INTRODUCTION

Extrahepatic bile duct carcinomas are typically slow-growing and locally invasive tumors, which spread along nerves and invade adjacent vascular structures^[1]. Optimal treatment of these tumors includes complete surgical resection with negative histologic margins^[2]. However, complete resection is sometimes difficult by local extension, which occur perineurally, via lymphatic channels, by subepithelial spread in the duct wall, and by direct invasion of adjacent blood vessels^[3]. Nonresected extrahepatic bile duct carcinoma has a dismal prognosis, with a life expectancy of about 6 mo to 1 year^[4].

Hyperthermia has been used in combination with radiation therapy and chemotherapy, and is considered to be effective for certain type of tumors^[5]. We have been conducting a clinical trial of regional hyperthermia in combination with chemoradiotherapy for advanced extrahepatic bile duct carcinoma. In this study, clinical effectiveness of thermo-chemo-radiotherapy (TCRT) for locally advanced extrahepatic bile duct carcinoma was evaluated.

MATERIALS AND METHODS

Study patients

Eight patients complaining of obstructive jaundice with advanced extrahepatic bile duct underwent TCRT. All tumors were located in the upper bile duct and involved hepatic bifurcation. Bile duct was completely obstructed on

percutaneous transhepatic or endoscopic retrograde cholangiography. Six patients underwent percutaneous transhepatic biliary drainage (PTBD). Unresectable reasons were involvement of the portal vein ($n = 5$) and extensive involvement of hepatic hilus ($n = 3$, Table 1). None of them showed distant metastasis.

Table 1 Cases with bile duct carcinoma treated with thermo-chemo-radiotherapy

Case	Age (yr)	Sex	Unresectable reasons
1	70	m	Extensive involvement of hepatic hilus
2	57	m	Involvement of the portal vein
3	73	m	Extensive involvement of hepatic hilus
4	70	m	Involvement of the portal vein
5	70	f	Involvement of the portal vein
6	78	m	Involvement of the portal vein
7	65	m	Involvement of the portal vein
8	71	m	Extensive involvement of hepatic hilus

Thermo-chemo-radiotherapy (TCRT) techniques

The heating equipment was radiofrequency (RF) capacitive heating device, Thermotron RF-8 (Yamamoto Vinita Company, Osaka, Japan)^[6]. The patient lay in the prone position. The target was sandwiched with upper and lower electrodes, and 8 MHz RF wave was applied. We administered heat to the patient for 40 min after the tumor temperature had risen to 42 °C. Tumor temperature was measured continuously using a needle thermosensor on each heating. The thermosensor was inserted beside the tumor from the skin surface through 18-G angiocatheter under the aid of ultrasonography. The chemotherapeutic agents employed were cis-platinum (CDDP, 50 mg/m²) in combination with 5-fluorouracil (5-FU, 800 mg/m²) or methotrexate (MTX, 30 mg/m²) in combination with 5-FU (800 mg/m²). The hyperthermia and chemotherapeutic agents were administered simultaneously once weekly immediately following radiotherapy at 2 Gy. Usually it started within 15 min after the irradiation (Figure 1). Number of heat treatments ranged from 2 to 8 sessions (mean±SD, 4.5±2.5). Two cases were retreated (Table 2).

Table 2 Thermo-chemo-radiotherapy in each case

Case	Heat session	Chemotherapy	Dose of radiation (Gy)
1	×4, ×4	MTX + 5Fu	50+40
2	×2, ×6	CDDP + 5Fu	46
3	×6	MTX + 5Fu	56
4	×4	MTX + 5Fu	56
5	×4	CDDP + 5Fu	50
6	×2	CDDP + 5Fu	46
7	×2	MTX + 5Fu	50
8	×2	MTX + 5Fu	16

MTX: Methotrexate, 5Fu: 5-fluorouracil, CDDP: cis-platinum.

Figure 1 Schedule of TCRT.

Response and toxicity criteria

The effectiveness of TCRT on the advanced bile duct carcinoma was evaluated about resolution of biliary obstruction by cholangiography. Response of obstructed bile duct was graded as complete regression (CR: more than 80% resolution), partial regression (PR: more than 50% and less than 80% resolution), and no change (NC).

We examined histologically the state of the bile duct at autopsy in three patients with advanced bile duct carcinoma treated with TCRT.

Side effects were evaluated and graded according to the National Cancer Institute Common Toxicity Criteria^[7].

RESULTS

Effectiveness of TCRT

In respect to resolution of the bile duct, there were 3 CR, 2 PR, and 3 NC. CR rate and CR+PR rate was 38% and 63%. Mean survival was 13.2±10.8 mo. Four patients survived for more than 20 mo (Table 3). We placed self-expandable metallic stent into the patency-restored bile duct for prevention of restenosis ($n = 1$) and partially resolved bile duct ($n = 2$) after TCRT for improvement of patients' quality of life (Figures 2A and B). In these three patients, PTBD tube could be withdrawn.

Figure 2 A: Completely obstructed upper bile duct was partially resolved after TCRT; B: self-expandable metallic stent was placed into the patency-restored bile duct, and PTBD tube could be removed.

Histological findings at autopsy in patients treated with TCRT

Marked hyalinization or fibrosis with necrosis replaced extensively bile duct tumor and wall, in which suppressed

Table 3 Effectiveness of thermo-chemo-radiotherapy and survival months

Case	Resolution of the bile duct	Survival months
1	Complete response	33
2	Complete response	22
3	Complete response	22
4	Partial response	21.5
5	Partial response	6
6	No change	13.5
7	No change	4
8	No change	2.5

cohesiveness of carcinoma cells and degenerative cells were sparsely observed. Carcinoma cells were also detected peripherally. Common bile duct of two cases was not completely obstructed, though it was partly obstructed with debris or necrotic mass.

Complication of TCRT

Treatment complications by TCRT were nausea and vomiting (grades 1 and 2, five cases), gastritis (grade 2, three cases), leukocytopenia (grade 2, three cases), and thrombocytopenia (grade 1, one case). These complications were successfully treated conservatively.

DISCUSSION

Optimal treatment of bile duct carcinoma is complete surgical resection with negative histologic margins^[2]. However, complete resection is sometimes difficult by local extension, especially when the tumor located near the hepatic bifurcation. Deeply invaded tumors are apt to spread to the intrahepatic bile duct or the connective tissues in the hepatoduodenal ligament, with encasement of major vessels. Moreover, tumor cells that spread to the ligament often cannot be cleared away completely, even when dissection of the tissue is performed. In nonresected cases, tumor involving the hepatic hilus frequently induces the development of obstructive jaundice which cannot be under control, resulting in early death from cholangitis. One of the desirable strategies for advanced bile duct carcinoma appears to control over involvement of the hepatic hilar bile duct and the hepatoduodenal ligament.

We have treated advanced gallbladder carcinoma with TCRT and reported the effectiveness^[8]. Then, we undertook a preliminary study involving TCRT for unresectable bile duct carcinomas. In respect to resolution of the bile duct, there were three CR and two PR of eight treated cases. Four patients survived for more than 20 mo. PTBD tube could be removed in three patients, in whom self-expandable metallic stent was placed into the patency-restored bile duct after TCRT.

Hyperthermia involves two biological interactions with radiation, a radiosensitizing effect^[9,10] and a direct cytotoxic effect on tumor cells^[11]. When the target lesion is heated up to around 42 °C, the cancer-killing effect of radiation or anticancer drug is enhanced^[12]. Experimental studies strongly

suggest that the extracellular pH of the tumor and a hypoxic environment sensitize tumor cells to direct heat killing^[13]. Hyperthermia in combination with radiotherapy for superficial malignancies has contributed to a better rate of complete response and reduction in the rate of recurrence compared with radiotherapy alone^[14]. Data on hyperthermia for deep-seated tumors were still preliminary, because the heating and thermal measurement techniques were not yet established. However, the effectiveness of TCRT for deep-seated tumors has been recently revealed by prospective randomized studies^[15,16]. The treatment protocol of TCRT was established and its effectiveness was evidenced by Sugimachi and his colleagues^[17]. They treated esophageal carcinoma with TCRT and demonstrated significant improvement in the clinical effectiveness and 5-year survival ratio. Anatomically, the bile duct is located near the abdominal wall, which is advantageous to heating and thermal measurement. Thus, it seems that TCRT may be a favorable treatment strategy for advanced bile duct carcinoma.

In conclusion, although our clinical trial was preliminary and the number of patients was small, the results were better than we expected. We prefer HCRT in place of aggressive surgical approach for patients with locally advanced bile duct carcinoma.

Abstract

AIM: Itopride is a newly developed prokinetic agent, which enhances gastric motility through both antidopaminergic and anti-acetylcholinesterasic actions. The importance of esophageal motor dysfunction in the pathogenesis of gastro-esophageal reflux disease (GERD) makes it interesting to examine the effect of itopride on esophageal acid exposure.

METHODS: The effect of itopride on esophageal acid reflux variables for 24 h was studied in 26 patients with GERD symptoms, pre-entry total acid exposure time (pH<4) of more than 5% and mild esophagitis (Savary-Miller grades I, II) proven by endoscopy. Ambulatory 24-h pH-metry and symptom assessment were performed after treatments with 150 or 300 mg itopride thrice a day (t.i.d.) for 30 d in random order, using an open label method. For evaluating the safety of itopride, blood biochemical laboratory test was performed and the serum prolactin level was also examined before and after treatment.

RESULTS: Total symptom score was significantly decreased after treatment in 150- or 300-mg group. Itopride 300 mg was significantly effective than 150 mg on decreasing the total per cent time with pH<4, total time with pH<4 and DeMeester score. No serious adverse effects were observed with administration of itopride in both groups.

CONCLUSION: Itopride 100 mg t.i.d. is effective on decreasing pathologic reflux in patient with GERD and therefore it has the potential to be effective in the treatment of this disease.

INTRODUCTION

Gastro-esophageal reflux disease (GERD) is characterized by the reflux of gastric content into esophagus with or without histological changes. However, the excessive reflux of gastric acid induces some complications such as esophagitis, esophageal stenosis, cancer, or Barrett's esophagus. Pathogenesis of GERD are lower esophageal sphincter (LES) dysfunction, abnormal clearing capacity of refluxed materials, delayed gastric emptying and abnormal resistance of esophageal mucosa to gastric acid, but the primary motor dysfunction is regarded as the most important factor in general^[1,2]. Therefore, prokinetic agent that restores gastric motility with increasing of LES and esophageal motility has been developed and used frequently in the treatment of GERD^[3]. There are several prokinetic agents such as bethanechol, metoclopramide, domperidone, and cisapride that potentiate acetylcholine effects on smooth muscle of gastrointestinal tract or antagonize the activity of dopamine.

However, these prokinetic agents have some limitations for prescribing to GERD patients, because they show uncertain efficacies on GERD except for cisapride and have some problems in safety^[4,5]. Especially, cisapride accelerates the esophageal acid clearance by an enhancement of esophageal propulsive motility, which strengthens LES and stimulates the gastric emptying. So it is regarded that cisapride has the same efficacy as an inhibitor of gastric acid secretion for GERD. In spite of these predominant effects, cisapride is restricted to use because of a safety problem that it provokes arrhythmia.

Itopride, a new type of the prokinetic agent, acts both as a dopamine D₂ receptor antagonist and as an acetylcholine esterase inhibitor. It accelerates gastric emptying, improves gastric tension and sensitivity, and has an anti-emetic action. And also, itopride was identified to have equivalent efficacy with cisapride in functional dyspepsia. These mechanisms of itopride may be useful to GERD patients, but no clinical data are available from them as yet.

The aim of this pilot study is to evaluate the efficacy of

itopride for the treatment of GERD by evaluating the improvement of the clinical symptom and esophageal pH change.

MATERIALS AND METHODS

Study design

This study was performed prospectively to evaluate the efficacy and dose-response of itopride for the treatment of GERD by estimating ambulatory 24-h pH-metry and clinical symptoms before and after treatment. Patients satisfying the entry criteria were assigned to two groups by the randomization allocation schedule and received either 150 or 300 mg of itopride per day.

Inclusion/exclusion criteria

Twenty-six patients (range 18-65 years) who visited the Department of Internal Medicine in Wonkwang University and agreed to participate in this study were recruited based on the following entry criteria:

Inclusion criteria were (1) more than moderate heartburn symptom; (2) more than one upper dyspeptic symptoms such as regurgitation, epigastric pain, nausea, vomiting, dysphagia, chest pain lasting for more than 4 wk; (3) less than grade II esophagitis by Savary-Miller classification by endoscopic examination; (4) abnormal acid exposure on 24-h pH-metry (fraction of time of >5% with pH below 4).

For each symptom, the severity scores are as follows: 0 (none) = absent; 1 (mild) = symptom was not spontaneously reported but elicited upon specific questions; 2 (moderate) = symptom needs to be treated but not interfered with normal activities; 3 (severe) = symptom interfered with normal activities; 4 (very severe) = impossible to do normal activities due to symptom.

Exclusion criteria were the following: (1) acute esophagitis related to strong stimuli; (2) corrosive esophagitis by a toxicant; (3) esophagitis or some symptoms by inflammatory infection or radiotherapy; (4) regular use of H₂ blockers, prokinetic or anticholinergic agents for previous 4 wk; (5) previous gastrointestinal surgery; (6) inflammatory bowel disease; (7) cardiological, respiratory, gastrointestinal disease, endocrine metabolic disease and neuro-psychological disease; (8) clinically significant hepatic or renal dysfunction; (9) pregnancy or lack of adequate contraception in the case of women at child-bearing age; (10) patients who are inappropriate to this study by investigator's opinion.

Study procedures

This study was approved by the institutional review board of Wonkwang University Hospital and informed consent was obtained from patients for inclusion in this study. The patients were asked about basic information and previous treatment history. And they were screened as physical examination, vital sign and lab examination. Any drugs that could influence the study were postponed for at least 1 wk before that examination.

The baseline symptom of GERD was evaluated by questionnaire. Endoscopic examination was performed to check the organic lesion like cancer or ulcer, and to evaluate the severity of esophagitis. After examination, ambulatory

24-h pH-metry was carried out.

Patients who met the entry criteria were allocated randomly to 150- or 300-mg group of itopride. Fifty or 100 mg of itopride was administered thrice per day for 4 wk. After treatment of itopride for 4 wk, physical examination, vital sign, laboratory test, and symptoms of GERD were evaluated and ambulatory 24-h pH-metry was performed.

Efficacy parameters were (1) changes in acid reflux episodes measured by ambulatory pH-metry such as number of reflux episodes, number of reflux episodes lasting for more than 5 min, duration of longest episodes, % time with pH <4, and DeMeester score; (2) changes in subjective symptom of patient with GERD.

Safety parameters were (1) results of laboratory test (biochemistry, complete blood count, urinalysis and prolactin level); (2) occurrences of adverse events after the treatment. If adverse events occurred, the time of onset, duration, severity, relationship to itopride and the requirement of treatment were evaluated.

Statistical analysis

Two sample *t*-test and paired *t*-test were used for continuous variables presented as a normal distribution; Wilcoxon signed rank test and Wilcoxon rank sum test were used for those not presented as a normal distribution. And χ^2 test or Fisher's exact test was used for categorical variables. All data were statistically analyzed with SAS package (version 8.0) and differences with a value of *P*<0.05 were considered significant.

RESULTS

Patients' characteristics

The mean age and body weight of patients in 150-mg group were 44±9 years and 64±11 kg, those of patients in 300-mg group were 45±12 years and 61±12 kg. Seven were men, six were women in 150-mg group and five were men, eight were women in 300-mg group.

Baseline characteristics of patients in two groups are detailed in Table 1 and no statistical differences were noted

Efficacy of itopride on GERD symptoms

A significant improvement of all symptoms including heartburn, a main symptom of GERD, was identified after the 150 and 300 mg of itopride treatment compared with the pre-treatment (Figure 1A). No statistically significant differences were found between two groups in the symptom improvement (Figure 2B).

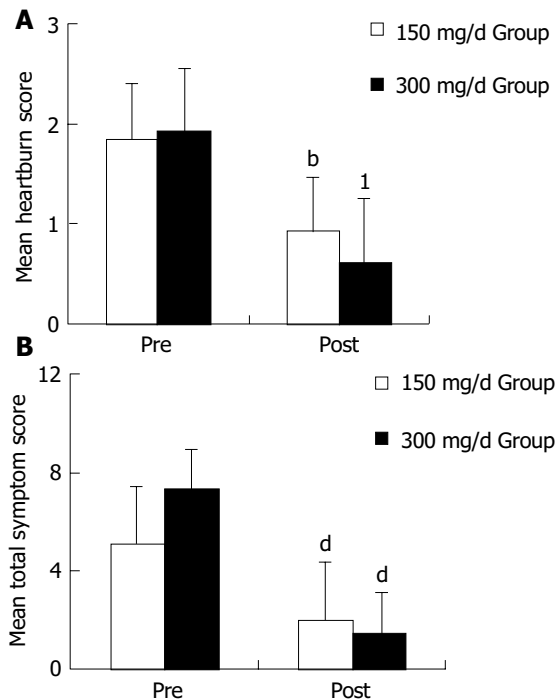

Figure 1 A: Change in mean heartburn score after treatment of itopride. The heartburn score of patients with GERD was improved in both groups of itopride significantly. ^b $P < 0.0001$, ¹ $P = 0.0006$ vs pretreatment by paired *t*-test; B: Change in mean total symptom score after treatment of itopride. The mean total symptom score of patients with GERD was improved in both groups of itopride significantly. ^d $P < 0.0001$ vs pretreatment by paired *t*-test.

Figure 2 Change in mean number of acid refluxes after itopride treatment. Mean number of acid refluxes was significantly improved in 300-mg group. ¹ $P = 0.057$ vs pretreatment by Wilcoxon's signed rank test.

Efficacy of itopride on esophageal acid reflux variables

Among the acid reflux variables recorded, total time of

pH<4, per cent time with pH<4 and DeMeester score were significantly improved in 300-mg group compared with the pre-treatment (Figure 2). In 150-mg group, itopride significantly reduced the duration of longest episode compared with the pre-treatment. The individual values of acid reflux variable before and after treatment with 150 or 300 mg of itopride are given in Table 2.

Safety of itopride

Itopride was well tolerated and only minor adverse events were reported. There were no significant changes in the mean level of prolactin with the 4-wk treatment of 150- or 300-mg itopride (Figure 3). In two patients of the 300-mg group, prolactin level was increased over 15 ng/mL, but there were no adverse events like lacteal secretion.

Figure 3 Change in mean level of prolactin after itopride treatment. The level of prolactin was not changed after treatment of itopride in GERD.

DISCUSSION

The result of this pilot study demonstrates that itopride decreases esophageal acid reflux and relieved symptoms without any significant adverse event in patients with GERD. These results show that itopride can improve the pathologic conditions of GERD.

The aims of treatment for GERD are relief of symptoms and healing of damaged lesion if endoscopic or pathologic examinations revealed mucosal damage of esophagus. Currently, it is being considered that long-term treatment is required because GERD has been regarded as chronic-relapsing disease like hypertension and diabetes mellitus^[12,13].

Among several therapeutic drugs, a prokinetic agent has been used for the treatment and improvement of pathogenic mechanism of GERD such as gastrointestinal motility disorder, incompetent LES relaxation, impaired esophageal acid clearance, and prolonged gastric emptying. Among the kinds of prokinetic drugs, many studies have focused on the effect of cisapride on GERD. In one of them, cisapride increased tones of esophageal peristalsis and LES dose-dependency in healthy subjects^[14,15]. On the contrary, in the other study, cisapride did not have any influence on the postprandial esophageal peristalsis, gastric acid^[16] and LES pressure^[17] in healthy subjects.

Even though this study does not confirm the efficacy of itopride on the esophageal peristalsis and LES, considering that itopride improves symptoms of the patients with GERD and decreases acid reflux effectively, we can speculate that

itopride exerts some effects on improving esophageal motor dysfunction. Further studies will be required for making out the effect of itopride on the esophageal motor dysfunction of GERD.

From the viewpoint of improving symptom and healing mucosa, it was observed that administration of cisapride 10 mg four times a day (q.i.d.) and 20 mg twice a day (b.i.d.) improved the esophageal reflux compared with placebo, and cisapride had the same effect as H₂ blocker on treatment of patients with mild esophagitis^[6,7]. Additionally, it was reported that a combination therapy with cisapride and H₂ blocker was more effective than monotherapy in patients with severe reflux esophagitis^[18].

Although a few studies on functional dyspepsia show that the efficacy of itopride was equivalent to that of cisapride^[11], this is the first study reporting that administration of itopride for 4 wk improves symptoms of GERD including heartburn (the main symptom of GERD) in both 150- and 300-mg group. So hereafter, additional studies will be required for evaluating the effect of itopride monotherapy or combination therapy with H₂ receptor inhibitors on the esophagitis with mucosal damage as the initial and maintenance treatment.

The most standard method to measure the variation of esophageal acid is ambulatory 24-h pH-metry. In other studies using a similar method, cisapride 10 mg q.i.d. for 8 wk was more effective than placebo in terms of decreasing the number of reflux episodes, duration of longest episode, and percent time with pH<4. These results suggest that cisapride is useful for acid reflux in patients with GERD^[19].

In the study of mosapride 40 mg every day (q.d.) for 2 d, it reduced the number of reflux episodes, the number of reflux episodes >5 min, and percent time with pH<4 and improved acid clearance time^[20]. In this study, itopride

100 mg t.i.d. for 4 wk was effective in decreasing percent time with pH<4 and DeMeester score. In this regard, it can be considered that itopride has a similar effect on decreasing acid reflux as cisapride or mosapride, although it is different in the action mechanism or duration of treatment from cisapride or mosapride^[9,10].

The action mechanism of itopride on the reflux variables is unclear so far. But, dual mechanism of itopride, acetylcholine esterase inhibitory action and antagonistic activity on dopamine D₂ receptor, which is known to inhibit activities of acetylcholine^[21], seems to make this drug effective on promoting the esophageal and gastrointestinal movement and on improving acid clearance. It has been known that the threshold of itopride to promote gastrointestinal motility is higher than that of cisapride, metoclopramide and domperidone^[8].

Prokinetic drugs that inhibit dopamine D₂ receptor may elicit some adverse events such as fatigue, confusion, extrapyramidal symptom, and hyperprolactinemia that cause lacteal secretion or breast enlargement. Although there was no extensive study concerned about safety of itopride, the development of extrapyramidal symptom or hyperprolactinemia was uncommon with the administration of usual dosage of itopride (150 mg/d). In this study, there was no hyperprolactinemia and extrapyramidal symptoms in 150-mg group of itopride and there were two cases showing over 15 ng/mL of prolactin level in 300-mg group of itopride without adverse events like lacteal secretion^[22].

Taken together, these results demonstrate that the administration of 150 or 300 mg of itopride for 4 wk improves symptoms of GERD and that the administration of 300 mg of itopride for 4 wk improves mild esophagitis and pathologic acid reflux. Therefore, itopride can be useful for treatment of the patients with GERD.

Abstract

AIM: To analyze the characteristics of multiple primary malignancies (MPMs) of digestive system; including incidence, types of tumor combinations, time intervals between development of multiple tumors, clinical course, and prognostic factors affecting survival and mortality.

METHODS: Data from a total of 129 patients treated from January 1991 to December 2000 for pathologically proved MPMs, including at least one originating from the digestive system, were reviewed retrospectively.

RESULTS: Among 129 patients, 120 (93.02%) had two primary cancers and 9 (6.98%) had three primary cancers. The major sites of MPMs of the digestive system were large intestine, stomach, and liver. Associated non-digestive cancers included 40 cases of gynecological cancers, of which 31 were carcinoma of cervix and 10 cases of genitourinary cancers, of which 5 were bladder cancers. Other cancers originated from the lung, breast, nasopharynx, larynx, thyroid, brain, muscle, and skin. Reproductive tract cancers, especially cervical, ovarian, bladder, and prostate cancers were the most commonly associated non-GI cancers, followed by cancer of the lung and breasts. Forty-three cases were synchronous, while the rest (86 cases) were metachronous cancers. Staging of MPMs and treatment regimes correlated with the prognosis between survival and non-survival groups.

CONCLUSION: As advances in cancer therapy bring about a progressively larger percentage of long-term survivors, the proportion of patients with subsequent primary lesions will increase. Early diagnosis of these

INTRODUCTION

Many types of cancer, when treated early and aggressively, can be cured. The potential, however, for cancer to occur independently a second time, or more often, in the same patients remains an ever present risk. Interest in multiple primary malignancies (MPMs) is long-standing since Warren and Gates in 1932. He proposed that each suspected primary tumor (1) must be clearly malignant as determined by histological evaluation; (2) must be geographically separate and distinct. The lesion should be separated by normal appearing mucosa. If a secondary neoplasm is contiguous to the initial primary tumor or is separated by mucosa with intraepithelial neoplastic changes, the two should be considered as confluent growth rather than multi-centric carcinomas; and (3) the possibility that the second neoplasm represents a metastasis should be excluded. The observation that the invasive carcinoma arises from an overlying epithelium, which demonstrates a transition from carcinoma *in situ* to invasive carcinoma, is helpful, and when the separate foci have significant differences in histology, the diagnosis of separate primary cancers is appropriate^[1,2].

Multiple primary cancers may be synchronous or metachronous depending on the interval between their diagnosis. Synchronous cancers are diagnosed simultaneously or within an interval of about 6 mo, and metachronous cancers are secondary cancers that developed more than 6 mo after the diagnosis of primary cancers usually after treatment of primary lesions^[2].

MPMs were classified into four types: (1) multicentric, if the two distinct carcinomata arise in the same organ or tissue; (2) systemic, if they arise on anatomically or

functionally allied organs of the same system (colon and rectum cancers), (3) paired organs, as in the breasts, and (4) random, if they occur as a co-incidental or accidental association in unrelated sites^[3].

The development of more sophisticated invasive and non-invasive diagnostic tools has made it possible to detect cancer at an early stage. Furthermore, it has contributed to the detection of synchronous occult tumors, which were formerly overlooked.

An individual developing more than one primary tumor in anatomically and functionally unrelated organs may be considered as cancer-prone. People with a family history of cancer will inherit genetic cancer susceptibility as a risk factor for cancer. Gene mutations influence cancer susceptibility through changes of metabolism and catabolism of carcinogens. Tumor suppressor genes, such as *p53* and *FHIT*, may be candidates for target genes of these risk factors^[4]. Genetic instability is also considered as a driving force behind carcinogenesis and the alterations of the length of single repetitive genomic sequences or microsatellite instability, implicating impaired DNA repair mechanism^[5]. People with newly diagnosed cancers and survivors of earlier cancers who have genetic cancer susceptibility, therefore, have an increased risk of MPMs.

This study has analyzed the incidence of MPMs in digestive system, as well as the different tumor combinations, time interval between occurrence of tumors, staging, clinical course, and prognostic features of survival and non-survival groups.

The purpose of this study is to determine whether certain organs or systems are particularly susceptible to second or third primary cancers and, by clarifying this tendency, to aid in the early diagnosis of these lesions.

MATERIALS AND METHODS

Retrospective data from a total of 9 807 patients treated at the Mackay Memorial Hospital from January 1991 to December 2000 for pathologically proven cancer were reviewed from the Cancer Registry. Of these, 246 patients had multiple primary cancers, among which 129 (58 males and 71 females) had MPMs in the digestive system and were included in this study.

The histological criteria described by Warren and Gates^[1] and Moertel *et al.*^[3], were used for diagnosing multiple separate primary malignancies.

Clinical histories, diagnostic methods, histology, staging, and clinical course of each tumor were reviewed in all patients. The age at the onset of the primary cancer and the time intervals between two or more cancers were recorded. The distribution of the digestive and associated non-digestive cancers in these 129 patients was also investigated. Fifty-two patients had received previous radiotherapy or chemotherapy for their first cancers, and interval between the first and second cancers were recorded. All tumors had been staged according to the American Joint Committee on Cancer TNM staging system^[6]. The prognostic factors between survival and non-survival groups were analyzed for double primary cancers.

The differences between groups were analyzed by Student's *t*-test for continuous variables and the χ^2 test for

categorical data. A *P* value of <0.05 was considered as statistical significance.

RESULTS

Among the 9 807 pathologically proven cancer patients, 246 had MPMs, with an incidence of 2.5%. Among these, 129 (52.43%), including 58 males (44.96%) and 71 females (55.04%), had MPMs of the digestive system. One hundred and twenty patients (93.02%) had two primary malignancies, and nine (6.98%) had three primary malignancies. The age at onset of the primary cancers ranged from 29 to 89 years (mean 60.3 ± 13.05 years) in double cancers, and 43 to 68 years (mean 50.22 ± 7.9 years) in triple cancers. Forty-three patients (35.8%) were over 65 years of age. Fifty-two patients (40.3%) had received previous radiotherapy or chemotherapy for their first cancer. The interval between the first and second cancers was 0.5-28 years (mean 8.1 ± 2.5 years) and 0.5-5 years (mean 3.2 ± 3.7 years) in the 32 patients receiving radiotherapy and the 17 patients receiving chemotherapy respectively.

The distribution and incidence of MPMs of the digestive system are shown in Table 1. The major site for MPMs of the digestive system was the large intestine (colon, 23.17%; rectum, 25.82%), followed by the stomach (23.17%) and liver (15.23%).

Distributions of associated non-digestive cancers in patients with MPMs are shown in Table 2. There were

Table 1 Distribution of MPMs in digestive tract

Site	Number of MPMs	Total number	Incidence (%)	% in GI MPMs
Esophagus	8	374	2.14	5.29
Stomach	35	1 770	1.98	23.17

40 cases (45.97%) with gynecological cancers, of which 31 cases (77.5%) were carcinoma of uterine cervix; 10 cases (11.49%) with genitourinary cancer, among which 5 (50%) had bladder cancers and 3 (30%) had prostate cancers.

The most common tumor combination in double primary malignancies (both cancers originating from the digestive tract) was colon and rectum (10 cases), as shown in Tables 5-8.

The most common tumor combination in double primary malignancies (at least one originating from the digestive system) was rectum and cervical cancer (14 cases) and shown in Table 4.

Nine patients had triple cancers (Table 9). Mean time interval between diagnosis of the first and second primary cancer was 7.2 ± 3.86 years and for the second and third cancer was 5.24 ± 3.85 years. Two out of these nine patients had initial squamous cell cancers of cervix and nasopharynx

¹Excluding double primary GI tract cancers (22 cases). (1): Primary GI tract cancer, secondary cancers of other sites. (2): Primary cancers of other sites, secondary GI tract cancers. (3): Synchronous.

and developed synchronous adenocarcinoma of rectum and colon, with disease intervals of 9.4 and 5.9 years respectively.

Most of the tumors in double or triple primary malignancies were diagnosed at stages 3 or 4. Synchronous cancers were found in 43 cases, while 86 cases had metachronous cancers, among which 13 cases developed secondary cancers more than 10 years after diagnosis of primary malignancies (Tables 3 and 10).

There were no significant differences between the survival and non-survival groups in terms of age, gender, and time interval between first and second primary cancers. However, stage of tumor, especially stages 1-3 and radical treatment regimes correlated with prognosis in these two groups.

¹Excluding triple primary cancers nine cases. ²Radical treatment includes radical surgery±radiotherapy±chemotherapy. Palliative treatment includes palliative surgery±radiotherapy±chemotherapy. ^aP<0.05, ^bP<0.01 vs others.

DISCUSSION

The presence of a single tumor does not offer immunity against the development of second, third, or additional

primary malignant lesions in the same patient. Multiple primary malignant tumors in the same individual are experienced more frequently as advances in cancer treatment prolong life. Improved survival rates for patients with neoplastic disease, largely due to early diagnosis, allow more patients to survive long enough to develop subsequent primary tumors.

The incidence of MPMs has been carried out by the review of cancer registries in several countries, and ranged from 0.7 to 11%^[7-10]. In our study, the incidence of MPMs was 2.21%, which was similar to the 2.6% as reported by Okamoto *et al.*^[11].

In our study, the major site of MPMs in the digestive system was the large intestine, followed by stomach and liver. Cancers of the large intestine, particularly hereditary nonpolyposis colorectal cancers, were associated with increased frequencies of endometrial and ovarian cancers^[12]. However, MPMs of large intestine in our study were most commonly associated with carcinoma of cervix (17 cases) and stomach (8 cases), while only two were associated with carcinoma of endometrium and six were with ovarian cancers. The significance of these differences may be due to the fact that carcinoma of cervix is much more common than endometrial cancer in our country. Unfortunately, no genetic evaluation was performed in our patients.

The predilection of MPMs for the large intestine is noted in numerous reports in the literatures^[13-15]. In our series, 49 of 129 patients (37.98%) had colorectal malignancy as the first primary lesion. Of these, seven (14.28%) had a second primary cancer in the colon or rectum and four (8.16%) had a second primary cancer in the stomach. The interval between the diagnosis of the first primary colorectal cancer and the development of the second colorectal carcinoma averaged 7 years, and ranged from 1½ to 14 years. This suggests that patients without evidence of disease for 5 years after operation of colorectal cancers still require careful follow-up studies of gastrointestinal tract.

Genitourinary cancers, especially cervical and ovarian cancers, bladder and prostate cancers were the common associated non-GI cancers, followed by cancers of lung and breast. Thus, attention should be paid to these sites during the period of post-operative follow-up of the first primary cancer.

The majority of MPMs may occur as a result of random chance^[16]. Nonetheless, different mechanisms have been considered to be involved in MPMs, such as intense exposure to carcinogens, the effects of chemo- and/or radiotherapy and the influence of genetic predisposition.

Both the chemo- and radiotherapy have been shown to be carcinogenic in several reports^[17,18]. In our study, 52 patients (40.3%) had received previous radiotherapy or chemotherapy for their first cancer, and the interval between the first and second cancers was 0.5–28 years (mean 8.1 years) and 0.5–5 years (mean 3.2 years) in the 32 patients receiving radiotherapy and the 20 patients receiving chemotherapy respectively. This suggests that radiotherapy and/or chemotherapy may play an important role in the development of MPMs.

The main problem in proving a correlation between antineoplastic therapies and secondary cancer may be

attributable to detection bias rather than to carcinogenic therapy^[19]. Beyond an increased zeal in searching, diagnostic agents and methods have improved such that the detection of cancer today is enhanced by improvements in technology, cytogenetics, and surveillance.

Based on a pooled analysis involving 316 relatives of 12 families, Lynch *et al.*^[20], have demonstrated a 21.5% incidence of MPMs, a consistent 3% risk for a second primary cancer in each year of survival following the first onset, and a significantly higher 6.9% risk per year for the development of a third primary cancer following the second neoplasm.

In our study, there were no significant differences between the survival and non-survival groups in terms of age, gender, and time intervals between first and second primary cancers. Only stage of tumors, especially stages 1-3, and radical treatment regimes correlated with prognosis in these two groups.

Two important inferences can be obtained from our analysis: (1) the early diagnosis of a second primary lesion may alter survival rate. Hence more intensive surveillance and appropriate cytogenetic and molecular studies should be developed in order to improve strategies to detect MPMs, and (2) multidisciplinary treatment strategies are important to ameliorate quality of life and survival rates in patients with MPMs.

It is fundamental that patients who have been treated for cancers require careful follow-up studies. When symptoms and signs of tumor develop in a patient who has been treated for an initial cancer, they should not be assumed to represent metastases. The possibility of a localized and curable second primary cancer should be considered and evaluated. As advances in cancer therapy bring about a progressively large percentage of long-term survivors, the proportion of patients with subsequent primary lesions will increase. Early diagnosis of these lesions, based on an awareness of the possibility of second and third cancers, and multidisciplinary treatment will substantially increase the survival of these patients.

Abstract

AIM: To outline the surgical experience with donor liver splitting in split liver transplantation.

METHODS: From March 1 to September 1 in 2004, 10 donor livers were split *ex situ* into a left lateral lobe (segments II and III) and a right extended lobe (segments I, IV-VIII) in Medical School of Hannover, and thereafter split liver transplantation was performed successfully in 19 cases. The average age, weight and ICU staying period of the donors were 32.7 years (15-51 years), 64.5 kg (45-75 kg) and 2.4 d (1-8 d) respectively.

RESULTS: The average weight of the whole graft and the left lateral lobe was 1 322.6 g (956-1 665 g) and 281.8 g (198-373 g) respectively, and the average ratio of left lateral lobe to the whole graft was 0.215 (0.178-0.274). The average graft to recipient weight ratio (GRWR) of the left lateral lobe and the right extended lobe reached 2.44% (1.22-5.41%) and 1.73% (1.31-2.30%) respectively. On average it took approximately 105 min (85-135 min) to split the donor liver. Five donor organs showed anatomic variation including the left hepatic vein variation in two cases, the left hepatic artery variation in two cases and the bile duct variation in one case.

CONCLUSION: Split liver transplantation has become a mature surgical technique to expand the donor pool with promising results. In the process of graft splitting, close attention needs to be paid to potential anatomic variations, especially to variations of the left hepatic vein, the left hepatic artery, and the bile duct.

INTRODUCTION

Orthotopic liver transplantation (OLT) has been widely accepted as an effective treatment for end-stage liver diseases. The advent of new immunosuppressive agents and refinement of the surgical techniques have accounted for remarkable progress in the years since the first OLT was performed in 1963. Thousands of patients who would have died otherwise have been saved by the improved results of organ transplantation. However, the past two decades have also witnessed an exceptional increase in the number of patients awaiting liver transplantation, and the ever-growing great disparity between demand and supply of donor organs has become the major limiting factor for further expansion of liver transplantation. Hence, a death rate on the waiting of 10-15% would even be underestimated^[1]. Historically, the situation has been worse for children because of the difficulty of finding size-matched donor organs^[2]. However, the development of a reduced-size liver transplant technique has provided a first step to alleviate this problem^[3-5]. Although such technique does not increase the number of grafts available, it shifts available organs from adult to pediatric recipient. Obviously, split liver transplantation, first successfully performed in the Medical School of Hannover^[6], is becoming an efficient approach to expand the donor pool for both adults and children.

MATERIALS AND METHODS

From March 1 to September 1 in 2004, a total of 10 donor livers were split *ex situ* in Medical School of Hannover. All these donor livers were divided into a left lateral lobe (segments II and III) and a right extended lobe (segments I, IV-VIII), and thus making available split liver transplantation to 19 patients (in 6 cases the right extended lobe was sent to another transplantation center). The average age and weight of those 10 brain death donors were 32.7 years (15-51 years) and 64.5 kg (45-75 kg) respectively. Before the organ procurement, the average ICU stay of the donors was 2.4 d (1-8 d), and the average serum level of AST, creatinine, sodium and total bilirubin was 53.0 IU/L (14-122 IU/L), 0.91 mg/dL (0.40-1.25 mg/dL), 148.5 mmol/L (137-158 mmol/L), and 0.70 mg/dL (0.09-1.60 mg/dL) respectively.

Ten pediatric patients, three boys and seven girls, received left lateral lobe liver transplantation. The average age and weight of the pediatric recipients were 48.1 mo (5-82 mo) and 14.3 kg (6.9-23.8 kg) respectively. Indications included seven cases of congenital biliary atresia (one child receiving liver re-transplantation due to chronic rejection after the first transplant), two cases of progressive familial intrahepatic cholestasis and one case of acute liver failure. Nine adult or adolescent patients, five males and four females, received right extended lobe liver transplantation. The average age and weight of the adult recipients were 30.7 years (10-49 years) and 64.1 kg (39.9-88.5 kg) respectively. Indications included four cases of postnecrotic cirrhosis, two cases of primary sclerosing cholangitis, one case of Wilson's disease, one case of autosomal recessive polycystic kidney deficiency combined with liver fibrosis, and one case of acute liver necrosis caused by ligation of the hepatic artery due to rupture of the hepatic arterial aneurysm. Two patients were emergency cases, one due to postnecrotic cirrhosis and the other due to acute liver necrosis (Tables 1 and 2).

The key to successful liver division is to share vascular and biliary structures between the two sides but without handicapping either, and preferably to provide either graft with single first order arterial and biliary elements. Normally, the inferior vena cava, the common bile duct, and the main trunk of the portal vein as well as the hepatic artery are preserved for the right extended graft. We emphasize on performing dissection of the hepatic hilum only from the left side and always keeping the right side untouched, the steps of *ex situ* splitting the donor liver into a left lateral lobe and a right extended lobe were described briefly as

follows: (1) completing the conventional bench hepatic graft preparation and resecting the gallbladder, briefly checking the portal vein, the hepatic artery, the bile duct, and the hepatic vein; (2) exposing the left hepatic artery and identifying the segment IV artery, and then transecting the left hepatic artery distally to the origin of segment IV artery; (3) isolating and transecting the left portal vein, and ligating the branches supplying segment IV originating from left portal vein; (4) splitting the liver parenchyma step by step along with umbilical scissure from downward to upward, and the various tiny vessels and bile ducts handled with ligation or metal clips; (5) exposing the left hepatic vein when dividing close to suprahepatic inferior vena cava, and then transecting the left hepatic vein leaving a suitable stump; (6) finally transecting the bile duct connecting the two parts of donor liver; and (7) injecting cold preservation solution via portal vein, hepatic artery as well as bile duct to check for leaks. None of these 10 cases of donor livers was applied cholangiography or angiography in the process of splitting.

RESULTS

All the 10 donor livers were split successfully into a left lateral lobe (segments II and III) and a right extended lobe (segments I, IV-VIII), and subsequently split liver transplantation was performed in 19 cases. The average weight of the whole graft before splitting was 1 322.6 g (956-1 665 g), and the average weight of the left lateral lobe and the right extended lobe after splitting was 281.8 g (198-373 g) and 1 075.8 g (726-1 299 g) respectively. The average ratio of left lateral lobe to total graft was 0.215

The right extended lobe from case 6 was sent to the other center.

(0.178-0.274). The average GRWR of the left lateral lobe and the right extended lobe reached 2.44% (1.22-5.41%) and 1.73% (1.31-2.30%) respectively. The average weight ratio of donor to pediatric recipient was 5.47 (2.52-10.87). The average time required to split the donor liver was 105 min (85-135 min).

A total number of five anatomic variations occurred in the process of graft splitting. The left hepatic vein variation occurred in two cases, where the segment II hepatic vein, the segment III hepatic vein and the middle hepatic vein draining separately into inferior vena cava appeared to be a trifurcation at the junction. In order to obtain a sufficiently long left hepatic vein, some part of the lateral wall of the middle hepatic vein and suprahepatic inferior vena cava was sacrificed, the defect was repaired with part of donor common iliac vein (Figures 1 and 2). Two donor organs had anatomical variations of the left hepatic artery. In one case with the segment IV artery arising very distal from the left hepatic artery, only 3 mm of the common trunk of segments II and III arteries could be obtained after painstakingly dissecting the liver parenchyma of the left lateral lobe. There was one case where the replaced left hepatic artery originated from the left gastric artery (Figure 3). Although partial blood supply of the segment II liver from the segment IV artery could be identified, the diameter of this branch was less than 2 mm with quite good backflow under perfusion, consequently no reconstruction was required. Finally there was the anatomical bile duct variation. In this case the union of segments II and III bile ducts was right to the umbilical fissure resulting in two separate

openings of bile duct on the cutting surface of left lateral lobe. Fortunately in this case the distance between the two bile duct openings was quite close and in the shape of a figure '8'; therefore, one opening could be achieved by plastic reconstruction (Figure 4).

DISCUSSION

Pichlmayr *et al.*^[6], reported the first clinical attempt of split liver transplantation in 1988, and 1 year later Bismuth *et al.*^[7], described two patients with fulminant hepatic failure, each receiving a split graft. In 1990, Broelsch *et al.*^[8], presented the first series of 30 split liver transplantations in 21 children and 5 adults. In this early experience, patient survival was inferior to that reported in series of cadaveric whole-size orthotopic liver transplants. Despite skepticism as to the lasting role of split liver transplantation, several European centers, faced with an increasing waiting list of death rate due to the scarcity of donor organs, pursued the split liver options. In 1995, the results of a collective experience of 50 donor livers, providing 100 grafts during a 5-year period from the European Split Liver Registry^[9] demonstrated no significant difference when compared to conventional whole-sized OLT during the same period.

With the present improved surgical techniques, it is commonly acceptable to split the donor liver into two transplantable grafts, one for a pediatric and the other for an adult recipient. A series comprising 110 consecutive split liver transplantations in 55 adults and 55 pediatric recipients showed that patient survival of split liver transplantation

Figure 4 Appearance after plastic reconstruction of separate openings of segments II and III bile ducts nearby.

was not significantly different from whole-organ OLT^[10]. Similar results are also reported by Broering *et al.*^[11]. Such view is strongly evidenced by more and more current clinical data^[12-15]. Our experience with more than 150 cases of split liver transplantation since 1988 has confirmed these results. Between 1993 and 1999, split liver transplantation activities increased in central Europe from 1.2% to 10.4%^[16]. Currently split liver transplantations make up more than 20% of all liver transplantations performed at the Medical School of Hannover. With the refinement of surgical skill, split liver transplantation could even be applied in the cases of retransplantation and emergency.

What kind of donor liver is suitable for splitting calls for thorough consideration and evaluation whenever an organ donor is available. Besides meeting the basic prerequisites regarding the donor livers, the following factors are worth to be considered based on our experience and opinions from other authors^[10,11,17]: (1) a donor age below 50 years and above 10 years; (2) hemodynamic stability, if in use of vasopressor, maintaining good blood pressure at least; (3) the preferable donor ICU stay less than 5 d; and (4) no status of hypernatremia, a serum sodium concentration of <170 mmol/L or even better <150 mmol/L. Although donor parameters are critical when selecting livers for a splitting procedure, the experience accumulated over the years clearly indicates that the most reliable basis for the decision on splitting is the judgment of an experienced transplant surgeon. Microscopic examination should become a kind of supplement to macroscopic observation. It is pivotal to scrutinize whether the donor liver has a soft consistency, a sharp edge and is well perfused. One has to appreciate the frank remark of Busuttill on criteria for splittable donor livers^[10]: "I think that the ultimate exclusion criterion is when you go and look at the liver, if the liver does not look good, you do not split it."

With the current technique, it is quite reliable to split a donor liver into a left lateral lobe (segments II and III) and a right extended lobe (segments I, IV-VIII) for one child recipient and one adult recipient. Our results confirmed that the right extended liver lobe would account for about 80% of the standard volume in humans, and can be allocated like a full-size liver if careful consideration is given to recipient selection^[18]. Actually in our group the maximum weight of recipients was up to 88.5 kg with satisfactory outcome of transplantation. In this study, the average GRWR of the right extended lobe was 1.73%. For the right extended lobe graft 1% GRWR is sufficient for the low risk recipient in stable condition and good nutritional status. However, GRWR should be not less than 1.5% for the high risk recipient with decompensatory liver function and severe portal hypertension^[19,20]. For the left lateral lobe graft the ideal weight ratio of donor to child should be 3-10 times.

Compared to splitting liver into a full left lobe and a full right lobe^[21,22], fewer anatomical variations might occur when splitting liver into a left lateral lobe and a right extended lobe. Nevertheless, it is crucial for the success of the subsequent liver transplantation how the various potential variations are handled in the process of splitting. Considering that the left liver lobe is more constant regarding anatomical variations,

it can be said that the more one stays on the left, the fewer anatomical variants one is confronted with.

In most of cases, the left hepatic vein joins the middle hepatic vein, thus forming the common trunk entering the antero-left surface of the inferior vena cava^[23]. Instead of joining the segment II hepatic vein to form the left hepatic vein, the segment III hepatic vein seldom joins the middle hepatic vein individually with the probability for about 5-10%. The diameter of the extrahepatic portion of the left hepatic vein is around 10 mm, and the smaller diameter less than 7 mm is sufficient to suspect such circumstance. In the present study, left hepatic vein variation occurred in two cases, the segments II and III draining of hepatic veins appeared with the middle hepatic vein as a trifurcation. Under certain circumstances, the dividing line needs to be moved slightly to the right slightly in order to guarantee one venous drainage from the graft of left lateral lobe. The defect of middle hepatic vein and inferior vena cava could be repaired by the common iliac vein from the donor.

Intrahepatic portal venous variations can be seen in approximately 20% of the population^[24]. However, unless the rare absence of a portal vein bifurcation with only 0.9% possibility, will it become the contradiction of graft splitting. In the majority of cases the portal vein inflow to segment IV is accomplished by the left umbilical section of the left portal vein. However, those branches originating from umbilical section will inevitably be transected. Fortunately, in most cases the additional portal vein branches to segment IV arising from the portal vein bifurcation and the right portal vein could be expected. By preserving these veins and moving the transection line to the left, partial portal vein supply to segment IV can be achieved.

Variations of the hepatic artery are comparatively frequent^[25]. Only 50-70% of livers present with "normal" anatomy^[26,27]. If the left main hepatic artery originates from the left gastric artery (10-15%) both the length and the diameter of this artery would be adequate for the anastomosis in the recipient. Such a situation occurred in one case. Although one branch from the segment IV artery supplying segment II could be identified, no reconstruction was required with small diameter and good backflow under perfusion. Since in most cases the portal vein supply to segment IV has to be sacrificed in the process of splitting, arterial supply will largely determine survival of this segment, and therefore, every effort should be made to preserve the segment IV artery. In most cases the segment IV artery originates from the left hepatic artery, and its origin should have some distance to the union of segments II and III arteries. The segment IV artery rarely arises far distal from the left hepatic artery, and the three arteries of segments II, III, and IV might form a trifurcation at their origins. A similar situation occurred in one of our cases when with painstaking efforts only a length of 3 mm of the common trunk of segments II and III arteries could be obtained at last. In case the segment IV artery has to be cut down, it is suggested to anastomose it with the stump of the left hepatic artery on the backtable.

Close attention should also be paid to variations of bile ducts. During the initial period of left lateral split liver transplantation, many groups isolated the main left hepatic

duct next to the main bile duct bifurcation when harvesting the left lateral lobe, in order to create a nice bile duct stump for anastomosis. However, this technique seems to be associated with a high rate of biliary complications on both grafts for the following reasons. First, leaving the long stump of bile duct with the left lateral graft might result in ischemic necrosis due to damaging the parabiliary vascular plexus in the isolation of the left hepatic duct^[8]. Second, a high incidence of damage to the segments I and IV bile duct of the right extended graft might occur with such a method^[28]. Therefore, we kept the connective tissue surrounding bile ducts untouched, and only used a metal probe or Arrow[®] catheter to identify the trend of bile duct, and transected bile duct as the last step of the whole splitting procedure. Although in 15% of donor livers the union of segments II and III bile ducts is located right to the umbilical fissure, which means two separate openings of bile duct appear on the cutting surface of the left lateral graft, we would still rather keep the transecting line curving a little to the left in order to retain an undamaged segment IV bile duct. If the distance between two separate bile duct openings is quite close, they might be merged into one through plastic reconstruction.

Undoubtedly, split liver transplantation has become a well-established approach to extend the donor pool for both pediatric and adult patients. Careful donor and recipient selection, good knowledge of the liver anatomy, excellent surgical skills and meticulous postoperative management all contribute to the success of each case of split liver transplantation.

Abstract

AIM: Proteolytic degradation of the extracellular matrix facilitates cancer invasion and promotes metastasis. The study aims at evaluation of preoperative and postoperative serum cathepsins B and D levels in correlation with selected anatomoclinical features of colorectal cancer.

METHODS: Blood samples were collected from 63 colorectal cancer patients before curative operation of the tumor 10 d later. Blood that was obtained from 20 healthy volunteers, served as a control. The activity of cathepsin B was measured with Bz-DL-arginine-pNA as a substrate at pH 6.0, while cathepsin D activity was determined with urea-denatured hemoglobin (pH 4.0).

RESULTS: The preoperative and postoperative activities of cathepsin B were significantly ($P < 0.00001$) lower in serum of colorectal cancer patients than in control group. However, postoperative values of this protease were significantly increased in comparison with preoperative ones ($P = 0.031$). Activity of cathepsin D appeared to be significantly higher in colorectal cancer sera ($P < 0.00001$) compared with controls. No statistically significant differences between preoperative and postoperative activity of cathepsin D were noted ($P = 0.09$). We revealed a strong linkage of cathepsins' levels with lymph node status and pT stage of colorectal cancer.

CONCLUSION: Blood serum activities of cathepsin B and D depend on the time of sampling, tumor size and lymph node involvement. Significantly, increased activity of cathepsin D could indicate a malignant condition of the large intestine. In our work, the serum postoperative decrease of cathepsin B activity appears as an obvious concomitant of local lymph node metastasis-the well-known clinicopathological feature of poor prognosis.

INTRODUCTION

Normal cells undergo several changes to converse into invasive malignant clones with metastatic capability. Progress of these alternations is manifested in distinguishable histological and temporal stages-for instance: normal tissue, hyperplasia with a high incidence of proliferating cells, dysplasia with the induction of angiogenesis that precedes following metamorphosis of observed cell clusters into tumors with metastasis. Analysis of the subsequent stages of tumor progression has provided a multistage theory of carcinogenesis on the basis of genetic changes that include activation of oncogenes, inactivation of tumor suppressor genes, and altered expression of tumor-associated molecules.

Cellular transformation provokes tissue remodeling inside neoplastic lesions and in the periphery of the tumor. Disorders in stroma or extracellular matrix (ECM) play an essential role in cancer progression. It is suggested that perturbation of the tissue microenvironment may be sufficient to induce tumor formation. Moreover, local carcinomatous invasion and metastasis also require the destruction of the EMC during local dissemination of malignant cells, angiogenesis, intravasation and extravasation. These processes are enabled by multiple degradation of stromal structure which is achieved due to cooperation of various specific intra- and extracellular proteases. Lysosomal aspartyl and cysteine enzymes-cathepsin D and B are the most important of intracellular proteases that participate in stromal destruction, which facilitates tumor invasion of deeper tissue layers^[1]. These enzymes can act directly by proteolysis of EMC components or indirectly by costimulation of a cascade of other proteases such as metalloproteases or elastase, which then decompose protein elements of the EMC and basal membranes. This stromal disarrangement allows migration of malignant cells to different regions and compartments of the human body, what accelerates tumor growth and favors metastasis. Not only does overexpression of cathepsin B and D in cancer cells reflect intensity of

neoplasm development, but also increased serum activity of mentioned proteases does the same as well. Apart from mentioned functions, independently of its catalytic activity human cathepsin D stimulates tumor growth as a direct or indirect mitogenic factor for cancer cells^[1]. Cathepsin D affects tumor angiogenesis in a mysterious way. It was suggested that cathepsin D might favor angiogenesis by releasing ECM-bound bFGF^[2]. Suggestions of its proangiogenic function contrast with the fact that pro-cathepsin D is responsible for the generation of specific inhibitor of angiogenesis-angiostatin^[3]. Now it is presumed that cathepsin D may stimulate endothelial cell growth via a paracrine loop, acting as a protein ligand, by directly or indirectly triggering a yet unidentified cell surface receptor^[4].

Increased expression, enhanced secretion and cell surface association of cathepsin B were found in different types of tumor cells especially in their more malignant variants^[5]. Last studies have revealed that augmented production and release of cathepsin B in tumor cells lead to tumor cell growth, invasion and metastasis^[6]. This cathepsin may act at the contact regions of tumor cells and basement membrane or interstitial stroma. Low pH is necessary for activation of secreted precursors to active forms, which degrade the protein components of basement membranes and interstitial connective matrix including laminin, fibronectin, elastin, and various types of collagen^[7]. Cathepsin B split fibronectin into smaller parts and change conformation of this protein components. In such a way the CS-1 sequence and alternatively spliced type III connecting segment (IIICS) are uncovered, exposed and recognized by the integrin $\alpha_4\beta_1$ -receptor^[8]. Thereby, cathepsin B may be involved in cellular signal transduction beside extracellular protein degradation.

Therefore, the aim of this work was to investigate the activity of lysosomal proteases-cathepsin B and D in blood serum and their potential impact on cancer progression and metastasis in cases of colorectal cancer.

MATERIALS AND METHODS

The study included 63 patients (42 men and 21 women) with a mean age of 64 years that were required to undergo a colorectal cancer operation. Thirty tumors were located in the rectum and 33 were found in the colon. The patients had no preoperative chemo- or radiotherapy. All the patients were monitored after the operation. Two independent pathologists assessed conventional histopathological parameters (including AJCC/UICC TNM stage, tumor type and grade of differentiation). Differentiation and histological type of the tumors was determined following the World Health Organization guidelines. Fifty-eight colorectal cancers were classified histopathologically as adenocarcinoma and 5 as mucinous adenocarcinoma: 43 cases with G2 grade and 15 cases with G3 grade. Because of too small a number of tumors that were classified as pT1, pT2 and pT4 patients were divided into two groups: five tumors comprised pT1+pT2 group and 53 cancer cases belonged to pT3+pT4 group. Forty-six percent patients had involved lymph nodes at the time of diagnosis.

Biochemical analysis

The blood samples were collected from colorectal cancer

patients twice: before and 10 d after the curative operation. The blood was centrifuged at 4 °C and the serum samples were stored at -80 °C until examination. The control group included of 20 healthy volunteers (12 men and 8 women) with a mean age of 59 years. The control blood samples were collected only once. Serum was gained from collected blood and the activity of cathepsin B was determined with Bz-DL-arginine-pNA as a substrate at pH 6.0^[9], while the cathepsin D activity was measured with urea-denatured hemoglobin (pH 4.0)^[10].

RESULTS

The preoperative and postoperative activities of cathepsin B were significantly ($P < 0.00001$) smaller than in control group. However, postoperative values of this protease were significantly increased in comparison with preoperative ones ($P = 0.031$). On the other hand the activity of aspartyl protease-cathepsin D appeared to be significantly higher ($P < 0.00001$) in comparison with the control group data. In addition, no statistically significant differences between preoperative and postoperative activity were noted ($P = 0.09$, Table 1).

Table 1 Activity of cathepsin B and D in serum of patients with colorectal carcinoma

	Healthy people (n = 20)	Control serum	66.9±2.8
	Colorectal patients (n = 63)	Before operation1 (serum sample a) After operation (serum sample b)	7.9±8.5 ^{1b} 21.0±8.7 ^f
Cathepsin B nmolPNA/mL			
	Healthy people (n = 20)	Control serum	30.2±2.2
	Colorectal patients (n = 63)	Before operation (serum sample a) After operation (serum sample b)	58.7±24.2 ^{2d} 49.9±16.9 ^b
Cathepsin D nmol Tyr/mL			

Statistical differences: ¹ $P = 0.031$ -comparison between cathepsin B serum samples a and b. ² $P = 0.09$ -comparison between cathepsin D serum samples a and b. ^b $P < 0.00001$, ^d $P < 0.00001$, ^b $P < 0.00001$, ^f $P < 0.00001$ vs control serum.

We revealed a strong linkage of cathepsins' levels with lymph node status and pT stage of colorectal cancer. As referred to TNM classification, patient group of pT1 and pT2 tumors showed significantly higher preoperative serum activity of cathepsin B than it was detected in preoperative serum of patients with tumors classified to pT3 and pT4 group ($P = 0.0057$). This trend of differences was not apparent enough to reach a level of statistical significance in case of postoperative serum values of cathepsin B. We assume that statistical significance could not be achieved in analysis of homologous postoperative data because of wide variation of postoperative cathepsin B values in set of patients with pT1 and pT2. Similarly values of cathepsin D before operations (serum sample A) were more increased with nearly statistical significance in pT1 and pT2 vs pT3 and pT4 groups respectively ($P = 0.053$).

As shown in Table 2, node-negative (N-) colorectal cancer patients displayed significantly higher postoperative

serum levels of cathepsin B in opposition to patients with lymph node involvement (N+) ($P = 0.0054$). These groups of patients did not significantly differ in cathepsin B levels before operation. We drew out a similar comparison between activities of cathepsin D in node negative and node positive sets of colorectal cancer-but inversely to cathepsin B-remarkable distinction of cathepsin D serum levels appeared before surgery. Namely, the preoperative serum activity of cathepsin D was increased in node negative (N-) *vs* node positive (N+) colorectal cancer patients with statistical significance ($P = 0.019$).

DISCUSSION

Cancer development is characterized by severe disarrangement of the intra- and extracellular metabolism and structural alterations. Cancer cells overexpress and secrete a large proportion of lysosomal proteases-cathepsins. The activity increase of cathepsin B and D was discovered to be statistically significant in both the neoplastic tissue cytosol and homogenate, compared to the cytosol and homogenate of adjacent healthy tissue^[11]. Marked tissue immunoreactivity of cathepsin B and D takes place in carcinoma of uterus, ovary, lung, intestines and many other organs^[12-15]. Moreover, it was reported that tumor cell lines secrete cathepsin B and D^[16]. On the other hand it was reported that serum cathepsin B level did not differ significantly both in benign and malignant neoplasms of ovaries^[17]. In cancers there was elevated serum value of cystatin C in comparison with benign ovarian tumors and controls, which negatively affected the amount of cathepsin B. However, ovarian cancer cells are strongly positive for cathepsin B in immunohistochemical analysis, while benign ovarian tumors lacked any positive reaction of this kind^[17].

It is suggested that colorectal cancer development is enhanced by oxidative stress. Oxidative stress is maintained as the effect of excessive concentration of lipid hydroperoxides in the vascular net and their participation in the oxidant generation. The other possible explanation might be overproduction of oxidants by inflammatory and/or cancer cells and suppression of antioxidant system in cancer cells. In these conditions free radicals may enhance lipid peroxidation.

Products of this process are responsible for membrane alteration. Reactive oxygen species cause protein damage and as a result changes in biological function of active proteins and membrane permeability for intracellular compounds may appear due to increased susceptibility for drugs that induce apoptosis of neoplastic cells^[1,18]. It may explain translocation of cathepsins from lysosomes via cytosol and cellular membrane into body fluids.

As we have demonstrated in our previous works, generation of free radicals accompanies the development of cancer^[18]. Reactive oxygen species cause an oxidative damage of cell membranes which results in an increase of membrane permeability. That implies influx of cathepsin D to extracellular fluid. Therefore, elevated activity of cathepsin D is observed in the serum as an evidence for impairment of general cellular functions like maintenance of the barrier between intracellular and extracellular environment. Advancement of tumor growth and neoplastic spreading across the whole organism seem to reflect the severity of cellular damage. Cathepsin B -cysteine protease is so sensitive to free radicals, that the latter probably inactivate cathepsin B. Thereby it would explain why serum activity of cathepsin B is lower in serum of patients with colorectal cancer in comparison to serum values of this protease in healthy volunteers. Production of free radicals is upregulated and activity of cathepsin B falls down along with the enlargement of tumors and neoplastic extent into lymph nodes. This statement is supported by our present study in which we detected lower levels of cathepsin B in group pT3 and pT4 *vs* pT1 and pT2 as well as in node positive (N+) *vs* node negative (N-) patients after surgery. Total resection of cancer could contribute to limit ROS generation and by means of the inactivation of cathepsin B, ROS generation was reduced enough which is shown in the results obtained.

The concentrations of cathepsin B and D were increased also in the blood serum of patients with other carcinomas^[19-21]. Additionally, the increase of cathepsin B correlated with the advancement of cancer assessed with Duke's scale. Moreover patients with both elevated levels of cathepsin B and CEA were classified as the group of poor prognosis^[20]. Nevertheless, in our present investigations, we discovered

only the increase of cathepsin D while levels of cathepsin B were decreased in sera of colorectal cancer patients.

Overexpression of cathepsins may prelude the loss of integrity of ECM protein components. It is known that cathepsin D as endopeptidase degrades ECM proteins and proteins of the basal epithelium as well as many intracellular and endocytosed proteins. It occurs mainly in phagosome-like acid vesicles with acidic pH where EMC components are trapped^[22]. Cathepsin D may cooperate with cathepsin B in the process of proteolysis and cancer progression. Cathepsin D probably activates cysteine procathepsins B and L^[23]. Cathepsin B activates the urokinase-type plasminogen which can subsequently activate the plasmin-metalloproteinases proteolytic pathway^[24,25]. Moreover, cathepsin B may change the balance of metalloproteinases and their inhibitors and directly cleave and inactivate some of MMPs inhibitors -TIMP-1 and TIMP-2^[26]. In such a way cathepsin B assists tumor cells in their detachment from ECMs and metastasis. Furthermore during proteolysis of interstitial extracellular structure some ECMs-bound growth factors, e.g. bFGF, EGF, TGF- β , IGF-I and VEGF, may get free from their chains of connections to the matrix and thanks to the fact that they can escape to join suitable receptors of stromal and tumor cells which indicates their bioavailability for growth modulation^[27].

Cathepsin B can multiply the effect of protein digestion and disarrangement by triggering trypsinogen activation^[28]. Lysosomal cathepsin B activates trypsinogen *in vitro* and the intensity of trypsinogen activation improves with acidic pH^[15,29]. Human trypsinogen is produced on a wide scale by human colorectal cells^[30]. Anyway further findings in colon cancer cell lines suggest that this production is limited only to such trypsin levels that are enough to activate PAR-2 receptor on the same cancer cells in possible autocrine/paracrine manner^[31]. It is worth mentioning that trypsin triggers matrilysin (matrix metalloproteinase-7) activity. So it is an important factor of colorectal cancer progression as immunohistochemical labeling of trypsin correlated with the depth of carcinomatous infiltration, lymphatic and venous involvement, metastasis, recurrence and shorter overall survival of patients^[32]. In our study the activity of cathepsin B could be insufficient to recruit trypsinogen activation in volume that would significantly affect tumor invasion as we detected lower cathepsin B activities in colorectal cancer compared with healthy volunteers.

The role of cathepsin B is supposed to be diverse. Namely, it can promote neoplastic invasion by lysis of EMC protein nets. Furthermore, by paracrine loop, it could cause death of neighboring cancer cells directly by proteolytic damage of cell membranes and changes in structure superficial cell receptors. Indirectly cathepsin B might act as TNF- α -induced apoptotic second messenger that mediates damage of mitochondria and release cytochrome c from these organelles^[33]. Thus, the components of cellular producer cathepsin B can be responsible for harmful suicidal injury. It can explain why higher serum levels of cathepsin B were associated with smaller size of tumor.

Cathepsin comes from two kinds of cells: carcinomatous ones and inflammatory cells that constitute immunologic response to neoplasm. According to our present results, we

suspect that along with progression of colorectal cancer, inflammatory cells might become significant producers of cathepsins. We observed lower activity of cathepsins in cases of larger tumors (pT3 and pT4 group) in comparison with smaller ones (pT1 and pT2 group) in measurements before surgery. The cause of it, can be a more escalated immunologic reaction in the onset and early stages of cancer than in advanced and late phases of neoplastic disease. Simultaneously, the outflow of cathepsins into extracellular environment destroys stromal protein structure, which is suspected to facilitate neoplastic spreading, but on the other hand, it can influence the vitality of cancer cells. So cathepsins particularly cathepsin B (probably in lower concentrations that do not induce trypsinogen activity) may disable neoplastic cells in such a way that they cannot forcibly invade surroundings despite promoting invasion by proteolysis of the interstitium. This action of cathepsin B is presumably responsible for relatively higher postoperative levels of serum cathepsin B in case of node negative patients *vs* node positive ones.

Blood serum activity of cathepsin B and D depends on the time of sampling, tumor size and lymph node involvement. Significantly increased activity of cathepsin D could indicate malignant colorectal condition. However, decreased activity of cathepsin B indicates that also different mechanisms besides proteolytic ones, participate in cancer invasion and metastasis. In comparison with analogous higher activity in node negative colorectal cancers, the significant downfall of postoperative cathepsin B activity coexisted with cancerous node involvement. Therefore, in our work, the decrease of this serum protease levels appears as an obvious concomitant of local lymph node metastasis the well-known clinicopathological feature of poor prognosis.

Abstract

AIM: Although the radiological features of acute appendicitis have been well documented, the value of plain radiography has not been fully appreciated. The aim of this study was to determine the frequency of the association of acute appendicitis with images of fecal loading in the cecum.

METHODS: Plain abdominal radiographs of 400 patients operated upon for acute appendicitis ($n = 100$), acute cholecystitis ($n = 100$), right acute pelvic inflammatory disease ($n = 100$) and right nephrolithiasis ($n = 100$) were assessed. The presence of fecal loading was recorded and the sensitivity and specificity of this sign for acute appendicitis were calculated.

RESULTS: The presence of fecal loading in the cecum occurred in 97 patients with acute appendicitis, 13 patients with acute cholecystitis, 12 patients with acute inflammatory pelvic disease and 19 patients with nephrolithiasis. The sensitivity of this sign for appendicitis was 97% and its specificity to this disease was 85.3%. Its positive predictive value for appendicitis was 68.7%; however, its negative predictive value for appendicitis was 98.8%.

CONCLUSION: The present study suggests that the presence of radiological images of fecal loading in the cecum may be a useful sign of acute appendicitis, and the absence of this sign probably excludes this disease. This is the first description of fecal loading as a radiological sign for acute appendicitis.

INTRODUCTION

Abdominal pain in the right lower quadrant is probably one of the most challenging problems in Medicine^[1-4]. In most patients, acute appendicitis is diagnosed on the basis of clinical examination, white blood cell count, abdominal radiographic studies, and abdominal ultrasound^[1-5]. However, the less than perfect accuracy of these exams leads to a high rate of misdiagnosis leading to a rate of negative appendicectomies of about 15%^[1,2,6,7]. In order to avoid the unnecessary removal of the appendix, other investigation methods, such as computed tomography and abdominal scintigraphy have been proposed, without real advantages^[2-5].

In the presence of acute abdominal pain, abdominal radiographs are relevant and helpful, but little significance is attached to this exam in appendicitis although associated radiological features have been documented, such as localized adynamic ileum (51-81% of cases), increase in soft-tissue density in the right lower quadrant (12-33%), appendicoliths (7-14%) and deformity of cecum (4-5%)^[1,5,8-10]. The aim of this prospective study was to evaluate an apparently new sign present in the plain abdominal radiography of patients with acute appendicitis, i.e., images of fecal loading in the cecum. This sign was studied comparatively with other patients presenting acute right abdominal pain due to other diseases. This is the first description of fecal loading as a radiological sign for acute appendicitis.

MATERIALS AND METHODS

Four hundred consecutive patients with acute right abdominal pain were prospectively studied at the Alfa Institute of Gastroenterology of the Hospital of Clinics and Hospital Julia Kubitshek between 2002 and 2004. No patient was discarded from this investigation.

Plain abdominal radiographies were obtained for all patients before treatment in order to verify the presence of fecal images in the cecum. These patients were divided into the following four groups, with 100 patients each, according to their disease.

Acute appendicitis

Patients of both sexes (62 men and 38 women) ranging in age from 10 to 73 (28.3 ± 12.2) years. All patients were operated for acute appendicitis and the diagnosis was confirmed in all cases by histologic examination of the removed appendix. Fifty of the patients with positive fecal loading in the cecum during the appendicitis period were submitted to a new plain abdominal radiography on the

second postoperative day, to verify the presence of this sign after the appendicectomy.

Acute cholecystitis

Patients of both sexes (30 men and 70 women) ranging in age from 17 to 75 (mean 49.4 ± 16.3 years). All patients were operated for acute cholecystitis and the diagnosis was confirmed in all cases by histologic examination of the removed gallbladder. Eight of these cases presented acute cholangitis as well.

Right pelvic inflammatory disease

Women of the age from 20 to 45 (mean 32.3 ± 8.1 years). The complaint of these cases was due to right hydrosalpingitis (69 cases), right Fallopian pregnancy (14 cases), rupture of a right ovarian cyst (12 cases) and torsion of the right ovary (5 cases). The diagnoses were confirmed in all cases by clinical follow-up, pelvic ultrasound, laparoscopy, and surgical procedures.

Right nephrolithiasis

Patients of both sexes (42 men and 58 women) ranging in age from 10 to 73 (43.5 ± 14.3) years. The diagnosis was confirmed in all these cases by plain abdominal radiography, urography, ultrasound and CT scan.

The radiological image studied was cecal intraluminal mass consisting of a mixture of soft tissue and internal gas bubble like feces, suggesting fecal impaction, or residual feces. The amount of fecal material and consequent cecal dilatation were considered.

The sensitivity and specificity of this radiological sign, as well as its positive and negative predictive values for acute appendicitis were calculated.

The present study followed the Ethics Principles of Research in Humans, according to World Medical Association Helsinki Declaration, adopted in 1964 and amended in 1996, and was approved by the Ethical Committee of the Department of Surgery of the Medical School of the Federal University of Minas Gerais, Belo Horizonte, Brazil. All exams performed on these patients are routinely employed in the presence of acute abdominal pain in the hospitals where this investigation was carried out.

RESULTS

Table 1 describes the presence of fecal loading in the cecum of the patients of the four groups (Figure 1A). Some of these radiographs showed cecal dilatation by the large amount of fecal mass (Figure 1B).

The sensitivity of this sign was 97% for acute appendicitis, 13% for acute cholecystitis, 12% for right acute pelvic inflammatory disease and 19% for right nephrolithiasis. The specificity of fecal loading in the cecum for acute appendicitis was 85.3%. The positive predictive value of this sign for acute appendicitis was 68.7%; however, its negative predictive value for appendicitis was 98.8%.

On the second postoperative day, only two of the 50 patients with previous positive radiological sign preserved the fecal loading in the cecum. In the other 48 patients, this sign disappeared from the cecum.

Table 1 Presence of fecal loading in plain abdominal radiographs of 400 patients with right acute abdominal pain divided into four groups ($n = 100$ each)

Disease	Fecal loading			
	Present		Absent	
	<i>n</i>	(%)	<i>n</i>	(%)
Acute appendicitis	97	97	3	3
Acute cholecystitis	13	13	87	87
Right pelvic inflammatory disease	12	12	88	88
Right nephrolithiasis	19	19	81	81

DISCUSSION

Although a few studies have suggested that plain abdominal radiography is not helpful anymore in patients with acute abdominal pain, its indiscriminate use remains the rule in most emergency units^[6,8,9-11]. However, the radiological signs described in the literature are not constant or characteristic of appendicitis. Recent investigations have called into question the value of routine use of plain abdominal radiography in patients with suspected appendicitis^[1,3,4,9]. Many physicians consider ultrasound studies as standard in acute abdominal pain, believing the impact of radiograph is not of value.

In this prospective study, the association of acute

Figure 1 Plain radiographs of the abdomen in the presence of acute appendicitis, showing the fecal loading (cecal intraluminal mass consisting of a mixture of soft tissue and internal gas bubble like feces). **A:** The image of fecal loading in the

cecum (arrow) and right colon (arrow); **B:** The film of another patient with acute appendicitis. Observe residual gross fecal loading with consequent dilatation of the cecum (arrow).

appendicitis with images of fecal loading in the cecum had a sensitivity of 97% and a specificity of 85.3% when compared with other common causes of acute right abdominal pain. This rate is higher than the frequency of other clinical, laboratory, or radiological signs associated with acute appendicitis.

Another important result of the present study is based on the predictive value. According to these data, the possibility of appendicitis in the presence of fecal loading in the cecum is 68.7%. However, the absence of this sign practically excludes the diagnosis of appendicitis, which may occur in only 1.2% of cases.

We could not understand the pathophysiology to answer why appendicitis could lead to fecal loading in the cecum. However, we believe it is worth supposing that this sign may be related to a local ileum of the cecum with stool, which occurred in the presence of an acute inflammatory condition. This is the first description of fecal loading as a radiological sign for acute appendicitis.

In conclusion, the results of the present work suggest that the presence of images of fecal loading in the cecum on plain abdominal radiographs may be a useful sign associated with acute appendicitis. This association should be emphasized, mainly considering that this sign is rare in the presence of other acute inflammatory abdominal

diseases and disappears when the inflamed appendix is removed.

Abstract

AIM: Autologous blood donation (ABD) is mainly used to reduce the use of banked blood. In fact, ABD can be regarded as acute blood loss. Would ABD 2-3 d before operation affect the CVP level and subsequently result in less blood loss during liver resection was to be determined.

METHODS: Eighty-four patients undergoing living donor left hepatectomy were retrospectively divided as group I (GI) and group II (GII) according to have donated 250-300 mL blood 2-3 d before living donor hepatectomy or not. The changes of the intraoperative CVP, surgical blood loss, blood products used and the changes of perioperative hemoglobin (Hb) between groups were analyzed and compared by using Mann-Whitney *U* test.

RESULTS: The results show that the intraoperative CVP changes between GI ($n = 35$) and GII ($n = 49$) up to graft procurement were the same, subsequently the blood loss, but ABD resulted in significantly lower perioperative Hb levels in GI.

CONCLUSION: Since none of the patients required any blood products perioperatively, all the predonated bloods were discarded after the patients were discharged from the hospital. It indicates that ABD in current series had no any beneficial effects, in term of cost, lowering the CVP, blood loss and reduce the use of banked blood products, but resulted in significant lower Hb in perioperative period.

INTRODUCTION

Donor hepatectomy with maximal safety while preserving graft viability and adequacy, in terms of size and function for both recipient and donor, is of principal concern in living donor liver transplantation (LDLT). There are compelling reasons for avoiding surgical blood loss with subsequent blood transfusion^[1]. Allogenic blood transfusion cannot only transmit the infectious diseases, but also induce variety of immunologic responses, such as alloimmunization, transfusion-associated graft vs host diseases, and immunosuppression, which would result in malignant tumor recurrence and increased postoperative infection rate^[2]. Preoperative autologous blood donation (ABD) has been successfully applied in reducing the use of allogenic blood transfusion in liver resection^[3,4]. It is recommended that the last blood donation should not be collected later than 72 h before surgery, to allow for restoration of intravascular volume^[5]. Indeed, ABD can be regarded as acute blood loss. On the other side, low intraoperative central venous pressure (CVP) is associated with less surgical blood loss in hepatectomy surgery^[4,6,7]. Would preoperative ABD 2-3 d before living donor hepatectomy, without intravenous (IV) crystalloid replacement of the loss, affect the intraoperative CVP levels, subsequently reduce the blood loss and blood transfusion during living donor hepatectomy is to be determined. Aims of this retrospective study were to compare the intraoperative CVP levels, blood loss, and the requirement of blood transfusion in patients with and without preoperative ABD during living donor hepatectomy.

MATERIALS AND METHODS

Only consanguineous relatives up to the fifth degree and

lawfully wedded spouses are considered legal live donors in Taiwan. Donor volunteers underwent anthropometric measurements, thorough laboratory analysis, psychosocial evaluation, and detailed imaging studies including Doppler ultrasonography to check the quality of liver parenchyma and patency of blood vessels, and magnetic resonance, venography, arteriography, and cholangiography to check hepatic and portal venous anatomy and hepatic artery and biliary tree branching patterns as previously reported^[8]. Donors should be free of the active liver disease and the donor-recipient pair must be blood group identical or compatible.

After obtaining approval from the Ethics Committee of the Department of Health, Taiwan and written informed consent for surgery and anesthesia from the patients, the patients came into operation room without premedication and IV line. After establishment of the IV line, the anesthesia was induced with thiopental and fentanyl. Succinylcholine was used for facilitating the tracheal intubation. The anesthesia was maintained with isoflurane in oxygen-air mixture and atracurium was used as muscle relaxant. All patients were monitored with electrocardiography, arterial line for continuous blood pressure monitoring, CVP, pulse oximetry, end tidal CO₂, body temperature and urine output.

IV fluids restriction combined with the use of furosemide were applied to lower the intraoperative CVP levels. The deficit of the insensible fluids loss from no per os intake of the patients was not replaced before graft procurement; the intraoperative fluids were maintained to 2-4 mL/(kg · h) before the liver graft is dissected. If the CVP was higher than 10 cm H₂O, furosemide was given; second dose of furosemide was also given if the urine output was lower than 0.5 mL/(kg · h). After the liver graft was procured, IV fluid was increased to approximately 10 mL/(kg · h) until the end of the surgery to replace the cumulative deficits from the procedure. Concerning the surgical procedure and liver parenchymal transection with strict adherence to a meticulous surgical technique without vascular inflow, occlusion to either side of the liver has been previously published^[1].

The anesthesia records were retrospectively reviewed. Patients who had donated 250-300 mL blood 2-3 d before operation was grouped in group I (GI), while no blood donation in group II (GII). The grouping was not at random or blinded; ABD was performed without normovolemic replacement of the loss by IV infusion of the crystalloid in the first 37 cases. Since none of those patients required blood transfusion after successful LDLT, the protocol of ABD was stopped. Data such as anesthesia time, CVP levels (hourly), blood loss, blood transfusion, crystalloids, doses of furosemide and urine output were collected, compared and analyzed between groups by using Mann-Whitney *U* test. All the data were given in mean±SD. Statistical calculations were performed using the SPSS advanced statistics module (SPSS Inc., Chicago, IL, USA). *P* value <0.05 was regarded as significant.

RESULTS

From June 1994 to October 2002, 123 LDLT were performed. Only patients with healthy liver (Table 1) and

undergoing left hepatectomy were enrolled in this study. Right hepatectomy (2/37 in GI and 37/86 in GII) was excluded due to most of the patients of ABD received left hepatectomy. Thirty-five patients were included in ABD group (GI) and 49 in non-ABD group (GII). Table 1 shows the characteristics of the patients of GI and GII. The age, weight, liver functions, anesthesia time, blood loss, and mean dose of furosemide used was not significantly different. Likewise, the crystalloids infusion before and after graft procurement was not significantly different either, but the preoperative hemoglobin (Hb) as well as postoperative d 1-4 of GI was significantly lower in GI in comparison to GII. Figure 1 shows the changes of the CVP levels of both groups, the initial CVP of both groups were higher than 10 cm H₂O, it decreased gradually, under the influence of fluids restriction and diuresis effect of furosemide, and reached a level of 7.9±2.5, 7.7±2.2 and 7.8±1.7, 8.3±1.8 cm H₂O at 6th-7th h after anesthesia begin for GI and GII respectively. It was at that time that the parenchymal transection was performed. After procurement of the liver graft, the IV infusion rate was increased from 3.0±2.3 and 3.4±0.9 to 9.4±6.3 and 10±3.7 mL/(kg · h) for GI and GII respectively. The recovery of the CVP of GI was significantly slower after graft procurement in comparison to GII.

