and accessory spleen.

A diagnosis of hepatic encephalopathy, anemia and intravascular volume depletion was established based on the clinical and laboratory data. Hydration with normal saline at 125 cc/h and treatment with lactulose 445 cc qid (titrated to bowel movement) were given. The rest of the management included administration of resperidol, thiamine, folate and ativan (prn). His anti-hypertensive medications were continued and patient was placed under close observation for alcohol withdrawal.

During the following 2 d (d 4 and 5) the patient's mental status improved to full orientation without any signs of confusion, agitation and/or suicidal ideation. Ammonia level dropped to 85 um. A drop in H/Hct (9.7/29.7) was related to intravascular volume depletion.

On d 6 of admission, the patient's clinical status deteriorated with a recurrence of confusion and lethargy. Patient was found to have tachycardia (heart rate of 120/min), a blood pressure of 105/70, a positive stool guaiac test, BUN/Creatinine of 68/3, ammonia of 105 um and a drop in his H/Hct (7.8/22). His management at this point included continuous intravenous hydration, blood transfusion with 3 units of packed red blood cells and intravenous proton pump inhibitors. His anti-hypertensive medications were held. The patient was transferred to a monitored setting for further observation and an esophageal gastro-duodenoscopy (EGD) was scheduled.

EGD revealed a continuous segment (15-35 cm) of necrosis with exudates, ulcerations and friable mucosa in the middle and distal parts of the esophagus. The gastro-esophageal (GE) junction showed no evidence of varices, stomach and duodenum linings were normal. A biopsy taken from the necrotic area confirmed the findings of fibrinoid necrotic debris with hemosiderin deposits and acute inflammatory cells on pathological examination of the specimen. An ultrasound of the abdomen revealed a medical renal disease without obstruction, liver texture consistent with cirrhosis with reversal of portal venous flow and mild ascites.

The patient made an uneventful recovery over the next 3 d. He was transferred to the medical floor from where he was discharged with a follow up in the outpatient clinic. No recurrences of any GI symptoms were reported in his 3-month follow-up.

DISCUSSION

'Black esophagus' has been described primarily in post-mortem studies^[3,4]. Goldenberg *et al.*^[5] gave us a detailed endoscopic description of 2 cases in the early 1990s. In a one-year prospective study conducted in Rouen University Hospital,

France, 8 (0.2%) cases of 'acute esophageal necrosis' were identified among the 3 900 patients who underwent EGD^[6]. Since then there have been only a handful of case reports. The numbers reported in the literature may highly underestimate the real incidence of this condition as suggested by this prospective trial. Acute esophageal bleeding is the most common presentation. The condition is generally seen in the elderly and those having co-morbid conditions.

A variety of mechanisms have been proposed to account for the development of this condition, and low systemic perfusion seems to play the dominant role. Other mechanisms cited include direct toxic effect^[7,8], as well as indirect mucosal breakdown and acid effect^[9], however, none of these have been proved. The frequent involvement of distal 1/3 esophagus^[10], absence of gastric lesions, presence of necrosis of mucosal/submucosal necrosis, presence of thrombus microscopically and rapid regression of disease after hemodynamic stability were similar to ischemic colitis^[11,12] and strongly support the ischemic basis for the insult.

Other conditions associated with this disease entity were prolonged hypertension^[13], ischemia^[5,14], hyperglycemia^[1], hypersensitivity to antibiotics^[15], herpetic infection^[16], gastric volvulus^[17], posterior mediastinal haematoma and aortic dissection^[3,18], anti-cardiolipin antibodies^[19] and Steven Johnson syndrome^[20]. In short, a multi-factorial etiology to absence of any disease (idiopathic) is possible. The pathogenesis of ischemic insult in our case can be accounted for by the low systemic perfusion with reversal of portal venous flow and worsening of hepatic encephalopathy.

Diagnosis is established with endoscopy with or without biopsy. The differential diagnosis included melanosis^[21], pseudo-melanosis^[22], and acanthosis nigrans^[23].

The main reported complications of AEN were esophageal stenosis and stricture formation^[1,2]. Lacy *et al.*^[1] reported a 15% complication rate, whereas other case series have reported very low to none. Recurrence was less than 10%^[6,24] and mortality ranged between 0-33%^[1,6,25]. The prognosis depends on the patient's general status rather than the extent of local esophageal necrotic lesions.