Table 1 Characteristics of patients of GI and GII

	GI (n = 35)	GII (n = 49)
Age (yr)	31.1±5.9	33.9±8.7

DISCUSSION

LDLT is a new form of therapy for pediatric and adult patients with end-stage liver diseases to overcome the problem of organ donor shortage. However, the major medical and ethical concern of this technique is the risk to the healthy donor. This concern is legitimate, since

Figure 1 The CVP changes were not significantly different between GI and GII from the first measurement up to the graft procurement, but the recovery of the CVP of GI was slower in comparison to GII after increasing the infusion rate from T8 till the end of the operation ^a $P < 0.05$ vs GI.

hepatectomy is a major upper abdominal surgery with potential risk of massive blood loss and subsequent requirement for blood transfusion, which is correlated significantly with postoperative morbidity and mortality^[9]. It is known that low CVP resulted in significant less blood loss during liver resection. Therefore, maintaining a low CVP has been regarded as a simple and effective way to reduce blood loss during parenchymal transection^[3,4,6]. A low CVP is accompanied by low pressure in the hepatic veins and sinusoids, theoretically favoring less blood loss during parenchymal transection and allows easier control of inadvertent venous injury^[1]. Low CVP indicates less intravascular volume and ABD is in fact a kind of acute blood loss. If the volume loss is not replaced, theoretically would result in lowering of the intravascular volume, subsequently the CVP and blood loss of liver resection. Our results show that donation of 250-300 mL of blood 2-3 d before donor hepatectomy without IV fluids replacement seemed not to affect the changes of the CVP levels during the surgical procedure in comparison to the group without ABD (Figure 1). The mechanism is probably due to the fact that the volume loss of the donated blood has been fully compensated by the oral intake of the healthy donors within 2-3 d. Figure 1 shows that, under the same anesthesia, same regime in lowering the CVP by fluids restriction and forced diuresis with furosemide, the changes of the CVP, from the first measurement to graft procurement, were not significantly different between GI and GII. The CVP of both groups decreased gradually from 10.5 ± 3.6 and 10.8 ± 2.8 to 7.9 ± 2.5 , 7.7 ± 2.2 and 7.8 ± 1.7 , 8.3 ± 1.8 cm H₂O at the time of parenchymal transection (around T6-7) for GI and GII respectively. The recovery of the CVP level after procurement of the liver graft to the end of the operation was slower in GI after increasing the infusion rate aimed to replace the cumulative fluid deficit to expand intravascular volume and to preserve renal function. Table 1 shows that the blood loss was not significantly different between groups. Both had only minimal blood loss with a mean loss of 63.8 ± 56 and 67 ± 63 mL for GI and GII respectively.

Current results indicated that ABD itself did not have favorable effect in lowering the intraoperative CVP levels and likewise the blood loss in comparison to non-ABD

group. In contrary, it significantly lowered the preoperative Hb level as well as its levels at postoperative d 1-4 (Table 1). It indicated that GI patients would reach earlier low Hb and transfusion threshold. Heiss *et al.*, reported that the blood transfusion rate was indeed higher in the autologous blood group than in the homologous group in patients undergoing colorectal cancer surgery, mainly because these patients had lower preoperative Hb concentrations owing to the blood donation^[10].

Allogenic blood transfusion is often life saving and crucial in the treatment of major blood loss^[11]. Although the safety of the banked blood supply has been improved recently but it can still have adverse effects^[2,12]. The risks of autologous transfusion are less than those of allogenic RBC transfusions^[12,13], but it is still not risk free^[13-16]. Complications such as bacterial contamination, hemolysis due to administrative error, volume overload were reported^[14]. Furthermore, studies have unexpectedly shown similar postoperative infectious complications and immunosuppression in patients receiving autologous blood donated before surgery, as with those receiving homologous blood^[13,17]. Factors such as histamine, plasminogen activator, superoxide and eosinophil cation protein, released into the plasma during storage may be of major importance in enhancing overall immunosuppression^[18]. The best policy in avoiding blood transfusion is to improve the surgical and anesthetic technique to minimize blood loss. Anyway, ABD is still an acceptable alternative measurement to reduce the use of allogenic blood if the amount of expected surgical blood loss is large enough requiring blood transfusion^[3,4]. Since none of our patients required any blood products perioperatively, the predonated autologous bloods of GI were discarded after the patients being discharged from the hospital. In contrary to previous reports^[3,4], ABD in current series had no any beneficial effect, in terms of cost, lowering the CVP, blood loss and reducing the use of banked blood products, but resulted in significant lower Hb in perioperative period, subsequently increasing the chance of getting autologous blood transfusion from their anemia.

In conclusion. Autologous donation of 250-300 mL blood 2-3 d before liver hepatectomy in LDLT seemed not to affect the intraoperative CVP level and subsequently no favorable effect in reducing the blood loss during liver resection. In contrary, it resulted in significant lower Hb in perioperative period, subsequent increasing the chance of getting autologous blood transfusion from their anemia. ABD in living donor left hepatectomy is not recommended if minimal surgical bleeding can be maintained.

Abstract

AIM: We studied the effect of colchicine combined with radiation on the survival of human hepatocellular carcinoma (HCC) HA22T/VGH cells.

METHODS: Twenty-four hours after treatment with 0-8 ng/mL colchicine, HA22T/VGH cells were irradiated at various doses (0, 1, 2, 4, and 8 Gy). Colony assay was performed to assess the surviving cell fraction. Survival curves were fitted by using a linear-quadratic model to estimate the sensitizer enhancement ratio (SER). Flow cytometry was used for cell cycle analysis.

RESULTS: Colchicine at lower concentrations (1 and 2 ng/mL) had obvious synergy with radiation to inhibit HCC cell growth, whereas higher concentrations (4 and 8 ng/mL) had only additive effect to radiation. Pretreatment with 1 and 2 ng/mL colchicine for 24-h enhanced cell killing by radiation with SERs of 1.21 and 1.53, respectively. G₂/M arrest was only observed with higher colchicine doses (8 and 16 ng/mL) after 24-h treatment; this effect was neither seen with lower doses (1, 2, and 4 ng/mL) nor with any dose after only 1 h of treatment.

CONCLUSION: Our results suggest that colchicine has potential as an adjunct to radiotherapy for HCC treatment. Lower doses of colchicine possess radiosensitizing effects via some mechanism other than G₂/M arrest. Further study is necessary to elucidate the mechanism.

INTRODUCTION

Colchicine interferes with microtubule formation, thereby affecting mitosis and other microtubule-dependent functions^[1]. It has been used in clinical practice for a long time, including for the treatment of acute gout^[2], prophylaxis of recurrent gout^[3], Behcet's disease^[4], chronic hepatitis B^[5], and primary biliary cirrhosis^[6]. It is a relatively safe and an effective drug when used with appropriate dosage^[7].

Hepatocellular carcinoma (HCC) is a highly malignant tumor with poor prognosis and high mortality. It is a common malignancy in Asian countries. In China, the incidence has been increasing over the past two decades. The age-adjusted rate of death per 100 000/year was 20.37 in the 1990s. In the USA, the incidence of HCC has approximately doubled over the past three decades^[8]. Aggressive treatment with a variety of modalities, including surgery, transarterial chemoembolization, percutaneous ethanol injection, radiofrequency ablation, microwave coagulation therapy, and laser-induced thermotherapy have all been used in an attempt to control this disease. However, the overall 5-year survival is still around 5%. Few tumors are resectable because of advanced stage or the presence of associated liver disease^[9,10].

Radiation therapy (RT) has not played an important role in HCC treatment in the past because normal liver tissue has low tolerance to radiation. Radiation hepatitis usually develops with whole liver irradiation at or above 35 Gy, yet this dose level may not be sufficient to eradicate the tumor. However, small portions of the liver can be irradiated with 50-60 Gy without significant long-term morbidity. Recent advances in RT including three-dimensional conformal radiation therapy (3DRT) limits the exposure of normal liver tissue and allows delivery of higher RT doses (40-80 Gy)^[11]. 3DRT has improved treatment outcome and reduced normal liver damage in unresectable HCC^[12]. There is a dose-response relationship with 3-DRT for primary HCC, with only the

radiation dose being a significant factor for predicting treatment response^[13]. It is important to develop novel ways to improve the efficacy of RT, not only by physical technique but also by pharmacological agents. The development of radiosensitizers in order to reduce the required cytotoxic RT dose for HCC is especially important for this disease that arises in the midst of radiosensitive normal tissue.

Other studies have demonstrated that cells are most radiosensitive in the G₂/M phase, whereas the most resistant are in late S phase^[14]. Because colchicine arrests the cell cycle at the G₂/M phase, we designed this study to assess its effect in combination with radiation on HA22T/VGH, a poorly differentiated HCC cell line^[15,16].

MATERIALS AND METHODS

Preparation of colchicine

Colchicine (C₂₂H₂₅NO₆, molecular weight 399.4, purity 95%) was purchased from Sigma Co. (St. Louis, MO, USA). The powder was dissolved in distilled water to form an aqueous stock solution and diluted with PBS before use.

Cell culture

The human poorly differentiated HCC cell line HA22T/VGH^[15,16] was cultured in DMEM (GIBCO, Grand Island, NY, USA) supplemented with 10% heat-inactivated fetal calf serum (FCS, Hyclone, Logan, UT, USA), NaHCO₃ (10 mmol/L) and HEPES (20 mmol/L) at 37 °C in a humidified 50 mL/L CO₂ incubator. For routine subculturing, the cells were grown to near confluence, collected by 0.25% trypsin, counted using the trypan blue exclusion test, and adjusted to an initial density of approximately 10⁴ cells/mL.

Colchicine treatment and radiation delivery

In preliminary work, we determined the cytotoxic effect of different colchicine concentrations on HA22T/VGH HCC cells by using a 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide (MTT) assay and found that concentrations up to 2 ng/mL were non-toxic. Based on these preliminary results, we used colchicine concentrations of 0-8 ng/mL to test for radiosensitization. HA22T/VGH HCC cells were treated with 0, 1, 2, 4, and 8 ng/mL colchicine for 24 h, and the colchicine was washed out before RT. RT with 6 MeV electron beam energy was delivered by a linear accelerator (Clinac® 1800, Varian Associates, Inc., CA, USA; dose rate 2.4 Gy/min) at various doses (0, 1, 2, 4, and 8 Gy) in a single fraction. Full electron equilibrium was ensured for each fraction by a parallel plate PR-60C ionization chamber (CAPINTEL, Inc., Ramsey, NJ, USA). One hundred and fifty viable tumor cells were plated onto 35-mm six-well culture dishes and were allowed to grow in DMEM medium containing 10% heat-inactivated FCS and the various concentrations of colchicine at 37 °C in a humidified 50 mL/L CO₂ incubator for 24 h. Then the cells were treated with various radiation doses. Following radiation, a colony assay was performed.

Colony assay

After 10-14 d, the culture dishes were stained with 3%

crystal violet and colonies (≥ 50 cells) were counted. The surviving fraction was calculated as mean colonies/cells inoculated. The mean plating efficiency for untreated HA22T/VGH HCC cells was 43%. Survival curves were fitted by using a linear-quadratic model^[17]. The sensitizer enhancement ratio (SER) was calculated as the radiation dose needed for radiation alone divided by the dose needed for colchicine plus radiation at a surviving fraction of 37% (D₀ in radiobiology).

Cell cycle analysis by flow cytometry

Cells were treated with various doses of colchicine (0, 1, 2, 4, 8, and 16 ng/mL) for 1 or 24 h, then harvested and fixed at 4 °C for 1 h with 70% ethanol. The cells were stained for 30 min with propidium iodide (PI) solution (PI, 0.5 mg/mL; RNase, 0.1 mg/mL; Sigma Co.) from a CycleTEST plus DNA reagent kit (Becton Dickinson, Lincoln Park, NJ, USA). Analysis of DNA content was performed using a FACScalibur flow cytometer (Becton Dickinson). The data from 10⁴ cells were collected and analyzed using ModFit software (Becton Dickinson).

Statistical analysis

Data were expressed as percentage and mean \pm SE.

We used Sigma Plot software (version 8.0, SPSS Inc., Chicago, IL, USA) to fit survival curves with a linear-quadratic model. One-way analysis of variance was used to compare the colony formation between different groups (SPSS, version 10.0, Chicago, IL, USA).

RESULTS

Cell survival and SER

The results of colony assays of various doses colchicine combined with radiation are shown in Table 1. There was an obvious synergistic effect of low-dose colchicine (1 and 2 ng/mL) plus radiation. When the dose was increased to 4 and 8 ng/mL, only mild additive effects were noted.

As the survival curves in Figure 1 demonstrate, low-dose colchicine sensitized HA22T/VGH HCC cells to radiation in a dose-dependent manner. The RT doses required for a surviving fraction of 37% (D₀ in radiobiology) after pretreatment with 0, 1, and 2 ng/mL colchicine were 9.45, 7.80, and 6.16 Gy respectively. The calculated SERs of colchicine were 1.21 for 1 ng/mL and 1.53 for 2 ng/mL.

Figure 1 Radiation survival curves for human HA22T/VGH hepatocellular carcinoma cells. Cells were treated with vehicle (●), colchicine 1 ng/mL (○) and 2 ng/mL (▼) for 1 h before radiation.

Cell cycle analysis after varying doses of colchicine

Although colchicine is reported to arrest mitosis, no HA22T/VGH HCC cells were clearly seen in the G₂/M phase 1-h treatment (data not shown). After 24 h of colchicine treatment, significant G₂/M arrest was induced by higher doses (8 and 16 ng/mL) but not by doses, which were less than 8 ng/mL (Table 2). The DNA histograms after 24 h of treatment with varying doses of colchicine are shown in Figure 2.

Table 2 Cell cycle analysis of human HA22T/VGH hepatocellular carcinoma cells. Cell were treated with various doses of colchicine for 24 h and analyzed by flow cytometry

Colchicine (ng/mL)	Cell cycle distribution (%)		
	G ₀ /G ₁	S	G ₂ +M
0	49.0±1.4	24.6±1.1	26.4±1.0

DISCUSSION

The present study demonstrates that pretreatment with colchicine is capable of reducing the survival of irradiated human HCC HA22T/VGH cells. The combined effect varies with the dose of colchicine. Pretreatment with colchicine at lower doses (1-2 ng/mL) 1 h prior to RT yielded a synergistic effect on radiation-induced cytotoxicity. Higher doses gave only a mild additive effect. However,

the G₂/M arrest phenomenon was not found with low doses or short-term (1 h) colchicine treatment. Evident G₂/M arrest was observed after treatment with higher doses (8 and 16 ng/mL) of colchicine for 24 h. Alteration of cell cycle distribution therefore may not play a major role in the radiosensitizing effect of colchicine in this combined therapy.

RT plays an important role in combined treatment for several malignant tumors^[18,19]. However, the risk of radiation-induced toxicity limits its use in liver tumors^[20]. While 3DRT is increasingly used for HCC, limiting the volume of irradiated normal liver and allowing adjustment of the radiation dose to improve the therapeutic index, it still has many limitations. Advanced liver cirrhosis or poor liver reserve is a common problem in patients with HCC^[21]. The risk of hepatic failure after cytotoxic doses of RT therefore remains as a great problem. Radiosensitizers may give patients with poor liver reserve a better chance of controlling their tumor. Pentoxifylline and ganglioside GD3 have been shown to act as radiosensitizers in the human HCC cell line HepG2. Pentoxifylline may do so by causing cell cycle arrest in the G₂/M phase. Ganglioside GD3 may have a dual action in producing radiosensitization by interacting with mitochondria and by inactivating NF-κB^[22,23].

The safety and therapeutic range of colchicine are well established. The doses of colchicine (0-8 ng/mL) we used before RT are much lower than those in previous reports for other *in vitro* disease models^[7]. Our results demonstrate that colchicine enhances the radiation effect *in vitro*, thus reducing the radiation dose needed to inhibit tumor growth. Most RT-related complications develop not early in the course of RT but rather after a high cumulative dose. Using colchicine at low doses yielded an SER of 1.21 at 1 ng/mL and 1.53 at 2 ng/mL. This means that if the original planned RT dose was 50 Gy, the same cytotoxic effect would be achieved by only 32.68 Gy after pretreatment with 2 ng/mL of colchicine. This reduced RT dose is close to 30 Gy, the threshold for whole liver irradiation, which may result in lethal liver damage with a 5% probability in 5 years (TD 5/5)^[20].

Our results suggest that lower doses of colchicine sensitize HA22T/VGH HCC cells to radiation. At lower doses (1 and 2 ng/mL), 24 h of treatment with colchicine did not change the G₂/M phase distribution significantly. At higher doses (8 and 16 ng/mL), the drug arrested that cell cycle at the G₂/M phase. There was an accompanying evident sub-G₁ peak noted on the DNA histogram (Figure 2). This implies that the synergistic effect of colchicine and RT may involve multiple mechanisms,

**Figure 2** DNA histograms in cell cycle analyses of HA22T/VGH cells by flow cytometry. A: Control; B: Colchicine 2 ng/mL; C: Colchicine 8 ng/mL;

D: Colchicine 16 ng/mL.

perhaps including cell cycle regulation, induction of apoptosis, and others.

In conclusion, colchicine at optimal doses sensitizes human HA22T/VGH HCC cells to radiation by a mechanism other than cell cycle arrest at the G₂/M phase.

Abstract

AIM: The clinical significance of co-infection of SENV-D among patients with chronic hepatitis C (CHC) and response of both viruses to combination therapy with high-dose interferon-alfa (IFN) plus ribavirin remain uncertain and are being investigated.

METHODS: Total 164 (97 males and 67 females, the mean age 48.1 ± 11.4 years, range: 20-73 years, 128 histologically proved) naive CHC patients were enrolled in this study. SENV-D DNA was tested by PCR method. Detection of serum HCV RNA was performed using a standardized automated qualitative RT-PCR assay (COBAS AMPLICOR HCV Test, version 2.0). HCV genotypes 1a, 1b, 2a, 2b, and 3a were determined by using genotype-specific primers. Pretreatment HCV RNA levels were determined by using the branched DNA assay (Quantiplex HCV RNA 3.0). There are 156 patients receiving combination therapy with IFN 6 MU plus ribavirin for 24 wk and the response to therapy is determined.

RESULTS: Sixty-one (37.2%) patients were positive for SENV-D DNA and had higher mean age than those who were negative (50.7 ± 10.6 years vs 46.6 ± 11.6 years, $P = 0.026$). The rate of sustained viral response (SVR) for HCV and SENV-D were 67.3% (105/156) and 56.3% (27/48), respectively. By univariate analysis, the higher rate of SVR was significantly related to HCV genotype non-1b ($P < 0.001$), younger ages ($P = 0.014$), lower

pretreatment levels of HCV RNA ($P = 0.019$) and higher histological activity index (HAI) score for intralobular regeneration and focal necrosis ($P = 0.037$). By multivariate analyses, HCV genotype non-1b, younger age and lower pretreatment HCV RNA levels were significantly associated with HCV SVR (odds ratio (OR)/95% confidence interval (CI): 12.098/0.02-0.19, 0.936/0.890-0.998, and 3.131/1.080-9.077, respectively). The SVR of SENV-D was higher among patients clearing SENV-D than those who had viremia at the end of therapy ($P = 0.04$).

CONCLUSION: Coexistent SENV-D infection, apparently associated with higher ages, is found in more than one-third Taiwanese CHC patients. Both HCV and SENV-D are highly susceptible to combination therapy with high-dose IFN and ribavirin and SENV-D co-infection does not affect the HCV response. HCV genotype, pretreatment HCV RNA levels and age are predictive factors for HCV SVR.

INTRODUCTION

A new family of DNA viruses was recently isolated and designated as SEN virus (SENV)^[1,2]. SENV is a single-stranded circular DNA virus distantly related to the large TT virus family with eight different variants (A-H) shown by phylogenetic analysis^[3]. Two strains of SENV (SENV-D and SENV-H) are more prevalent among patients with transfusion-associated non-AE hepatitis than in healthy blood donors that suggested the significant associations between SENV-D/H and transfusion-associated hepatitis^[2,4]. Nevertheless, the clinical implication and etiological importance in association with liver diseases of SENV infection still remain undetermined.

HCV is the major etiologic agent of post-transfusion hepatitis and leads to chronic liver disease and primary

hepatocellular carcinoma^[5,6]. With the prevalence rate of chronic hepatitis C (CHC) ranging from 0.95% to 2.6% among the general population^[7,8], we had previously reported a positive rate of anti-HCV up to 57.9% in some communities in southern Taiwan^[9]. For CHC, the combination therapy with interferon- α (IFN) and ribavirin has been considered as first-line therapy. Previous reports have demonstrated the increased rate of sustained viral response (SVR) to 31-43% after combination therapy for 24 or 48 wk than 6-19% of IFN monotherapy^[10,11]. Lai *et al.*, reported a SVR rate of 43% after combination therapy with standard IFN dose in Taiwan^[12]. In our previous study, the rate of HCV SVR with a high-dose IFN monotherapy achieved 41.2% among Taiwanese CHC patients^[13] and the tailored-dose IFN monotherapy according to the virological characteristics of CHC patients yielded a better efficacy^[14]. The benefits of high-dose IFN may be gained in the combination therapy for CHC.

The clinical significance of SENV infection in combination with HCV infection remains controversial. For patients with CHC, Rigas *et al.*, reported that co-infection with SENV might adversely affect the outcome of treatment with combination therapy^[15]. Another study, however, did not support their findings^[16]. The aims of the present study are to survey the prevalence and clinical implications of SENV-D co-infection on biochemical, pathological, and virological profiles among CHC patients. The response of HCV and SENV-D to combination therapy with high-dose IFN and ribavirin are also investigated. Furthermore, we elucidate the predictive factors for HCV SVR and the influence of concurrent SENV-D infection on HCV response to combination therapy.

MATERIALS AND METHODS

Patients

Between May 1998 and May 2001, a total of 164 Taiwanese CHC patients in the clinics of hepatological division of the Kaohsiung Medical University Hospital, 97 men and 67 women, aged between 20 and 73 years (mean 48.1 ± 11.4 years) were enrolled in the study. All patients were diagnosed with chronic HCV infection based on continuous positivity for second-generation antibody to HCV (anti-HCV) in serum for more than 6 mo and positive for HCV RNA. Liver biopsies were carried out in 128 patients and the disease activity grade and fibrosis stage were quantitatively scored according to the histological activity index (HAI) scoring system^[17]. Patients who were positive for hepatitis B surface antigen (HBsAg) had human immunodeficiency virus type I infection, autoimmune liver disease, metabolic liver diseases including α -1 anti-trypsin deficiency hemochromatosis or Wilson's disease, alcoholic liver disease or intravenous drug abuse were excluded. All the serum samples, when collected from patients at the time of their evaluation, were stored at -70°C before testing. The study had been approved by the Ethics Committee of Kaohsiung Medical University Hospital and all patients had given their informed consent.

Methods

Laboratory tests Serum HBsAg was assayed using

commercially available kits (General Biological HBsAg radio-immunoassay; General Biological Cooperation, Taiwan) and second-generation HCV antibody (anti-HCV) was detected with commercially available ELISA kits (Abbott, North Chicago, IL, USA). Alanine aminotransferase (ALT, normal upper limit of serum ALT = 34 IU/L) was measured on a multichannel autoanalyzer.

Detection of SENV-D DNA and detection/quantification/genotyping of serum HCV RNA The presence of SENV-D DNA was determined by PCR as described previously^[18]. Detection of serum HCV RNA was performed using a standardized automated qualitative RT-PCR assay (COBAS AMPLICOR HCV Test, version 2.0; Roche, Branchburg, NJ, USA). The detection limit was 50 IU/mL. HCV genotypes 1a, 1b, 2a, 2b, and 3a were determined by amplification of the core region using genotype-specific primers described by Okamoto *et al.*^[19]. Pretreatment HCV RNA levels were determined by using the branched DNA assay (Quantiplex HCV RNA 3.0, Bayer, Emeryville, CA, USA), performed strictly in accordance with the manufacturer's instructions. The quantification limit was 615 IU of HCV RNA per milliliter.

Combination therapy with high-dose IFN and ribavirin Total 156 CHC-naïve patients (92 males, 64 females, mean age: 48.0 ± 11.5 years, 122 patients with liver biopsies) received combination therapy for 24 wk using IFN subcutaneously at a dosage of 6 MU thrice a week and ribavirin by mouth at a dosage of 1 000-1 200 mg daily. After the cessation of therapy, all of them received 24 wk of follow up for evaluation of the response. A SVR for HCV was defined as clearance of serum HCV RNA at the end of the therapy and 24 wk after the cessation of combination therapy. All other patients were defined as non-responders (NR). To evaluate the response of SENV-D, the presence of SENV-D DNA was determined at wk 24 and 48. An end-of-treatment viral response (ETVR) and a SVR for SENV-D were indicated by negative PCR results at wk 24 and 48, respectively.

Statistical analysis

Serum HCV RNA levels were expressed as the mean \pm SD after logarithmic transformation of original values. Frequency was compared between groups using the χ^2 test or Fisher's exact test, and group means were compared using the *t*-test. For all tests a *P* value lesser than 0.05 was considered to be significant. Stepwise logistic regression was used to analyze factors associated with response to combination therapy in CHC patients. Odds ratios (ORs) and their associated 95% confidence intervals (CIs) were used to quantify the magnitude of their associations.

RESULTS

Study population

The mean pretreatment ALT and HCV RNA levels of the 164 CHC patients was 136.9 ± 168.9 IU/L and 5.79 ± 0.67 log IU/mL, respectively. There were 140 (85.4%) patients with abnormal ALT levels. The HCV genotype distribution was as follows: 1b in 80 (48.8%) patients, 2a in 48 (29.3%) patients, 2b in 18 (11.0%) patients, mixed in 13 (7.9%)

patients and unclassified in 5 (3.0%) patients. Of 128 patients undergoing liver biopsies, the mean scores for peri-portal necrosis, intralobular necrosis, portal inflammation (grading) and fibrosis were 1.11 ± 1.34 , 0.52 ± 0.88 , 1.91 ± 1.24 , 3.51 ± 2.55 , and 1.25 ± 1.36 , respectively.

SENV-D viremia in chronic hepatitis C patients

Of 164 CHC patients, 61 patients were positive for SENV-D DNA showing a prevalence of 37.2%. The comparison of clinical characteristics between patients with and without SENV-D co-infection was shown in Table 1. The mean age was higher among patients with positive SENV-D DNA than those who were negative for SENV-D DNA (50.7 ± 10.6 years *vs* 46.6 ± 11.6 years, $P = 0.026$). No other clinical and virological factor was related to positive SENV-D DNA. Among 128 patients that underwent liver biopsies, all the mean scores were similar between SENV-D DNA-positive and -negative patients.

Table 1 Comparison of clinical characteristics between individuals with and without SENV-D viremia in 164 CHC patients

	SENV-D viremia		<i>P</i>
	Positive (<i>n</i> = 61)	Negative (<i>n</i> = 103)	
Sex (male) (%)	36 (59.0)	61 (59.2)	NS
Age (yr)	50.7 ± 10.6	46.6 ± 11.6	0.026
Serum ALT (IU/L)	144.0 ± 164.3	125.8 ± 164.2	NS
Normal (≤ 34 IU/L) (%)	8 (33.3)	16 (66.7)	NS
Abnormal (> 34 IU/L) (%)	53 (37.9)	87 (62.1)	
HCV RNA levels (log IU/mL)	5.72 ± 0.70	5.85 ± 0.63	NS
HCV genotype 1b (%)	26 (42.6)	54 (52.4)	NS
Histology (HAI scores)	46	82	
Peri-portal necrosis	1.11 ± 1.34	1.11 ± 1.35	NS
Intralobular necrosis	0.70 ± 1.00	0.41 ± 0.78	NS
Portal inflammation	1.80 ± 1.31	1.98 ± 1.21	NS

Fibrosis	1.39 ± 1.50	1.16 ± 1.28	NS

Results are expressed as mean \pm SD. HAI: histological activity index, NS: no significance.

HCV virological response to combination therapy

Of all 156 naive CHC patients receiving combination therapy, the HCV genotype distribution was as follows: 1b in 76 (48.7%) patients, 2a in 47 (30.1%) patients, 2b in 16 (10.3%) patients, mixed in 12 (7.7%) patients, and unclassified in 5 (3.2%) patients. The mean pretreatment ALT and HCV RNA levels were 134.8 ± 166.8 IU/L and 5.79 ± 0.66 log IU/mL, respectively with 133 (85.3%) and

99 (63.5%) patients having abnormal ALT levels and high serum HCV levels ($\geq 200\ 000$ IU/mL). Of 122 patients undergoing liver biopsies, the mean scores for peri-portal necrosis, intralobular necrosis, portal inflammation (grading), and fibrosis were 1.09 ± 1.31 , 0.52 ± 0.89 , 1.93 ± 1.22 , 3.52 ± 2.48 , and 1.23 ± 1.33 , respectively. After combination therapy with high dose IFN and ribavirin for 24 wk, 105 (67.3%) of 156 patients achieved SVR. The clinical and virological features between CHC patients with HCV SVR and those with NR are shown in Table 2. In comparison between these two groups by univariate analysis, the higher rate of SVR was significantly related to younger ages ($P = 0.014$), lower pretreatment levels of HCV RNA ($< 200\ 000$ IU/mL, $P = 0.019$), HCV genotype non-1b ($P < 0.001$) and higher HAI score for intralobular regeneration and focal necrosis ($P = 0.037$). No significant association between other clinical and virological factors and HCV response of combination therapy was observed. Based on multivariate regression analyses, the significant factors associated with HCV SVR after combination therapy were HCV genotype non-1b, younger age and pretreatment HCV RNA levels less than $200\ 000$ IU/mL with the OR and 95%CI of these factors summarized in Table 3.

Table 2 Comparison of clinical and virological features between sustained viral responders (SVR) and non-responders (NR) of CHC patients after combination therapy

	HCV response		<i>P</i>
	NR (<i>n</i> = 51)	SVR (<i>n</i> = 105)	
Sex (male) (%)	31 (60.8)	61 (58.1)	NS
Age (yr)	51.24 ± 11.3	46.4 ± 11.3	0.014
Serum ALT (IU/L)	122.2 ± 105.0	140.9 ± 189.9	NS
Normal (≤ 34 IU/L) (%)	4 (18.2)	18 (81.8)	NS

Clearance of SENV-D DNA after combination therapy

SENV-D DNA was followed in 48 CHC patients (28 males, 20 females, mean age: 50.2 ± 10.5 years) concomitant with SENV-D viremia before combination therapy. Their mean ALT level was 154.6 ± 179.8 IU/L (range: 16-112 years) and 41 patients were abnormal. The HCV genotype distribution is as follows: 1b in 19 patients, 2a in 19 patients, 2b in 4 patients, mixed in 5 patients, and unclassified in 1 patient. The clinical characteristics and virological features between individuals with and without SENV-D DNA after combination therapy were analyzed and shown in Table 4. At the end of treatment, SENV-D DNA was negative in 37 patients (77.1%). Thirteen of thirty-seven patients (35.1%) had reappearance of serum SENV-D DNA when followed 24 wk after the cessation of therapy. Three of eleven patients (27.3%) with positive SENV-D DNA at the end of treatment were cleared of SENV-D DNA 24 wk after the cessation of therapy. The rate of SVR of SENV-D DNA after combination therapy was 56.3% (27/48). As shown in Table 4, the SVR of SENV-D was higher among patients with ETVR than those who were SENV-D viremia at the end of treatment (88.9% *vs* 61.9%, $P = 0.04$). No other clinical and virological factor was related to SVR for SENV-D.

Table 4 Comparison of clinical characteristics and virological features between 48 CHC patients with and without sustained clearance of SENV-D after combination therapy

	SENV-D response		<i>P</i>
	NR (<i>n</i> = 21)	SVR (<i>n</i> = 27)	
Sex (male) (%)	15 (71.4)	13 (48.2)	NS
Age (yr)	48.3 ± 10.6	51.7 ± 10.3	NS
Serum ALT (IU/L)	157.6 ± 122.9	152.4 ± 216.3	NS
High HCV RNA level ($\geq 200\ 000$ IU/mL) (%)	9 (42.9)	18 (66.7)	NS
HCV genotype 1b (%)	7 (33.3)	12 (44.4)	NS
SENV-D ETVR (%)	13 (61.9)	24 (88.9)	0.04
HCV SVR (%)	17 (81.0)	18 (66.7)	NS

Results are expressed as mean \pm SD. ETVR: end-of-treatment viral response, SVR: sustained viral responder, NR: non-responders, NS: no significance.

DISCUSSION

The geographic distribution of different SENV variants has been noted. In Japan, SENV-D is more prevalent than SENV-H^[20-23], but the predominant strain of SENV-H has been reported in the USA^[4]. Kao *et al.*, reported that the prevalence of SENV-H was 2-7 times higher than that of SENV-D in different northern Taiwanese individuals^[16,24]. The findings of the present study revealed that 37.1% of Taiwanese patients with CHC were co-infected with SENV-D which is higher by 28% than reports by Kao *et al.*^[16]. Our previous studies have shown that the prevalence of SENV-D was also higher than SENV-H not only among southern Taiwan blood donors (19.7% and 5.8%)^[18] but also among patients on maintenance hemodialysis (46.5% and 27.3%)^[25]. Furthermore, we found the prevalence of SENV-H was 19.2% among Taiwanese CHC patients (unpublished data) which is lower than that of SENV-D. It is interesting that a

marked difference of genotypic distribution of SENV between southern and northern Taiwan exists.

There was a higher mean age among CHC patients who were SENV-D viremic than non-viremic. We found similar results among blood donors too^[18]. However, we did not observe significant correlation between age and the prevalence of SENV-H among blood donors^[18] and CHC patients (unpublished data). The cause of discrepancy between trends of change in the prevalence of SENV-D and -H was not clear. Whether the possible assumptions such as the different exposure rate or routes of infection or different rates of spontaneous clearance between these two strains can clarify the issues needs further large-scale and longitudinal studies.

The clinical significance of SENV infection in combination with HCV infection remains unclear^[15,16]. Kao *et al.*, reported the relevance between HCV genotype 2a and SENV co-infection^[16]. The present study revealed that the pretreatment mean ALT levels and HCV RNA levels, and the histological scores between CHC patients with and without SENV-D co-infection were compatible and failed to show association between SENV-H and HCV genotype. Nevertheless, we have found a correlation between SENV-H co-infection and HCV genotype 1b among CHC patients (unpublished data). The discrepancy needs further studies. The biochemical and histological characteristics of CHC patients were not influenced by SENV-D co-infection that indicated the irrelevance between severity of liver disease and SENV-D co-infection.

As previous reports from researchers in Taiwan, the SVR rate of CHC patients was high (40-43%) after combination therapy with IFN 3 MU and ribavirin for 24 wk^[12,16]. In the present study, the HCV SVR rate was 67.3% after combination therapy with 6 MU IFN and ribavirin for 24 wk, which may further indicate the favorable results of combination therapy for Taiwanese CHC patients. The positive predictors of SVR to combination therapy with high-dose IFN were elucidated as HCV genotype non-1b, lower pretreatment HCV RNA levels and younger age. HCV genotype non-1b, having 12 times of SVR rate than genotype 1b in the present study, is the most important factor predicting SVR. Previous reports have demonstrated that HCV with SENV co-infection affected HCV response to combination therapy with IFN plus ribavirin adversely^[15] but the other report denied the relevance between HCV response and SENV co-infection^[16,22]. Our data here indicates that SENV-D co-infection does not affect the HCV response in the combination therapy with high dose IFN and ribavirin. In addition to co-infection with GB virus C/hepatitis G virus or TT virus that had no impact on the response to IFN monotherapy in CHC patients in our previous studies^[13,26,27], it seems unnecessary to determine whether CHC patients coinfect these viruses or not before they received combination therapy.

After combination therapy with 6 MU IFN and ribavirin for 24 wk among 48 CHC patients concomitant with SENV-D viremia, the rates of viral clearance at the end of follow-up achieved 56.3%. In an earlier study on the response of SENV-D among CHC patients, the sustained response rate of SENV-D has recently been reported by Umemura

et al., (73.3%) after high-dose IFN monotherapy^[22] and by Kao *et al.*, (87.5%) after combination therapy with 3 MU IFN and ribavirin for 24 wk^[16]. The lower SVR rate of SENV-D than SENV-H (78.3%, unpublished data) in our study from southern Taiwan was different from results from northern Taiwan that showed higher SENV-D SVR rate (87.5%) than SENV-H (26.8%)^[16]. The causes of different response to combination therapy, in addition to the different prevalence, of these two strains in southern and northern Taiwan need further research.

In conclusion, we find that more than one-third Taiwanese patients with CHC are coinfectd with SENV-D and coexistent SENV-D infection is apparently associated with higher ages but does not have an influence on the clinico-pathological characteristics of HCV infection. SENV-D is highly susceptible and does not affect the HCV response to combination therapy. After combination therapy with high dose IFN and ribavirin, two-thirds of Taiwanese CHC patients achieve SVR and HCV genotype non-1b, lower pretreatment HCV RNA levels and younger age are predictive factors for SVR.

Abstract

AIM: Endoscopic sphincterotomy (ES) is a well-established therapeutic modality for the removal of common bile duct (CBD) stones. After ES there are still around 10% of patients that experience recurrent CBD stones. The aim of this study is to investigate the composition of CBD stones before and after ES and its clinical significance in Chinese patients.

METHODS: From January 1996 to December 2003, 735 patients with CBD stones received ES at Kaohsiung Veterans General Hospital and stone specimens from 266 patients were sent for analysis. Seventy-five patients had recurrent CBD stones and stone specimens from 44 patients were sent for analysis. The composition of the stones was analyzed by infrared (IR) spectrometry and they were classified as cholesterol or bilirubinate stones according to the predominant composition. Clinical data were analyzed.

RESULTS: In the initial 266 stone samples, 217 (82%) were bilirubinate stones, 42 (16%) were cholesterol stones, 3 were calcium carbonate stones, 4 were mixed cholesterol and bilirubinate stones. Patients with bilirubinate stones were significantly older than patients with cholesterol stones (66 ± 13 years vs 56 ± 17 years, $P = 0.001$). In the 44 recurrent stone samples, 38 (86%) were bilirubinate stones, 3 (7%) were cholesterol stones, and 3 were mixed cholesterol and bilirubinate stones. In 27 patients, both initial and recurrent stone specimens can be obtained, 23 patients had bilirubinate stones initially and 2 became cholesterol stones in the recurrent attack. In the four patients with initial cholesterol stones, three patients had bilirubinate stones and one patient had a cholesterol stone in the recurrent attack.

INTRODUCTION

The prevalence of gallstone diseases varied from 10% to 30% in the normal population and increased with age^[1-3]. Most gallstones are asymptomatic, but symptomatic gallstones may occur due to either cystic duct obstruction or common bile duct (CBD) stone formation. Endoscopic sphincterotomy (ES) is a well-established therapeutic modality for the removal of CBD stones. In follow-up studies after ES, 3-21% of patients developed recurrent CBD stones^[4-6] and most of them can be treated successfully by endoscopy^[4,7].

The main composition of gallstones is cholesterol and bile pigments^[8]. The major composition of GB stones obtained from Western patients is cholesterol (consisting of more than 50% cholesterol)^[8]. However, in the Asian patients, most gallstones are pigmented stones^[9]. Pigmented stones can be classified as black stones, associated with hemolysis or brown stones, associated with infection or bile stasis^[10-13]. Stones in the CBD are often brown, pigmented stones^[14-16]. After ablation of sphincter, bactobilia may happen and the pathogenesis of CBD stone formation may be different from the patients with intact sphincters^[17,18]. There have been few studies reporting the composition of recurrent CBD stones in patients after ES.

The aim of this study is to determine the composition of initial and recurrent CBD stones by infrared (IR) spectrometry and investigate the relationship of clinical characteristics and the change of the composition of recurrent stones after ES.

MATERIALS AND METHODS

Since January 1996 to December 2003, total 735 patients

with CBD stones received successful ES with clearance of CBD stones in Kaohsiung Veterans General Hospital and 266 stone specimens were collected and sent for stone analysis. During clinical follow-up, 75 patients had recurrent stones and 44 stone specimens were collected for stone analysis. Clinical data such as age, sex, diameter of CBD, size, number and color of stones, presence of juxtaapillary diverticulum (JPD), gallbladder (GB) status, and GB stones were recorded. GB stone was detected by sonogram or computed tomography of abdomen. Diameter of CBD and size and number of stones were measured during endoscopic retrograde cholangiopancreatography.

The stone sample was retrieved by Dormia basket (FG-22Q-1, Olympus) or snarenet (Roth snarenet, U.S.E.) from the bile duct. The stone specimen was pulverized into a homogenous powder, mixed with KBr and ground into fine particles. The mixed powder was pressed with a hydraulic pressure of 400 psi for 1 min to form a disc. Sample disc was analyzed with IR spectrometer. The stones were classified as cholesterol or bilirubinate stone according to the predominant composition. The characteristic band features and key band locations were in accordance with those reported in the literature^[9,19]. Bilirubinate stones had characteristic IR absorption bands at 970, 1 186, 1 250, 1 568, 1 627, and 1 650/cm with a key band at 1 250/cm; cholesterol stones had characteristic IR absorption bands at 728, 836, 952, 1 050, 1 375, 1 470, and 2 950/cm with key bands at 1 050 and 1 470/cm.

This protocol was approved by the Department of Medical Research and Education of Kaohsiung Veterans General Hospital. The values are expressed as mean \pm SD. Categorical variables were analyzed with χ^2 -test or Fisher's exact test and continuous variables were analyzed by Student's *t*-test. A *P* value <0.05 was regarded as significant.

RESULTS

Among the 735 patients with CBD stones and receiving successful ES, there were no significant differences in age, sex, presence of JPD, or cholecystectomy between the patients whose stones were collected for analysis or not (Table 1). In the group of patients with stone collection, their CBD diameter and stone size were larger.

Table 1 Patients' characteristics between stone collected and uncollected groups

	Collected (n = 266)	Uncollected (n = 469)	<i>P</i>
Age (yr)	64 \pm 14	65 \pm 14	0.454
Sex (M/F)	156/110	297/172	0.210
JPD ¹ (%)	105 (39) ²	158 (34)	0.116
Cholecystectomy (%)	65 (24) ²	108 (23)	0.665

With stone	111 (51)	20 (48)	

Seven patients were excluded (three were calcium carbonate stones, four were mixed cholesterol and bilirubinate stones). CBD: Common bile duct; S/M: single/multiple; JPD: juxtaapillary diverticulum; GB: gallbladder. ¹Number of cases; the number inside the parenthesis shows the percentage.

A total 75 patients had recurrent CBD stones and received another endoscopic treatment. Stone specimens were collected from 44 patients for stone analysis. In the 44 recurrent stone samples, 38 (86%) were bilirubinate stones, 3 (7%) were cholesterol stones, and 3 were mixed cholesterol and bilirubinate stones. Among the three patients with recurrent cholesterol stones, two patients had intact GBs with stones and one had received a cholecystectomy 6 mo prior to recurrence. There were no significant differences in age, sex, CBD diameter, size or number of CBD stones, GB status, or presence of gallstones between patients with recurrent bilirubinate or cholesterol stones (Table 3).

Table 3 Patients' characteristics and compositions of recurrent CBD stones

	Bilirubinate (n = 38)	Cholesterol (n = 3)	<i>P</i>
Age (yr)	66 \pm 10	65 \pm 6	0.836
Sex (M/F)	21/17	3/0	0.254

With stone	15 (39)	2 (67)	

Three patients with mixed cholesterol and bilirubinate stones were excluded. CBD: Common bile duct; S/M: single/multiple; JPD: juxtaapillary diverticulum; GB: gallbladder. ¹Number of cases; the number inside the parenthesis shows the percentage.

In 27 patients, both initial and recurrent stone specimens can be obtained and sent for analysis, 23 patients had bilirubinate stones at initial treatment, 21 of them still had bilirubinate stones and 2 patients had cholesterol stones after recurrence. Both the patients with recurrent cholesterol stones also had GB stones. Four patients had cholesterol stones in the initial attack, three of them had bilirubinate stones, one patient still had cholesterol stones with recurrence and this patient had received cholecystectomy 6 mo prior to recurrence (Table 4).

Table 4 Change of stone compositions between initial and recurrent stone

Recurrent	Initial	
	Bilirubinate (n = 23)	Cholesterol (n = 4)
Bilirubinate (n = 24)	21	3
Cholesterol (n = 3)	2	1

Among the initial 266 stone samples, colors of stones were recorded. In the 217 patients with bilirubinate stones, 55 were yellowish, 93 were blackish, 64 were brownish and 5 were greenish. In the 42 patients with cholesterol stones, 15 were yellowish, 12 were blackish, 15 were brownish. In patients with mixed bilirubinate and cholesterol stones, two were yellowish and two were blackish. In patients with calcium carbonate stones, two were yellowish and one was blackish (Table 5).

Table 5 Compositions and color of stones

	Bilirubinate stone (n = 217)	Cholesterol stone (n = 42)	Mixed bilirubinate and cholesterol stone (n = 4)	Calcium carbonate stone (n = 3)
Yellow	55	15	2	2
Black	93	12	2	1
Brown	64	15	0	0
Green	5	0	0	0

DISCUSSION

We found that 82% of our patients had bilirubinate stones in the first attack, so the mechanism of CBD stone formation is different from the Western countries, but it is similar to some Asian studies^[9,20,21]. After ablation of sphincter of Oddi by ES, bactobilia may happen from direct extension of duodenal organisms into the CBD and β -glucuronidase released by the bacteria can promote the formation of bilirubinate stones^[17,18,22-24]. This explains why bilirubinate stone is the predominant composition of recurrent CBD stones (86%) after ES. Unlike the cholesterol stones, bilirubinate stones are often soft and easily broken^[16], so complete clearance of bilirubinate stones even after ES may be inadequate; some radiologically undetectable small fragments of bilirubinate stones may be left in the CBD; in addition to impaired biliary emptying, it may lead to bilirubinate stone formation at a later time.

Among the initial 42 patients with cholesterol stones, 8

patients received cholecystectomy at least 3 mo (median: 60 mo, range: 3-120 mo) before ES and 14 patients had intact GB but no GB stones. Besides spontaneous pass-out of stones, *de novo* formation of cholesterol stones from CBD may also be possible in these patients^[14,16].

In previous reports, JPD may facilitate primary CBD stone, but not GB stones formation^[16,25]. In our study, patients with initial bilirubinate stones had higher incidence of JPD than patients with initial cholesterol stones (43% *vs* 29%), but the difference did not reach statistical significance ($P = 0.084$).

In the 23 patients with initial bilirubinate stones, 21 had bilirubinate stones at recurrence, 2 had cholesterol stones when recurrence and these 2 patients also had GB stones at the time of recurrence, so stone pass-out from the GB may possibly explain the cholesterol composition of their CBD stones. In the four patients with initial cholesterol stones, three patients had bilirubinate stones and one had cholesterol stones at recurrence. The patient, who had recurrent cholesterol stones, had received cholecystectomy 6 mo before. It is difficult to determine whether the cholesterol stone is formed in the bile duct or GB. Our results indicated that different mechanism of CBD stone formation might occur in the same patient after ablation of sphincter leading to the formation of a different composition of stones.

In this study, we found that patients with bilirubinate stones are older than patients with cholesterol stones. Similar data have been found in Western patients with cholesterol *vs* pigment GB stones^[26]. It is well known that the duodenum is usually sterile in young healthy patients, but immunological and motor function of the alimentary tract may deteriorate gradually with age^[27]. The bacterial colonization of the CBD is an age-dependent phenomenon^[23] and this may explain the higher incidence of bilirubinate stones in older patients.

Cholesterol stones were usually yellowish or brownish^[15,28], but 12 out of 42 (29%) cholesterol stones in our patients were black in color, whereas 93 out of 217 (43%) bilirubinate stones were black in color. The nature of CBD stones cannot be completely determined by gross appearance alone^[28,29] and the IR spectroscopy is an important tool to determine the exact composition of stones.

For most patients, endoscopic retrieval of stones for analysis is more difficult than surgical procedure. In our study, only 266 out of 735 patients had received the analysis of stones. It could be speculated that different stone composition may influence the collection of stone for analysis during extraction procedure. Cholesterol stones are often smoother and harder while bilirubinate stones, on the other hand, are softer and tend to be broken down into small fragments when retrieved by basket or even a snarenet. This infers that the real percentage of bilirubinate stones in our patients may be actually higher. However, our analysis does not show significant difference in age, sex, presence of JPD, or cholecystectomy between patients whose stones were collected for analysis or not. Even though the CBD diameter and stone size are larger in the patients with stone analysis, there is no difference in CBD size or stone size between bilirubinate or cholesterol stones. We believe that little selection bias has taken place in our patients, despite only about 36% of patients' stones were collected for analysis.

In conclusion, bilirubinate stones are the predominant composition of initial and recurrent CBD stone after ES in Chinese patients. Patients with bilirubinate stones are older than those with cholesterol stones. The composition of stones may change after ES.

Abstract

AIM: To investigate the correlation between the serum soluble intercellular adhesion molecule-1 (sICAM-1) and the clinicopathologic features and to evaluate the possible prognostic significance of sICAM-1 concentration in colorectal cancer.

METHODS: A total of 56 patients (mean age 57.3 years) having transitional cell carcinoma of the colorectal and 25 control patients (mean age 42.6 years) were enrolled in the study. The serum samples of the patients were obtained on the day before surgery. Sera were obtained by centrifugation, and stored at -80 °C until assay. Serum concentrations of ICAM-1 were measured with enzyme-linked immunoassay. Differences between the two groups were analyzed by Student's *t*-test.

RESULTS: No significant increase of serum sICAM-1 could be demonstrated in the Dukes A₁ patients (352.63±61.82 µg/L) compared to the control group (345.72±49.81 µg/L, *P*>0.05), Dukes A₁ patients (352.63±61.82 µg/L) compared to Dukes A_{2,3} patients (491.17±86.36 µg/L, *P*<0.05). Furthermore, the patients with Dukes B had significantly higher serum concentrations of sICAM-1 than those of the control group (496.82±93.04 µg/L vs 345.72±49.81 µg/L, *P*<0.01). Compared with Dukes A_{2,3}, B colorectal cancer patients, patients with more advanced clinical stage (Dukes C and D) had higher levels of sICAM-1 (743.68±113.74 µg/L vs 491.17±86.36 µg/L and 496.82±93.04 µg/L, *P*<0.001). The difference was statistically significant in sICAM-1 levels between patients with positive lymph node status and those without lymph node involvement (756.25±125.57 µg/L vs 445.62±69.18 µg/L, *P*<0.001). Patients with poorly differentiated colorectal cancer had

a higher level of sICAM-1 than those with differentiated and highly differentiated cancer (736.49±121.97 µg/L vs 410.23±67.47 µg/L, *P*<0.001).

CONCLUSION: In this study, serum ICAM-1 levels were found to be related to tumor presence, clinical stages, and grade. Increased ICAM-1 in patients with colorectal cancer which should be considered when the diagnostic and/or prognostic usefulness of soluble ICAM-1 is to be evaluated. sICAM-1 should prove useful for monitoring malignant disease stage and for evaluating the effectiveness of various therapeutic approaches for colorectal carcinomas.

INTRODUCTION

Colorectal cancer is the third most common malignant neoplasm worldwide^[1] and has a higher incidence rate in Guangdong, Shanghai, Jiangsu, and Zhejiang Province. Moreover, with the development of economy, diets are high in total fat, protein, calories, alcohol, and meat (both red and white) and low in calcium and folate, which incline to increased incidence of colorectal cancer. The prevalence of colorectal cancer increased gradually in recent years. Efforts to identify causes and to develop effective preventive measures have led scientists pay much attention to it.

Intercellular adhesion molecule-1 (ICAM-1) is a monomeric, transmembrane molecule of the immunoglobulin superfamily with a molecular weight of 95-110 ku. Two ligands, the lymphocyte function-associated antigen-1 and the membrane adhesion complex-1, mediate adhesion and transvascular migration^[2]. This protein mediates adhesion and transmigration of leukocytes through the endothelium. Surface expressed ICAM-1 is apparently shed from the cells and then circulates as soluble ICAM-1 (sICAM-1). Although the source of sICAM-1 has not been fully elucidated, it can be released by cancer cells and also by mononuclear blood, endothelial, and fibroblastic cells^[3]. It has been reported that

the upregulated expression of ICAM-1 on cell surfaces occurred in a variety of diseases, including autoimmune diseases, endocrine diseases, and some cancers^[4,5]. A soluble form of ICAM-1 (sICAM-1) lacking cytoplasmic tail and transmembrane region has also been found^[5]. sICAM-1 can compete with membranous ICAM-1 to bind LFA-1, so that it can block leukocyte LFA-1 and prevent effective recognition and lysis of target cells by effector leukocyte. This phenomenon represents an important mechanism for tumor escape from immune surveillance^[6,7]. Shedding of ICAM-1 by circulating tumor cells may allow their escape from surveillance by cytotoxic T cell and natural killer cells and thus promote metastasis^[8]. In our research, we have found that some anticancer gene and proto-oncogene have different expression in colorectal cancer^[9,10]. In this study, we investigate the clinical significance of serum adhesion molecule levels at the time of diagnosis in patients with colorectal carcinoma and to evaluate the usefulness of these assays in terms of prognosis and survival.

MATERIALS AND METHODS

Patients and specimens

Serum samples were taken from 56 patients (32 men, 24 women, average age 57.3 years) with colorectal cancer admitted to the Affiliated Hospital of Guangdong Medical College from 2001 to 2002. In all patients the diagnosis was proven by histology. Staging was performed according to the criteria of Dukes system (Table 1). The reference group consisted of 25 others with non-malignant diseases (9 women and 16 men, average age 42.6 years). Blood samples were obtained from patients before the initial treatment. All blood samples were processed immediately for centrifugation. All sera were stored at -80 °C until assayed and determined not taking clinical information into account.

Table 1 Colorectal cancer patients and disease characteristics

Stage	n	%
Dukes A ₁	3	5.36
Dukes A _{2,3}	6	10.71
Dukes B	21	37.50
Dukes C and D	26	46.43
Histologic differentiation		
Highly	22	39.29
Moderate	24	42.86
Poorly	10	17.85
Localization		
Right colon	17	30.36
Left colon	21	37.50
Rectum	18	32.14

Measurement of sICAM-1

The serum levels of soluble receptors were determined quantitatively by specific enzyme-linked immunosorbent assay (ELISA). The serum samples were diluted 10 times according to the manufacturer's instructions (R&D Systems), and as described previously^[11]. Soluble receptor concentrations were calculated from standard curves generated by standard dilutions of known concentrations. The mean intra-assay CV, determined by assaying the sICAM-1 concentration in three serum samples in replicates of 10, is reported to be

4.4%. The mean inter-assay CV, determined by assaying three serum samples in duplicate in 18 separate assays by four operators, has been determined to be 7.4%. The cut-off values were calculated as the mean±SD were 860 ng/mL for sICAM-1. The reported sensitivity of the ELISA is less than 0.35 ng/mL.

Statistical analysis

The Student's *t*-test was used for statistical significance of differences between groups. *P*<0.05 was considered to be significant.

RESULTS

We studied the correlation between the sICAM-1 levels and clinicopathological factors, Table 1 shows the relationships between the concentration of sICAM-1 antigen in the sera and various clinicopathologic features of the patients. No significant increase of serum sICAM-1 could be demonstrated in the Dukes A₁ patients (352.63±61.82 µg/L) compared to a control group (345.72±49.81 µg/L, *P*>0.05). There is a significant statistic difference when Dukes A₁ patients (352.63±61.82 µg/L) compared to Dukes A_{2,3} patients (491.17±86.36 µg/L, *P*<0.05). Furthermore, serum sICAM-1 levels were significantly higher in patients with Dukes B when compared to the control group (496.82±93.04 µg/L *vs* 345.72±49.81 µg/L, *P*<0.01). Among patient groups, while there was no significant difference between Dukes A_{2,3} and Dukes B, a significant difference was found between Dukes B and Dukes C and D. Compared with Dukes A_{2,3}, B colorectal cancer patients, the patients with more advanced clinical stage Dukes C and D, had higher levels of sICAM-1 (743.68±113.74 µg/L *vs* 491.17±86.36 µg/L and 496.82±93.04 µg/L, *P*<0.001). Difference was statistically significant in sICAM-1 levels between patients with positive lymph node status and those without lymph node involvement (756.25±125.57 µg/L *vs* 445.62±69.18 µg/L, *P*<0.001). Poor differentiation was observed to have a higher level of sICAM-1 than moderated and highly differentiated patients *P*<0.001. The positive rates of each group were calculated with mean±SD of normal control sICAM-1 as a limit. The results are shown in Table 2.

Table 2 Correlation between soluble ICAM-1 concentrations and clinicopathologic factors in colorectal cancer

Factors	n	ICAM-1 (mean±SD, µg/L)	χ ²	P
Clinical staging				
Dukes A ₁	3	352.63±61.82 ^a		
Dukes A _{2,3}	6	491.17±86.36	2.88	<0.05
Dukes B	21	496.82±93.04 ^d	0.18	>0.05
Dukes C and D	26	743.68±113.74	12.38	<0.001
Grade of differentiation				
Highly differentiated	22	410.23±67.47 ^b

Lymph node negative	30	445.62±69.18	16.98	<0.001

^a*P*<0.05, Dukes A₁ *vs* Dukes A_{2,3}; ^b*P*<0.01, highly differentiated *vs* differentiated;

^d*P*<0.001, Dukes B *vs* Dukes C and D; Differentiated *vs* poorly differentiated; lymph node positive *vs* lymph node negative.

DISCUSSION

Soluble forms of cell adhesion molecules have been identified in the circulation and may be monitored as markers of inflammation and endothelial dysfunction^[4]. Neoplastic transformation and the evolution to metastatic disease are characterized by a dramatic aberration in cellular cohesive interactions. The adhesion molecules have also been shown to facilitate tumor cell motility, adhesion of tumor cells to endothelium, neovascularization at the metastatic sites, and host inflammatory response to cancer. Evaluation of sICAM-1 has shown important clinical implications in many types of cancer. In particular, the measurement of serum concentrations of ICAM-1 might provide important prognostic values independent of conventional pathologic factors in cancer patients^[12-14].

In the present study of colorectal cancer, revealed that serum sICAM-1 levels were elevated in patients with colorectal cancer. These parameters were elevated in both local and metastatic disease and significant correlations between the parameters and stage of disease were seen. The data of the present study are in agreement with those previously reported which described an increase in the sICAM-1 content of serum in colorectal carcinoma^[15,16]. We have also demonstrated that concentrations of sICAM-1 are increased in colorectal cancer, particularly in patients with distant metastasis. Our study also showed that sICAM-1 levels were correlated with both clinical staging and lymph node during liver metastasis involvement. Basoglu^[17] reported that the concentrations of sICAM-1 and TSA were significantly higher in patients with Dukes C and D, and they presume that sICAM-1 and TSA are the best of the tested markers. These markers should prove useful for monitoring malignant disease stage and for evaluating the effectiveness of various therapeutic approaches for colorectal carcinomas. In contrast to our study, it was demonstrated that the expression of sICAM-1 was inversely correlated with lymph node metastasis^[18].

With regard to prognosis, Liu reported in gastric cancer that serum sICAM-1 concentration may be a valuable parameter for predicting the prognosis and degree of the gastric cancer. Liu^[19] measured the circulating ICAM-1 in the sera of nasopharyngeal, oral, and laryngeal cancer cases and indicated that the circulating ICAM-1 was not elevated in the sera of oral and laryngeal cancer patients, but increased in nasopharyngeal cancer patients. They speculated that the discrepancy in the level of ICAM-1 among these three groups of patients with head and neck carcinoma might be attributed to either the different immunological reaction profiles or a cell-specific response. The cellular source and the mechanisms for releasing the soluble components of these endothelial adhesion molecules, although not well known, could involve either shedding or enzymatic cleavage from endothelial cells, leukocyte surfaces or tumor cells^[20]. Some mechanisms have been proposed concerning the elevation of sICAM-1 in serum, such as enzymatic cleavage of cell surface adhesion molecules or secretion of alternatively spliced forms lacking the transmembrane domain. Additionally, that sICAM-1 has been described on malignant epithelial tissue may be the source of at least some of the sICAM-1 present in sera of cancer patients^[21]. It is widely accepted

that histological stage is a powerful prognostic factor in colorectal cancer. In this study, it was revealed that ICAM-1 status has prognostic value coincide with histological stage. Therefore, these results suggested that it may be possible to add ICAM-1 status to conventional clinicopathological factors to predict recurrence.

In conclusion, our study demonstrates that ICAM-1 expression may be a useful indicator of prognosis in patients with colorectal cancer. Patients with lymph node, liver invasion, and advanced clinical stage of tumors had significantly higher serum concentrations of sICAM-1. Invasion status and clinical stage are significant prognostic indicators. Though serum level of sICAM-1 cannot be served as a specific parameter for colorectal cancer, it is no doubt that the measurement of the ICAM-1 level may provide a convenient means to obtain a general indication of colorectal cancer. Therefore, sICAM-1 may be a valuable predictor for colorectal cancer clinically.

Abstract

AIM: To study the effects of concentrated liquor from male zooid of *Antheraea pernyi* on immunological mice.

METHODS: For each experiment, 40 mice were randomly divided into normal saline group (control group) and three tested groups that were administered different dosages of concentrated liquor from male zooid of *A. pernyi* and food for 15 d. The typical FSR and HC_{50} value, monocyte-phagocytic exponent K and emendated monocyte-phagocytic exponent α were determined and calculated respectively.

RESULTS: After 24 and 48 h, the FSR values of the three tested groups improved significantly in comparison to the control group by variance analysis. The HC_{50} values showed a significant difference between the high dosage group and the control group, as well as between the high dosage group and other two tested groups. The monocyte-phagocytic exponent K and emendated exponent α showed rising tendencies, but no significant differences were found by variance analysis.

CONCLUSION: The concentrated liquor from male zooid of *A. pernyi* can significantly enhance cellular and humoral immune function in mice, but has no distinct influence on the monocyte-phagocytic system in mice.

INTRODUCTION

The concentrated liquor from male zooid of *Antheraea pernyi* is a pure preparation of traditional Chinese medicine, which possesses many health-care functions. According to The Great Dictionary of Traditional Chinese Medicine, *A. pernyi* is the matured insect of silkworm. The major components of male zooid are proteins and more than 20 kinds of free amino acids, cytochrome $C^{[1]}$, with the actions of tonifying the liver and invigorating the kidney, strengthening Yang Qi and astringing essence^[2]. So male zooid is mainly employed to treat impotence, seminal emission, and stranguria with hematuria. This agent is made from unmated male zooid of *A. pernyi*. The effective components are extracted from its combined lixivium of edible level, then isolated, purified, and concentrated with advanced cryogenic techniques. The qualitative and quantitative analyses are tested by thin-layer chromatography. We undertook this animal experiment to study the effects of the concentrated liquor on cellular, humoral, and monocyte-phagocytic immune functions in mice.

MATERIALS AND METHODS

Experimental materials

Raw materials from male zooid of *A. pernyi* were provided by the Silkworm Research Institute of Shandong Agriculture Science Academy, purified and concentrated in our laboratory^[3].

The whole blood of Guinea pig was sampled and centrifuged. The concentrated RBCs of mice were added to 5 mL of extracted Guinea pig serum and stored at 4 °C for 30 min before use, then centrifuged at 1 500 r/min for 15 min. Preclusion of unspecific hemolysis caused by complement was eliminated by extraction of supernatant. The processed serum diluted in normal saline at 1:10 served as the experimental complement.

Effects of concentrated liquor from male zooid of *Antheraea pernyi* on cellular immune function of mice

Forty Kunming mice (6-8 wk) weighing 18-20 g were randomized into three tested groups (high-, medium-, and low-dosage group), and treated with 16.53, 2.62, and 0.564 mg/kg of concentrated liquor from male zooid of *A. pernyi* respectively. During the 15-d process of continuous oral filling, a dosage of 2% 0.2 mL (1×10^6 /mL) (V/V) SRBC was injected into the abdominal cavity of each mouse on the 10th d. Four days later, sizes of the left plantars of the immunized mice were measured with slide gaud, then another dosage of 20 μ L (1×10^6 /mL) 20 mol/L (V/V)

SRBC was injected subcutaneously at the measured site of each mouse. Twenty-four and forty-eight hours after injection, thickness of the left plantar of each treated mouse was measured respectively. Each site was measured thrice, and the average value was used to calculate the FSR. $\text{FSR} = \text{thickness of the left plantar before injection} - \text{thickness of the left plantar after injection (mm)}$.

Effects of concentrated liquor from male zooid of *Antheraea pernyi* on humoral immune function of mice

Kunming mice (6–8 wk) weighing 18–22 g were randomized into three testing groups and fed with concentrated liquor from male zooid of *A. pernyi* at the dosages of 16.53, 2.62, and 0.564 mg/kg, respectively. During the 15-d process of continuous oral filling, a dosage of 0.2 mL (1×10^6 /mL) 20 mol/L (V/V) SRBC was injected into the abdominal cavity of each mouse on the 10th d. Five days later, whole blood was sampled from each mouse by eye extraction, and then the serum was prepared. Hemolysis in serum was determined as follows: the prepared serum from each mouse was diluted at 1:50, 1 mL of the diluted serum was added into a 10-mL test tube, and then 0.5 and 1 mL complement of 10% SRBC was added into the tube. A control tube was added with normal saline instead of serum. After incubation at 37 °C for 30 min, the reaction was stopped in ice bath, centrifuged at 2 000 r/min for 10 min, the supernatant was extracted and 3 mL of Du's reagent was added. At the same time, 0.25 mL 10% SRBC was added into Du's reagent to a final volume of 4 mL and placed at room temperature. The optical densities of all preparations were tested by type-722 spectrophotometer in 1-cm color matching cups, the optical density of the control test tube was defined as zero value. The semi-hemolytic value (HC_{50}) was calculated as: $\text{HC}_{50} = \frac{\text{optical density value of each sample tube}}{\text{optical density value of SRBC at semi-hemolysis} \times \text{dilution multiples}}$.

Effects of concentrated liquor from male zooid of *Antheraea pernyi* on monocyte-phagocytic function of mice

Kunming mice (6–8 wk) weighing 18–22 g were randomized into three tested groups and fed with concentrated liquor from male zooid of *A. pernyi* for 15 d at the same dosages as the above. After the last dosage was given, charcoal particle clearance test was performed. The detailed procedure was as follows: Each mouse was injected with diluted Chinese ink through its tail vein, 20 μL whole blood was sampled from the medial canthus of each mouse at the 2nd and 10th min respectively, distilled water was added to a final volume of 2 mL, and the A value at 600 nm was determined. Then, the mice were killed by dearticulation, the liver, and spleen were removed and weighed. The monocyte-phagocytic exponent K was calculated as $K = (\lg A_2 - \lg A_{10}) / (t_2 - t_1)$, and the emended monocyte-phagocytic exponent α as $\alpha = \text{body weight} / (\text{liver weight} + \text{spleen weight}) \times K^{1/3}$. The A_2 and A_{10} were the values at the 2nd and 10th min respectively, t_1 and t_2 represented the sampling time (both representing the ability of monocyte-phagocytic system to clear colloid charcoal particles in mice).

Statistical analysis

Variance analysis was performed with the statistical software

SPSS (version 10.0). The data were expressed as mean \pm SD, $P < 0.05$ was considered statistically significant.

RESULTS

Effects of concentrated liquor from male zooid of *Antheraea pernyi* on cellular immune function of mice

Twenty-four and forty-eight hours after immunization with SRBC, the FSR values of the three tested groups improved significantly compared to the control group by variance analysis (Table 1), indicating that the cellular immune function of mice could be improved obviously by concentrated liquor from male zooid of *A. pernyi*.

Table 1 Effects of concentrated liquor from male zooid of *A. pernyi* on cellular immune function of mice (mean \pm SD)

Group	Dosage (mg/kg)	Animal (n)	FSR (mm)	
			24 h	48 h
Control	dH ₂ O	10	0.66 \pm 0.25 ^b	0.20 \pm 0.16 ^d
Low-dosage	0.564	10	1.22 \pm 0.28	0.61 \pm 0.26
			<0.01	<0.01
Medium-dosage	2.62	10	1.24 \pm 0.23	0.61 \pm 0.19
			<0.01	<0.01
High-dosage	16.53	9	1.45 \pm 0.25	0.66 \pm 0.26
			<0.01	<0.01

^b $P < 0.01$, FSR (mm) of control group vs that of high-, medium- and low-dosage groups at 24 h respectively. ^d $P < 0.01$, FSR (mm) of control group vs that of high-, medium- and low-dosage groups at 48 h respectively.

Effects of concentrated liquor from male zooid of *Antheraea pernyi* on humoral immune function of mice

As shown in Table 2, the HC_{50} values representing the humoral immune function of mice showed a significant difference between the high dosage group and the control group by variance analysis ($F = 7.965$, $P < 0.01$). The same results were also observed between the high-dosage group and the other two tested groups ($P < 0.01$). The concentrated liquor from male zooid of *A. pernyi* had certain positive effect on the humoral immune function of mice.

Table 2 Effects of concentrated liquor from male zooid of *A. pernyi* on humoral immune function of mice (mean \pm SD)

Group	Dosage (mg/kg)	Animal (n)	HC_{50}
Control	dH ₂ O	7	42.2 \pm 18.2 ^b
Low-dosage	0.564	8	46.4 \pm 23.01 ^b
Medium-dosage	2.62	8	40.13 \pm 15.16 ^b
High-dosage	16.53	8	91.16 \pm 37.6
			<0.01 ^{b,d}

^b $P < 0.01$, high-dosage group vs control group. ^d $P < 0.01$, high-dosage group vs low- and medium-dosage groups respectively.

Effects of concentrated liquor from male zooid of *Antheraea pernyi* on monocyte-phagocytic function of mice

The monocyte-phagocytic exponent K and emended

Table 3 Effects of concentrated liquor from male zooid of *A. pernyi* on monocyte-phagocytic function of mice (mean±SD)

Group	Dosage (mg/kg)	Animal (n)	K	α
Control	dH ₂ O	10	0.0514±0.0122 ^a	6.249±0.772 ^c
Low-dosage	0.56	10	0.0527±0.0157 P>0.05	6.304±0.967 P>0.05
Medium-dosage	2.62	10	0.0517±0.0104 P>0.05	6.354±0.761 P>0.05
High-dosage	16.53	10	0.0570±0.0111 P>0.05	6.438±0.690 P>0.05

^aP>0.05, K value, high-, medium-, and low-dosage groups vs control group respectively. ^cP>0.05, α value, high-, medium-, and low-dosage groups vs control group respectively.

monocyte-phagocytic exponent α (both representing the ability of monocyte-phagocytic system to clear colloid charcoal particles in mice) are shown in Table 3. Both exponent K and emendated exponent α displayed a rising tendency, but no significant differences were observed among the groups by variance analysis ($P>0.05$).

DISCUSSION

The male zooid is an animal material medicine in China, whose functions are well documented in Compendium of Materia Medica as follows^[4]: invigorating essential Qi, strengthening vagina, untiring of sexual intercourse, and arresting essence. In Ri Hua Zi Ben Cao (Ri Hua Zi Materia Medica), it is documented to have the following actions: strengthening sexual function, checking spermatorrhea and stranguria with hematuria, warming kidney, extinguishing sore and scar, indications: wound from metal instrument injury, acute catarrhal and allergic conjunctivitis, and frostbite, heat-induced sore. Thus, male zooid can tonify the liver and invigorate the kidney, consolidate essence and strengthen Yang, check bleeding and promote muscle growth. The male zooid of *A. pernyi* contains many active substances, such as brain hormone, pro-thymosin, hormone of *A. pernyi*, diuretics, which can adjust metabolism and restore immune functions^[5-10].

Hu *et al.*^[11], using the fruit fly (*Drosophila melanogaster*) as a longevity model, examined the effect of hu-bao (HB) and seng-bao (SB), two marketed health products made from a mixture of natural ingredients, and found that the effect of HB and SB are specific for the male fly. The life-span of the male significantly increased when HB or SB was added to the culture medium. When the male silkworm moth ingredient was removed from HB or SB, the life-span prolongation effect of HB and SB drastically diminished, suggesting that the male silkworm moth is a key ingredient in combination with other components for specific prolongation of the life-span of male flies. The immune system in the Chinese oak silk moth, *A. pernyi*, originated from a single ancestral gene with that of the Cecropia moth whose antibacterial activity has been tested against nine different bacterial species^[12]. Zhang *et al.*^[13], reported that the cecropins from Chinese oak silkworm *A. pernyi* possess effective anti-tumor activity with no cytotoxicity against normal eukaryotic cells, and impede the neoplastic process in murine large intestines.

T cells play a role in immune response, killing tumor cells and suppressing tumor growth. Due to the actions of

estrogen, paracrine of tumor, negative nitrogen balance, the immune functions of patients can be suppressed and lead to immune escape, proliferation, and metastasis of tumor cells^[14]. Th1 and Th2 are two subgroups of CD4+Th cells. Most tumor tissues can secrete functional cytokine of Th2, causing the shift from Th1 to Th2 and immune suppression. Thus, promoting shift from Th2 to Th1 may be a method of tumor immunotherapy. The androgen-like action of male zooid can antagonize the immuno-suppression of high-level E2, promote high-expression of IL-18, induce production of IFN- γ , IL-2, IL-12, IL-18, and GM-CSF by monocytes, enhance cytotoxicity of NK and Th1 cells, accelerate proliferation of T cells and induce differentiation of Th1 cells^[15]. Amino acids in male zooid can adjust negative nitrogen balance and restore immune functions. Peptides in male zooid can also improve immune functions, enhance T cell activity by killing tumor cells^[16].

In general, the concentrated liquor from male zooid of *A. pernyi* can enhance non-specific immunity and CTL-mediated specific immunity, and has therapeutic functions in tumor therapy and adjuvant therapy.

Our study showed that the concentrated liquor from male zooid of *A. pernyi* could suppress tumor growth and improve immune function in mice. For immune modulation, it was observed in animal experiments that it could enhance cellular immunity significantly in all the three tested groups. In the high dosage group, the humoral immunity also obviously improved. A rising tendency was shown without significant difference.

In conclusion, the concentrated liquor from male zooid of *A. pernyi* is a potential anti-tumor agent by strengthening anti-pathogenic Qi. Further researches should be performed on its immuno-modulating effects on pancreatic and liver cancer.

Abstract

AIM: To summarize the operative experiences for giant leiomyoma of esophagus.

METHODS: Eight cases of giant esophageal leiomyoma (GEL) whose tumors were bigger than 10 cm were treated surgically in our department from June 1980 to March 2004. All of these cases received barium swallow roentgenography and esophagoscopy. Leiomyoma located in upper thirds of the esophagus in one case, middle thirds of the esophagus in five cases, lower thirds of the esophagus in two cases. Resection of tumors was performed successfully in all of these cases. Operative methods included transthoracic extramucosal enucleation and buttressing the muscular defect with pedicled great omental flap (one case), esophagectomy and esophago-gastrostomy above the arch of aorta (three cases), total esophagectomy and esophageal replacement with colon (four cases). Histological examination confirmed that all of these cases were leiomyoma.

RESULTS: All of the eight patients recovered approvingly with no mortality and resumed normal diet after operation. Vomiting during meals occurred in one patient with esophagogastronomy, and remained 1 mo. Reflux esophagitis occurred in one patient with esophago-gastrostomy and was alleviated with medication. Thoracic colon syndrome (TCS) occurred in one patient with colon replacement at 15 mo postoperatively. No recurrence occurred in follow-up from 6 mo to 8 years.

CONCLUSION: Surgical treatment for GEL is both safe and effective. The choices of operative methods mainly depend on the location and range of lesions. We prefer to treat GEL via esophagectomy combined with esophago-gastrostomy or esophagus replacement with colon. The long-time quality of life is better in the latter.

INTRODUCTION

Leiomyoma is the most common benign tumor found in the esophagus but it is, however, a rare neoplasm. It is found mainly in the lower and middle thirds of the esophagus and, in most cases are single lesions^[1]. Leiomyoma can occur at any age but 90% of cases occur in patients between the ages of 20 and 69 years, with peak incidence in the third to fifth decades^[2]. The male-to-female ratio is approximately 2:1. About half the patients with leiomyoma are asymptomatic and malignant change is rare. Transthoracic extramucosal enucleation is a safe and effective procedure for about 96% of esophageal leiomyoma^[3]. However, few of esophageal leiomyoma becomes giant-sized gradually (diameter of tumor larger than 10 cm) and show the symptoms caused by compression of tumor, obstruction of esophagus or dysfunction of cardia. The surgical treatment strategy of such GEL is not the same of common esophageal leiomyoma, especially when mucosa is damaged by leiomyoma or lesions have potential sarcomatous change. This report summarized the operative experience of GEL in our department.

MATERIALS AND METHODS

Materials

Between June 1980 and March 2004, there were 8 cases of GEL whose tumors were larger than 10 cm that underwent surgical treatment in our department. These patients comprised five males and three females, whose age ranged from 25 to 58 years (mean age, 42.5 years). Duration of symptoms was from 5 to 12 years. All of the eight patients had dysphagia and complained of retrosternal pain and backache in five cases, superior belly distention in five cases, weight loss in four cases, heartburn in three cases, cough in two cases, took normal diet in two cases, semi-liquid diet in four cases, liquid diet in two cases. All of the eight patients received barium swallow roentgenography and esophagoscopy. CT scan was performed in five cases, MRI in three cases, endoscopic ultrasonography (EUS) in one case. Leiomyoma located in upper thirds of the esophagus

in one case, middle thirds of the esophagus in five cases, lower thirds of the esophagus in two cases. The shapes of tumors were multinode-like in four cases, spiral-like in three cases, horseshoe-like in one case.

Methods

All patients received operation under general anesthesia. One patient underwent extramucosal enucleation of tumor and buttressing of the muscular defect with pedicled greater omental flap. In this case, the tumor located in lower thirds of the esophagus (Figure 1). Left posterolateral thoracotomy was performed through the sixth intercostal space. After removing the tumor, the muscular defect was found too large to allow a tension-free suture. Through a radial incision near esophageal hiatus, we made the great omentum into a pedicle flap (26 cm×9 cm) and pulled it up into thoracic cavity to cover the muscular defect. Three patients accepted esophagectomy and esophagogastrostomy above the arch of aorta through left posterolateral thoracotomy. Nasogastric tube and plasmatic canal were placed to aid in drainage and nutrition. Another four patients underwent total esophagectomy and esophageal replacement with colon. In these cases, patients were laid in supine position at the beginning. Esophageal interposition was performed with left colon (isoperistaltic, retrosternal) through left cervical abdominal incision. Then the patient's position was changed to full left lateral decubitus. Tumor and total esophagus were resected through right posterolateral thoracotomy. A feeding jejunostomy was used in these four patients, and enteral feeding was begun after 24 h with 5% dextrose in water and continued with an elemental diet after 48 h. The minimum size of tumor was 10 cm×10 cm×6 cm, the maximum was 20 cm×15 cm×15 cm. Histological examination confirmed that all of these were leiomyoma.

Figure 1 A 42-year-old male with giant esophageal leiomyoma. MRI image shows the tumor located in lower thirds of the esophagus. The size of tumor is 10 cm×10 cm×6 cm.

RESULTS

All of the eight patients recovered approvingly with no mortality and resumed normal diet after operation. Postoperative complications included leakage of cervical esophageal stoma (one case), pulmonary atelectasis (one case), thoracic infection (one case), chylothorax (one case). They all healed with conservative interventions and drainage. Patients were followed up from 6 mo to 8 years. Vomiting

after meals occurred in one patient with esophagogastrostomy, and remained for 1 mo. Vomiting after meals was not seen in patients with colonic interposition. Reflux esophagitis occurred in one patient with esophagogastrostomy and was alleviated with medication. Thoracic colon syndrome (TCS) occurred in one patient with colon replacement at 15 mo postoperatively, and recovered with re-operation. No recurrence occurred.

DISCUSSION

Leiomyoma is the most common benign tumor found in the esophagus but is nonetheless rare. Of all esophageal tumors, benign tumors account for fewer than 10%, of which 4% are leiomyomas^[4]. These tumors are usually found in middle age and are almost twice as common in men. They are located mainly in the lower and middle thirds of the esophagus. Leiomyoma may undergo cystic degeneration, calcification occurs infrequently and malignant change is rare^[5]. Leiomyoma is a slow growing tumor and the size of the lesion may not change for many years. Approximately one-half of all tumors are smaller than 5 cm, but 5% may be larger than 10 cm. Giant leiomyoma involving the entire esophagus and weighing up to 5 kg have been reported^[6]. Giant leiomyoma of esophagus should be removed when diagnosed, but its operative method is not the same of common leiomyoma.

Since most leiomyomas are intramural, eccentric, and well encapsulated, they can be easily shelled out (enucleated) without resorting to esophageal resection. One concern after enucleation of a large leiomyoma is that the myotomy may result functionally in achalasia. It is generally accepted that tumors up to 8 cm can be safely enucleated without significant postoperative dysphagia as long as the mucosa is intact and the myotomy is reapproximated^[3,7]. Larger lesions can be removed via enucleation but often result in the muscular defects too large to allow a tension-free suture, requiring a tissue flap to prevent mucosal bulging. We resected a 10 cm×10 cm×6 cm esophageal leiomyoma successfully with extramucosal enucleation and buttressing the muscular defect with pedicled greater omental flap. No postoperative dysphagia occurred during follow-up.

The greater omentum (GO) square is large and allows the covering of various tissue defects. The pedicled GO flap has the advantages of its own blood supply and anti-inflammatory effect^[14]. Using the GO to fill or buttress tissular defect is not novel in thoracic surgery^[14]. Angiography shows many types of vascular supply for the GO. Therefore, the GO flap exsection technique is very important. The flap transposition through the diaphragm is not difficult. The opening should not be very wide for good great omentum tissue adhesion and too narrow to prevent compression of the vessels.

Majority of GEL may require esophageal resection. The choices of this method depend on several factors: (1) The esophageal leiomyoma is too large to allow a resection without damaging the mucosa; (2) Adhesion between leiomyoma and the esophageal mucosa is tight and extensive; (3) Unrepairable mucosal defect caused by resection of tumor; (4) Large leiomyomas locate in the distal esophagus and extend downward across the cardia; (5) Leiomyosarcoma

is suspected. Resection for GEL is typically performed with esophagectomy and gastric pull-up through left posterolateral thoracotomy. In our experience, blood supply of the GEL was abundant, especially at the region posterior to the arch of aorta and upper part of the diaphragm. Careful dissection and hemostasia was necessary. Be cautious not to damage thoracic duct. For this purpose, transfixing the trunk of thoracic duct above the diaphragm between descending aorta and azygos vein was helpful. Gastric pull-up has some postoperative morbidity including reflux esophagitis, stricture formation, dumping, diarrhea, reduced meal capacity, and weight loss^[8]. Many of these complications are thought to be caused by division of the vagal nerves and the subsequent loss of parasympathetic innervation to the foregut^[9].

The rationale for use of the colon is that there will be fewer complications related to acid reflux than when the stomach is used for esophageal replacement. If the GEL is located in the upper thirds of the esophagus and the mucosa is damaged by GEL, esophageal replacement with colon (ERC) might be the best choice in this situation. Our techniques of ERC are different to others. The retrosternal colon replacement is performed through left cervical abdominal approaches in supine position at first, and then resects tumor and total esophagus through right posterolateral thoracotomy in full left lateral decubitus. We prefer this approach to synchronous abdominothoracic incision, for the former has allowed better exposure.

Several factors are important to decrease the mortality and postoperative complications of ERC: (1) Choosing suitable colonic segment and ensuring an adequate arterial supply. Before cutting the mesocolon, we usually clamp the communicating branches for 3~5 min in order to ensure that blood supply is enough; (2) Adopting isoperistaltic interposition. Studies show that isoperistaltic interposition is superior to antiperistaltic interposition and the long-time quality of life is better in the former^[10,13]; (3) Single-layer esophagocolonic anastomosis. Our studies show that single-layer anastomosis can reduce the morbidity of fistula and stricture^[11]; (4) Choosing colonic pull-up approach properly. The upward approach of colonic segment is decided by the condition of individual patient and the experience of the surgeon; (5) Avoiding redundancy of the colonic segment. Colon redundancy can be due to technical error at the time of operation (i.e., leaving redundancy in the interposition graft), intrathoracic herniation of colon, or differential colon growth. Proper attention to the length of the colon segment is important to prevent intrathoracic redundancy^[16]. Yildirim *et al.*^[17] suggest that the colon is one of the best substitutes for the esophagus, and there is no need to perform a routine pyloroplasty or antireflux procedure as an adjunct to the primary surgery. Our patients

healed satisfactorily and the long-time quality of life was good during follow-up and it was coincident with the literature^[12,13,15].

Abstract

AIM: To observe the Lamivudine resistance character of a DHBV strain *in vitro* and *in vivo*, and to analyze if the Lamivudine resistance character is caused by gene mutation or by abnormality of the Lamivudine metabolism.

METHODS: Congenitally DHBV-negative Guangdong brown ducks and duck embryo liver cells were respectively taken as animal and cell model. The Lamivudine-susceptible DHBV and Lamivudine-resistant DHBV (LRDHBV) were infected and Lamivudine was administered according to the divided groups. The changes of DHBV quantity in the animal and cell model were tested. Three Lamivudine-resistant and two Lamivudine-susceptible DHBV complete genomes were successfully amplified, sequenced and then submitted to GenBank. All the DHBV complete sequences in the GenBank at present were taken to align with the three LRDHBV to analyze the mutational points related to the Lamivudine-resistant mutation.

RESULTS: Both the animal and cell model showed that the large and the small dosage Lamivudine have no significant inhibitory effect on the LRDHBV. Five sequences of DHBV complete genomes were successfully cloned. The GenBank accession numbers of the three sequences of LRDHBV are AY521226, AY521227, and AY433937. The two strains of Lamivudine-susceptible DHBV are AY392760 and AY536371. The correlated mutational points are KorR86Q and AorE591T in the P protein.

CONCLUSION: The Lamivudine resistance character of this DHBV strain is caused by genome mutation; the related mutational points are KorR86Q and AorE591T and have no relations with the YMDD motif mutation.

INTRODUCTION

More than 400 million people worldwide are chronically infected by HBV^[1]. HBV infections, the 10th leading cause of death worldwide, result in 500 000 to 1.2 million deaths per year caused by chronic hepatitis, cirrhosis, and hepatocellular carcinoma^[2]. Lamivudine had been considered to be a great progress in the area of anti-virus drug. It can make the blood HBV DNA of more than 90% of patients changed to negative when administered for 1 year by 100 mg/d^[3,4]. But it can also lead to YMDD mutant and cause Lamivudine resistance. YMDD mutations developed in 12.1%, 49.7% and 70.5% of the patients respectively at year 1, 2, and 3^[5]. So the searching of Lamivudine-resistant problem is very important. It is believed consistently that the cause of Lamivudine resistance is HBV gene mutation. The main mutant motif is the YMDD in the P protein of HBV^[6-8]. But there are no animal and cell models of Lamivudine-resistant HBV which can be conveniently used, which cause very little progress that has been the problem of Lamivudine-resistant HBV.

After the finding of the DHBV by Summers *et al.*^[9,10], the process of replication and genome sequence of DHBV had been discovered rapidly. These facilitated the understanding of the related aspects of HBV. Because of the similarity of the DHBV and HBV in the replicating manner and pathogenesis, the duck hepatitis B model had been used as animal model of anti-HBV drug screening and HBV pathogenesis searching. When we persistently used the congenitally infected duck as animal model to screen anti-HBV drug, one congenitally infected duck had been found to have the character of Lamivudine resistance. We named it Lamivudine-resistant duck (LRD). The LRD-infected virus was named as Lamivudine-resistant DHBV (LRDHBV). We proved the character of Lamivudine resistance of LRDHBV in embryo duck liver cell model and postnatally infected duck model. Then the complete genome of LRDHBV and Lamivudine-susceptible DHBV were cloned and sequenced. The LRDHBV-related mutant points were analyzed.

MATERIALS AND METHODS

Animals

One-day-old Guangdong brown ducks were obtained from

a duck factory on the Shi-Jing town of Guangzhou city. Congenitally DHBV-negative ducks were chosen by dot blot assay to be experimental animals. The ducks were fed a standard duck diet and water according to the guidelines approved by the China Association of Laboratory Animal Care.

Primary hepatocytes

Guangdong brown duck eggs were purchased from a commercial supplier. The eggs were incubated for 20 d in the environment of 37.6 °C and 50-60% humidity. The eggs were opened and were proved to be congenitally DHBV negative using PCR method. The duck embryo liver was plucked out and digested with 0.2% collagenase (type II, Gibco) in 3 mL of serum-free William E medium (Sigma) supplemented with 2 mol/L L-glutamine, 15 mol/L HEPES (N-2-hydroxyethylpiperazine-N'-2-ethane-sulfonic acid [pH 7.2]), 100 U of penicillin per mL, 100 µg of streptomycin, 10⁻⁵ mol/L hydrocortisone, 1 µg of insulin per mL, and 1.5% dimethyl sulfoxide (all from Sigma, Germany) for 30 min at 37 °C. After washing twice with 5 mL of medium, the cells from one liver were suspended in 20-24 mL of medium, seeded onto 10-12 tissue culture dishes (60-mm diameter; 2 mL per dish, the density is 5×10⁵ cells per well), and cultivated at 37 °C and 50 mL/L CO₂. The medium was first changed 30 min after seeding, and further medium changes were done daily. Cellular toxicity was tested daily by light microscope examination and MTT assay of Mosmann^[11] as described by Alley *et al.*^[12].

Serum and DHBV infection

Lamivudine-susceptible DHBV serum was from congenitally infected ducks that had been proved to be DHBV positive by dot blot method. LRDHBV serum was from LRD at the time point of 10-d Lamivudine administration. In the animal model, 0.2 mL of Lamivudine-susceptible DHBV or LRDHBV was injected to the shank vein of every duck that were 2 d old. The primary hepatocytes were infected between 24 and 48 h after seeding by adding 50 µL Lamivudine-susceptible DHBV or LRDHBV per dish directly to the medium. After 3-h incubation at 37 °C, the inoculum was removed, and 2 mL of fresh medium was added.

Groups and dot blot assay

Twelve ducks infected with Lamivudine-susceptible DHBV and 18 ducks infected with LRDHBV were chosen and randomly divided into five groups. Group A were infected with Lamivudine-susceptible DHBV; group B were infected with LRDHBV; group C were infected with LRDHBV and fed with large dosage Lamivudine (100 mg/kg, b.i.d.); group D were infected with LRDHBV and fed with small dosage Lamivudine (20 mg/kg, b.i.d.); group E were infected with Lamivudine-susceptible DHBV and fed with small dosage Lamivudine (20 mg/kg, b.i.d.). The serum samples were collected at time points of 1 d before drug administration (D0), 5th d of drug administration (D5), 10th d of drug administration (D10) and 3rd d post stopping of drug administration (P3). The primary hepatocytes were also divided into five groups similar to the animal experiment. The hepatocytes were also

treated with two concentrations of Lamivudine (100 and 1 000 µmol/L) starting from 3 d after virus inoculation. The hepatocytes were collected and DNA was extracted at the time points of 3, 6, 9, and 12 d after virus inoculation respectively. Forty microliters of serum or twenty-five microliters of hepatocytes DHBVDNA extraction dissolution was spotted, and DHBVDNA was detected with a full-length DHBV genomic DNA probe labeled with [α -³²P] dCTP as described previously^[13]. A quantity analysis was carried out using enzyme photometer. The limit of detection of serum viral DNA by this assay is 100 pg/mL.

Amplification of the DHBV complete genome

Three samples of LRDHBV DNA were extracted from the serum of LRD which was the same as the LRDHBV serum used to infect the congenitally DHBV-negative ducks and duck embryo liver cells. Two samples of Lamivudine-susceptible DHBVDNA were extracted from serum of two ducks that were susceptible to Lamivudine. One pair of primers was used to test if there was DHBVDNA in the extraction solutions. The primer sequences^[14] are: P1 -5'-GCG CTT TCC AAG ATA CTG GAG CCC AA-3' (sense) and P2-5'-CTG GAT GGG CCG TCA GCA GGA TTA TA-3' (anti-sense). The PCR condition is: 94 °C 30 s, 55 °C 30 s, 72 °C 1 min, 30 cycles. One pair of primers was designed to amplify the complete genome of DHBV. The primer sequences are Q1-5'-ACC CCT CTC TCG AAA GCA ATA-3' (sense) and Q2-5'-GTG TAT GTA AGA GCC GTC CAA TC-3' (anti-sense). The LAPCR condition is: 94 °C 30 s; 52 °C 1 min; 72 °C 3.5 min, after 30 cycles, another 72 °C 5 min was supplemented. One percent agarose gel was used to analyze the LAPCR product.

Cloning and sequencing of DHBV complete genome

The 3.0-kb PCR product was inserted into the pMD18-T vector using the TAKARA Ligation kit. JM109 competent cells were made with the method of CaCl₂ which was found by Mandel *et al.*^[15,16]. Three LRDHBV DNA recombinants and two Lamivudine-susceptible DHBV DNA recombinants were transformed into the JM109 competent cells. The five kinds of *E. coli* containing the five kinds of recombinants were conserved and sent to TAKARA to do bidirectional sequencing. The sequencing results were analyzed with related software.

Statistical analysis

Results were expressed as mean±SD. Statistical comparisons between the groups were done using Nemenyi method. *P* values less than 0.05 were considered statistically significant.

RESULTS

Lamivudine could not inhibit LRDHBV in duck animal model

We first examined if the LRDHBV could be inhibited in body of the other duck. We injected the LRDHBV-positive serum to the congenitally DHBV-negative ducks. These ducks were infected with LRDHBV and treated with Lamivudine. Lamivudine were used in large and small dosage groups. The feeding was maintained for 10 d. Serum samples were collected at four time points from 1 d before administration to 3rd d post stopping of administration. The DHBV in the

serum samples were quantified by dot blot assay. After 10 d of Lamivudine administration, the quantity of Lamivudine-susceptive DHBV in the duck blood markedly got down. But 3 d after stopping of administration, the quantity of susceptible DHBV rose up to former level. No significant effect was observed when the large and small dosage of Lamivudine was fed to the LRDHBV-infected ducks (Table 1 and Figure 1). So it can be concluded that the LRDHBV can also show the character of Lamivudine resistance in the ducks postnatally infected with the LRDHBV.

Table 1 and Figure 1 showed that no significant effect was observed when the large and small dosage of Lamivudine was fed to the LRDHBV-infected ducks. While the 10-d Lamivudine administration could make the Lamivudine-susceptive DHBV markedly get down in the duck model.

The dynamic change of the DHBV quantity in the blood before and after lamivudine administration

Figure 1 A: Lamivudine-susceptive DHBV control group; B: LRDHBV control group; C: LRDHBV-infected group administrated by large dose Lamivudine group; D: LRDHBV-infected group administrated by small dose Lamivudine group; E: Lamivudine-susceptive DHBV-infected group administrated by small dose Lamivudine group.

Lamivudine could not inhibit LRDHBV in the duck embryo liver cells

We inoculated the LRDHBV to the primary duck embryo liver cells and administrated Lamivudine according to the divided groups to observe if the LRDHBV have the Lamivudine-resistant character in the liver cells. Lamivudine administration was started from 3rd d post DHBV inoculation and maintained for 9 d. The liver cells were collected at four time points from 3 to 12 d post DHBV inoculation. The total DHBV in the cells was extracted immediately after cell collection. The DHBV quantity was tested by dot blot assay. The results showed that the Lamivudine-susceptive DHBV got down markedly at the time points of 6th, 9th, and 12th d post DHBV inoculation, while both the small and large dosage Lamivudine have no significant effect on the LRDHBV in the duck embryo liver cells (Figure 3). So

the LRDHBV showed Lamivudine-resistant character in the duck embryo liver cells too. We also tested the cytotoxicity of Lamivudine to the embryo liver cells. However, no significant cytotoxicity was detected in liver cells cultured with different concentrations of Lamivudine for 9 d by daily microscope examination (Figure 2) and by MTT method.

Lamivudine-susceptive DHBV was inhibited markedly at the time points of 6th, 9th, and 12th d post DHBV inoculation, while both the small and large dosage Lamivudine have no significant effect on the LRDHBV in the duck embryo liver cells.

Figure 2 Duck embryo liver cells (5 d after DHBV inoculation, optic microscope ×40). They have no significant effect of Duck embryo liver cells infected with DHBV or LRDHBV.

Effects of lamivudine to the lamivudine susceptible and resistant DHBV in duck embryo liver cell culture

DHBV complete genomes were successfully amplified and cloned

We designed two pairs of primer to amplify the DHBV complete genome. One was designed according to the method

Table 1 DHBV quantity in the duck blood of various groups expressed by $A_{570\text{ nm}}$ value (mean±SD)

^bP<0.01 group A vs group E.

of Gunther to amplify the HBV complete genome^[17]. It covered the DR1 of DHBV genome. Another pair of primer covered the DR2 of DHBV genome and LAPCR was used to amplify. We found that the primer covering the DR1 could not amplify the DHBV genome after optimizing the LAPCR condition. However, when we used the primer covering the DR2, the complete genome of DHBV was easily amplified (Figure 4). So we amplified three strains of LRDHBV and two strains of Lamivudine-susceptible DHBV complete genome. Then we inserted these DHBV complete genomes into the pMD18-T vector and transformed them to the JM 109 competent cells (Figure 4). Then the *E. coli* that included the five DHBV complete genomes were sent to the TAKARA to sequencing. The five complete sequences of DHBV complete genomes were submitted to the GenBank. Three strains of LRDHBV are AY521226, AY521227, and AY433937. Two strains of Lamivudine-susceptible DHBV are AY392760 and AY536371.

Lanes 1 and 7: λ -EcoT14I digest marker; lane 2: the LAPCR product of DHBV complete genome; lane 3: the cloning product of DHBV complete genome; lane 4: *EcoRI* enzyme cutting product of DHBV complete genome recombinants; lane 5: loop product of pMD18-T vector; lane 6: *EcoRI* enzyme cutting product of loop product of pMD18-T vector.

Analyze the related mutant points in the LRDHBV genome

Firstly, we compared the complete nucleotide sequences of the AY521226, AY521227, and AY433937, and the identity is the same 98%. The identity of the AY392760 and the AY536371 is also 98%. But comparing the nucleotide sequences of the LRDHBV (AY521226, AY521227, and AY433937) with the Lamivudine-susceptible DHBV (AY392760 and AY536371), the identity in the nucleotide level is the same 92%. So it seems that there are marked differences between LRDHBV and the Lamivudine-susceptible DHBV in nucleotide level. As the HBV or DHBV P protein is the target of Lamivudine, we turned to the P protein sequences of these DHBV. We initially aligned the P protein sequences of AY521226, AY521227, AY433937 with AY392760, AY536371. There were too many mutant points to analyze which points were related to the Lamivudine-resistant character. As the identities of AY392760 and AY433937 is only 88%, alignment should be done in a wider range. We downloaded all the DHBV protein sequences and aligned with the three Lamivudine-resistant sequences AY521226, AY521227, and AY433937. We found that there were two mutational points in the P protein. The two mutational points are KorR86Q and AorE591T (Figures 5A and B). We have not found any

significant mutational points in S or C protein sequences. The KorR86Q is located in the TP (terminal protein) domain, and the AorE591T is located in the RT (reverse transcriptase) domain. So we guessed that these two mutational points were related to the character of Lamivudine resistance.

DISCUSSION

We referred to Gunther's method^[17] when we designed the primers of amplifying the DHBV complete genome. This method noted that only the primers cover the DR1 sequence of HBV, the HBV genome can be wholly amplified. We first used one pair of primers that cover the DR1 of DHBV to amplify DHBV complete genome. Though all kinds of methods of optimizing the PCR condition were tested, the DHBV complete genome could not be amplified. So we guessed that the DR2 of DHBV sequence is also an important obstacle of amplifying the DHBV complete genome. In our experience, it is very hard to get the target products when the primers are located at both sides of the DR2. Additionally, the DR2 is located at the terminal of DHBV-positive strand. There is nick part followed by DR2 in the positive strand of DHBV. So we designed one pair of primers to cover the DR2 to amplify the whole DHBV genome. To our surprise, the complete genomes of DHBV were easily amplified. This phenomenon may be because the genome structure of DHBV is different to the HBV.

If Lamivudine-resistant character of LRDHBV was caused by unusual metabolism of Lamivudine in the duck body and did not correlate with virus genome mutation, it should not have the Lamivudine-resistant character in duck embryo liver cells and other ducks infected with the LRDHBV. Our results showed that the LRDHBV resistant to the Lamivudine appeared both in duck embryo liver cells and in duck body. So we concluded that the Lamivudine-resistant character is caused by DHBV mutation.

To our present knowledge, most of the Lamivudine-resistant phenomena of HBV are related to the YMDD motif mutation^[6-8,18]. Similar to HBV, mutagenesis *in vitro* in the YMDD motif of DHBV can also cause Lamivudine resistance^[19]. So we speculate that the mutational points were also located in the YMDD motif of LRDHBV. But the sequencing results denied this speculation.

After we obtained the five DHBV complete sequences, we found that there are no YMDD motif mutations in the P protein sequences of the three LRDHBV sequences. Then we aligned the P protein sequences of three LRDHBV with the two Lamivudine-susceptible DHBV P protein sequences. There were too many different points to analyze the mutational points related to the character of Lamivudine resistance. So we planned to align these three LRDHBV P protein sequences with more DHBV P protein sequences. There should be a prerequisite that the DHBV P protein sequences aligned with the three LRDHBV P protein sequences come from the DHBV which are susceptible to Lamivudine. Because it was never reported that there was a naturally occurred LRDHBV and we found only one strain of DHBV that have the Lamivudine-resistant character in so many years of laboratory work, we believed that the LRDHBV that occurred naturally is very few. So we

Figure 5 A: KorR86Q mutant point in the P protein of the LRDHBV;

mutant point in the P protein of the LRDHBV.

presumed that the DHBV sequences in the GenBank up to now come from DHBV that are susceptible to Lamivudine. So we downloaded all the DHBV sequences in the GenBank and aligned the P protein sequences of these DHBV. The results showed that there were two mutational points that occurred in the P protein sequences of LRDHBV. It is KorR86Q in the TP domain and AorE591T in the RT domain. The TP domain of DHBV P protein mainly acts as a primer to originate the synthesis of DHBV-negative strand^[20]. But it is the tyrosine residue in 96aa of TP domain that primed the reverse transcription of negative strand^[21,22]. AorE591T is located in the lower reaches of YMDD motif. So the roles of KorR86Q and AorE591T in the Lamivudine-resistant phenomenon need deeper research.

For both hepadnaviruses and HIV, the mechanism of action of Lamivudine requires phosphorylation to 3TC-5'-triphosphate (3TC-TP), which in turn specifically inhibits the viral polymerase^[23-26]. The specificity is conferred by the much lower affinity of 3TC-TP for the cellular α - and β -polymerase^[25,27]. The mechanism of inhibition of hepadnavirus involves inhibition of the viral polymerase^[26,28,29]. Acting as a chain terminator for the DNA polymerase activities, the Lamivudine inhibit the reverse transcriptase in a manner that resemble competitive inhibition with respect to dCTP^[30]. The side groups of isoleucine and valine of the YMDD mutants sterically prevent Lamivudine from appropriately configuring into the nucleotide binding site of the reverse transcriptase^[31]. This can cause Lamivudine resistance. Can the KorR86Q and AorE591T mutants also prevent Lamivudine from appropriately configuring into the nucleotides binding site of the reverse transcriptase? It needs more research.

A 4-year clinical research showed that YMDD mutants only could explain the 75% of Lamivudine resistances. Polymerase gene mutations were observed in 82.5% of virological breakthroughs but also in 75% of the non-responders^[32]. So the mutations outside the YMDD motif in the P protein can independently cause DHBV resistant to Lamivudine is not very strange.

Abstract

AIM: To identify the distribution of *N*-acetyltransferase 2 (NAT2) polymorphism in Hebei Han Chinese and the effects of the polymorphism on the development of colorectal cancer.

METHODS: We performed a hospital-based case-control study of 237 healthy individuals and 83 colorectal cancer patients of Hebei Han Chinese. DNA was extracted from peripheral blood and cancer tissues. The genotypes of the polymorphisms were assessed by PCR-restriction fragment length polymorphism (RFLP).

RESULTS: There were four NAT2 alleles of WT, M1, M2, and M3 both in the healthy subjects and in the patients, and 10 genotypes of WT/WT, WT/M1, WT/M2, WT/M3, M1/M1, M1/M2, M1/M3, M2/M2, M2/M3, M3/M3. M2 allele was present in 15.61% of healthy subjects and 29.52% of patients ($\chi^2 = 15.31$, $P < 0.0001$), and M3 allele was present in 30.59% of healthy subjects and 16.87% of patients ($\chi^2 = 25.33$, $P < 0.0001$). There were more WT/M2 ($\chi^2 = 34.42$, $P < 0.0001$, odd ratio = 4.99, 95%CI = 2.27-9.38) and less WT/M3 ($\chi^2 = 3.80$, $P = 0.03$) in the patients than in the healthy subjects. In 70.3% of the patients, there was a difference in NAT2 genotype between their tumors and blood cells. Patients had more WT/M2 ($\chi^2 = 5.11$, $P = 0.02$) and less M2/M3 ($\chi^2 = 4.27$, $P = 0.039$) in their blood cells than in the tumors. Furthermore, 53.8% (7/13) of M2/M3 in tumors were from WT/M2 of blood cells.

CONCLUSION: There is a possible relationship between the NAT2 polymorphisms and colorectal cancer in Hebei Han Chinese. The genotype WT/M2 may be a risk factor for colorectal cancer.

INTRODUCTION

Colorectal cancer is one of the common tumors in Hebei Province of China. *N*-acetyltransferase 2 (NAT2) is polymorphic and catalyzes both *N*-acetylation (usually deactivation) and *O*-acetylation (usually activation) of a variety of heterocyclic amine drugs and carcinogens^[1]. Heterocyclic amines which are found mainly in well-cooked meat, require metabolic activation to function as mutagens and animal carcinogens. Enzymes such as cytochrome P4501A2 (CYP1A2) and NAT2 perform this task. Genetic studies in humans have shown that individuals may be classified as rapid or slow acetylators according to the rates at which drugs are acetylated by NAT2^[2]. NAT2 polymorphism is a representative genetic trait of individual's susceptibility to several cancers^[3]. Epidemiological studies suggest that the NAT2 acetylation polymorphisms modify the risk of developing carcinoma of urinary bladder, colorectal and breast cancer, head and neck cancer, pulmonary and prostatic cancer. Associations between slow NAT2 acetylator genotypes and urinary bladder cancer as well as between rapid NAT2 acetylator genotypes and colorectal cancer are the most consistently reported^[3]. However, whether there is a true association between colorectal cancer and NAT2 polymorphism is controversial. Human epidemiological studies suggest that rapid acetylator phenotypes may be associated with higher incidences of colorectal cancer in American populations^[4]. Researchers in UK^[5] found that no significant differences in NAT2 allelic frequencies (WT, M1, M2, M3 alleles) or genotypes are observed between colorectal cancer patients and the healthy population. Ethnic differences exist in NAT2 genotype frequencies that may be a factor in cancer incidence, emphasizing the need to investigate the distribution frequency of NAT2 genotypes and the association of their polymorphism with colorectal cancer in Hebei Han Chinese population.

We identified the distribution of NAT2 polymorphisms in Chinese healthy individuals and colorectal cancer patients from Hebei Province. We also performed a case-control study to investigate whether the NAT2 genetic polymorphism was a risk factor for colorectal cancer in these Chinese population.

MATERIALS AND METHODS

Subjects

We conducted a case-control study of colorectal cancer patients between April 2001 and April 2003. Both patients and controls were Hebei Han Chinese. Eighty-three patients (46 males, 37 females) with histopathologically confirmed diagnosis of colorectal cancer, were recruited from the Department of Surgery at Hebei No. 4 Hospital. Their mean age was 47.5 years (ranging 25-77 years). The control group consisted of 237 (124 males, 113 females) healthy individuals selected from the blood donors in Hebei Province Blood Center. Their average age was 42.6 years (ranging 20-80 years).

DNA extraction

The peripheral blood was treated with EDTA. Tumor samples were obtained from colorectal cancer patients and immediately frozen in liquid nitrogen and stored at -80 °C until used. Genomic DNA was isolated from peripheral leukocytes by PEL-FREEZE reagent protocol or from the tumor samples by the standard procedure of proteinase K/RNase digestion and phenol/chloroform extraction.

Typing NAT2 polymorphism

PCR-RFLP was performed to investigate the NAT2 allele. PCR was performed in 40 µL reaction mixture containing 50-200 ng DNA, 20 mmol/L of each primer, 1.25 mmol/L of dNTPs, 25 mmol/L of MgCl₂, 1 PCR buffer, 5U of thermostable Taq DNA polymerase using a programmable thermocycler. The primer sequences were 5'-GGA ACA AAT TGG ACT TGG-3' and 5'-TCT AGC ATG AAT CAC TCT GC-3'. PCR conditions were 5 min at 95 °C; 35 cycles of 1 min at 95 °C, 1 min at 57 °C and 1.5 min at 72 °C; followed by a final extension for 5 min at 72 °C. After amplification, the 1 093 bp PCR-products were digested with *Kpn*I (M1 allele), *Bam*HI (M3 allele), *Msp*I/*A*luI (M4 allele) for 16-18 h at 37 °C and *Taq*I (M2 allele) for 16-18 h at 65 °C separately in a 25 µL final volume. Digested fragments were then separated by electrophoresis on 20 g/L agarose gel (M1, M3) or 40 g/L agarose gel (M2, M4) and visualized by ethidium bromide staining. All the experiments included positive and negative controls for each studied polymorphism.

Statistical analysis

Statistical analysis was performed with SAS 6.0 for Windows. Hardy-Weinberg equilibrium test was carried out using statistical software for linkage analysis. χ^2 and Fisher's exact test were used for comparisons of frequencies. Associations were expressed as odd ratios (OR) with 95% confidence interval (95%CI). $P < 0.05$ was considered statistically significant.

RESULTS

Polymorphism of NAT2 gene in Hebei Han Chinese

The results of genotype analysis are shown in Figure 1. In 237 healthy and 83 colorectal cancer patients of Hebei Han Chinese, there were four kinds of NAT2 alleles including wild-type gene WT allele and polymorphisms of M1, M2, and M3 alleles (Table 1). No M4 polymorphism was found. Ten genotypes including WT/WT, WT/M1, WT/M2, WT/M3, M1/M1, M1/M2, M1/M3, M2/M2, M2/M3, M3/M3 and their frequencies in both groups are shown in Table 2. M3 (59.67%) was the major polymorphism in healthy group. The distribution of NAT2 genotypes in healthy group was consistent with Hardy-Weinberg equilibrium ($\chi^2 = 7.2533$, $g = 8$, $P > 0.5$). In healthy group, 71.3% and 28.7% were classified as rapid-acetylator genotypes (WT/WT, WT/Mx, $x = 1, 2, 3$) and slow-acetylator genotypes (Mx/Mx), respectively. The frequency of WT/M3 (29.1%) in the rapid-acetylator genotypes was the highest.

The frequency of allele M2 (29.5%) was the highest in the 83 patients, 18 (21.7%) were slow-acetylator genotypes (Mx/Mx), and 65 (78.3%) were rapid-acetylator genotypes (WT/WT, WT/Mx), 35 (53.8%) of them being WT/M2 (Table 2).

Association of NAT2 polymorphism with susceptibility to colorectal cancer in Hebei Han Chinese

M3 allele was present in 30.59% (154/474) of the healthy subjects and in 16.87% (28/166) of the patients ($\chi^2 = 25.33$, $P < 0.0001$). The M2 allele frequency was significantly different between healthy (15.61%) and patient groups (29.52%) ($\chi^2 = 15.31$, $P < 0.0001$). There was no difference in rapid-acetylator or slow-acetylator frequency between healthy and patient groups. However, there was a significant

Figure 1 NAT2 genotype analysis by PCR-RFLP. M: DNA Marker (100, 250, 500, 750, 1 000, 2 000 bp); **A**: digest with *Kpn*I (M1 allele) shows wildtype genotype (lane 2: 660 and 433 bp, WT/WT), variant genotype (lane 3: 1 093 bp, M1/M1) and heterozygote genotype (lane 1: 1 093, 660 and 433 bp, WT/M1); **B**: digest with *Taq*I (M2 allele) shows wildtype genotype (lane 1: 380, 317, 226 and 170 bp, WT/WT), variant genotype (lane 3: 396, 380 and

317 bp, M2/M2) and heterozygote genotype (lane 2: 396, 380, 317, 226 and 170 bp, WT/M2); **C**: digest with *Bam*HI (M3 allele) shows wildtype genotype (lane 2: 811 and 282 bp, WT/WT), variant genotype (lane 3: 1 093 bp, M3/M3) and heterozygote genotype (lane 1: 1 093, 811 and 282 bp, WT/M3); **D**: digest with *Msp*I/*A*luI (M4 allele) shows wildtype genotype (lane 1: 759, 189, 91 and 53 bp, WT/WT).

χ^2	2.20	0.64	34.42	3.80	1.54	0.00	0.00	0.007	0.12	2.06	2.01	1.54
<i>P</i>	0.14	0.42	<0.0001	0.03	0.22	1.00	1.00	0.94	0.73	0.15	0.16	0.22

difference between WT/M2 ($\chi^2=34.42$, $P<0.0001$) and WT/M3 ($\chi^2=3.80$, $P<0.05$) compared to the healthy controls. The risk associated with combinations of NAT2 genotypes is shown in Table 3. The genotype WT/M2 might be a risk factor for colorectal cancer (OR = 4.99, 95%CI = 2.27-9.38).

Comparable analysis of WT/M2 and M2/M3 genotypes in blood cells and cancer tissues of colorectal cancer patients

In 70.4% of patients, there was a difference in NAT2 genotype between tumor tissues and blood cells. The frequency of NAT2 genotypes, especially WT/M2 and M2/M3, was significantly different between tumor tissues and blood cells ($\chi^2=5.11$, $P<0.05$; $\chi^2=4.27$, $P<0.05$, Table 4). The frequency of genotype M2/M3 was 9.3% in

peripheral blood cells and 24.1% in cancer tissue. Furthermore, 53.8% (7/13) of the tumors had M2/M3 while the corresponding blood cells had WT/M2.

DISCUSSION

Human NAT2 is a genetic polymorphism. Different genotypes (WT/WT, WT/Mx, Mx/Mx, x = 1, 2, 3, 4) are composed of different NAT2 alleles (wild type allele WT, mutation allele Mx). According to the intensity of acetyl action, a different genotype shows a different phenotype (rapid-acetylase genotype and slow-acetylase genotype). Genotypes composed of any two mutation alleles (Mx/Mx) show slow-acetylase genotypes, while those consisted of WT/WT or WT/Mx show rapid-acetylase genotypes. Bell

et al.^[6], reported that there are significant differences in the frequency of WT, M1, and M4 alleles between Caucasian and African-Americans, while the frequency of M2 and M3 alleles is similar. The M4 allele is not detectable in Caucasian-Americans, while 18% African-Americans carry at least one M4 allele. The frequencies of NAT2 WT, M1, M2, M3, and M4 alleles in Singapore Chinese are 0.51, 0.07, 0.32, 0.10, and 0.00, respectively^[7]. The proportions of rapid and slow acetylators do also vary remarkably between ethnic groups as well as between populations of different geographical origins^[8]. For example, the percentage of slow acetylators is 5% in Canadian Eskimos, over 80% in Egyptians and 90% in Moroccans^[9,10]. Singapore Chinese have 72% of rapid-acetylator genotypes. In our study, four NAT2 alleles (WT, M1, M2, M3) and ten NAT2 genotypes (WT/WT, WT/M1, WT/M2, WT/M3, M1/M1, M1/M2, M1/M3, M2/M2, M2/M3, M3/M3) were found in Hebei Han Chinese. M4 was not present in Hebei Han Chinese, while 29.1% of healthy controls carried at least one M3 allele. Hebei Han Chinese had 71.3% of rapid-acetylator genotypes. The frequencies of the NAT2 M4 allele and rapid-acetylator genotypes are similar in both Hebei Han Chinese and Singapore Chinese, but there are significant differences in the frequencies of WT, M1, M2, and M3 between the two populations.

NAT2 is an important enzyme for the detoxification and/or bioactivation of several carcinogenic arylamines, its activity directly affects metabolic response of carcinogen *in vivo* and intensity of toxic reaction^[11]. It was reported that the polymorphism of NAT2 gene is associated with the occurrence of colorectal cancer^[12]. Genetic epidemiological studies suggest that rapid acetylator phenotype may be associated with the higher incidence of colorectal cancer in the UK populations^[12]. Lee *et al.*^[7], also showed that the rapid acetylator genotype is associated with cancer occurring in Singapore Chinese. However, our results suggest that rapid-acetylator genotype or slow-acetylator genotype does not appear to be associated with colorectal cancer development, but there is an association between the WT/M2 genotype and colorectal cancer. The M2 allele was more frequent in the patients than in the healthy subjects ($\chi^2 = 15.31$, $P < 0.0001$). Odds ratio (OR) for genotype WT/M2 was 4.99 (95%CI = 2.27-9.38). The data suggest that genotype WT/M2 may be a risk factor for colorectal cancer in Hebei Han Chinese.

Schnakenberg *et al.*^[13], detected the loss of heterozygosity in slow and rapid acetylator genotypes in bladder cancer patients. They observed allelic loss at the NAT2 locus in 11 of 60 tumor samples (18.3%), but not in controls. The

present study also demonstrated changes of NAT2 genotypes in 70.4% of the tumor specimens. The rising M2/M3 in tumors seems to be transformed from genotype WT/M2 of blood cells, and also suggests that WT/M2 may be a risk factor for colorectal cancer. Our findings may contribute to the early diagnosis of colorectal cancer.

Abstract

AIM: To explore the expression of albumin (ALB), insulin-like growth factor (IGF)-1, and insulin-like growth factor binding protein (IGFBP)-3 in tumor tissues and adjacent non-tumor tissues of hepatocellular carcinoma (HCC) patients with cirrhosis.

METHODS: Twenty-four HCC patients with cirrhosis who underwent hepatectomy were studied. ALB mRNA, IGF-1 mRNA, and IGFBP-3 mRNA in liver tissues (including tumor tissues and adjacent non-tumor tissues) were detected by reverse transcriptase-polymerase chain reaction (RT-PCR). Liver Ki67 immunohistochemistry staining was studied. At the same time, 12 patients with cholelithiasis or liver angioma who underwent operation were segregated as normal control.

RESULTS: In HCC patients with cirrhosis, hepatic ALB mRNA, IGF-1 mRNA, and IGFBP-3 mRNA of tumor tissues or adjacent non-tumor tissues were lower than the normal liver tissues, while in tumor tissues, hepatic ALB mRNA and IGFBP-3 mRNA were lower, hepatic IGF-1 mRNA was higher than in adjacent non-tumor tissues. Liver Ki67 labeling index (Ki67 LI) in tumor tissues or adjacent non-tumor tissues were higher than that in the normal liver tissues, while in tumor tissues it was higher than that in adjacent non-tumor tissues.

CONCLUSION: Imbalance of IGF-1 and IGFBP-3 may play a role in hepatocarcinogenesis and tumor development of liver cirrhosis patients.

INTRODUCTION

Extensive research on insulin-like growth factors (IGFs) during the last decade has greatly advanced our understanding of these peptides that are not only the endocrine mediators of growth hormone (GH)-induced metabolic and anabolic actions but also polypeptides that act in a paracrine and autocrine manner to regulate cell growth, differentiation, apoptosis, and transformation^[1]. In biological fluids, IGFs are complexed with specific binding proteins (IGFBPs)^[2-4]. The functions of IGFBPs are to modulate the biologic activity of IGFs. Imbalance of these diverse processes may preferentially favor uncontrolled cell proliferation leading to malignant transformation. Recent evidence from epidemiologic studies has confirmed an association between serum levels of IGFs and several malignancies at the population level and has resulted in a resurgence of scientific interest in this field.

IGF-1 and IGF-2 are single chain polypeptides, which have 62% homology with proinsulin. Serum concentrations of IGF-2 are higher than IGF-1 (400-600 ng/mL *vs* 100-200 ng/mL) in humans of all ages, are relatively stable after puberty and are not regulated by GH. IGF-2 has proliferative and antiapoptotic actions similar to IGF-1 since its effects are exerted by the IGF-1R^[5]. However, IGF-2 plays a fundamental role in embryonic and fetal growth, whereas its role in the postnatal period is less important as it is substituted by IGF-1.

The liver is the central organ of the endocrine GH/IGF-1 axis. GH is secreted by the somatotrophic cells of the anterior pituitary, transported in the circulation by the high affinity growth hormone binding protein and acts through the hepatic GH receptor to regulate the production of the potent mitogenic growth factor IGF-1. The availability of IGF-1 to its tissue receptors is further regulated by the high affinity IGFBPs (IGFBP-1 to -6) of which the liver is also a significant source, with IGFBP-3 being most abundant^[6]. Epidemiologic studies have found high circulating IGF-1 and low IGFBP-3 levels to be associated with an increased risk of developing breast, endometrial, lung, colorectal, and prostate cancer. IGFBP-3 was reported to be a growth suppressor in variable pathways^[7,8].

Hepatocellular carcinoma (HCC) is the fifth most common cancer worldwide, with estimated 467 000 new cases per year^[9]. HCC is one of the most common malignant tumors in the world. Since the 1990s HCC has become the second killer in various cancers in China. Most HCC cases arise in HBV and liver cirrhosis. In carcinogenesis induced by viral infection, the frequency of gene mutation is considered to increase as the mitotic activity of cells gets greater. Under conditions that increase the proliferative activity of hepatocytes such as chronic hepatitis and liver cirrhosis, the probability of mutation increases, resulting in increased occurrence of HCC.

Albumin (ALB) is the major protein produced in the liver, and its primary functions include transportation of a variety of substances in the blood and maintenance of osmotic pressure. In normal adults, ALB constitutes more than 65% of the total plasma protein content. The plasma concentration of ALB reflects its synthesis, degradation, and distribution. Thus, the expression of hepatic ALB mRNA was more useful in reflecting the degree of liver injury or liver functional reserve than serum ALB.

In this study, we used the reverse transcriptase-polymerase chain reaction (RT-PCR) technique to detect ALB mRNA, IGF-1 mRNA, IGFBP-3 mRNA in tumor tissues and adjacent non-tumor tissues of HCC patients with cirrhosis. At the same time, we have immunochemically detected Ki67 antigen which appears in all phases of the cell cycle of proliferating cells but is negative in G₀^[10] on paraffinized section by microwave antigen retrieval method and compared the proliferative activity between adjacent non-tumor tissue as well as tumor tissues. We explored the roles of IGF-1 and IGFBP-3 in hepatocarcinogenesis and tumor development of liver cirrhosis patients.

MATERIALS AND METHODS

Patients and tissue samples

Of the patients at our department who underwent curative resection for HCC with liver cirrhosis between September 2002 and June 2003. Curative resection was defined as complete resection of all macroscopically detectable tumor with histological tumor clearance (the entire tumor mass was included in the surgical specimen without exposure of tumor cells on the cut edge). At the time of study entry, the inclusion criteria had no evidence of endocrine disease. Twenty-four HCC patients with liver cirrhosis who underwent hepatectomy were studied. At the same time, 12 patients with cholelithiasis or liver angioma who underwent operation were segregated as normal control and these patients had no liver cirrhosis and endocrine disease.

Liver samples (including HCCs and adjacent non-tumor tissues) were excised at the operation, immediately freeze clamped with liquid nitrogen, and stored at -70 °C for analysis of ALB mRNA, IGF-1 mRNA, and IGFBP-3 mRNA. For histological examination, some liver samples were fixed in 10% neutral-buffered formalin, embedded in paraffin.

Reverse transcriptase polymerase chain reaction (RT-PCR)

RT-PCR was performed to measure the expression levels

of ALB mRNA, IGF-1 mRNA, and IGFBP-3 mRNA in liver tissues. The primers used were deduced from the cDNA sequence. The sequences of the primers for ALB sense and antisense were 5'-CCCAAGTGTCAACTCCAAC-3' (sense) and 5'-GCAGGTCTCCTTATCGTCAG-3' (antisense), a 456 bp long fragment was amplified. The sequences of the primers for IGF-1 sense and antisense were 5'-AGCAGTCTTCCAACCCAATTA-3' (sense) and 5'-CACGGACAGAGCGAGCTG-3' (antisense), a 355 bp long fragment was amplified. The sequences of the primers for IGFBP-3 sense and antisense were 5'-ATATGGTCCCTGCCGTAGA-3' (sense) and 5'-AAATCGAGGCTGTAGCCAG-3' (antisense), a 345 bp long fragment was amplified. The sequences of the primers for β -actin sense and antisense were 5'-ACTCTTCCAGCCTTCCTTCCT-3' (sense) and 5'-TCACCTTCACCGTTCAGTTT-3' (antisense), a 513 bp long fragment was amplified.

Total RNA was extracted from frozen liver specimens by the guanidinium isothiocyanate method. The RNA was quantified and checked for purity by spectrophotometry at 260 and 280 nm. Aliquots of total RNA were reverse transcribed using *SperSriptII* Reverse Transcriptase (Invitrogen Corp.) and subsequently amplified by PCR using the Taq DNA polymerase (Promega Corp.).

The PCR was carried out in 25 μ L of reaction mixture containing 0.5 μ L cDNA template, 2.5 μ L 10 \times PCR-Buffer, 1.5 μ L 25 mmol/L MgCl₂, 0.5 μ L 10 mmol/L dNTPs, 0.5 μ L 10 μ mol/L ALB or IGF-1 or IGFBP-3 primers, 0.15 μ L 10 μ mol/L β -actin primers, 0.5 μ L 5 IU/ μ L Taq DNA polymerase. The mixture was heated for 5 min at 94 °C for initial DNA denaturation, followed by 30 cycles of denaturation (at 94 °C for 45 s), annealing (ALB at 50 °C for 45 s, IGF-1 at 48 °C for 45 s, IGFBP-3 at 55 °C for 45 s), polymerization (at 72 °C for 1 min) and then a final extension of 10 min at 72 °C. PCR reactions were stored frozen until analysis by agarose gel electrophoresis.

PCR reactions were electrophoresed on 1.5% agarose gel, stained with ethidium bromide and quantitated using the interactive build analysis system. The band intensity of the ALB or IGF-1 or IGFBP-3 was compared with the band intensity of the β -actin, and the amount of ALB mRNA, IGF-1 mRNA, and IGFBP-3 mRNA was estimated.

Immunohistochemistry

Two-step immunohistochemical staining technique was used. Main reagent included rabbit polyclonal antibody Ki67 Ab-4 (Neomarkers Corp.) and PV-6000 PicTure™ Kits. Briefly, sections were deparaffinized, rehydrated, and then immersed in 0.1 mol/L citric acid buffer (pH 6.0) and boiled for 5-10 min in a microwave oven. The slides were then rinsed gently with PBS at pH 7.2-7.4, and treated with 0.3% hydrogen peroxide in absolute methanol for 1 h at room temperature to remove endogenous peroxidase. The sections were then incubated with the primary antibody Ki67 Ab-4 (1:200 dilution) for 30 min at 37 °C. After rinsing thrice with PBS, each for 2 min, the sections were incubated with PV-6000 for 30 min at 37 °C. They were then rinsed thrice with PBS for 2 min, and visualized with DAB. Finally, the sections were then counterstained with hematoxylin.

On each slide, Ki67-positive nuclei were evaluated by

means of light microscopy at 400 magnification. A minimum of 1 000 cells, evaluated through a minimum of 200 cells per field in five different fields. The Ki67 labeling index (Ki67 LI) is the number (%) of positive cells.

Statistical analysis

Data are expressed as mean \pm SE. The statistical software SPSS 10.0 was used. Statistical significance was set at $P<0.05$.

RESULTS

In HCC patients with cirrhosis, hepatic ALB mRNA, IGF-1 mRNA, IGFBP-3 mRNA of tumor tissues or adjacent non-tumor tissues were lower than the normal liver tissues, while in tumor tissues, hepatic ALB mRNA and IGFBP-3 mRNA were lower, hepatic IGF-1 mRNA was higher than in adjacent non-tumor tissues. Liver Ki67 LI in tumor tissues was higher than that in adjacent non-tumor tissues, while in adjacent non-tumor tissues it was higher than that in the normal liver tissues (Table 1).

Table 1 Comparison of hepatic ALB mRNA, IGF-1 mRNA, IGFBP-3 mRNA and liver Ki67 LI

	<i>n</i>	ALB mRNA	IGF-1 mRNA	IGFBP-3 mRNA	Liver Ki67 LI (%)
Normal liver tissues	12	0.69 \pm 0.05	0.95 \pm 0.02	2.02 \pm 0.04	0 \pm 0
Tumor tissues	24	0.38 \pm 0.01 ^a	0.76 \pm 0.03 ^a	0.45 \pm 0.13 ^a	17.3 \pm 5.9 ^a
Adjacent non-tumor tissues	24	0.50 \pm 0.05 ^{a,c}	0.43 \pm 0.06 ^{a,c}	0.72 \pm 0.17 ^{a,c}	0.2 \pm 0.1 ^{a,c}

^a $P<0.05$, tumor tissues or adjacent non-tumor tissues vs normal liver tissues;

^c $P<0.05$, adjacent non-tumor tissues vs tumor tissues.

DISCUSSION

The liver is probably the major source of circulating IGF-1 with GH confirmed as the dominant regulator of IGF-1 gene expression and serum levels in human disease^[11-13]. IGF-1 is an important anabolic polypeptide with various effects. IGF-1 synthesis is disturbed in liver cirrhosis and reflects the severity of the clinical stage. It represents a good marker of hepatic function. The etiology of cirrhosis does not seem to influence its levels^[14]. Serum IGFBP-3 proves to be a better marker for the hepatic synthetic capacity than serum ALB or cholinesterase^[15]. Serum IGF-1, IGF-2, and IGFBP-3 may provide a new dimension in the assessment of liver dysfunction. Combined detection of serum IGF-1, IGF-2, and IGFBP-3 with Child-Pugh score is more effective in predicting prognosis than Child-Pugh score alone.

Giovannucci presented a model integrating nutrition, insulin and IGF-1 physiology ("bioactive" IGF-1), and carcinogenesis based on the following: (1) insulin and the IGF-1 axis function in an integrated fashion to promote cell growth and survival; (2) chronic exposure to these growth properties enhances carcinogenesis; and (3) factors that influence bioactive IGF-1 will affect cancer risk. The model presented here summarizes the data that chronic exposure to high levels of insulin and IGF-1 may mediate many of the risk factors for some cancers that are high in

Western populations. This hypothesis may help explain some of the epidemiologic patterns observed for these cancers, both from a cross-national perspective and within populations^[16]. In HCC, HBV stimulates IGF-1R expression^[17] and enhances IGF-2 gene expression^[18]. Hepatitis C virus has also been related to increased IGF-2 transcription in HCC^[19]. HCC is associated with a higher IGF-1:IGFBP-3 ratio than that found in patients with liver cirrhosis and a similar degree of liver failure^[20].

IGF-1 and IGFBP-3 play a crucial role in the regulation of growth, cellular proliferation and transformation, and apoptosis. The local tissue expression of IGF-1 and IGFBP-3 has been associated with tumor grade, pathologic stage, and disease progression for patients with various malignancies. Epidemiologic studies have found high circulating IGF-1 and low IGFBP-3 levels to be associated with an increased risk of developing breast, endometrial, lung, colorectal, and prostate cancer. IGFBP-3 was reported to be a growth suppressor in variable pathways^[7,8]. In the IGF receptor dependent pathway, IGFBP-3 binds to IGF-1 and 2 and suppresses its growth signal. In the IGF receptor independent pathways, the IGFBP-3 mediates wide varieties of growth suppression signal.

This study showed hepatic IGF-1 mRNA, IGFBP-3 mRNA of tumor tissues or adjacent non-tumor tissues were lower than the normal liver tissues, while in tumor tissues, hepatic IGFBP-3 mRNA was lower but hepatic IGF-1 mRNA was higher than in adjacent non-tumor tissues. Thus, imbalance of IGF-1 and IGFBP-3 are thought to be important in hepatocarcinogenesis and tumor development of liver cirrhosis patients. IGFBP-3 mRNA which decreased in local tissues may take part in important roles in carcinogenesis. As the IGFBP-3 is produced mainly in the liver, IGFBP-3 may play an important role in the carcinogenesis of HCC. IGFBP-3 functions as a general mediator of growth inhibitory and apoptosis-inducing pathways.

IGFBP-3 is the most abundant IGFBP in human serum and has been shown to be a growth inhibitory, apoptosis-inducing molecule, capable of acting via IGF-dependent and IGF-independent mechanisms. Over the last decade, several clinical studies have proposed that individuals with IGFBP-3 levels in the upper normal range may have a decreased risk for certain common cancers. This includes evidence of a protective effect against breast, prostate, colorectal, and lung cancer. In addition, a series of *in vitro* studies and animal experiments point towards an important role for IGFBP-3 in the regulation of cell growth and apoptosis. Epidemiologic and experimental evidence suggesting a role for IGFBP-3 as an anti-cancer molecule^[21]. At the intracellular level this may either involve modulation of the bcl-2/bax ratio^[22] or the p53 protein^[23]. Kuemmerle *et al.*, reported that endogenous IGFBP-3 directly inhibits proliferation of human intestinal smooth muscle cells by activation of TGF-betaRI and Smad 2, an effect which is independent of its effect on IGF-1 stimulated growth^[24]. Interestingly, IGFBP-3 has been localized in the nucleus, implying a more direct transcriptional regulatory role, but it remains largely unknown how extracellular IGFBP-3 enters the cell^[25].

The liver has the unique capacity to regulate its growth

and mass both in humans and in animals. This property is particularly remarkable because hepatocytes are cells which in their normal state rarely divide. However, their proliferative capacity and the ability of the liver to adapt to variable metabolic demands are not lost. To assess the proliferating cells, we have immunochemically detected Ki-67 nuclear antigen. Characterization of the Ki-67 antibody revealed an interesting staining pattern. The antibody was reactive with a nuclear structure present exclusively in proliferating cells. A detailed cell cycle analysis revealed that the antigen was present in the nuclei of cells in the G₁, S, and G₂ phases of the cell division cycle as well as in mitosis. Quiescent or resting cells in the G₀ phase did not express the Ki-67 antigen. Because the Ki-67 antigen was present in all proliferating cells (normal and tumor cells), it soon became evident that the presence of this structure is an excellent operational marker to determine the growth fraction of a given cell population. For this reason, antibodies against the Ki-67 protein were increasingly used as diagnostic tools in cell proliferation.

ALB is a ubiquitous protein that is synthesized only by hepatocytes. ALB is a polypeptide chain of 580 amino acids that is produced by hepatocytes^[26]. The number of ALB molecules produced by a single hepatocyte has been estimated to be ~40 000^[27]. The expression of ALB gene is reduced in various liver diseases and the degree of reduction in the hepatic ALB mRNA level is generally correlated with the severity of the disease^[28]. This study showed that liver Ki67 LI in tumor tissues was higher than that in adjacent non-tumor tissues, which was higher than that in normal liver tissues, but hepatic ALB mRNA in tumor tissues was lower than that in adjacent non-tumor tissues, which was higher than that in normal liver tissues. It represented that proliferating hepatocytes or tumor tissues had less function.

The IGF system performs a fundamental role in the regulation of cellular proliferation, differentiation, and apoptosis. Disruptions in the balance of IGF system components leading to excessive proliferation and survival signals have been implicated in the development of different tumor types. This study represented the imbalance of IGF-1 and IGFBP-3 which are thought to be important in hepatocarcinogenesis and tumor development of liver cirrhosis patients. Epidemiologic evidence indicates that increased levels of IGF-I, reduced levels of IGFBP-3 or an increased ratio of IGF-1 to IGFBP-3 in the circulation are associated with an increased risk for the development of several common cancers, including those of the breast, prostate, lung, and colon. The results of preclinical studies indicate that a diversity of interventions which antagonize IGF-1R signaling or augment IGFBP-3 function inhibit tumor cell growth in models of human cancers. A more comprehensive understanding of the interplay between cellular targets of the IGF system and antineoplastic agents will facilitate the development of novel strategies for the prevention and treatment of cancer^[29]. Thus, the GH/IGF-I axis may be a target for cancer prevention and treatment.

Abstract

AIM: To investigate the potential role of nuclear factor kappa-B (NF- κ B) activation on the reactive oxygen species in rat acute necrotizing pancreatitis (ANP) and to assess the effect of pyrrolidine dithiocarbamate (PDTC, an inhibitor of NF- κ B).

METHODS: Rat ANP model was established by retrograde injection of 5% sodium taurocholate into biliopancreatic duct. Rats were randomly assigned to three groups (10 rats each): Control group, ANP group and PDTC group. At the 6th h of the model, the changes of the serum amylase, nitric oxide (NO), malondialdehyde (MDA), superoxide dismutase (SOD) and pancreatic morphological damage were observed. The expressions of inducible nitric oxide (iNOS) were observed by SP immunohistochemistry. And the expressions of NF- κ B p65 subunit mRNA were observed by hybridization *in situ*.

RESULTS: Serum amylase and NO level decreased significantly in ANP group as compared with PDTC administrated group [(7 170.40 \pm 1 308.63) U/L vs (4 074.10 \pm 1 719.78) U/L, P <0.05], [(76.95 \pm 9.04) μ mol/L vs (65.18 \pm 9.02) μ mol/L, P <0.05] respectively. MDA in both ANP and PDTC group rose significantly over that in control group [(9.88 \pm 1.52) nmol/L, (8.60 \pm 1.41) nmol/L, vs (6.04 \pm 1.78) nmol/L, P <0.05], while there was no significant difference between them. SOD levels in both ANP and PDTC group underwent a significant decrease as compared with that in control [(3 214.59 \pm 297.74) NU/mL, (3 260.62 \pm 229.44) NU/mL, vs (3 977.80 \pm 309.09) NU/mL, P <0.05], but there was no significant difference between them. Though they were still higher than those in Control group, pancreas destruction was slighter in PDTC group, iNOS expression and NF- κ B p65 subunit mRNA expression were lower in PDTC group as compared with ANP group.

CONCLUSION: We conclude that correlation among NF- κ B activation, serum amylase, reactive oxygen species level and tissue damage suggests a key role of NF- κ B in the pathogenesis of ANP. Inhibition of NF- κ B activation

may reverse the pancreatic damage of rat ANP and the production of reactive oxygen species.

INTRODUCTION

Acute pancreatitis is clinically classified into mild and severe forms. Mild or edematous acute pancreatitis is a self-limiting disease with a low complication and mortality rate. However, ANP has an unacceptably high morbidity and mortality rate. Multiple therapeutic modalities have been suggested for acute pancreatitis, but none has been unambiguously proven to be effective yet. The major problem is that the pathophysiology of the disease is not fully understood^[1,2].

Oxygen free radicals are molecules produced continuously in cells by several mechanisms. The generation of oxygen free radicals is physiologic. In most circumstances, oxygen free radicals are neutralized immediately by enzymatic scavengers. But when formation of oxygen free radicals overwhelms radical neutralization in cells, oxidative stress occurs. As they are very reactive, they react well with all biological substances such as proteins, polysaccharides, and nucleic acids, resulting in tissue injury. It has been suggested that oxygen free radicals are responsible for a wide variety of diseases or conditions, for they play an important role in the pathogenesis of pancreatitis in some experimental models, and they are involved in the initiation of pancreatitis. Also, it was reported that oxygen free radicals acted as important mediators of tissue damage in experimental acute pancreatitis^[3,4].

Nuclear factor kappa-B (NF- κ B) is a sequence-specific transcription factor known to be involved in inflammatory and immune responses. It plays an important role in physiologic and pathologic conditions as an inducible nuclear factor. NF- κ B is able to mediate a variety of inflammatory mediators involved in acute pancreatitis, including cytokines and adhesion molecules, as well as specific inducible isoform of nitric oxide synthase enzymes. Recent experimental studies appeared to have shed some light on the intracellular signaling

pathway in the inflammatory cascade in acute pancreatitis^[5-7]. Hence, the role of NF- κ B in acute pancreatitis has attracted more and more attention.

Therefore, this study was conducted to evaluate the role of NF- κ B in experimental model of rat ANP and to analyze the role of NF- κ B activation on nitric oxide (NO) and other reactive oxygen species in the pathogenesis of ANP.

MATERIALS AND METHODS

Experimental groups and models

We randomized 30 male Wistar rats (weighing 250-300 g) to three groups, Control group, ANP group, and PDTC group. After having fasted for 24 h before the experiment, and allowed only drinking water freely, all rats were intraperitoneally infused with 2.5% pentobarbital sodium. When the abdominal cavity was opened through the median incision, the common bile duct and the pancreatic duct were found. After intubation from the end of pancreatic duct, the pancreatic duct was shut both at the duodenal ampulla and near the hepatic hilum transiently to prevent regurgitation of the infusion into the liver or duodenum. The ANP and PDTC group were induced by slow and even infusion of 5% sodium taurocholate (Sigma, St. Louis, MO, USA) into the pancreatic duct. The Control group received infusion of saline of the same amount instead of sodium taurocholate. In addition to sodium taurocholate, PDTC group received intravenous infusion of PDTC (Sigma, St. Louis, MO, USA) 10 mg/kg, while Control and ANP group received the same amount of saline instead.

Tested parameters

At the 6th h of the model, blood was collected from the abdominal aorta of rats, and the pancreas was removed according to the following measurement: (1) Serum amylase detected by HITACHI 7170 automatic biochemical analyzer; (2) Ratio of NO₂⁻ to NO₃⁻ determined by copper-zinc-cadmium reductive chromatometry, which reflects NO level; (3) Malondialdehyde (MDA) detected by TBA chromatometry; (4) Superoxide dismutase (SOD) detected by hydroxylamine chromatometry; (5) Morphological damage to pancreas observed microscopically after fixation in 10% neutral formaldehyde solution and HE stain, morphological alterations were graded using a scale of the degree of inflammation, necrosis and edema; (6) Expressions of iNOS in pancreatic tissue detected by iNOS immunohistochemical kits (Beijing Zhongshan Biotechnology Co., Ltd. Beijing, China) iNOS antibody was diluted 50 fold, tested with SP method, and cells stained with brown-yellow granules were considered to be positive; (7) Expressions of NF- κ B p65 subunit mRNA in pancreatic tissue: After fixation in 4%

citromint and 1% DEPC, expression of NF- κ B p65 subunit mRNA *in situ* kits (Wuhan Boster Bioengineering Co., Ltd. Wuhan, Hubei, China) Plasma and nucleus of pancreatic acinar stained with brown-yellow granules were considered to be positive. All immunohistochemistry or *in situ* images were analyzed and processed using MetaMorph v4.6 software (Universal Imaging Corp.). The intensity of expression was represented by average gray value, and the difference of average gray value reflected the difference of expression. Two pathologists assessed all of histopathologic sections in 20 fields/organ, and they were not aware as to which groups the sections belonged.

Statistical analysis

SASS 6.12 statistical analytic software was applied to process the data collected, and $P < 0.05$ was considered statistically significant.

RESULTS

Change of serum amylase, NO, MDA, and SOD (Table 1)

After the above treatment, serum amylase in ANP group rose rapidly. Although it was significantly higher than that in control group ($P < 0.05$), serum amylase of PDTC group was still significantly lower than that in ANP group ($P < 0.05$). NO levels in both ANP and PDTC group increased. The former, however, was significantly higher than the latter ($P < 0.05$). MDA in both ANP and PDTC group rose significantly over that in control group ($P < 0.05$), while there was no significant difference between the two results themselves. SOD levels in both ANP and PDTC group underwent a significant decrease as compared with that in control group ($P < 0.05$), but there was no significant difference between either of them.

Morphological change of the pancreatic tissue (Figure 1)

The only gross change in the abdominal cavity in control group was the mildly edematous pancreas. No structural damage was found microscopically in the pancreatic tissue, except for some local interstitial edema. In ANP group, bloody ascites, necrotic foci in pancreas, and fat necrosis in mesentery and omentum were found grossly. Interstitial lobular inflammatory infiltrations were observed in pancreas microscopically, as well as diffusive bleeding and piecemeal necrosis. In PDTC group, ascites and fat necrosis diminished notably compared with those in ANP group. Microscopically, slight bleeding, mild acinar degeneration and mild structure damage to lobules were observed together with declining inflammatory infiltration. The damage of ANP group is obviously grave than PDTC group [Histopathologic score: (5.76 ± 1.12) *vs* (4.00 ± 1.50) , $P < 0.05$].

Table 1 Changes of serum amylase, NO, MDA, SOD

Group	Amylase (U/L)	NO (umol/L)	MDA (nmol/L)	SOD (NU/mL)
Control	990.20 \pm 189.32	56.97 \pm 13.31	6.04 \pm 1.78	3977.80 \pm 309.09
ANP	7170.40 \pm 1308.63 ^c	76.95 \pm 9.04 ^c	9.88 \pm 1.52 ^c	3214.59 \pm 297.74 ^c
PDTC	4074.10 \pm 1719.78 ^{a,c}	65.18 \pm 9.02 ^a	8.60 \pm 1.41 ^c	3260.62 \pm 229.44 ^c

^a $P < 0.05$ vs ANP group; ^c $P < 0.05$ vs control group.

Figure 1 Morphological change of the pancreatic tissue (original magnification, $\times 400$). A: Control group; B: ANP group; C: PDTC group.

Figure 2 Expression of NOS in pancreatic tissue (DAB, original magnification, $\times 400$). A: Control group; B: ANP group; C: PDTC group.

Expressions of iNOS in pancreatic tissue (Figure 2)

Expression of iNOS was negative in control group while positive in both ANP and PDTC group, mainly found in endotheliums and smooth muscle cells. The iNOS expression is significantly lower with PDTC group than ANP group [Average gray value: (80.43 ± 10.48) *vs* (64.26 ± 9.18) , $P < 0.05$].

Expressions of NF- κ B p65 subunit mRNA in pancreatic tissue (Figure 3)

In control group, expression of NF- κ B was negative in all acinar nuclei, and positive only in some plasma. In ANP group, however, the expression was positive in both nucleus and plasma of pancreatic acinar. And the expression in nucleus and plasma decreased significantly in PDTC group [Average gray value: (104.25 ± 19.08) *vs* (67.28 ± 8.95) , $P < 0.05$].

DISCUSSION

One of the most severe complications of ANP is multiple system organ failure (MSOF) in early stage. The early systemic complication is the major cause of death in ANP, which leads to a mortality rate of 20%. Although it has been indicated that trypsin activation, auto-digestion of pancreas, cytokines, endotoxin, reactive oxygen species, and arachidnate^[8-11] play an important role in the progression of MSOF in ANP, the mechanisms of the development of this disease remain obscure.

Like what happens in other inflammatory diseases, reactive oxygen species are generated in the early stage of

ANP, and they play quite a vital role in the onset and development of ANP^[11]. During ANP, activated neutrophils are attached to endothelial cells, infiltrate into tissues, and produce large amount of reactive oxygen species and a kind of cytokines, which may cause severe damage to the pancreatic tissue. NO, in addition to potent function of vasodilation, can also inhibit the adherence, infiltration, and activation of white blood cells, and affect the production of reactive oxygen species^[11,12]. NO is generated by two classes of nitric oxide synthase (NOS): One that is constitutive, Ca^{2+} -dependent and physiologically activated (cNOS) and the other is inducible (iNOS). cNOS produces temperate amount of NO relieving ANP, whereas iNOS produces excess NO exacerbating the damage of ANP to the body^[12].

Excessive production of NO causes vasodilatation and hypotension leading to organ hypoperfusion, edema, and organ dysfunction. Moreover, the reaction of NO with superoxide causes the formation of peroxynitrite, which is a powerful oxidant and cytotoxic agent and may play an important role in the cellular damage associated with the overproduction of NO. The spontaneous reaction of peroxynitrite with proteins makes the nitration of tyrosine residues to form nitrotyrosine, which is a specific nitration product of peroxynitrite and a marker for peroxynitrite-induced oxidative tissue damage. In this study, we found the concentration of SOD as an antioxidant decreased and that of MDA as the lipid peroxide increased, indicating the role of NO on the free radical reaction and oxidation response could intensify ANP.

Figure 3 Expression of NF- κ B p65 mRNA in pancreatic tissue (DAB, original

magnification, $\times 400$). **A:** Control group; **B:** ANP group; **C:** PDTC group.

NF- κ B is a kind of pleiotropic regulative protein of transcription. Its activation takes part in the pathogenesis of ANP. Inhibition of the action can ameliorate the rat ANP^[13,14]. NF- κ B is also capable of regulating the expression of multiple inflammatory genes, such as tumor necrosis factor α (TNF- α), interleukin-6,8 (IL-6,8), and iNOS^[15]. Over-expressions of these discussed genes, however, can cause damage to the pancreatic and extra-pancreatic tissues in ANP. NF- κ B activation does relate to the reactive oxygen species in ANP.

Our study provides evidence that the injection of sodium taurocholate can cause ANP, with manifestation of the rise of serum amylase and NO, MDA level, damage to pancreas, inflammatory infiltration, and the decrease of SOD. Hybridization *in situ* and immunohistochemical results suggest that NF- κ B is activated immediately at the onset of ANP, accompanied by high expression of iNOS. And there is otherwise no expression of NF- κ B and iNOS under physiological conditions. The lower expression of NF- κ B p65 subunit mRNA in PDTC group indicates that the administration of PDTC may inhibit the NF- κ B activation. PDTC also leads to lower increase in serum amylase and slighter histological damage to pancreas. All these results are consistent with previous studies, substantiating that NF- κ B activation is involved in the pathogenesis of ANP, and inhibition of the activation may reverse rat ANP^[13,14]. Compared with those in ANP group, the NO and MDA level decreases, SOD level increases, and iNOS expression decreases. It is the increase of iNOS expression that aggravates ANP. Expression of iNOS is regulated by NF- κ B activation and inhibition of the activation may reduce iNOS expression, thus relieve ANP. Correlation among NF- κ B activation, NO, MDA, SOD level, tissue damage, and iNOS expression suggests a key role of NF- κ B activation in the pathogenesis of ANP model. By inhibiting iNOS expression, NF- κ B activation sets back over-production of reactive oxygen species like NO, therefore it reverses the damage of ANP to rats.

We may finally draw the conclusion from the above study that NF- κ B activation in rat ANP may reduce over-production of reactive oxygen species, thus ameliorate the

severity of ANP, all of which is achieved by inhibiting iNOS expression. The drug that can inhibit the activation of NF- κ B may become a way of the therapy of ANP.

Abstract

Hemangiopericytoma is a rare tumor especially when it rises in the peritoneal cavity. We present a case of a 60-year-old woman with an isolated recurrent hemangiopericytoma of the liver. The patient presented with a palpable right upper quadrant abdominal mass, which occurred 7 years after undergoing resection of a malignant hemangiopericytoma arising from the greater omentum. She had not followed up 6 mo after surgery. Various imaging studies showed a single large, well-capsulated liver tumor with central necrosis, accompanied by hypervascularity typical of a vascular tumor. Preoperative laboratory HBsAg and anti-HCV workup were both negative. Under the impression of recurrent malignant hemangiopericytoma, right trisegmentectomy was performed to completely resect the tumor. Pathological examination confirmed the diagnosis of recurrent hemangiopericytoma. Even though the incidence of the hemangiopericytoma is relatively low, malignant hemangiopericytoma has a tendency to recur frequently after a long-term disease-free interval. Also, the recurrent hemangiopericytoma is not easily detected early during follow-up until it becomes symptomatic because there are no specific tumor markers, and because of the diversity with regard to site of recurrence. The authors suggest that Positron Emission Tomogram (PET) may be a useful tool for the detection of recurrent hemangiopericytoma. We describe herein some characteristics and behaviors of malignant hemangiopericytoma, particularly after surgical resection.

INTRODUCTION

Hemangiopericytoma was first described in 1942 by Stout

and Murray, and approximately 1 000 cases have been reported to date in the literature. Hemangiopericytomas arise from the pericyte of Zimmermann, and although it may occur in any part of the human body, the frequency of occurrence has been reported to be the lower extremities, pelvic cavity, retro-peritoneum, thoracic cavity, and upper extremities, in descending order. Most tumors have been reported to occur in the deep portions of the body, and those arising within the peritoneum are rare^[1]. Generally, although hemangiopericytomas arising in the peritoneal cavity show better prognosis compared to adenocarcinomas that occur in the gastrointestinal tract, surgery seems to be the only effective mode of therapy.

Histologically benign hemangiopericytomas are known to be curable by complete surgical resection, while the malignant type, albeit characterized by slow growth, has been known to recur frequently after curative surgical resection. Another reported characteristic of hemangiopericytomas is the development of non-islet-cell-tumor hypoglycemia in the latter phase of the natural course^[1], and this has been related to the production of the insulin-like growth factor II by the tumor^[2,3]. Malignant hemangiopericytomas are characterized by an indolent rate of growth, but recurrence has been demonstrated in more than half of the cases which had been followed up. In addition, the diversity of the sites of recurrence via hematological and lymphatic routes and lack of specific tumor markers has contributed to the difficulty in detecting recurrent disease. The lungs have been shown to be the most common distal site of recurrence, while other sites include the brain, scalp, chest wall, liver, subcutaneous lymph node, gastrointestinal tract, and ovaries^[4,5].

The authors report a surgically treated case of hemangiopericytoma of the greater omentum, and which recurred as a metachronous solitary liver metastasis 7 years after complete resection. We also suggest the employment of the positron emission tomography (PET) method as a useful tool in the post-operative follow-up of patients with a history of hemangiopericytomas, as there is no other definite established mode of follow-up.

CASE REPORT

A gravida 6, para 5, at present 60-years old, female patient had presented with a palpable lower abdominal mass referred initially from a private gynecologic clinic in March 1997, under the impression of a myoma of the uterus. Her past gynecologic history showed that she had entered menopause at 49 years of age. Physical examination showed a mobile, solid mass in the lower abdomen. Transvaginal ultrasonography demonstrated that the mass did not originate from the uterus. A magnetic resonance imaging was performed to determine if the mass was of ovarian origin, and which

showed that an 8 cm sized, solitary mass of unknown origin was present in the pelvic cavity. There was no evidence of lymph node enlargement. The tumor markers β -HCG, CA19-9, CA-125, CEA were all within the normal range. The patient subsequently underwent exploratory laparotomy under the impression of a possible ovarian malignancy, upon which a 10 cm \times 8 cm \times 7 cm mass originating from the greater omentum was observed. There was no gross evidence of other pathology such as surrounding adhesions or lymph node pathology, and the patient consequently underwent tumor excision including a portion of the omentum. Pathologic examination revealed necrosis in the central portion of the tumor, atypical hyperplasia of spindle-shaped tumor cells, and five mitoses per 10 HPF, suggestive of a malignant hemangiopericytoma. The patient was discharged 7 d after surgery and no further adjuvant anti-cancer therapy was administered. She had not followed up 6 mo after surgery.

The patient was asymptomatic until October 2004, when she began to complain of a palpable right upper quadrant mass, and she visited our department for evaluation. Initial abdominal computerized tomography (CT) demonstrated a large mass in the right hepatic lobe. To ascertain whether this lesion was a possible hepatocellular carcinoma, a common cause of liver tumors in Korea, viral marker studies were conducted, and which showed HBsAg (-), anti-HBs (+), anti-HBc (+), and anti-HCV (-). Also, the tumor markers

AFP, CEA, CA19-9, and CA125 were all within normal limits. Plain chest X-ray was also normal.

Abdominal CT scan showed that the tumor was of a hypervascular nature, with active contrasting from the periphery of the tumor in the arterial phase, and remaining contrast in the delayed phase suggesting a tumor of vascular origin. The hepatic artery angiogram confirmed that the tumor was hypervascular, with vessels from major arteries providing branches surrounding and entering into the deep portions of the tumor (Figure 1). These findings were highly suggestive of a recurrent malignant hemangiopericytoma. To determine the presence of any distant metastatic lesion, a head and neck CT (normal) was performed, while the 18 F-FDG PET scan showed a standardized uptake value (SUV) of 4.8 in the right hepatic lobe indicative of 18 F-FDG uptake. There were no other suspicious sites other than the liver (Figure 2). The patient therefore underwent laparotomy and right trisegmentectomy of the liver under the impression of recurrent malignant hemangiopericytoma. Gross findings showed a 15 cm, large solitary sarcomatous lesion with central necrosis. Microscopic examination of the tumor confirmed the presence of malignant hemangiopericytoma identical to that of the lesion of 1997, with free resection margins (Figures 3 and 4). The patient was discharged on the 20th postoperative day without complications.

Figure 1 A: Liver CT scan showed a huge tumor in the right lobe of the liver with enhancement from the periphery in the arterial phase; B: The hepatic arteriogram

demonstrated numerous feeding vessels surrounding and entering into the tumor. The patient had variation of the right hepatic artery from the superior mesenteric artery.

Figure 2 A: 18 F-FDG PET showed high uptake at the tumor without any distant lesions. The silent area in the center of the tumor suggests central necrosis (arrow); B: The highest uptake area measured 4.8 SUV (red line mark).

Figure 3 Resected specimen showed a huge single tumor with sarcomatous consistency. The margin was irregular because of the constrictive envelopment of feeding vessels. The central necrosis is indicated (arrow).

Figure 4 Microscopic examination demonstrated numerous atypical vessels (stag-horn appearance) in the high population of spindle-shaped tumor cells. A mitotic figure is seen (arrow), H&E, $\times 200$.

DISCUSSION

Hemangiopericytomas primarily occurring in the abdominal cavity are very rare, and only 12 cases in the world-wide literature have reported those occurring in the greater omentum. It is thought that surgical removal of the tumor is the most effective mode of therapy for hemangiopericytomas, but as yet there is no established range of surgical resection for malignant types that occur in the abdomen. As demonstrated in our case, in light of the fact that secondary surgery confirmed recurrent metastatic liver tumor 7 years after initial simple excision, and that there was no local recurrence in the omentum and the peritoneal cavity, we do not feel that complete anatomical removal of the total greater omentum would lead to superior prognosis compared to simple excision only. This finding is similar to previously reported cases of greater omental hemangiopericytomas^[6].

Grossly, malignant hemangiopericytomas have been reported usually as a solitary lesion, but in some series, several hundred, multiple nodules have also been observed^[7]. In most cases, the tumor is observed as smoothly encapsulated, while the areas where the vessels enter into the tumor surface are characterized as irregular due to local tumor retraction. As hemangiopericytomas are hypervascular tumors, angiography demonstrates a feature of numerous feeding vessels surrounding and entering into the tumor, sometimes being observed as multiple cork-screw type feeding vessels. These findings, however, are not common findings, and are not highly regarded as a distinctive diagnostic feature^[8,9]. Moreover, it is difficult to ascertain both a diagnosis of hemangiopericytoma and malignant characteristic with these radiological and gross findings alone.

Microscopic observation of H&E staining demonstrates numerous neovascularized vessels within a highly concentrated area of tumor cells, and which also frequently show a stag-horn feature. The tumor cells are mostly spindle-shaped, but may be spherical or other shapes, the nuclear to cytoplasm ratio is increased, while the cytoplasm is pale staining. Differential diagnosis includes glomus tumor, fibrous histiocytoma, synovial sarcoma, and mesenchymal sarcoma, and advances in immunohistochemical techniques usually allows differentiation from a malignant hemangiopericytoma. It has been reported in the previous literature that malignant

hemangiopericytomas comprise about half of all cases, and that after local excision and long-term follow-up, approximately 60% of patients experience local or distant recurrence^[4]. The disease-free interval has been reported to vary markedly between 2 mo and 26 years^[10]. Specific features that qualify a hemangiopericytoma as a malignant lesion are more than four mitoses per 10 HPF, pleomorphic cells with abnormal chromatin pattern, and accompanied by either central tumor necrosis or intra-tumoral hemorrhage.

Observations of previous data regarding hemangiopericytomas arising in the greater omentum have shown that the presence of more than four mitoses per 10 HPF is closely related to recurrence of disease. Also, the number of increased mitoses has also been suggested to be related with increased tumor size, and that tumors of more than 20 cm in diameter imply poor prognosis^[6].

Other modes of therapy for malignant hemangiopericytoma may consist of anticancer chemotherapy and radiotherapy for residual or metastatic tumors^[11,12], and these are usually the preferred mode of adjuvant therapy after surgery because of limited efficacy.

From the clinical perspective, compared to other common malignant tumors of the gastrointestinal tract, malignant hemangiopericytomas have a comparatively longer disease-free interval after surgical resection and an indolent natural history^[13]. However, it should be mentioned that in many cases of recurrent disease after a long disease-free interval, it is common that either the qualified gastrointestinal surgeon concludes that the disease has been completely cured after a certain length of follow-up, or that the patient refuses further follow-up. This is also reflected in our case, whereby the patient presented with a recurrent large intra-abdominal mass, or with related cancer symptoms such as hypoglycemia.

Another difficulty involving postoperative management of hemangiopericytoma is that since there is no established follow-up protocol after surgery, the length of follow-up and the diagnostic methods employed varies from surgeon to surgeon. Moreover, the absence of specific tumor markers makes it all the more difficult to detect recurrent disease. The authors of this study suggest that the PET scan is a valid, non-invasive diagnostic procedure in the ascertainment of recurrent malignant hemangiopericytoma. This may be particularly true in patients where if the preoperative PET demonstrates a hemangiopericytoma, the presence of a recurrent tumor of a similar character will be detected by PET in the follow-up. However, it should be noted that there may be differences in the degree of uptake between histologically identical hemangiopericytomas. In our case ^{18}F -FDG uptake was increased within the tumor, but other series have shown that ^{11}C -methionine and ^{15}O - H_2O uptake was increased rather than ^{18}F -FDG^[14]. That report is different from ours, so we think further evaluations about useful radio-isotope of PET for malignant hemangiopericytoma are needed. Another study suggested the correlation between the high uptake of ^{18}F -FDG in hemangiopericytomas and poor prognosis^[15]. Consequently, it is the opinion of the authors that such variable uptakes by malignant hemangiopericytoma as seen in PET scans contribute more to the detection of recurrent disease after surgical removal, rather than to the

establishment of preoperative differential diagnosis. Also, the PET scans the whole body, and therefore allows detection of recurrent hemangiopericytoma, which has a wide pattern of recurrence.

In conclusion, although the pattern of recurrent malignant hemangiopericytoma is diverse, surgical intervention after early detection may allow another long disease-free period. For this to be accomplished, long-term follow-up is imperative, and we suggest that yearly PET scans are useful in attaining this goal.

Abstract

A 75-year-old male with malignant lymphoma (ML) accompanied with gastric lesion was treated with combination chemotherapy. The patient produced tarry stool on the 4th d, and emergency gastroscopy showed arterial bleeding from the lesion. Hemostasis was achieved by injecting pure ethanol and using hemostatic clips. There is only one previous report on endoscopic hemostasis being effective for bleeding due to lymphoma. Since gastric bleeding causes significant mortality, endoscopic hemostasis should be considered as first-line treatment for ML patients who were treated with chemotherapy.

INTRODUCTION

Patients with stage I-II primary gastric lymphoma are

commonly treated with chemotherapy alone or in combination with radiation therapy to avoid long-term sequelae after gastric resection^[1,2]. Although gastrointestinal bleeding during chemotherapy has been observed in only 3% of cases^[2], it is a definite cause of mortality. However, only emergency gastrectomy may be able to rescue patients with neutropenia and thrombocytopenia after chemotherapy^[3].

Endoscopic hemostasis has been established as a first-line treatment for acute bleeding in all patients with peptic ulcer. Among various methods employed, injection with pure ethanol or the use of hemostatic clips is one of the most effective treatments for achieving definitive hemostasis^[4-8]. However, there has been only one report describing a case of successful endoscopic hemostasis for bleeding from lymphoma in the stomach. However, this case underwent hemostatic treatment before chemotherapy^[9].

Our report concerns an elderly patient with gastric bleeding due to invasion of lymphoma after standard chemotherapy. Although this patient was considered inoperable before chemotherapy, we managed to achieve hemostasis by injecting pure ethanol and using hemostatic clips.

CASE REPORT

A 75-year-old man was admitted to our hospital in January 2004 because of lumbar pain. Computed tomography detected a huge mass at the kidney and swelling of the paraaortic lymph nodes. He was diagnosed as having renal cell carcinoma with lymph node invasion and underwent surgical treatment in March. However, the swelling of the lymph nodes was histologically diagnosed as diffuse large B-cell lymphoma (DLBCL), and because ⁶⁷Ga-citrate scintigraphy showed uptake at the stomach, we performed upper gastrointestinal endoscopy. An ulcerative lesion was detected in the upper body (Figure 1), which, although suspected of being invasion of lymphoma, a biopsy sample showed to be a benign ulcer. Because there were no other signs of lymphoma, the patient was treated with interferon therapy for renal cell carcinoma as adjuvant therapy. Omeprazole and cimetidine were administered for the gastric lesion. After 2 mo, multiple superficial lymph node swelling was observed. Biopsy of the cervical lymph node indicated recurrence of DLBCL, but because our patient was considered inoperable, we started CHOP therapy (cyclophosphamide, adriamycin, vincristine, and prednisolone) on 6th July. However, the patient produced massive tarry stool on d 4, resulting in a drop in the hemoglobin level to 44 g/L. Emergency endoscopy was performed that detected arterial bleeding from the ulcerative lesion in the upper body (Figure 2).

The condition had not changed since the previous examination in spite of the treatment with antipeptic agents. Ethanol injections (0.1 mL at a time) into the surrounding tissue close to the bleeding vessels, at a few injecting sites 2 mm from the bleeding vessels, suppressed the pulsatile bleeding, and definitive hemostasis was achieved with the concomitant use of hemostatic clips. During the following 2 weeks, the ulcerative lesions became smaller and no further bleeding was detected (Figure 3).

The second biopsy samples were histologically compatible with lymphoma.

Figure 1 Giant ulcer at cardia of stomach.

Figure 2 Emergency gastroscopy showed pulsatile arterial bleeding.

Figure 3 No bleeding was observed in the ulcer injected with ethanol.

DISCUSSION

This report concerns a patient with arterial bleeding from the stomach due to lymphoma invasion. We had considered surgical resection of the stomach before chemotherapy to avoid bleeding, but we performed chemotherapy as first treatment instead, because surgery was considered to carry serious risks. The reasons for these were that (1) the patient had previously undergone laparotomy for renal cell carcinoma and adhesion of viscera was suspected to be severe, (2) paraaortic lymph nodes were swollen making it difficult to create anastomoses for a gastroduodenostomy, and (3) lymphoma was expected to progress rapidly during recovery from the operation.

Because the mechanism of hemostasis is thought to consist of solidification caused by vascular shrinking resulting from the direct action of ethanol and degeneration of the vascular endothelial cells, there is good reason for attempting endoscopic hemostasis for bleeding due to lymphoma. We successfully achieved hemostasis with ethanol injection and clips, although the fundus of the ulcer remained fragile due to necrosis of the lymphoma after chemotherapy. Because lymphoma is curable with chemotherapy alone, endoscopic hemostasis should be considered as a first-line treatment for bleeding due to lymphoma.

ACKNOWLEDGMENT

The authors are grateful to Ms. Yuko Kanbayashi for her pharmacological advice.