Generally there is no standardized treatment but the overall consensus favours conservative treatment with intra-venous proton pump inhibitors and short-term parenteral nutrition. The main aim is to avoid extension of insult with time for a spontaneous and aided recovery.

In short, AEN is still uncommon with exact etiology and pathogenesis largely unclear. The majority do not have any long-term sequel, only a few develop strictures and stenosis. Prognosis varies, and a majority recover with conservative treatment with death being an uncommon outcome.

Abstract

AIM: Late onset of dysphagia due to vascular abnormalities is a rare condition. We aimed to present a case of right subclavian artery abnormalities caused dysphagia in the elderly.

METHODS: A 68-year-old female was admitted with dysphagia seven months ago. Upper endoscopic procedures and routine examinations could not demonstrate any etiology. Multislice computed thorax tomography was performed for probable extra- esophageal lesions.

RESULTS: Multislice computed thorax tomography showed right subclavian artery abnormality and esophageal compression with this aberrant artery.

CONCLUSION: Causes of dysphagia in the elderly are commonly malignancies, strictures and/or motility disorders. If routine examinations and endoscopic procedures fail to show any etiology, rare vascular abnormalities can be considered in such patients. Multislice computed tomography is a usefull choice in such conditions.

INTRODUCTION

Dysphagia Lusoria was first described by Bayford in 1794 in a 62 year-old woman^[1]. Postmortem examination of this case showed the abnormal origination of right subclavian artery from aortic arch and compression on the esophagus. Abnormalities of the thoracic aorta and great vessels are not uncommon and can result in esophageal compression and dysphagia. The most common congenital abnormality of the aorta is an isolated aberrant right subclavian artery^[2]. Usually this abnormality does not lead to symptoms. However, sometimes dysphagia (dysphagia lusoria) develops. Mass effect on the esophagus can cause dysphagia. A right aortic arch with an aberrant left subclavian artery is less common but may also result in esophageal compression^[3]. A pulmonary sliding occurs when an aberrant left pulmonary artery arises from the right pulmonary artery and passes between trachea and esophagus. Compression

on both trachea and esophagus can occur. This abnormality can also be reliably detected with contrast-enhanced CT. We aimed to present a 68-year-old woman who had late onset dysphagia due to such a rare condition.

CASE REPORT

A 68-year-old female was admitted to our hospital with dysphagia nearly for seven months. Dysphagia was occurring both solid and liquids. There were no clear symptoms except dysphagia, such as loss of weight, fever, sweating at night, diarrhea, hematemesis, melena or hematochesia. She complained about odinophagia, bloating, regurgitation and epigastric pain especially after analgesic using. She also had chest pain radiating to the left arm with effort. She had a history of operation for discal hernia, ischemic heart disease and diabetes mellitus. She was using anti-ischemic drugs, analgesics (Including aspirin), beta blockers and diuretics.

In physical examination her general condition was good, thyroid was palpable. She had mild epigastric pain with palpation and no other signs. Hgb was 136 g/L, WBC (White blood cell count) was 77 000 μ L, PLT was 290 000 μ L in laboratory tests. Erythrocyte sedimentation rate was 10 /h, SGOT was 57 U/L, SGPT was 84 U/L, ALP was 245 U/L. Other biochemical parameters were normal (BUN, creatinine, glucose, etc). Markers for hepatitis A,B,C were negative. Thyroid function tests were normal. She had esophagus graphy with radiopaque two months ago showing slight compression on esophagus in lower levels. Esophagogastroduodenoscopy (EGD) 5 mo ago showed minimal hiatus hernia, reflux esophagitis and antral gastritis. Some drugs were given to the patient for these findings but her dysphagia symptoms did not relieve. EGD 3 mo after, only showed antral gastritis. Other drugs (PPIs, antacids) were given also, but dysphagia of the patient did not relieve. After admission to our clinic, the major complaint of the patient was persistent dysphagia despite the treatments. Thorax CT was performed (Multislice spiral CT) to exclude thoracic lesion-dysphagia, it showed right subclavian artery abnormality and esophageal compression on this aberrant artery (Figures 1A, B). Multislice computed thorax tomography (MCT) showed the right subclavian artery originating from the posterior wall of the aortic arch as its last branch distal to the origin of the left subclavian artery and it passed obliquely between esophagus and vertebral column and then coursed upwards on the right side.