Abstract

Ciliated hepatic foregut cyst (CHFC) is a very rare cystic lesion of the liver that is histologically similar to bronchogenic cyst. We report one case of CHFC that was hard to distinguish from solid-cystic neoplasm in imaging features. Magnetic resonance imaging was helpful in differentiating these cysts from other lesions.

INTRODUCTION

Ciliated hepatic foregut cyst (CHFC) is a very rare, benign and solitary cyst^[1,2]. It is most often unilocular^[2]. To our knowledge, 5 cases of CHFC were reported in the 19th century, 53 cases in the 20th century and 5 cases in the 21st and its medical imaging findings are seldom reported^[1,3]. It is difficult to differentiate the CHFC from malignant tumor^[1,4,5]. Herein, we present the radiologic features from one CHFC that was not similar to other nonparasitic cysts, but rather mimicked cystic-solid mass of the liver on the images obtained.

CASE REPORT

A 30-year-old man presented with a 5-mo history of left upper abdominal discomfort and mild fatigue. Physical examination and laboratory studies had no positive findings including hepatitis.

A plain radiograph of the abdomen was normal. Sonographic examination revealed a well-delineated hypoechoic mass, 3 cm×4 cm in size, in the liver. It was located in the medial segment of the left lobe (segment IV),

just adjacent to the surface of the liver. Unenhanced computed tomographic (CT) scan was obtained, and the lesion appeared slightly hypoattenuating relative to surrounding liver parenchyma (Figure 1A). The attenuation value of the lesion was 47 HU. At contrast material-enhanced CT, this lesion was not enhanced and appeared slightly hypoattenuating with well-defined margin (Figure 1B). On delayed CT scan, it had still no enhancement. Magnetic resonance (MR) imaging at 1.5 T was performed for more detailed examination. The lesion appeared isointense relative to surrounding liver parenchyma on T1-weighted imaging (Figure 1C) and markedly homogeneously hyperintense on T2-weighted imaging (Figure 1D). It was also not enhanced after Gd-DTPA administration (Figure 1E).

The lesion was resected surgically because the possibility of hypovascular neoplasm could not be excluded completely according to the imaging. The resected specimen revealed an unilocular cystic lesion containing a mucinous fluid.

On pathologic examination, the cyst had a fibrous wall lined by ciliated pseudostratified columnar epithelial cells, which was consistent with a CHFC (Figure 1F).

DISCUSSION

The histogenesis of CHFC is still unclear, but most authors consider that it arises from the embryonic foregut in the liver^[1,2,5]. CHFC is usually a benign, solitary cyst consisting of a ciliated pseudostratified columnar epithelium, a subepithelial connective tissue layer, a smooth muscle layer and an outer fibrous capsule^[2,6]. It is often smaller than 3 cm in diameter and found most commonly in the medial segment of the left hepatic lobe, just beneath the hepatic surface^[5,7]. CHFC is not actually a neoplasm and usually found incidentally on radiologic imaging during surgical exploration or autopsy. It is mostly asymptomatic and surgical resection should be avoided^[5]. However, on the other hand, it was reported recently that one case causes portal vein compression and the other shows malignant transformation through squamous metaplasia (it is not surprising to find squamous mucosa because tracheobronchial tree derives from the embryologic foregut), which warns to examine CHFC cautiously^[8,9], and suggests that a large-sized symptomatic CHFC should be excised, especially when radiologic studies yield equivocal results^[10].

Generally CHFC is a well-delineated anechoic or slightly hypoechoic small mass on ultrasonography. Because CHFC can contain various elements ranging from clear serous material to milky white to brown mucoid material, and these have variable viscosities, and the different CT attenuation numbers can be shown^[5]. The lesion can be hypoattenuating as our case or isoattenuating relative to surrounding liver parenchyma at unenhanced CT. Even it has very high

Figure 1 CHFC in a 30-year-old man. **A:** Unenhanced CT scan shows a slightly hypoattenuating (47 HU) mass in the medial segment beneath the hepatic surface; **B:** On enhanced CT scan, a well-defined hypoattenuating mass is revealed with no enhancement; **C:** On axial T1-weighted imaging, the lesion appears isointense relative to surrounding liver parenchyma; **D:** Axial

T2-weighted imaging shows markedly homogeneously hyperintense mass in the left liver; **E:** Enhanced T1-weighted imaging delineates slightly hypointense mass just beneath the hepatic surface; **F:** Photomicrograph reveals a cyst lined by ciliated pseudostratified columnar epithelial cells (HE $\times 400$).

attenuation numbers because the lesion contains calcium^[5]. All the CHFCs have no enhancement after injection of contrast materials, which is one of the characteristics of CHFC and has significance in the differential diagnosis. On MR imaging, all lesions are hyperintense on T2-weighted sequences. However, on T1-weighted images, they may be hypointense, isointense, or hyperintense according to the various elements the lesions contain, including clear serous material or milky white or brown mucous with abundant protein and lipid sometimes^[5,11,12].

When a CHFC appears hypoechoic at US and the attenuation at CT ranges from that of soft tissue to very high attenuation, it is hard to differentiate the CHFC from a solid lesion. However, MR imaging is found to be useful in differential diagnosis, especially on T2-weighted imaging. When a CHFC is demonstrated as anechoic lesion at US,

cystadenoma may be included in the differential diagnosis because the lesion may be malignant. Differential points are that cystadenomas are usually multilocular and sometimes reveal mural nodules, and these features are well revealed on radiologic imaging^[5].

CHFC occurs more frequently in men and is found most commonly in the medial segment of the left hepatic lobe just beneath the hepatic surface, unlike most other solitary cysts that show a female predominance and greater occurrence in the right hepatic lobe^[7]. Therefore, this location is also one of the characteristics of CHFC and probably an important diagnostic consideration. Meanwhile, MRI is helpful to differentiate CHFC from other solitary cysts that usually show markedly homogeneously hypointense on T1-weighted imaging.

In conclusion, when a well-demarcated subcapsular

lesion of the left hepatic lobe with the varied internal appearance as we described above is demonstrated, CHFC should be considered.

Abstract

Uncomplicated reflux disease comprises the non-erosive reflux disease (NERD) and erosive reflux disease (ERD). The objectives of treatment are the adequate control of symptoms with restoration of quality of life, healing of lesions and prevention of relapse. Treatment of NERD consists in the administration of proton pump inhibitors (PPI) for 2-4 wk, although patients with NERD show an overall poorer response to PPI treatment than patients with ERD owing to the fact that patients with NERD do not form a pathophysiologically homogenous group. For long-term management on-demand treatment with a PPI is probably the best option. In patients with ERD, therapy with a standard dose PPI for 4-8 wk is always recommended. Long-term treatment of ERD is applied either intermittently or as continuous maintenance treatment with an attempt to reduce the daily dosage of the PPI (step-down principle). In selected patients requiring long-term PPI treatment, antireflux surgery is an alternative option. In patients with troublesome reflux symptoms and without alarming features empirical PPI therapy is another option for initial management. Therapy should be withdrawn after initial success. In the case of relapse, the long-term care depends on a careful risk assessment and the response to PPI therapy.

of patients with GERD, the disease does not lead to complications, instead presents with often severe symptoms. Some 60% of patients in primary care with troublesome reflux symptoms have no endoscopically recognizable lesions of the esophageal mucosa, 35% have erosive esophagitis (75% of which are mild, corresponding to Los Angeles A/B, and 25% severe, corresponding to Los Angeles C/D). In about 5% of the patients, complications, such as stricture, ulcer and in particular Barrett's esophagus or even adenocarcinoma, must be expected (Figure 1)^[2]. Epidemiological data support the hypothesis that GERD is not a spectrum disease with occasional reflux symptoms but no lesions at the one end, and severe complications at the other, but can instead be classified into three distinct categories-nonerosive reflux disease (NERD)-erosive reflux disease (ERD), and Barrett's esophagus-in each of which the respective patient remains, that is, progression of the disease over time is, overall, very rare^[3]. This category model of GERD is supported by the latest data from a large prospective European study (ProGERD) involving more than 6 000 patients with NERD and ERD: the rate of progression (to severe esophagitis or Barretts') for patients with NERD and mild erosive esophagitis (Los Angeles A/B) was less than 1% per year (Labenz *et al.*, unpublished data).

INTRODUCTION

Gastroesophageal reflux disease (GERD) is a common condition affecting approximately 10-20% of the adult population of industrialized countries^[1]. In the great majority

INITIAL MANAGEMENT OF GERD

Uncomplicated reflux disease comprises the non-erosive form, that is, symptoms that impact negatively on the patient's quality of life, but which are not associated with endoscopic evidence of mucosal breaks in the esophagus, and erosive reflux esophagitis of varying degrees of severity, e.g. grades A-D in the Los Angeles classification^[4].

Contrary to commonly held beliefs, symptom evaluation is the most important assessment for the initial phase of GERD management^[5], although an evidence-based analysis of symptoms is hardly possible^[6]. Characteristic symptoms are heartburn and acid regurgitation^[6]. However, these symptoms are predictive of GERD in only 70% of the patients, even in cases with an unequivocal history^[7]. It must

be emphasized that there is no diagnostic gold standard for GERD: endoscopy has a sensitivity of only 30-40%, microscopic features such as dilated intracellular spaces and regenerative changes in the absence of endoscopically visible mucosal breaks of the squamous epithelium in the distal esophagus are currently not sufficiently validated, and pH-monitoring is far from being a diagnostic gold standard, since 30-60% of patients with NERD, as well as 10-20% of those with ERD, have normal results of 24-h pH-monitoring, and intra-individual comparisons have also shown that pH-metry is subject to appreciable fluctuations^[4,8]. Moreover, there is consistent observation that there is virtually no correlation between the severity of endoscopic findings and symptom severity (Figure 2)^[9]. All these aspects have an important impact on the clinical management of GERD which is distinct in the initial phase and long-term care.

Basic goals of treatment are:

- to provide complete, or at least sufficient, control of symptoms,
- to maintain symptomatic remission,
- to heal underlying esophagitis and maintain endoscopic remission, and
- to treat or, ideally, prevent complications.

Adequate control of symptoms is considered to have been achieved when mild reflux symptoms occur at most once a week-more frequent or more pronounced complaints are not accepted as satisfactory by the patient^[10]. Initially, a symptom-based diagnosis is established, and an individual risk assessment made (Figure 3). If such alarming symptoms such as dysphagia, unintended weight loss and/or signs of bleeding are present, an endoscopic examination is mandatory, with further management dictated by the endoscopic findings. Other indications for endoscopy at this point in time may include, for example, a family history of upper gastrointestinal tract malignancies, a long prior history of severe complaints, age over 50 years, use of NSAIDs, and a positive *Helicobacter pylori* status^[11]. Otherwise, empirical therapy can be offered (Figure 3). Withholding endoscopy in the initial phase is, of course, associated with the theoretical risk that serious complications of GERD or other significant pathologies in the upper gastrointestinal tract mimicking the symptoms of reflux disease may be overlooked or recognized too late. On the other hand, given the facts that GERD is extremely common, and complications are generally rare, endoscopic evaluation of all patients with GERD is hardly justifiable, especially since an endoscopy-based management strategy has not been subjected to appropriate evaluation. In a cross-sectional study from Finland the detection rate of serious complications of GERD did not differ between regions with low and those with high referral to endoscopy^[12]. Considering that most patients have mild GERD and that the disease is not progressive over time, restricted use of endoscopy does not appear to put the patients at risk. However, the economic impact of different diagnostic strategies on expense remains to be established, at least in countries with low endoscopy costs^[13]. A recent study in 742 patients with uncomplicated GERD showed no correlation between endoscopic findings and subsequent therapeutic decisions^[14]. Further arguments

for a primarily symptom-driven strategy are that the ultimate benchmark for the clinical efficacy of treatment of GERD is patient satisfaction and that accurate determination of esophagitis requires the withholding of therapy before endoscopy, which in many cases is not possible^[15].

For the sake of simplicity, the following sections first discuss the initial and long-term treatment of patients with NERD and ERD (endoscopy-based approach), and then consider the management of uninvestigated GERD, which is doubtless the more common treatment that is applied in the clinical setting.

Figure 2 No correlation between endoscopic findings and symptom severity in patients with GERD^[9].

Figure 3 Initial management of patients with symptoms suggestive of GERD.

TREATMENT OF NERD

While NERD is the most common manifestation of reflux disease, patients with this entity do not form a pathophysiologically homogeneous group. A differentiation can be made between patients with unequivocally pathological acid reflux, patients with an acid-sensitive (hypersensitive) esophagus, which means that more than 50% of the symptomatic episodes were associated with acid reflux (positive symptom index), and those with symptoms that are independent of acid-reflux events (functional heartburn)^[8,16]. This latter category explains the observation that patients with NERD did not respond as well to acid suppressants as patients with erosive esophagitis do^[17,18]. Possible pathophysiological causes of functional heartburn include non-acid reflux (liquid, gas, mixed), minute changes in the esophageal acidity above a pH of 4, motility disorders such as sustained contractions of the longitudinal musculature, visceral hypersensitivity, and emotional and psychological abnormalities^[19].

Initial therapy of NERD

Initially, patients should receive a proton pump inhibitor (PPI) for 2-4 wk (Figure 4). The effect of other substances such as H₂ blockers or prokinetic drugs is hardly better than that of placebo^[20]. In a large, placebo-controlled study, a dose-response relationship was established for omeprazole: omeprazole 20 mg proved to be more effective than omeprazole 10 mg^[21]. In a further controlled study, lansoprazole 30 mg was no more effective than lansoprazole 15 mg^[22]. The S-isomer of omeprazole, esomeprazole, was investigated in two large, double-blind, multicenter studies involving patients with NERD^[23]. Esomeprazole at a dose of 20 and 40 mg per day proved more effective than placebo, but a dose-response effect could not be shown. Three further randomized, double-blind, multicenter studies involving a total of more than 2 600 patients with NERD treated for 4 wk with omeprazole 20 mg, and esomeprazole 20 or 40 mg revealed comparable success rates (resolution of symptoms in 60-70% of the patients)^[24]. Assessment of the response to treatment in studies like these are greatly influenced by the target criterion (e.g. complete elimination of symptoms, satisfactory symptom control), so that the studies can hardly be compared. From the above remarks it may be concluded that appropriately dosed PPI treatment can achieve a satisfactory initial response in some two-thirds of the patients. If initial treatment with 4 wk of PPI fails to elicit adequate symptom control (Figure 4), increasing the PPI dose (e.g. standard dose PPI twice daily) is recommended, since studies have shown that patients with acid-sensitive esophagus respond better to a high PPI dose^[25-27]. In non-responders to appropriate PPI treatment, it is recommended that esophageal pH-monitoring be performed during PPI therapy and, if symptomatic acid reflux can be excluded, to discontinue PPI therapy and initiate a trial with a low-dose tricyclic antidepressant at bedtime^[28]. Potential therapeutic options for the future might be serotonin reuptake inhibitors, kappa agonists and substances with an impact on transient sphincter relaxation such as baclofen.

Figure 4 Initial therapy and long-term care of patients with NERD.

Long-term care of patients with NERD

If initial treatment is successful, medication should be discontinued, since 25% (or more) of the patients may remain in remission over prolonged periods of time^[29], and this clinical entity does not appear to necessitate measures aimed at preventing complications. In the event of a relapse, indicating the need for long-term management, a number

of different options are available: continuous maintenance therapy starting with a PPI and subsequent attempts to step down to lower dosages of the PPI or even less potent drugs (Figure 5)^[5], intermittent courses of treatment for 2-4 wk with initially successful PPI^[30], and patient-controlled on-demand therapy with a PPI^[11]. On-demand therapy means that the patient himself determines both the start and the end of treatment. Medication should be discontinued when the symptoms have been eliminated. This last option in particular, has met with great interest in recent years on account of its potential economic advantages^[31,32]. In a first large randomized, controlled study lasting 6 mo, Lind *et al.*, were able to show that more than 80% of the patients were satisfactorily treated with an on-demand strategy employing omeprazole 20 mg^[33]. In this study, omeprazole 20 mg proved more effective than omeprazole 10 mg. The convincing efficacy of this new treatment option was then confirmed with esomeprazole 20 mg^[34,35]. All these studies also showed that roughly one-half of these patients were satisfactorily treatable with placebo medication and the use of antacids as required. In a recently presented randomized, open international multicenter study involving 598 patients, on-demand treatment with esomeprazole 20 mg was compared with continuous treatment with esomeprazole 20 mg o.d. in patients with NERD^[36]. The vast majority of patients in both treatment groups were satisfied with the regimen, and medication consumption was considerably lower in the on-demand therapy arm (average consumption: 0.41 *vs* 0.91 tablets per day). However, the final endoscopic examination revealed mild erosive esophagitis (Los Angeles A: *n* = 14; Los Angeles B: *n* = 1) in 5% of the patients receiving on-demand treatment, while none of the patients on continuous treatment had this finding. From the viewpoint of a clinician, this observation

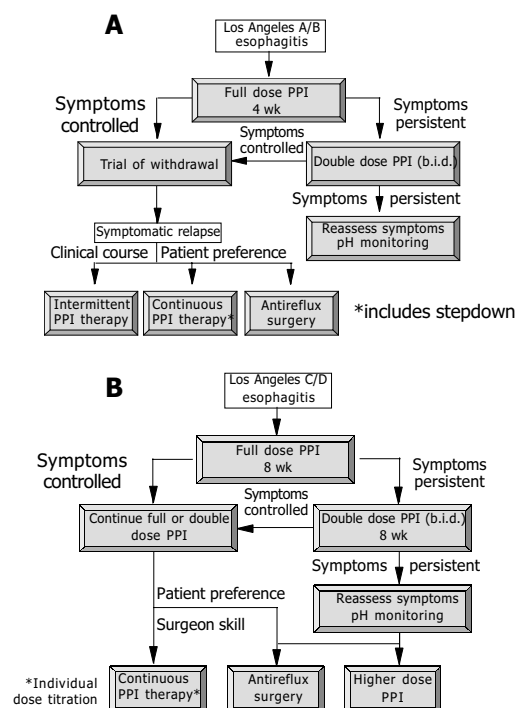

Figure 5 Management of patients with mild to moderate erosive esophagitis (A) and moderate to severe esophagitis (B) [after 4,5].

occasions no major concern, since alternation between the categories NERD and mild ERD (corresponding to Los Angeles A and B) often occurs during the spontaneous course of the disease. In another large scale study, 622 patients with NERD were randomized to esomeprazole 20 mg on demand or lansoprazole 15 mg o.d. for 6 mo after an initial successful treatment with esomeprazole^[37]. Based on the target criterion “willingness to continue” on-demand treatment was superior to continuous treatment (93% *vs* 88%; *P* = 0.02). Patients on continuous treatment complained more often about heartburn and adverse events, the main reasons for “unwillingness to continue”. Other PPIs (lansoprazole, pantoprazole, rabeprazole) have also proven their superiority to placebo in on-demand treatment in individual studies^[11]. Head-to-head comparisons between various PPIs are, however, lacking, so that a comparative assessment is not possible.

TREATMENT OF ERD

Erosive reflux esophagitis can be found in about 30-40% of GERD patients^[2]. Endoscopically, reflux esophagitis is categorized into various degrees of severity. In recent years, and especially in therapeutic studies, the Los Angeles classification in particular has been applied^[38,39]. This distinguishes the four degrees of severity A-D (A: mucosal breaks of less than 5 mm on the top of folds; B: mucosal breaks >5 mm in extent on mucosal folds; C: circumferential spreading of mucosal breaks involving less than 75% of the circumference; D: mucosal breaks involving more than 75% of the circumference). The gradings A and B correspond to mild to moderate esophagitis and C and D to moderate to severe esophagitis. One fourth of patients with erosive esophagitis are categorized in grade C or D^[40-42].

Numerous controlled studies have investigated the efficacy of a variety of medications in the healing of esophagitis and the elimination of symptoms. In a meta-analysis, Chiba *et al.*^[43], showed that PPIs (omeprazole, lansoprazole, pantoprazole) heal the esophagitis within 8 wk in 83.6% of the patients, with a symptom-resolution rate of 77.4%. All other medications (H_2 -receptor antagonists, cisapride, sucralfate) were appreciably less effective. A placebo-related healing rate of 28.2% documents the fluctuating nature of the course of reflux disease in some patients, with spontaneous remissions and exacerbations. When using highly potent PPIs, elimination of symptoms after 8 wk is predictive for healing of the esophagitis^[41,42].

Initial therapy of ERD

In patients with erosive reflux esophagitis, treatment with a standard dose of a PPI is always recommended (Figure 5)^[4]. Mild cases (Los Angeles grade A/B) usually heal within 4 wk, while severe cases (Los Angeles C/D) often require longer treatment-eight or, in some cases, more weeks. Resolution of symptoms in those responding to therapy is achieved appreciably more quickly (median time to sustained symptom resolution 5-10 d). The major predictive factor for the healing rate is the severity of the erosive esophagitis, but also of significance are concomitant Barrett's metaplasia in the lower esophagus, which reduces the healing rate,

and infection with *H. pylori*, which enhances the efficacy of the PPI^[44,45].

Is there any clinically relevant difference between the PPIs available in the market? Racemic PPIs (omeprazole, lansoprazole, pantoprazole, rabeprazole) differ in such pharmacokinetic characteristics as bioavailability and the rapidity with which an effect occurs. This, however, is irrelevant for the healing of esophagitis at 4 and 8 wk^[46,47], although the substances do differ in terms of the time required to eliminate symptoms. In a large randomized, controlled study involving more than 3 500 patients with erosive esophagitis, lansoprazole 30 mg o.d. relieved heartburn significantly faster than did omeprazole 20 mg o.d.^[48]. There is a linear relationship between the degree of acid suppression measured by the time per day that gastric pH is higher than 4, and the healing kinetics of esophagitis^[49]. With regard to the healing rates of reflux esophagitis after 4 and 8 wk, no differences are to be seen between the standard doses of the racemic PPIs (omeprazole 20 mg, lansoprazole 30 mg, pantoprazole 40 mg, rabeprazole 20 mg)^[46,47], nor did doubling the individual dose (e.g. lansoprazole 60 mg, pantoprazole 80 mg) increase efficacy. Of significance for the healing rates and symptom elimination, however, is cytochrome 2C19 polymorphism. Thus, it has been recently shown that the response to treatment with lansoprazole 30 mg o.d. is poorer in extensive metabolizers than in intermediate and poor metabolisers^[50].

Cross-over pH-monitoring studies in healthy volunteers and patients with GERD have shown that esomeprazole is more effective than corresponding doses of the racemic PPIs omeprazole, lansoprazole, pantoprazole and rabeprazole^[51,52]. In large controlled studies, significantly higher healing rates were achieved with esomeprazole at a dose of 40 mg o.d. than with omeprazole 20 mg o.d., lansoprazole 30 mg o.d., and pantoprazole 40 mg o.d.^[40-42,53,54]. The therapeutic advantage of esomeprazole over the other PPIs increased with increasing severity of the esophagitis as defined by the Los Angeles classification^[55]. These studies also showed a significant superiority of esomeprazole in terms of the time to sustained symptom (heartburn) resolution. Small non-inferiority studies claiming equivalence between different PPIs did not have the statistical power to detect a difference of the magnitude that has been consistently established by the large scale studies mentioned above^[56-58].

In the event of inadequate efficacy (insufficient control of symptoms or healing of the esophagitis), doubling the individual dose of PPI does not reliably improve clinical efficacy, but switching to another PPI, or shortening the interval between doses (e.g. twice daily) might increase the response to treatment^[59]. In recent years there has been intense discussion on the clinical relevance of nocturnal acid breakthrough (NABT) in difficult-to-treat cases^[60,61]. NABT is defined as a decrease in gastric pH to <4 for more than 1 h during the course of the night. The clinical relevance of this phenomenon has not yet been established. H_2 -receptor antagonists given at bedtime can prevent this acid breakthrough, but when administered over a longer period of time, they rapidly lose this effect^[62]. Treatment with combinations of PPI and prokinetic drugs is of unproven value.

Long-term care of patients with ERD

After responding well to initial treatment, ERD shows a tendency to relapse. Up to 90% of the patients will relapse already within the next 6 mo^[29]. Patients with mild esophagitis (Los Angeles A/B) often have a longer relapse-free interval than patients with severe esophagitis (Los Angeles C/D), who frequently suffer a relapse within days of discontinuing successfully the initial treatment^[63,64]. In the light of these observations, it is recommended that, in patients with mild esophagitis, therapy should first be discontinued and the further course of the disease kept under surveillance, while in severe esophagitis, initial successful therapy should be followed, *a priori*, by maintenance treatment (Figure 5). Established options for long-term management are intermittent treatment for some weeks and continuous maintenance treatment with an attempt to reduce the daily dosage of the PPI (step-down principle)^[4,30]. On-demand therapy has, to date, been investigated in only two studies in patients with erosive esophagitis^[65,66]. Satisfactory control of symptoms was achieved in the vast majority of patients, but continuous therapy proved to be superior with respect to maintenance of remission of erosive esophagitis, so that an evidenced-based recommendation is currently not possible. However, since GERD is usually not progressive, attempts to realize on-demand treatment does not appear to harm the patients^[3].

For the prevention of relapse in patients with healed esophagitis, PPIs are clearly superior to H₂-receptor antagonists, prokinetic drugs and combinations of these medications^[67-69]. The yield between a standard dose of a PPI and one-half of this dose is, in individual studies, often small, although significant, and even probably clinically relevant differences have occasionally been observed^[67]. On the basis of a cost effectiveness analysis using a Markov model designed to simulate the economic and clinical outcomes of GERD in relation to the cost per symptom-free patient years gained and the cost per QALY gained treatment with a standard dose of a PPI appears to be superior despite the higher drug costs^[69]. Nevertheless, in view of the overall high response rates, an initial attempt with half the standard dose of a PPI is recommended in patients with mild erosive esophagitis, while patients with more severe disease should be kept on the dose of PPI required to induce remission (Figure 5). If this approach proves successful, a dose reduction, or a changeover to a less potent drug can be attempted^[70,71]. If the reduced dose proves unsuccessful, the dose must be increased appropriately. Occasionally, a higher-than-standard dose may be necessary to maintain remission^[72].

With long-term therapy also, differences are found between the isomeric PPI esomeprazole, and the racemic PPIs lansoprazole or pantoprazole. In large double-blind randomized studies in patients with healed esophagitis, esomeprazole 20 mg o.d. applied over 6 mo was significantly more effective than lansoprazole 15 mg o.d. (therapeutic gain 8-9%), or pantoprazole 20 mg o.d. (therapeutic gain 12%)^[73-75]. As in the case of acute treatment, this superiority was more pronounced with increasing disease severity. Apart from the severity of the baseline esophagitis, concomitant Barrett's esophagus (poorer results) and *H pylori* infections

(better results) also have a role as predictors of treatment outcome^[76].

Eradication of *Helicobacter pylori* in patients with GERD

Whether a concomitant *H pylori* infection in patients with GERD should be treated or not is still under discussion^[77,78]. Since *H pylori* is probably not involved in the pathogenesis of GERD, it cannot be expected that its eradication can heal this condition^[79] nor, according to the data of Moayyedi *et al.*, is an aggravation of the spontaneous course of GERD to be expected. *H pylori* does, however, have an impact on the pH-elevating effect of PPIs, which leads to higher healing rates and faster elimination of symptoms in patients with reflux esophagitis^[45]. PPI treatment in *H pylori*-infected patients leads to an aggravation of corpus gastritis, possibly also accompanied by an accelerated development of atrophy, while at the same time, antral gastritis is improved. The resulting gastritis type (corpus dominant) is found more frequently in patients with gastric cancer, and is therefore termed as "risk gastritis" or "gastritis of the cancer phenotype". Whether long-term PPI treatment in patients with *H pylori* gastritis actually does increase the gastric cancer risk is unclear. It does, however, appear certain that PPI treatment for over more than 10 years is also safe in patients infected with *H pylori*^[72]. Whether this also applies to treatment for over 20, 30 or more years is not known at present. On the basis of these considerations, some authors advocate the eradication of *H pylori* before initiating long-term PPI treatment^[80].

Antireflux surgery

In selected patients requiring long-term PPI treatment, a possible alternative option is antireflux surgery, which, however, is no more effective than tailored PPI therapy, and also carries a significant complication risk^[81-83]. To date, no advantages of surgery in terms of economics have been unequivocally demonstrated^[83,84]. The best candidates for fundoplication are probably those with esophagitis documented by endoscopy, a need for continuous PPI therapy, abnormal pH monitoring studies, normal esophageal motility studies, and at least partial symptom relief with PPI therapy^[85]. Further arguments for surgery are high-volume reflux and young age. Relevant concomitant diseases, in contrast, tend to militate in favor of sticking with a conservative approach. A "treatment-refractory" GERD patient should certainly not be automatically referred for antireflux surgery.

Endoscopic antireflux procedures

In recent years, a number of different methods for endoscopic endoluminal treatment of GERD have been investigated (endoscopic gastroplication with differing suturing techniques, application of radiofrequency energy to the lower esophageal sphincter, endoscopic submucosal or intramuscular injection of inert materials). To date, the efficacy of endoluminal therapy for GERD is not supported by a high level of evidence^[86]. Only a single fully published controlled study (radio-frequency energy delivery *vs* sham procedure) that documented a benefit in terms of symptom relief, but no effect on acid reflux, has been reported^[87].

Overall, too few data are currently available on efficacy and safety, so that the use of these methods outside of controlled studies cannot be recommended. In particular, controlled studies comparing endoscopic antireflux procedures with the established options of treatment would be desirable.

UNINVESTIGATED GERD

In patients with troublesome reflux symptoms but no alarm symptoms (e.g. dysphagia, unintended loss of weight, signs of bleeding), empirical PPI therapy is another option for initial management.

The goals of empirical therapy are: (1) to succeed with initial therapy; (2) to determine need for ongoing therapy; (3) to maintain satisfactory symptom control; (4) to minimize risks from esophagitis and other consequences of abnormal reflux.

These aims should be achieved at the lowest possible cost and with minimal risks^[88]. Initial therapy should via rapid relief of symptoms confirm the symptom based diagnosis, reassure the patient as to the benign and treatable nature of the reflux disease, and if present cure the esophagitis. For many years, patients with GERD received step-up therapy beginning with weakly effective substances, such as antacids and H₂-receptor antagonists, and increasing the intensity of the treatment if the effect was inadequate. With this strategy, the above-mentioned aims of empirical treatment cannot be achieved. For this reason, initiation of treatment with a PPI at a standard dose applied for 4 wk is favored (step-in approach) (Figure 6). However, few scientific data are available on this approach. In a four-arm controlled double-blind study involving 593 patients and conducted over 20 wk, the patients initially received lansoprazole 30 mg o.d. or ranitidine 150 mg b.i.d. over a period of 8 wk, followed by either continuation of this medication, or a step-down from lansoprazole to ranitidine or a step-up from ranitidine to lansoprazole^[89]. The most effective strategy was step-in with a PPI and continuation with this medication. These results were confirmed in another study comparing omeprazole with ranitidine^[90].

Therapy should be withdrawn after initial success. In the case of a relapse, the long-term care depends on a careful assessment of the risk and the response to PPI therapy. Potential strategies are on-demand therapy or intermittent treatment. In a controlled three-arm study involving 1 357 patients with uninvestigated GERD, Meineche-Schmidt *et al.*^[91], compared on-demand therapy with esomeprazole 20 mg and GP-controlled intermittent strategy with esomeprazole 40 mg o.d. for 2 or 4 wk applied over 6 mo. The direct medical costs were similar in all three arms, but the total costs were substantially higher in patients treated with a GP-controlled intermittent strategy. If continuous maintenance therapy is needed to preserve remission, or if an initial positive response is rapidly followed by relapse, an endoscopic evaluation to exclude/detect severe erosive esophagitis or complicated reflux disease is recommended. If initial treatment is not successful, and if the clinical data militate against a severe form of GERD, the PPI dose can be increased (standard dose twice daily) or a changeover to a more potent substance implemented^[59]; otherwise, in this clinical situation, too, endoscopy should

be performed^[88]. It is not clear whether patients who respond to initial treatment with a PPI and are then well controlled with on-demand therapy need to be submitted to endoscopy at all. Earlier calls for “once in a life-time” endoscopy for every patient with reflux disease are no longer considered mandatory. Moreover, the timing of endoscopy is critical: endoscopy off therapy is required to correctly assess the severity of esophagitis, which is important for the choice of further management, and endoscopy on therapy is needed to assess Barrett’s esophagus which is important with regard to cancer risk and the planning of surveillance.

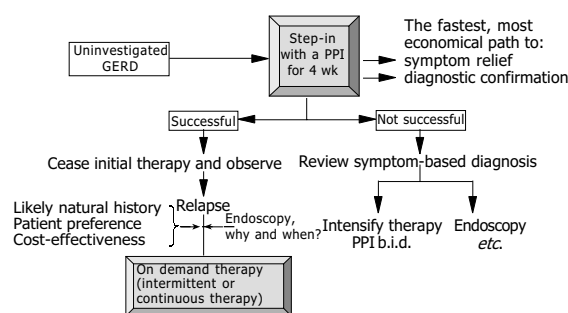

Figure 6 Proposal for the empirical management of patients with uninvestigated GERD^[88].

Abstract

AIM: To compare the effect, adverse events, cost-effectiveness and dose intensity (DI) of oral Xeloda vs calcium folinate (CF)/5-FU combination chemotherapy in patients with advanced gastrointestinal malignancies, both combined with bi-platinu two-way chemotherapy.

METHODS: A total of 131 patients were enrolled and randomly selected to receive either oral Xeloda (X group) or CF/5-FU (control group). Oral Xeloda 1 000 mg/m² was administered twice daily from d 1 to 14 in X group, while CF 200 mg/m² was taken as a 2-h intravenous infusion followed by 5-FU 600 mg/m² intravenously for 4-6 h on d 1-5 in control group. Cisplatin and oxaliplatin were administered in the same way to both the groups: cisplatin 60-80 mg/m² by hyperthermic intraperitoneal administration, and oxaliplatin 130 mg/m² intravenously for 2 h on d 1. All the drugs were recycled every 21 d, with at least two cycles. Pyridoxine 50 mg was given t.i.d. orally for prophylaxis of the hand-foot syndrome (HFS). Then the effect, adverse events, cost-effectiveness and DI of the two groups were evaluated.

RESULTS: Hundred and fourteen cases (87.0%) finished more than two chemotherapy cycles. The overall response rate of them was 52.5% (X group) and 42.4% (control group) respectively. Tumor progression time (TTP) was 7.35 mo vs 5.95 mo, and 1-year survival rate was 53.1% vs 44.5%. There was a remarkable statistical significance of TTP and 1-year survival between the two groups. The main Xeloda-related adverse events were myelosuppression, gastrointestinal toxicity, neurotoxicity and HFS, which were mild and well tolerable. Therefore, no patients withdrew from the study due to side effects before two chemotherapy cycles were finished. Both groups finished pre-arranged DI and the relative DI was nearly 1.0. The average cost for 1 patient in one cycle was ¥9 137.35 (X group) and ¥8 961.72 (control group), or US \$1 100.89

in X group and \$1 079.73 in control group. To add 1% to the response rate costs ¥161.44 vs ¥210.37 respectively (US \$19.45 vs \$25.35). One-month prolongation of TTP costs ¥1 243.18 vs ¥1 506.17 (US \$149.78 vs \$181.47). Escalation of 1% of 1-year survival costs ¥172.74 vs ¥201.64 (US \$20.75 vs \$24.29).

CONCLUSION: Oral Xeloda combined with bi-platinu two-way combination chemotherapy is efficient and tolerable for patients with advanced gastrointestinal malignancies; meanwhile the expenditure is similar to that of CF/5-FU combined with bi-platinu chemotherapy, and will be cheaper if we are concerned about the increase of the response rate, TTP or 1-year-survival rate pharmaco-economically.

INTRODUCTION

Pharmaco-economics is a method to study the various economic costs associated with prescribing a given drug or a treatment regimen. This field of health services research and technology assessment developed in the 1960s, and it is only in the last decade that scholars have been trying to develop strong standards for its use^[1]. There are four main kinds of cost analysis involved. First, the analysis of cost minimization is to find the most inexpensive treatment. Second, the cost-effectiveness analysis takes a single outcome into account, such as years of life saved, and attempts to determine the cost for each year of those additional years. The third analysis is cost utility. It is a subtype of cost-effectiveness and incorporates quality-of-life measures that focus on a patient's Quality Adjusted Life Year. The fourth is cost-benefit analysis. This analysis puts a dollar amount on additional years of life. Among the four analyses, the cost-effectiveness analysis is widely and more often used to compare the costs and clinical outcomes of competing treatment options^[2]. This analysis provides an estimate of

the costs incurred to achieve a particular outcome. It is measured by dividing a therapy's total cost by its therapeutic effectiveness, which might be cure rate, remission rate, or some other end point depending on the drug and disease involved^[3-5]. Oncology pharmacoeconomics differs slightly from pharmacoeconomics for drugs for other diseases. Pharmacoeconomics of anticancer drugs is to offer an effective, safe and economic regimen for patients with end-stage cancer under the precondition of limited medical cost.

Gastrointestinal cancer ranks the top of the morbidity and mortality of the cancer in China. The general chemotherapy usually has little effect on the end-stage patients with little opportunity to resect because of implantation in cavity, local recurrence after operation, or metastasis of lymph node or viscera. From December 2001 to April 2004, 131 end-stage cases of carcinoma of stomach and colorectum in our department were admitted for the new combination chemotherapy. Among them, 51 cases received the regimen of oral Xeloda with bi-platinu (oxaliplatin and cisplatin) in two ways (intravenous and intraperitoneal administration), the other cases received the regimen of calcium folinate (CF)/5-FU with bi-platinu in the same two ways as the former. The cost-effectiveness and quality-of-life index effect of this new chemotherapy regimen were compared with another chemotherapy. The dosage intensity of these two chemotherapy regimens were also compared.

MATERIALS AND METHODS

Patients

A total of 131 cases of advanced gastrointestinal cancer with 80 men and 51 women, mean age being 57.6 years ranging from 33 to 83 years were included. There were 61 cases of gastric carcinoma and 70 cases of colorectal cancer. All the patients were in stage IV by clinical assessment, which was confirmed by biopsy. About 83.7% of patients had received one combination chemotherapy at least, but no chemotherapy was administered to them within a month. Karnofsky performance status of all these patients measured at baseline was ≥ 60 , and the anticipative survival time was ≥ 3 mo with observable objective index of the focus. They were randomly divided into two groups, Xeloda and control group (abbreviated as X group and C group, respectively). The main clinical characteristics of the two groups are listed in Table 1.

Table 1 Clinical characteristics of stage IV gastrointestinal cancer

Clinical characteristics	Gastric cancer		Colorectal cancer	
	X group	C group	X group	C group
Male/female	21/11	17/12	19/16	23/12
Age: mean (range/yr)	63.6 (36-83)	61.0 (33-80)	62.9 (45-75)	60.8 (34-74)
Recurrence (%)	14 (43.8)	14 (48.3)	8 (22.9)	9 (25.7)
Metastasis

Lung (%)	8 (25.0)	7 (24.1)	11 (31.4)	10 (28.6)
Celiac lymph node (%)	21 (65.6)	21 (72.4)	14 (40.0)	15 (42.9)
Others (%)	8 (25.0)	9 (31.0)	12 (34.3)	10 (28.6)
Previous chemotherapy	23 (71.9)	22 (75.9)	17 (48.6)	19 (54.3)

Drugs

Xeloda® was supplied as white film-coated tablets containing 500 mg capecitabine manufactured by Roche Pharmaceutical Ltd. CF and oxaliplatin were purchased from Jiangshu Henrui Pharmaceutical Co. Ltd, packed in 100 or 50 mg per vial and 20 mg of cisplatin in a vial was supplied by Shandong Qilu Pharmaceutical Factory. 5-FU was packed in 250 mg per ampule and manufactured by Shanghai Pharmaceutical Factory.

Treatment regimen

Oral Xeloda 1 000 mg/m² was administered twice daily from d 1 to 14 in X group, while CF 200 mg/m² was taken as a 2-h intravenous infusion followed by 5-FU 600 mg/m² intravenous infusion for 4-6 h on d 1-5 in C group. Cisplatin and oxaliplatin were given in the same way to both the groups: cisplatin 60-80 mg/m² hyperthermic intraperitoneal abdominal administration, and oxaliplatin 130 mg/m² intravenous infusion for 2 h on d 1. All the drugs were recycled every 21 d, with at least two cycles. Granisetron 40 µg/kg was given by intravenous before intravenous or intraperitoneal chemotherapy. Pyridoxine (vitamin B6) 50 mg was given t.i.d. orally for prophylaxis of the hand-foot syndrome (HFS).

Effectiveness and side effects

The short-term effect is classified into four grades as complete remission (CR), part remission (PR), no-change (NC) and progress of disease (PD) by the evaluation standard of short-term effect introduced by WHO^[6]. The responsible effective rate (RR) is prescribed to CR+PR (%). There are two other indexes, TTP (time of tumor progress) and 1-year survival rate, which have been adopted to evaluate the mid-term effect. Side effects were added up by standard grade, also introduced by WHO^[7] in both the groups regardless of the kind of disease. The classification HFS was graded according to the criteria of WHO^[8]: I-dysesthesia/paresthesia, tingling in the hands and feet; II- discomfort in holding objects and upon walking, painless swelling or erythema; III-painful erythema and swelling of palms and soles, periungual erythema and swelling; IV- desquamation, ulceration, blistering, severe pain.

Dose intensity estimation

Two indexes of dose intensity (DI) were calculated by the following formula: DI = total dosage (mg/m²)/duration of treatment (weeks), relative DI = actual DI/standard DI^[9].

Costs estimation

The costs evaluated consisted of two parts, the direct medical cost and the indirect one^[5]. The cost of drugs (chemical drug, GM-CSF or G-CSF, the drug to ameliorate gastrointestinal side effect, and so on), hospital stays, the required medical staff, laboratory and diagnostic tests were included in the direct medical cost. The part indirect cost contained the material loss because of the absence of the patients and their relatives from work. Two periods of treatment were added up, then the average cost per patient in one cycle was obtained. The cost of therapy was expressed in Chinese currency (Ren-Min-Bi, ¥) and in US dollars

(US \$). The rate of exchange between them was 1:8.3.

Cost-effectiveness analysis

Based on the total costs, the expenses that add to 1% of the response rate (costs/total efficient rate), one-month prolongation of TTP (costs/TTP) and the escalation of 1% of 1 year (costs/1-year survival rate) were calculated, respectively.

Statistical analysis

All data are expressed as mean±SD, except as otherwise stated. Parameters were compared by using *t* test, or χ^2 test.

RESULTS

Effect

In 131 cases, 17 patients (13.0%) terminated treatment after one cycle because of disease progression, refusal to continue chemotherapy or other reasons. Fifty-eight cases (44.3%) finished two or three cycles of chemotherapy, 33 patients (25.2%) finished four or five cycles of chemotherapy, the other 23 cases (17.6%) finished six or more cycles of chemotherapy. The average number of completed chemotherapy cycles was 2.6. These 114 who finished more than two chemotherapy cycles were analyzed. For both the short-term and mid-term effect, the X group was better than C group. But there was no statistical difference in the short-term effect. Short-term effect of gastric cancer group was superior to that of colorectal cancer group, whereas mid-term effect of the former was inferior to that of the latter (Table 2).

Side effects

To 114 patients who finished more than two chemotherapy cycles, the side effects were observed and summed up when

the second cycle ended (Table 3). In X group, the rates of leukopenia, thrombocytopenia, nausea, vomiting, diarrhea and neurotoxicity above grade II were 23.6%, 10.9%, 56.4%, 29.1%, 21.8%, and 20.0%, respectively. In C group, the rates were 20.3%, 10.2%, 55.9%, 28.8%, 13.6%, and 22.0%, respectively. No statistical difference was revealed between the two groups.

The occurrence of HFS that appeared in X group was higher than that of C group (63.6% *vs* 16.9%, *P*<0.05), but 97.1% of HFS episodes were grade 1 or 2. No patient withdrew from the study, and none required dose modification due to side effects before two chemotherapy cycles were finished.

Dose intensity

Relative DI mg/(m²×week) cannot be achieved due to the delay in the treatment (including side effect and noncompliance), which means that the actual DI is lower than standard DI. There was no statistical difference in relative DI between the two groups (Table 4).

^aP<0.05 vs C group.

time between the two groups ($P<0.05$, Table 5). The drug costs of X group was higher than that of C group, but other costs (the costs of hospitalization, cancer clinic care and others) were adverse, so there was no difference in the total costs between the two groups. The cost-effectiveness ratio obtained from X group was more satisfactory than that of C group no matter what the cost of percentage response rate, per TTP and per life-year survival (Table 6).

DISCUSSION

The morbidity caused by gastric and colorectal carcinoma are respectively the first and the fourth in China^[10,11]. It is difficult to cure the patients at the end stage without a chance for operation or with recurrence and metastasis. 5-FU is a basic drug for gastrointestinal cancer, but its effective rate is only 10-20%. Increasing the dosage, intravenous injection continually or in combination with intensifier can enhance the effect of 5-FU, whereas its side effects and medical costs will increase too. For example, increasing the dosage can result in higher incidence of stomatitis and extremity syndrome, and intravenous injection continually or in combination with intensifier leads to more severe phlebitis, and all of which raise the cost. The regimen of 5-FU combined with CF and levamisole has stood the dominant status in treating tumor of the digestive system for more than 20 years^[12,13]. Recently, oxaliplatin combined with 5-FU and CF has become the most frequent and effective chemical therapy for patients with colorectal cancer, and also has been used to treat gastric cancer^[14-17].

Xeloda (capecitabine) is a novel, oral, selectively tumor-activated fluoropyrimidine carbamate and absorbed by small intestine in antetype term. It can be activated and transformed to 5-FU by thymidine phosphorylase that has high competence in tumor. So the concentration of 5-FU in tumor tissue is much higher than that in normal tissue and its systemic side effect is lower^[18-21]. Xeloda has already been used to treat advanced gastrointestinal cancer with much better result. If combined with oxaliplatin, there will be good results.

The heat-chemical therapy of abdominal cavity includes heat and chemical drug treatments. This therapy has many advantages. It can increase the concentration, the contact surface and the time of the drug in abdominal cavity by

perfusing heat drug into abdominal cavity, which is in favor of prolonging action time and killing of cancer cell. A part of the drug can be absorbed by the peritoneum and come into the liver *via* portal vein, which can prevent and eliminate metastatic focus in liver. Its heat effect (40-45 °C) can reduce the pH value in and around the tumor, which will result not only in metabolic disturbance of the tumor, but also the amelioration of the function of the cellular immunity. Furthermore, the heat can kill the tumor cell directly by cytotoxic effect^[22-24]. Considering those advantages, the oral Xeloda combined with bi-platinu two-way heat-chemical therapeutic regimen was adopted to treat 55 patients with advanced gastrointestinal cancer and this regimen was compared with another regimen, 5-FU/CF combined with bi-platinu two-way heat-chemical therapeutic regimen simultaneously. Our results revealed that the effect, 1 year survival and TTP of the former were much better than the latter, and that there was little difference in primary side effect, such as the reaction of the alimentary system and nervous system, bone marrow depression and extremity syndrome between the two groups.

There is a relationship between the dose and effect for cancer chemotherapy. Following the increasing dosage, the effect will be improved, but the side effect and expenses will be increased. So a balance between effect, side effect and expense is needed. Pharmacoeconomics and the study of DI are the new hot points in cancer chemotherapy. To choose the optimal regimen and distribute the limited medical cost, the cost-effectiveness and quality-of-life index effect of oral Xeloda were investigated and compared with CF/5-FU combination chemotherapy in patients with advanced gastrointestinal malignancies, both combined with bi-platinu two-way chemotherapy. Generally, the expenses of the treatment include the direct medical and non-medical fees and indirect medical fee. The average cost for a patient in one cycle was ¥9 137.35 in X group. This cost was a little higher than that in control group (¥8961.72). But the cost-effectiveness analysis is more important, because the elongation of survival time and increasing the survival rate should be emphasized in addition to the effective rate^[25]. The costs of Xeloda group and the cost of unit effect were fewer than C group. Because Xeloda was administered in

lower dosage (1 000 mg/m² twice daily) in our study, not 1 250 mg/m² twice daily as recommended, the incidence of grade 3 or 4 of HFS was reduced. Pyridoxine being given at a high dose from the beginning may be useful for the prophylaxis of the occurrence of HFS^[7,26]. For other minor side effects of the two regimens, all patients having accomplished the treatment on time, would mean the relative DI of two groups is close to one. However, the shorter intermission of Xeloda group (about 7 d) leads to the stronger of the actual DI [8 662.7 mg/(m²·wk)] which probably is another reason for the better effect of Xeloda group than control group. The DI is an index to evaluate the drug or regimen. The analysis of relation between DI and effect will help to improve the effect of the chemical therapy by increasing the dosage of unit time or decreasing intermission of chemical therapy^[27-29].

In summary, oral capecitabine can mimic continuous infusion of 5-FU and avoid the inconvenience, complications, and additional costs associated with intravenous chemotherapy. The regimen of oral Xeloda with bi-platinu in two ways (intravenous and intraperitoneal administration) to treat the advanced gastrointestinal cancer has better short-term and long-term effect. It is an effective, safe and economic regimen for patients, even for the old. For ideal pharmacoeconomics, satisfying DI and good compliance, this regimen has a good prospect in the future.

Abstract

AIM: To investigate the relationship between the superoxide dismutase (SOD), malondialdehyde (MDA) metabolic changes and the gastric carcinogenesis.

METHODS: The SOD activity and MDA content were measured in the gastric tissues from the focus center, peripheral and far-end areas of gastric carcinoma ($n = 52$) and gastric ulcer ($n = 10$). All the tissues were subjected to routine histological examinations and classifications.

RESULTS: The SOD activity was greatly reduced but the MDA content was markedly increased in the center areas of the non-mucous gastric carcinoma (non-MGC); and the poorly differentiated gastric carcinoma varied. The SOD activity was gradually decreased and the MDA content was gradually increased in the tissues from the focus far-end, peripheral to center areas of non-MGC. Both of the SOD activity and the MDA content were significantly declined and were respectively at same low level in the tissues from the focus center, peripheral, and far-end area with the mucous gastric carcinoma (MGC). In contrast to the gastric ulcer and grade I or II of non-MGC, the same level of the SOD activity and the MDA content were found in the focus center areas. Between non-MGC (groups A-D) and gastric ulcer (group F), the differences of SOD activity and MDA content were very noticeable in the gastric tissues from the focus peripheral and far-end areas, in which the SOD activity showed noticeable increase and the MDA content showed noticeable decrease in the gastric ulcer.

CONCLUSION: The active free radical reaction in the gastric tissues can induce the carcinogenesis of non-MGC. The utmost low ability of antioxidation in the gastric tissues can induce the carcinogenesis of MGC. The metabolic

change of the free radicals centralized mostly in the center of ulcerated lesions only, which suggested the ability of antioxidation was declined only in these lesions. However, the metabolism of free radicals varied significantly and the ability of antioxidation declined not only in the local focus area but also in the abroad gastric tissues with gastric carcinoma.

INTRODUCTION

Free radical is the middle product during the phase of the biochemical metabolism in the body^[1], and it is the intense toxicant because of being very active in the biochemical nature and oxidizing ability^[2-5]. Although recent work has shown that free radical is related to the causing and development of many digestive system diseases^[6-8], it did not distinct the relationship between the free radical and the gastric carcinogenesis^[9,10]. In the investigation, it was researched that metabolic changes of the free radical play a role in the gastric carcinogenesis, development of gastric carcinoma by investigating the metabolism condition and regularity of the free radicals in the fresh samples of the gastric carcinoma tissues.

MATERIALS AND METHODS

Patients and tissues

From 1998 to 2002, 52 cases of gastric carcinoma and 10 cases of gastric ulcer were obtained from the Central Hospital of Shantou City. All fresh stomach samples were surgically removed from these patients and regular routine histological examination and classification were made. The patients with gastric carcinoma were 11 women and 41 men. The mean age was 59.83 years, ranging from 34 to 76 years. The patients with gastric ulcer were 1 woman and 9 men and the mean age was 53.30 years, ranging from 19 to 69 years.

Measurement of SOD activity and MDA content

Stomach samples were obtained, the tissues at the center,

peripheral (2 cm away from focus lesion) and far-end areas (8-10 cm away from focus lesion) sampled respectively. The fresh tissues were made into 10% tissue homogenate for measurement of the superoxide dismutase (SOD) activity and malondialdehyde (MDA) content. The SOD activity was examined with xanthine oxidase method and the MDA content was examined with sulfur barbituric acid method^[11]. SOD and MDA detection kits were purchased from Nanjing Jiancheng Bioengineering Institute.

Statistical analysis

All data were disposed by SPSS9.0 statistical software. Statistical comparisons between interior groups were analyzed with ANOVA followed by Student's *t*-test. Statistical comparisons between different groups were analyzed with one-way ANOVA followed by *q*-test. Experimental results were finally expressed as mean \pm SD. *P* value less than 0.05 was considered statistically significant.

RESULTS

Histological examination

Fifty-two patients with gastric carcinoma were confirmed by histological examination. Among the 52 cases, 44 were non-mucous gastric carcinoma (non-MGC) including papillary, tubular, poorly differentiated, undifferentiated carcinoma, and were graded into four groups: grade I, 12 cases (group A, Figure 1A); grade II, 15 cases (group B, Figure 1B); grade III, 11 cases (group C, Figure 1C); grade IV, 6 cases (group D, Figure 1D). Eight cases were mucous gastric carcinoma (MGC) including mucinous adenocarcinoma and signet-ring cell carcinoma (group E, Figure 1E). Another 10 patients who were confirmed had gastric ulcer (group F, Figure 1F).

Detection of SOD activity (Table 1 and Figure 2)

The SOD activity was declined gradually in the tissues from the focus far-end, peripheral, to center areas in non-MGC (groups A-D). The SOD activity in the focus center areas was the lowest in the measured gastric tissue. SOD activity reduction was correlated with the grade and differentiation of gastric carcinoma in the focus center areas, in which the level of the SOD activity in groups A and B (grades I and II) was higher than that in groups C and D (grades III and IV). There was no significant difference of the SOD activity in the tissues from the focus far-end areas between groups A-D.

The level of SOD activity was extremely low in the focus center areas in MGC (group E). The level of SOD activity was noticeably low in the focus peripheral and far-end areas. Although reduction tendency was minimized, there were no significant differences of the SOD activity in the tissues from the focus far-end, peripheral to center areas; suggesting that the SOD activity in these areas was at the same low level.

The level of SOD activity was low in the focus center area with gastric ulcer (group F). Notable reduction tendency about SOD activity was shown in the tissues from the focus far-end, peripheral to center areas. The common metabolic characteristics were found in gastric ulcer (group F) and non-MGC (groups A-D). The SOD activity was gradually declined from the focus far-end, peripheral to center areas. The SOD activity was at the same level in the tissues from the focus center areas between gastric ulcer (group F) and non-MGC (grades I and II, groups A and B). Importantly, the SOD activity was noticeably higher in the tissues from the focus peripheral and far-end areas in the gastric ulcer (group F) than non-MGC (groups A-D). To compare the gastric ulcer (group F) and the MGC (group E), the level

of SOD activity was noticeably higher in all the tissues in the former than the later, and the SOD activity showed a gradual reduction tendency in the former, same low level in the later from the focus far-end, peripheral to center areas.

Detection of MDA content (Table 2 and Figure 3)

The MDA content increased gradually in the tissues from the focus far-end, peripheral to center areas in non-MGC

(groups A-D). The MDA content in the focus center areas was the highest in the measured gastric tissue. The level of MDA content correlated with the grade and differentiation of gastric carcinoma in the tissues from the center areas. The study showed that the level of the MDA content in the groups A and B (grades I and II) was lower than groups C and D (grades III and IV). There were significant differences of the MDA content in the tissues from far-end areas, in which the level of MDA content was noticeably lower in

the groups A and B than the groups C and D.

The level of MDA content was extremely low in the center, peripheral, and far-end areas in MGC (group E). There was no significant difference of the MDA content; it was at the same low level, although a minimum gradual increase tendency was found in the tissues from the focus far-end, peripheral to center areas.

The level of MDA content was noticeably high in the tissues from the focus center areas in the gastric ulcer (group F). The gradual increase tendency also showed in the tissues from the focus far-end, peripheral to center areas. The common metabolic characteristics were that the MDA content showed a gradual increase tendency in the tissues from the focus far-end, peripheral to center areas between gastric ulcer (group F) and non-MGC (groups A-D). And both in the group F and groups A and B, the MDA content was at the same level in the tissues from the focus center areas. However, when the gastric ulcer (group F) compared to the non-MGC (groups A-D), there was a significant difference: the MDA content declined markedly and varied in the tissues from the focus peripheral and far-end areas. The MDA content was noticeably higher in the tissues from the focus center areas in the gastric ulcer (group F) than the MGC (group E). But, the MDA content was at the same level in the tissues from the peripheral and focus far-end. And in the gastric ulcer (group F) compared to the MGC (group E), it showed a gradual increase tendency in the former, the later was at same low level in the tissues from the focus far-end, peripheral to center areas.

DISCUSSION

SOD is the most important substance that eliminated free radical system in the cell; it makes superoxide anion free radical (O₂⁻), dismutates into H₂O₂ and protects the cells from the focus damage by cleaning up O₂⁻. The level of

SOD activity represents the intracellular antioxidation ability^[8,10,12]. MDA is the main metabolite in the lipid peroxidation reaction. The free radicals affect on the membrane structures of the cells, including the membranes of the cell, mitochondrion, lysosome, endoplasmic reticulum, *etc.*, then injury of the cells. The level of MDA content represents the extent of the intracellular lipid peroxidation reaction^[13-15]. The SOD activity and the MDA content are the main index of the metabolic condition of the free radicals. We acquired the new knowledge that the free radicals play a key role in the mechanism of the gastric carcinogenesis from our experimental data.

Active free radical reaction in gastric tissue advances the arising of non-MGC

The gastric mucosa from the focus far-end, peripheral to center area in non-MGC showed a pathological change from normal, atypical hyperplasia to carcinoma, by morphological observation. The SOD activity also showed a gradual reduction and the MDA content a gradual increase in gastric tissues from the focus far-end, peripheral to center areas. These results showed that the intracellular antioxidation ability in the gastric tissue was gradually reduced and the free radical reaction was gradually active, resulting in the injury of cells by the lipid peroxidation reaction, which stimulated the pathological changes from normal gastric mucous membrane to carcinoma^[16-18].

The results further showed that the lower the differentiation degree of the gastric carcinoma, the more prominent the change of the free radicals metabolism. The SOD activity was lower and the MDA content higher in the groups C and D (gastric carcinoma grades III and IV) than the groups A and B (gastric carcinoma grades I and II). These results suggest two possible mechanisms: the first one was that the active free radical reaction severely damages the gastric mucous membrane cells, resulting in malignant

change in the gastric mucous membrane from the normal cell to poorly differentiated and undifferentiated carcinomas. The second was that the carcinoma cells with poorly differentiated, undifferentiated need to produce an amount of the active free radicals for cells blooming division and breeding for themselves^[15,19].

Interestingly, our results showed that there was no significant difference of the SOD activity in the far-end area between groups A, B, C, and D. However, the differences of the MDA content were very noticeable, i.e., the MDA content of the groups C and D (gastric carcinoma grades III and IV) were very much higher than groups A and B (gastric carcinoma grades I and II), indicated that abnormal lipid peroxidation reaction of the gastric tissue in far-end areas in groups C and D was not regulated by the SOD activity, and the reduction of the ability of the antioxidation was correlated with the widespread infiltration of the gastric carcinoma tissue (gastric carcinoma grades III and IV).

The tendency changes of the SOD activity and the MDA content of gastric tissues in non-MGC (groups A-D) were consistent with that in gastric ulcer (group F) from the focus center, peripheral to far-end areas. Between groups A, B and group F, the same level of the SOD activity and the MDA content were found in the gastric tissues from the focus center areas. Importantly, between the non-MGC (groups A-D) and the gastric ulcer (group F), the differences of the SOD activity and the MDA content were highly noticeable in the gastric tissues from the focus peripheral and far-end areas, which the SOD activity showed noticeable increase and the MDA content showed noticeable decrease in the gastric ulcer. It was suggested that there was high ability of the antioxidation for protecting itself against damage by the free radicals and could balance free radical metabolism in the gastric tissue from the focus peripheral and far-end areas in the gastric ulcer (group F). Meantime, it was suggested that the changes of the free radicals metabolism centralized mostly in the center area of gastric ulcer, where the ability of the antioxidation was reduced only in the local focus. Compared to the gastric ulcer (group F), the variation of the SOD activity and the MDA content were very small in the peripheral area and far-end area in the non-MGC (groups A-D), suggested that the ability of the antioxidation was reduced not only in the local focus area but also in the abroad gastric tissues. This imbalance of the free radical metabolism occurs in whole gastric tissue, resulting in the reduction of the protection itself of the gastric tissue and inducing the gastric carcinogenesis, i.e., the arising of non-MGC^[20,21].

Extreme reduction of the antioxidation ability in the gastric tissue contributes to the arising of MGC

The mucinous adenocarcinoma and the signet-ring cell carcinoma arising from the gastric mucosa possess large quantity of mucus, inside or/and around the cancer cells. And because of that characteristic nature, the cancer cells have strong ability of infiltration and widespread distribution in the gastric tissue. There were obvious differences of the SOD activity and the MDA content in gastric mucinous adenocarcinoma and signet-ring cell carcinoma, and classified

as a special group (group E), compared to other type gastric carcinoma. The obvious reduction and the same low level of the SOD activity and the MDA content were found in the tissues of the focus center, peripheral and far-end areas in the MGC, where the free radical metabolism changed obviously. The data in previous experiments showed an inverse relationship between the SOD activity and the MDA content in the tissues^[13,15]. The low SOD activity induced the reduction of the antioxidation ability and the increase of the lipid peroxidation reaction, the metabolic product, MDA, in the tissues. On the contrary, the increase of the SOD activity inhibited the reaction of the lipid peroxidation, resulting in the reduction of the metabolic product, MDA, in the tissues. But in this study, the SOD activity decreased greatly in the gastric tissue in the MGC, and the MDA content as well. Interestingly, the SOD activity and the MDA content decreased markedly to the same low level in the tissues wherever focus center, peripheral and far-end areas in the MGC. This condition of the free radicals metabolism maybe related with the special pathological changes, where there was an abundance of mucus in the tissues. The SOD is the most important substance to eliminate free radical system in cells and tissues and the level of SOD activity represents the intracellular antioxidation ability^[12,22]. The utmost low level of the SOD activity represents the utmost low level of the intracellular antioxidation ability in gastric tissue with the MGC. It was considered accordingly that the antioxidation ability was the base and precondition in maintaining the normal physiological function, differentiation, division, multiplication of the cells^[20,23]. The loss of the antioxidation ability may contribute to make the normal cells become carcinoma cells^[9,24-26] and the gastric tissues cannot resist the infiltration of the cancer cells, resulting in cancer cells spreading extensively in stomach wall.

Compared to gastric ulcer, there was a very low level of the SOD activity in gastric tissues of center, peripheral and far-end areas with the MGC and the low antioxidation ability and the low defense function by themselves. The MDA content, in the tissues from the focus peripheral and far-end areas with the MGC and the ulcer, both were at the same low level. But the SOD activity was increased greatly in the tissues from the focus peripheral and far-end area with gastric ulcer (group F). It suggested that there was still a very strong antioxidation and protecting ability in the gastric tissues from the peripheral and far-end areas with the gastric ulcer (group F). It also confirmed that the extreme low antioxidation ability and the low SOD activity in the gastric tissues in the MGC (group E) were related to the causing and development of the MGC, and can induce the formation of the MGC. On the other hand, the very low level of the MDA suggests the lipid peroxidation reaction was inactive, which indicated that the arising of the MGC was not related with the lipid peroxidation reaction to damage of the tissues.

Abstract

AIM: To investigate the association between nutrient intakes and high incidence rate of gastric cancer among residents in Zhoushan Islands.

METHODS: A frequency-matched design of case-control study was used during the survey on dietary factors and gastric cancer in Zhoushan Islands, China. A total of 103 cases of gastric cancer diagnosed in 2001 were included in the study and 133 controls were randomly selected from the residents in Zhoushan Islands. A food frequency questionnaire was specifically designed for the Chinese dietary pattern to collect information on dietary intake. A computerized database of the dietary and other relative information of each participant was completed. Total calories and 15 nutrients were calculated according to the food composition table and their adjusted odds ratios (ORs) and 95% confidence intervals (CIs) were estimated by gender using unconditional logistic regression models.

RESULTS: High intakes of protein, saturated fat, and cholesterol were observed with the increased risk of gastric cancer particularly among males (OR_{Q4 vs Q1} were 10.3, 3.24, 2.76 respectively). While carbohydrate was a significant high-risk nutrient (OR_{Q4 vs Q1} = 14.8; *P* for linear trend = 0.024) among females. Regardless of their gender, the cases reported significantly higher daily intake of sodium mainly from salts. As to the nutrients of vitamins A and C, an inversed association with the risk of GC was found. Baseline characteristics of participants were briefly described.

CONCLUSION: The findings from this study confirm the role of diet-related exposure in the etiology of gastric cancer from the point of view of epidemiology. An

INTRODUCTION

Though a decreasing trend is observed in nearly all countries, gastric cancer is one of the most common cancers in the world and the second leading cause of cancer death^[1]. Although many risk factors have been suggested, the causative and protective agents for gastric cancer remain to be clarified. Nutritional factors are thought to be paramount, with *N*-nitroso and other dietary compounds acting as carcinogens, while anti-oxidants and other protective substances in foods inhibit the carcinogenic process^[2].

In China, parts of high-risk areas for gastric cancer are located in the eastern coastlands including Zhoushan Islands, the fourth archipelago and also the largest fishing ground in China. As the first leading cancer in Zhoushan, the age-standardized annual incidence rate of gastric cancer varied from 35 to 40 per 100 000 in 1980-1985, which is higher than the national level (about 25.0 per 100 000). To investigate the risk factors for this common cancer in the coastal areas, we conducted a population-based case-control study in Zhoushan to obtain information on the frequency of consumption and portion size of common foods, and found that intake of certain nutrients in these foods influences the risk of gastric cancer.

MATERIALS AND METHODS

The data-collection period for the study spanned through the whole year of 2001 and comprised all the islands in Zhoushan, Zhejiang Province. The study population included 138 newly diagnosed patients with gastric cancer between December 1, 2000 and November 30, 2001 and 140 controls as a representative sample of residents in the same area.

All the cases were identified at the five largest hospitals in Zhoushan Islands. Of the 138 eligible patients, 10 (7.3%) died before interview, 18 (10.2%) could not be contacted as they were from distant islands, 7 (5.1%) refused to participate. Of the 103 (81 men and 22 women) patients included in the analysis, 56.3% were confirmed by histology according to the Lauren classification^[3] and 43.7% by other diagnostic methods including surgery, endoscopy, X-ray and ultrasound. Controls were selected from permanent residents in Zhoushan Islands, frequency matched to the expected distribution of cases by gender, age (10-year groups), and residents of the islands. Of the 140 eligible controls randomly selected from the Zhoushan resident files, 133 (95 men and 38 women) were interviewed, yielding a response rate of 95.0%. Each subject was interviewed face-to-face by trained interviewers.

Dietary information

A questionnaire was designed to collect information on demographic and socio-economic conditions, diet, cigarette smoking, alcohol drinking, history of selected diseases, family history of cancer, occupation, and other factors. Frequency of intake and portion size in a 12-mo period 1 year before the interview were assessed for more than 60 food and beverage items, which included information on dairy products, fruits, meat, processed meat, fish, vegetables and candies, *etc.* These items accounted for over 85% of food intake in Zhoushan residents. For each food, amount consumed was estimated according to models of the more frequently consumed foods. Consumption of seasonal vegetables and fruits was assessed on the basis of average intake during the relevant period of the year.

Nutrient intake

Fifteen priority nutrients and total calories were selected beforehand as previously described^[4-6]. Quantitative estimate of cumulative nutrient intake per day in each food was based on food tables derived from the Chinese Food Composition Tables. Total intake of each nutrient was summed over all foods consumed. The Matlab5.0 software was used for processing these procedures by the method of multiplication of matrix^[7].

Data analysis and control of confounding

Descriptive analysis of nutrient intake for cases and controls was carried out by computing medians and percentages because of biased distributions of the data, which could not be transformed into normal with logarithmic transformations. The medians were compared by the nonparametric median test.

Then continuous variables of nutrient intake were divided into quartiles based on the distribution in controls, with an approximately equal number of controls in each intake stratum. The amount of intake varied substantially between the sexes, hence sex-specific cutpoints were used for amount of nutrient intake. Risk of gastric cancer associated with dietary factors was estimated by odds ratios (ORs) and its 95% confidence intervals (CIs), using unconditional logistic regression models. Each classified nutrient was introduced into the model as a dummy variable.

The lowest level of consumption was used as the reference category in the estimation. All ORs were adjusted for age, economic status (based on monthly family *per capita* income), present residence, educational level and total calories. In addition, ORs for men were further adjusted for cigarette smoking and alcohol drinking, confounding factors common in Chinese men but not in Chinese women (only 5% of women smoke, and 6.7% drink alcohol regularly).

For testing of linear trends, the ordinal nutrient intake variables were treated as continuous variables. In this step, $P \leq 0.05$ was considered as evidence for a dose-response relationship. All analyses were carried out by the SPSS version 10.0 software.

RESULTS

Selected characteristics of the study population are shown in Table 1. Due to the frequency-matching procedure by age, gender and present residence, the characteristics of these three variables were similar. Compared to controls, only the age of patients was slightly older (median age 63 years for cases and 60 years for controls). Among

¹Three categories of islands were classified according to the number of permanent residents on islands: Dinghai, Putuo, and Daishan Islands, which are the three main islands in Zhoushan, predefined as the large islands; the islands on which the number of permanent residents is over 25 000, defined as the medium islands; the residual defined as the small islands.

non-dietary variables considered, the major determinants of gastric cancer risk were indicators of socio-economic status. For instance, 41.8% of the cases and 33.8% of the controls reported less than 7 years of education, 58.2% of the cases and 66.2% of the controls reported 7 years or more of education. As for the economic status, patients tended to have lower monthly income (44.7% of cases and 22.6% of controls with an average *per capita* income of 36 Chinese Yuan/month or less). No material difference in smoking/drinking habits was observed between cases and controls.

Table 2 shows the medians of daily nutrient intakes in the gastric-cancer cases and the controls according to gender.

Overall, the cases reported significantly higher consumption of protein, cholesterol and Na (sodium) than controls, but these differences were significant only in the females. For controls, consumption of carotene and vitamin E was much higher, and on the contrary, the differences were significant in the males.

The multivariate-adjusted ORs for the quartile distributions of the macronutrients (Table 3) showed a significant positive linear trend for the risk of gastric cancer with increasing consumption of protein and cholesterol in males, whereas total fat and carbohydrates in females. The ORs for the highest quartile compared to the lowest quartile of consumption frequency significantly elevated for protein

Table 3 Odds ratios¹ (ORs) and 95% confidence intervals (CIs) of gastric cancer in relation to quartiles of macronutrients by sex, Zhoushan, China

¹Adjusted for age, present residence, education, economic status, smoking (males only), alcoholics (males only) and total calories intake; ²Data are ORs, with 95% CIs in parentheses; ³OR_{Q4 vs Q1} and 95%CI_{Q4 vs Q1} could not be calculated because of the null value of cases in the 4th group among females.

(OR, 10.30; 95%CI, 1.83–58.12), saturated fat (OR, 3.24; 95%CI, 1.11–9.49) and cholesterol (OR, 2.76; 95%CI, 1.01–7.53) in males. In females the risks remained elevated with increasing consumption of total fat (OR_{Q4 vs Q1}, 8.26; 95%CI, 1.03–66.51) and carbohydrates (OR_{Q4 vs Q1}, 14.78; 95%CI, 1.11–197.32). A marginally significant inverse linear trend was also observed for frequent consumption of polyunsaturated fat (OR_{Q4 vs Q1}, 0.10; 95%CI, 0.01–0.80) with the test for trend ($P = 0.068$).

The results of the micronutrient-intake (Table 4) uncovered a protective effect of vitamin A, with a marginally significant linear trend that held only for females (OR_{Q4 vs Q1}, 0.10; 95%CI, 0.01–0.89). Similarly, a protective effect was seen for the highest category of vitamin C consumption in female cases of gastric cancer (OR, 0.07; 95%CI, 0.01–0.95), but no linear trend was found ($P > 0.10$). In this data set, we found no significant relationship of gastric cancer with intake of vitamin E and carotene, although most OR values suggested a protective effect of them. Results from the analysis of mineral salt intake suggested a significant high-risk effect of sodium, regardless of their gender (OR_{Q4 vs Q1}, 3.22; 95%CI, 1.25–8.26 in males; OR_{Q4 vs Q1}, 8.4; 95%CI, 1.09–64.77 in females).

Further adjustment for other potential confounding factors, such as green tea drinking, occupation and family history of cancer, did not affect the associations with nutrient intakes. While 44% of the cases were diagnosed by methods other than histological confirmation, exclusion of these cases also did not alter our main findings.

DISCUSSION

The findings of this study confirm that several dietary factors identified elsewhere can also explain the incidence of gastric cancer in Zhoushan, Zhejiang Province, though gastric cancer did not decline in Zhoushan during the last 20 years. We also found that the incidence of gastric cancer in males and females is differently related to the intake of specific nutrients.

The results pertaining to an increased risk of gastric cancer due to the consumption of protein, fat and cholesterol are similar to those reported by Palli *et al.*, in Italy^[4]. In our study, the relationship between protein, saturated fat and cholesterol intake and gastric cancer was stronger in males after adjustment for other confounding

factors. Nitrites and salt in processed and smoked meats, commonly in the Zhoushan diet, are thought to play a role in the etiology of gastric cancer^[9]. In this regard, it is possible that saturated fat, cholesterol and protein consumption should be considered as proxy indicators for processed-meat consumption. We also found a protective effect of polyunsaturated fat against gastric cancer particularly in females, which is supported by other studies^[10,11].

A positive association with dietary carbohydrates has been reported in several studies of gastric cancer^[5,12,13]. In our study, the excess risk associated with carbohydrates contained in rice, noodles, and biscuits in the Chinese diet, could not be explained by education, present residence and economic status, although residual confounding by these or other unmeasured variables remains possible. Furthermore, the risk effect was stronger in females. The mechanism by which high consumption of carbohydrates may increase the risk of gastric cancer is unclear, but several possibilities have been suggested, including physical irritation (especially from rough whole-grain cereals), reduction in gastric mucin, and lowering of gastric pH with promotion of acid-catalyzed nitrosation^[14].

The most consistent finding in the relation between diet and gastric cancer is the protective effect of vegetables and fruits^[15–17]. A large number of potentially anti-carcinogenic agents are found in these food sources, such as carotenoids, vitamin C, vitamin A, fiber, and vitamin E, *etc.* In our study, we found a strong protective effect of vitamin A and vitamin C consumption against gastric cancer, particularly in females. Although the protective effect of vitamin C against gastric cancer has been mostly ascribed to its ability to inhibit formation of *N*-nitroso compounds from secondary amines and nitrite in the stomach, the role of vitamin C as a free-radical scavenger may be equally important^[18,19]. Vitamin A is also a well-known antioxidant, but its protective effect against gastric cancer is only occasionally reported^[12,20]. The decrease of gastric cancer risk in association with consumption of dietary fiber has also been observed^[21]. However, the mechanism of this protective effect has not yet been identified^[9]. Because vegetables and fruits not only are sources of fiber, but are the main contributions of vitamins A and C. Fiber may simply be a good indicator of consumption of plant food. As for the protective effect of vitamin E against gastric cancer, the epidemiologic results

are also inconsistent^[6,13,22-24]. In view of the anti-oxidant properties of vitamin E, it has the same mechanism as ascorbic acid. Our results are more inclined to support the hypothesis that vitamin E might reduce the risk of gastric cancer.

The analysis of mineral salts suggested that only sodium mainly from salts had an increased risk for gastric cancer, regardless of the gender. Foods that are high in salt or preserved with salt in some form (dried or pickled food) are associated with an increased risk for gastric cancer^[1,23,25]. Although the exact mechanism by which salt predisposes to gastric cancer is not known, salt can irritate the gastric cancer mucosa, making it more susceptible to carcinogenic change. Salt may also lead to atrophic gastritis, which is associated with increased risk for gastric cancer^[26-29]. Atrophic gastritis can lead to colonization by bacteria that can catalyze the conversion of nitrites to carcinogenic N-nitroso compounds^[30,31].

Although our findings are consistent with most previous studies of gastric cancer conducted in other countries, several potential limitations of our study should be noted. While the participation rate of the controls was relatively high (95%), only 75% of the eligible cases participated. Since there was generally a 3-mo delay between diagnosis and interview with cases, a few (10%) could not be connected for living in distant islands. Another main reason for non-participation was the death that occurred among cases (7.3%), thus raising the possibility of survival bias. If the identified risk factors could also affect the survival of gastric cancer patients, then exclusion of deceased cases may underestimate the true risks associated with these factors. On the other hand, selection bias, which tends to shift the risk estimates away from unity, should also be minimal since a small percentage of subjects refused to participate. As for the recall bias commonly existed in the dietary survey, efforts have been made to minimize it in various ways, including extensive training of interviewers, use of a standardized questionnaire and models of the more frequently consumed foods. But there were still many other potential recall biases not considered.

An additional limitation is that many nutrients are contained in the same food, and there is some correlation between the intake of certain nutrients, making it difficult to differentiate individual effects. Associations may also appear merely by chance because of the associations analyzed.

In summary, our results from the coastal areas confirm again that the diet plays an important role in the etiology of gastric cancer, and interventions against bad dietary structures may be important for the prevention of gastric cancer.

Abstract

AIM: To investigate the damaging effect of high-intensity focused ultrasound (HIFU) on cancer cells and the inhibitory effect on tumor growth.

METHODS: Murine H₂₂ hepatic cancer cells were treated with HIFU at the same intensity for different lengths of time and at different intensities for the same length of time *in vitro*, the dead cancer cells were determined by trypan blue staining. Two groups of cancer cells treated with HIFU at the lowest and highest intensity were inoculated into mice. Tumor masses were removed and weighed after 2 wk, tumor growth in each group was confirmed pathologically.

RESULTS: The death rate of cancer cells treated with HIFU at 1 000 W/cm² for 0.5, 1, 2, 4, 8, and 12 s was 3.11±1.21%, 13.37±2.56%, 38.84±3.68%, 47.22±5.76%, 87.55±7.32%, and 94.33±8.11%, respectively. A positive relationship between the death rates of cancer cells and the length of HIFU treatment time was found ($r = 0.96$, $P < 0.01$). The death rate of cancer cells treated with HIFU at the intensity of 100, 200, 400, 600, 800, and 1 000 W/cm² for 8 s was 26.31±3.26%, 31.00±3.87%, 41.97±5.86%, 72.23±8.12%, 94.90±8.67%, and 99.30±9.18%, respectively. A positive relationship between the death rates of cancer cells and the intensities of HIFU treatment was confirmed ($r = 0.98$, $P < 0.01$). The cancer cells treated with HIFU at 1 000 W/cm² for 8 s were inoculated into mice *ex vivo*. The tumor inhibitory rate was 90.35% compared to the control ($P < 0.01$). In the experimental group inoculated with the cancer cells treated with HIFU at 1 000 W/cm² for 0.5 s, the tumor inhibitory rate was 22.9% ($P < 0.01$). By pathological examination, tumor

growth was confirmed in 8 out of 14 mice (57.14%, 8/14) inoculated with the cancer cells treated with HIFU at 1 000 W/cm² for 8 s, which was significantly lower than that in the control (100%, 15/15, $P < 0.05$).

CONCLUSION: HIFU is effective on killing or damage of H₂₂ hepatic cancer cells *in vitro* and on inhibiting tumor growth in mice *ex vivo*.

INTRODUCTION

High-intensity focused ultrasound (HIFU) consists of focused ultrasound (ULS) waves emitted from a transducer and is capable of inducing tissue damage. By means of this thermal effect and other mechanisms, HIFU-treated tumor tissues result in direct thermal cytotoxic necrosis and fibrosis, thus leading to inhibition of tumor growth. Therefore, HIFU is a new-sophisticated high-technology based minimally invasive treatment option for some cancers, which allows radiation-free treatment. Until now there are many kinds of tumors, such as tumors of prostate, liver, kidney, bladder, breast, and brain, that were treated with HIFU clinically and experimentally, some cancers were effectively controlled after HIFU treatment. As one of the minimally invasive surgical techniques for cancer treatment, HIFU is of great interest today^[1,2].

Malignant cells are sensitive to therapeutic ULS treatment, which leads to a transient decrease in cell proliferation^[3] through inducing a complex signaling cascade with upregulation of proapoptotic genes and downregulation of cellular survival genes^[4]. In *in vitro* study, it was confirmed that CZ901 HIFU inhibits proliferation and induces apoptosis of cancer cells^[5]. This study aimed to investigate the effects of HIFU on cancer cell damage *in vitro* and tumor growth inhibition *ex vivo*.

MATERIALS AND METHODS

Experimental materials

Cancer cell line in mouse Murine hepatoma H₂₂ cell line

was kept in liquid nitrogen for regular use in our laboratory^[6].

Experimental animals Female Balb/C mice, weighing 18-22 g, were purchased from Beijing Biological Products Research Institute under Ministry of Public Health (approval number: 013072). The procedures involving animals and their care were conducted in accordance with institutional guidelines for Laboratory Animal Care of Experimental Animal Center, Sichuan University.

Experimental device CZ901 HIFU device for cancer treatment was designed and supplied by Mianyang Electronic Equipment Factory.

Experimental methods

Experiment *in vitro* Ascites taken from H₂₂ hepatic cancer bearing mouse on d 8 or 9 was diluted with normal saline at 1:5 (2.5×10^7 cells/mL) and distributed into 14 PVC tubes, 7 tubes in each test, each containing 1.8 mL. Twelve tubes were treated with HIFU, and two were used as controls. H₂₂ hepatic cancer cells were treated with HIFU at the frequency of 1.048 MHz and at the intensity of 1 000 W/cm² for 0.5, 1, 2, 4, 8, and 12 s, respectively, and for 8 s at intensity of 100, 200, 400, 600, 800, and 1 000 W/cm², respectively. After HIFU treatment, the cells were incubated in a humidified atmosphere of 50 µg/mL CO₂ at 37 °C for 6 h, and then the viability of cancer cells was determined by exclusion of trypan blue staining. The viable cells were not stained, the dead cells were stained blue. The viable cells and dead cells were counted with an erythrocytometer under microscope, respectively (total cell number counted >1 000). The death rate was determined by $\text{death rate} = \frac{\text{dead cell number}}{\text{dead cell number} + \text{viable cell number}} \times 100\%$. Each experiment was performed in triplicate.

Inoculation of HIFU-treated cancer cells *ex vivo* Cancer

cells including viable and dead cells treated with HIFU at 1 000 W/cm² for 8 s were inoculated into 14 mice, 2×10^6 cells/0.2 mL per mouse. The same number of untreated cancer cells was inoculated into 20 mice as control. In addition, cancer cells treated with HIFU at 1 000 W/cm² for 0.5 s were inoculated into 18 mice, 2×10^6 cells/0.2 mL per mouse. The same number of untreated cancer cells was inoculated into 20 mice as control.

Examining the tumor growth *ex vivo* The animals inoculated with cancer cells were raised routinely, with free access to food and water and weighed every 2 d. After 2 wk of inoculation, the animals were killed, the tumor masses were removed and weighed, and the tumor inhibitory rate was calculated^[6].

Histopathological examination Tumor masses were fixed with 4% paraformaldehyde, embedded with paraffin, sectioned and stained with HE. The tumor growth inhibition was confirmed by microscopy.

Statistical analysis

The experimental data were expressed as mean \pm SD and analyzed with χ^2 test. $P < 0.05$ was considered statistically significant.

RESULTS

Cell damage effect of HIFU *in vitro*

The death rate of cancer cells in controls was 3-5% (Figure 1A), and increased significantly after HIFU treatment (Figure 1B). The death rate of cancer cells treated with HIFU at 1 000 W/cm² for 0.5, 1, 2, 4, 8, and 12 s were $3.11 \pm 1.21\%$, $13.37 \pm 2.56\%$, $38.84 \pm 3.68\%$, $47.22 \pm 5.76\%$, $87.55 \pm 7.32\%$, and $94.33 \pm 8.11\%$, respectively (Figure 1C). A positive

Figure 1 Cell damage effect of HIFI *in vitro*. **A:** Murine hepatic cancer cells before HIFU treatment; **B:** murine hepatic cancer cells treated with HIFU at 1 000 W/cm² for 8 s; **C:** significant difference between cell death rate and time of HIFU

treatment; **D:** significant difference between the cell death rate and intensity of HIFU treatment.

Figure 2 Tumor growth inhibition of HIFU *ex vivo*. **A**: Tumor growth inhibition of HIFU at 1 000 W/cm² for 8 s; **B**: significant difference in average tumor weight between the control and HIFU-treated mice; **C**: tumor growth inhibition of HIFU

at 1 000 W/cm² for 0.5 s; **D**: significant difference in average tumor weight between the control and HIFU-treated mice.

relationship was found between the death rate of cancer cells and the time of HIFU treatment ($r = 0.96$, $P < 0.01$).

The death rate of cancer cells treated with HIFU at the intensity of 100, 200, 400, 600, 800, and 1 000 W/cm² for 8 s was $26.31 \pm 3.26\%$, $31.00 \pm 3.87\%$, $41.97 \pm 5.86\%$, $72.23 \pm 8.12\%$, $94.90 \pm 8.67\%$, and $99.30 \pm 9.18\%$, respectively (Figure 1D). A positive relationship was confirmed between the death rates of cancer cells and the intensities of HIFU treatment ($r = 0.98$, $P < 0.01$).

Tumor growth inhibition of HIFU *ex vivo*

Tumor growth inhibition of cancer cells treated with HIFU *ex vivo* is listed in Table 1. In experiment 1, six mice in the control group died of tumor burden spontaneously, none died in the HIFU-treated group. There was no significant difference in body weight increase between two groups of animals. In the group of animals inoculated with cancer cells treated with HIFU at 1 000 W/cm² for 8 s, the average tumor weight was 0.11 ± 0.16 g, and the average tumor weight in control group was 1.14 ± 0.4 g (Figures 2A and B), the tumor inhibition rate was 90.35% compared to the control ($P < 0.01$). In experiment 2, cancer cells treated with HIFU

at 1 000 W/cm² for 0.5 s were inoculated. The average tumor weight in HIFU-treated group and control was 1.36 ± 0.33 and 1.75 ± 0.53 g, respectively (Figures 2C and D), the tumor inhibitory rate was 22.90% ($P < 0.01$).

By pathological examination, tumor growth was confirmed in 8 out of 14 mice (57.14%, 8/14) inoculated with cancer cells treated with HIFU at 1 000 W/cm² for 8 s, which was significantly lower than that of the control (100%, 15/15, $P < 0.05$).

DISCUSSION

HIFU consists of focused ULS waves emitted from a transducer and is capable of inducing tissue damage. By means of this thermal effect and other mechanisms, HIFU-treated tumor tissues resulted in direct thermal cytotoxic necrosis and fibrosis, thus leading to inhibition of tumor growth. Therefore, HIFU is a new-sophisticated high-technology based, minimally invasive treatment option for some cancers^[1,4,5]. But, there are many factors affecting its therapeutic effect, such as, intensity of the transmitted pulse, the exposure time, the signal frequency, the time interval

Table 1 Inhibitory effect of HIFU on growth of hepatic cancer *ex vivo* (mean \pm SD)

Experiment group	HIFU treatment (1 000 W/cm ²)	Animals (n)		Average BW (g)		Tumor wt (g)	TIR (%)
		d _i	d ₁₄	d _i	d ₁₄		
1	Control	0	20	15	19.05 ± 2.03	19.62 ± 2.13	1.14 ± 0.40
	HIFU	8	14	14	19.69 ± 1.34	21.45 ± 0.99	0.11 ± 0.16^b
2	Control	0	20	19	21.03 ± 2.14	28.39 ± 3.83	1.75 ± 0.53
	HIFU	0.5	18	18	22.68 ± 2.73	27.46 ± 4.03	1.36 ± 0.33^b

BW: Body weight; wt: weight; TIR: tumor inhibitory rate. ^b $P < 0.01$ vs control.

between two firing bursts, and biological medium, *etc.*^[1,7-9].

The HIFU device used in this experimental study was designed and manufactured in Mianyang Electronic Equipment Factory. Its signal frequency emitted is 1.048 MHz, the intensity of the transmitted pulse and exposure time can be manipulated^[5]. In this experimental study, H₂₂ hepatic cancer cells were treated with HIFU at the same intensity for different lengths of time and for the same length of time at different intensities *in vitro*. It showed a intensity and time-dependent damaging effect on cancer cells (Figures 1B-D), suggesting that HIFU has a damaging or killing effect on cancer cells *in vitro*. The effective parameters are: an intensity of 1 000 W/cm² and an exposure time of 8 s.

There are many experimental and clinical studies on treatment of tumors with HIFU^[1,10-14], especially hepatic cancers^[15-19]. The results of these studies *in vitro* and *in vivo* indicate that HIFU has damaging or killing effect on cancer cells *in vitro* and inhibitory effect on tumor growth *in vivo*. However, to our best knowledge, there is no study on the growth potential of cancer cells after HIFU treatment. The findings in this study indicate that most cancer cells treated with HIFU at 1 000 W/cm² would die and lose the proliferating potential, but few cells may survive and form tumors.

Although minimally invasive methods for the treatment of cancer, such as HIFU, and high-energy shock waves, have been proposed recently, their feasibility for treatment of human cancers needs to be confirmed^[1,20]. This experimental study has confirmed that HIFU has effects on killing or damage of H₂₂ hepatic cancer cells *in vitro* and on the inhibiting tumor growth in mice *ex vivo*. Its inhibitory and therapeutic effects on other cancers, and mechanisms of action need to be studied and confirmed further.

Abstract

AIM: To describe a new classification method of right hepatectomy according to the different special positions of tumors.

METHODS: According to positions, 91 patients with malignant hepatic tumor in the right liver lobe were divided into six groups: tumors in the right posterior lobe and (or) the right caudate lobe compressing the right portal hilum ($n = 14$, 15.4%), tumors in the right liver lobe compressing the inferior vena cava and (or) hepatic veins ($n = 11$, 12.9%), tumors infiltrating diaphragmatic muscle ($n = 7$, 7.7%), tumors in the hepatorenal recess (infiltrating the right fatty renal capsule, transverse colon and right adrenal gland, $n = 8$, 8.8%), tumors deeply located near the vertebral body ($n = 3$, 3.3%), tumors at other sites in the right liver lobe (the control group, $n = 48$, 52.75%). The values of intraoperative blood loss (IBL), tumor's maxim cross-section area (TMCSA), and time of hepatic hilum clamping (THHC) and incidence of postoperative complications were compared between five groups of tumor and control group, respectively.

RESULTS: The THHC in groups 1-4 was significantly longer than that in the control group, the IBL in groups 1-4 was significantly higher than that in the control group, the TMCSA in groups 2-4 was significantly larger than that in the control group, and the ratio of IBL/TMCSA in group 1 was significantly higher than that in the control group. There was no significant difference in the indexes between group 5 and the control group.

CONCLUSION: The site of tumor is the key factor that determines IBL.

INTRODUCTION

Clinically, 60% of malignant tumors occur in the right liver which has a great physical volume and complicated anatomic structure, with a large number of vessels inside and important organs around, such as diaphragmatic muscle, right kidney, right adrenal gland, colon, and inferior vena cava. Therefore, tumors in the right liver lobe with different sizes and diversified positions may induce a widely different series of problems in the process of resection of these tumors. Generally, the easily removed tumor has a diameter less than 5 cm and is located on the surface of liver without infiltrating the surrounding important organs, or does not compress the main blood vessels in the liver. The features of tumors which are different to resect are as follows. (1) The diameter of tumor is larger than 5 cm and the tumor is close to or even infiltrates the major vessels of liver; (2) Although the diameter of tumor is less than 5 cm, it protrudes from the liver surface infiltrating surrounding organs. The tumor is deeply located and hard to be exposed during surgery. The tumor which meets one or more of the above standards is defined as the malignant tumor within the right liver with special position (MTRLSP). For the much more intraoperative blood loss (IBL), the longer the time of hepatic hilum clamping (THHC), the more the postoperative complications. MTRLSP has been a difficulty in right hepatectomy. Little information is available on the classification of right hepatectomy for MTRLSP. This paper presents a prospective observation on the surgical features of 91 cases of right hepatectomies, and the classification according to the standards mentioned above.

MATERIALS AND METHODS

Study population

Ninety-one patients with malignant tumor within the right liver underwent right hepatectomy from 2002-05 to 2003-09 at Eastern Hepatobiliary Surgery Hospital of Second Military Medical University. There were 73 male and 18 female patients, ranging 25-78 years of age, including 87 cases of primary liver cancer, 2 cases of colon metastatic cancer, 1 case of rectum metastatic cancer, and 1 case of

liver lymphoma. There were four cases of tumor thrombosis in portal vein and two cases in the bile duct. No death occurred in hospital.

Grouping

Forty-three cases of MTRLSPs were divided into five groups in light of tumor positions, and 48 cases of tumors at other sites within right liver lobe in the corresponding period served as the control (Table 1).

Table 1 Grouping of 91 cases of right hepatectomies

	Tumor position	Cases (%)	Total (%)
MTR			
LSP	Group 1 Tumors within right posterior lobe and (or) right caudate lobe compressing right portal hilum	14/91 (15.4)	43/91 (47.25)
	Group 2 Massive tumors within right liver lobe compressing the inferior vena cava and (or) hepatic veins	11/91 (12.09)	
	Hepato-renal infiltrating transverse colon	7/91 (7.7)	
	Recess infiltrating right adrenal gland	4/91 (4.4)	
	Group 3 Tumors infiltrating diaphragmatic muscle	3/91 (3.3)	
	Group 4 Tumors in the infiltrating right fatty renal capsule	1/91 (1.1)	
	Group 5 Tumors deeply located near vertebral body	3/91 (3.3)	
	control		
	Group 6 Tumors in other places	48/91 (52.75)	

Methods

The Pringle's maneuver was routinely adopted in tumor resection to control bleeding. The THHC was recorded during surgery, and the IBL and the TMCSA were measured after surgery. The postoperative complication of each patient was also recorded. The IBL, THHC (used for evaluating tumor size), TMCSA and postoperative complications in each group were compared to those in the control group respectively.

Statistical analysis

The data were expressed as mean±SE. SPSS for Windows, version 11.0 was used with Dunnett-*t* or Wilcoxon signed rank test.

RESULTS

The values of THHC in each group are shown in Table 2. The time in groups 1-4 was much longer than that in group 6 ($P<0.05$), but not in group 5 ($P>0.05$). For *F*-test = 0.078>0.05, bilateral Dunnett-*t* was used.

The values of IBL in each group are shown in Table 3. The value of IBL in groups 1-4 was much greater than that in group 6 ($P<0.05$), but not in group 5 ($P>0.05$). For *F*-test = 0.007<0.05, bilateral Wilcoxon signed rank test was used.

The values of TMCSA in each group are shown in Table 4. The value of TMCSA in groups 2-4 was much larger than that in group 6 ($P<0.05$), but not in groups 1 and 5 ($P>0.05$). For *F*-test = 0.000<0.05, bilateral Wilcoxon signed rank test was used.

The ratios of IBL/TMCSA in each group are shown in Table 5. The value of IBL in groups 2-5 was not significantly higher than that in group 6 ($P>0.05$), but not in group 1 ($P<0.05$). For *F*-test = 0.114>0.05, bilateral Dunnett-*t* was used.

The rate of blood transfusion during surgery and the

Blood transfusion	35.71	45.45	42.86	37.5	0	0
Incidence of postoperative complications	14.29	36.36	71.43	37.5	0	0

incidence of postoperative complications in each group are shown in Table 6, the above two values were all zero in groups 5 and 6. The main postoperative complication in groups 1, 2, and 4 was right pleural effusion. The main postoperative complications in group 3 were right pleural effusion and rupture of diaphragm.

DISCUSSION

According to the definition of MTRLSP, the proportion of MTRLSP is 47.25% (Table 1), which shows that nearly half of right hepatectomies for malignant tumors are the high-risk resections for MTRLSPs. The IBL, THHC, and postoperative complications are the three risk factors for the resection for MTRLSP; tumor size and site determine these factors. In this study, taking the influence of tumor size as the index of IBL/TMCSA, we divided the MTRLSPs into five groups according to their positions to analyze and identify the main reason for high-risk resections of tumors in each group.

Tumors in the group 1 (*n* = 14, 15.4%) within the right posterior lobe and (or) right caudate lobe usually compressed or even infiltrated the right posterior portal vein (RPPV, Figure 1), occasionally with the tumor thrombus in vessels. Tumor thrombi almost all occurred in this (in portal branch, *n* = 3, 3/4 = 75%; in bile duct, *n* = 2, 2/2 = 100%). The tumor was usually located between the first and third hepatic hilum with some main blood vessels around, such as the RPPV, inferior vena cava (IVC). It was difficult to control bleeding in an extremely dangerous state once these main vessels rupture when the tumor was exposed, and to injure

the first hepatic hilum if blind suture was used to stop bleeding. Therefore, the IBL (642.85±132.89 mL) was much greater than that in the control group (257.40±29.44 mL, *P* = 0.033), and the THHC (31.00±3.53 min) was also significantly longer than that in the control group (19.148±1.27, *P* = 0.001), though there was no statistical difference (*P* = 0.683) in TMCSA between this group (20.61±4.67 cm²) and control group (22.77±3.67 cm²). The main reason for high-risk resection of tumors of this group is the site but not the size of tumors, which is further proved by the fact that the index of IBL/TMCSA (38.14±9.91) was significantly higher than that in the control group (13.42±2.24, *P* = 0.003).

For example, an operation of 1 patient with the tumor in the right caudate going down to left caudate ran into trouble. After the tumor was ablated from the wall of the compressed IVC and RPPV, it was impossible to suture the wound because the nude right portal branch was just on the surface of the incision wedge. A drainage tube was placed instead of suture of the wound. A bile leakage was found 3 d after surgery which was closed after drainage.

Generally, to handle the tumor at this site, we should remove it as soon as possible, and suture the liver wound by any possible way, and observe the characteristics of drainage carefully in case the severe bile leakage occurs after surgery^[1].

Tumors (*n* = 11, 12.9%) in group 2 compressing part or completely at the inferior vena cava (*n* = 6, Figure 2) and (or) hepatic veins (*n* = 4, Figure 3) had the largest size in groups 1-6, with TMCSA being 84.95±11.76 cm², larger than that in the control group 22.77±3.67 cm², *P* = 0.003. They were so large that they almost occupy the whole right

**Figure 1** Tumor infiltrating right posterior portal vein (→).**Figure 2** Tumor compressing IVC (→).

liver lobe.

The IBL ($1\,054.54 \pm 200.16$ mL) and THHC (36.72 ± 2.41 min) were much greater and longer than those in the control group (IBL: 257.40 ± 29.44 mL, $P = 0.005$; THHC: 19.148 ± 1.27 min, $P = 0.000$), suggesting a higher risk for surgery in this group. But there was no statistical difference in the index of IBL/TMCSA (14.81 ± 2.79) between this group and control group (13.42 ± 2.24 , $P = 1.000$), suggesting that IBL is not much greater than that in the control group when the influence of tumor size is excluded. Apparently, the biggest tumor size is the main reason for the top 36 min THHC and 1 054 mL IBL in this group.

Some troubles caused by the compression of the IVC from tumors are as follows. When the tumor is removed from normal liver, severe bleeding may occur due to lacerated breakage on the IVC wall or crevasse of the hepatic short vein (HSV) with ligation falling off. After the tumor is removed, the remnant liver with full-length IVC uncovered on a wide surface of the incision wedge may be hard to be sutured for the fear of IVC obstruction due to compression from suture of wound. The obstruction can induce liver swelling and severe cirrhosis. The treatment strategies may be summarized as follows. (1) If the image of a tumor shows preoperatively that the tumor compresses or infiltrates the IVC, the blocking string should be preplaced around the superior and inferior IVC to the effect that severe bleeding can be easily controlled. The breakage is better sutured with 3-0 prolene, but not clamped. In addition, the HSV and the right adrenal gland vein should be abscised and ligated carefully; (2) To avoid compression of the IVC, an incision wedge should be shaped 'arc' so that both sides can be sutured with the IVC untouched at the bottom of the wound, and the remnant liver can be suspended to the abdomen wall. If the above measures do not work, the sutures of liver wound should be taken out, and then after careful hemostasis, the epiploon can be sutured to the incision wedge. Recently, some studies reported^[2,3] that fibrin sealant can be ejected to the surface of liver wound to hemostasis, and results are quick and good.

The other sort of troubles comes from compression and infiltration of right hepatic veins (RHV) by a tumor under which there is usually a part of normal liver (Figure 3). Whether this part of normal liver should be excised with the tumor depends on the following two situations: (1) If a patient has severe liver cirrhosis and small left liver lobe,

the normal liver in right posterior should be retained, and so does the RHV or dilated HSV to ensure blood flowing back^[4]; (2) If a patient has mild liver cirrhosis and thick left liver lobe, the remnant liver and RHV can be excised with the tumor.

Tumors in group 3 ($n = 7$, 7.7%) had the highest value of IBL among all groups ($1\,085.71 \pm 310.47$ mL *vs* the control 257.40 ± 29.44 mL, $P = 0.046$). One reason is that tumors usually grow out of liver surface and adhere to diaphragm with abundant bypass blood vessels. The other reason is the large TMCSA (56.38 ± 12.50 cm² *vs* the control 22.77 ± 3.67 cm², $P = 0.028$). The larger the tumor and the wider the interface between tumor and diaphragm, the more the bleeding during surgery. But there was no statistical difference in the index of IBL/TMCSA (22.85 ± 6.76) between this group and control group (13.42 ± 2.24 , $P = 0.788$), suggesting that IBL is not much greater than that in the control group when the influence of tumor size is excluded. The higher IBL and bigger TMCSA induce longer THHC (31.42 ± 4.56 min *vs* the control 19.148 ± 1.27 min, $P = 0.013$) and higher incidence of postoperative complications ($n = 5/7 = 71.43\%$, Table 6) such as right pleural effusion ($n = 3$) and diaphragm rupture ($n = 2$).

Tumors which infiltrate the diaphragm growing in an expansible fashion are usually too big to control during surgery, and should be excised integrally without the diaphragm being broken. But because of limited operational space for removal of surrounding ligaments around the liver, it is inevitable that tumors are occasionally oppressed. Once tumor ruptures, a large quantity of low osmosis water should be used to wash the peritoneal cavity to prevent tumor planting. In addition, a part of the diaphragm approaching the liver is also flimsy and frangible^[5] (Figure 4).

Thoracoabdominal approach for resection of this sort of tumors has been adopted by Xia *et al.*^[6]. They found that the IBL is less and better exposed to hemostasia than abdominal approach, without an increasing incidence of postoperative complications, but with increased trauma and more complicated operative procedure. Our study also found a higher volume of the IBL and a higher incidence of postoperative complications. Therefore, along with the development of surgical technique and perioperative intensive care, thoracoabdominal approach may be reasonable for the resection of this sort of tumors.

Figure 3 Tumor compressing RHV (→).

Figure 4 Tumor infiltrating diaphragm muscle (→).

Figure 5 Tumor infiltrating colon (→) and right fatty renal capsule (←).

Figure 6 Tumor (→) deeply located at the level of posterior margin of vertebral body.

Tumors in group 4 ($n = 8$, 8.8%; infiltrating right fatty renal capsule $n = 4$, transverse colon $n = 3$, right adrenal gland, $n = 1$) protruding to hepatorenal recess were prone to infiltrate the right fatty renal capsule, transverse colon (Figure 5) or right adrenal gland and induce wide conglutination which caused the following difficulties. (1) Abundant bypass vessels between tumor and its surroundings were likely to bleed in the course of exploration and liberation. The IBL of this group (850.00 ± 185.16 mL) was significantly greater than that in the control group (257.40 ± 29.44 mL, $P = 0.011$); (2) Because of larger size (TMCSA 46.87 ± 5.59 cm² *vs* the control 22.77 ± 3.67 cm², $P = 0.012$) and severe infiltration and conglutination with surrounding tissues, tumor became a mass which did not leave enough space for hands to move the liver lobe for liberating right ligaments. But there was no statistical difference in the index of IBL/TMCSA (14.81 ± 2.79) between this group and the control group (13.42 ± 2.24 , $P = 1.000$). The retrograde hepatectomy can be used to deal with this situation, and this method has been used for difficult hepatectomy for years^[7-9].

Tumors in group 5 were located within the right posterior-inferior segment (Figure 6), and difficult to be exposed during surgery, and had to be padded with absorbent gauze on the surface of post-parietal peritoneum to lift liver and tumors up for a good exposure after liberation of ligaments. As long as there was good exposure, it was not very difficult to remove the tumor in this group.

In conclusion, this study isolated the MTRLSP from malignant tumors in the right liver and classified them into

five sorts in terms of their position. The surgical features of each sort are described, which may improve the resection rate of malignant tumors within the right liver lobe and reduce the complications after surgery.

Abstract

AIM: To investigate the effect of hepatitis B virus (HBV) X gene on apoptosis and expressions of apoptosis factors in X gene-transfected HepG₂ cells.

METHODS: The HBV X gene eukaryon expression vector *pcDNA₃-X* was transiently transfected into HepG₂ cells by lipid-media transfection. Untransfected HepG₂ and HepG₂ transfected with *pcDNA₃* were used as controls. Expression of HBx in HepG₂ was identified by RT-PCR. MTT and TUNEL were employed to measure proliferation and apoptosis of cells in three groups. Semi-quantified RT-PCR was used to evaluate the expression levels of Fas/FasL, Bax/Bcl-xL, and c-myc in each group.

RESULTS: HBV X gene was transfected into HepG₂ cells successfully. RT-PCR showed that HBx was only expressed in HepG₂/*pcDNA₃-X* cells, but not expressed in HepG₂ and HepG₂/*pcDNA₃* cells. Analyzed by MTT, cell proliferation capacity was obviously lower in HepG₂/*pcDNA₃-X* cells (0.08910 ± 0.003164) than in HepG₂ (0.14410 ± 0.004927) and HepG₂/*pcDNA₃* cells (0.12150 ± 0.007159) ($P < 0.05$ and $P < 0.01$). Analyzed by TUNEL, cell apoptosis was much more in HepG₂/*pcDNA₃-X* cells (980/2 000) than HepG₂ (420/2 000), HepG₂/*pcDNA₃* cells (520/2 000) ($P < 0.05$ and $P < 0.01$). Evaluated by semi-quantified RT-PCR, the expression level of Fas/FasL was significantly higher in HepG₂ cells transfected with HBx than in HepG₂ and HepG₂/*pcDNA₃* cells ($P < 0.05$ and $P < 0.01$). Bax/Bcl-xL expression level was also elevated in HepG₂/*pcDNA₃-X* cells ($P < 0.05$ and $P < 0.01$). Expression of c-myc was markedly higher in HepG₂/*pcDNA₃-X* cells than in HepG₂ and HepG₂/*pcDNA₃* cells ($P < 0.05$ and $P < 0.01$).

CONCLUSION: HBV X gene can impair cell proliferation capacity, improve cell apoptosis, and upregulate expression of apoptosis factors. The intervention of HBV X gene on the expression of apoptosis factors may be a possible mechanism responsible for the change in cell apoptosis and proliferation.

INTRODUCTION

Hepatitis B virus (HBV) is a small DNA virus with partial double-stranded DNA genome. HBV contains four opening reading frames (ORF) namely preS₁/preS₂/S, preC/C, P, and X. X gene is a unique ORF which is well conserved in different mammalian hepadnaviruses, its product consists of 154 amino acids with a molecular weight of 16.7 ku. Based on epidemical data, HBx is thought to be associated with HBV-related primary hepatocellular carcinoma (HCC), but the molecular basis for the oncogenic activity of HBx remains elusive. HBx is a multiple-functional protein and plays an essential role in viral pathogenesis. HBx can deregulate cell cycle check points, transactivate cells and viral genes, which involve in transcription regulation, single transduction pathway, cell cycle regulation, *etc.*^[1] It has been shown that HBx can co-ordinate balance between proliferation and programmed cell death, and it is able to induce or block apoptosis. The deregulation of apoptosis is involved in a wide range of pathological processes, including development of HCC.

In the present study, we investigated the effect of HBx expression on apoptosis in human hepatoma cell line HepG₂, and its effect on the expression level of apoptosis factors.

MATERIALS AND METHODS

Materials

PcDNA₃ expression vector and HBV X gene eukaryon expression vector *pcDNA₃-X* were previously constructed. Human hepatoma cell line HepG₂ was provided by Cell Bank of Chinese Academy of Sciences. Modified Eagle's medium (MEM) was bought from Hyclone Company, USA. Reverse transcription system, DNA purification system, and TransfastTM transfection reagent were obtained from Promega Biotech (USA). Total RNA isolation kit was purchased from Jingmei Biotech Company (Shanghai, China). PCR primers were synthesized by Shanghai Biotechnology Company. In-site cell apoptosis detection kit was provided by Roche Company.

Methods

Cell culture and DNA transfection HepG₂ cells were cultured in MEM supplemented with 10% heat-inactivated

fetal bovine serum, 100 IU/mL penicillin and 100 mg/mL streptomycin in a humidified incubator with 50 mL/L CO₂. A total of 1.5×10^6 cells/mL were seeded into a 25 cm² cell plate before the experiment. When cells were grown to 80% confluence, *pcDNA3* or *pcDNA3-X* plasmid was transfected into HepG₂ cells by lipofection technique, which were named as HepG₂/*pcDNA3* cells and HepG₂/*pcDNA3-X* cells. A mixture containing 2 mL serum-free MEM (prewarmed to 37 °C), 5 µg plasmid DNA, 15 µL transfect reagent was added to a cell plate. After incubation for 24 h, 4 mL complete medium was added into cell plate and then incubated for another 48 h. HepG₂ cells, untransfected with any plasmid DNA, were used as controls.

Detection of X gene expression by RT-PCR Total RNA was extracted from HepG₂, HepG₂/*pcDNA3*, and HepG₂/*pcDNA3-X* cells respectively, and reverse transcribed into cDNA. One microliter of RT product was used as template, PCR was carried out. The sequences of X gene primers were: 5'-ATGCAAGCTTATGGCTGCTAGGC-TGTACTG-3' and 5'-TGCGAATTCTTAGGCAGAGG-TGAAAAAGTTG-3'. The expected amplification fragment was 467 bp. PCR conditions were as follows: pre-denaturation at 95 °C for 5 min, 32 amplification cycles (denaturation at 94 °C for 35 s, annealing at 65 °C for 35 s, and extension at 72 °C for 1 min), and a final extension at 72 °C for 7 min. The PCR products were separated by electrophoresis on 1.5% agarose gel, and detected by ultraviolet radiography.

Cell viability assay Cell viability was assayed by MTT. HepG₂, HepG₂/*pcDNA3*, and HepG₂/*pcDNA3-X* cells were planted into 96-well plates. Cells in logarithmic growth were used in experiments. One day before the experiment, complete medium was replaced by serum-free medium. During experiment, 75 µL MTT (5 mg/mL, containing in 0.01 mol/L PBS) was added into each well and incubated for 4 h. Then, the medium was replaced by DMSO (75 µL each well) and shaken gently until all crystals were dissolved. A₄₉₂ was detected to measure the proliferative capacity of each group.

Cell apoptosis assay Cell apoptosis was estimated by TUNEL staining. HepG₂, HepG₂/*pcDNA3*, and HepG₂/*pcDNA3-X* cells were planted into 96-well plates. Cells at 80% confluence were fixed with 4% paraformaldehyde, and chilled in ice

bath for 2 min with permeabilization solution (0.1% Triton X-100 in 0.1% sodium nitrate). Then, 50 µL TUNEL mixture was added, incubated in a humidified chamber at 37 °C for 1 h. TUNEL mixture was removed, 50 µL Converter-AP was added and incubated for another 30 min. The cells were rinsed with PBS, counterstained with NBT/BCIP, and detected by optic microscopy.

Effect of HBx transient transfection on apoptosis factor mRNA expression Expressions of Fas/FasL, Bax/Bcl-xL, and c-myc gene were assayed by semi-quantitative RT-PCR. β-Actin was used as internal control. Total RNA was extracted respectively with RNA isolation kit, and reverse transcribed into cDNA. PCR was performed in a 50 µL reaction volume containing 5 µL 10× PCR buffer, 5 µL 2 mmol/L MgCl₂, 1 µL 10 mmol/L dNTP, 1 µL 20 pmol/µL target gene sense and anti-sense primers, 0.5 µL 12.5 pmol/µL β-actin primer pair, 2 µL RT product, 1.5 U Taq DNA polymerase. The sequences of gene primers and amplification conditions are listed in Table 1. The initial denaturation was at 94 °C for 5 min. An additional extension step at 72 °C for 10 min was done finally. About 10 µL PCR products was separated by electrophoresis on 1.5% agarose gel, and detected by ultraviolet radiography. The densities of bands were analyzed by Bio imaging system, the ratio of target gene density to β-actin density was representative of the relative expression level of mRNA. The semi-quantitative detection was analyzed five times.

Statistical analysis

All data were expressed as mean±SE. The significance for the difference between groups was assessed with SPSS 10.0 by one-way ANOVA. *P*<0.05 was considered statistically significant.

RESULTS

Expression of HBV X mRNA in HepG₂ cells

Expressions of HBx mRNA were detected by RT-PCR. The expected band between 400 and 500 bp was found in HepG₂/*pcDNA3-X* cells, but not in HepG₂ and HepG₂/*pcDNA3* cells (Figure 1).

Cell viability assay

Cell viability was assessed by MTT. All data are shown in Table 2. A_{492} of HepG₂/pcDNA₃-X cells obviously decreased compared to that in other groups ($P < 0.05$ and $P < 0.01$), indicating that transient expression of HBx impaired the proliferative capacity of HepG₂ cells (Figure 2).

Table 2 A_{492} of HepG₂, HepG₂/pcDNA₃ and HepG₂/pcDNA₃-X cells (mean \pm SE)

Group	<i>n</i>	A_{492}
HepG ₂	10	0.14410 \pm 0.004927
HepG ₂ /pcDNA ₃	10	0.12150 \pm 0.007159
HepG ₂ /pcDNA ₃ -X	10	0.08910 \pm 0.003164

Figure 2 Effect of HBx on cell viability in HepG₂ cells.

Cell apoptosis assay

Apoptosis in the three groups was assessed with in-site cell death detecting kit (TUNEL). A total of 2 000 cells of each group were calculated. The number of apoptosis cells was 980 in HepG₂/pcDNA₃-X, 520 in HepG₂/pcDNA₃ and 420 in HepG₂. Cell apoptosis markedly increased in HepG₂/pcDNA₃-X (Table 3 and Figure 3), indicating that transient expression of HBx could promote apoptosis of HepG₂ cells (Figure 4).

Table 3 Effect of HBx on cell apoptosis of HepG₂ cells (mean \pm SE)

Group	<i>n</i>	Apoptosis
HepG ₂	5	0.2200 \pm 0.1000
HepG ₂ /pcDNA ₃	5	0.2800 \pm 0.1000
HepG ₂ /pcDNA ₃ -X	5	0.4750 \pm 0.015

Effects of HBx transient transfection on apoptosis factors' mRNA expression

Fas/FasL mRNA mRNA level of Fas and FasL was

Figure 3 Effect of HBx on apoptosis of HepG₂ cells.

elevated in HepG₂/pcDNA₃-X cells (Figures 5A and B, 6A and B), indicating that transient expression of HBx induced expression of Fas and FasL in HepG₂ cells.

Bcl-xL/Bax mRNA mRNA level of Bcl-xL and Bax was enhanced in HepG₂/pcDNA₃-X cells (Figures 5C and D, 6C and D), indicating that transient expression of HBx induced expression of Bcl-xL or Bax in HepG₂ cells.

C-myc mRNA mRNA level of c-myc in HepG₂/pcDNA₃-X cells was the highest (Figures 5E and 6E), indicating that transient expression of HBx induced expression of c-myc in HepG₂ cells.

DISCUSSION

In previous studies, it was found that HBx inhibits cell apoptosis in different ways. For example, HBx antagonizes TNF- α -induced apoptosis through activating PI3-kinase signaling pathway^[2], and inhibits apoptosis in p53-independent manner^[3]. There is evidence that HBx activates NF- κ B and induce it to translocate into nuclei, NF- κ B acts as an inhibitor of cell apoptosis; HBx also downmodulates expression of Bid and blocks Bid-mediated cell apoptosis^[4], inactivates caspase-3 through inhibition of CCP32 enzyme, and blocks caspase pathway^[5]. It is thought that anti-apoptosis function of HBx is an important mechanism in the development of HCC.

HBx can either inhibit or promote cell apoptosis in a dose-dependent manner. When HBx expresses at high level, it displays pro-apoptosis effect; whereas it inhibits apoptosis when expressing at physiological level. It was reported that moderate expression level of HBx can inhibit liver regeneration in HBx-expressing transgenic mice after partial hepatectomy^[6]. HBx stimulates expression of FasL, which plays an important role in cell's escaping from immune surveillance by inducing apoptosis of T cell bearing Fas^[7,8]. HBx boosts cell survival by abrogating Bcl-2-mediated cell protection^[9,10]. It can also induce expression of myc protein in certain settings, myc sensitizes cells to be killed plus TNF- α ^[11]. HBx acts through the way that involves DDB2-independent nuclear function of DDB1^[12]. Some researchers found that HBx can also localize in mitochondria, bind to voltage-dependent anion channel, which results in alteration of the mitochondrial transmembrane potential, promotes cytochrome C and apoptosis-inducing factors to release into cytosol and induces cell apoptosis^[13]. In short, HBx has bi-directional function on cell apoptosis regulation. HBx expression levels, availability of survival vs apoptogenic factors, and stage of infection may profoundly influence

Figure 4 Apoptosis in HepG₂/pcDNA₃-X (A), HepG₂/pcDNA₃ (B), and HepG₂ (C) cells.

cells; lane 2: HepG₂/pcDNA₃ cells; lane 3: HepG₂/pcDNA₃-X cells.

the fate of cells.

Higher organisms have several mechanisms to eliminate cells by apoptosis. One important role is the signaling pathway mediated by “death factors” including TNFR1, Fas, TNFR2, and their cognate ligand (TNF- α , FasL, and TRAIL) Fas (CD₉₅). The first identified member of “death factors”, is a type I glycoprotein which expresses on cell surface. Crosslinking Fas by binding to the ligand FasL leads to conformational changes of Fas, which results in formation of death induced signal complex (DISC) followed by activation of caspase-8. Activated caspase-8 activates itself and other caspases that switch on apoptosis signal cascade^[14,15]. It has been found that Fas and FasL express in hepatocytes and hepatoma cells. Since hepatocytes are highly sensitive to Fas/FasL-mediated apoptosis, Fas/FasL pathway plays an essential role in liver lesion and eliminating virus. In our research, HBx elevated expression of Fas and FasL in HepG₂ cells. Although the precise mechanism remains unclear, HBx can activate FasL promoter through binding site for Egr and enhance Egr binding to the co-activator cAMP-response element-binding protein, and induce pro-inflammatory cytokines at transcriptional level such as IL-18 which can amplify the expression of FasL^[16]. c-FLIP, a key regulator of the DISC, inhibits the Fas/FasL-mediated death pathway in tumors. HBx abrogates the apoptosis-inhibiting function of c-FLIP and renders cells hypersensitive towards the TNF- α apoptotic signal even below the threshold concentration^[17,18].

Members of Bcl-2 family are also involved in apoptosis regulation. Members of this family are divided into three subgroups. One group is composed of anti-apoptosis proteins

such as Bcl-2, Bcl-xL, with four Bcl-2 homology domains (BH1, BH2, BH3, and BH4). Another group consists of pro-apoptosis proteins such as Bax, Bak, with BH1, BH2, BH3 domains. The last group includes pro-proteins such as Bid, Bik, with only BH3 domain^[4,19]. As Bcl-2 family members reside in upstream of irreversible cell damage, they play a pivotal role in deciding whether cells die or live. Indeed, the ratio between pro- and anti-apoptosis molecules determines, in part, the susceptibility of cells to death signal^[20]. It was reported recently that the anti-apoptosis members lose their ability to inhibit release of pro-apoptosis factors (such as cytochrome C) and trigger apoptosis if they interact with activated pro-apoptosis members^[21]. Our data demonstrate that HBx upregulates either pro-apoptosis subset Bax or anti-apoptosis subset Bcl-xL. MTT and TUNEL displayed that apoptosis of HepG₂ cells transfected with HBx was enhanced while cell viability was impaired. We postulated that though HBx can upregulate expression of Bax and Bcl-xL, it may promote expression of Bax ever more than Bcl-xL, thus resulting in the predominance of pro-apoptosis protein in the ratio between pro- and anti-apoptosis subsets, then cell apoptosis. On the other hand, interacting with activated Bax, Bcl-xL may lose its anti-apoptosis function and trigger cell death.

C-myc belongs to cell oncogene. HBx accelerates development of primary liver tumors by co-operating with c-myc^[22-25]. It was reported that myc can sensitize cells to apoptosis by about two folds in certain conditions such as exposure to TNF- α or other apoptosis factors. In our study, HBx promoted expression of c-myc. Overexpression of c-myc is essential for acute sensitization of cells to be killed

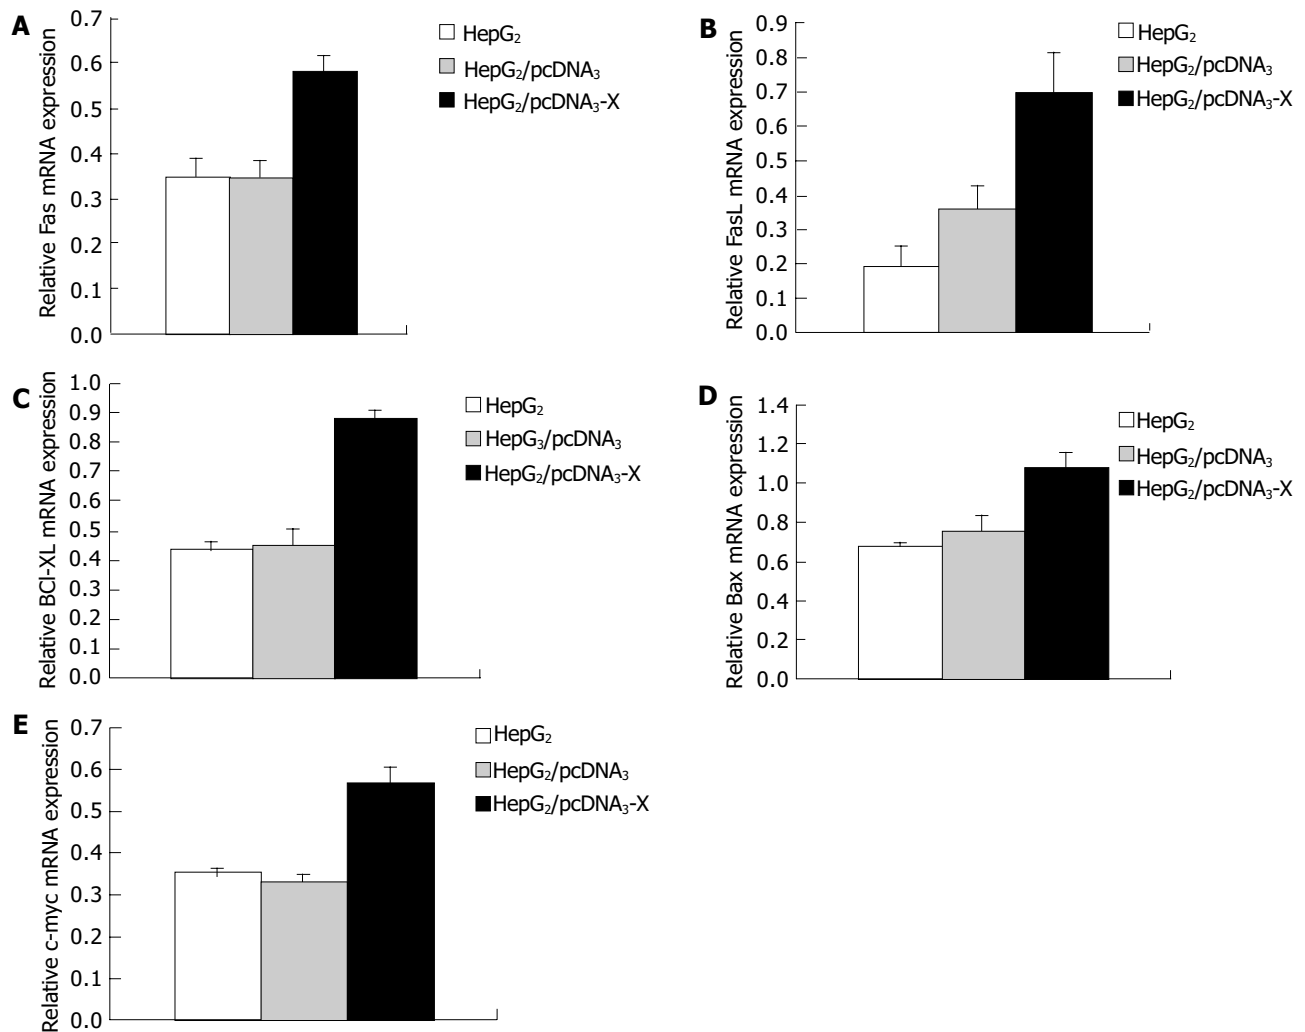

Figure 6 Relative mRNA expression levels of Fas (A), FasL (B), Bcl-XL (C),

Bax (D), and c-myc (E) in HepG₂ cells.

by HBx plus TNF- α ^[11,26-28], and may enhance cell apoptosis. This result agrees with the data of MTT and TUNEL in our study.

In hepatocarcinogenesis, preneoplastic, and neoplastic cells display an increased ratio of apoptosis as well as enhanced cell proliferation^[30]. It is believed that the anti-apoptosis function of HBx is the major determinant factor for development of HCC. The pro-apoptosis function of HBx, however, is also thought to contribute to hepatocarcinogenesis. Firstly, HBx-induced cell apoptosis results in releasing of hepatocyte growth factor that enhances regeneration of liver cells and accumulation of genetic mutation, thus paving the way for cell malignant transformation^[29-31]. Secondly, increased apoptosis increase the opportunity of mutation, leading cells to grow out of control and develop to HCC^[28,32]. Thirdly, HBx induces expression of FasL in liver cells which can attack T cell bearing Fas and lead to impair of immune defense, which is beneficial for cell bearing HBx to escape from immune detection^[33]. Finally, although the accurate mechanism of apoptosis induced by HBx has not been elucidated completely, it may facilitate propagation of viral infection by permitting efficient particle release from cells while minimizing the antiviral inflammation response^[14].

Further study should be focused on protein level. Besides, apoptosis mechanic on stably transfected HBx gene in HepG₂ cells is another pivot.

Abstract

AIM: Tumor angiogenesis has been shown to be promoted by vascular endothelial growth factor (VEGF) via stimulating endothelial cell proliferation, migration, and survival. Blockade of VEGF signaling by different means has been demonstrated to result in reduced tumor growth and suppression of tumor angiogenesis in distinct tumor entities. Here, we tested a recombinant adenovirus, AdsFlt1-3, that encodes an antagonistically acting fragment of the VEGF receptor 1 (Flt-1), for systemic antitumor effects in pre-established subcutaneous CRC tumors in mice.

METHODS: Murine colorectal carcinoma cells (CT26) were inoculated subcutaneously into Balb/c mice for *in vivo* studies. Tumor size and survival were determined. 293 cell line was used for propagation of the adenoviral vectors. Human lung cancer line A₅₄₉ and human umbilical vein endothelial cells were transfected for *in vitro* experiments.

RESULTS: Infection of tumor cells with AdsFlt1-3 resulted in protein secretion into cell supernatant, demonstrating correct vector function. As expected, the secreted sFlt1-3 protein had no direct effect on CT26 tumor cell proliferation *in vitro*, but endothelial cell function was inhibited by about 46% as compared to the AdLacZ control in a tube formation assay. When AdsFlt1-3 (5×10⁹ PFU/animal) was applied to tumor bearing mice, we found a tumor inhibition by 72% at d 12 after treatment initiation. In spite of these antitumoral effects, the survival time was not improved. According to reduced intratumoral microvessel density in AdsFlt1-3-treated mice, the antitumor mechanism can be attributed to angiostatic vector effects. We did not detect increased systemic VEGF levels after AdsFlt1-3 treatment and liver toxicity was low as judged by serum alanine

aminotransferase determination.

CONCLUSION: In this study we confirmed the value of a systemic administration of AdsFlt1-3 to block VEGF signaling as antitumor therapy in an experimental metastatic colorectal carcinoma model in mice.

INTRODUCTION

Colorectal carcinoma (CRC) is one of the most common malignant diseases in the Western countries. Even after successful resection of the primary tumor, about one-third of the patients develop tumor recurrence. The most common place of distant CRC metastases are liver and lung^[1]. In particular, metastatic CRC disease is associated with limited life expectancy and progressive tumor disease in CRC is associated with increased VEGF levels^[2]. Considering clinical studies successfully employing tyrosine kinase inhibitors for systemic tumor therapy^[3] and experimental studies showing the antitumor efficacy of VEGF-antagonism in a pancreatic adenocarcinoma animal model^[4] and follicular thyroid carcinoma animal model^[5], including successful local treatment of subcutaneous CRC^[6], we evaluated and confirmed the antitumoral efficacy and mechanism of a systemic gene delivery of a Flt-1 fragment (sFlt1-3) in subcutaneous metastatic CRC in mice.

Vascular endothelial growth factor (VEGF) expression correlates with tumor vascularization in most tumor types, also in CRC^[2,7,8]. VEGF binds with different affinity to its cell surface receptors, VEGF receptor 1 (Flt-1), VEGF receptor 2 (Flk-1) and VEGF receptor 3 (Flt-4). All three VEGF receptors are members of the class III receptor-type tyrosine kinase receptor family^[9]. Several findings suggest that binding of VEGF to Flt-1 regulates angiogenesis by controlling intercellular endothelial interactions^[10].

Since angiostatic therapies do not attack the malignant tumor cell itself, but address tumor vascularization, a systemic

treatment is of particular interest. Therefore, we investigated the effect of interruption of the VEGF cascade by systemic gene delivery on pre-established tumors.

MATERIALS AND METHODS

Animals, cell lines and culture conditions

Balb/c mice, 6 wk old, were purchased from Charles River (Sulzfeld, Germany) and kept in the local central animal facility. The mice were housed under standard conditions and had free access to water and food. Animal procedures were performed in accordance to approved protocols and followed recommendations for proper care and use of laboratory animals.

For propagation of adenoviral vectors, 293 cells (embryonic E1 transformed kidney cell line) were obtained from American Type Culture Collection (ATCC, Manassas, VA, USA). Cells were maintained in Dulbecco's modified Eagle medium (DMEM) with 10% heat-inactivated fetal bovine serum (FBS).

To demonstrate vector function and gene expression standard techniques using the human lung cancer cell line A₅₄₉ (ATCC, Manassas, VA, USA) were employed for *in vitro* transfection experiments. Cells were cultured in DMEM supplemented with 10% heat-inactivated FBS. Human umbilical vein endothelial (HUVE) cells were obtained from Cascade Biologics (Portland, OR, USA) and were cultured according to the supplier's instructions.

Murine CRC CT26 cells have originally been described by Brattain^[11]. Cells were cultured in DMEM supplemented with 10% heat-inactivated FCS and 1% penicillin/streptomycin.

Construction of recombinant adenoviruses encoding a soluble form of Flt1-3 and vector propagation

The recombinant adenoviruses encoding the LacZ-gene was constructed as described previously^[12]. The AdsFlt1-3 construct was generously provided by R. Mulligan, Boston, MA, USA, it consists of the extracellular immunoglobulin-like domains 1-3 of the VEGF-receptor 1 (Flt-1) and has a His-tag; its construction has been described elsewhere^[13]. Recombinant adenoviruses were expanded, and purified by double cesium-chloride ultra-centrifugation. Purified viruses were dialyzed against 10 mmol/L Tris/1 mmol/L MgCl₂ and stored in glycerol aliquots at -80 °C. Virus concentrations were determined by measuring virus particles (opu/mL) and by cytotoxic plaque assay (pfu/mL) in 293 cells. Virus productions were tested for wild-type adenovirus contamination by cytotoxic plaque assay in A₅₄₉ cells.

Analysis of protein expression in vitro

A₅₄₉ tumor cells were transfected with 250 multiplicity of infection (MOI) of AdLacZ or AdsFlt1-3. Forty-eight hours later, cells and culture medium (CM) were harvested. RNA was isolated from the using the GenElute Total Mammalian RNA Kit (Sigma, Taufkirchen, Germany) according to the manufacturer's protocol. RNA was then digested with RQ1 DNase (Promega, Mannheim, Germany). RNA concentrations were determined and 1 µg RNA was used in the RT reaction with random primers (Promega, Mannheim, Germany) and MMLV reverse transcriptase (Promega, Mannheim,

Germany). PCR for sFlt1-3 was performed with the forward primer 5'-CGTTCCAGTCTTTCAACACC-3' and reverse primer 5'-CCAAGGAAACGTGAAAGC-3'. As positive control, primers for human β-actin were used. The size of the amplified product was about 250 bp. Analysis of the PCR products occurred by electrophoresis on a 1% agarose gel.

For detection of sFlt1-3 100 µL of the harvested CM was dispensed in a 96-well ELISA plate and incubated at 4 °C overnight. After washing thrice with PBS, the ELISA plate was incubated for 2 h with anti mouse VEGF-R1 (Flt-1) antibody (1:200, R&D Systems, Wiesbaden-Nordenstadt, Germany). After antibody incubation, the plate was washed with PBS and incubated with secondary antibody (1:25 000, monoclonal anti-sheep/goat peroxidase conjugate, Sigma, St. Louis, MO, USA) 2 h. After washing with PBS the plate was incubated for 15 min with TMB substrate (Biozol, Eching, Germany). Color intensity was measured in an ELISA reader (Dynatech Laboratories, Frankfurt, Germany).

BrdU proliferation assay

Five thousand CT26 cells were resuspended in 40 µL of culture medium and dispensed in each well of a 96-culture plate and pre-incubated with 50 µL of CM. After 30 min of pre-incubation time, 150 µL of RPMI 1640 containing 10% FCS was added. Cell culture was continued for 18 h and then cells were labeled with BrdU for further 24 h. The BrdU assay was performed according to the manufacturer's protocol (BrdU proliferation assay, Roche Diagnostics, Mannheim, Germany).

In vitro testing of antiangiogenic effects (tube formation assay)

A 24-well plate was coated with 300 µL Matrigel (BD Biosciences, Bedford, MA, USA). Twenty-four hours later, HUVE cells (passage number <10) in 75 µL Medium200 (2.5×10⁴ cells) were seeded on the Matrigel and pre-incubated for 30 min with 75 µL of CM (derived from Huh7 cells). One hundred and fifty microliters of Medium200 was added and the cells were additionally incubated for 4-6 h. Tube-like formations were counted under the light microscope in high power fields.

Tumor induction

In vivo antitumoral efficacies were studied in a subcutaneous CRC mouse model in C3H mice. 10⁶ CT26 cells were resuspended in 100 µL FCS-free culture medium and injected subcutaneously via a 28-G syringe.

In vivo antitumor treatment

When reaching a tumor volume of 40 mm³, tumor treatment was initiated by intravenous injection of 5×10⁹ pfu/animal AdLacZ (*n* = 11) and AdsFlt1-3 (*n* = 10) in 150 µL NaCl. Tumor volumes were calculated by the formula: *v* = length × width² × 0.52. From a subgroup of animals treated intravenously with AdLacZ (*n* = 2), or AdsFlt1-3 (*n* = 3) serum and tumor samples were taken at different time points (at d 3, 6, 9, 14, 19, and 25) for VEGF-ELISA and histology, respectively.

Immunohistochemistry

Tumor samples were embedded in tissue tech (DAKO), snap

frozen in liquid nitrogen and stored at -80°C for anti-von Willebrand staining. Five millimeters of cryostat sections were gently warmed up at RT. Then fixed in acetone for 10 min and dried on air. Sections were stained with dilution of primary antibody (polyclonal rabbit antihuman von Willebrand factor, 1:1 600). After washing with PBS, sections were incubated with secondary antibody dilution of biotinylated pig antirabbit immunoglobulin G (1:300) and streptavidin conjugated to horseradish peroxidase (DAKO). Sections were visualized by using the Dako ChemMate™ detection kit and counterstained with hematoxylin (DAKO).

Statistical analysis

All measured data are given with mean \pm SE. Differences between values of different experimental groups were analyzed for statistical significance by a non-parametric, two-tailed test (Mann-Whitney test) for unpaired samples and in case of histology by unpaired Student's *t*-test. Survival rates are presented as Kaplan-Maier curves. An error level $P < 0.05$ was supposed to indicate significance.

RESULTS

Propagation of adenoviral vectors

Wild-type contamination of the adenoviral stock solutions was analyzed in A_{549} cells in a cytotoxic plaque assay. Virus concentrations were determined as optical particle units and ranged from 2.13×10^{12} opu/mL for AdLacZ to 7.04×10^{12} opu/mL for AdsFlt1-3, respectively. Virus titration in 293 cell plaque assays showed corresponding concentrations of 8.0×10^{12} pfu/mL for AdLacZ and 1.027×10^{12} pfu/mL for AdsFlt1-3.

Protein expression and secretion of sFlt1-3

CM of infected A_{549} cells was harvested to demonstrate sFlt1-3 gene expression and protein secretion into cell supernatant. The analysis of the RT-PCR showed similar bands for β -actin (500 bp) in all samples and only AdsFlt1-3 infected cells showed an extra band at about 250 bp representing the encoded transgene sFlt1-3 (Figure 1). Protein expression was confirmed by ELISA in AdsFlt1-3 infected cells (106 ng/mL). This data demonstrate correct vector function and protein secretion.

Figure 1 Gene expression of sFlt1-3 *in vitro*. RT-PCR was performed with A_{549} cells infected with AdsFlt1-3 or AdLacZ. Specific primer pairs for sFlt1-3 resulted in bands of about 250 bp (C_1 and C_2), whereas no bands were detectable in the negative control AdLacZ (A_1 and A_2). Expression of the house keeping gene β -actin (514 bp) was similar for AdLacZ (B_1 and B_2) and AdsFlt1-3 (D_1 and D_2).

BrdU proliferation assay

To check for direct effects of sFlt1-3 on CRC tumor cells,

conditioned CM was tested for antitumor effects on CT26 tumor cells. As expected, we did not observe any direct anti-proliferative effects (data not shown). We concluded that potential antitumor effects were mediated by indirect (angiostatic) mechanism and not by cytotoxic effects.

In vitro testing of antiangiogenic effects (tube formation assay)

The tube formation assay tests the capability of HUVE cells to form tube-like structures comprising endothelial cell function like migration and tube formation. The results showed that sFlt1-3 inhibited these cell functions by about 46% (Figure 2) compared to the AdLacZ control. This indicates biological activity of sFlt1-3 *in vitro*.

Figure 2 Tube formation assay *in vitro*. HUVE cells were incubated on Matrigel with CM from AdsFlt1-3- or AdLacZ-infected tumor cells. **A:** Exemplary light microscope image (40 \times magnifications) of HUVE cells incubated with CM of AdLacZ-infected cells and with CM of AdsFlt1-3-infected cells; **B:** So called tube-like formations were quantified per high power field. Data are shown as mean and SE ($P = 0.10$ compared to the control).

Systemic treatment

Since CT26 tumor cells express and secrete VEGF (68 pg/mL) into cell supernatant, the CT26 tumor model is suitable to study antitumor effects of an anti-VEGF therapy. The systemic injection of 5×10^9 pfu/mL AdsFlt1-3 significantly

Figure 3 Tumor treatment of pre-established CT-26 CRC. Vectors were administered systemically (5×10^9 pfu, AdsFlt1-3, $n = 10$; AdLacZ, $n = 11$). Data are given as mean tumor volume and SE ($P = 0.006$ compared to the control).

Figure 4 No effect of AdLacZ and AdsFlt1-3 on the survival rate of tumor bearing mice. Tumor treatment of pre-established CT-26 CRC. Vectors were administered systemically (5×10^9 pfu, AdsFlt1-3, $n = 10$; AdLacZ, $n = 11$).

Figure 5 Time course of *in vivo* VEGF serum levels of tumor bearing mice that had been treated with AdLacZ or AdsFlt1-3 (mean \pm SE).

Figure 6 Time course of ALT serum levels as marker of liver toxicity at d 3, 6, 9, 14, 19, 25, 32, and 42 after AdLacZ and AdsFlt1-3 treatment initiation (mean \pm SE).

reduced tumor growth by 72% compared to the AdLacZ control 12 d after treatment initiation (Figure 3), but did not improve the survival rate (Figure 4). VEGF serum levels were similar in both groups, AdLacZ and AdsFlt1-3, (Figure 5) and we did not observe any compensatory upregulation of VEGF levels in serum. Liver toxicity was tolerable according to alanine aminotransferase levels in serum (Figure 6).

Inhibition of tumor angiogenesis by AdsFlt1-3 in vivo

Intratumoral microvessels density was determined by immunohistochemistry for von Willebrand factor. Tumors

were removed 9 d after treatment and as shown in Figure 7, tumors of animals that had received AdLacZ showed intense staining for von Willebrand factor, indicating effective tumor vascularization, and tumor sections of AdsFlt1-3-treated animals showed a marked reduction by 42% in microvessel density (Figure 7).

DISCUSSION

VEGF has been acknowledged as one of the most important pro-angiogenic factors that are known to be involved in

Figure 7 Effective inhibition of tumor angiogenesis *in vivo* by treatment with AdsFlt1-3. Pre-established CRC tumors were treated with AdLacZ or AdsFlt1-3. Animals were killed on d 9 after treatment and tumor tissue was removed. Microvessel density was determined by anti-von Willebrand factor staining. **A** and **B**: Representative

photomicrographs show microvessel staining in tumors of AdLacZ- or AdsFlt1-3-treated mice; **C**: quantitative analysis of microvessel density was made by counting the positively stained cells per high-power fields (200 \times magnification). Data are given as mean of cell number/HPF and SE ($P = 0.02$ compared to the control).

tumor angiogenesis^[7,14-16]. In particular, VEGF expression has been shown to be elevated in metastatic CRC disease^[2]. In the case of metastatic CRC, therapeutic options are still limited and innovative approaches are warranted. Therefore, we intended to confirm the antitumor efficacy of blocking VEGF signaling by systemic administration of an adenovirus delivering the VEGF receptor 1 fragment sFlt1-3 in a subcutaneous metastatic murine CRC tumor model. Our data show that the systemic vector application of AdsFlt1-3 induced significant antitumor effects in CRC.

Recently, several angiostatic antitumor approaches have been used to inhibit experimental CRC. In a previous publication, we were able to show that the local gene delivery of angiostatin-like molecule (K1-3) inhibited tumor growth in the same CRC model by 41% at d 8 after treatment initiation. Another group had used a similar approach employing an adenoviral construct encoding a distinct Flt-1 fragment to treat subcutaneous tumors, but then only the local treatment was effective^[6]. But principally, angiostatic antitumor strategies do not intend to directly control growth of the malignant tumor cell but rather to curb tumor vascularization. Therefore, systemic gene delivery of angiostatic proteins might even be more effective than local applications. The vector construct we used in this study had been shown to inhibit e.g. tumor growth of fibrosarcoma and lung cancer in experimental studies after systemic vector administration^[13]. Here, we were able to confirm the antitumoral efficacy of the AdsFlt1-3 construct in a metastatic subcutaneous CRC model. But, according to other angiostatic gene therapy studies and own findings, the survival rate was not improved.

Since we could not observe any direct antiproliferative effects of sFlt1-3 on CT26 CRC cells, antitumoral effects most probably were mediated by indirect angiostatic effects. This was supported by immune staining for von Willebrand factor revealing decreased microvessel density in the AdsFlt1-3 treatment group. Taken together, these results correspond well to other publications reporting anti-angiogenic effects of similar constructs in corneal or ocular neovascularization assays^[13].

Recently, potential side effects of adenoviruses have provoked severe concerns of systemic vector applications regarding particularly liver toxicity. Indeed, we observed some ALT elevations, but at the dosage applied toxicity was well tolerated.

In summary our data demonstrate that the systemic gene transfer of sFlt1-3 induced significant antitumor effects on pre-established subcutaneous metastatic CRC and antitumor mechanism based on angiostatic effects. Thus, these data further confirmed the value of blocking VEGF signaling as an effective approach to treat CRC disease.

Abstract

AIM: To investigate the effect of NS398 on the metastasis-associated gene expression in LoVo colorectal cancer cells.

METHODS: LoVo cells were treated with NS398 at the concentration of 100 $\mu\text{mol/L}$ for 24 and 48 h respectively. Total RNA was extracted with TRIZOL reagents and reverse transcribed with Superscript II and hybridized with cDNA microarray (containing oncogenes, tumor suppressor genes, signal transduction molecules, adhesive molecules, growth factors, and ESTs) fabricated in our laboratory. After normalization, the ratio of gene expression of NS398 treated to untreated LoVo cells was either 2-fold up or 0.5-fold down was defined as the differentially expressed genes. Semi-quantitative RT-PCR was used to validate the microarray results.

RESULTS: Among the 447 metastasis-associated genes, 9 genes were upregulated and 8 genes were downregulated in LoVo cells treated with NS398 for 24 h compared to untreated cells. While 31 genes were upregulated and 14 genes were downregulated in LoVo cells treated with NS398 for 48 h. IGFBP-5, PAI-2, JUN, REL, BRCA1, and BRCA2 might be the new targets of NS398 in treatment of colorectal cancer.

CONCLUSION: NS398 might exert its anti-metastasis effect on colorectal cancer by affecting several metastasis-associated gene expression.

INTRODUCTION

N-[2-(cyclohexyloxy)-4-nitrophenyl] methanesulfonamide (NS398) is a highly selective cyclooxygenase-2 (COX-2) inhibitor. Its mechanism in anticancer effects involves many signal pathways. One is induction of apoptosis of different tumor cells. NS398 inhibits the viability of colon cancer cell lines by apoptosis by the release of cytochrome C from mitochondria and by the activation of caspase-9 and caspase-3 and cleavage of poly (ADP-ribose) polymerase. Cytochrome C pathway plays an important role in NS398-induced apoptosis in colon cancer cell lines^[1]. NS398 may also suppress the growth of tumor cells by inhibiting the cell cycle progression. It can increase the inhibitor of cell cycles p27Kip1 by inhibiting protein degradation to suppress the proliferation of human lung cancer cells, and this in turn is caused by modulating p27Kip1 proteolysis. Non-steroid anti-inflammatory drugs (NSAIDs) suppress the expression of chymotrypsin-like catalytic subunits (LMP5, LMP7, and LMP2), but do not directly block enzymatic activity and inhibit proteasome activity. Reverse transcriptase-competitive PCR and promoter activity assays showed that this inhibition occurred at the transcriptional level^[2]. NS398 can exert its anti-angiogenesis and anti-metastasis effects by inhibiting the expression of vascular endothelial growth factor (VEGF)^[3]. Its inhibitory effects on the metastasis *in vitro* and *in vivo* are mainly mediated by regulating the matrix metalloproteinase (MMP) family components. NS398 can inhibit the invasiveness of prostate cancer by reducing the release of MMP-2 and MMP-9 and increase of TIMP-2 but not TIMP-1^[4]. NS398 inhibits MMP-2 mRNA expression and also decreases the amount of MMP-2 in human lung cancer cells. Additionally, this COX-2 inhibitor attenuates the degrading activity of MMP-2. The synthesis and processing of MMP-2 was significantly suppressed by NS398. NS398 directly inhibits MMP-2 promoter activity. However, the inhibitory effect of NS398 is not fully dependent on inhibition of COX-2 because a high concentration of NS398 is needed to suppress MMP-2 expression and addition of prostaglandin E2 only partially reverses the action of NS398^[5].

NS398 and aspirin also upregulate RECK mRNA level in CL-1 human lung cancer cells. Additionally, NSAIDs increase

RECK protein level which was associated with reduction of MMP-2 activity. NSAID-activated RECK expression may not be mediated via inhibition of COXs because addition of prostaglandin E₂ (PGE₂) cannot counteract the effect of NSAIDs and overexpression of COX-2 cannot downregulate RECK^[6]. To promote the application of NS398 in the treatment and chemoprevention of colorectal cancer, and observe whether it has other target genes, we detected the effect of NS398 on the expression of metastasis-associated genes in colorectal cancer cell lines by cDNA microarray.

MATERIALS AND METHODS

Microarray fabrication

A total of 447 cDNA clones were obtained from Research Genetics (Invitrogen, Life Technologies, USA). *E. coli* with inserted metastasis-associated genes were cultured with Luria-Bertain culture medium supplemented with ampicillin (50 mg/L in final concentration) or chloromycin (170 mg/L) in InnovaTM4330 refrigerated incubator shaker (New Brunswick Scientific, USA) at the speed of 250 r/min overnight at 37 °C. Clone plasmids were extracted with Edge BioSystems (Gaithersburg, MD, Germany). Clone inserts were PCR-amplified from the plasmids with M13 vector-specific universal primer (M13F: 5'-GGT GTA AAA CGA CGG CCA GTG-3'; M13R: 5'-CAC ACA GGA AAC AGC TAT G-3') in 96-well PCR microtiter. The PCR products were purified with protocols published^[7], and resuspended in Arrayit spot solution. The purified PCR products were printed on silanated slides (CEL Associates, Houston, TX, USA) with Cartesian PixSys 5500 robot (Cartesian Technologies, Irvine, CA, USA) and cDNA microarrays were UV-cross-linked at 3 500 mJ using Cl-1000 ultraviolet cross-linker (Stratagene). Microarrays were post-processed according to protocol online^[8].

Cell culture and drug treatment

LoVo cells were grown in the culture incubator at 37 °C with 50 mL/L CO₂ in RPMI 1640 (Life Technologies, USA) supplemented with 10% neonatal bovine serum. After the cells were cultured to 60-70% confluence, 12 µL of NS398 dissolved in dimethyl sulfoxide (Me₂SO) was added to make the final concentration 100 µmol/L and further cultured for 24 and 48 h respectively. The same amount of Me₂SO was added to the control.

RNA extraction

LoVo cells treated with NS398 or Me₂SO were lysed with TRIzol (Life Technologies Inc., Rockville, MD, USA) according to the manufacturer's protocol and total RNA was extracted and stored at -80 °C. The concentration of total RNA were measured with a biophotometer (Eppendorf AG22331, Hamberg, Germany) and the 260/280 ratio of RNA was 1.8-2.0.

Probe preparation

Probes were prepared as described previously^[9,10] with some modifications. First strand cDNA was synthesized by priming 10 µg total RNA with 6 µg random hexamers (Life Technologies Inc., Rockville, MD, USA) by heating at

70 °C for 10 min, snap-cooling on ice for 30 s and placed at room temperature for additional 5-10 min. Reverse transcription was performed in the presence of 500 µmol/L each of dATP, dCTP and dGTP, 200 µmol/L aminoallyl-dUTP (Sigma Chemical Co., St. Louis, MO, USA), 300 µmol/L dTTP, 1× first strand buffer, 10 mmol/L dithiothreitol, and 400 U superscript II (Life Technologies) in 30 µL reaction at 42 °C overnight. Reactions were quenched with 0.5 mol/L EDTA and RNA template was hydrolyzed by addition of 10 µL NaOH of 1 mol/L followed by heating at 70 °C for 10 min. Reactions were neutralized with 10 µL 1 mol/L HCl and cDNA was purified with Amicon Microcon YM100 (Millipore Corporation, Bedford, MA, USA) according to the manufacturer's protocol. cDNA was dried in speed vacuum concentrator 5301 (Eppendorf, Germany) and resuspended in 4.5 µL 0.1 mol/L (pH 9.0) sodium carbonate buffer. Aliquot of Cy3 NHS ester dye (Amersham Pharmacia Biotech, UK) was dissolved in 4.5 µL Me₂SO (1 mg dye from one tube was dissolved in 73 µL of Me₂SO and aliquot in 16 tubes, dried in speed vacuum and stored at 4 °C) and added to the resuspended cDNA and reactions were incubated at room temperature in the dark for 1 h. Coupling reactions were quenched by addition of 41 µL 0.1 mol/L sodium acetate (pH 5.2), and unincorporated dye was removed using QIAquick PCR purification kit (Qiagen, Germany) following manufacturer's instructions.

Hybridization and image processing

Each slide was printed with duplicate microarrays. Slides were pre-hybridized in 1% BSA, 5× SSC, 0.1% SDS for 45 min, washed twice in de-ionized double distilled H₂O and 2-propanol and air-dried and used in 1 h. Fluorescent cDNA probes were dried in speed vacuum and resuspended in 10 µL hybridization buffer p5 µL formamide, 2.5 µL 20× SSC, 1.0 µL reagent grade double distilled water (RGDD H₂O), 0.5 µL 2% SDS and 1 µL human cot-1DNA]. Probes were denatured at 100 °C water bath for 2 min and cooled at room temperature for 5 min. Room temperature probes of NS398 treated and untreated group were applied to the duplicate microarrays on the same pre-hybridized microarrays, covered with hybridized coverslip (Sigma) and placed in the hybridization chamber (Corning). Hybridizations was carried out at 42 °C water bath for 20-22 h followed by washing in 2× SSC and 0.1% SDS for 3 min, 1× SSC for 2 min and 0.2× SSC for 1 min and 0.05× SSC for 10 s, and dried by spin at horizontal plate centrifuge at 90 r/min for 4 min. Microarrays were scanned using a ScanArray 4000 (Packard Bioscience, PE, USA) dual color confocal laser scanner. Data were saved as paired TIFF images.

Data analysis

Spots were identified and local background subtracted in the QuantArray 3.0. In the first step, a grid consisting of square cells was drawn around each array element. Spot segmentation was then performed using a fixed segmentation method that uses the distribution of pixel intensity to separate probable signal from background and a binary threshold approach to identify spots, followed by a procedure to exclude disconnected features. Raw intensity for each

element was obtained by first excluding saturated pixels, then summing all remaining pixel intensities inside the spot contours. The area outside the spot contour but inside the cell was used to calculate local background. Background per pixel was estimated as a median of the pixels in this area and multiplied by the spot area to give an estimated spot background value. In the final step, this integrated background value was subtracted from the raw integrated spot intensity to produce the background-subtracted integrated intensities used for further analysis. Furthermore, a quality control filter was used to remove questionable array features. Two criteria for spot rejection were the spot shape deviating greatly from a circle and a low signal to noise ratio. Spots for which the ratio of area to circumference deviated by more than 20% from the value for an ideal circle and spots containing less than 50% of pixels above the median background values were flagged and eliminated from further consideration. The spot intensity above blank plus 2SD was used for the final analysis. Then the data were normalized to total with software supplied by the manufacturer. The two fold up- or down-regulated genes were shown in red or green respectively.

Semi-quantitative RT-PCR validation of microarray results

The upregulated gene IGFBP-5 was measured by RT-PCR to verify the microarray results. RT-PCR was performed on MJ-PTC200 DNA engine using TaKaRa two-step reaction with protocols supplied by the manufacturer. The primers for IGFBP-5 were forward: 5'-TTG CCT CAA CGA AAA GAG C-3', reverse: 5'-AGA ATC CTT TGC GGT CAC A3'^[11]. The primers for β -actin were forward: 5'-AAG TAC TCC GTG TGG ATC GG -3', reverse: 5'-TCA AGT TGG GGG ACA AAA AG -3'^[12]. PCR was performed at 94 °C for 2 min, and 30 cycles at 94 °C for 30 s, at 50 °C for 30 s and at 72 °C for 60 s and a final extension at 72 °C for 5 min. PCR products were electrophoresed on 1% agarose gel. Images were captured with Alpha Image™ 2000. The band density was measured with the software supplied by the same system.

RESULTS

Plasmid extraction

The plasmids were extracted by Edge biosystems plasmids extraction kit (Gaithersburg, MD, Germany). The extracted plasmids were run on 1% agarose gel. The results shown in Figure 1 are representative of the 447 clones. PCR amplification of the 447 clones for the inserts is shown in Figure 2. The single band amplification rate was 93%.

Figure 1 Electrophoresis of clone 73-95 plasmids on 0.7% agarose. M: DL2000, lanes 1-24 represent plasmids of clone 73-95.

Figure 2 Electrophoresis of PCR products in 1% agarose. M: DL2000, lanes 1-24: the PCR amplification of clone 73-95.

To identify metastasis-associated genes affected by NS398, LoVo cells were treated with 100 μ mol/L NS398 for 24 and 48 h respectively. The representative image is shown in Figure 3. Image A represents the hybridized results of untreated cells. Image B represents the hybridization results of the NS398-treated LoVo cells and image C is the overlay image of NS398-treated to control LoVo cells.

After treatment with NS398 for 24 h, 9 genes were upregulated and 8 genes downregulated (Table 1). The

The number in parenthesis represents the IMAGE clone number.

downregulated genes included lipocalin 2 (oncogene 24p3) (LCN2), intercellular adhesion molecule 5, telencephalin (ICAM5), v-jun avian sarcoma virus 17 oncogene homolog (JUN), v-rel avian reticuloendotheliosis viral oncogene homolog (REL). Five genes after being treated for 24 h were still highly expressed until 48 h and one gene was still inhibited until 48 h.

After 48 h of treatment more genes were regulated by NS398. Of the 447 genes analyzed, 31 genes were upregulated and 14 genes downregulated (Table 2). IGFBP-5,

APAF, LAMP2, CLCA2, laminin gamma3, HOXA1, WNT2, N-cadherin, PAI-2, TIMP could inhibit the metastasis of tumor.

Validation of microarray results by semi-quantitative RT-PCR

IGFBP-5 gene expression was validated with TAKARA version 2.1 RT-PCR kit. The expression level was measured with alpha InnoTech™ 2000 spot density method. The NS398-treated LoVo cells expressed more IGFBP-5 mRNA (Figure 4). The relative expression ratio to β -actin was 0.21,

NS398-treated LoVo cell to control.

Figure 4 IGFBP-5 mRNA expression in NS398-treated LoVo cell. **A:** mRNA level measured with semi-quantitative RT-PCR. M: DL2000, lanes 1-4 control

and 3 replicates of NS398 treated loVo cell; **B:** Relative ratios of the IGFBP-5 to actin.

0.22, 0.39, and 0.47 for the control and the three NS398-treated replicate experiments. The IGFBP-5 mRNA level in NS398-treated LoVo cells to untreated LoVo cells was 1.05, 1.85, and 2.23 respectively for the three replicate experiments. It was in accord with the microarray results.

DISCUSSION

NS398 is a highly selective COX-2 inhibitor. Its anticancer effects have been linked to cell apoptosis and inhibition of MMP and anti-angiogenesis. NS398 also exerts its synergistic effect with radiotherapy for the treatment of head and neck squamous cell cancer (HNSCC) by inhibiting radiation-induced expression of COX-2^[12] and increases the sensitivity of chemotherapy by enhancing the expression of cyclin-dependent kinase inhibitors p21 (Waf1) and p27 (Kip1), promoting apoptosis of tumor cells, therefore makes the cells stay in G₁ arrest^[13].

cDNA microarray has been widely used in the screening of drug targets. To identify whether NS398 had other target genes in the treatment of colorectal cancer, we treated LoVo cells with NS398 and the expression of metastasis-associated genes were measured with microarray. The results showed that NS398 influenced the expression of some metastasis genes. After being treated for 24 h, NS398 increased the production of NS1-associated protein 1, PIBF1 gene, CD24 antigen, and some ESTS. Simultaneously NS398 can inhibit the expression of some oncogenes such as alpha-1-antichymotrypsin, LCN2 (oncogene 24p3), ICAM5, JUN

and REL. It was reported that NS398 downregulates the expression of COX-2, nuclear factor-kappaB, p50 and Rel A p65, and its anti-tumor effect is associated with COX-2 transcription inhibition^[14].

After being treated for 48 h with NS398, the metastasis-associated genes expressed by LoVo cells changed more profoundly. Thirty-one genes were upregulated, including NS1-associated protein 1, IGFBP5, spectrin, nucleotide binding protein 2, alpha-1-antichymotrypsin, apoptotic protease activating factor, LAMP2, CLCA2, tumor-associated antigen L6, putative insulin-like growth factor, chromosome-associated polypeptide-c, HOXA1, WNT2, FIGF, N-cadherin, PAI2, macrophage-stimulating 1 receptor (MST1R), TIMP1, tachykinin, and precursor.

E-cadherin and N-cadherin are members of the cadherin family of calcium-dependent cell adhesion molecules that play an important role in the embryonic development and maintenance of normal tissues. N-cadherin present in the most invasive and dedifferentiated breast cancer cell lines, and its exogenous expression in tumor cells induces a scattered morphology and high motility, invasion, and metastasis. N-cadherin co-operates with the fibroblast growth factor receptor, resulting in signals that lead to the upmodulation of MMP-9 and cellular invasion. N-cadherin probably also supports the systemic dissemination of tumor cells by enabling the circulation of tumor cells to associate with the stroma and the endothelium at distant sites^[15]. Ectopically expressed N-cadherin fails to assemble cadherin/catenin adhesion complexes and to inhibit invasion. The

association of N-cadherin with long P120 (ctn) and tyrosine may explain why N-cadherin cannot replace E-cadherin in pancreatic carcinoma cells^[16]. But there are conflicting results of the expression of N-cadherin with the invasion of tumor. P-cadherin is detectable in 40%, N-cadherin in 30%, and E-cadherin in 81% invasive carcinomas. P-cadherin but not E/N-cadherin expression in breast carcinomas shows a strong correlation with higher grade (poorer differentiation), lack of ERs, and presence of EGFR, and its expression may aid in the further subdivision of high grade carcinomas^[17]. In the upregulated genes, IGFBP-5 is of great importance. Until now the role of IGFBP-5 in the tumor development is different in different tumors. Expression of IGFBP-5, both by stable transfection and adenoviral-mediated infection, can inhibit the growth of MDA-MB-231 and Hs578T human breast cancer cells over a 13-d period. IGFBP-5 is a potent growth inhibitor and proapoptotic agent in human breast cancer cells via modulation of cell cycle and apoptotic mediators^[18].

IGFBP5 is also overexpressed in thyroid tumors. IGFBP-5 and gene 44 are significantly overexpressed in papillary carcinoma^[19]. IGFBP-5 mRNA levels are the highest in the benign group without edema of meningiomas, whereas IGFBP-6 mRNA levels are the highest in the group with brain invasion^[20]. The presence of IGFBP-5 significantly inhibits cell death induced by C2 or RGD. IGFBP-5 promotes the attachment and survival of Hs578T cells by modulating the balance between ceramide and opposing survival signals^[21]. IGFBP-5 has no effect on the proliferation, migration and invasiveness of RSVT2/C cells *in vitro*^[22].

Insulin-like growth factor (IGF)-I and -II are potent mitogens, and can exert autocrine and paracrine effects on growth regulation in human gastric cancer. Their mitogenic effects are regulated by the IGFBPs. The expression pattern of IGFBPs was heterogeneous in the gastric cancer cell lines. IGFBP-2 is expressed in all gastric cancer cell lines, whereas IGFBP-1 is not detectable in any cell line. IGFBP-4 is expressed in most cell lines. IGFBP-3, IGFBP-5, and IGFBP-6 are expressed in approximately 50% of cell lines. In addition, exogenous IGF-I and -II stimulate the proliferation of gastric cancer cells, suggesting the existence of a functional IGF system in gastric cancer. Our data suggest that the IGF-IGFBP system may play an important role in the initiation, progression, and metastasis of gastric cancer^[23].

Osteosarcoma cells transfected with IGFBP-5 reduce proliferation under both anchorage-dependent and -independent manner. The increase of proliferation observed in IGFBP-5-secreting clones after addition of exogenous IGF is significantly less than that observed in mock-transfected cells or parental cells. A similar result has been obtained with long [R3] IGF-I which has a low affinity for all IGFBPs, suggesting that the inhibitory effect of IGFBP-5 is only partially IGF-dependent and this effect may be due to an induction of differentiation in these cells because IGFBP-5 increases the normal component secretion of osteosarcoma cells^[24].

Upregulation of PAI-2 in LoVo cells may be another mechanism of NS398 underlying the inhibitory effects of

tumor cells. PAI-2 is downregulated in esophageal adenocarcinoma compared to normal esophageal tissues^[25].

Plasminogen activator inhibitor-2 (PAI-2), a gene whose expression has been linked to cell invasion, has been identified in head and neck tumor cell line. In addition, immunohistochemical evaluation of biopsy samples reveals a high expression of PAI-2 in both normal and dysplastic epithelia with a marked decrease of expression in areas of the biopsies containing HNSCC^[26].

The downregulated genes include Max-interacting protein, spectrin, beta-2-microglobulin, CD58 antigen, JUN, APS, BRCA2, CASP1, and some ESTS. BRCA1 and BRCA2 staining increases in the apical cell pole of epithelial malignant cells and in colorectal tumor specimens. Increased BRCA1 and BRCA2 expression may be explained by the fact that colorectal tissue is subjected to very active proliferation and differentiation^[27]. High BRCA2 mRNA level is associated with poor outcome and correlates positively and strongly with cell proliferation in breast cancer^[28]. NS398 may inhibit the growth of colorectal cancer by downregulating the expression of BRCA2.

In conclusion, the upregulated and downregulated genes identified by cDNA microarray may be the new target genes of NS398.

Abstract

AIM: We set to determine factors that determine clinical severity after the development of resistance.

METHODS: Thirty-five Asian patients with genotypic lamivudine resistance were analyzed in three groups: 13/35 (37%) were non-cirrhotics with normal pre-treatment ALT (Group IA), 12/35 (34%) were non-cirrhotics with elevated pre-treatment ALT (Group IB), and 10/35 (29%) were cirrhotics (Group II). Patients were followed for a median of 98 wk (range 26-220) after the emergence of genotypic resistance.