DISCUSSION

Dysphagia is a common problem that lowers quality of life for the elderly and a symptom that may originate from many different causes. Esophageal dysphagia could be caused by esophageal carcinoma, esophageal stricture and webs, achalasia, diffuse esophageal spasm and scleroderma, caustic esophagitis and infectious esophagitis^[4]. The other rare cause of dysphagia in the elderly is vascular compression on the esophagus (Dysphagia lusoria). Based on autopsy findings, the lusorian artery had a prevalence of 0.7% in the general population^[5]. Recently Fockens *et al.* found a prevalence of 0.4% in 1 629 patients who underwent endoscopy for various reasons^[6]. Dysphagia lusoria might be seen in young adults^[7], and in middle and/or elder ages as in our case^[8]. Why it gives symptoms in

Figure 1 Axial (A) coronal (B) sagittal (C) MIP multislice CT images from the arterial phase showing right subclavian artery originating from the posterior wall of aortic arch, and compression with antero-right lateral displacement of esophagus by this right subclavian artery.

elderly is not clear. Some theories have been suggested, such as increased rigidity of the esophagus itself or the vessel wall, aneurysm formation, especially in the presence of a Kommerell's diverticulum^[9], elongation of the aorta, and the combination of an aberrant artery and a truncus bicaroticus^[10]. Interestingly in our patient, she had a history of dysphagia for 7 mo. She had not any lesion except minimal esophagitis in EGD. Reflux esophagitis can explain dysphagia sometimes. After the treatment of esophagitis with proton pump inhibitors (PPI), our patient's dysphagia symptom did not relieve. The late onset of dysphagia in our patient could be explained by the changes in vertebral column. Retrosternal goitre which may be responsible for dysphagia was not found in CT. Radiopaque graphy of the esophagus could be used to show the compression of aberrant artery on esophagus, but CT scanning and/or angiography can usually confirm the diagnosis of dysphagia lusoria. Aberrant artery could be shown with multislice CT as three dimension angiographic images were non-invasive without the need of invasive angiography^[11]. Here, we also presented the multislice computed tomography angiography images of the patient with a symptomatic aberrant retro-esophageal subclavian artery compression (Figure 2).

Figure 2 Volume-rendered three-dimensional image by computed tomography demonstrating aberrant artery right subclavian artery originating from the posterior wall of aortic arch.

We showed the aberrant right subclavian artery abnormality and compression on the esophagus clearly. That is why we did not repeat the radiopaque graphy of the esophagus. Coronary angiography was planned but the patient refused this procedure. So the patient was referred to a cardiovascular surgeon.

In conclusion, dysphagia in an elder patient can be caused by a rare abnormality of the subclavian artery insertion. Multislice CT can reveal this abnormality.

Abstract

We have encountered an unusual case of gastric carcinoid tumor. Gastroscopic examination of this 32-year-old male patient showed a smooth protrusion at the greater curvature of the gastric body with a central depression, identified by subsequent biopsy as carcinoma. The patient had a normal serum gastrin level and was negative for anti-parietal cell antibody. Histological examination of the resected gastric tissues showed that the tumor was a carcinoid, 0.3 cm×0.3 cm in size with only one regional lymph node metastasis. We reviewed the pathogenesis, clinical presentation, diagnosis and treatment of gastric carcinoids and raise the possibility of being a lymph vessel-related metastasis even for a minute carcinoid tumor. Sentinel lymph node biopsy is recommended for surgery of minute carcinoid tumors.

Xie SD, Wang LB, Song XY, Pan T. Minute gastric carcinoid tumor with regional lymph node metastasis: A case report and review of literature. *World J Gastroenterol* 2004; 10 (16): 2461-2463

<http://www.wjgnet.com/1007-9327/10/2461.asp>

INTRODUCTION

Carcinoid tumors represent an unusual and complex disease spectrum with protean clinical manifestations. Gastric carcinoids account for 3 of every 1 000 gastric neoplasms. Gastric carcinoids types I and II generally follow a benign course, with 9% to 30% developing metastases, usually multiple and small characterized by infiltration restricted to the mucosa and submucosa. The third type of gastric carcinoids (type III, sporadic tumors) occurs without hypergastrinemia but often progresses in an aggressive course, 54% to 66% of which may develop metastases. Approximately 50% of these often large, single tumors have atypical histology, and some patients may develop carcinoid syndrome; but except for rare cases, carcinoid tumor of the stomach less than 1 cm in size generally does not give rise to regional metastasis.