RESULTS: Group IA patients tended to retain normal ALT. Group IB patients showed initial improvement of ALT with lamivudine but 9/12 patients (75%) developed abnormal ALT subsequently. On follow-up however, this persisted in only 33%. Group II patients also showed improvement while on treatment, but they deteriorated with the emergence of resistance with 30% death from decompensated liver disease. Pretreatment ALT levels and CPT score (in the cirrhotic group) were predictive of clinical resistance and correlated with peak ALT levels and CPT score.

CONCLUSION: The phenotype of lamivudine-resistant HBV correlated with the pretreatment phenotype. The clinical course was generally benign in non-cirrhotics. However, cirrhotics had a high risk of progression and death (30%) with the development of lamivudine resistance.

INTRODUCTION

Treatment of CHB was revolutionized by the introduction of orally administered antiviral agents. Lamivudine, a nucleoside analog and the first orally available antiviral agent for CHB, had demonstrated significant results in clinical trials, with universal suppression of HBV DNA level by 3 logs, 55% improvement in histological necroinflammatory score, normalization of ALT in the majority of patients after 1 year of treatment^[1,2]. Even among patients with decompensated hepatitis B cirrhosis, there was clinical improvement^[3], thus enabling some of them to be taken off liver transplant waiting lists.

However, drug resistance with lamivudine occurs with prolonged usage, rising from 14-24% at the end of first year, to 57% by the end of year 3^[4,5]. Resistance occurred primarily as a result of mutations in the YMDD motif of the polymerase gene although subsequently, mutations at other sites have been reported^[6]. Initial reports suggested that lamivudine-resistant HBV virus may be less virulent and replication-defective, as the ALT and HBV DNA levels caused by these mutant viruses were lower than the pretreatment values^[7]. However, subsequent reports of decompensation, acute exacerbations, and deaths from such mutant viruses suggested otherwise^[8,9]. This has given rise to the suggestion of limiting lamivudine therapy to 12 mo duration in order to avoid the development of these mutants^[10].

Lamivudine resistance can be divided into genotypic and clinical phenotypic resistance. Genotypic resistance refers to the presence of a lamivudine-resistant strain such as the YMDD mutants, which in itself may not lead to any clinical sequela, since such strains have been detected in patients who have not had prior exposure to lamivudine^[11]. Clinical phenotypic resistance refers to the presence of genotypic resistance with the subsequent development of clinical deterioration, defined as elevation of transaminases and/or deterioration of liver histology and liver function. Factors that predict the development of genotypic resistance^[5,12] had been evaluated in many studies, which included pretreatment HBV DNA level, ALT level, body mass index, adw serotype, and core promoter mutations^[13-15]. However, these studies did not address the more important question of which factor(s) actually lead to clinical resistance.

Hence, we set to examine variables that determined the clinical phenotypes after the development of genotypic lamivudine resistance.

MATERIALS AND METHODS

Patients

From January 1996 to April 2003, we prospectively followed

all patients started on lamivudine 100 or 150 mg daily monotherapy for clinical indications, or who had completed trials of lamivudine monotherapy, at 3 monthly intervals. These included patients who were recruited from the Asian Multicentre Lamivudine Trial and its subsequent rollover follow-up study NUCB3018^[1,4,16], which also included patients with normal pre-treatment ALT levels. Patients were also given lamivudine if it was clinically indicated, such as persistently abnormal ALT levels (greater than twice upper limit of normal for at least 3 mo duration), decompensated liver disease (development of variceal hemorrhage, ascites, and hepatic encephalopathy), or were on the liver transplant waiting list. All patients had detectable HBV DNA by a non-PCR based assay prior to initiation of therapy. Lamivudine was prescribed for at least a year and was continued even when genotypic resistance developed. During the duration of the study, none of the patients were given adefovir dipivoxil as a rescue therapy as it was not yet available in Singapore. This study was approved by the Institutional Review Board of the National University Hospital, Singapore.

Exclusion criteria

Patients who tested positive for anti-HCV, anti-HDV, and HIV, had significant history of alcohol intake (defined as more than seven drinks per week), or were non-compliant with lamivudine were excluded from the study. Patients who developed resistance after liver transplants were also excluded.

Measurement of HBV DNA

Prior to March 2000, the Abbott HBV DNA assay (Abbott Laboratories, North Chicago, IL, USA) was used for HBV DNA viral load quantification. After March 2000, this assay was substituted to a branched-chain assay (Chiron QuantiplexTM, Chiron Corp). Results of the Abbott HBV DNA assay were converted using the Multimeasurement Method^[17].

Phenotypes

Eligible patients were classified into three distinct phenotypes according to their baseline characteristics. The presence of cirrhosis was determined by liver biopsy or by ultrasonographic features in those with clinical decompensated disease.

Group IA	Non-cirrhotic patients with normal baseline ALT level
Group IB	Non-cirrhotic patients with abnormal baseline ALT level
Group II	Cirrhotic patients

Genotypic lamivudine resistance

Genotypic resistance was defined as reappearance of at least two consecutive detectable HBV DNA levels after a period of undetectable level whilst on continuous lamivudine therapy for more than 6 mo.

Characterization of lamivudine resistance by sequencing

Confirmation of genotypic resistance was performed by comparison of results from direct sequencing of the HBV polymerase of the HBV DNA samples before starting lamivudine, and after development of resistance. DNA was extracted and direct sequencing was performed at a 750 bp region between nt 253 and 1 006 of the HBV genome

using the two primers:

Forward primer: 5'-GAC TCG TGG TGG ACT TCT CTC AA- 3'.

Reverse primer: 5'-CCC ACA ATT CTT TGA CAT ACT TTC C-3'. The forward and reverse sequences were aligned using the Seqman program (DNASTar). This segment has been known to contain all the mutations known to confer lamivudine resistance. New mutations emerging after treatment of lamivudine were determined for their resistance conferring properties from previously published data and categorized using the new nomenclature^[6,18].

Clinical resistance

All patients were followed for a minimum of 6 mo after the emergence of genotypic resistance and for as long as the patients were continued on lamivudine. Serial analysis of ALT, bilirubin, prothrombin time, HBeAg, anti HBe and HBV DNA level by Chiron QuantiplexTM, at 3 monthly intervals were done. Serial Child-Pugh Turcotte (CPT) scores were also calculated. No serial liver biopsy was performed in our patients.

In the non-cirrhotic group, clinical resistance was defined as abnormal rise in ALT greater than twice upper limit of normal. In the cirrhotic group, clinical resistance was defined as abnormal rise in ALT greater than twice the normal upper limit, or an increase of CPT Score by two points or more.

Clinical severity was assessed at four time points: timepoint 1 (baseline or pretreatment), timepoint 2 (6 mo after the commencement of lamivudine therapy), timepoint 3 (peak ALT or CPT levels after the development of genotypic resistance), and timepoint 4 (last ALT or CPT on follow-up).

HBV genotyping

HBV genotyping was performed using restriction fragment length polymorphism created by Ava2 and Dpn2 action on an amplified segment of the pre-S region as previously described^[19].

Statistical analysis

Changes in ALT level and CPT Score were compared at four timepoints within each group of patients. Statistical analysis was performed by Wilcoxon Matched-Pairs Signed Rank Test to avoid the effect of pooling results from different patients. The relationship of two continuous variables was tested by Spearman ρ Correlation test. *P* values of less than 0.05 were considered statistically significant.

The following parameters: age, sex, baseline ALT, ALT at the point of emergence of resistance, baseline HBV DNA level, peak HBV DNA post genotypic resistance, duration of lamivudine treatment, type of mutation, genotype and HBeAg seroconversion were analyzed by univariate analysis to determine factors associated with phenotypic resistance. Categorical variables and continuous variables were compared by Fisher's exact test and Student's *t*-test, as appropriate. Significant factors from univariate analysis were then analyzed by multivariate analysis by forward logistic regression to determine independent factors associated with phenotypic resistance.

All statistical analysis was performed using computer software, SPSS 10.0 for Windows (SPSS Inc., Chicago, IL, USA).

RESULTS

Patients

A total of 78 patients were prescribed lamivudine for hepatitis B related indications or had completed a clinical trial of lamivudine therapy at our institution for a minimum of 1 year during the study period. Of these, 35 patients (45%) developed genotypic resistance to lamivudine while on treatment after a median of 143 wk (range 35-212 wk) and were included in this study. Twenty-one (60%) were part of the Asian Lamivudine Trial (NUCB 3009/NUCB3018)^[1], of which 11 received uninterrupted lamivudine treatment while 10 were restarted on open label lamivudine after viral breakthrough when they were on placebo. The remainder of the patients was given lamivudine for clinical indications of chronic hepatitis ($n = 4$, 11%) and cirrhotic liver disease ($n = 10$, 29%), respectively. One patient was eligible to enter a trial of adefovir/lamivudine (NUCB 20904) treatment for persistent abnormal transaminases at 56 wk after emergence of resistance. Data up to the point of trial entry was used for analysis but data thereafter was censored. No patient received liver transplant after the emergence of resistance. Thus in total, 35 patients were eligible for analysis. There were no missing patients or dropouts from the cohort.

All 35 patients were stratified into three groups (Table 1): 13 patients (37%) were in Group IA (non-cirrhotic patients with normal baseline ALT), 12 (34%) of patients were in Group IB (non-cirrhotic patients with abnormal baseline ALT), and the remainder of the patients

($n = 10$, 29%) were in Group II (cirrhotic patients). Group IA and B patients were predominantly from the Asian Lamivudine trial and had a median age of 35 years (range: 21-48 years) and 34 years (range 20-45 years), respectively. Patients in Group II were expectedly older with median age of 52 years (range 42-68). There was a preponderance of male patients (M:F = 30:5). With the exception of one Malay patient, all remaining patients were Chinese (97%). Of these 35 patients, genotypic resistance developed at a median of 143 wk after being on lamivudine (range 35-212). Median patients follow-up after genotypic resistance was 102 wk (range 26-220).

HBV genotypes

Majority of the patients had either genotypes B or C. Eighteen (51%) were of HBV genotype B while 13 patients (37%) had genotype C. Four (12%) had other genotypes: one was Genotype A, one had a mixture of B/C genotypes, and two were untypable (Table 2).

Mutations involved in lamivudine resistance

Sixteen of thirty-five patients (46%) were found to have the rtM204I (YIDD) mutation at the YMDD motif, whilst 12/35 (34%) demonstrated the rtM204V (YVDD) mutation and the remainder had at least one acquired mutation that was not present at the baseline and was known to confer resistance against lamivudine. (Figure 1). These included various combinations of mutations at rtA181T, rtL80V/I and rtL187I.

Table 1 Baseline characteristics of all patients

	Group IA $n = 13$ (37%)	Group IB $n = 12$ (34%)	Group II $n = 10$ (29%)	All patients $n = 35$ (100%)
Median age (range)	35 (21-48)	34 (20-45)	52 (42-68)	38 (20-68)
Male (%)	9 (69)	11 (92)	10 (100)	30 (86)
Chinese ethnicity (%)	13 (100)	11 (92)	10 (100)	34 (97)
Median (range) baseline ALT, U/L	28 (16-58)	136 (78-1 124)	87 (33-761)	74 (16-1 124)
Median (range) baseline HBV DNA, Meg/mL	294 (120-1 680)	253 (38-616)	291 (20-786)	280 (20-1 680)
Median baseline CPT score	NA	NA	7.0 (5-13)	NA

Figure 1 Distribution of the type HBV DNA mutations in the polymerase gene.

Clinical resistance

(1) Group IA (non-cirrhotic with normal baseline ALT), $n = 13$ (Figure 2A).

Only three patients (23%) developed abnormal ALT after the emergence of genotypic resistance at median follow-up of 96 (range: 48-220 wk). The changes in ALT in the group between the four timepoints were non-significant. All three patients normalized their ALT after a median duration of 6 (range: 4-12 wk), one of whom achieved HBeAg seroconversion; (2) Group IB (non-cirrhotic with abnormal

baseline ALT), $n = 12$ (Figure 2B).

Normalization of ALT levels 6 mo after starting lamivudine was seen in all patients (Wilcoxon signed Rank $P = 0.012$). However, with the emergence of genotypic resistance, 9 out of 12 patients (75%) developed abnormal ALT (Wilcoxon signed Rank $P = 0.017$) after median follow-up of 124 (range: 26-208) wk. Two patients registered peak ALT elevations of more than 10 times upper limit of normal, one of whom had the highest ALT ($>17 \times \text{ULN}$) at the baseline. ALT level at timepoints 3 and 4 were similar to the baseline level at timepoint 1 ($P > 0.05$). Five of the nine (56%) patients normalized their ALT after a median duration of 8 (range: 4-14) wk, two of whom achieved HBeAg seroconversion.

(3) Group II (patients with cirrhosis), $n = 10$ (Figure 3).

Six patients (60%) had abnormal ALT at the baseline (Figure 3A). All patients showed ALT improvement after treatment with lamivudine (Wilcoxon signed Rank Test, $P = 0.015$). With the emergence of genotypic resistance, abnormal ALT elevations occurred in five patients (50%) after a median follow-up of 64 (range: 34-102) wk. The development of abnormal ALT at timepoint 3 compared to timepoint 2 was statistically significant ($P = 0.017$). When ALT levels among timepoints 1, 3, and 4 were compared, no significant difference was found. All the five patients with flares of ALT normalized their ALT level after a median duration

1P = 0.895, 2P = 0.182, 3P = 0.08, 4P = 0.609, (Wilcoxon sign rank test)

Figure 2 ALT of Group IA and IB. **A:** ALT of Group IA: non cirrhotic patients with normal pre-treatment ALT ($n = 13$); **B:** ALT of Group IB: non-cirrhotic patients with

1P = 0.38, 2P = 0.30, 3P = 0.012, 4P = 0.017, (Wilcoxon sign rank test)

elevated pre-treatment ALT ($n = 12$).

1P = 0.33, 2P = 0.615, 3P = 0.015, 4P = 0.017, (Wilcoxon sign rank test)

1P = 0.77, 2P = 0.32, 3P = 0.002, 4P = 0.004, (Wilcoxon sign rank test)

of Cirrhotic patients.

of 4 (range: 4-8 wk).

CPT score analysis showed a similar trend in this group (Figure 3B). The CPT score at timepoint 2 showed significant improvement compared to timepoint 1 (Wilcoxon Signed Rank, $P = 0.016$) but deteriorated with the emergence of resistance at timepoint 3 (Wilcoxon Signed Rank, $P = 0.041$). No statistical significance was detected between CPT Score at timepoint 1 and timepoint 3 as well as between timepoints 1 and 4, with follow-up median duration of 64 wk after resistance (range 34-102). Three patients died from liver decompensation at 42, 78, and 96 wk, respectively after resistance developed, two of whom had the poorest pretreatment CPT score. None of the patients achieved HBeAg seroconversion although 40% (4 out of 10) were eAg negative Hepatitis B cirrhotics to begin with.

Factors that determine clinical severity of lamivudine-resistant mutants

At univariate analysis, only the baseline ALT in non-cirrhotics and the baseline CPT score in cirrhotics were predictive of phenotypic resistance ($P = 0.018$ and $P = 0.038$, respectively, Table 2).

Multivariate analysis was then performed with these two parameters. Using logistic regression analysis, the baseline ALT was shown to be significantly predictive of phenotypic resistance (OR 9.6, 95%CI 1.2-4.0, $P = 0.03$). The peak ALT level post resistance also correlated with the baseline ALT. (Spearman's $\rho = 0.441$, $P = 0.027$).

Similarly for CPT score, regression analysis showed baseline CPT score to be predictive of phenotypic resistance in terms of deterioration in CPT score after resistance ($P = 0.022$). Every additional CPT score at baseline predicts an additional 1.19 CPT score after resistance ($B = 1.19$, 95% CI: 0.235-2.15). Expectedly, peak CPT score after resistance showed strong correlation with baseline CPT score (Spearman's $\rho = 0.785$, $P = 0.007$).

Interestingly, neither the pretreatment nor the peak HBV DNA post-resistance were shown to be predictive of phenotypic resistance although the peak HBV DNA level post-resistance was noted to correlate with the pretreatment HBV DNA level (Spearman's $\rho = 0.414$, $P = 0.013$).

DISCUSSION

The most important finding of our study was that the course of lamivudine-resistant hepatitis B was generally benign except in cirrhotics. In Group IA (patients with normal baseline ALT), despite the emergence of lamivudine resistance, most (10 of 13, 77%) of the patients maintained normal ALT up to median follow-up of 96 wk. In addition, all three patients in Group IA who developed elevated ALT subsequently normalized their ALT level on follow-up. In Group IB (patients with persistently elevated baseline ALT), lamivudine normalized ALT during therapy, but upon development of resistance, ALT increased in 75% of patients. However, only 4/12 (33%) of patients continued to have persistently elevated ALT on follow-up. Finally, in Group II (patients with decompensated cirrhosis), there was normalization of ALT levels and reduction in CPT scores during lamivudine therapy, but both parameters increased

to baseline levels once lamivudine resistance occurred.

Thus the clinical picture of lamivudine-resistant hepatitis B virus demonstrates a spectrum of disease from normal ALT to hepatitis B flares and liver decompensation. Our findings suggest that at the peak of abnormality, the clinical picture correlates most closely with baseline clinical characteristics of the patient. On subsequent follow-up however, the course was relatively benign except for cirrhotics.

The inclusion of patients with normal baseline ALT (Group 1A) provided an invaluable group of patients for studying the pathogenic effects of lamivudine-resistant Hepatitis B virus. This group of patients were treated with lamivudine only because they were part of the Asian Lamivudine Multicenter Trial. Yet on developing lamivudine resistance, most of them retained normal ALT in their follow up. Even in the few who had transient abnormal ALT, these universally resolved in contrast to those with abnormal baseline ALT or liver function. This suggests that lamivudine-resistant virus may not be more pathogenic than the wildtype virus. Although further study with larger number of patients is needed to confirm this, such study would be difficult to perform as clinical guidelines from America, Europe and Asia did not recommend lamivudine treatment for patients with normal baseline ALT levels^[20-22].

Our findings also fit the known biology of HBV. Clinical disease in chronic Hepatitis B is a complex interplay between the virus and the immune system. Mutations in the YMDD motif confer resistance to lamivudine and allow high viral replication to resume. On the other hand, it is the mutations in the core region that have been most closely associated with increased immune responses to the virus^[23].

Our study complements that of Yuen, who concluded that the majority of patients with lamivudine-resistant hepatitis B flares recovered except some with cirrhosis^[24]. In our patients with abnormal baseline ALT, although 75% had elevation of ALT at any time, only 33% had persistently elevated ALT on prolonged follow-up suggesting that the final clinical outcome in those without cirrhosis generally shows a benign course. Similarly, Lok^[25] also concluded that lamivudine-resistance led to good outcomes in non-cirrhotics, but this cannot be extrapolated to cirrhotics. Cirrhotic patients, having poorer liver reserve, are less able to tolerate the further necroinflammation that may resume with the return of viral replication in those phenotypically susceptible. Our cohort of cirrhotic patients (Group II) developed decompensation following lamivudine resistance, resulting in death in 30% of patients. These findings concur with the results of NUCB 4006 (CALM study)^[26]. In this landmark study, lamivudine therapy in cirrhotic patients proved to provide significant benefit in terms of reduced progression of liver disease and reduction in hepatocellular carcinoma. Patients who developed lamivudine-resistant mutations showed a reduction in this endpoint efficacy, as we have shown, developing progression of their liver disease. Nevertheless, they still had less clinical endpoints than patients on placebo. Unlike the CALM study which enrolled patients with early and non-decompensated cirrhosis, most of the cirrhotic patients in our study had decompensated liver disease and had poor outcomes when lamivudine resistance developed.

We acknowledge the following limitations of our study. Firstly, we did not have histological confirmation of progression of liver disease. However, abnormal ALT has been accepted as a good surrogate marker for necroinflammation of the liver^[27]. In addition, an increase in CPT score clearly signifies progressive liver damage and deterioration. Consequently, we feel that the lack of histological data does not detract from the findings of this study. Although our sample size was relatively small, the spectrum of patients included in our study is typical of those seen in a normal hepatology practice or hospital, rather than the pre-selected patients included in clinical trials. In addition, the findings in general are also observed in larger clinical studies. Our study also includes patients with normal ALT and decompensated cirrhosis, which have not been previously described. The duration of follow-up in our series was 102 wk, longer than in most other published studies^[8,12,24].

We believe the results of our study could have two therapeutic implications. Firstly, the clinical severity of lamivudine-resistant HBV resembled the baseline phenotype, although on follow-up, the vast majority of the increased ALT normalized. Recent updated American guidelines for Hepatitis B recommends options of continuing or stopping lamivudine or converting to other antiviral drug when lamivudine resistance develops, depending on the patient's clinical state, ALT and HBV DNA levels^[20]. Our study suggests that baseline activity can be used as predictive factor in identifying patients who are likely to resume active disease and who thus, should be monitored more closely. Secondly, in patients with poor liver reserve at baseline who developed lamivudine resistance, additional rescue therapy such as adefovir dipivoxil should be instituted early, before clinical deterioration occurred.

In conclusion, the clinical phenotype of patients with genotype resistance to lamivudine resembled the baseline clinical phenotype, suggesting loss of virus suppression and return to the pre-treatment state. Patients with high baseline ALT level or CPT score tended to return to a high ALT level or CPT score once lamivudine resistance occurred. With time, there was normalization of raised ALT levels in those with non-cirrhotic lamivudine resistance. Consequently, in treatment of hepatitis B, lamivudine therapy need not be stopped prematurely for fear of developing more pathogenic lamivudine-resistant strains. However, patients with cirrhosis, particularly decompensated cirrhosis, need to be monitored closely and adefovir dipivoxil started expeditiously when resistance occurs.

ACKNOWLEDGMENTS

We would like to thank GlaxoSmithkline (Singapore) Private Limited for permission and access to the data for patients in the Asian Multicentre Lamivudine Trial, and Ms. Shen Liang from the Clinical Trials and Epidemiology Research Unit, Singapore Ministry of Health, for statistical support.

Abstract

AIM: To investigate the possible mechanism for HBV X gene to induce apoptosis of hepatocyte HL-7702 cells.

METHODS: HBV X gene eukaryon expression vector pcDNA3-X was established and transfected into HL-7702 cells by lipid-mediated transfection, including transient and stable transfection. Positive clones were screened by incubating in the selective medium with 600 µg/mL G418 and named HL-7702/HBV-encoded X protein (HBx) cells. The expressions of Fas/FasL, Bax/Bcl-2, and c-myc mRNA were measured by semi-quantitative RT-PCR in HL-7702/HBx and control group, respectively.

RESULTS: RT-PCR analysis confirmed that HBV X gene was transfected into HL-7702 cells successfully. By semi-quantitative RT-PCR analysis, Bax and c-myc mRNA levels in HL-7702/HBx cells of transient transfection were significantly higher than those in control, FasL and c-myc mRNA levels in HL-7702/HBx cells of stable transfection were significantly higher than those in control, whereas the Bcl-2 mRNA levels in HL-7702/HBx cells of transient and stable transfection were significantly lower than those in control.

CONCLUSION: HBV X gene may promote the apoptosis of hepatocytes by regulating the expressions of Fas/FasL, Bax/Bcl-2, and c-myc gene in a dose-dependent manner.

INTRODUCTION

HBV X gene is the smallest open reading frame of HBV, codes for a 16.5-ku protein (X protein, HBx) consisted of 154 amino acids. Previous studies showed that HBV X gene and HBx modulate apoptosis of hepatocytes and play an important role in HBV-associated liver disease^[1]. HBV X gene could inhibit apoptosis of hepatocytes in several ways and contribute to the generation of hepatocellular carcinoma (HCC). It was reported that HBx displays a pro-apoptotic function and induces apoptosis of liver cells^[2-5]. But the relationship between this function of HBx and HBV-associated liver disease remains obscure. So far no molecular mechanism or target for HBx-mediated apoptosis has been clearly elucidated. In this study, we transfected X gene into hepatocyte line HL-7702 by transient and stable transfection. Thus, cell lines that expressed different levels of HBx were established. To explore the possible mechanism for HBx to modulate apoptosis, we investigated the effect of HBx on expressions of apoptosis-associated genes in hepatocytes. The expressions of Fas/FasL, Bax/Bcl-2, and c-myc mRNA were measured by semi-quantitative RT-PCR in HL-7702/HBx and control group, respectively.

MATERIALS AND METHODS

Materials

PcDNA3 expression vector and HBV X gene eukaryon expression vector pcDNA3-X were previously constructed and stored^[6]. The normal hepatic cell line HL-7702 was provided by Cell Bank of Chinese Academy of Sciences. Reverse transcription system, DNA purification system, G418, and TransFast™ transfection reagent were obtained from Promega Biotech. Total RNA isolation kit was purchased from Jingmei Biotech Company. PCR primers were synthesized by Shanghai Biotechnology Company. RPMI-1640 was bought from Gibco BRL Company.

Transfection and expression of HBV X gene in HL-7702

Cell culture and DNA transfection HL-7702 cells were cultured in RPMI-1640 supplemented with 20% FBS. The cells in logarithmic growth were separately transfected with pcDNA3-X and pcDNA3 plasmids using lipid-mediated transfection technique according to the protocol for transient or stable transfection of adherent cells. About 2 mL transfection mixture containing 5 µg plasmid DNA, 15 µL TransFast™ reagent and RPMI-1640 was added to a 25-mm² culture plate. At 48 h post-transfection, all cells were trypsinized. Cells for transient transfection were

transferred to a 25-mm² culture plate and cultured in RPMI-1640 supplemented with 20% FBS for 72 h. Cells used for stable transfection were cultured in the selective medium with 600 µg/mL G418 for 2 wk. Then, drug-resistant individual clones were isolated and transferred to a 96-well plate for further amplification in the presence of selective medium. Cells that transiently transfected with pcDNA3-X and pcDNA3 were named as HL-7702/HBx^T and HL-7702/pcDNA3^T, respectively. Cells that stably transfected with pcDNA3-X and pcDNA3 were named as HL-7702/HBx^S and HL-7702/pcDNA3^S, respectively. HL-7702 was used as control.

Determination of X gene expression by RT-PCR analysis Total RNA was extracted separately from the cells of each group with a RNA isolation kit, and RT-PCR was carried out. β-Actin served as an internal control, 2 µL of RT product was used as template, X gene and β-actin were amplified together. The sequence of β-actin primers was 5'-GGCATCGTGATGGACTCCG-3' and 5'-GCTGGAAGGTGGACAGCGA-3'. The sequence of X gene primers was: 5'-ATGCAAGCTTATGGCTGCT-AGGCTGTACTG-3' and 5'-TGCGAATTCTTAGGCA-GAGGTGAAAAAGTTG-3'. The expected amplification fragment length of β-actin and X gene was 607 and 467 bp, respectively. PCR was carried out as follows: pre-denaturation at 95 °C for 5 min, 32 amplification cycles (denaturation at 94 °C for 35 s, annealing at 65 °C for 35 s, and extension at 72 °C for 1 min), and a final extension at 72 °C for 7 min.

Effect of HBV X gene on apoptosis-associated gene mRNA expression in hepatocytes by transient and stable transfection RT-PCR for Fas/FasL, Bax/Bcl-2, and c-myc Total RNA was extracted from HL-7702/HBx, HL-7702/pcDNA3, and HL-7702 according to the RNA isolation kit instructions. The content and purity of total RNA were determined by spectrophotography. RNA (260/280 was between 1.8 and 2.0) was further used for reverse transcription reaction, which was carried out according to the reverse transcription kit instructions. Two microgrammes of total RNA was used

in each reverse transcription reaction and the final volume was 20 µL. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used as an internal control and amplified together with target genes. PCR was performed in 50 µL reaction volume containing 5 µL 10×PCR buffer, 5 µL 2 mmol/L MgCl₂, 1 µL 10 mmol/L dNTP, 1 µL 20 pmol/µL target gene sense and anti-sense primers, 0.4 µL 12.5 pmol/µL GAPDH primer pair, 2 µL RT product, 1.5 U *Taq* DNA polymerase. The specific sets of primers and the target gene amplification conditions are shown in Table 1. All initial denaturations were at 94 °C for 5 min. Finally an additional extension step at 72 °C for 7 min was done.

Result determination The PCR products were electrophoresed on 2% agarose gel and visualized by ethidium bromide staining. Bioimaging system was used to detect the densities of bands of the PCR products. The ratio of target gene density to GAPDH density was respectively used to represent the relative expression level of Fas/FasL, Bax/Bcl-2, and c-myc mRNA. The semi-quantitative detection was analyzed five times.

Statistical analysis

All data were expressed as mean±SE. The significance for the difference between the groups was assessed with SPSS 10.0 by one-way ANOVA. *P*<0.05 was considered statistically significant.

RESULTS

Expression of HBV X gene mRNA in HL-7702 cells

HBV X gene mRNA was detected in HL-7702/HBx^T and HL-7702/HBx^S cells by RT-PCR. The expected band was found between 400 and 500 bp in both kinds of transfected cells (Figure 1). The relative level of HBV X gene mRNA in HL-7702/HBx^T was higher than that in HL-7702/HBx^S by about 2.5-folds (0.815±0.013 vs 0.308±0.021), indicating that HBV X gene mRNA could be expressed in HL-7702 after transient or stable transfection, and cell lines that expressed different levels of HBx were established.

Table 1 Primer sequences for PCR and amplification conditions for each target gene

Primer	Sequence	Amplification conditions	Product (base)
Fas	5'-TCAGTACGGAGTTGGGGAAG-3' 5'-CAGGCCTTCCAAGTTCTGAG-3'	Denaturation at 94 °C for 45 s, annealing at 63 °C for 30 s and synthesizing at 72 °C for 1 min for 35 cycles	207
FasL	5'-GATGATGGAGGGGAAGATGA-3' 5'-TGGAAGAATCCCAAAGTGC-3'	Denaturation at 94 °C for 45 s, annealing at 58 °C for 30 s and synthesizing at 72 °C for 1 min for 30 cycles	203
Bax	5'-TTTGCTTCAGGGTTTCATCC-3' 5'-CAGTTGAAGTTGCCGTCAGA-3'	Denaturation at 94 °C for 45 s, annealing at 58 °C for 30 s and synthesizing at 72 °C for 1 min for 30 cycles	246
Bcl-2	5'-CGACGACTTCTCCCGCCGCTACCGC-3' 5'-CCGCATGCTGGGGCCGTACAGTTCC-3'	Denaturation at 94 °C for 45 s, annealing at 67 °C for 30 s and synthesizing at 72 °C for 1 min for 30 cycles	318
c-myc	5'-TTCGGGTAGTGAAAACAG-3' 5'-CAGCAGCTCGAATTCTTCC-3'	Denaturation at 94 °C for 45 s, annealing at 58 °C for 30 s and synthesizing at 72 °C for 1 min for 28 cycles	203

Effects of HBV X gene on apoptosis-associated genes mRNA expression in HL-7702 by transient transfection

Fas/FasL mRNA As shown in Figures 2A, B, and 3A, both Fas mRNA and FasL mRNA were expressed in HL-7702 of each group. Both of their expression levels had no significant differences among the three groups, indicating that HBx had no effect on Fas and FasL expression in normal hepatocytes though it was expressed at a relatively high level after transient transfection.

Bcl-2/Bax mRNA Both Bax and Bcl-2 mRNA were expressed in HL-7702 after transient transfection (Figures 2C, D, and 3B). As it could be seen from Figures 2C, 3B, and C, the expression level of Bax mRNA in HL-7702/HBx^T was higher than that in HL-7702 or in HL-7702/pcDNA3^T (0.614 ± 0.014 *vs* 0.536 ± 0.009 or 0.494 ± 0.015 , $P < 0.01$). The expression level of Bcl-2 mRNA in HL-7702/HBx^T was lower than that in HL-7702 or in HL-7702/pcDNA3^T (0.811 ± 0.010 *vs* 1.243 ± 0.033 , $P < 0.01$) (0.811 ± 0.010 *vs*

0.901 ± 0.014 , $P < 0.05$). There was also a significant difference in Bcl-2 mRNA expression level between the two control groups (0.901 ± 0.014 *vs* 1.243 ± 0.033 , $P < 0.01$; Figures 2D, 3B, and D). The data indicated that HBx could induce the pro-apoptotic factor Bax expression in normal hepatocytes and inhibit the anti-apoptotic factor Bcl-2 expression.

c-myc mRNA c-myc mRNA was expressed in both HL-7702 and HL-7702/pcDNA3, and there was no significant difference between them. The expression level of c-myc mRNA was significantly higher in HL-7702/HBx^T, suggesting that HBx was able to promote the c-myc expression in normal hepatocytes (0.719 ± 0.020 *vs* 0.569 ± 0.026 , $P < 0.01$, 0.719 ± 0.020 *vs* 0.630 ± 0.012 , $P < 0.05$; Figures 2E and 3C).

Effects of HBV X gene on apoptosis-associated gene mRNA expression in HL-7702 by stable transfection

Fas/FasL mRNA The expression levels of Fas mRNA had no significant difference among the three groups (Figures 4A and 5A). There was no significant difference in FasL mRNA expression between HL-7702 and HBV X gene expressing stable cell line HL-7702/HBx^S. The expression of FasL in HL-7702/HBx^S was significantly higher than that in HL-7702/pcDNA3^S (0.261 ± 0.043 *vs* 0.217 ± 0.012 , $P < 0.01$), suggesting that HBx at a low level could improve the FasL expression, which was different from the effect of HBx at a relatively higher level as shown in the former part (Figures 4B, 5A, and B).

Bax/Bcl-2 mRNA HBV X gene stably expressed in HL-7702/HBx^S seemed to have no effect on Bax mRNA expression (Figures 4C, 5B, and C). The expression level of Bcl-2 mRNA had no significant difference between the

expression levels; **E**: relative c-myc mRNA expression levels. ^a $P < 0.05$ *vs* HL-7702/HBx^T, ^b $P < 0.01$ *vs* HL-7702/HBx^T, ^d $P < 0.01$ *vs* HL-7702, ^f $P < 0.01$ *vs* HL-7702/pcDNA3^T, $P > 0.05$ between random two groups.

Figure 3 RT-PCR results of apoptosis-associated gene mRNA expression in HL-7702 of different transiently transfected groups. **A:** RT-PCR results of Fas/FasL mRNA expression; **B:** RT-PCR results of Bax/Bcl-2 mRNA expression;

C: RT-PCR results of c-myc mRNA expression; M: 100-bp DNA ladder; lane 1: HL-7702; lane 2: HL-7702/pcDNA3^S; lane 3: HL-7702/HBx^S; a: Fas; b: FasL; c: Bax; d: Bcl-2; e: c-myc.

two control groups, HL-7702 and HL-7702/pcDNA3^S, but it was lower in HL-7702/HBx^S (0.300 ± 0.028 vs 0.498 ± 0.035 , $P < 0.01$; 0.300 ± 0.028 vs 0.420 ± 0.032 , $P < 0.05$; Figures 4D, 5B, and D), suggesting that HBx could downregulate Bcl-2 expression in normal hepatocytes.

c-myc mRNA Similar to the effect of HBV X gene transient transfection, c-myc was expressed in both HL-7702 and HL-7702/pcDNA3^S, and there was no significant difference between them. The expression level of c-myc mRNA was significantly higher in HL-7702/HBx^S, suggesting that even a low level of HBx was able to upregulate the c-myc expression in normal hepatocytes (0.603 ± 0.035 vs 0.449 ± 0.023 or 0.461 ± 0.022 , $P < 0.01$; Figures 4E and 5C).

DISCUSSION

HBV infection is a major cause of chronic hepatitis, cirrhosis, and hepatocellular carcinoma and accounts for one million

deaths annually. HBx is a multifunctional protein that is implicated in the pathogenesis of HBV-associated liver disease by regulating gene transcription, causing cell proliferation, suppressing DNA repair and inducing cell death^[7]. The role of HBx in carcinogenesis and its transactivation function have been well documented^[8]. The role of HBx in liver cell proliferation and apoptosis is still controversial. A number of studies have revealed that HBx exert dual activity on cell apoptosis^[9,10].

On the one hand, HBx has an anti-apoptosis function in different ways and plays an important role in the development of HCC. HBx can activate and upregulate transcription factor NF- κ B^[11]. It induces Fas-ligand in human hepatoma cells, which contributed to the apoptosis of T cells, thus the hepatoma cells might escape from immune surveillance^[12]. There is evidence that HBx blocks apoptosis via downregulating expression of Bid in human hepatocellular carcinoma^[13]. The distal C-terminal domain of HBx, independent of its

transactivation activity, is complexed with p53 in the cytoplasm and partially prevents its nuclear entry and ability to induce apoptosis^[14]. On the other hand, HBx induces or sensitizes cells to apoptotic killing by pro-apoptotic stimuli^[2-5]. The possible mechanisms may include upregulating the expression of Fas and Fas-ligand in hepatocytes^[15,16], inducing cell death by causing loss of mitochondrial membrane potential and mitochondrial aggregation at the nuclear periphery^[17,18], antagonizing the anti-apoptosis function of the normal level of p53^[19], abrogating the apoptosis-inhibitory function of c-FLIP and enhancing the death-inducing signal^[20], inducing TNF- α expression and sensitizing liver cells to TNF- α -mediated apoptosis even below the threshold concentration^[20-22], affecting the apoptosis control function of Bcl-2 family members by interaction with mitochondria^[23]. The above data suggest that the possible mechanism for HBx to regulate cell apoptosis is a “network” implicated with multiple factors and various pathways, and the exact mechanism remains obscure.

Fas and FasL are regarded as the most important factors that switch on the Fas/FasL-mediated apoptosis. The Bcl-2 family proteins play an important role in modulating cell survival and apoptosis. Bcl-2 and Bax act as an anti-apoptotic factor and a pro-apoptotic factor respectively. The proportion of apoptosis-inducing forces and apoptosis-inhibiting forces determines the cells’ response to death-inducing signals and their final fate^[24-26]. C-myc, usually acting as a proto-oncogene and exerting a dual activity on cell proliferation and apoptosis, is also involved in apoptosis regulation. We have previously demonstrated that the apoptosis rate in HBx-expressing cells by transient or stable transfection is much higher than that in control groups, suggesting that there is a quantity-effect relationship between HBx expression and apoptosis rate, and that HBx can induce apoptosis in normal hepatocytes, during which the expression level of HBV X gene may play a vital role. This study aimed to investigate the possible mechanism for HBV X gene to induce apoptosis of hepatocytes. Thereby, we established cell models that expressed different levels of HBV X gene by transfecting HBV X gene into HL-7702 through transient and stable transfection, and studied the effect of HBx on the mRNA expression of apoptosis-associated genes.

We found that HBx at a relatively higher level could induce the pro-apoptotic factor Bax expression in normal

hepatocytes and inhibit the anti-apoptotic factor Bcl-2 expression, though it had no effect on Fas and FasL expression. However, HBx at a low level could improve FasL expression, while it had no effect on Bax. The data show that HBx may induce the apoptosis of HL-7702 by reinforcing the death signal of Fas-FasL pathway and increasing the proportion of pro-apoptotic forces and anti-apoptotic forces in Bcl-2 family members. The dose of HBx may decide which is the chief pathway. The c-myc expression in HL-7702 significantly increased after transient or stable transfection with X gene expression vector, which is consistent with previous reports^[9,27]. C-myc protein could sensitize cells to apoptotic killing in certain conditions, such as during exposure to TNF- α or other factors^[28-30]. Thus, c-myc may also act as an important medium in HBx-mediated apoptosis. Su *et al.*^[30], found that the combination of HBx and c-myc increases the sensitivity of WT 3T3 cells to TNF- α killing by about 10-fold. They also demonstrated that cell killing by HBx plus TNF- α is suppressed by activation of NF- κ B, but can be overridden by a high level of c-myc protein.

Our results show that different levels of HBV X gene expression have different effects on apoptosis-associated gene expression. Wang *et al.*^[31], studied the effects of regulatory endoplasmic HBx expression on hepatic cell apoptosis and found that low HBx expression cannot induce apoptosis. Thereby, the effect of HBx on apoptosis may be dose dependent. We hypothesize that there may be a threshold concentration for HBx to induce apoptosis, only that beyond the threshold can exert a pro-apoptosis function. Further studies are needed to confirm it.

In conclusion, HBx may induce apoptosis in part via regulating the expression of apoptosis-associated genes. HBV X gene expression may play a vital role, although the underlying mechanism may be complicated and crisscrossing.

Abstract

AIM: A high percentage of early-stage high-grade gastric mucosa-associated lymphoid tissue (MALT) lymphomas remain *Helicobacter pylori* (*H pylori*)-dependent. However, unlike their low-grade counterparts, high-grade gastric MALT lymphomas may progress rapidly if unresponsive to *H pylori* eradication. It is mandatory to identify markers that may predict the *H pylori*-dependent status of these tumors. Proliferation of MALT lymphoma cells depends on cognate help and cell-to-cell contact of *H pylori*-specific intratumoral T-cells. To examine whether the expression

of co-stimulatory marker CD86 (B7.2) and the infiltration of CD56 (+) natural killer (NK) cells can be useful markers to predict *H pylori*-dependent status of high-grade gastric MALT lymphoma.

METHODS: Lymphoma biopsies from 26 patients who had participated in a prospective study of *H pylori*-eradication for stage I_E high-grade gastric MALT lymphomas were evaluated. Tumors that resolved to Wotherspoon grade II or less after *H pylori* eradication were classified as *H pylori*-dependent; others were classified as *H pylori*-independent. The infiltration of NK cells and the expression of CD86 in pre-treatment paraffin-embedded lymphoma tissues were determined by immunohistochemistry.

RESULTS: There were 16 *H pylori*-dependent and 10 *H pylori*-independent cases. CD86 expression was detected in 11 (68.8%) of 16 *H pylori*-dependent cases but in none of 10 *H pylori*-independent cases ($P = 0.001$). *H pylori*-dependent high-grade gastric MALT lymphomas contained significantly higher numbers of CD56 (+) NK cells than *H pylori*-independent cases ($2.8 \pm 1.4\%$ vs $1.1 \pm 0.8\%$; $P = 0.003$). CD86 positive MALT lymphomas also showed significantly increased infiltration of CD56 (+) NK cells compared to CD86-negative cases ($2.9 \pm 1.1\%$ vs $1.4 \pm 1.3\%$; $P = 0.005$).

CONCLUSION: These results suggest that the expression of co-stimulatory marker CD86 and the increased infiltration of NK cells are associated with *H pylori*-dependent state of early-stage high-grade gastric MALT lymphomas.

INTRODUCTION

Extranodal marginal zone B-cell lymphoma of mucosa-

associated lymphoid tissue (MALT) of the stomach is the most common extranodal lymphoma of humans. Although not completely acknowledged by all experts, gastric MALT lymphoma is often classified into high-grade and low-grade subtypes by histological criteria^[1-3]. Low-grade gastric MALT lymphoma is characterized by its close association with *Helicobacter pylori* (*H. pylori*) infection; and eradication of *H. pylori* by antibiotics, cures 70% of these tumors^[4-6]. However, high-grade gastric MALT lymphomas, in contrast to their low-grade counterparts, are believed to consist of highly-transformed cells, the growth of which is independent of *H. pylori*^[7-9].

Recently, several groups of investigators have demonstrated that a substantial portion of early-stage high-grade gastric MALT lymphomas remains *H. pylori*-dependent, and can be cured by *H. pylori* eradication^[10-12]. However, high-grade gastric MALT lymphoma, unlike its low-grade counterpart, may progress rapidly if unresponsive to *H. pylori* eradication therapy. Molecular markers such as chromosomal aberration $t(11;18)$, which is highly predictive of *H. pylori*-independent status of low-grade gastric MALT lymphoma, are rarely found in the high-grade counterpart^[13]. It is mandatory to identify cellular or molecular markers which can help predict the *H. pylori*-dependent status of newly diagnosed patients.

In the early process of MALT lymphomagenesis, the proliferation response depends at least partly on the stimulation of *H. pylori*-specific intratumoral T-cells^[14]. *In vitro* experiments have demonstrated that the growth and differentiation of MALT lymphoma cells requires CD40-mediated signaling and T helper-2 (Th-2)-type cytokines^[15,16]. The dependence on T-cells for the growth of malignant B-cell clones may explain the tendency of early-stage low-grade MALT lymphomas to remain localized and to regress after *H. pylori* eradication. Expression of co-stimulatory molecules, including CD80 (B7.1), CD86 (B7.2), and their ligands, has been demonstrated in gastric MALT lymphoma cells^[17]. The presence of the co-stimulatory marker CD86 (B7.2) on lymphoma cells may promote T-cell-mediated neoplastic B cell proliferation. We hypothesized that a loss of co-stimulatory markers might preclude tumor cell/reactive T-cell interaction and thereby contribute to the transition from a *H. pylori*-dependent to a *H. pylori*-independent state in high-grade gastric MALT lymphoma.

CD56 (+) natural killer (NK) cells are important components of the innate immune system, and have the ability to modulate both humoral- and cell-mediated immune responses^[18,19]. *H. pylori* can stimulate T-cells and thereby enhance the production of Th-2 cytokines, which can promote the proliferation of CD56 (+) NK cells in gastric MALT lymphomas^[20,21]. Although low-grade gastric MALT lymphomas contain significantly higher numbers of CD56 (+) NK cells than high-grade gastric MALT lymphomas^[21], the presence of CD56 (+) NK cells in high-grade gastric MALT lymphomas indicate that the promotion of these lymphoma cells triggered by *H. pylori*-specific intratumoral T-cells and Th-2 type cytokines may still be present *in vivo*. Therefore, these CD56 (+) NK cells may limit the autonomous growth of MALT lymphoma cells, and may contribute to the remission of high-grade MALT lymphomas after the eradication of *H. pylori*.

This study, was conducted to examine the expression of CD86 and the infiltration of CD56 (+) NK cells in 16

H. pylori-dependent and 10 *H. pylori*-independent high-grade gastric MALT lymphomas.

MATERIALS AND METHODS

Patients, treatment, and evaluation of the tumors

Twenty-six patients who had participated in a prospective study of *H. pylori* eradication for stage I_E high-grade gastric MALT lymphomas at our institutions from June 1995 to June 2003 were included in this study. The clinicopathologic features of the 22 patients have been previously reported^[13]. Although high-grade MALT lymphomas are classified as diffuse large B-cell lymphomas (with areas of marginal zone/MALT-type lymphoma) in the REAL/WHO classification^[2], and a consensus on the use of the term "high-grade MALT lymphoma" has not been achieved, many experts consider it as a useful and reasonable clinicopathologic entity^[1,3,10,21]. In this study, the diagnosis of high-grade gastric MALT lymphoma was made using the histologic criteria as described by Chan *et al.*^[1], and de Jong *et al.*^[3], based on the presence of a diffuse increase of large cells resembling centroblasts or lymphoblasts to between 1% and 10% of the total tumor cells within predominantly low-grade centrocyte-like cell infiltrate, or the predominance of a high-grade lymphoma with only a small residue, low-grade foci and/or the presence of lymphoepithelial lesions. Specimens with occasional clusters of transformed blast cells or sheets of transformed blast cells (upto 20 cells not forming larger sheets) confined within the colonized follicles were found within a low-grade lymphoma, they were considered as an immune response to *H. pylori* stimulation rather than high-grade MALT lymphoma. Patients with primary pure large cell lymphoma, without evidence of a low-grade component of the stomach were excluded from this study. All specimens were immunohistochemically stained by CD20, CD79a, CD3, and CD45RO for routine diagnostic purposes and to highlight lymphoepithelial lesions. Moreover, to exclude misinterpretation of reactive, benign germinal centers as transformed foci, CD21 (follicular dendritic cells markers) and BCL-2 (highly suggestive of a neoplastic origin of the blast cells) were included in all cases. The histopathologic characteristics of all tumor specimens were independently reviewed by two expert hematopathologists. Staging was based on Musshoff's modification of the Ann Arbor staging system^[22]. Staging procedures included physical examination, routine laboratory tests, inspection of Waldeyer's ring, chest radiography, chest and abdominal CT scan, bone marrow aspiration, and trephine biopsy. Diagnosis of *H. pylori* infection was based on histologic examination, biopsy urease test, or bacterial culture. When at least one test was positive, the cases were considered as *H. pylori* infected. All patients consented to a brief trial of *H. pylori* eradication therapy.

At the beginning of the study period in June 1995, the eradication regimen consisted of amoxicillin 500 mg and metronidazole 250 mg q.i.d., with either bismuth subcitrate 120 mg q.i.d. or omeprazole 20 mg b.i.d., for 4 wk. The regimen was changed to amoxicillin 500 mg q.i.d., clarithromycin 500 mg b.i.d., plus omeprazole 20 mg b.i.d. for 2 wk beginning in March 1996. Patients were scheduled to undergo a first follow-up upper gastrointestinal endoscopic examination 4-6 wk after completion of antimicrobial

therapy, and follow-up was then repeated every 6–12 wk until histologic evidence of remission was found. At each follow-up examination, four to six biopsy specimens were taken from the antrum and body of the stomach for a *H. pylori* infection evaluation, and a minimum of six biopsy specimens were taken from each of the tumors and suspicious areas for histologic evaluation. Tumors that resolved to Wotherspoon grade II or less were considered as histological complete remission^[4]. Tumors showing both histological and endoscopic complete remission were considered *H. pylori*-dependent. Tumors showing stable or progressive disease on follow-up endoscopic examination and persistent or increasing proportion of large cells on microscopic examination were considered *H. pylori*-independent.

Immunohistochemistry

Formalin-fixed paraffin embedded sections cut at a thickness of 4 µm were deparaffinized and rehydrated through xylene and a graded descending series of alcohol. After antigen retrieval by heat treatment in 0.1 mol/L citrate buffer at pH 6.0, endogenous peroxidase activity was blocked by 3% H₂O₂. Briefly, slides were incubated for 30 min in 2.5% normal donkey serum or goat serum. The slides were then incubated overnight at 4 °C either with goat polyclonal anti-CD86 antibody (1:50; AF-141-NA; R&D Systems, Abingdon, UK) or mouse monoclonal anti-CD56 antibody (1:100; NCL-CD56-1B6, Novacastra), and incubated with secondary antibodies (CD86, donkey antigoat immunoglobulin; CD56, goat antimouse immunoglobulin; Santa Cruz Biotechnology, Santa Cruz, CA, USA), following the manufacturer's instructions. Finally, antibody binding was detected with the avidin–biotin–peroxidase method. Reaction

products were developed using 3', 5'-diaminobenzidine (Dako) as a substrate for peroxidase. Sections were counterstained with Mayer's hematoxylin. All the washes were performed in PBS (pH 7.4). Staining was considered as positive for CD86 when the protein was detected in more than 10% of tumor cells. A minimum of 1 000 cells (normal and neoplastic) were counted for each single determination and reported as the percentage of CD56 (+) NK cells in total mononuclear cells.

Statistical analysis

The primary aims of this study were to investigate the correlation between the *H. pylori*-dependent status of MALT lymphomas, the expression of CD86 and the infiltration of CD56 (+) NK cells. Fisher's exact test and χ^2 test were used to analyze the correlation between the *H. pylori*-dependent status of MALT lymphomas with CD86 expression patterns. The results for the CD56 (+) NK cells are expressed as mean \pm SD of percentages of positive cells in the total cell count for a given marker. Nonparametric Mann-Whitney *U* test was used to evaluate the difference in the distribution of positive CD56 (+) NK cell count between *H. pylori*-dependent and *H. pylori*-independent high-grade MALT lymphomas and the difference in the distribution of positive CD56 (+) NK cell count between CD86 positive and CD86 negative high-grade MALT lymphomas.

RESULTS

Patients and tumor response

There were 16 patients with *H. pylori*-dependent and 10 patients with *H. pylori*-independent tumors. The clinicopathologic features of these patients are summarized in Table 1. The

negative staining for CD86; **C:** *H. pylori*-dependent case (case 8) carries a larger proportion of CD56 (+) NK cells; **D:** *H. pylori*-independent case (case 5) contains a lower proportion of CD56 (+) NK cells. Original magnification, $\times 400$.

median duration between *H. pylori* eradication and complete histologic remission was 5.0 mo (range, 1.5-17.7 mo). At a median follow-up of 56 mo (range, 8.0-90 mo), all 16 patients who had achieved complete histologic remission after eradication of *H. pylori* were alive and free of lymphoma. Seven patients whose tumors grossly increased in size or had microscopic findings of an increased large-cell fraction and three patients whose tumor remained grossly stable at the first follow-up endoscopic examination, were immediately referred for systemic chemotherapy.

Correlation of expression of CD86 and infiltration of CD56 (+) NK cells with tumor response to *H. pylori* eradication

The expression of CD86 was detected in 11 (68.8%) of 16 *H. pylori*-dependent high-grade gastric MALT lymphomas, but in none of 10 *H. pylori*-independent MALT lymphomas ($P = 0.001$, Figure 1 and Table 1). Therefore, the expression of CD86 had a sensitivity of 68.8% and a specificity of 100% in predicting the *H. pylori*-dependence of high-grade gastric MALT lymphomas.

As shown in Figure 2, the infiltration of CD56 (+) NK cells differed between *H. pylori*-dependent and *H. pylori*-independent high-grade gastric MALT lymphomas. *H. pylori*-dependent high-grade gastric MALT lymphomas contained significantly higher numbers of CD56 (+) NK cells than *H. pylori*-independent MALT lymphomas ($2.8 \pm 1.4\%$ vs $1.1 \pm 0.8\%$; $P = 0.003$). Meanwhile, CD86 positive MALT lymphomas also showed significantly increased infiltration of CD56 (+) NK cells compared to CD86-negative cases ($2.9 \pm 1.1\%$ vs $1.4 \pm 1.3\%$; $P = 0.005$).

DISCUSSION

In this study, we found that expression of CD86 on tumor

Figure 2 Histograms showing the mean percentage (\pm SD) of cells staining CD56 (+) NK in *H. pylori*-dependent and *H. pylori*-independent high-grade gastric MALT lymphomas ($2.8 \pm 1.4\%$ vs $1.1 \pm 0.8\%$; $P = 0.003$).

cells and increased infiltration of NK cells in tumor tissues were associated with the *H. pylori*-dependent status of early-stage high-grade gastric MALT lymphomas. These findings suggest that the interaction of B- and T-cells may play a pivotal role in the determination of antigen-dependence, as well as in the subsequent response to *H. pylori* eradication therapy in a substantial portion of early-stage high-grade gastric MALT lymphomas. Since high-grade gastric MALT lymphomas may progress rapidly if unresponsive to *H. pylori* eradication therapy, this information is invaluable for the physician who must select a first-line treatment.

It has been demonstrated that the growth of MALT lymphomas requires the help of *H. pylori*-reactive tumor-infiltrating T-cells. For effective communication between T-cells and neoplastic B-cells, two subsets of co-stimulatory molecules, CD80 (B7.1) and CD86 (B7.2), of the neoplastic B-cells should interact with CD28 or CTLA-4 of the

T-cells^[23]. However, the precise role of CD80 and CD86 molecules in the signaling of B-cells remains unclear. In earlier studies, the CD28-CTLA4/B7-signaling pathway was found to be involved in the proliferation and differentiation of B-cells^[24,25]. There is also evidence that CD86 may promote proliferation and immunoglobulin synthesis of normal B-cells and malignant B cells^[26]. Compared with CD86, CD80 delivered a down-regulator signal for B-cell response^[26]. In a recent study of low-grade gastric MALT lymphomas, the expression of CD86 was significantly associated with *H pylori*-dependence, while CD80 and CD40 and their ligands were not^[27]. These results are in line with our observation that the co-stimulatory molecule CD86 is present in high-grade gastric MALT lymphomas, and is also significantly associated with *H pylori*-dependence. Our findings support the notion that the growth of a substantial portion of early-stage high-grade gastric MALT lymphomas, as well as their low-grade counterparts, remains dependent on functional B-cell/T-cell interaction.

In addition to promoting the proliferation and differentiation of malignant B-cell clones, tumor-infiltrating T-cells in low-grade gastric MALT lymphomas are found to be defective in both perforin-mediated cytotoxicity and Fas-Fas ligand mediated apoptosis^[28]. On the other hand, the tumor tissues of high-grade MALT lymphomas appear to contain a much higher number of apoptotic lymphoma cells and CD8+ cytotoxic T lymphocytes (CTLs)^[21]. Study using a murine model demonstrated that Th-1 response and CD8+ CTLs activity were strongly inhibited in the presence of persistent gastric *H pylori* infection^[29]. Moreover, activated CD8+ CTLs may compete with CD56 (+) NK cells and downregulate the function of the latter^[17]. Besides regulating the differentiation of CD8+ CTLs, CD56 (+) NK cells may have an equally important role in immune regulation, where they limit the host response to foreign antigens and prevent autoimmunity^[18]. Recently, it has been demonstrated that CD56 (+) NK cells can be functionally activated by co-stimulatory molecules through the interaction of their activation receptor and CD86 on target cells, and thereby limit the extent of *H pylori*-related auto-reactive and neoplastic B lymphoid cells in the stomach^[30]. In the current study, we found that *H pylori*-dependent high-grade MALT lymphomas showed significantly increased infiltration of CD56 (+) NK cells compared to *H pylori*-independent lymphomas. Interestingly, we also found that CD86 positive MALT lymphomas showed significantly increased infiltration of CD56 (+) NK cells compared to CD86-negative cases. These findings suggest that the loss of *H pylori*-dependence may be associated with a change in the immunological microenvironment, including a shift towards a Th-1 response that enhances the activity of CD8+ CTLs, and decreases the activity of CD56 (+) NK cells.

In conclusion, the expression of co-stimulatory marker CD86 on lymphoma cells and the increased infiltration of CD56 (+) NK cells in tumor tissues are useful markers in the identification of *H pylori*-dependent tumors and in the selection of patients for first-line *H pylori* eradication therapy.

Abstract

AIM: To investigate the relationship between *Helicobacter pylori* (*H. pylori*) infection, microsatellite instability and the expressions of the *p53* in gastritis, intestinal metaplasia and gastric adenocarcinoma and to elucidate the mechanism of gastric carcinogenesis relating to *H. pylori* infection.

METHODS: One hundred and eight endoscopic biopsies and gastric adenocarcinoma were available for the study including 33 cases of normal, 45 cases of gastritis, 30 cases of intestinal metaplasia, and 46 cases of gastric adenocarcinoma. Peripheral blood samples of these patients were also collected. *H. pylori* infection and *p53* expressions were detected by means of streptavidin-peroxidase (SP) immunohistochemical method. Microsatellite loci were studied by PCR-SSCP-CE using the markers BAT-26, D17S261, D3S1283, D2S123, and D3S1611. MSI was defined as the peak shift in the DNA of the gastric tissue compared with that of the peripheral blood samples. Based on the number of mutated MSI markers, specimens were characterized as high MSI (MSI-H) if they manifested instability at two or more markers, low MSI (MSI-L) if unstable at only one marker, and microsatellite stable (MSS) if they showed no instability at any marker.

RESULTS: *H. pylori* infection was detected in the samples of gastritis, intestinal metaplasia, and gastric adenocarcinoma and the infection frequencies were 84.4%, 76.7%, and 65.2%, respectively, whereas no *H. pylori* infection was detected in the samples of normal control. There was a significant difference in the infection rates between gastritis and carcinoma samples ($P = 0.035$). No MSI was detected in gastritis samples, one MSI-H and two MSI-L were detected among the 30 intestinal metaplasia samples, and 12 MSI-H and 3 MSI-L were detected in the 46 gastric carcinomas. In those gastric carcinomas, the MSI-H frequency in *H. pylori*-positive group was significantly higher than that in *H. pylori*-

negative group. No *p53* expression was detected in the normal and gastritis samples from dyspeptic patients. *p53*-positive immunohistochemical staining was detected in 13.3% of intestinal metaplasia samples and in 43.5% of gastric carcinoma samples. The levels of *p53* in *H. pylori*-positive samples were higher than those in the negative group when the carcinoma samples were subdivided into *H. pylori*-positive and -negative groups ($P = 0.013$). Eight samples were detected with positive *p53* expression out of the 11 MSI-H carcinomas with *H. pylori* infection and no *p53* expression could be seen in the *H. pylori*-negative samples.

CONCLUSION: *H. pylori* affect the *p53* pattern in gastric mucosa when MMR system fails to work. Mutations of the *p53* gene seem to be an early event in gastric carcinogenesis.

INTRODUCTION

Gastric cancer is one of the most common forms of malignant tumors in adults and is the leading cause of death from carcinomas in China. A close association between *Helicobacter pylori* (*H. pylori*) and gastric cancer has been found^[1,2], mainly on the basis of epidemiological data. Although *H. pylori* has been classified as a type I carcinogen for gastric cancer by the International Agency for Research on Cancer (IARC), the exact pathway has remained indistinct^[3,4]. It has been known that some gastric carcinomas are characterized by microsatellite instability resulting from defect of mismatch repair. Mismatch repair genes, as house keeping genes, have a central role in maintaining genomic stability by repairing DNA replication errors and inhibiting recombination between non-identical sequences. Loss of MMR genes causes destabilization of the genome and results in high mutation rates, which predisposes human to diverse cancers including gastric carcinoma^[5-7]. The *p53* protein is a transcriptional factor that arrests the cell cycle in the G1 phase when DNA is damaged by inducing the expression of the p21 protein, an inhibitor of Cdk kinase and PCNA^[8,9]. Thus, damaged

DNA cannot replicate, allowing time for the repair system to act^[8]. If this system fails, *p53* induces apoptosis by transactivation of the *bax* gene^[10]. Both mismatch repair and suppressor are two main pathways involved in the tumorigenesis of gastric carcinoma. In this study, we examine microsatellite instability and *p53* protein accumulation in patients with *H. pylori*-infected gastric mucosa and in patients with gastric adenocarcinoma to elucidate whether any relationship exists between these genetic alterations and *H. pylori* infection.

MATERIALS AND METHODS

Patients

One hundred and eight dyspeptic patients (65 men and 43 women; median age, 46 years; range, 20-73 years) undergoing upper endoscopy, and 46 consecutive patients (29 men and 17 women; median age, 56 years; range, 32-69 years) who underwent surgical excision for gastric adenocarcinoma at the hospitals of Dalian area entered the study. Peripheral blood samples of these patients were also collected. The ethical approval for this study was granted by the Local Research Ethics Committee. Endoscopic biopsies were removed with standard gastric biopsy forceps and then cut in half with sterile scalpel blades. Half the biopsy sample was fixed in 10% buffered neutral formalin and embedded in paraffin and serial sections (4- μ m thick), while the other half was stored at -80 °C. Hematoxylin-eosin (HE) staining was used for the histopathological diagnosis. Among the 108 endoscopic biopsies, 33 samples were normal, 45 samples were gastritis and 30 samples were intestinal metaplasia.

DNA extraction

DNA was extracted from the frozen gastric tissues and peripheral leukocytes using a regular phenol-chloroform method and stored at -20 °C until use.

Microsatellite analysis

Microsatellite instability was studied using five markers (Table 1), PCR was performed in 12.5 μ L of reaction mixture containing 1.5 mmol/L MgCl₂, 200 μ mol/L each dNTP, 0.5 Unit ampli Taq polymerase (TaKaRa Biotech., Dalian, China), 0.5 μ mol/L of each primer, and 50 ng genomic DNA. The reaction was carried out in a thermal cycler (Perkin-Elmer Model 2700, CA, USA) at 94 °C for 30 s, 58-60 °C for 30 s, and 72 °C for 30 s, for 35 cycles with an initial denaturation step of 94 °C for 5 min and a final extension step of 72 °C for 5 min. 0.5 μ L each PCR product was mixed with 1 μ L GeneScan 500 size standard and 12 μ L water, and heated at 95 °C for 10 min, then immediately put into ice water and kept for 5 min. Microsatellite was analyzed by an ABI PRISM 310 (Perkin-Elmer, ABI Prism) with 6% SLP and 8 mol/L urea as sieving medium under constant voltage 15 kV at 60 °C. Single-stranded microsatellite fragments were detected by LIF and the data were collected and analyzed by GeneScan. MSI was defined as the peak shift in the DNA of the gastric tissue compared with that of the peripheral blood samples. Based on the number of mutated MSI markers, specimens were characterized as high MSI (MSI-H) if they manifested instability at two or more markers, low MSI (MSI-L) if unstable at only one

marker, and microsatellite stable (MSS) if they showed no instability at any marker.

Table 1 Primers of microsatellite markers

Immunohistochemical staining

Immunostaining was performed using the streptavidin-peroxidase (SP) method as previously described by Lan *et al.* Negative control sections were processed in the same manner, replacing the primary antibody with buffered saline. A total of 300 cells were counted in random fields from representative areas and the immunoreactive cells were assessed and expressed as percentages. Samples with *p53* staining in more than 10% were considered positive (the nuclei, staining brown-yellow). However, the *H. pylori* immunostaining was assessed positive as long as the brown-black dotish were stained on the surface of mucosa.

Statistical analysis

The χ^2 test and the Fisher's exact probability test were used to compute the frequencies by SPSS 12.0 for Windows. $P < 0.05$ was considered to be statistically significant.

RESULTS

H. pylori status

Sixty-one of the 108 (56.5%) dyspeptic patients and 30 of the 46 (65.2%) gastric cancer patients showed *H. pylori* infection. None of the normal gastric mucosa was infected with *H. pylori*. The infection rates of gastritis, intestinal metaplasia and tumor samples were largely more than the normal. χ^2 tests also revealed a significant difference in the infection rates between gastritis and carcinoma samples ($P = 0.035$, Table 2).

Table 2 *H. pylori* infection in the normal, gastritis, intestinal metaplasia, and tumor samples

Tissue type	Number of samples	Infection number of <i>H. pylori</i>	Infection rates (%)
Normal	33	0	0
Gastritis	45	38	84.4
Intestinal metaplasia	30	23	76.7
Carcinoma	46	30	65.2

Microsatellite analysis

In the 33 normal and 45 gastritis samples, no microsatellite status shift was detected. One MSI-H and two MSI-L were

Table 3 MSI frequency according to *H pylori* status

MSI frequency	<i>H pylori</i> positive (30)	<i>H pylori</i> negative (16)	P ¹
MSI-H (12)	36.7% (11/30)	6.3% (1/16)	0.035
MSI-L (3)	6.7% (2/30)	6.25 % (1/16)	1.000

samples from dyspeptic patients. Four of the 30 intestinal metaplasia samples showed *p53*-positive immunohistochemical staining, and in the 46 patients with gastric cancer, 20 (43%) *p53*-positive samples were identified. Eight manifested *p53* positivity out of the 11 MSI-H carcinomas with *H pylori* infection and no *p53* expression could be seen in the *H pylori*-negative group. When the carcinoma samples were subdivided into *H pylori*-positive and -negative groups, immunohistochemical staining revealed that the levels of *p53* in *H pylori*-positive samples were higher than those in the negative samples ($P = 0.013$, Tables 4 and 5, Figures 2A and B).

DISCUSSION

Both genetic and environmental factors are crucial in gastric cancer development and progression. *H pylori* infection has been documented as an important risk factor for gastric cancer^[12]. It is fully agreed that the bacterium is effectively able to induce chronic mucosal injury with increased mucosal proliferation that could facilitate malignant transformation^[13-15]. In this study, we detected a high infection rate of *H pylori* in both dyspeptic samples and gastric adenocarcinoma samples, which is consistent with the documents^[16,17]. The reason why infection rate was significantly higher in gastritis samples than that in carcinoma samples is probable that *H pylori* density is lower in atrophic gastritis mucosa and very low in the intestinal metaplasia and in patients with gastric cancer, the degree of atrophic gastritis and intestinal metaplasia is

showing nuclear *p53* immunoreactivity.

higher than in patients without cancer. Another reason may be that different strains contribute differently to the occurrence of gastritis or gastric carcinoma, and it is not adequate to compare *H pylori* infection only by histology.

Epithelial cell proliferation is not carcinogenic in itself. It is likely that *H pylori* promote neoplastic transformation in combination with additional factors. In this study, we detected microsatellite instability and p53 protein expression in accordance with the development from gastric gastritis, intestinal metaplasia to gastric cancer with regard to *H pylori* infection status.

Microsatellites are short sequences of tandem repeats dispersed throughout the mammalian genome. Repeat units range from 1 to 4 bp in length, and the entire sequence of a typical repeat tract is less than 100 bp long^[18,19]. Microsatellite instability is characterized by the insertion or deletion of one or more repeat units, which is caused by a failure of the DNA-MMR system to repair errors that occur during the replication of DNA^[20]. MSI has been regarded as one of the most important indication of MMR defect. In this study, we detected five microsatellite loci sensitive to gastric cancer and found MSI-H in 26% carcinoma samples. The frequency of MSI-H in *H pylori*-positive group was significantly higher than that in *H pylori*-negative group. Among gastritis and intestinal metaplasia samples, the MSI-H frequency was 0% and 3% respectively although with higher *H pylori* infection. MSI existed in intestinal metaplasia samples although the frequency was much lower than that in carcinoma samples. That is to say, MMR defect happened before the malignant transformation of gastric mucous membrane cells. These results together indicated that *H pylori* infection induce tumorigenesis of gastric carcinoma when MMR system of gastric mucosa fails to work functionally.

It has been proved that wild type p53 protein can induce cell apoptosis but the intracellular accumulation of mutant p53 protein can inhibit cell apoptosis and promote cell transformation and proliferation, resulting in carcinogenesis. The overexpression of p53 protein is generally mutant forms, for the half-life of wild-type p53 is very short and p53 protein expression is usually negative in normal tissues. In our present study, p53 expressions were found in 0% of the control, 0% of gastritis samples, 13.3% of intestinal metaplasia samples and 43% gastric carcinomas samples. The detection of p53 expression in intestinal metaplasia indicates that p53 mutation can be an early event in the pathogenesis of gastric cancer. When the carcinomas samples were subdivided into *H pylori*-positive and -negative, and the positive rates of their p53 expression compared, we found a higher expression rate in *H pylori*-positive group than that in *H pylori*-negative group. The carcinoma samples from MSI study were also analyzed to determine whether there was any relationship with p53 protein accumulation. No significant difference was shown to exist between samples in terms of their MSI status and p53 expression. Nevertheless, MSI was found in 11 with *H pylori* infection, 8 manifested p53 positive, this suggests that *H pylori* infection may play a role by inducing p53 gene mutations in those MSI or MMR defect gastric mucosa, but only in certain individuals.

In conclusion, the association between *H pylori* infection, MSI and p53 mutations observed in intestinal metaplasia and gastric carcinoma samples leads us to hypothesize that *H pylori* affect p53 pattern in gastric mucosa when MMR system fails to work. Mutations of the p53 gene seem to be an early event in gastric carcinogenesis.

Abstract

AIM: Sensitization most likely plays an important role in chronic pain disorders, and such sensitization can be mimicked by experimental acid perfusion of the esophagus. The current study systematically investigated the sensory and motor responses of the esophagus to controlled mechanical stimuli before and after sensitization.

METHODS: Thirty healthy subjects were included. Distension of the distal esophagus with a balloon was performed before and after perfusion with 0.1 mol/L hydrochloric acid for 30 min. An impedance planimetry system was used to measure cross-sectional area, volume, pressure, and tension during the distensions. A new model allowed evaluation of the phasic contractions by the tension during contractions as a function of the initial muscle length before the contraction (comparable to the Frank-Starling law for the heart). Length-tension diagrams were used to evaluate the muscle tone before and after relaxation of the smooth muscle with butylscopolamine.

RESULTS: The sensitization resulted in allodynia and hyperalgesia to the distension volumes, and the degree of sensitization was related to the infused volume of acid. Furthermore, a nearly 50% increase in the evoked referred pain was seen after sensitization. The mechanical analysis demonstrated hyper-reactivity of the esophagus following acid perfusion, with an increased number and force of the phasic contractions, but the muscle tone did not change.

CONCLUSION: Acid perfusion of the esophagus sensitizes

INTRODUCTION

Pain arising from the esophagus is very common clinically and in the normal population, but the mechanisms involved are poorly understood^[1]. Due to the difficulties in characterizing clinical pain, human experimental models have been developed to investigate the pain pathways in a standardized way in volunteers and patients. These models provide the possibility to control the stimulus parameters and to assess the response quantitatively^[2,3]. Furthermore, the nociceptive system can be sensitized in the laboratory, resulting in allodynia (painful sensations to stimuli that are not normally painful), hyperalgesia (increased sensation to stimuli that are normally painful) and increase in the evoked referred pain area^[4]. The sensitization most likely plays an important role in chronic visceral pain disorders^[3,5]. Experimental chemical stimulation with acid has been used to sensitize the esophagus^[6-8]. However, the literature has not been consistent with respect to the evoked mechanical hyperalgesia, probably due to methodological problems related to the stimulus modalities used^[9].

Distension of the gut is a physiologic stimulus, and consequently most researchers have used experimental balloon distension models to investigate basic pain mechanisms in the gastrointestinal (GI) tract^[10]. Most previous studies have used volume and pressure as proxies of the mechanical deformation and force applied to the gut wall^[10]. However, the mechanical parameters tension, stress and strain are of more value than pressure and volume when studying the esophagus, as these parameters provide more valid information about the mechanical forces and deformation (elastic properties) during distension^[11-15]. Furthermore, the muscle function is better evaluated when

the forces and tensions can be quantitated, rather than measuring the luminal pressure^[16-18]. However, the sensory-motor responses of the organ during a mechanical stimulus cannot be evaluated independently of the mechanical forces and deformation. Thus, phasic contractions and changes in muscle tone can influence the sensory response themselves^[18], and in diseases of the esophagus hyper-reactivity may give major contribution to the symptoms^[19,20]. Methods to estimate and control the mechanical response will thus allow better explanations of the effects on the sensory-motor response during the mechanical stimulations with and without sensitization of the pain system.

Systematic investigation of both the sensory and motor responses to controlled mechanical stimuli following experimental sensitization of the esophagus has to the best of our knowledge never been investigated. The aims of the current study were to (1) investigate the effect on sensitization of the esophagus with acid on the sensory response to controlled mechanical stimulation; (2) calculate the evoked referred pain areas to the mechanical stimulation before and after sensitization as a proxy for the central neuronal changes; and (3) evaluate the motor response to the sensitization by a new *in vivo* method evaluating the change in tension during contraction (the afterload tension) as function of the initial muscle length before the contraction (the preload radius).

MATERIALS AND METHODS

Thirty healthy subjects, 14 males and 16 females, mean age 36.5 ± 12.9 years, were included. The subjects did not suffer from any kind of chronic pain, GI symptoms or disturbances in personality. All subjects gave informed written and verbal consent prior to the study. The protocol was approved by the local ethics committee and performed in accordance with the Helsinki Declaration.

Mechanical stimulations

The impedance planimetry system including the principle for measurement of the cross-sectional area (CSA) has been described in detail previously^[18,21,22]. The 70-cm long probe with a diameter of 4.5 mm had a cylindrical large-sized bag near the tip. The bag was 40 mm in length and was made of 35- μ m thick, non-conducting polyester urethane. A side-hole for acid perfusion was placed 2 cm above the bag. The probe had a four-electrode impedance planimetry system with four sets of ring electrodes inside the bag (GMC Aps, Hornslet, Denmark). The bag could be inflated with electrically conducting fluid (0.09% saline) through a pair of infusion channels. The change in impedance of the fluid during distension of the bag reflects the change in the CSA^[18]. The infusion channels were connected to an infusion pump (Type 111, Ole Dich Instrument Makers, Hvidovre, Denmark) that was able to fill or empty the bag continuously. The bag could be inflated to a CSA of approximately 2 000 mm² (diameter equal to 50 mm) without stretching the wall of the bag. The fluid in the connecting tube between the pump and the probe was heated to 37 °C. A safety valve was connected with the pump allowing the subjects to stop the infusion at any time. The system was calibrated before

the probe was inserted into the esophagus. Non-linearity of the CSA was corrected for in the whole measurement range by means of a software feature. The pressure was measured by means of a low-compliance perfusion system connected to external transducers.

Sensory ratings

The sensory intensity was assessed continuously during the experiment using an electronic visual analog scale (VAS, GMC, Hornslet, Denmark). The volunteers were trained in assessment of sensation to deep pressure at the muscles on the right forearm several times before the visceral stimuli were given. A scale for both non-painful and painful sensations was used^[3]. The intensities of the *non-painful* sensations were scored with the following descriptors added to facilitate the scoring: 1 = vague perception of mild sensation; 2 = definite perception of mild sensation; 3 = vague perception of moderate sensation; 4 = definite perception of moderate perception; 5 = the pain threshold. For the *painful* sensations the patients used the scale from 5 to 10 anchored at 5 = pain threshold to 10 = unbearable pain, with the following anchor words: 6 = slight pain; 7 = moderate pain; 8 = medium pain intensity; 9 = intense pain; and 10 = unbearable pain. This part of the scale was red to clearly separate the non-painful and painful range of sensations. The first three distensions were used to practice the sensory ratings^[3]. The subjects were carefully instructed to score the evoked chest pain and to differentiate this from the unpleasantness in the throat caused by traction due to the distension-evoked esophageal contractions. The scale has previously been shown to be robust, and to discriminate sensations in the esophagus^[8,11,12], and the small and large intestine^[13,14,23,24].

After the last distension before butylscopolamine injection (see below) the volunteers were asked about referred pain to the chest or other remote areas evoked by the distensions at moderate pain (VAS = 7). If present the referred pain area was marked with a pen and transferred to a transparent paper. Later the area was digitized (ACECAD D900+ Digitizer, Taiwan) and the size calculated (Sigma-Scan, Jandel Scientific, Canada).

Protocol

The subjects fasted for at least 4 h prior to the experiment. Intubation was performed through the mouth. The bag was inserted into the stomach and then retracted to identify the location of the lower esophageal sphincter as a zone of high resting pressure that decreased with swallowing. Then the bag was placed 7 cm proximal to the sphincter and the probe was taped to the cheek. The subjects were asked to lie down with the head tilted by 30° after the placement of the bag. The experiment was performed in that position after 30 min of rest.

Three bag distension stimuli with a constant infusion rate of 25 mL/min were done to precondition the tissue and to obtain repeatable sensory data^[3,13,15,23,24]. The inter-stimulus interval was 60 s for all experiments. When the subjects reported slight pain (6 on the VAS), the bag was deflated using the same flow rate as during the inflation until it was empty. After these stimuli, two more distensions

were done at the same infusion rate. When moderate pain intensity (7 on the VAS) was reached, the pump was reversed and the bag deflated. Then 20 mg butylscopolamine was given intravenously and after abolishment of the contractile activity the two last distensions were repeated.

After the first series of mechanical stimuli, the participants underwent a modified acid perfusion test^[25]. Hence, during a perfusion channel in the catheter 0.1 mol/L hydrochloric acid was infused at a rate of 7 mL/min for 30 min. If the evoked sensations due to the acid stimulation were reported unpleasant (rated ≥ 5 on the VAS), the perfusion was stopped for 30 s and the subjects were allowed to swallow 10 mL water. In case the perfusion was too unpleasant for the subjects, it was stopped and the amount of infused acid was measured.

After the acid perfusion, bag distensions before and after butylscopolamine were given using the same protocol as described above, before acid perfusion.

During all stimuli autonomic reactions were monitored and displayed on-screen using a Biopac MP100 system (Biopac Systems Inc., Santa Barbara, CA, USA) including sensors and recording system for electrocardiogram, pulse rate and respiration.

Data analysis

The circumferential wall tension was calculated according to the law of Laplace for cylindrical structures as

$$T = \Delta P r$$

where T is the circumferential wall tension, r is the balloon radius, and ΔP is the transmural pressure. The geometry of the esophagus during distension can be considered circular except at very low pressure levels^[18]. Therefore, the radius was determined as

$$r = \sqrt{\frac{\text{CSA}}{\pi}}$$

All subjects stated that they more reliably rated the sensory intensity at the second distension compared to the first. Therefore, only data from the second distension were used in the analysis. After butylscopolamine the first distension was used as the maximal decrease in contractile activity was seen at the first few minutes after the injection.

As criteria for valid contractions before and after acid perfusion a pressure amplitude above 2.5 kPa was used.

In a representative sample of 10 subjects (5 males and 5 females, mean age 36.1 ± 14.3 years) the change in tension during individual distension-induced contractions (afterload tension) was computed and expressed as function of the radius immediately before the contractions (preload radius). The diagrams were made before and after perfusion of the distal esophagus with a mean of 123 mL hydrochloric acid. An example from an individual subject is shown in Figure 1. The data were fitted with a third order polynomial. These diagrams correspond to the well-known heart ventricular function curves in terms of the ventricular stroke working as function of the mean atrial length. Such curves demonstrate the Frank-Starling mechanism of the heart now adapted to the esophagus-see appendix.

The pressure and CSA data obtained between the evoked contractions (without infusion of butylscopolamine) were

used to compute the total tonic tension, whereas the tracings during butylscopolamine infusion were used for calculation of the passive tension. The active tonic tension was obtained by subtracting the passive tension from the total tonic tension^[14,18].

Figure 1 Raw data in a typical subject showing the change in pressure during bag-distension-induced contractions. The change in tension during maximal distension-induced contractions (afterload tension) was computed at the open triangles and expressed as function of the radius immediately before the contractions marked with solid triangles (preload radius). The radius was calculated on the basis of the CSA measured simultaneously. For details regarding the calculations see Methods section.

Statistical analysis

The results are expressed as mean \pm SD unless otherwise indicated. Continuous data were analyzed using t -tests. For multiple comparisons, two-way analysis of variance (ANOVA) was used with the factors: (1) before and after acid and (2) the different VAS levels. $P < 0.05$ was considered significant. The software package SPSS v. 10.0 was used for the statistical analysis.

RESULTS

Mechanical stimuli before and after acid

All subjects completed the experiment. After the preconditioning stimuli, the curve characteristics and sensory ratings were reproducible in all subjects. The stimulus-response curves after preconditioning the tissue are shown in Figure 2 for the infused volume, CSA, pressure, and tension. The sensation intensity was approximately linear as functions of all four stimulation variables. The sensory rating increased after acid, when expressed as a function of the volume ($F = 4.75$, $P = 0.03$), whereas no differences were found for the CSA ($F = 1.0$, $P = 0.3$), pressure ($F = 0.7$, $P = 0.4$) and tension ($F = 1.2$, $P = 0.3$). The curves during butylscopolamine infusion showed the same pattern as described above, before and after acid perfusion (data not shown).

The acid infusion resulted in a more hyper-reactive esophagus as the number of contractions with pressure amplitudes above 2.5 kPa during the distensions increased from 2.9 ± 1.5 to 3.5 ± 1.5 after acid perfusion ($P = 0.03$).

The change in tension during bag-distension-induced contractions (the afterload tension) was plotted as a function of the preload radius for 10 representative subjects (Figure 3). No contractions were observed at radii below 5 mm. Before acid infusion the afterload tension increased until a plateau was reached. This corresponds to the "Frank-Starling mechanism" relating to the less interdigitation of

Figure 2 Sensory response to bag distension of the distal esophagus expressed as functions of the volume, CSA, pressure and tension. The curves were drawn before (\square) and after (\blacksquare) perfusion of the distal esophagus with acid. The

sensory response increased after acid perfusion when expressed as a function of the volume.