CASE REPORT

The patient in question was male, aged 32 years old, admitted for upper gastric discomfort after dinner for six mo, which worsened in the past two mo prior to admission. The patient complained of epigastric distention, but this did not affect his

normal diet. He had no vomiting, abdominal pain, melena or regurgitation. The symptoms waxed and waned, but clearly worsened in the last two mo. Physical examination revealed no obvious anemia, the lung and heart sounds were normal, the abdomen was soft and flat, and no hepatomegaly or splenomegaly was noted, nor was an abdominal mass palpated; rectal examination found no abnormalities, and no enlargement of the superficial lymph nodes was present. The patient was free of symptoms of hypergastrinemia or carcinoid. Gastroscopy identified a nodule on the greater curvature of the stomach, 0.6 cm by 0.6 cm in size, with erosive lesion above the nodule. Biopsy was done and the results indicated carcinoid. The patient received subsequently laparotomy in which a node was found near the pylorus, yellowish in color and 0.5 cm by 0.5 cm in size. The node was extensively resected along with the marginal area 2 cm in width. One enlarged lymph node below the pylorus was also resected. Post-operative histology revealed a 0.3 cm node, gray-white or gray-red, beneath the mucosa. Under microscope, tumor cells were seen in the submucosa and mucosa propria, uniform in shape and arranged in cribriform nests. A radical distal subtotal gastrectomy was subsequently performed, and the post-operative histology reported no residual cancer or additional metastasis in the 23 lymph nodes. The patient was then discharged and followed up for one year without findings indicative of recurrence or distant metastasis.

DISCUSSION

Carcinoid is also known as chromaffin cell carcinoma and belongs to an unusual type of tumor with relatively low malignant potential. The most frequent sites for carcinoid tumors in human are the gastrointestinal (GI) tract (74%) and the bronchopulmonary system (25%). Within the GI tract, most carcinoid tumors occur in the small bowel (29%), appendix (19%), and rectum (13%)^[1]. However, the frequency of gastric carcinoid tumors has increased markedly due to endoscopic screening, performed in patients with chronic atrophic gastritis. In Japan, mass endoscopic screening for gastric lesions is common, which results in an identified frequency of gastric carcinoid tumor as high as 41% of all carcinoid tumors^[2]. Zhen *et al.* reviewed 26 reports of carcinoid in China and reported 126 cases of carcinoid in the stomach from a total of 1 080 cases of GI tract carcinoid. Most gastric carcinoids occur in 40- to 60-year-old patients, irrespective of genders. Recently, a classification system was proposed to distinguish gastric carcinoid tumors into three types, namely, tumors associated with chronic atrophic gastritis (type I), tumors associated with Zollinger-Ellison syndrome (ZES, type II), and biologically more aggressive, sporadic lesions (type III)^[3,4]. Currently little is known about the factors that may induce or promote the malignant growth of carcinoids^[5]. For some gastric carcinoids, studies show that gastrin is an important growth factor^[6], and an increased incidence of gastric carcinoids can be expected in disease states (pernicious anemia, atrophic gastritis, Zollinger-Ellison syndrome) that result in hypergastrinemia. In pernicious anemia and atrophic gastritis, 4% to 11% of the patients develop gastric carcinoids^[7,8]. Patients with Zollinger-Ellison syndrome

also develop gastric carcinoids, although they are much more frequent in the subgroup with MEN 1^[9]. Studies suggest that other important growth factors in some carcinoid tumors include transforming growth factor alpha (TGF- α) and TGF- β ^[10,11], insulin-like growth factor-1 (IGF-1)^[7,11], trefoil peptides (TFF1, TFF2, TFF3)^[7], platelet-derived growth factor^[10], vascular endothelial growth factor^[12], acidic and basic fibroblast growth factor, and epidermal growth factor^[10,11]. Mutations in common oncogenes, such as *K-ras*, are uncommon in GI carcinoids. Over amplification of *HER2/neu*, *c-myc*, and *c-jun* have been described in some cell lines derived from GI endocrine tumors and some carcinoids^[13]. Alterations in the common tumor suppressor gene *p53* are also uncommon in carcinoids. MEN 1 has been shown to be due to defects in the 10-exon gene on chromosome 11q13 that encodes a 610-amino acid nuclear protein^[14,15]. Loss of heterozygosity at this locus has been reported to occur in 26% to 78% of cases of carcinoids, and mutations in the MEN I gene in 18%^[16-18]. Microsatellite instability is rare in carcinoids^[19]; however, by comparative genomic hybridization, both frequent gains (of chromosome 5, 14, 17q, 7) and losses (especially of chromosome 9p) are reported^[20].