Figure 3 Tension during bag-distension-induced contractions (the afterload tension) plotted as functions of the radius immediately before the contractions (the preload radius) as shown in Figure 1. Five to eight datasets were computed

during the distension for 10 representative subjects. Data calculated at painful sensations were all above preload radii of 11.5 mm and are shown as open markings.

muscle filaments when the muscles are overstretched. Painful sensations ($VAS \geq 5$) were experienced at preload radii higher than 11.5 mm. After the acid infusion higher afterload tensions were observed at both low and high radii as compared to baseline, and there was a tendency to more spreading of the data as some individuals obtained very high afterload tensions. The painful sensations were also only evoked at radii higher than 11.5 mm.

The total, passive and active tonic tensions before and after acid infusion are shown in Figure 4. There was no difference in curve shape between before and after acid, indicating that acid infusion does not change esophageal muscle tone.

High and low acid responders

The subjects tolerated a mean of 101 ± 53 mL of acid. To see if the sensory response was related to the amount of acid infused, the subjects were divided into two groups. One group could accept 100-200 mL of acid ($n = 17$) and

the other group, less than 100 mL of acid ($n = 13$). There was a relation between the evoked sensitization and the acid load as those who accepted more than 100 mL were sensitized to volume ($F = 5.3$, $P = 0.02$), pressure ($F = 5.5$, $P = 0.02$) and tension ($F = 6.0$, $P = 0.01$), but not to CSA ($F = 0.9$, $P = 0.3$). The group tolerating less than 100 mL were not sensitized to neither volume ($F = 0.3$, $P = 0.6$), pressure ($F = 0.6$, $P = 0.4$), tension ($F = 0.8$, $P = 0.4$) nor CSA ($F < 0.01$, $P = 0.99$).

Referred pain areas

All subjects reported referred pain to the stimulations. The referred pain areas to mechanical stimuli at moderate pain are shown in Figure 5. Additionally one male and two females had referred pain in the back. The referred pain areas increased from 27.9 ± 29.3 cm² before acid to 41.4 ± 39.0 cm² after acid ($P = 0.047$), although the volume was smaller at the distensions after acid.

Figure 4 Plots of the total tonic (top), the passive (dotted) and the active (thin) tonic tensions as functions of radius before and after acid infusion. For explanations

see text. Acid did not change the curve shapes. Hence, esophageal muscle tone was not affected by the acid infusion.

Figure 5 A schematic illustration of the referred pain areas drawn by the subjects following mechanical stimuli of the esophagus before and after perfusion with acid. The stimuli were given with an intensity corresponding to moderate pain. The chest was divided into eight areas by a horizontal line 5 cm above the xiphoid process, a vertical midline and two vertical lines 5 cm lateral to the midline. The numbers on the figure refer to the number of subjects reporting referred pain to that particular region of the chest. The referred pain area increased following the sensitization with acid.

DISCUSSION

The current experiment used controlled ramp distensions and preconditioning to evoke experimental pain in the esophagus in 30 subjects. The sensory response was assessed before and after sensitization of the lower esophagus by acid perfusion. The sensory rating increased after acid when expressed as a function of the volume, and the degree of sensitization was related to the infused volume of acid. Furthermore, an increase in referred pain to a standardized distension was seen reflecting activation of central facilitatory pain mechanisms. The mechanical analysis demonstrated hyper-reactivity of the esophagus following acid perfusion, with an increased number and force of the phasic contractions, but the muscle tone did not change. This illustrates that acid perfusion not only sensitizes the sensory pathways, but also facilitates motor reflexes.

Sensory response to sensitization with acid

Chronic pain is associated with modifications of the central nervous system such as central sensitization^[4]. Animal experiments have demonstrated neuronal changes such as increased spontaneous activity, decreased firing threshold, and expansion of the receptive fields of spinal neurons subjected to activation and/or experimental sensitization

of their peripheral afferents^[5,26,27]. Sensitization of the human esophagus with acid is a valuable experimental pain model, as the evoked allodynia, hyperalgesia and referred pain patterns reflect sensitization of the nervous system and can be studied systematically^[3]. Hence, decreased thresholds to physiologic stimuli seem to contribute to many of the symptoms reported by patients with inflammatory and functional diseases in the gut^[28,29]. Thus, a combination of mechanical stimulation and sensitization of the esophagus may mimic the widespread pain and other sensations reported by patients with reflux disease and unexplained chest pain^[16,30,31].

Acid-sensitive fibers have been demonstrated in animal studies, and mucosal afferents are often sensitive to different chemical stimuli^[32,33]. Increased responses to mechanical, electrical and thermal stimuli after acid perfusion of the esophagus have also been demonstrated in human beings^[6-9,34], although previous studies using latex balloons were not consistent. This can be due to methodological problems using latex balloons, where the distension data must be corrected for the intrinsic mechanical properties of the balloons and for the uncontrollable deformation in longitudinal direction^[9,16]. Non-compliant polyester urethane bags overcome these problems. The effect of preconditioning the tissue by several distensions until the stress-strain relationship becomes reproducible has also not been considered in most previous studies^[3,18]. Different modifications of the acid perfusion test have been used as a chemogenic stimulus by several authors^[6,7,9,35,36]. When the current material was divided into those who tolerated below and above 100 mL of acid, significant increased sensation to the mechanical stimulus was only seen in the high acid group. Hence, it is recommended to use volumes higher than 100 mL in future studies.

The present study demonstrated increased sensation to the infused bag volume, but not to pressure and tension. The intraluminal pressure and tension are highly dependent of the contractile force state of the esophageal muscles, and hence not as reliable parameters as the deformation^[18]. Despite the decrease in volume after acid infusion, the CSA did not decrease significantly. Thus it seems that the bag conforms to a shape where it is shorter after acid infusion. Such a shape change is likely caused by changes in the contractile activity in the acid exposed area and even in regions affected by nerve-mediated reflex responses.

Secondary contractions and muscle hyper-responsiveness can be evoked by acid in the distal esophagus due to reflex loops between mucosal afferents and the motor system^[37-40]. After acid perfusion increased force of the secondary contractions was evoked by the distension in the non-painful and painful range. Animal studies have shown that in contrast to the somatic system-afferents encoding both non-painful and painful sensations can sensitize in the viscera^[41]. The current observations in the human esophagus are in line with these studies, as the sensitization of afferents encoding conscious sensations to distension seems to change the contractile activity in the muscle via local and/or central reflexes^[42,43]. However, the curve form changed mostly in the pain range (to the right of the vertical line in Figure 3) and hence there seems to be a higher effect of sensitization on the painful sensations. The Frank-Starling mechanism predicts a decrease in contractile activity when the muscle is overstretched corresponding to less optimal interdigitation of actin and myosin filaments. In the current experiment the baseline curve form showed no decrease in afterload tension at maximal distension. The fact that the afterload tensions were higher after acid infusion indicates that bag distension itself does not activate the muscle maximally.

Another manifestation of the acid perfusion was the increased referred pain area to the mechanical stimulation, although the bag volume was lower after the perfusion. Enlarged referred pain areas is also a characteristic in clinical gut disorders^[44-46], and are very similar to what is observed in patients suffering from chronic musculoskeletal pain^[47]. Previously, we have shown that sensitization of the esophagus results in increased referred pain areas^[8], a finding which was confirmed in the current study. The mechanism is of central origin^[4], which was also shown in previous papers using neurophysiological assessment of the spinal and supraspinal pain response after acid perfusion of the esophagus^[8,48].

Mechanical and motor responses to sensitization with acid

The sensitization resulted not only in allodynia and hyperalgesia to the distension volumes, but the esophagus also exhibited hyper-reactivity as illustrated by the increased number of contractions after the acid perfusion. Such hyper-reactivity has also been seen in animal studies^[37,38]. The contractions were also stronger to a given preload radius. However, the acid infusion did not change the total tonic tension, the passive tension and the active tonic tensions (Figure 4). Hence, the hyper-reactivity only accounts for phasic contractions, not for tone in the esophageal body. Previously, Sifrim *et al.*^[49], showed that acid reflux into the esophagus stimulated tone in the esophageal body. However, simultaneous distension seemed to inhibit the acid induced tone. These issues obviously need further investigations.

The preload radius where contractions were evoked by the painful stimuli (VAS = 5 and higher) did not change after acid (vertical line in Figure 2). This corresponds with the "strain theory", *i.e.*, that the mechanoreceptors are activated by circumferential stretch independent of the contractile state of the muscles^[12,13,15,50]. The receptors encoding distension of the gut are mainly believed to be localized in the muscle and nerve layers, where they are not

exposed to acid^[33,43]. Hence, the contractions are probably initiated by reflex loops between strain-sensitive mechanosensitive afferents localized in the muscle layers and the smooth muscle cells. Whether such reflexes are local or mediated via central (vagal and/or spinal) afferents cannot be concluded from the current data^[40,42,43]. We believe, however, that a central component is important as the contractions were more powerful after perfusion with acid. The acid perfusion may thus result in sensitization of mucosal afferents as well as central hyperexcitability^[8,43,48]. As the enteric nervous system is partly under inhibitory central control^[51], the sensitization may result in dampening of the central control. This mechanism is expedient as such reflexes will tend to move acid from reflux towards the stomach where it is harmless.

Modeling diseases of the esophagus

Sensation and pain detection thresholds to distension, electrical and acid stimuli of the esophagus were found to be lower in patients with non-cardiac chest pain compared to healthy subjects^[6,7,52,53]. Such hypersensitivity can be mimicked in the current model. Furthermore, the muscles of the esophagus are hyper-reactive in patients with unexplained chest pain^[19,54-56]. In the present model the acid perfusion evoked an increased number of contractions, which were characterized by a higher force. Thus diseases characterized by primary and secondary motor disorders can also be mimicked experimentally, and in patients the preload-afterload plots will be valuable for description of the aberrant motor function. The model can therefore be used to study abnormal sensory-motor mechanisms in visceral organs, and may also prove useful in pharmacological studies with drugs targeted to treat patients with unexplained chest pain and motor disorders of the esophagus.

Appendix

The preload is considered in this study to be initial muscle length (radius) preceding the contraction during the distension, whereas the afterload is evaluated as the active tension during the contraction. In cardiac physiology the preload is usually considered to be the end-diastolic pressure or radius and the afterload is considered to be the arterial pressure during the systole. The explanation of the Frank-Starling mechanism is that when an extra amount of blood flows into the ventricles, the cardiac muscle itself is stretched to greater length. This in turn causes the muscle to contract with increased force because the actin and myosin filaments then are brought to a more nearly optimal degree of interdigitation for force generation. In cardiac physiology the importance of the concept of preload and afterload is that in many abnormal functional states of the heart and circulation, the pressure during filling of the ventricle or the arterial pressure against which the ventricle must contract, or both, are severely altered from the normal. The Frank-Starling mechanism has been important in the understanding of drugs with effect on the myocardial function, and transferring this concept to esophageal physiology, the development in the current model will have interest for evaluation of normal esophageal physiology and in the pathophysiology of esophageal disorders.

Abstract

AIM: Delayed gastric emptying and an enlarged fasting gastric antrum are common findings in functional dyspepsia but their relationship with gastrointestinal (GI), and the frequently associated extra-GI symptoms remains unclear. This study evaluated the relationship between GI and extra-GI symptoms, fasting antral volume and delayed gastric emptying in functional dyspepsia.

METHODS: In 108 functional dyspeptic patients antral volume and gastric emptying were assessed with ultrasonography (US). Symptoms were assessed with standardized questionnaire. The association of symptoms and fasting antral volume with delayed gastric emptying was estimated with logistic regression analysis.

RESULTS: Delayed gastric emptying was detected in 39.8% of the patients. Postprandial drowsiness (AOR 11.25; 95%CI 2.75-45.93), nausea (AOR 3.51; 95%CI 1.19-10.32), fasting antral volume (AOR 1.93; 95%CI 1.22-3.05), were significantly associated with delayed gastric emptying. Symptoms, mainly the extra-GI ones as postprandial drowsiness and nausea, combined with fasting antral volume predicted the modality of gastric emptying with a sensitivity and specificity of 78%.

CONCLUSION: In functional dyspeptic patients, (1) an analysis of fasting antral volume and of symptoms can offer valuable indication on the modality of gastric emptying, and (2) it seems appropriate to inquire on postprandial drowsiness that showed the best correlation with delayed gastric emptying.

INTRODUCTION

The term dyspepsia is widely used in clinical practice to describe symptoms arising from the upper abdomen and, depending on the definition, its prevalence has been reported to vary from 20% to 40%^[1-3] in the adult population. Although dyspeptic symptoms may arise from several pathological conditions, more than 70%^[4-8] of patients, do not have definite structural or biochemical alterations^[9-11] and, based on the Rome Diagnostic Criteria functional dyspepsia (FD) is made^[12,13]. In the assumption that symptoms may predict specific underlying pathophysiology of FD it has been suggested that patients be subdivided in accordance with symptom clusters^[12] such as ulcer-like and dysmotility-like dyspepsia or, more recently, with the predominant symptom^[13]. Several studies have looked for possible correlation between symptoms and pathophysiological abnormalities such as *Helicobacter pylori* infection, visceral hypersensitivity and abnormal motor function of the stomach. Up to 40% of patients with FD evaluated in referral centers have delayed gastric emptying^[14] and 40% impaired postprandial relaxation of the proximal stomach^[15]. So far however, there is little evidence^[16] that gastric motor abnormalities correlate unequivocally with different symptom clusters^[17-19] and not even in those patients with dysmotility-like dyspepsia, referring symptoms suggestive of an abnormal motor function of the stomach such as postprandial fullness, nausea, early satiety and vomiting. Female gender, and, severe and predominant, postprandial fullness and vomiting have been reported to be associated with delayed gastric emptying^[20], a finding not confirmed in a subsequent study^[21] performed in a large cohort of patients with dysmotility-functional and organic (i.e., diabetic) dyspepsia. Drowsiness is a subjective experience often reported after food ingestion and it has been shown that solid meal results in a decreased sleep onset latency in healthy volunteers^[22].

Patients with functional dyspepsia complain of several gastrointestinal (GI) and extra-GI symptoms^[23], some of the latter like drowsiness^[24,25] and headache^[24] are related to meal ingestion. It is not known, however, whether postprandial drowsiness and other extra-GI symptoms have any relationship with gastric functions.

An enlarged fasting antral volume assessed by ultrasonography (US)^[26,27] is an additional finding in patients with FD but its relationship, if any, with delayed gastric emptying is not known.

We, therefore aimed to evaluate in functional dyspeptic patients whether and which symptoms either GI or extra-GI are related to, and might predict, delayed gastric emptying of a regular meal. Additional aim was to assess whether the US measurement of basal antral volume may predict the modality of gastric emptying.

MATERIALS AND METHODS

Two hundred and ten consecutive patients referring symptoms of dyspepsia (140 F; age 42.8 ± 12.5 years, mean \pm SD) referred to the gastroenterology outpatient clinic were assessed. Functional dyspepsia was defined as persistent or recurrent pain or discomfort centered in the upper abdomen for at least 3 mo in the preceding 12 mo, in the absence of any known organic disease that is likely to explain the symptoms^[12,13] and no evidence that dyspeptic symptoms were exclusively relieved by defecation or associated with the onset of a change in stool frequency or stool form^[13].

Organic abnormalities, psychiatric illnesses, history of alcohol abuse, use of NSAIDs, steroids or drugs affecting gastric functions, previous surgery of the GI tract (except appendectomy and cholecystectomy) and systemic disorders were ruled out by history, clinical examination, biochemical investigations, upper GI endoscopy, and transabdominal US. Dyspeptic patients with Rome diagnostic criteria of irritable bowel syndrome (IBS) and/or referring heartburn and/or regurgitation as predominant or frequent symptoms, were excluded from the study.

Epigastric pain and upper abdominal discomfort were graded 0-4 according to its influence on patient's daily activities: 0, absent; 1, mild (present but easily bearable if distracted by usual activities); 2, moderate (bearable but not influencing usual activities); 3, relevant (influencing usual activities); 4, severe (interruption of usual activities).

Patients were enrolled into the study if symptomatic at the time of evaluation with a symptom score value of ≥ 2 for epigastric pain or discomfort.

Overall 102 patients (67 F, age 46 ± 13.2 years, mean \pm SD) were excluded from the study because of the following diagnosis: gastroesophageal reflux disease, 52; IBS, 15; peptic ulcer, 14; migraine, 16; psychiatric disorders, 3; celiac disease, 2.

One hundred and eight patients with functional dyspepsia entered the study (73 F, age 42 ± 12.5 years, mean \pm SD). Twenty-eight healthy asymptomatic volunteers (10 F, mean age 31 ± 5.5 years, mean \pm SD) were also investigated. None of them had GI disorders or symptoms or were taking medications of any kind. None had been previously submitted to surgery of the GI tract.

Informed consent was obtained from each subject and the study protocol was approved by the local ethics committee.

Analysis of symptoms

Consecutive patients were interviewed with a standardized questionnaire^[28] made of 50 items, inquiring on demography (5 items), daily habits (10 items) that included meal timing

and composition, alcohol consumption, smoking and sleep, past medical history (3 items), GI symptoms (15 items), gastroesophageal symptoms (4 items), bowel pattern (7 items), and somatic extra-GI symptoms that included 5 items as indicated in a previously published study^[23]. Postprandial drowsiness, defined as a state of impaired awareness associated with a desire or inclination to sleep^[29] was also included in the questionnaire since this meal-related symptom has been reported^[2] and confirmed by personal observations, to be bothersome in dyspeptic patients. Dyspeptic symptoms were defined according to Rome criteria^[12,13].

Frequency and time relationship with meal assumption was assessed for each investigated symptom and, relationship of drowsiness with sleep disturbances was specifically looked for.

In addition patients were requested to refer any other symptom they considered to be bothersome and relating to meal ingestion.

Assessment of gastric emptying

Gastric emptying was evaluated with US according to previously validated and standardized methods^[30-34]. Gastric antral volume was evaluated by US according to previously published methods^[33,34] with a 4 MHz linear probe and 3.5 MHz convex probe (Toshiba SAL 38B, Tosbee, Toshiba, Japan).

All drugs affecting the GI tract were discontinued at least 3 d before the gastric emptying studies. Subjects refrained from smoking for a 12-h period preceding, and during, the examination. After an overnight fast the subjects ate an ordinary standard solid 1 050 kcal meal containing 140 g bread, 70 g cheese, 80 g ham, (50% carbohydrates, 25% lipids, 25% proteins), 3.5 g alimentary fibers, 250 mL of water. The time of meal ingestion did not exceed 30 min (range 15-30 min). Gastric antral US measurements were performed by the same operator with the subjects standing in the upright position, in fasting condition, immediately, and at 30 and 60 min after the end of the meal ingestion, and at 60-min intervals thereafter over a total period of 300 min. In the intervals between measurements subjects could move freely.

Delayed gastric emptying was defined as the final antral volume (i.e., gastric antral volume at 300 min after meal ingestion) exceeding the mean value plus 2SDs of the 28 healthy volunteers (31 mL).

Statistical analysis

Descriptive statistics as median values and interquartile ranges were calculated. Box-plots^[35] were used for inter-group comparison of antral volume distributions. The Mann-Whitney test^[35] was used to compare the median values of antral volume between healthy controls, FD patients with delayed and those with normal gastric emptying.

Sensitivity and specificity of each symptom for three different threshold levels of fasting antral volume were calculated. Odds ratios (OR) were also calculated as a synthetic measure of both sensitivity and specificity^[35].

Logistic regression analysis^[36] was then applied to estimate crude and adjusted odds-ratios (AOR) and 95% confidence intervals (95%CI) of having delayed gastric emptying for

each symptom, fasting antral volume, gender, age, and body mass index (BMI). In addition, we reported results from two multivariate logistic regression analyses, respectively, without and with fasting antral volume, obtained through a backward selection strategy having excluded factors with a log-likelihood P -value >0.20 ^[35]. Two-sided P values were defined statistically significant when $P < 0.05$, and marginally significant when $0.05 < P < 0.2$.

Estimated coefficients from multivariate logistic regression were used to calculate the probability of having (or not having) delayed gastric emptying. Through these probabilities, it is possible to calculate sensitivity, specificity, and the percentage of patients correctly classified^[36]. All the analyses were performed using STATA release 5.0^[37].

RESULTS

Figure 1 shows antral volume values before, immediately, and in the 300 min after meal ingestion in normal controls and in functional dyspeptic patients with normal and delayed gastric emptying.

In healthy volunteers, the mean gastric antral volume was 13 ± 5 mL in the fasting state and reached its maximal value at the end of meal ingestion (67 ± 24 mL), then decreased almost linearly to reach 18 ± 6.5 mL at the end of the study. In FD patients, the mean fasting antral volume was 14 ± 8 mL (ns *vs* controls) and reached its maximal value at the end of the meal (53 ± 21 mL) (ns *vs* controls), then decreased to reach the final value of 30 ± 16 mL ($P < 0.0001$ *vs* controls).

Gastric emptying was delayed in 43 (39.8%) patients (28 F; mean age 41.4 years; range 23–64 years) and their final AV was 46 ± 11 mL (Figure 1). The mean fasting AV (17 ± 10 mL) was larger in patients with delayed gastric emptying than in those with normal gastric emptying (12 ± 5 mL, $P = 0.005$, Figure 1). The mean delta variation between fasting and final antral volume was 29 ± 14 mL in

dyspeptic patients with delayed gastric emptying and 7 ± 8 mL in those with normal gastric emptying ($P < 0.0001$).

Frequency, as well as sensitivity, specificity, and crude OR in predicting delayed gastric emptying of each of the GI and extra-GI symptoms reported by at least eight patients as well as fasting antral volume are reported in Table 1. Delayed gastric emptying was not related to age (OR = 1.03; $P = 0.84$), gender (OR = 0.7; $P = 0.4$), while there was a marginally significant inverse association, with BMI (OR = 0.89 per 1 kg/m² increase; $P = 0.06$, data not shown in Table 1).

None of the patients with post-prandial drowsiness complained of sleeplessness.

Figure 1 Box-and-whiskers plots of gastric antral volume before (fasting), immediately (0) at 30- and 60-min intervals, after the end of the ingestion of a standard meal, in controls (left) and in dyspeptic patients with normal (middle) and delayed (right) gastric emptying. The boxes at each time unit extend from the 25th percentile ($X_{[25]}$) to the 75th percentile ($X_{[75]}$), i.e., the interquartile range (IQ); the lines inside the boxes represent the median values. The line emerging from the boxes (i.e., the "whiskers") extend to the upper and lower adjacent values. The upper adjacent value is defined as the largest data point $\leq X_{[75]} + 1.5 \times \text{IQ}$, and the lower adjacent value is defined as the smallest data point $\geq X_{[25]} - 1.5 \times \text{IQ}$. Observed values more extreme than the adjacent values, if any, are individually plotted (circles). The widths of the boxes are proportional to the number of observations available at each time unit.

Table 1 Prevalence, sensitivity and specificity and crude OR for delayed gastric emptying of symptoms and of fasting antral volume at three cut-off levels

	Prevalence %	Sensitivity %	Specificity %	OR
Pain centered in the upper abdomen	45.4	58.1	63.1	2.37
Discomfort centered in the upper abdomen	79.6	81.4	21.5	1.20
Upper abdominal bloating	84.3	88.4	18.5	1.72
Fullness	68.5	62.8	27.7	0.64
Early satiety	45.4	48.8	56.9	1.26
Nausea	42.6	53.5	64.6	2.10
Heartburn	26.9	34.9	78.5	1.95
Epigastric burning	11.1	9.3	87.7	0.73
Belching	74	74.4	26.1	1.03
Vomiting	27.8	20.9	67.7	0.55
Acid regurgitation	19.4	23.3	83	1.48
Drowsiness	16.7	32.6	93.9	7.36
Headache	41.7	46.5	61.5	1.39
Palpitation	7.4	6.9	92.3	0.90
Fasting antral volume (mL)				
<10 mL (reference group)	33.3	18.6	43	1.09
10–14 mL	34.3	39.5	30.8	2.97
>15 mL	32.4	41.9	26.2	3.71

Table 2 AOR with 95%CI of having delayed gastric emptying on the basis of symptoms and fasting antral volume (FAV)

	Without FAV and BMI		With FAV and BMI	
	AOR	95%CI	AOR	95%CI
Pain centered in the upper abdomen	3.74	1.34-10.41	2.78	0.92-8.41
Nausea	2.92	1.15-7.44	3.51	1.19-10.32
Postprandial fullness	0.41	0.14-1.14	0.27	0.08-0.84
Discomfort centered in the upper abdomen	3.42	0.88-13.25	4.59	0.99-21.20
Vomiting	0.44	0.15-1.31	0.32	0.09-1.11
Heartburn	-	-	2.31	0.80-6.71
Drowsiness	9.37	2.47-35.45	11.25	2.75-45.93
BMI	-	-	0.89	0.77-1.02
Fasting antral volume ¹	-	-	1.93	1.22-3.05

FAV: Fasting antral volume; AOR: adjusted odds-ratio. ¹AOR estimated per 5 mL increase (e.g., a FAV of 20 mL vs 15 mL).

The AOR for symptoms with or without fasting antral volume and BMI included in the multivariate analyses are shown in Table 2. Not taking into consideration fasting antral volume and BMI in the multivariate analyses, upper abdominal pain, nausea, and drowsiness showed a statistically significant association, whereas upper discomfort showed only a marginally significant association with delayed gastric emptying. Post-prandial fullness or vomiting showed a marginally significant association with normal gastric emptying. Including fasting antral volume and BMI in the multivariate analyses, nausea and drowsiness were highly significantly associated with delayed gastric emptying, while upper abdominal pain, upper abdominal discomfort, and heartburn were only marginally significantly associated with delayed gastric emptying. Post-prandial fullness showed a highly significant, and vomiting a marginally significant, association with normal gastric emptying. Fasting antral volume was significantly associated with delayed gastric emptying increasing the OR of 93% for any additional volume increase of 5 mL. BMI showed a marginally

significant inverse association with delayed gastric emptying with an OR decrease of 11% for any 1 kg/m² increase.

Using other two different cut-points (29 and 33 mL), instead of 31 mL, as discriminant final antral volume for normal and delayed gastric emptying, all the results of univariate and multivariate analyses did not vary.

Furthermore probabilities of having delayed gastric emptying were assessed with the selected symptoms, fasting antral volume, and BMI as reported from the second model (Table 2 and Figure 2). Sensitivity and specificity of the applied model are plotted for different values of estimated prevalence of delayed gastric emptying ranging from 0 to 1. At the cut-off value of 0.398, i.e., the estimated prevalence of delayed gastric emptying in this sample, sensitivity and specificity were about 78% with a correct classification of 73.3% of the patients. Applying a model based on selected symptoms only, the estimated sensitivity and specificity were negligibly lower, than those obtained with the model including fasting antral volume and BMI, with a correct classification of 68.1% of the patients at the cut-off value of 0.398 (data not shown).

Figure 2 Proportion of patients with delayed and normal gastric emptying who were correctly classified on the basis of their predicted probabilities obtained from the estimated coefficients of the second model reported in Table 2 (i.e., sensitivity and specificity, respectively). These proportions are plotted with cut-off levels varying between 0 and 1 (see "lsens" function in Ref. [37]). As expected, when the cut-off value is close to zero all individuals with an actual delayed gastric emptying will be correctly classified and thus having a very high sensitivity. In contrast, with very low cut-off values also those having a normal gastric emptying will be classified as "delayed" by the model and thus having a very low specificity. As the cut-off value used for classification increases, the model will provide the worst performances for the sensitivity and the best performances for the specificity. Circles identify sensitivity and squares specificity. Arrow indicates the probability cut-off value of 0.398, i.e., the estimated prevalence of delayed gastric emptying in this sample.

DISCUSSION

In the attempt to clarify the pathophysiology of symptoms in functional dyspepsia it has been proposed to classify patients with functional dyspepsia into clinically distinct subgroups on the basis of symptom clusters^[12]. Thus the presence of the variable combination of upper abdominal bloating, upper abdominal fullness, early satiety, nausea, belching, retching, and vomiting have been regarded as suggestive of impaired gastric motor activity^[38-40]. However several studies^[16-19] have so far failed to demonstrate in this subgroup of patients a close correlation between symptoms and disturbances of motor function. More recently^[13] it has been proposed to classify dyspeptic subgroup on the basis of the predominant symptom. Nevertheless two studies^[15,20] in the attempt to assess the relationship between predominant symptoms and gastric dysfunction reported non-univocal results in populations that did not exclude patients with IBS and gastroesophageal reflux disease (GERD). Delayed gastric emptying was independently associated with severe post-prandial fullness and severe vomiting in the first study^[20] and with severe nausea in the second one^[15] that also reported early satiety as specifically

associated with impaired gastric accommodation to a meal. In both studies, however, the association between the mentioned symptoms and the altered gastric function was not a universal finding but limited to a subgroup of patients. The uncertainty of the matter is further illustrated by a third study^[21] that failed to find an association between any of the dyspeptic symptoms, as well as their severity, and delayed gastric emptying.

Although reported in previous studies^[23-25] and frequently referred by dyspeptic patients little attention has been paid to other symptoms not referable to the GI tract. The present study aimed to assess whether single GI or extra-GI symptoms and the simple non-invasive US measure of the gastric antral volume in fasting condition could predict the presence of delayed gastric emptying, in a group of dyspeptic patients in whom symptoms of IBS and GERD were excluded.

The present study differs from the previous ones also for other aspects. A meal having the same composition of a normal everyday lunch was used in the present study whereas unusual experimental and/or low caloric meals (≤ 700 kcal)^[17-19] used previously might have not sufficiently challenged the upper GI function. Most of the previously published studies evaluated gastric emptying with the scintigraphic technique that, differently from the US technique, assesses the emptying of the radiolabeled component of the meal rather than of the entire postcibal gastric contents. In addition previous scintigraphic studies have assessed the gastric emptying rate or $t^{1/2}$ gastric emptying time extrapolated from a limited observation period after meal ingestion, two variables that had been shown to be unable to express final gastric emptying time in functional dyspeptic patients^[41]. The serial US measurements of the antral volume enables to assess two relevant aspects of the gastric function, i.e., the antral volume, which is the expression of antral distension and the final gastric emptying time. The former cannot be assessed with scintigraphy and the latter has been shown to be the variable that best correlates with the scintigraphic method and to discriminate patients with delayed gastric emptying from controls^[30-32,42]. In the present study extra-GI symptoms were reported by 53.7% of the patients. Of relevance is that of all investigated symptoms, including GI symptoms usually regarded characteristic of dyspepsia, post-prandial drowsiness is the one that most correlates with, and is the best predictor of, delayed gastric emptying. Also nausea and pain centered in the upper abdomen, albeit to a lesser degree than post-prandial drowsiness, showed a statistical correlation with delayed gastric emptying. Differently from typical abdominal dyspeptic symptoms, drowsiness showed a high specificity in predicting delayed gastric emptying. The other most frequently referred extra-GI symptoms such as headache and palpitation were not statistically related with delayed gastric emptying. Drowsiness can occur in several neurological conditions, including autonomic failure and truncal vagotomy. In none of the investigated patients drowsiness could be explained with any detectable disorders. In healthy subjects it has been shown that in comparison with an equal volume of water and equicaloric liquid meal, solid meal results in a decreased sleep onset latencies^[22].

Furthermore it has been reported a transient decrease in sleep latency after consuming a meal compared to sham feeding^[43]. These results together with the observation of a increased feeling of drowsiness after intravenous injection of CCK administration^[44], support the hypothesis of a GI effect on postprandial sleepiness. It is conceivable that meal ingestion may release CCK and other neuroendocrine substances, such as serotonin, or activate nervous afferences, that affect the state of consciousness and delay gastric emptying. Alternatively prolonged postprandial antral distension may participate via vagal afferences in the activation of central nervous network regulating the state of consciousness. The sensation of drowsiness may vary from slight to severe and be related to sleep disturbances. Postprandial drowsiness reported in the present investigation refers to a sensation regarded to be bothersome enough to interfere with the daily activities and it was not related to sleeplessness.

In addition this study shows that the fasting antral volume of 15 mL is the cut-off value that may be used to predict delayed gastric emptying. Adjusting data for fasting antral volume and BMI, the following symptoms: nausea and drowsiness appear to be significant independent predictors of delayed gastric emptying.

None of the symptoms conventionally considered to be manifestation of dyspepsia was of value to discriminate between patients with normal and delayed gastric emptying.

The different results of the present study from previously mentioned scintigraphy-based studies, may be due to the use of a different technique and/or the different selection of the patients and/or the different assessment of patient's symptoms^[20].

Alternatively, the different results may express a different underlying dysfunction for some of the dyspeptic symptoms. So it may be hypothesized that in patients with functional dyspepsia early satiety^[15] is mainly related to impaired relaxation of the proximal stomach; postprandial fullness and vomiting to a reduced rate of gastric emptying^[20]; post-prandial drowsiness, nausea, to a delayed final gastric emptying.

This study confirms^[26,27] the frequent occurrence in patients with FD of an abnormally distended antral volume during fasting. Whether increased antral volumes may reflect hypotonia of the antral muscular wall or intraluminal distension secondary to gastric retention could not be addressed in the present study.

An increased final antral volume does not necessarily indicate delayed gastric emptying as it may coexist with a normal gastric emptying rate if the fasting antral volume is increased. In the present study, however, the mean final antral volume of dyspeptic patients with delayed gastric emptying exceeded the fasting antral volume of 28 mL indicating the presence of a genuine slowing of the gastric emptying rate.

To identify the cut-off level of 31 mL to discriminate normal and delayed gastric emptying we used data from a control group of healthy people. Similar results were obtained with additional assessments based on other cut-off levels chosen below and above 31 mL. Compared to our patients the control group had a lower percentage of women

and a younger age. However, these differences did not affect the results because these two factors (age and gender) did not have, in the multivariate analysis, any relationship with the gastric emptying. This study confirms previous observations of a statistical correlation between BMI and delayed gastric emptying^[20]. This relationship may be interpreted as an effect of gastric dysfunction often associated with symptoms, such as nausea or pain that limit food ingestion. Patients with eating disorders may be underweight and show abnormal gastric function. In the present study patients with such disorders were excluded and the finding of equally delayed gastric emptying in both genders would support that eating disorders were not present. We did not routinely test for *H. pylori* in this study, but there is no evidence that Hp infection has any relationship with symptoms and delayed gastric emptying in functional dyspepsia^[45-49]. Thus, it seems unlikely that knowledge of the Hp status would have altered the conclusions of the present study.

In conclusion, the presence or, alternatively, the absence of nausea and post-prandial drowsiness, appear to be indicative of delayed or, respectively, normal gastric emptying in functional dyspeptic patients.

Interestingly, despite that the symptom of post-prandial drowsiness is often reported by dyspeptic patients and in some of them it may be the predominant disturbance, it has not been considered part of the definition of dyspepsia. This study shows that post-prandial drowsiness is the symptom that most correlates with delayed gastric emptying and would suggest including it in the clinical definition of functional dyspepsia.

Although it would appear that in FD patients an analysis of dyspeptic symptoms and fasting antral volume can offer valuable indication on the modality of gastric emptying, their ability, either alone or in combination, of correctly classifying individuals with or without delayed gastric emptying was not greater than 73%.

Abstract

AIM: To examine the expression of intercellular adhesion molecule-1 (ICAM-1) and lymphocyte function-associated antigen-1 (LFA-1) expression on canals of Hering (CoH) and bile ductules associated with the autoimmune process of bile duct destruction in primary biliary cirrhosis (PBC).

METHODS: Ten wedged liver biopsies of PBC (five cases each of stages 2 and 3) were studied. The liver specimens were processed for transmission electron microscopy. Immunohistochemistry was performed using anti-ICAM-1 and anti-LFA-1 mouse mAbs. *In situ* hybridization was done to examine the messenger RNA expression of ICAM-1 in formalin-fixed, paraffin-embedded sections using peptide nucleic acid probes and the catalyzed signal amplification (CSA) technique. Immunogold-silver staining for electron microscopy was performed using anti-ICAM and anti-LFA-1 mouse mAbs. The immunogold particles on epithelial cells of bile ductules and cholangiocytes of CoH cells were counted and analyzed semi-quantitatively. Western blotting was performed to confirm ICAM-1 protein expression.

RESULTS: In liver tissues of PBC patients, immunohistochemistry showed aberrant ICAM-1 expression on the plasma membrane of epithelial cells lining bile ductules, and also on mature cholangiocytes but not on hepatocytes in CoH. LFA-1-positive lymphocytes were closely associated

with epithelial cells in bile ductules. ICAM-1 expression at protein level was confirmed by Western blot. *In situ* hybridization demonstrated ICAM-1 mRNA expression in bile ductules and LFA-1 mRNA in lymphocytes infiltrating the bile ductules. By immunoelectron microscopy, ICAM-1 was demonstrated on the basal surface of epithelial cells in bile ductules and on the luminal surfaces of cholangiocytes in damaged CoH. Cells with intermediate morphology resembling progenitor cells in CoH were not labeled with ICAM-1 and LFA-1.

CONCLUSION: *De novo* expression of ICAM-1 both on mature cholangiocytes in CoH and epithelial cells in bile ductules in PBC implies that lymphocyte-induced destruction through adhesion by ICAM-1 and binding of LFA-1-expressing activated lymphocytes takes place not only in bile ductules but also in the CoH.

INTRODUCTION

The canal of Hering (CoH) is named after Hering who in 1855 described the structure as a link between the hepatocyte canalicular system and biliary tree^[1]. Under the electron microscope, the small cells of CoH have a basement membrane like the more distal portions of the biliary tree but an apical surface that appears similar to hepatic canalicular membrane^[2]. Functionally, bile canalicular contraction is involved in the canalicular bile flow as demonstrated by an inverted microscope linked to a SIT camera, and disturbance of canalicular contraction would lead to intrahepatic cholestasis^[3]. Moreover, contraction of the CoH has been demonstrated, and the interval between contractions was approximately five times longer than that seen in canaliculi^[4]. Hepatic cholestasis and hepatic injury are accompanied with

striking morphologic changes. Examination of periportal changes in the liver of graft-*vs*-host disease mice shows that hepatocytes in close contact with lymphocytes had minor degenerative changes, whereas periportal bile ductules and CoH are constantly injured by inflammatory cells^[5]. Study of the three-dimensional structure of ductular reactions in massive necrosis suggests that cytokeratin 19-positive reactions are in fact proliferations of the cells lining the CoH^[6].

Primary biliary cirrhosis (PBC) is a chronic, progressive cholestatic liver disease characterized by inflammatory obliteration of the intrahepatic bile ducts, leading to fibrosis and ultimately to cirrhosis complicated by liver failure or hypertension^[7,8]. Although the pathogenesis of bile duct destruction in PBC remains unknown, increasing evidence has suggested that it is related to autoimmune abnormalities^[8-10]. Immunohistochemical analysis of the lymphocytes infiltrating the portal tracts including the bile duct lesions indicates that activated T lymphocyte subsets may play an important role in bile duct destruction^[11]. Therefore bile ducts (centrally located, accompanied by a hepatic arterial branch) are the prime targets for immune-mediated damages in PBC and are reduced in number as the disease progresses. Bile ductules (peripherally located, usually without a conspicuous lumen) increase in number in response to bile duct damage (ductular reaction). Bile ductules are frequently associated with a mixed population of inflammatory cells. However, there is no clear evidence that these inflammatory cells are associated with bile ductular destruction^[12]. Recent studies have demonstrated increased expression of intercellular adhesion molecule (ICAM)-1 on the bile duct epithelium in PBC^[13,14], suggesting that the activated T lymphocytes may specifically react with the bile duct epithelial cells through these adhesion molecules. Expression of intracellular adhesion molecules and their specific ligands are essential for cell-to-cell interactions in autoimmune mechanism^[15]. In PBC, ICAM-1 is expressed on plasma membrane of epithelial cell in bile ducts characterized by chronic non-suppurative destructive cholangitis (CNSDC) and on the sinusoidal endothelial cells^[16,17]. While immunohistochemical findings of ICAM-1 and lymphocyte function-associated antigen (LFA)-1 expression in PBC tissue have been reported^[17], no studies have correlated protein expression of the antigens on CoH by examining serial sections using immunoelectron microscopy. The aim of the present study was to clarify the roles of ICAM-1 and LFA-1 expression on the bile ductule and CoH in PBC. The aim of the present study was to clarify ICAM-1 and LFA-1 expression on the bile ductule and CoH in PBC. We conducted immunohistochemistry, *in situ* hybridization and immunoelectron microscopy on liver biopsy specimens from PBC patients.

MATERIALS AND METHODS

Materials

Surgical liver biopsy specimens were obtained from 10 patients (all female, mean age 55.9 years, range 48-65 years) with PBC (five cases each of Scheuer's stages 2 and 3). PBC was diagnosed clinically and histologically according to the criteria proposed by the Japanese Joint Research Group for Autoimmune Hepatitis^[18]. As controls, wedge biopsy specimens from normal portions of the liver were obtained

from five patients (four male and one female; aged from 54 to 71 years with a mean of 62.6 years) who underwent surgical resection for metastatic liver carcinoma (four colonic carcinomas).

Electron microscopy

The liver specimens were cut into small blocks (approximately 1 mm×1 mm×1 mm). The blocks were fixed in fresh 2.5% glutaraldehyde solution for 1 h at 4 °C, followed by post-fixation in 2% osmium tetroxide with 0.1 mol/L cacodylate buffer (pH 7.4), and then dehydrated in a graded series of ethanol solutions. For transmission electron microscopy, the liver tissue blocks were embedded in Epon after dehydration. Ultrathin sections were cut with a diamond knife on a LKB ultramicrotome (Bromma), stained with uranyl acetate and lead citrate and observed under a transmission electron microscope (JEM-1200 EX, JEOL, Tokyo, Japan) with a 80-kV acceleration voltage.

Immunohistochemical staining

Liver tissues (approximately 5 mm×5 mm×5 mm) were fixed in periodate-lysine-paraformaldehyde^[19], rinsed in 0.01 mol/L phosphate buffer (pH 7.4) containing 15-30% sucrose, embedded in Tissue-Tek OCT-compound (Miles Inc., Elkhart, Inc., Germany) and frozen at -80 °C until use. The tissue was incubated overnight at 4 °C with anti-ICAM-1 mouse mAb (CD54; DAKO, Glostrup, Denmark) diluted at 1:50 or anti-LFA-1 mouse mAb (CD11a; DAKO, Glostrup, Denmark) diluted at 1:20, and then incubated with horseradish peroxidase-conjugated anti-mouse IgG goat antibody (Cosmo Bio Inc., Tokyo, Japan) diluted 1:100. After repeated washes with PBS, the sections were reacted with diaminobenzidine solution containing 0.01% H₂O₂, and counterstained with hematoxylin for light-microscopic study.

In situ hybridization technique

Messenger RNA of ICAM-1 was detected in formalin-fixed, paraffin-embedded sections by *in situ* hybridization using peptide nucleic acid (PNA) probes^[20] and the catalyzed signal amplification (CSA) technique. Liver tissues were cut into 4 µm-thick sections and adhered to silanated RNase-free glass slides (prepared by heating in an oven at 60 °C for 30 min). The sections were dewaxed in xylene (for 15 min, each twice), treated with a graded ethanol series, rehydrated in RNase-free distilled water, and incubated for 30 min in target retrieval buffer (DAKO Japan, Kyoto, Japan) preheated and maintained at 95 °C. The slides were allowed to cool at room temperature for 20 min and then digested with 20 µg/mL proteinase K (DAKO) at room temperature for 30 min. The slides were rinsed in distilled water and rapidly air dried. The air-dried sections were covered with approximately 15 mL of hybridization solution containing 100 g/L dextran sulfate, 10 mmol/L NaCl, 300 mL/L formamide, 1 g/L sodium pyrophosphate, 2 g/L polyvinylpyrrolidone, 2 g/L Ficoll, 5 mmol/L Na₂EDTA, 50 mmol/L Tris-HCl, pH 7.5, and 1 µg/mL PNA probe. Probes were constructed according to the sequence information of ICAM-1 and LFA-1^[21,22]. The following probes were used: ICAM-1 antisense (FITC-ATTATGACTGCGGCTGC), ICAM-1 sense (FITC-GCAGCCGCAGTCATAAT),

LFA-1 antisense (FITC-CATCCAGCTGCAGAGTGT), and LFA-1 sense (FITC-ACACTCTGCAGCTGGATG). The slides were evenly covered with the hybridization solution and incubated in a moist chamber at 43 °C for 90 min. Following hybridization, the cover slips were removed, and the slides were transferred to pre-warmed TBS in a water bath at 49 °C and washed for 30 min with gentle shaking (PNA Hybridization Kit; DAKO, Tokyo, Japan). A non-isotopic, colorimetric signal amplification system (GenPoint kit, DAKO Japan) was used to visualize specific hybridization signals. Briefly, tissue sections were incubated with a FITC-horseradish peroxidase reagent for 15 min, washed thrice with TBST (150 mmol/L NaCl, 10 mmol/L Tris; pH 7.5, 11 mL/L Tween 20), incubated with a solution containing H₂O₂ and biotinyl tyramide for 15 min, and washed thrice with TBST^[23]. This step resulted in CSA by additional deposition of biotin at the site of probe hybridization. The sections were then incubated in streptavidin-horseradish peroxidase for 15 min, and washed thrice in TBST. Colorimetric signals were developed by incubation in diaminobenzidine solution containing 0.01% H₂O₂, and counterstained with hematoxylin for light microscopic examination.

Immunogold-silver staining method for electron microscopy

For light microscopy, the sections were immersed in three changes of 0.01% PBS (pH 7.4) for 15 min, and then incubated overnight in a moist chamber at 4 °C with anti-ICAM-1 mouse mAb at 1:50 dilution and anti-LFA-1 mouse mAb at 1:20 dilution. After washing thrice with PBS for 15 min, the sections were incubated for 40 min with 10-nm colloidal gold-conjugated anti-mouse IgG antibody (Cosmo Bio Co., Tokyo, Japan) diluted at 1:100. The slides were developed with a developing solution described below for 50 min at 20 °C in a dark room. After having washed in running water, the sections were briefly counterstained with 0.1% nuclear fast red in 5% aluminum sulfate aqueous solution, dehydrated, cleared and mounted on Biolet. The developing solution had two components. Solution A contained 45 mL of 20% gum arabic aqueous solution (Kanto Chemical Co., Tokyo, Japan) and 1 mL of 10% silver nitrate solution. The gum arabic solution was prepared by centrifuging a 20% suspension at 18 000 g for 30 min at 0 °C and separating the supernatant for use. Solution B contained 200 mg of hydroquinone (Kanto Chemical Co., Tokyo, Japan) and 300 mg of citric acid monohydrate (Kanto Chemical Co., Tokyo, Japan) in 10 mL of distilled water. The working developing solution was prepared by mixing solutions A and B in a dark room under illumination of a photographic safety lamp^[24].

For electron microscopy, the tissue specimens processed for light microscopy as above were treated thrice, with PBS for 15 min, and fixed for 1 h at 4 °C in 1.2% glutaraldehyde buffered with 0.01% phosphate buffer (pH 7.4), followed by a graded series of ethanol solutions. After postfixation with 1% osmium tetroxide in 0.01% phosphate buffer (pH 7.4), the liver tissues were embedded in Epon. Ultrathin sections cut with a diamond knife on a LKB ultramicrotome were stained with uranyl acetate and observed under a transmission electron microscope (JEM-1200 EX, Tokyo, Japan) operated at an acceleration voltage of 80 kV.

Western blotting

Western blotting was conducted using fresh control and PBC liver tissues. Briefly, liver tissues were homogenized in 10 volumes of homogenization buffer (20 mmol/L Tris-HCl; pH 7.5, 5 mmol/L MgCl₂, 0.1 mmol/L PMSF, 20 μmol/L pepstatin A, and 20 μmol/L leupeptin) using a polytron homogenizer at setting 7 for 90 s. The homogenates were centrifuged at 100 000 g for 45 min. The membranes were washed thrice, resuspended in 10 volumes of homogenization buffer, homogenized using a Teflon/glass homogenizer, and centrifuged. The membrane proteins thus obtained were used for immunoblotting. Proteins were separated on SDS/PAGE (4-20% gel, Daiichi-Ikagaku, Tokyo, Japan) and transferred onto polyvinylidene difluoride (PVDF) membranes (Millipore, Bedford, MA). The blots were blocked with 50 g/L dried milk in PBS for 30 min, incubated with 20 μg/mL anti-ICAM-1 (G-5; Santa Cruz Bio., Santa Cruz, CA, USA), washed in 0.1% Tween 20 in PBS, and transferred onto PVDF membranes (NTN Life Science Products). The blots were blocked with 50 g/L dried milk in PBS for 30 min, incubated with anti-mouse goat IgG conjugated with horseradish peroxidase (Amershampharmacia) in 0.1% Tween 20 in PBS, and then processed by the Vectastain ABC system (Vector laboratories, Inc., Burlingame, CA, USA). The immunoreactive bands were visualized with diaminobenzidine solution containing 0.01% H₂O₂.

Semi-quantitative analysis

The immunogold particles on epithelial cells of bile ductules and cholangiocytes of CoH cells were counted. Photographs from 10 fields between the bile ductules and canal of Hering were investigated. The magnification was ×2 000.

RESULTS

Electron microscopic finding

Electron microscopic observation of the PBC liver specimens revealed lymphocytes associated with the bile ductular membrane in bile ductules (Figure 1A). Lymphocytes frequently migrated into the epithelial layer of CoH through their basement membrane (Figure 1B).

Immunohistochemical finding

We examined the immunohistochemical reactions of both ICAM-1 and LFA-1 in serial sections. In control liver specimens, ICAM-1 protein was expressed on sinusoidal lining cells but no specific immunoreactivity was observed on bile duct epithelial cells (Figure 2A). Immunostaining for LFA-1 appears to be present in portal lymphoid cells. Interlobular bile ducts appear to be negative for LFA-1, although there was sparse expression in bile duct epithelial cells (Figure 2B). In PBC liver tissue, *de novo* expression of ICAM-1 was found on the plasma membrane on the luminal side of epithelial cells in bile ductules and on some lymphocytes infiltrating small bile ductules or possibly small blood vessels. ICAM-1 immunoreactivity was also seen on the sinusoidal endothelial cells (Figure 2C). LFA-1 protein was expressed mainly in lymphocytes around and among the proliferated bile ductules (Figure 2D). Immunostaining of ICAM-1 and LFA-1 in CoH was less clearly depicted by immunostaining examined under a light microscope.

Figure 1 Electron microscopic finding in small bile ductule and CoH in liver specimen of PHC. **A:** Interaction of lymphocytes appear to interact with the bile ductule. Lymphocytes frequently migrate into the epithelial layer of small bile duct through the basement membrane. BD: bile ductule, Ly: lymphocyte; **B:** Association of lymphocytes with the cholangiocytes of the CoH. CoH: canal of Hering. S: sinusoid, H: hepatocytes, Ly: lymphocytes, Bar: 5 μ m.

Western blot

To confirm the immunohistochemical results, we investigated ICAM-1 protein expression by Western blotting. Samples containing 20 μ g of protein were subjected to SDS/PAGE (4–20% gel) and analyzed by blotting with anti-ICAM-1 antibody. A band around 110 ku indicating ICAM-1 was found in abundance in PBC liver tissue (Figure 3).

In situ hybridization

Next, we investigated the expression of ICAM-1 and LFA-1 at mRNA level in PBC liver samples using *in situ* hybridization with PNA probes (Figure 4). Signals showing ICAM-1 mRNA were typically localized in bile ductular

epithelial cells surrounding the CNSDC lesions (Figures 4A and B). Interestingly, signals showing LFA-1 were localized in lymphocytes inside the bile ductules of CNSDC lesions (Figures 4C and D).

Immunoelectron microscopy

Light microscopic examination of PBC liver samples depicted the localization of ICAM-1 and LFA-1 in bile ductules, but the localization in the CoH was less clear. We therefore conducted immunoelectron microscopic examination. By immunogold electron microscopy, gold-labeled ICAM-1 particles were observed on cholangiocytes, distributing on the luminal surfaces of small bile ductules. ICAM-1 immunoreactivity was also observed on small portal or peripheral blood vessels and sinusoidal endothelial cells (Figure 5A). In the canal of Hering, gold-labeled ICAM-1 particles were observed on the luminal surfaces of cholangiocytes and hepatocytes (Figure 5C). LFA-1 labeling was concentrated on lymphocytes that were found around bile ductules (Figure 5B) and also around cholangiocytes of CoH (Figure 5D). Immature cells resembling progenitor cells were observed in CoH, and these cells did not show ICAM-1 immunoreactivity (Figure 5E). Around these cells, infiltration of lymphocytes was also absent (Figure 5F).

In the semi-quantitative analysis, immunogold–silver complex particles on epithelial cells of bile ductules and cholangiocytes of CoH were enumerated on immunoelectron micrographs (Figure 6). ICAM-1 immunoreactivity was found in CoH in 4 of the 10 PBC cases and in bile ductules

Figure 2 Immunohistochemical distributions of ICAM-1 (**A** and **C**) and LFA-1 (**B** and **D**) in control liver tissue (**A** and **D**) and liver tissue of PHC (**C** and **D**). **A:** ICAM-1 protein expression on sinusoidal lining cells but no specific immunoreactivity on bile duct epithelial cells in control liver specimens; **B:** LFA-1 immunoreactivity in portal lymphoid cells, negative in interlobular bile ducts and sparse expression in bile duct epithelial cells; **C:** Marked ICAM-1 immunoreactivity on the plasma

membrane on the luminal side of bile ductules or possibly small blood vessels. Some lymphocytes around the bile ducts were also positive for ICAM-1. Arrowheads denote localization of ICAM-1 (arrows); **D:** LFA-1 immunoreactivity in lymphocytes around and among damaged bile ducts (arrowheads). Original magnification; $\times 400$, hematoxylin counterstained.

Figure 3 Western blot analysis of expression of ICAM-1 protein in human control and PBC liver tissue. Samples containing 20 μ g protein were subjected to SDS/PAGE (4-20% gel) and analyzed by blotting. ICAM-1 was found in abundance in PBC liver tissues. Lanes 2 and 3: PBC liver tissue, lane 1: control liver tissue. Positions of molecular mass markers are shown (ku).

in 8 of the 10 cases. LFA-1 immunoreactivity was found in CoH in 4 of the 10 PBC cases and in bile ductules in 7 of the 10 cases. The extent of immunoreactivity (number of immunogold particles per unit CoH or bile ductule) was also stronger in bile ductules than in CoH. No immunogold-silver complex particles for ICAM-1 and LFA-1 were found in bile ductules and CoH of control liver tissues.

DISCUSSION

Bile duct inflammation and destruction are the fundamental lesions of PBC^[25]. Interlobular bile ducts with external diameters of 30-100 μ m are selectively affected, displaying variable necrotic and proliferative changes of biliary epithelial cells, as well as periductal lymphoplasmacytic infiltration. These findings are also frequently noted around damaged bile ducts, especially in the early histologic stages of the disease^[25]. In our immunohistochemical study, ICAM-1 was strongly expressed on damaged bile ducts and infiltrating inflammatory cells, while LFA-1 was expressed on infiltrating lymphocytes. The presence of ICAM-1/LFA-1 linkage has been reported in CNSDC in PBC^[16,17].

In our previous study, we correlated protein and mRNA expression of ICAM-1 and LFA-1 by conducting immunohistochemical and *in situ* hybridization studies on serial sections of CNSDC lesions^[26]. We demonstrated abundant protein and mRNA expression of ICAM-1 on damaged biliary epithelial cells and LFA-1 on lymphocytes in CNSDC lesions, strongly suggesting the ICAM-1/LFA-1 linkage^[26].

Figure 4 Localization of ICAM-1 (A and B) and LFA-1 (C and D) mRNA at bile ductules in PBC liver tissue by *in situ* hybridization with CSA. A: ICAM-1 mRNA was expressed in a cytoplasmic pattern on epithelial cells of bile ductile. (A: $\times 100$ and B: $\times 300$) Arrowhead denotes reaction product; C: LFA-1 mRNA is

expressed in a cytoplasmic pattern in lymphocytes around bile ductile. (C: $\times 100$ and D: $\times 300$). Negative controls: E: ICAM-1 sense probe, F: LFA-1 sense probe. All panels: color was developed by DAB chromogen and hematoxylin counterstained. Arrowhead denotes reaction product.

Figure 5 Immunoelectron microscopic findings of ICAM-1 (A, C, and E) and LFA-1 (B, D, and F) in periportal small bile ductule and canal of Hering in PBC liver. **A:** Gold-labeled ICAM-1 particles on the surface of cholangiocytes (arrowhead) facing the lumen of small bile ductule, a small portal or peripheral blood vessel, and also on sinusoidal endothelial cells (arrowheads). BD denotes bile ductule; **B:** Lymphocytes with dense labeling of LFA-1 (arrowhead) around small ductule; **C:** Gold-labeled ICAM-1 particles on the luminal surfaces of

hepatocytes and cholangiocytes of CoH, on bile canaliculus and also on sinusoidal endothelial cells (arrows); **D:** Lymphocytes densely labeled with LFA-1 (arrows) on the basolateral membrane of cholangiocytes of the CoH; **E:** No ICAM-1 immunoreactivity show immature cells resembling progenitor cells (asterisk) in CoH, and these cells; **F:** No infiltration of lymphocytes is observed around the progenitor-like cells (asterisk). Bar, 5 μ m; BD, bile ductile; Ly, lymphocyte; CoH, canal of Hering; H, hepatocyte. Uranyl acetate stain.

Frequent and variable infiltration of lymphocytes, mainly T cells, and other inflammatory cells of the biliary epithelium has been reported in PBC^[27]. Some lymphocytes infiltrate

by crossing the basement membrane of bile ducts. These changes appear as necro-inflammatory lesions inside the basement membrane of bile ducts and ductules.

Our immunoelectron microscopic study has confirmed for the first time the ultrastructural localization of ICAM-1 on cholangiocytes and LFA-1 on infiltrating inflammatory cell in damaged CoH. The lymphocytes and other inflammatory cells then penetrated the peribiliary vascular plexus and portal venules, and migrated into perivenular tissue toward the bile ducts^[12]. When early stage PBC specimens were immunostained for cytokeratin 19 and HLA-DR, the CoH were found mostly around portal tracts in stages 2 and 3 PBC, but they were destroyed in concert with the destruction of bile ductules^[28]. Therefore, CoH in PBC specimens are difficult to be depicted by immunohistochemistry using light microscopy. Our immunoelectron microscopic study successfully demonstrated the ultrastructural localization of ICAM-1 and LFA-1 on CoH.

Previous studies of cell adhesion molecules, especially ICAM, in PBC have reported conflicting results. Adams *et al.*^[14], reported a series of 13 patients with PBC studied at liver transplantation and found that ICAM was expressed on interlobular bile ducts and proliferating bile ductules. In contrast, Broome *et al.*^[29], found ICAM in 3 of 10 patients with PBC while almost all patients expressed HLA-DR on biliary epithelium. Bloom *et al.*^[30] found ICAM-1 expression on bile ducts in two of seven cases of early disease and in only one of five patients with stage three or four disease. According to these reports, ICAM-1 expression in PBC is not very common and not clearly associated with a particular

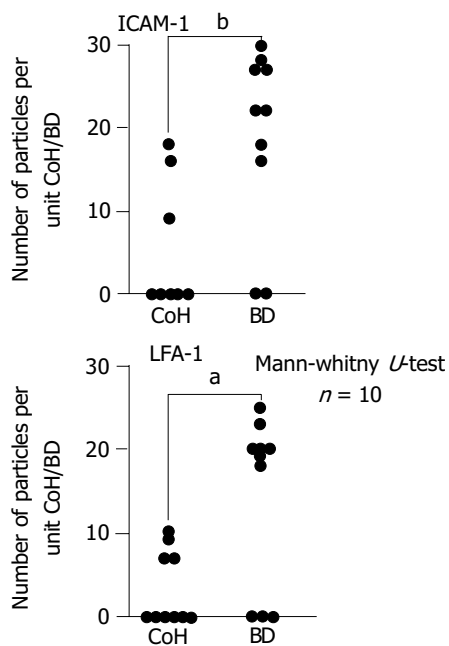

Figure 6 Semi-quantitative analysis of immunogold-silver complex particles on epithelial cells of bile ductules and cholangiocytes of CoH enumerated on immunoelectron micrographs (expressed in number of particles per unit CoH or small bile ductule). Immunoreactivity was significantly greater on bile ductules (Mann-Whitney test). BD, bile ductile; CoH, canal of Hering. ^a $P < 0.05$, ^b $P < 0.01$ vs CoH.

disorder. Using immunoelectron microscopy, we found that 8 of 10 PBC patients expressed ICAM-1 and 7 of 10 patients expressed IFA-1 on bile ductules. The higher rate probably reflects the higher sensitivity of our method.

In this study, we observed membranous staining of hepatocytes and bile ductules with different intensity with ICAM-1 antibodies (Figure 1C) in PBC. However, ICAM-1 expression on hepatocytes is indefinite or only faint in normal livers. These findings may suggest the involvement of immune-mediated hepatocytolysis related to expression and presentation of target antigens^[12].

Bile duct loss can be evaluated semi-quantitatively by calculating the ratio of portal tracts devoid of interlobular bile ducts and also the proportion of hepatic arterial branches without parallel running interlobular bile ducts^[12]. Regrowth of bile ducts has been reported, and a ductular reaction precedes the reappearance of neo-bile ducts. In this process, hepatic stem cells or progenitor cells migrate from the periportal area into the biliary tree^[31]. On the other hand, in rat liver injury, the role of ICAM-1 is to adhere to neutrophils, and excessive parenchymal apoptosis may be a signal for this neutrophil-induced inflammatory and necrotic reaction^[32]. Apoptosis of bile ductules could be one of the processes that explain the reduced proliferation of bile ductules^[33]. Therefore, strong expression of ICAM-1 on bile ductules may be a cause of the reduction in proliferation of bile ductules^[25,33].

Our semi-quantitative study of immunogold-silver complex in bile ductile epithelium and cholangiocytes in CoH of PBC liver revealed that the rate and intensity of ICAM-1 and IFA-1 expression were higher in the bile ductules than in the upstream CoH. The reason is that there are less mature cholangiocytes in the CoH. We observed cells with intermediate morphology in CoH, which may be progenitor cells labeled with ICAM-1 and LFA-1. Since the adhesion molecules appear to be expressed only on the mature cholangiocytes, this implies that the mature cholangiocytes are targeted for autoimmune destruction in PBC. Destruction in the CoH upstream of bile ductules also occurs because of the presence of mature cholangiocytes. Recently, a human bipotent liver progenitor cell line has been established, which shows comparable immunophenotype restricted to bile neoductules^[34]. The mechanisms of how progenitor cells are protected from destruction by the host immune system should be studied.

Abstract

AIM: To study whether severe acute respiratory syndrome coronavirus (SARS-CoV) could be excreted from digestive system.

METHODS: Cell culture and semi-nested RT-PCR were used to detect SARS-CoV and its RNA from 21 stool and urine samples, and a kind of electropositive filter media particles was used to concentrate the virus in 10 sewage samples from two hospitals receiving SARS patients in Beijing in China.

RESULTS: It was demonstrated that there was no live SARS-CoV in all samples collected, but the RNA of SARS-CoV could be detected in seven stool samples from SARS patients with any one of the symptoms of fever, malaise, cough, or dyspnea, in 10 sewage samples before disinfection and 3 samples after disinfection from the two hospitals. The RNA could not be detected in urine and stool samples from patients recovered from SARS.

CONCLUSION: Nucleic acid of SARS-CoV can be excreted through the stool of patients into sewage system, and the possibility of SARS-CoV transmitting through digestive system cannot be excluded.

INTRODUCTION

By the end of 2002, there were reports from Guangdong Province in southern China of cases of severe acute respiratory syndrome (SARS). Over 8 439 SARS cases and 812 SARS-related deaths were reported to WHO from 32 countries around the world till 5th July, 2003^[1,2]. In response to this outbreak, WHO coordinated an international collaboration that included clinical, epidemiological, laboratory investigations, and initiated efforts to control the spread of SARS. Attempts to identify the etiology of SARS outbreak were successful during the 3rd wk of March 2003, when laboratories in the USA, Canada, Germany, Hong Kong, and China isolated a novel coronavirus from SARS patients^[3-6]. Unlike other human coronaviruses, it was possible to isolate the novel coronavirus in Vero cells. Evidence of the coronavirus infection was documented in SARS patients throughout the world. The coronavirus RNA was frequently detected in respiratory specimens, and convalescent-phase serum specimens from SARS patients containing antibodies that reacted with the coronavirus. There was a strong evidence that this new virus was etiologically linked to the outbreak of SARS^[5-8].

Investigations of the global outbreak of SARS have shown that the major mode of transmission of SARS virus was through close personal contact, in particular exposure to droplets of respiratory secretions from an infected person^[1,9-14]. While in a cluster of SARS cases in an apartment block in Hong Kong, sewage was believed to have played a role through droplets containing coronavirus from the sewage system^[11,12]. However, there is no direct evidence to prove that the coronavirus exists in sewage system and is contagious.

In order to confirm whether the digestive system was a possible major transmission way of SARS-CoV, cell culture and the semi-nested RT-PCR were used to directly detect SARS-CoV and its RNA. A kind of electropositive filter media particle^[15] was used to concentrate the SARS-CoV from the sewage of hospitals receiving SARS patients in Beijing of China, and then the virus and its RNA were detected.

MATERIALS AND METHODS

Viruses and culture methods

To identify viruses that existed in stools, urine samples, and sewage system, we inoculated a variety of specimens onto Vero E6. Because of the toxicity of sewage concentrates, all cell cultures were inoculated in the presence of growth medium for 1 h at 37 °C. This procedure virtually eliminated problems with the toxicity of sewage concentrates. Medium was replaced after 1–2 d of incubation. Culture was terminated 7 d after inoculation, and the culture was observed daily for cytopathic effects. Cultures exhibiting identifiable cytopathic effects were subjected to several procedures to identify the cause of the effect^[16–18]. If there was no cytopathic effect on the cell culture, the supernate was harvested and added into additional flasks to isolate viruses. The cultures were then used until three generations without cytopathic effects.

Stools and urine samples of SARS patients

Twenty-one stool and urine samples were collected from the Xiao Tang Shan Hospital and 309 Hospital of PLA, which were specially assigned to receive SARS patients in Beijing in 2003, among which 11 samples were collected from the SARS patients with any one of the symptoms of fever, malaise, cough, or dyspnea, and 10 samples were from recovered patients.

Sewage and disinfection

Ten sewage samples were collected at 7 o'clock in the morning from Xiao Tang Shan Hospital and 309 Hospital of PLA for 7 d. Two thousand and five hundred milliliters of sewage before disinfection or 25 000–50 000 mL after disinfection by chlorine was collected.

Electropositive filter media particle

The positively charged filter media particles, which were used to concentrate SARS-CoV from sewage, were prepared as previously described^[15].

Detection of residual chlorine

The residual chlorine in sewage was determined by the *N*, *N*, diethyl-*p*-phenyldiamine colorimetric method^[19].

Concentration of SARS-CoV from sewage

Two thousand and five hundred milliliters and 25 000 mL sewage from the hospitals before or after disinfection by chlorine were placed in a 25-L capacity plastic bucket, and 10 mL Na₂S₂O₃ (100 g/L) was added to neutralize the residual chlorine. Five hundred or 820 g filter media was packed in a polymethyl methacrylate column (89 or 130 mm i.d.). The filter media bed height was 14 cm. The flow rate was kept at 10 mL/min per cm² of the filter surface area. The adsorbed viruses were eluted from filter media with 700 or 900 mL 6× nutrient broth (pH 7.2). The collected eluates were re-concentrated by PEG precipitation and centrifugation. The pellets were resuspended in 40 mL PBS and assayed.

RNA extraction

Virus RNA extracting kit (TRIzol Reagent) made by Invitrogen™ Life Technologies for extraction of exceedingly pure viral RNA was utilized in our experiment to extract

virus RNA, and all procedures were strictly implemented in accordance with the reagent instruction manual.

Primer design for assay of SARS-CoV nucleic acid

Three sets of primers from WHO Network Laboratories^[20] were used to detect the SARS-CoV RNA: Cor-p-F2 (+) 5'-CTAACATGCTTAGGATAATGG-3', Cor-p-F3 (+) 5'-GCCTCTCTTGTCTTGCTCGC-3', and Cor-p-R1 (-) 5'-CAGGTAAGCGTAAACTCATC-3'. Cor-p-F2/Cor-p-R1 gave a 368-bp product, and Cor-p-F3/Cor-p-R1 yielded a 348-bp segment.

Primer design for assay of enterovirus nucleic acid

A pair of consensus primers of enteroviruses was from the 5' non-coding region because of their presence in many enterovirus serotypes. The sequences of primers were as follows: E1 5'-ATTGTCACCATAAGCAGCCA-3', E2 5'-CCAGCACTTCTGTTCCCGG-3', and the product size was 440 bp^[21].

Detection of SARS-CoV by semi-nested RT-PCR

Two microliters of RNA solution was analyzed with RT-PCR assay. The KaTaRa one step RNA PCR kit (KaTaRa Biotechnology, Dalian) was used for the reaction (20 µL total volume). Positive and negative RT-PCR controls were included in each run. Reactions contained 10 µL of buffer concentrate, 2 mmol/L of magnesium sulfate, 0.8 µL of enzyme mixture, and 1.9 µmol/L of each of Cor-p-F2 and Cor-p-R1 primers. Thermal cycling comprised 42 °C for 30 min, 95 °C for 3 min; 10 cycles of 95 °C for 10 s, 55 °C for 15 s (decreasing by 1 °C per cycle), 72 °C for 40 s; 40 cycles of 95 °C for 10 s, 56 °C for 10 s, and 72 °C for 40 s. To confirm the PCR products, a semi-nested PCR was developed. The template was the first PCR product, and the primers were Cor-p-F3 and Cor-p-R1, and yielded a 348-bp product. The amplification efficiency of the primers was confirmed by SARS-CoV of BJ-01 isolated from a SARS patient in Guangzhou city, China (Figure 2).

Detection of enteroviruses by RT-PCR

As most of enteroviruses can also grow on the Vero cells, and yield cytopathic effects, enteroviruses should be detected by the specific primers^[21]. The RT-PCR method was similar to that for SARS-CoV.

Detection of PCR products

PCR products were analyzed by electrophoresis with 15 g/L agarose gels containing 0.5 µg of ethidium bromide per mL, and visualized with UV illumination and photographed. DNA molecular size standards (100-bp ladder, Gibco/BRL) were included in each run of agarose gel electrophoresis.

In view of the serious nature of SARS and the person-to-person transmission, all clinical specimens were treated in a biosafety level 3 environment. All divisions into aliquots, pipetting, concentration for small sewage and culture attempts were performed in laminar-flow safety cabinets. A similar environment was used when specimens from which nucleic acid was to be extracted and placed in a buffer solution.

Nucleotide sequence analysis

The PCR products from four different samples were purified

with the QIAquick PCR purification kit (QIANEN, Inc.) and sequenced with the ABI PRISM dye terminator cycle sequencing ready reaction kit with AmpliTaq DNA polymerase FS (Perkin-Elmer, Applied Biosystem) following the manufacturer's instructions. The sequences were compared with the genome of SARS-CoV in the GenBank and EMBL databases by using the FASTA program of the GCG.

RESULTS

Detection of SARS-CoV by the semi-nested RT-PCR

The detection specificity and sensitivity of semi-nested RT-PCR were confirmed by the isolated SARS-CoV (BJ-01) from Institute of Microbiology and Epidemiology, Academy of Military Medical Sciences, Beijing, China. It was shown that two amplicons were yielded, which were in agreement with the information on the designed primers (Figure 1). The minimum amount of SARS-CoV RNA detected by semi-nested PCR was equivalent to 10 TCID₅₀ (Figure 2).

Figure 1 Amplification of SARS-CoV RNA BJ-01 by semi-nested RT-PCR. M: DNA marker (pUC19 DNA/MSP I marker); lane A: 348 bp; lane B: 368 bp; lane C: positive RT-PCR control, 462 bp; lane N: negative RT-PCR control.

Figure 2 Sensitivity of semi-nested RT-PCR for SARS-CoV. M: DNA marker (pUC19 DNA/MSP I marker); lane A-G: virus concentration was 10⁶-10¹⁰ TCID₅₀; lane H: negative control.

Isolation of SARS-CoV and detection of SARS-CoV RNA from stool samples of patients

All the 21 stool samples tested for the presence of infectious SARS-CoV in cell culture were negative. SARS-CoV RNA could be detected in 7 of 11 stool samples from patients with symptoms by semi-nested RT-PCR (Figure 3). However, SARS-CoV RNA could not be detected from the samples of patients who recovered.

Figure 3 Amplification of SARS-CoV RNA from stool samples. M: DNA marker (pUC19 DNA/MSP I marker); lanes 1-11: samples from different SARS patients; N: negative control; P was the positive RT-PCR control from the RNA of SARS-CoV BJ-01.

Isolation of SARS-CoV and detection of SARS-CoV RNA from urine samples of patients

All the 21 urine samples tested for the presence of infectious SARS-CoV in cell culture were also negative. SARS-CoV RNA could not be detected from the samples or the supernate of cell cultures by semi-nested RT-PCR.

Concentration and detection of SARS-CoV from sewage before disinfection

All sewage samples tested for the presence of infectious SARS-CoV in cell culture were negative. SARS-CoV RNA could be found in the concentrates of sewage from the two hospitals by semi-nested PCR, and in the inoculated cells of the sewage concentrates from 309 Hospital but not from Xiao Tang Shan Hospital. However, SARS-CoV RNA copies in the samples were too low to be detected by the first amplification reaction, the semi-nested RT-PCR in which the products of first amplification reaction were the template of the second PCR, gave the positive amplification results (Tables 1 and 2).

Concentration and detection of SARS-CoV from sewage after disinfection

The samples (25 000 or 50 000 mL) from the two hospitals were all negative by the infectivity methods. SARS-CoV RNA was detected from the concentrates and inoculated cells in three samples (June 11, 13, and 15) from 309 Hospital by semi-nested RT-PCR, while the other samples were negative (Tables 3 and 4).

Result of nucleotide sequence analysis

The PCR products from the sewage samples of the two hospitals were sequenced, and submitted to GenBank. The accession numbers are bankit579728 and bankit579738, respectively. Comparison of the nucleotide sequences of PCR products with data from GenBank revealed that the sequences of the PCR products were close to those of SARS-COV genomes, showing about 99% nucleotide homolog.

DISCUSSION

Most SARS cases to date have occurred in young adults. The health care workers in hospitals, patient family members and international travelers were the commonly infected people^[22,23].

The isolation of a novel coronavirus was obtained from the respiratory secretions of patients with SARS, and points to the etiologic association with SARS^[3-6,8,24-26].

The mechanism of transmission of SARS-CoV is not yet understood completely. However, the fact that transmission has been limited to close contacts with patients, such as household members, health care workers, or other patients who were not protected with contact or respiratory precautions, suggests that either droplet secretions or direct or indirect contact probably has a role^[1,10-14,27].

On 15th April, 2003, health authorities reported a total

of 321 individuals infected with SARS virus who were residents in Amoy Gardens. A large proportion of cases were concentrated in vertically linked flats in a single building, Block E. On April 17, the Hong Kong Government announced that not one single factor could account for the outbreak in Block E of Amoy Gardens, and attention was focused on possible transmission via the sewage system because laboratory studies showed that patients with the disease excreted coronaviruses in their stools and these viruses were able to survive much longer in feces than on ordinary surfaces, and noted a swab sample taken from the toilet of an infected resident showed a positive test for the coronavirus' genetic material, and about 60% of patients in Amoy Gardens had diarrhea during their illness, and probably would have discharged a large amount of viruses into the soil stacks. Finally, the virus would spread with water droplets through the U-traps of the floor drains, which were dried up in many cases^[11,24,28,29].

The elevated levels of aspartate aminotransferase and lactate dehydrogenase indeed suggest that SARS-CoV was also replicating outside the respiratory tract^[1]. Electron microscopic examination showed that virus-like particles with 100-150 nm in diameter were found in cytoplasm and dilated reticular endoplasm of the infected alveolar epithelial cells and endothelial cells^[6,26,30,31]. Shedding of the virus in feces might be an additional source of spreading, provided the virus was stable in this environment^[8].

Tsang *et al.*, reported that there were three nurses who worked at Hospital B, where a patient was admitted and remained for 6 d for treatment of pneumonia before he was transferred to Hospital C. During this period, the nurses spent five 8-h shifts stationed on the general ward where the patient was hospitalized. The three nurses recalled close encounter with the patient during which they cleaned him when he had fecal incontinence after an episode of diarrhea on March 3, 2003. The nurses did not wear masks or gowns during their routine nursing care of any patients on the ward and finally were all infected^[1].

The detection of SARS-CoV in fecal and serum samples from patients, as well as in respiratory specimens, suggested that this virus, like many animal coronaviruses, might spread both by fecal contamination and by respiratory droplets^[4].

Zhang reviewed the data of SARS transmission and believed that, as previously described, most coronaviruses could cause either a respiratory or an enteric disease, which is also transmitted by the fecal-oral route. During this outbreak of SARS, symptoms of the gastrointestinal tract in patients were noticed. Many investigators^[1,10,32] found that gastrointestinal symptoms, including diarrhea (19-50%), nausea and vomiting (19.6%), and abdominal pain (13%) were common in SARS patients.

All the above reports suggested that stools of SARS patients or sewage containing stools of SARS patients would transmit the coronavirus. However, except that the positive PCR results were obtained in some patient stools, there were no reports that live viruses were present in patient stool or sewage.

In this study, we isolated and detected the SARS-CoV in stools, urine samples, and sewage from hospitals which were assigned specially to receive SARS patients in Beijing of China. Just as expected, SARS-CoV RNA was detected from

stools of patients, but no live viruses were isolated from stool samples, and no SARS-CoV RNA was found in all stools from patients who recovered. It is suggested that the nucleic acid of SARS-CoV could be really excreted from stools of patients, but infectious SARS-CoV could not be confirmed to excrete through the digestive system. No live virus and its RNA were isolated from the urine samples of patients. It is suggested that SARS-CoV and its RNA could not be excreted from the urinary system.

In order to explore the growth and decline of SARS-CoV and its RNA in environment, SARS-CoV and its RNA were isolated from sewage of hospitals. Although the concentration method of SARS-CoV from sewage has not been reported yet, the concentration of enteroviruses from water using different methods was reported, and the electropositive filters have been considered as the most promising method^[34,35].

We developed a simple method for concentration of entero-viruses from water with electropositive particles, the adsorption of bacteriophage ϕ_2 was reliable and efficient, not affected by the pH value, temperature, turbidity, and organic materials in water, and gave a recovery of 88.7% for poliovirus I and a comparable recovery of HAV, CoxB₃, and Echo 7 from 100 L of tap water^[15].

We attempted to concentrate SARS-CoV in sewage from Xiao Tang Shan Hospital and 309 Hospital in Beijing by the electropositive particle adsorption method. The sewage systems in these two hospitals were similar, i.e. the sewage was collected from each isolation ward and converged into the reaction sedimentation basin, and disinfectant (chlorine) was added to inactivate SARS-CoV and other pathogenic microorganisms; finally, the sewage was discharged from the reaction sedimentation basin after a 60-min reaction.

Results of testing for the presence of SARS-CoV in the sewage indicated that no infectious SARS-CoV or live virus could be recovered in these two hospitals. The nucleic acid of SARS-CoV was found in the sewage before disinfection from both hospitals by semi-nested RT-PCR, while after disinfection of sewage by chlorine, SARS-CoV RNA could only be detected in the samples taken on 11th, 13th, and 15th June, 2003 from 309 Hospital.

Cell culture is a very demanding test. However, negative cell culture results or RT-PCR results could not exclude the presence of SARS-CoV. The detection of SARS-CoV from SARS patients could be negative for the following reasons^[17]. Patients were not infected with SARS coronavirus, the illness was due to another infectious agent (virus, bacterium, fungus) or a non-infectious cause. The test results were incorrect. Current tests need to be further developed to improve their sensitivity. SARS-CoV was so susceptible to environments that it was inactivated quickly out of the body. SARS-CoV might have been inactivated or eliminated by immunoglobulins (antibody) from the recovered patients before excretion, or in the sewage. Palmer *et al.*^[35], reported that human imm-uglobulins were used to eliminate the enteroviruses in concentrated sewage when they evaluated the immunodeficiency virus (HIV) in sewage effluent by infectivity assay and RT-PCR.

Hong Kong Government explained the reasons of a cluster of SARS cases in Amoy Gardens and believed that there was a combination of factors, including the presence

of an index patient who caused the first batch of infections, person-to-person spread, transmission via the sewage system, and environmental contamination^[11,29]. This study demonstrated that SARS-CoV RNA could be excreted through the feces or/and urine samples of patients into sewage system.

In conclusion, this study demonstrated that there was SARS-CoV RNA in stool samples of patients with symptoms and in sewage of hospitals though there was no live SARS-CoV isolated from all samples. It provides evidence that the nucleic acid of SARS-CoV can be excreted through the stools of patients into sewage system, but cannot exclude the possibility of SARS-CoV transmitting through the digestive system. Much attention should be paid to the treatment of stools of patients and the sewage of hospitals receiving SARS patients.

ACKNOWLEDGEMENTS

Abstract

AIM: Trace elements (TE) metabolism is altered in inflammatory bowel diseases. TE (zinc and copper) are constituents of antioxidant enzymes. Iron is involved in the pathogenesis of chronic inflammation. The aim was to evaluate zinc and copper status and the effects of iron manipulation in experimental colitis.

METHODS: Twenty-four male Sprague-Dawley rats were divided into four groups: standard diet, iron-deprived diet, iron-supplemented diet, and sham-treated controls. Macroscopic damage was scored. DNA adducts were measured in the colon. Liver and colonic concentration of TE were measured.

RESULTS: Macroscopic damage was reduced in iron-deprived groups and increased in iron-supplemented rats. Damage to the DNA was reduced in iron-deprived groups and increased in iron-supplemented groups. Liver and colonic iron concentrations were reduced in iron-deprived and increased in iron-supplemented rats. Liver zinc concentration was reduced after supplementation whereas colonic levels were similar in controls and treated rats. Liver copper concentration was reduced in all the colitic groups except in the iron-supplemented group whereas colonic concentration was increased in iron-deprived rats.

CONCLUSION: Iron deprivation diminishes the severity of DNBS colitis while supplementation worsens colitis. Zinc and copper status are modified by iron manipulation.

INTRODUCTION

Trace elements such as zinc and copper are essential for human health^[1]. Zinc is required for cell membrane integrity, cell proliferation, and immune function. Several zinc-dependent antioxidant enzyme such as superoxide dismutase and metallothionein can neutralize free radicals production. Copper is necessary for the function of many enzymes involved in cell respiration and in cellular iron metabolism. Copper and zinc are both components of antioxidant enzymes such as superoxide dismutase. On the other hand, copper excess increases free radical levels thus enhancing the biological damage free radicals mediated^[2].

In inflammatory conditions large amounts of reactive oxygen species are produced and this contributes with different mechanisms to damage tissue proteins, DNA chains and lipids^[3]. Iron is a major peroxidative agent and animal studies demonstrated increased oxidative stress and intestinal inflammation after iron supplementation^[4]. As previously reported by Kato *et al.*, in Long Evans Cinammon rats, a model of copper liver toxicity, increased iron level is associated to copper excess and iron-deprived diet reduced mortality and fulminant hepatitis^[5]. Trace elements homeostasis is altered both in human and animal models of inflammatory bowel diseases with possible implication for disease activity and carcinogenesis^[6-8].