Gastric carcinoids originate from parachromaffin cells of the gastric mucosa. Tumor cells can occur virtually anywhere in the stomach, but mostly occur in the antrum. Gastric carcinoid is often difficult to diagnose due to the absence of specific symptoms or signs, especially in the early stage. When the tumor protrudes into the gastric cavity, the patient usually feels epigastric pain, suffers bloody vomiting, melena, epigastric burning, nausea or other digestive disorders. Carcinoid syndrome is seen in only a few gastric carcinoid cases where extensive dissemination or liver metastasis can be present. Gastric carcinoid in its early stage frequently escapes detection, and is usually found by gastroscopy. When the tumor grows to more than 2 cm, barium meal will help the diagnosis. The patient in this report was a young man who had only non-specific symptoms like epigastric distension without carcinoid syndrome and the tumor was near the antrum only 0.5 cm in size. The pathology was typical carcinoid. This patient did not have chronic gastritis or Zollinger-Ellison syndrome and the lesion was single, which belonged therefore to type III.

Surgical resection is the major strategy for treatment of gastric carcinoid, and chemotherapy and radiotherapy have not proved to produce obvious effects. For gastric carcinoids, the treatment is generally decided on the basis of the presence of hypergastrinemia^[21-25]. Most researchers recommend that in patients with type I or II, in which hypergastrinemia is present with small lesions of less than 1 cm, the carcinoid should be removed endoscopically^[22,24,25], while when the tumor exceeds 2 cm or local invasion is present, disputes over total gastrectomy^[26] or only resection with antrectomy arise for type I (pernicious anemia) lesions^[21]. For type I or II lesions of 1 to 2 cm, no agreement has been reached on the treatment. Some recommend that these lesions should be treated surgically^[21], whereas others urge endoscopic treatment^[25]. In type III gastric carcinoids not associated with hypergastrinemia, which tend to be larger and more aggressive, excision and regional lymph node clearance is recommended when the tumor grows to larger than 2 cm^[21-23,25]. Some researchers prefer a similar approach for any carcinoid larger than 1 cm, whereas others consider such a resection be reserved for tumors in this size range showing histologic invasion. Most tumors smaller than 1 cm can be treated endoscopically. Tumors less than 1 cm in size are called minute carcinoids, which seldom give rise to regional lymph node metastasis, especially tumors less than 0.5 cm in size. But very rarely, minute carcinoids do have lymph node metastasis, as reported by a Japanese researcher Naitoh^[27]. Such a case has not previously been reported in China. The

case reported in this paper is similar to the case reported in Japan. The post-operative pathology showed only a single lesion 0.3 cm in size invading the submucosa. There was just one lymph node metastasis, which is also uncommon. Local resection of the stomach was done in the first operation, and one enlarged lymph node was resected that was identified as metastasis by histology, so subtotal gastrectomy and lymph node dissection were done in the second operation. The other lymph nodes were normal, however, we regarded this approach was appropriate.

Sentinel lymph node biopsy has been used widely for surgery of melanoma^[28,29] and is currently receiving intensive study on its application for other malignant tumors such as breast, rectal and gastric cancer^[30,31]. The sentinel node is the most likely lymph node that harbors metastasis. A negative sentinel lymph node (SLN) would suggest that metastatic disease has not occurred, whereas a positive SLN would indicate possible involvement of other nodes in the same basin. Therefore sentinel lymph node biopsy may be attempted in operations for minute carcinoid. If the sentinel lymph node is positive, excision and regional lymph node clearance is needed, otherwise, local resection of the stomach is sufficient.

The prognosis of gastric carcinoid is favorable and patients may expect long postoperative survival. In patients with localized disease, 5-year survival rate may reach 64%, and it was 40% for regional involvement. Postoperative chemotherapy or radiotherapy was not performed in this particular case and the one-year follow-up found no recurrence or distant metastasis.