We previously demonstrated that dietary iron deprivation is effective in reducing DNA damage and improves the outcome of colitis. The aim of this study was to evaluate the effects of iron supplementation compared to deprivation on disease activity, on trace elements status and on colonic DNA oxidative damage in a model of experimental colitis.

MATERIALS AND METHODS

Experimental protocol

Twenty-four male Sprague-Dawley rats weighing 200 g were divided into four groups; one group was fed with standard diet containing 200 mg/kg of iron and given drinking water ad libitum. The second group was fed with an iron-controlled diet (50 mg/kg) and allowed to drink iron-free water for 5 wk and the third with an iron-supplemented diet (1 700 mg/kg) for 5 wk. The fourth group was fed with a standard diet (200 mg/kg of iron) and at the time of colitis induction was sham treated with saline.

Colitis was induced by the intrarectal instillation of 58 mg dinitro-benzene-sulfonic acid (DNBS) dissolved in 50% ethanol. The rats were anesthetized with ether and a silicone catheter was introduced intrarectally to 5 cm. Animals were kept in the Trendelenburg position for 10 min

to avoid the rapid evacuation of the enema. On d 8, 1 wk after colitis induction, the animals were weighed and anesthetized with intraperitoneal chloral hydrate (400 mg/kg) after which the abdomen was opened with a midline incision and exsanguination was performed. The colon was removed, opened along the antimesenteric border, rinsed with iron-free water and weighed.

The damage was assessed by scoring the number and extension of ulcers, adhesions, and thickness of the colonic wall according to Morris *et al.*^[9].

Operators were unaware of the treatment of each group. Colonic tissue samples were obtained and processed for myeloperoxidase and 8-hydroxydeoxyguanosine (8-OHdG) determination and for measuring iron, zinc, and copper concentrations. Similarly liver samples were obtained for the determination of iron, zinc, and copper concentrations.

Iron, zinc, and copper determination

Trace elements concentrations were measured using atomic absorption spectrophotometry. Intestinal and liver tissues, obtained from rats, were dried at 42 °C for 24 h. The dried samples were weighed on an analytical balance, transferred into element-free tubes and then dissolved using 4.5 mL of 300 mL/L nitric acid solution. The tubes were incubated at 42 °C for 24 h. Iron, copper, and zinc standard solutions (0.05, 0.10, 0.20, 0.50, and 1 µg/mL) were prepared by dilution of concentrated stock solution (Titrisol, Merck Darmstadt, Germany) in deionized water. A Perkin Elmer 3100 atomic absorption spectrophotometer operated with an acetylene air mixture. A lean blue (oxidizing) flame was used with a cathode lamp current of 15 mA, a monochromator wavelength of 248.3 nm, and a slit width of 0.2 nm for Fe; lamp current of 25 mA, a wavelength of 213.9, and a slit width of 0.7 nm for Zn; lamp current of 15 mA, a wavelength of 324.8 nm, and a slit width of 0.7 mm for Cu.

Samples were aspirated directly and the concentration of the element of interest was determined from appropriate standard curves. Standard controls (Bovine liver, Trinital, Magenta, Milan, Italy) were prepared using the same extraction procedure used for sample preparation.

Results were expressed taking into account the dry weight and the dilution factor of the samples.

Myeloperoxidase

MPO activity was assessed following previously described methods^[10]. Briefly colonic tissue samples were minced in 1 mL of 50 mmol/L potassium phosphate buffer (pH 6.0) containing 14 mmol/L hexadecyltrimethylammonium bromide (Fluka), homogenized and sonicated. The lysates have to be frozen and thawed thrice, then centrifuged for 2 min in cold at 15 000 *g*. Aliquots of the supernatants

were mixed with potassium phosphate buffer containing o-dianisidine-HCl (Sigma-Aldrich, St. Louis, MO, USA) and 0.0005% H₂O₂. MPO activity was expressed as units/g of wet tissue. The enzyme unit was defined as the conversion of 1 mol of H₂O₂ per minute at 25 °C.

8-OHdG

Oxidative DNA damage was assessed following previously described methods^[11]. Briefly colonic biopsy specimens were thawed, homogenized in a separation buffer and approximately 20 µg of purified DNA per sample was injected in the HPLC (Shimadzu, Kyoto, Japan). The 8-OHdG was detected using an electrochemical detector (ESA Coulochem II 5200A, Bedford, MA, USA). The levels of 8-OHdG were expressed as the number of 8-OHdG adducts per 10⁵ dG bases. The coefficient of variation was <10%; 100 µg of DNA were required for the determination.

Statistical analysis

Data are expressed as mean +/- standard error. Statistical data were analyzed with Mann-Whitney *U* test for comparison of the four groups and Spearman's rank correlation test to evidence any relation between the evaluated parameters. *P* values less than 0.05 were considered significant.

RESULTS

Before colitis was induced body weight was similar in all groups of animals. The colon weight, a rough measure of edema and inflammation, was significantly increased in colitic animals with respect to controls (*P*<0.05), while iron-deprived rats had colonic weights similar to controls. The macroscopic damage score was significantly lower in the group receiving iron-deprived diet than in the colitis groups. MPO activity was significantly increased in iron-supplemented rats. Iron deprivation was associated with significantly higher MPO levels than controls.

Clinical and biochemical aspects of colitis in all rat groups are summarized in Table 1.

Dietary iron deprivation significantly decreased hepatic and colonic iron concentrations. Iron supplementation increases the iron concentration in liver and colon compared to healthy controls. Iron concentration was increased in the liver and colon of rats with colitis (Fe, 200 mg/kg) whereas supplementation did not affect hepatic iron concentration (Figure 1). There was a significant correlation between hepatic and colonic iron concentrations (*R* = 0.567, *P*<0.002).

Inflammation significantly increased hepatic zinc concentration but neither iron deprivation or supplementation modified zinc concentration in the liver. Although no

Table 1 Clinical and biochemical aspects of colitis

	Controls	Standard diet (Fe, 200 mg/kg)	Iron-supplemented diet (1 700 mg/kg)	Iron-deprived diet (45 mg/kg)
Colon wet weight (g)	2.2±0.2	4.0±0.9 ^a	3.8±0.8	2.1±0.4 ^c
Macroscopic damage score	0±0	8.75±2.5	7.4±1.4	3.6±1.1 ^c
Myeloperoxidase U/mg	3.5±0.6	19.4±5.2	61.4±7.9 ^b	24.5±7.1

^a*P*<0.05 vs controls; ^b*P*<0.01 vs standard diet; ^c*P*<0.05 vs standard diet.

significant change was revealed in any of the treatments the more the colon was damaged the lower was the colonic zinc concentration ($R = -0.460$, $P = 0.02$).

Hepatic copper concentration was reduced in all colitic groups with respect to controls except in the iron-supplemented group. On the other hand, copper colonic concentration was increased in the iron-deprived diet group irrespective of treatment and inflammatory status (Table 2). Hepatic copper concentration correlated with colonic copper ($R = 0.39$, $P < 0.04$).

Colonic DNA adducts were significantly reduced in rats fed with an iron-deprived diet for 5 wk (Figure 2). Colonic DNA adducts significantly correlated with iron colonic concentration ($R = 0.44$, $P < 0.02$).

Figure 1 Liver (A) and colonic (B) iron concentrations. ^a $P < 0.05$, ^b $P < 0.01$ vs controls; ^c $P < 0.05$ vs standard diet.

Figure 2 Colonic DNA adducts. ^a $P < 0.05$ vs controls; ^b $P < 0.01$ vs standard diet.

DISCUSSION

Iron has a major role in chronic inflammatory diseases. Lin *et al.*, demonstrated *in vitro* that iron chelation effectively

Table 2 Hepatic and colonic zinc and copper concentrations in controls and colitis

	Zinc $\mu\text{g/g}$		Copper $\mu\text{g/g}$	
	Hepatic	Colonic	Hepatic	Colonic
Controls	99.8 \pm 2.1	133.4 \pm 6.1	54.4 \pm 1.6	18.6 \pm 0.9
Standard diet	140.2 \pm 6.2 ^a	113.9 \pm 5.8	20.8 \pm 0.7 ^d	18.6 \pm 0.9
Iron-supplemented diet	92.6 \pm 5 ^b	132.2 \pm 10.2	44.2 \pm 3.9	21 \pm 2.1
Iron-deprived diet	117.2 \pm 4.4	101.6 \pm 5.1	19.7 \pm 0.8 ^d	36.2 \pm 5.9 ^c

^a $P < 0.05$ vs controls; ^b $P < 0.01$ vs standard diet; ^c $P < 0.05$ vs controls and standard diet; ^d $P < 0.001$ vs controls.

blocks NF-kappa B activation and upregulates TNF- α and IL-6 genes in a model of cholestatic liver injury, suggesting a basic role for iron in the activation of the inflammatory process^[12]. In patients with Crohn's disease and anemia, treatment with oral ferrous fumarate decreased cysteine and glutathione peroxidase with consequent altered plasma antioxidant status^[13]. Moreover, oxidative stress is increased *in vitro* cell lines from patients with ulcerative colitis treated with iron^[14].

Recent evidence showed that iron dietary deprivation is a reasonable approach to many diseases with a free radical component^[15]. It is known that Deferoxamine, an iron chelating agent, effectively reduces mucosal oxidant activity by decreasing the luminol-amplified chemiluminescence *in vitro* by 44% in active ulcerative colitis biopsies^[16]. This effect was attributed more to iron chelation than to a direct antioxidant activity.

We observed that iron deprivation was associated with less macroscopic colonic mucosal damage while iron supplementation worsened colitis. Iron and inflammation seem to have a synergic action since MPO levels were greatly increased in the iron-supplemented group. Our observations suggest that iron manipulation may modulate inflammatory damage.

The results of this study confirm that dietary iron deprivation reduces inflammation and oxidative DNA damage in the rat model of DNBS-induced colitis while iron supplementation worsens colitis as we previously reported (in press)^[17]. These results further reinforce our previous findings on the role of iron deprivation in DNBS colitis. Carrier *et al.*, recently reported that oral iron supplementation may aggravate inflammation and oxidative stress in dextran sulfate sodium-induced colitis^[18]. Oxidative damage, expressed by DNA adducts level, was decreased in iron-deprived rats. According to Seril *et al.*, reactive oxygen species, produced in abundance in the presence of iron during inflammation, can directly mediate DNA damage thus leading to alterations, which cause loss of suppressor genes and gain of oncogenes function^[19].

Trace elements are altered during inflammation and their status is critical for normal cell and enzymes function. Many enzymes, involved in DNA repair mechanisms, are zinc-dependent thus trace elements alteration could contribute to DNA damage^[20]. Several human and animal studies have demonstrated altered trace elements status during inflammation. Al Awadi *et al.*, reported a significant reduction of colonic zinc level in experimental colitis while copper and manganese remained unaltered^[8]. Zinc and copper serum levels were altered in well-nourished patients

with ulcerative colitis and correlated with hematological parameters of disease activity suggesting their role in inflammation^[21]. We previously demonstrated that zinc supplementation regulates tight junction permeability in experimental colitis with possible implication on mucosal healing^[22]. Several studies have pointed out that zinc, copper, and iron may affect the progression of colonic tumors in experimental model of preneoplastic lesions^[23]. Moreover, Ames has recently reported that zinc and other micronutrient deficiencies mimic the effect of radiation on DNA chain with strong implication for carcinogenesis^[24].

Hepatic zinc concentration is significantly reduced during iron dietary deprivation. Colonic zinc concentration is similar to controls in all treated groups and it is independent from iron metabolism. The inverse correlation with macroscopic score and colonic weight may suggest the relevant effect of zinc on mucosa healing. In fact as recently reported by Kruidenier superoxide dismutase Zn/Cu dependent is decreased in colonic mucosa of IBD patients with active inflammation^[25].

Colonic copper is increased during iron dietary deprivation. Iron supplementation does not seem to affect copper absorption as recently demonstrated in ileostomy subjects^[26]. Colonic copper alterations seem therefore a consequence of local inflammation. On the other hand our data showed that inflammation decreased copper concentration in the liver except in the presence of iron supplementation. This is in agreement with the results reported in Long Evans Cinammon rats, in which an iron deprived diet reduced mortality and fulminant hepatitis^[5].

In conclusion, we pointed out that iron manipulation affects the severity of experimental colitis. Iron manipulation results in changes of zinc and copper status which may, after a chemical insult, alter the natural course of intestinal inflammation and may have important implications for the development of antioxidant treatment of IBD patients.

Abstract

AIM: To investigate β -catenin expression in patients with intestinal metaplasia, and to look for a possible relationship between β -catenin expression and either epithelial proliferation values or *Helicobacter pylori* (*H pylori*) infection.

METHODS: Twenty patients with complete type intestinal metaplasia were studied. β -Catenin expression and epithelial cell proliferation in antral mucosa were assessed using an immunohistochemical analysis. *H pylori* infection was detected by histology and a rapid urease test.

RESULTS: Reduced β -catenin expression on the surface of metaplastic cells was detected in 13 (65%) out of 20 patients. Moreover, in eight (40%) patients intranuclear expression of β -catenin was found. When patients were analyzed according to *H pylori* infection, the prevalence of both β -catenin reduction at the cell surface and its intranuclear localization did not significantly differ between infected and uninfected patients. Cell proliferation was higher in patients with intranuclear β -catenin expression as compared to the remaining patients, although the difference failed to reach the statistical significance (36 ± 8.9 vs 27.2 ± 11.4 , $P = 0.06$). On the contrary, a similar cell proliferation value was observed between patients with reduced expression of β -catenin on cell surface and those with a normal expression (28.1 ± 11.8 vs 26.1 ± 8.8 , $P = 0.7$). *H pylori* infection significantly increased cell proliferation ($33.3 \pm 10.2\%$ vs $24.6 \pm 7.4\%$, respectively, $P = 0.04$).

CONCLUSION: Both cell surface reduction and intranuclear accumulation of β -catenin were detected in intestinal metaplasia. The intranuclear localization of β -catenin

INTRODUCTION

Catenins are a family of transmembrane proteins, which play a pivotal role in epithelial intercellular adhesion^[1]. Moreover, β -catenin participates in the regulation of cell proliferation, being a critical component of the surface-to-nucleus WNT signal transduction pathways^[2,3]. Alterations of β -catenin expression have been shown to be involved in cancer development^[4]. Indeed, such alterations have been detected in gastric cancer, showing a correlation with tumor type, degree of differentiation, and poor survival of patients^[5-9]. On the other hand, scanty data are available regarding β -catenin expression in precancerous conditions. Although alterations of some adhesion molecules have been detected in patients with intestinal metaplasia^[10], no significant remarks emerged from the studies regarding β -catenin expression in these patients^[10,11]. However, such studies were based on gastrectomy specimens of patients with gastric cancer and, therefore, only an advanced step of the carcinogenic process was evaluated.

Gastric carcinogenesis is a multistep process consisting of a cascade of alterations starting with chronic active gastritis and progressing to atrophy, metaplasia, and dysplasia^[12]. In particular, intestinal metaplasia is widely recognized as being the most prevalent precursor of intestinal type gastric carcinoma^[13]. Among environmental factors involved in carcinogenesis of the stomach, *Helicobacter pylori* (*H pylori*) infection appears to play an important role. Indeed, epidemiological studies have clearly demonstrated a significant association between this infection and gastric cancer development. Moreover, several changes involved in gastric carcinogenesis such as epithelial cell hyperproliferation,

free oxygen radical formation, ascorbic acid reduction, genetic alterations have been described in the gastric mucosa of infected patients^[14-16].

The present study was designed in order to assess β -catenin expression in patients with intestinal metaplasia but with neither dysplasia nor gastric cancer, and to look for a possible relationship between β -catenin expression and either epithelial proliferation index of gastric mucosa or *H. pylori* infection status.

MATERIALS AND METHODS

Patients

Patients with dyspeptic symptoms consecutively referred for upper endoscopy with presence of histology of intestinal metaplasia in the antrum and without concomitant evidence of either dysplasia in the stomach or neoplastic lesions in the upper gastrointestinal tract were selected. Patients were enrolled irrespectively of *H. pylori* status. Patients who received proton pump inhibitors, H_2 -receptor antagonists, antibiotics or NSAIDs in the 4 wk preceding the study as well as those previously treated for *H. pylori* infection were excluded from the study. Patients with either liver impairment or kidney failure were also excluded.

Endoscopic procedure

After overnight fasting, all patients underwent upper endoscopy and three biopsies were taken from the antrum and three from the gastric body. Two biopsies from the antrum and two from the gastric body were used for histological assessment. Biopsy specimens of the antrum were also used for immunohistochemical analysis. The remaining two biopsies (one each from the antrum and gastric body) were used to carry out a rapid urease test (CP-test, Yamanouchi, Milan, Italy). *H. pylori* infection was considered to be present when both the histological assessment on Giemsa staining revealed the presence of bacteria and rapid urease test was positive, as suggested in current guidelines^[17].

Immunohistochemical analysis

For β -catenin and proliferation assessment, immunohistochemistry was carried out by the avidin-biotin-peroxidase method. Briefly the sections were deparaffinized in xylene and rehydrated through a graded alcohol series to distilled water. Antigen retrieval was performed by immersing the slides in 10 mol/L citrate buffer (pH 6.0) and heating them in a microwave for 3 cycles, 5 min each, at 750 W. Endogenous peroxidase activity and non-specific bindings were blocked by incubation with 3% hydrogen peroxide and nonimmune serum, respectively. Sections were then incubated with mAbs against β -catenin (Clone 14, 1:500 dilution; Transduction Laboratories, Lexington, KY, USA) and mAbs against Ki-67 (Clone MIB-1, 1:100 dilution YLEM, Italy) for 1 h at room temperature. Immunoreactivity was revealed with the chromogen DAB test and the sections were counterstained with Mayer hematoxylin solution for 7 min. Negative control sections were prepared by substituting primary antibody with buffered saline.

A semiquantitative approach was used for scoring the

β -catenin expression according to the method previously described by Mingchao^[10]. Briefly, the staining pattern of the intestinal metaplastic areas was compared with that of the adjacent normal gastric mucosa. Expression of β -catenin in metaplastic areas was considered 'normal' when both the intensity and the frequency of the cell membrane stains were equivalent to those found on the bordering nonmetaplastic gastric mucosa, 'reduced' when the staining was less than the adjacent mucosa, and 'negative' in the absence of staining. In addition, when β -catenin stained clearly in the nuclei of more than 10% of gastric epithelial cells, expression was judged to be positive for nuclear staining.

A quantitative approach was used instead for scoring the Ki67 expression. The number of cells was determined by counting the positively-stained nuclei on 10-20 randomly selected fields at 400 \times .

All immunostaining evaluations were performed blindly and by two independent observers. All sections for which the two observers disagreed were re-evaluated and, after opportune discussion, a final agreement was achieved.

Statistical analysis

Data between patient subgroups were compared using the Student's *t*-test for unpaired data, and the Fisher's exact test with Yate's correction for small numbers. A *P* value less than 0.05 was considered statistically significant.

RESULTS

Overall, 20 consecutive patients (9 male and 11 female; mean age: 60.8 \pm 8.4 years) were enrolled. At endoscopy, no macroscopic alterations of the gastric mucosa were detected, whilst two patients showed erosions in the duodenal bulb. *H. pylori* infection was present in 13 (65%) patients and absent at both rapid urease test and histology in the seven remaining patients. Intestinal metaplasia was graded as complete type in all cases.

β -catenin expression in gastric mucosa

No case of completely negative β -catenin immunostaining was observed. A reduced expression of β -catenin on the surface of metaplastic cells as compared to adjacent normal glands was detected in 13 (65%) out of 20 patients. Moreover, in eight (40%) patients an intranuclear expression of β -catenin was detected. Among this group, six (75%) patients also showed reduced β -catenin expression. When patients were analyzed according to *H. pylori* infection, β -catenin expression was decreased in 8 out of 13 infected patients as well as in 5 out of 7 uninfected cases (*P* = 0.5). Similarly, the prevalence of intranuclear localization of β -catenin expression did not significantly differ between infected and uninfected patients (4/13 *vs* 4/7, respectively; *P* = 0.2).

Cell proliferation in gastric mucosa

The mean value of Ki67 labeling index proved to be distinctly higher in eight patients with intranuclear β -catenin expression as compared to the remaining 13 patients, although the difference failed to reach statistical significance (36 \pm 8.9 *vs* 27.2 \pm 11.4, *P* = 0.06). On the contrary, by

excluding those patients with intranuclear localization of β -catenin, a similar cell proliferation value was observed between the seven patients with reduced membranous expression of β -catenin and the five patients with normal expression (28.1 ± 11.8 vs 26.1 ± 8.8 , $P = 0.7$). As far the role of *H. pylori* infection is concerned, data found that patients with infection had a significantly increased cell proliferation value than that of uninfected patients ($33.3 \pm 10.2\%$ vs $24.6 \pm 7.4\%$, respectively, $P = 0.04$).

DISCUSSION

The integrity of the function of adhesion molecules, such as E-cadherin and α , β , γ -catenins, allows the maintenance of normal interactions between cells necessary during embryogenesis, cell growth, and differentiation^[1-3,18]. Loss of intercellular adhesiveness plays a role in the early steps of neoplastic transformation, and it is implicated in invasive growth and metastasization^[5-9,19]. β -catenin participates in the adhesion process by binding the cytoplasmic domain of E-cadherin and it has been involved in the surface-to-nucleus WNT signal transduction pathways. Its translocation into the nucleus may contribute to accelerated cell proliferation^[3]. β -catenin mutations in exon 3, interfering with the GSK-3 β phosphorylation domain and leading to intranuclear accumulation of the protein, have been reported in intestinal gastric carcinoma as well as in colorectal cancer^[20-23]. Moreover reduced β -catenin expression was recorded both in intestinal type of gastric cancer^[5,6,24] and in intestinal metaplasia surrounding cancer lesions^[25], although data are controversial^[10,11,24]. In order to determine whether β -catenin alterations could be detected early in gastric carcinogenesis, the present study focused on β -catenin expression in intestinal metaplasia not associated with gastric cancer. Unlike previous study^[26], in our series a reduction of β -catenin on the epithelial surface was observed in more than half of the patients. Intriguingly, a nuclear accumulation of β -catenin expression in 40% of patients with intestinal metaplasia was also found, and it was associated with reduced immunostaining at the intercellular boundaries in 75% of these cases. A previous study reported a nuclear accumulation of β -catenin in about 10% of 401 gastric carcinomas, all but one exhibiting reduced membranous staining^[24]. Similarly, an inverse correlation between decreased membranous and increased nuclear staining of β -catenin was also observed in colorectal cancer^[27,28]. Interestingly, we observed that patients with intranuclear β -catenin expression showed higher values of cell proliferation in the gastric mucosa as compared to those without it. This is a noteworthy remark in keeping with previously reported studies focused on the role of nuclear localization of β -catenin^[3]. Indeed, in an experimental model, colonocyte hyperproliferation was associated with immunohistochemical alterations in subcellular distribution of β -catenin and with accumulation of the protein in the nuclear compartment^[29]. This finding, however, has been not observed in gastric cancer^[23,24]. Therefore, it could be hypothesized that the nuclear β -catenin expression may be linked to the early stage of carcinogenesis, as seen in colorectal polyps^[30]. Conversely, loss of membranous expression could allow regenerating cells to dedifferentiate

and lose cell-cell cohesiveness, properties that would facilitate the process of epithelial regeneration, as reported for E-cadherin expression during the reparative process of peptic ulcer^[31]. Similarly, in endometrial glandular cells in the mid-to-late proliferative phase, nuclear accumulation of β -catenin was described, suggesting that it could play a physiological role in the rapid turnover of the cell cycle without gene mutation^[32].

As far the role of *H. pylori* infection is concerned, we failed to observe a significant difference in β -catenin expression between infected and uninfected patients, suggesting that this infection is not directly implicated in this phenomenon. On the contrary, in agreement with the results of several studies^[14,16], a significant increase in the epithelial cell proliferation index was detected in *H. pylori*-positive patients as compared to uninfected patients.

In conclusion, in the present immunohistochemical study, we described alterations in β -catenin expression in the gastric mucosa with intestinal metaplasia not associated to other more advanced histological lesions. β -catenin alterations consisted of both a weakness of membrane staining and in an intranuclear accumulation of the protein. Moreover, we observed a distinct increase in cell proliferation in those patients with intranuclear localization of β -catenin expression. *H. pylori* infection does not seem to play a role in β -catenin alterations, whilst it significantly increases cell proliferation in gastric mucosa with intestinal metaplasia.

Abstract

AIM: To investigate the possible role of c-erbB-2 and glutathione S-transferase (GST-Pi) in primary hepatocellular carcinogenesis and the relationship between liver hyperplastic nodule (LHN), liver cirrhosis (LC), and hepatocellular carcinoma (HCC).

METHODS: The expression of c-erbB-2 and GST-Pi was detected immunohistochemically in 41 tissue specimens of HCC and 77 specimens of its adjacent tissue.

RESULTS: The positive expression of c-erbB-2 in LHN (28.6%) was significantly higher than that in LC (0%) ($P = 0.032 < 0.05$), but no significant difference was seen between HCC and LHN or LC ($P > 0.05$, $\chi^2 = 0.002$, 3.447). The positive expression of GST-Pi in HCC (89.6%) or LHN (71.1%) was significantly higher than that in LC (22.9%, $P < 0.001$, $\chi^2 = 49.91$, 16.96). There was a significant difference between HCC and LHN ($P < 0.05$, $\chi^2 = 6.353$).

CONCLUSION: The c-erbB-2 expression is an early event in the pathogenesis of HCC. GST-Pi may be a marker enzyme for immunohistochemical detection of human HCC and its preneoplastic lesions. LHN seems to be a preneoplastic lesion related to hepatocarcinogenesis.

INTRODUCTION

Primary hepatocellular carcinoma (HCC) is one of the most common malignant tumors in Asia, and the incidence and mortality of HCC show a tendency to rise year by year. Therefore, the detection of preneoplastic lesions of HCC is crucial for the analysis of carcinogenic processes and developing strategies for prevention and treatment. For many years, liver hyperplastic nodule (LHN) has been considered as a preneoplastic lesion. Our previous studies have also confirmed that LHN is closely related to human HCC.

In the present study, the immunohistochemical LSAB method was used to detect the expression of c-erbB-2 oncogene and glutathione S-transferase-pi (GST-pi) in HCC and pericarcinomatous tissues, in order to investigate the possible roles of these genes in the HCC carcinogenesis, and to find out the relationship between LHN, liver cirrhosis (LC), and HCC.

MATERIALS AND METHODS

Materials

HCC specimens from 100 patients were selected during surgical resections or biopsies performed at the Affiliated Hospital of Medical College of Qingdao University, China. Of these patients, 76 were males and 24 females with an average age of 50.4 years. None of the patients received chemo- or radiotherapy before resection. We randomly selected 41 and 77 cases of HCC to detect the expression of c-erbB-2 and GST-pi, respectively. The same specimens from 16 cases were detected for both c-erbB-2 and GST-pi, which were too few to be analyzed in terms of the correlation between them in the present study. Forty-one specimens for detecting c-erbB-2 oncogene contained 18 pericarcinomatous tissues, including 14 LHN, 17 LC. Seventy-seven specimens for detecting GST-pi contained 40 pericarcinomatous tissues, including 38 LHN, and 35 LC.

Methods

All specimens were routinely processed, alcohol-fixed and paraffin-embedded. Serial paraffin sections of 4 μ m thickness were cut and used for hematoxylin and eosin and immunohistochemical staining. Immunohistochemical LSAB method was used to detect c-erbB-2 and GST-pi. Anti-c-erbB-2 multiple clonal antibody, anti-GST-pi multiple clonal antibody and LSAB kits were purchased from Dako Co. Before staining, the sections were microwave heated in 0.05 mol citric acid solution for antigen retrieval. In each staining run, a known c-erbB-2 or GST-pi positive section was added as positive control, PBS was used as substitutes

of the first antibodies for negative control.

Analysis of immunohistochemical staining

When brown granules were found on cell membrane of liver cells and cancer cells, c-erbB-2 was identified positive. When only cytoplasm was stained brown, c-erbB-2 was identified negative. The c-erbB-2 expression was graded semi-quantitatively according to the intensity and the percentage of positivity into negative (-): no positive cells or a weak staining of c-erbB-2 with positive cells <5%; positive (+): c-erbB-2 expression was relatively stronger with the positive cells >5%. For GST-pi, cells with brown granules in cytoplasm were regarded as positive. The criteria of the evaluation of GST-pi expression in this study were as follows. The positive number was semiquantitatively evaluated by counting that in 5-10 randomly chosen medium power ($\times 100$ magnification), and the three grades for GST-pi were considered as negative (-): no positive cells; positive (+): the positive reaction being brown and the positive cells <30%; strong positive (++): the positive reaction being brown and the positive cells >30% according to the intensity and extent of GST-pi staining.

Statistical analysis

Results were analyzed by χ^2 -test and direct probability calculation. $P < 0.05$ was considered statistically significant.

RESULTS

Expression of c-erbB-2 oncogene in HCC and its adjacent tissue

The positive staining for c-erbB-2 in cancer cells was exclusively located in cell membrane stained brown, the expression of c-erbB-2 was observed in both cell membrane and cytoplasm in one of four cases of LHN expressing c-

erbB-2 (Figure 1A). The c-erbB-2 positive rate was significantly higher in LHN (28.6%) than that in LC (0%, P value 0.032, direct probability calculation, $P < 0.05$), but no significant difference was seen between HCC (Figure 1B) and LHN or LC (χ^2 values 0.002, 3.447, $P > 0.05$, Table 1).

Table 1 Expression of c-erbB-2 oncogene in HCC and its adjacent tissue

Histological type	Case	Expression of c-erbB-2 oncogene		Positive rate (%)
		-	+	
HCC	41	31	10	24.4 ^a
LHN	14	10	4	28.6 ^a
LC	17	17	0	0

^a $P < 0.05$ vs LC.

Expression of GST-pi in HCC and its adjacent tissue

The positive staining for GST-pi appeared as brown granules, which was predominantly located in the cytoplasm, and the staining of the nuclei was seen in part of the cancer cells. There was strong staining of GST-pi in bile duct epithelial cells. A weak staining of GST-pi was observed in LC with a positive rate of 22.9% (8/35). GST-pi expression was markedly stronger in HCC or LHN (Figure 1C). The rates of positivity were 89.6% (69/77) and 71.1% (27/38), respectively, and significantly higher than that in LC (χ^2 values 49.91, 16.96, $P < 0.001$). There was also a significant difference between HCC (Figure 1D) and LHN (χ^2 value 6.353, $P < 0.05$, Table 2).

DISCUSSION

The c-erbB-2/neu is a transforming proto-oncogene encoding

a transmembrane glycoprotein of 185 ku (P185) with tyrosine kinase activity and extensive sequence homology to epidermal growth factor receptor. The c-erbB-2 is in a state of inactivation under normal condition, and is involved in regulating cell growth and proliferation^[1]. Having been affected by some endogenous or extraneous carcinogens, its structure or expression is dysregulated, thus being activated, and c-erbB-2 becomes oncogene with tumor transformation activity. In human malignancies, the activation of c-erbB-2 is most frequently caused by gene amplification, there is extremely high concordance between copy number of gene amplification and protein overexpression^[2,3]. The c-erbB-2 is frequently overexpressed in different tumors in humans, and the activation of c-erbB-2 appears to be an early event in tumorigenesis for some cancers^[4-7]. However, there seems to be conflicting reports concerning the role of c-erbB-2 oncogene in carcinogenesis of HCC. Some studies reported that c-erbB-2 does not play a role in tumorigenesis of HCC^[7], whereas others reported that the overexpression of c-erbB-2 is found in the middle stage of hepatocarcinogenesis, and might only have promoting effects during the development of this lesion^[8]. In the present study, c-erbB-2 overexpression was observed in 24.4% ($n = 41$) of HCC tissue specimens and 22.2% ($n = 18$) of its adjacent tissue specimens, suggesting that the overexpression of c-erbB-2 oncogene plays an initial role in hepatocarcinogenesis, and is an early molecule change in the carcinogenesis of HCC. In addition, the expression of c-erbB-2 did not decrease in the transition from pericarcinomatous tissues into HCC in the present study, indicating that c-erbB-2 expression also occurs later in the process of hepatocarcinogenesis and maintains the transformed hepatocyte phenotype. Apparently, c-erbB-2 expression can contribute to the initiation and progression of HCC.

Many studies have demonstrated that c-erbB-2 gene product not only contributes to the development and maintenance of malignant phenotype, but also plays a pivotal role in transformation and tumorigenesis^[4,5,9], because 3T3 cells or immortalized cells transfected with c-erbB-2 oncogene show a highly transformed and tumorigenic phenotype^[10,11]. It can be inferred from these studies that those cells overexpressing c-erbB-2 oncogene are either cancerous or have malignant phenotype. In the present study, all four cases overexpressing c-erbB-2 oncogene in pericarcinomatous tissues were LHN, thus, the positive expression rate of c-erbB-2 in LHN was 28.6% ($n = 14$), and similar to that of HCC, suggesting that those cells overexpressing c-erbB-2 oncogene in LHN have at least acquired the malignant phenotype, which may reflect the alterations in different biologic state of LHN. Some studies

reported that the increased oncogene expression brings cells into a state of active proliferation that results in an increased frequency of mutation^[12]. Therefore, it is reasonable to postulate that the overexpression of c-erbB-2 oncogene may make LHN transform malignantly, and parts of LHN are actually in the preneoplastic state or might be cancerous. In contrast to LHN, the expression of c-erbB-2 oncogene is negative in LC, implying that there is no activation of c-erbB-2 in LC, i.e., it is impossible in this situation for malignant transformation. There is also no mutation of p53 in LC, consequently, LC does not necessarily link with hepatocarcinogenesis. Our findings further confirm the notion that it is not LC but LHN, is a preneoplastic lesion for the occurrence of HCC in humans.

GSTs play an important role in protecting cells against cytotoxic and carcinogenic agents. GST-pi is an acid GST, isolated and purified from human term placenta, which possesses catalytic and ligand-binding properties, and is regarded as a new marker enzyme for tumors. Some studies reported that GST-pi or GST-pi mRNA is hardly detectable in normal liver, but markedly increases in preneoplastic hepatic lesions such as hyperplastic nodules and in HCC by immunohistochemical staining or *in situ* hybridization^[13-16], suggesting that GST-pi is a sensitive marker enzyme for preneoplastic lesions and neoplastic cells, not only at the protein level but also at the mRNA level, throughout the hepatocarcinogenesis in rat liver. In addition, other studies reported that single cells immunohistochemically positive for GST-pi induced in the rat liver carcinogenesis by chemical carcinogens are precursor-initiated cells of preneoplastic foci, GST-pi content in the single cells is higher than that in preneoplastic foci, and GST-pi is a more sensitive marker for detection of HCC than γ -GT or AFP^[17-20]. Therefore, it has been generally considered that GST-pi is the most accurate marker enzyme for detection of the very early "initiated cells" in chemically induced hepatocarcinogenesis in rats. It is known that human GST-pi has highly immunological cross-reaction with rat GST-pi, and the alteration of GST-pi precedes that of cell morphology. Studies in human HCC are not as advanced as in rats but have revealed close similarities. To investigate the relationship between GST-pi and HCC and its preneoplastic lesions, accordingly, may offer an important enzyme for the early diagnosis of HCC.

The expression of GST-pi might increase abnormally in the course of the carcinogenesis of many tumors, and it has been associated with preneoplastic and neoplastic changes^[21,22]. Recently, many researches demonstrated that loss of transcription activity of GST-pi gene promoter in human malignancies appears to be the result of CpG island DNA methylation, and this phenomenon is most frequent in breast and renal carcinomas, and might contribute to the carcinogenic process in these two carcinomas, while other tumor types show GST-pi promoter methylation only rarely or not at all^[21-23]. However, some studies reported that GST-pi promoter hypermethylation changes occur frequently in human HCC, suggesting that somatic GST-pi inactivation via CpG island hypermethylation might contribute to the pathogenesis of HCC^[24-27]. When cells display complete GST-pi hypermethylation in the CpG island, and they fail to express GST-pi mRNA and the corresponding protein

product, which is different from our findings. GST-pi expression was present in 89.6% of HCC and in 71.1% of LHN in the present study. There are several possibilities for this (1) There is rare or no GST-pi promoter hypermethylation in pathogenesis of HCC. (2) There is GST-pi promoter hypermethylation, but loss of GST-pi promoter hypermethylation in HCC may be due to the emergence of tumor subclones unmethylated at the GST-pi promoter during HCC transformation. Such subclones may gain additional genetic lesions that rendered GST-pi inactivation no longer necessary for neoplastic cell survival. (3) There is GST-pi promoter hypermethylation, but it is not responsible for GST-pi expression, it is the p53 gene mutation existing in LHN and HCC that activates GST-pi. p53 mutation is frequently observed in Asian HCC, but it is not a common event in Western HCC, thus, it is not difficult to interpret the reason why GST-pi is overexpressed in some studies whereas GST-pi is absent in other studies though GST-pi promoter hypermethylation may exist in pathogenesis of HCC. (4) GST-pi promoter hypermethylation is not a frequent event in pathogenesis of HCC, it may relate to the different etiologies of HCC in different geographical areas.

Markedly increased GST-pi content has been found in HCC investigated, indicating that HCC cells have characteristics of some fetal cells, as GST-pi content in fetal cells is noticeably higher than that in adult cells. It can be preliminarily inferred that GST-pi has relevance to detoxification of liver in pathogenesis of HCC. Meanwhile, the high expression of GST-pi in HCC might be associated with the resistance to anticancer drugs and might protect the tumor cells themselves against the cytotoxic effects of free radicals, as described in other tumors^[28-31]. It is well-known that GST-pi can detoxify not only electrophiles derived from xenobiotics, but also endogenous electrophiles usually with the consequence of free radical damage. These data indicate that the overexpression of GST-pi may impart a proliferative advantage in HCC cells due to induction of resistance to several different cytotoxic mechanisms. In the present study, the positive rate of GST-pi in HCC was higher than that in pericarcinomatous tissues, and was significantly higher in LHN than in LC, showing that GST-pi is activated during initiation stage or much earlier stage of cell transformation induced by chemical carcinogens, and may be acquired in increased amounts during malignant progression. Therefore, the data obtained in the present study suggest that GST-pi may be an effective marker enzyme for HCC and its preneoplastic lesions.

As an important enzyme of detoxification, GST-pi protects cells against the influence of carcinogenic materials. However, GST-pi is taken as a double-edged sword in tumorigenesis, namely, GST-pi protects all cells expressing it, including normal cells, cells with malignant phenotype, and tumor cells as well. Many cells in LHN are in a state of active proliferation, and have acquired the malignant phenotype, thus GST-pi evolves specifically to protect these proliferating cells, and these cells inevitably proliferate rapidly, presenting a clonal expansion. Our findings suggest that cells overexpressing GST-pi in LHN may relate to the carcinogenesis of LHN, and some cells in LHN are altered hepatocytes, which should be treated as preneoplastic cells

of HCC. In contrast to LHN, the cells in LC appear to represent quiescent phenotypes unlikely to progress into HCC.

Abstract

AIM: To investigate IL-1 β +3 594 in the 5th intron, IL-10-1 082 and CD14-159 polymorphisms in patients with acute pancreatitis (AP) and septic shock.

METHODS: The study included 215 patients (109 with acute severe pancreatitis (SAP), 106 with acute mild pancreatitis (MAP)) and 116 healthy volunteers. Genomic DNA was prepared from peripheral blood leukocytes. Genotypes and allele frequencies were determined in patients and healthy controls using restriction fragment length polymorphism analysis of PCR products.

RESULTS: The frequencies of IL-1 β +3 594T, IL-10-1082G and CD14-159T allele were similar in patients with mild or severe pancreatitis and in controls. Within SAP patients, no significant differences were found in the allele distribution examined when etiology was studied again. Patients with septic shock showed a significantly higher prevalence of IL-10-1082G allele than those without shock ($\chi^2 = 5.921$, $P = 0.015$).

CONCLUSION: IL-10-1082G plays an important role in the susceptibility of SAP patients to septic shock. Genetic factors are not important in determination of disease severity or susceptibility to AP.

INTRODUCTION

Acute pancreatitis (AP) is a common disease that normally runs a benign course in the majority of patients. However, in up to 20% of individuals the disease is severe and may have a mortality close to 20%^[1]. Two weeks after the onset of acute severe pancreatitis (SAP), sepsis-related complications resulting from systemic inflammatory response syndrome (SIRS) or infection of pancreatic necrosis or bacteria translocation often occur. There is evidence that the production of tumor necrosis factor- α , interleukin (IL)-1 β , IL-6, and IL-8 may play a vital role in AP. In addition, anti-inflammatory response, especially IL-10, plays an important role in determining prognosis of AP^[2]. Several methods for estimating the complications are widely used in clinic, such as Atlanta classification, Acute Physiology and Chronic Health Evaluation II, Imrie and Ranson scores, Balthazar computed tomographic scoring system, and C-reactive protein. However, these methods have little value in predicting which patients will develop pancreatic infection and SAP-associated septic shock.

It has been hypothesized that there is a correlation between polymorphisms in TNF- α , IL-1 β , and IL-10 genes and differential production of respective cytokines^[3]. Some of these polymorphisms affect clinical outcome in inflammatory diseases including AP^[3-5]. IL-10 is an anti-inflammatory cytokine and plays an important role in downregulating cell-mediated inflammatory responses. Human IL-10 gene is located on chromosome 1 and has been mapped to the junction between 1q31 and 1q32. Three single base pair (bp) substitutions in IL-10 gene promoter at positions -1 082G-A, -819T-C, and -592A-C from the transcriptional start site have been identified. At position -1 082 bp from the transcriptional start site, the presence of G is associated with higher and A with lower production of IL-10 by PBMC cultures^[6]. In contrast, IL-1 β is a potent proinflammatory cytokine released by macrophages in systemic inflammatory responses. It not only has important biologic effect but also regulates inflammatory reaction and immune response by promoting expression of other cytokines, such as IL-6 and IL-12. IL-1 β gene located on chromosome 2 is 7 kb, and has seven exons and six introns. A polymorphism is found at position +3 954 located in the 5th intron of IL-1 β gene with a T substitution of C. *In vitro* study demonstrated that IL-1 β +3 594 at the 5th exon significantly influences the production of IL-1 β ^[7]. Their polymorphisms may have some association with the development of severe AP and septic shock.

CD14, a 55 ku membrane-anchored protein, is a pattern-recognition receptor for several microbial products,

such as lipopolysaccharide (LPS). It can be expressed on neutrophils, monocytes/macrophages, and fibroblasts, all of which can produce cytokines such as IL-1 and TNF- α in response to LPS stimulation^[9]. Recently, a-159 G/A polymorphism in the promoter region of CD14 gene involves a C>T substitution at bp -159 of the 5' flanking region of CD14 gene. Genotypes include CC, CT, and TT alleles. Subjects carrying the T allele have been shown to have significantly higher sCD14 levels than those carrying the C allele^[8,9]. Therefore, CD14 polymorphism could be a genetic factor responsible for interindividual differences in the susceptibility to bacterial infection. However, to the best of our knowledge, there were no reports on the linkage of CD14 and pancreatitis.

Our previous studies have shown that some polymorphisms in TNF gene correlate with severe sepsis or SAP-associated septic shock, although no association has been found between TNF gene polymorphisms and SAP^[4,5,10]. The purpose of this study was to test the hypothesis that IL and CD14 gene polymorphisms have some correlation with the development of SAP and septic shock.

MATERIALS AND METHODS

Subjects

Patients with a first attack of unequivocal AP from July 2001 to December 2003 were prospectively considered. The diagnosis of AP was based on an increased-amylase activity (enzymatic colorimetric test) in serum and CT verification of pancreatitis. Etiology of AP was gallstones found in radiological and endoscopic retrograde cholangiopancreatography findings, alcoholic if patients were heavy consumers of alcohol (more than 80 g of alcohol per day for over 6 mo)^[11], and idiopathic if no other identifiable cause could be discovered. Pancreatitis was classified as severe when APACHE II score ≥ 8 ^[12] and CT severity index ≥ 4 ^[13]. Septic shock was defined according to ACCP/SCCM consensus conference criteria^[14]. The control group consisted of 116 healthy volunteers. All subjects gave written informed consent, and the protocol was approved by the local ethics committee.

In order to be eligible for the enrollment, all the subjects from the two groups were yellow Chinese Han. The exclusion criteria were defined as follows: age > 75 years, cardiac failure (class > III), liver insufficiency (Child C), patients with evidence suggestive of a diagnosis of chronic pancreatitis and consanguineous mating.

DNA extraction

Genomic DNA was purified from 5 mL of peripheral blood samples using Wizard genomic DNA purification kit (Promega) according to the manufacturer's instructions.

IL-10-1082 G to A substitution

PCR was used to amplify a 377-bp fragment of the IL-10 genomic sequence using primers: upstream, 5'-CCAAGACA-ACACTACTAAGGCTCCTTT-3'; downstream, 5'-GCTTCTTATATGCTAGTCAGGTA-3'^[15] (Nanjing Bio Eng Co.). The PCR conditions were at 95 °C for 2 min, 35 cycles of 95 °C for 40 s, 56 °C for 40 s, 72 °C for 40 s, 72 °C

for 7 min using reagents purchased from Promega on a gene cyclor (BIO-RAD, Japan). The PCR products were digested directly with 2 U *Xba*I restriction enzyme (Promega) at 37 °C for 6 h. Digested DNA was analyzed on 5% polyacrylamide gels. Ethidium bromide staining of the gel demonstrated three fragments of 253, 97, and 27 bp for G/G, four fragments of 280, 253, 97, and 27 bp for G/A, two fragments of 280 and 97 bp for A/A.

IL-1 β polymorphism

A 249-bp fragment of the IL-1 β genomic sequence including the polymorphic *Taq*I site was amplified using PCR. The following nucleotide sequences were used for PCR amplification: 5'-GTTGTCATCAGACTTTGACC-3', 5'-TTCAGTTCATATGGACCAGA-3'^[16] (Nanjing Bio Eng Co.). The PCR conditions were at 97 °C for 2 min, 35 cycles of 95 °C for 40 s, 55 °C for 40 s, 74 °C for 30 s, 72 °C for 7 min using reagents purchased from Promega on a gene cyclor (BIO-RAD, Japan). The PCR products were digested directly with 2 U *Taq*I restriction enzyme (Promega) at 37 °C for 4 h. Digested DNA was analyzed on 5% polyacrylamide gels. Ethidium bromide staining of the gel demonstrated the original 249 bp fragment for T/T, two fragments of 135 and 114 bp for C/C, three fragments of 249, 135, and 114 bp for C/T.

CD14-159 C/T polymorphism

PCR was used to amplify a 166-bp fragment of the CD14 genomic sequence using primers: upstream, 5'-TGCCAG-GAGACACAGAACCC-3'; downstream, 5'-TGTCATTCA-GTTCCCTCCTG-3'^[9] (Nanjing Bio Eng Co.). The PCR conditions were at 96 °C for 2 min, 35 cycles of 96 °C for 40 s, 54 °C for 40 s, 72 °C for 30 s, and 72 °C for 7 min using reagents purchased from Promega on a gene cyclor (BIO-RAD, Japan). The PCR products were digested directly with 2 U *Hae*III restriction enzyme (Promega) at 37 °C for 4 h. Digested DNA was analyzed on 5% polyacrylamide gels. Ethidium bromide staining of the gel demonstrated the original 166-bp fragment for T/T, two fragments of 86 and 80 bp for C/C, three fragments of 86, 80, and 166 bp for C/T.

In addition, 30% of samples were randomly selected to be genotyped a second time to ensure reproducibility. Genotyping for all subjects was performed with no knowledge of clinical status.

Statistical analysis

Allelic frequencies were determined for statistical significance by χ^2 test. Analysis was made by SPSS 11.0, and $P < 0.05$ was considered statistically significant.

RESULTS

Characteristics of the patients

On the basis of the selection criteria, 109 patients (59 females and 50 males) with SAP were studied. Thirty-three developed septic shock (septic shock group), and 76 did not develop septic shock (nonseptic shock group). The APACHE II and CT scores at the time of admission were similar in both septic shock group and nonseptic group.

This study was undertaken in selected patients with acute mild pancreatitis (MAP) ($n = 106$) as defined by CT severity index and APACHE II score, and matched with SAP for age, sex, and cause of pancreatitis. Patients with MAP had an uneventful recovery. The control group included 116 healthy volunteers (65 females and 51 males).

Polymorphisms of two IL genes

The distribution of IL-10-1 082 and IL-1 β polymorphisms in different groups is shown in Tables 1 and 2. The overall IL-10-1 082G and IL-1 β +3 594T allele frequencies were similar in patients with mild or severe pancreatitis. Further, no significant difference in allele frequencies studied was noted between patients with AP and control subjects.

Table 1 Comparison of allele frequency between MAP group and SAP group

The distribution of IL-10-1082G and IL-1 β allele frequencies between septic shock group and nonseptic shock group is shown in Table 3. Patients with septic shock showed a significantly higher prevalence of the IL-10-1082G than those without septic shock ($\chi^2 = 5.921$, $P = 0.015$). No significant difference in IL-1 β +3594T allele frequency was found between septic shock patients and nonseptic shock patients.

CD14-159 C/T polymorphism

The distribution of CD14-159 polymorphism in different groups is shown in Tables 1 and 2. The CD14-159T allele frequency was similar in patients with mild or severe

pancreatitis. No significant difference in CD14-159T allele frequency was noted between patients with AP and control subjects.

Comparison of CD14-159 allele frequency between septic shock group and nonseptic shock group is shown in Table 3. No significant difference was found in the allele frequency between septic shock patients and nonseptic shock patients.

Comparisons of polymorphisms in different etiologies of SAP

No significant differences were found in the distribution of allele frequency between any two groups (Table 4).

DISCUSSION

In humans, there is increasing evidence that the host's cytokine response is genetically determined^[17]. Polymorphic gene sequences of certain cytokines may be potential markers of susceptibility and clinical outcome in different human infectious diseases. In our study, the frequency of well-described variants in IL-1 β +3 594 at the 5th exon, IL-10-1 082, and CD14-159 was examined. Our results demonstrated that IL-1 β +3594T, IL-10-1082G, and CD14-159T had no correlation with the occurrence or severity of AP. However, the distribution of IL-10-1082G in SAP patients varied, and IL-10-1082G allele was found to be more frequent in septic shock patients than in nonseptic shock patients ($P < 0.05$). The association between septic shock patients and IL-10 polymorphism was restricted to the IL-10-1082G, no such a correlation was seen to either IL-1 β +3 594 at the 5th exon or CD14-159 variant.

Before evaluating the role of a cytokine polymorphism played in any disease, three questions need to be answered^[18,19]. First, are the subjects homogeneous? To avoid artifact in

population admixture, we selected only Chinese Han people in China. In addition, the consanguineous mating subjects were precluded from our study. Second, does the product of the studied gene play an important role in the pathogenesis of the disease? The central role of IL-1 β , IL-10, and CD14 in the occurrence or severity of AP and septic shock has been clearly demonstrated by many studies^[20-23]. Third, does the gene polymorphism produce a relevant alteration in the level or function of the gene product? *In vitro*, the *TaqI* polymorphism in human IL-1 β gene correlates with IL-1 β secretion^[10]. *In vitro* and *in vivo* studies showed that IL-10-1082 variant significantly influences the secretion of IL-10^[24-27]. With regard to CD14-159 polymorphism, there is mounting evidence that the SNP in CD14 genome significantly influences the production of CD14^[9].

IL-1 and TNF- α are the most prominent inflammatory mediators and regarded as the "first-line" cytokines. Administration of IL-1 β to human beings results in inflammation, tissue injury, and septic shock-like syndrome. Different polymorphisms of the IL-1 β gene have been described^[7,10], and at least two of them could influence the protein production. One is located within the promoter region, and the other is located in exon 5. In our present study, we examined the frequency of IL-1 β A *TaqI* RFLP at the 5th exon and found that it was comparable in patients with mild or severe pancreatitis. Similarly, no significant difference in the allele distribution was noted between patients and controls. In addition, no significant difference in the allele frequency was seen between septic shock patients and nonseptic shock subjects. The results suggest that IL-1 β A may not play a principle role in the onset of SAP or SAP-associated septic shock. Our results are in line with the report by Powell *et al.*^[28].

In the clinical setting, levels of IL-10 showed a steep increase within the first 24 h from disease onset, and the level of IL-10 on the first day was found to be higher in patients with mild AP than in those with severe AP, suggesting that at position-1082 bp from the transcriptional start site, the presence of G is associated with higher and A with lower production of IL-10^[6]. Based on the observation, we postulate that IL-10-1082 polymorphism may have some association with the occurrence or the severity of AP. In our study, no significant difference was found in the frequency of IL-10-1082G between any two groups, but significant difference was found in the distribution of IL-10-1082G between septic shock patients and nonseptic shock patients. The pathophysiology of septic shock is a complex and multifactorial process, involving an imbalance between proinflammatory and anti-inflammatory cytokine release. Our results suggest that in the late stage of SAP, anti-inflammatory cytokine polymorphism likely plays a more important role in the pathogenesis of septic shock than proinflammatory cytokine polymorphism. The ability to identify patients at high risk for developing septic shock may be a critically important factor that will lead to improvements in the management of septic shock.

CD14, a receptor of LPS, plays a vital role in the mechanism of SIRS and sepsis. Because of the important role of CD14 with respect to LPS binding and signaling, we postulate that the polymorphism in the promoter of CD14 gene might be

an important factor in determining the susceptibility to or the severity of AP. In our study, we failed to find an association in CD14-159T frequency between controls and AP or between AP and SAP, indicating that CD14-159T plays no part in disease severity or susceptibility to AP. To the best of our knowledge, there is no report on the association between CD14-159 polymorphism and pancreatitis so far. Our result did not show any difference between patients and controls or between mild pancreatitis and severe pancreatitis. Furthermore, no significant difference was found between CD14-159T frequency and septic shock secondary to severe pancreatitis, indicating that in the late stage of the disease, CD14-159 polymorphism plays little role in the onset of SAP-associated septic shock. This is in line with previous studies^[29,30].

Although SAP has many distinct etiologies, the immune system response appears to be almost identical regardless of the cause^[1]. In our study, we divided SAP patients into three groups: gallstone pancreatitis, alcohol pancreatitis, and idiopathic pancreatitis according to the etiology of the disease. The observed allele frequency of IL-1 β +3594T, IL-10-1082G and CD14-159T was comparable between groups of different etiologies, suggesting that environmental factors may play an important role in the occurrence of SAP.

In conclusion, gene polymorphisms have no association with the occurrence or severity of AP. However, the IL-10-1082G may play an important role in the susceptibility of SAP patients to septic shock.

Abstract

AIM: To study the effects of magnolol and honokiol on isolated smooth muscle of gastrointestinal tract and their relationship with Ca^{2+} , and on the gastric emptying and the intestinal propulsive activity in mice.

METHODS: Routine experimental methods using isolated gastric fundus strips of rats and isolated ileum segments of guinea pigs were adopted to measure the smooth muscle tension. The effects of magnolol 10^{-3} , 10^{-4} , 10^{-5} mol/L, and honokiol 10^{-4} , 10^{-5} , 10^{-6} mol/L on the contractility of gastric fundus strips of rats and ileum of guinea pigs induced by acetylcholine (Ach) and 5-hydroxytryptamine (5-HT) was assessed respectively. The method using nuclein and pigment methylene blue was adopted to measure the gastric retention rate of nuclein and the intestinal propulsive ratio of a nutritional semi-solid meal for assessing the effect of magnolol and honokiol (0.5, 2, 20 mg/kg) on gastric emptying and intestinal propulsion.

RESULTS: Magnolol and honokiol significantly inhibited the contractility of isolated gastric fundus strips of rats treated with Ach or 5-HT and isolated ileum guinea pigs treated with Ach or CaCl_2 , and both of them behaved as non-competitive muscarinic antagonists. Magnolol and honokiol inhibited the contraction induced by Ach in Ca^{2+} -free medium and extracellular Ca^{2+} -dependent contraction induced by Ach. Each group of magnolol and honokiol experiments significantly decreased the residual rate of nuclein in the stomach and increased the intestinal propulsive ratio in mice.

CONCLUSION: The inhibitory effect of magnolol and

INTRODUCTION

Cortex *Magnoliae officinalis* is a traditional Chinese herb, belonging to "prokinetic agent" of Chinese herbs. It can improve the symptoms of abdominal distention, dyspepsia, nausea, and vomiting, *etc.*, in gastrointestinal diseases. Magnolol and honokiol are the main components of magnoliae bark. Both can relieve spasm of smooth muscle and stop vomiting, *etc.* Magnolol also has an anti-allergic, anti-asthma and anti-inflammatory effect^[1], and honokiol has an anxiolytic effect^[2-4] and a cardiac muscle protective effect^[5]. We used the isolated gastric fundus strips of rats and isolated ileum segments of guinea pigs to measure the smooth muscle tension for assessing the effects of magnolol and honokiol on the contractility of gastric fundus strips of rats induced by acetylcholine (Ach) and 5-hydroxytryptamine (5-HT), and ileum of guinea pigs induced by Ach and CaCl_2 . Nuclein and pigment methylene blue were used to measure the gastric retention rate of nuclein and the intestinal propulsive ratio of a nutritional semi-solid meal for assessing the effect of magnolol and honokiol on gastric emptying and intestinal propulsion.

MATERIALS AND METHODS

Preparation of magnolol and honokiol: Magnolia bark (*Magnolia officinalis* Rehd. et Wils.) was purchased from Shenyang Medicinal Material Company. The voucher specimens of *Magnolia officinalis* Rehd. et Wils. was identified by Professor Sun of Shenyang Pharmacy University. Magnolol and honokiol were extracted in Shenyang Pharmacy University.

Magnolol and honokiol were dissolved in a very small amount of ethanol. In isolated and *in vivo* experiments the resultant solution was diluted with a 10% aqueous solution of Tween-80. Subsequently, the solution was diluted with distilled water, so that the final concentration of both ethanol and Tween-80 in the vehicle was 0.5%.

Propulsid (cisapride tablet, 5 mg/tablet) was produced by Xi'an Pharmaceutical Company Ltd (batch number: 030815020). Cisapride was crushed and dissolved in distilled water to make a 0.15 mg/mL cisapride solution.

Methylthioninium chloride injection (20 mg/2 mL) was produced by Beijing Yongkang Pharmaceutical Company Ltd.

Preparation of a semi-solid nutritious meal^[6]: Ten grams of carboxymethylcellulose was added to 250 mL of distilled water. After the mixture was agitated, 16 g of milk powder, 8 g of cane sugar and 8 g of cornstarch were added to the mixture. The resulting mixture was a white semisolid paste.

Animals

Rats (200–300 g) and guinea pigs (200–300 g) of either sex were raised in cages in groups of five male mice (18–22 g) at a constant temperature (22 ± 2 °C) with free access to food and water.

Method

Effects of magnolol and honokiol on contractility of gastric fundus strips of rats induced by Ach and 5-HT

Isolated gastric fundus strips of rats were prepared and mounted on an organ bath (Magnus' bath) containing 30 mL of Krebs' solution bubbled with 95% O₂+50 mL/L CO₂ (pH 7.3–7.4 at 37 °C) under a resting tension of 1 g. The muscular tension, measured with a force transducer, was displayed on a MS-302 biosignal recording and analyzing system. The preparations were allowed to equilibrate for 50 min. After equilibration, 3×10^{-3} mol/L Ach 0.1 mL or 3×10^{-6} mol/L 5-HT 0.2 mL was added in the bath to activate the gastric fundus strips. When it reached its maximum contraction, it was washed with Krebs' solution to regain spontaneous contraction. Then Ach or 5-HT was added to the bath from low to high logarithmic doses to make the final respective concentrations of 10^{-8} , 3×10^{-8} , 10^{-7} , 3×10^{-7} , 10^{-6} , 3×10^{-6} , 10^{-5} , 3×10^{-5} , 10^{-4} , 3×10^{-4} mol/L, or 10^{-10} , 3×10^{-10} , 10^{-9} , 3×10^{-9} , 10^{-8} , 3×10^{-8} , 10^{-7} , 3×10^{-7} , 10^{-6} , 3×10^{-6} mol/L. The accumulated concentration-efficacy curve was made. When the curve reached its peak, the gastric fundus strips were washed thrice at 5-min intervals with Krebs' solution to wash the Ach out. After 15-min equilibration the drugs were added to the organ bath in respective doses (final concentrations of magnolol were 10^{-5} , 10^{-4} or 10^{-3} mol/L, honokiol were 10^{-6} , 10^{-5} or 10^{-4} mol/L). The accumulated concentration-efficacy curve was made after 1 min.

We made the maximum efficacy (E_{\max}) of Ach or 5-HT as 100%, and calculated the effect percentage (E/E_{\max}) of each concentration of Ach or 5-HT. Then the cumulative concentration-efficacy curves were drawn with E/E_{\max} as the ordinates and the negative logarithm of final concentration of Ach or 5-HT ($-\log[A]$) as the abscissae.

Effects of magnolol and honokiol on the contractility of the ileum of guinea pigs induced by Ach Terminal ileum segments from guinea pigs were prepared and

suspended vertically in organ baths containing 30 mL of Tyrode's solution bubbled with 95% O₂+50 mL/L CO₂ (pH 7.3–7.4 at 37 °C) under a resting tension of 1 g. The spontaneous contractions were measured after equilibration for 50 min, 3×10^{-3} mol/L Ach 0.1 mL was added in the bath to activate the ileum. When it reached its maximum contraction, it was washed in Tyrode's solution to regain spontaneous contractions. The cumulative concentration-efficacy curves of Ach were made, then the curve was remade after magnolol and honokiol were added in the organ bath respectively (the final concentrations were the same in method 1).

Effects of magnolol and honokiol on the contractility of the ileum of guinea pigs induced by CaCl₂ After equilibration of guinea pig ileum segments in Ca²⁺-free Tyrode's solution (CaCl₂ was omitted from normal Tyrode's solution) for 40 min they were changed with Ca²⁺-free high K⁺-depolarized Tyrode's solution. Ca²⁺-free Tyrode's solution was (the equal mole NaCl was replaced with 80 mmol/L KCl in the Ca²⁺-free Tyrode's solution) to make the smooth muscle depolarization after 30 min, CaCl₂ was added to the bath from low to high logarithmic doses (final concentrations were 10^{-5} , 3×10^{-5} , 10^{-4} , 3×10^{-4} , 10^{-3} , 3×10^{-3} , 10^{-3} , and 3×10^{-3} mol/L respectively) and the cumulative concentration-efficacy curves were drawn. The ileum segments were washed with the Ca²⁺-free Tyrode's solution till the muscular tension regained the normal contraction. After 30 min, Ca²⁺-free Tyrode's solution was changed with Ca²⁺-free high K⁺ Tyrode's solution and magnolol and honokiol were added respectively. After 30 min, the cumulative concentration-efficacy curves were drawn.

Effects of magnolol and honokiol on the two contractile components of Ach After equilibration for 1 h in Tyrode's solution, guinea pigs ileum segments were washed with Ca²⁺-free Tyrode's solution thrice and incubated for 30 min, then 3×10^{-3} mol/L Ach 0.2 mL (2×10^{-5} mol/L) was added to the solution and it produced a brief contraction (the first or initial phasic contraction) that was induced by the release of intracellular calcium. When the ileum segments reached maximal contraction, CaCl₂ 0.2 mL (2×10^{-2} mol/L) was added and caused an advanced contraction (the second phasic contraction or sustained tonic component) induced by the extracellular calcium influx evoked by Ach. The ileum segments were washed with Ca²⁺-free Tyrode's solution and incubated in Ca²⁺-free Tyrode's solution for 30 min; meanwhile magnolol (final concentrations were 10^{-5} , 10^{-4} or 10^{-3} mol/L) or honokiol (final concentrations were 10^{-6} , 10^{-5} or 10^{-4} mol/L) was added respectively, then Ach and CaCl₂ were added successively. The guinea pig ileum segments produced the first and second contractions respectively.

Effects of magnolol and honokiol on gastrointestinal movement in mice Magnolol and honokiol were dispensed as before to the concentrations of 0.5, 2.0, and 20 mg/L. Mice were allocated randomly to a control group (administrated orally with distilled water), a cisapride group, and experimental groups. They were given orally either magnolol 0.5, 2.0, and 20 mg/L, or honokiol 0.5, 2.0, and 20 mg/L, respectively. Nuclide and pigment methylene blue were used to measure the gastric retention rate of nuclide and intestinal propulsive ratio of nutritious semi-solid meal. After having fasted for

12 h, the mice were given orally either 0.2 mL/10 g of each of the above substances or 0.2 mL/10 g of distilled water. After 30 min, each mouse was given orally a semi-solid nutritious meal containing ^{99m}Tc -DTPA 0.05 mCi/10 g and a small quantity of methylthioninium chloride. The mice were killed after 20 min, and dissected. Residual nuclide in the gastrointestinal tract was measured by a radioactivity monitor. The gastric residual nuclide rate (%) = (gastric retention nuclide/total nuclide in gastrointestinal tract) $\times 100\%$. Intestinal propulsive ratio (%) = (distance from sphincter of pylorus to the distal pigment methylene/distance from sphincter of pylorus to the ileocecum) $\times 100\%$.

Statistical analysis

Results were expressed as mean \pm SD. Comparisons between groups of data were made by the Student's *t*-test or *t*-test of paired comparison.

RESULTS

Effects of magnolol and honokiol on the contractility of gastric fundus strips of rats induced by Ach and 5-HT (Figure 1)

The data showed that magnolol and honokiol inhibited incompetitively the contraction of gastric fundus strips of rats induced by cumulative concentrations of Ach and 5-HT, and the effect increased with the increase of dosage. The antagonistic parameters (PD_2) of magnolol and honokiol were 3.66 and 4.31 for Ach, and 5.08 and 4.91 for 5-HT respectively.

Effects of magnolol and honokiol on the contractility of guinea pig ileum induced by Ach (Figures 2A and B)

The data showed that magnolol and honokiol antagonized incompetitively the contraction of gastric fundus strips of

rats induced by cumulative concentration of Ach, and the effect increased with the increase of dosage. The PD_2 values of magnolol and honokiol were 5.09 and 4.99 respectively.

Effects of magnolol and honokiol on the contractility of ileum segments of guinea pigs induced by CaCl_2 (Figures 2C and D)

The data showed that magnolol and honokiol antagonized incompetitively the contraction of gastric fundus strips of rats induced by cumulative concentration of CaCl_2 , and the effect increased with the increase of dosage. The PD_2 values of magnolol and honokiol were 4.34 and 4.84 respectively.

Effects of magnolol and honokiol on the two contractile components of Ach (Table 1)

Magnolol and honokiol inhibited the contraction of ileal segments induced by Ach in Ca^{2+} -free medium and the extracellular Ca^{2+} -dependent contraction induced by Ach.

Magnolol 10^{-5} , 10^{-4} or 10^{-3} mol/L and honokiol 10^{-6} , 10^{-5} or 10^{-4} mol/L inhibited significantly the two contractile components induced by Ach.

Table 1 Effects of magnolol and honokiol on the two contractile components of Ach (%), mean \pm SD, $n = 6$)

Group (mol/L)	First phase	Second phase
Magnolol 10^{-3}	89.08 \pm 7.32 ^b	86.89 \pm 8.04 ^b
Magnolol 10^{-4}	83.80 \pm 11.18 ^b	92.97 \pm 4.70 ^b
Magnolol 10^{-5}	66.48 \pm 12.95 ^b	75.39 \pm 10.53 ^b
Honokiol 10^{-4}	74.54 \pm 6.75 ^b	91.11 \pm 3.89 ^b
Honokiol 10^{-5}	68.93 \pm 10.90 ^b	82.11 \pm 5.51 ^b
Honokiol 10^{-6}	45.68 \pm 4.92 ^b	78.95 \pm 5.83 ^b

Effects of magnolol and honokiol on gastrointestinal movement in mice (Table 2)

In the experimental groups of magnolol 0.5, 2.0, and 20 mg/L, or honokiol 0.5, 2.0, and 20 mg/L, the gastric nuclide retention rate was significantly lower and the intestinal propulsive ratios were significantly higher than those in the control group, indicating that magnolol and honokiol could improve the gastric emptying of a semi-solid meal and intestinal propulsion in mice.

Table 2 Effects of magnolol and honokiol on gastrointestinal movement in mice (mean±SD, *n* = 20)

Group (mg/kg)	Rate of gastric residual nuclide (%)	Intestinal propulsive ratio (%)
Control	50.05±12.74	47.92±8.49
Cisapride	22.26±9.17 ^b	61.92±11.77 ^b

DISCUSSION

Magnolol and honokiol are neolignan-derivatives present in *Magnolia* bark, which is used in the treatment of abdominal distention and vomiting. The experimental results indicated that magnolol and honokiol significantly inhibited the contractility of isolated gastric fundus strips of rats treated with Ach or 5-HT and isolated ileum of guinea pigs treated with Ach or CaCl₂, and both of them behaved as non-

competitive muscarinic antagonists. Magnolol and honokiol inhibited the ileal contraction induced by Ach in Ca²⁺-free medium and extracellular Ca²⁺-dependent contraction induced by Ach.

The contraction of gastrointestinal smooth muscle depends on the mediation of intracellular Ca²⁺, and is accomplished by the process of excitation–contraction coupling (E-C coupling). The free Ca²⁺ originated from the release of intracellular calcium and the restoration of extracellular calcium^[7]. A high-K⁺ medium could depolarize the cellular membrane of ileum longitudinal smooth muscle, activate the potential-dependent calcium channel (PDC), and result in the inflow of calcium and the contraction of smooth muscles. Our experimental results indicated that magnolol and honokiol could block the transmembrane inflow of calcium through PDC, inhibit the contraction of smooth muscle, and relieve the spasm of smooth muscles.

Physical active substances Ach and 5-HT can increase the tension of gastrointestinal smooth muscle, and the agonist Ca²⁺ is derived from various resources. The two components of intracellular and extracellular calcium were involved in the contraction of smooth muscles induced by Ach. The first phasic contraction induced by Ach in Ca²⁺-free medium depended on the release of intracellular calcium. The second phasic contraction based on the first phase after the addition of calcium was caused by Ach facilitating the inflow of extracellular calcium through the receptor-operated calcium channel (ROC). In this study, magnolol and honokiol significantly inhibited the first and the second phasic contractions of smooth muscles induced by Ach, indicating that the two components of magnolia bark not only have an intracellular point of action but also inhibit the contraction of smooth muscles by blocking the inflow of calcium through ROC.

Normal gastric motility involves gastric fundus, corpus,

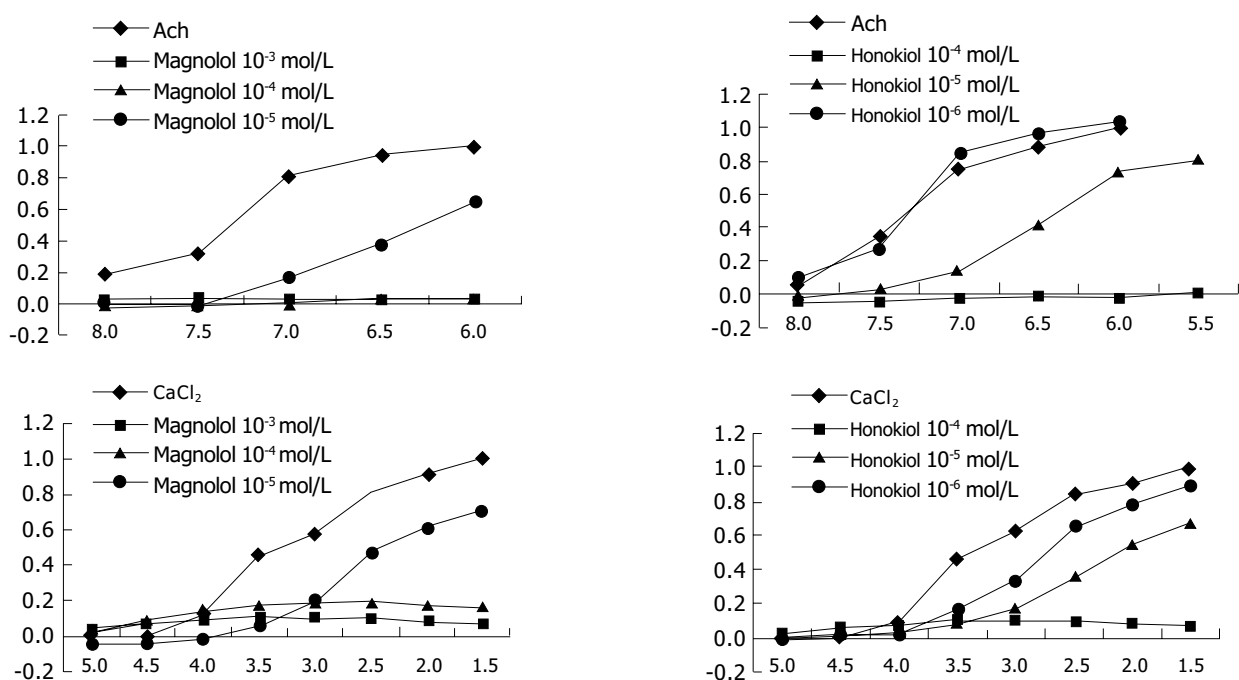

Figure 2 Effect of magnolol and honokiol on the contractility of guinea pig ileum segments induced by Ach and CaCl₂. Magnolol effects on the contractility of

guinea pig ileum induced by Ach (A) and CaCl₂ (C); Honokiol effects on contractility of guinea pig ileum segments induced by Ach (B) and CaCl₂ (D) (*n* = 6).

antrum, pylorus, and antroduodenal coordination. As food is swallowed, the gastric fundus relaxes to accommodate the incoming nutrients. This is termed receptive as relaxation, which is coordinated by vagal efferent activity via nonadrenergic, noncholinergic mechanisms. As swallowing during the meal continues, the fundic filling and relaxation continue with little increase in intraluminal pressure. Gastric distention and activation of mechanoreceptor and stretch receptors stimulate vagal afferent nerve activity, which in turn modifies vagal efferent traffic.

The emptying of solid foods is accomplished by complex interplays among intra-gastric pressure, gastric peristalses, pyloroduodenal resistance, and neuroendocrine responses elicited by the specific components of the particular meal. In this study, magnolol and honokiol could significantly decrease the residual rate of nuclein in stomach and increase the intestinal propulsive ratio of semi-solid nutritious meal in mice, and there was no significant difference between them and cisapride. Combined with the study above, the functions in improving the gastric emptying and intestinal propulsive action may relate to their functions of relaxation of gastrointestinal smooth muscles.

Disorders of stomach motility and intestinal propulsion are involved in functional gastroenterological diseases such as gastroesophageal reflux disease, functional dyspepsia, irritable bowel syndrome, chronic constipation, *etc.*^[8], gastroparesis^[9], postoperative gastrointestinal atony^[10], chronic intestinal pseudo-obstruction^[11], and many other diseases. Prokinetic agents such as domperidone and cisapride are important therapeutic drugs^[12,13]. But domperidone and cisapride have some severe side-effects, such as prolongation of the QT interval and cardiac arrhythmias^[14,15]. There are rich resources of natural herbs in China, which may provide a valuable source of effective prokinetic agents.

Abstract

AIM: To investigate the intestine and body development of intrauterine growth retardation (IUGR) rats under early different protein diet and to analyze the correlation between leptin and intestine and body development.

METHODS: An IUGR rat model was established by food restriction of pregnant female rats. Fifty-six neonatal IUGR rats and 24 neonatal normal rats were randomly divided into normal control group (C group), IUGR model group (SC group), low protein diet IUGR group (SL group), and high protein diet IUGR group (SH group). Eight rats were killed per group at wk 0, 4, and 12. Serum leptin, body weight (BW), body length (BL), intestinal weight (IW), intestinal length (IL), and intestinal disaccharidase (including lactase, maltase, and saccharase) were detected.

RESULTS: BW (4.50 ± 0.41 g), BL (5.96 ± 0.40 cm), IW (0.05 ± 0.01 g), and IL (15.9 ± 2.8 cm) in neonatal IUGR rats were much lower than those in C group (6.01 ± 0.55 g, 6.26 ± 0.44 cm, 0.10 ± 0.02 g, 21.8 ± 2.7 cm, $P < 0.05$), while intestinal lactase and maltase activities were higher than those in C group. SH group showed the fastest catch up growth and their BW, BL, IW, and IL reached the C group level at wk 4. SC group showed relatively slower catch up growth than SH group, and their BW, BL, IW did not reach the C group level at wk 4. SL group did not show intestine and body catch up growth. Intestinal maltase [344 ± 33 $\mu\text{mol}/(\text{min} \cdot \text{g})$] and saccharase activities [138 ± 32 $\mu\text{mol}/(\text{min} \cdot \text{g})$] in SL group were both markedly lower than those in C group [751 ± 102 , 258 ± 27 $\mu\text{mol}/(\text{min} \cdot \text{g})$, $P < 0.05$]. There were no significant differences in lactase activities at wk 4 and disaccharidase activities at wk 12 among all groups ($P > 0.05$). The leptin level in SL group (0.58 ± 0.12 ng/mL) was the highest in all groups, and much lower in SH group (0.21 ± 0.03 ng/mL) than that in any other IUGR groups at wk 4 ($P < 0.05$). Leptin was negatively related

to BW ($r = -0.556$, $P = 0.001$), IW ($r = -0.692$, $P = 0.001$) and IL ($r = -0.738$, $P = 0.000$) at wk 4, while no correlation was found at wk 12.

CONCLUSION: High protein diet is a reasonable early nutritional mode to IUGR rats in promoting intestine and body catch up growth.

INTRODUCTION

The incidence rate of intrauterine growth retardation (IUGR) is about 7.5-8.7% in our country. Development of the stomach and intestine is closely related to the body growth, it affects and is also reversely affected by nutrition. As a protein coded by ob gene (obesity gene), leptin is a neuroendocrine regulatory factor secreted from mature adipocytes into blood. Leptin can pass through blood-brain barrier and has a central effect on feeding behavior. It was reported^[1] that IUGR rats have temporarily high leptin level to regulate growth hormone secretion and growth during catch up growth. Since the infant growth is mainly regulated by nutrition, and nutritional intake is controlled by the development of stomach and intestine and leptin level, our study aimed to investigate the intestine, intestinal disaccharidase and body development and their relation to serum leptin at wk 4 (childhood) and 12 (adulthood) in order to offer some animal research data for early nutritional intervention of IUGR.

MATERIALS AND METHODS

Materials and animals

Leptin kit was purchased from Diagnostic Systems Laboratories (USA). Glucose and disaccharidase enzyme kits were purchased from Great Wall Company (Baoding, Hebei Province, China).

The second class SD female rats were bought from Animal Center of Sun Yat-Sen University and mated with

male rats. IUGR model was established by food restriction of pregnant female rats^[2]. The standard of IUGR was that the birth weight -2SD lower than control normal group (5.1 g). Fifty-six newborn IUGR rats and 24 newborn normal rats were randomly divided into normal control group (C group), IUGR model group (SC group), low protein diet IUGR group (SL group), and high protein diet IUGR group (SH group). The former two groups were fed with 22.5% normal protein diet, while the latter two groups with 11.3% low-protein diet and 28.6% high-protein diet respectively. All the rats were weaned when they were 3 wk old and fed with original diet till the 4th wk and then with normal protein diet till the end of the experiment. Components of the diets are shown in Table 1.

Table 1 Content ratio of different components (g) in 100 g food

Components	Protein	Fat	Carbohydrate	Total energy (kJ/100 g)
Normal diet	22.5	3.9	57.8	1 583.4
High protein diet	28.6	3.9	56.8	1 625.4
Low protein diet	11.3	8.5	58.7	1 558.2
χ^2	10.09	3.04	0.09	-
P	0.006*	0.22	0.96	-

* $P < 0.05$ vs other.

Methods

Body weight (BW) and body length (BL, from nose to tail) of each rat were measured at wk 0, 4, and 12. Eight newborn female rats of IUGR group and C group were killed right after birth. Another eight female rats were killed per group after being fasted for 10-12 h at wk 4 and 12 respectively. Blood sample was taken from the eyeballs and kept at -30 °C. Serum leptin was monitored by ELISA.

Abdomen was opened right after the rats were killed. Intestinal weight (IW) and intestinal length (IL) were measured from the beginning of jejunum to the end of ileum, and then 10 cm proximal end of the jejunum (about 3 cm from the beginning of jejunum) was cut, weighed, and homogenized. The disaccharidase activities (including lactase, saccharase, and maltase) were measured.

Statistical analysis

Results were expressed as mean \pm SD. All data were analyzed

by the SPSS 10.0 statistical package. ANOVA test was used to compare these four groups. Least significant difference was used to compare every two groups when variance was regular, while Dunnett T3 test was used when variance was irregular. Pearson's test was used in correlation analysis.

RESULTS

Development of body and intestine and disaccharide activity in newborn IUGR rats and normal rats

The BW, BL, IW, and IL of newborn IUGR rats were significantly lower than those of C group ($P < 0.05$), while lactase and maltase activities were higher than those in C group. There was no significant difference in saccharase activity between the two groups (Table 2).

Development of intestine and body of rats

SH group showed the fastest catch up growth, and BW, BL, IW, and IL reached the C group level at wk 4 ($P > 0.05$). BW, BL, IW, and IL in SL group at wk 4 and 12 were all markedly lower than those in normal control group ($P < 0.05$). BW, BL, and IW in SC group at wk 4 were all significantly lower than those in C group ($P < 0.05$). IL in SC group was lower than that in C group at wk 12. There were no significant differences in BW, BL, and IW between the two groups ($P > 0.05$).

Intestinal maltase and saccharase activities in SL group were markedly lower than those in C group ($P < 0.05$). There was no significant difference in lactase activity between the two groups at wk 4 ($P > 0.05$). Maltase activity in SH group was lower than that in C group ($P < 0.05$). There were no significant differences in disaccharidase activity between groups at wk 12 ($P > 0.05$).

Leptin in SL group was significantly higher than that in SC and C groups, and lower in SH group than that in SC group at wk 4 ($P < 0.05$). Leptin in SC group was higher than that in C group and lower in SH and SL group than that in SC group ($P < 0.05$). There were no significant differences between these two groups and C group at wk 12 ($P > 0.05$). Results are shown in Table 2.

Correlation analysis

The following results were found in correlation analysis of leptin and BW, BL, IW, and IL. Leptin and BW had a negative correlation at wk 4 ($r = -0.556$, $P = 0.001$), while

Table 2 Leptin, BW, BL, IW, IL, and disaccharidase activities in all groups (mean \pm SD) $n = 8$ /group

Disaccharidase activity unit: $\mu\text{mol}/(\text{min}\cdot\text{g})$ protein. ^a $P < 0.05$, IUGR group vs C group; ^c $P < 0.05$, SL, and SH groups vs SC group. ND: not determined.

had no correlation at wk 12; leptin and BL had no correlation at wk 4 and 12; leptin and IW had a negative correlation at wk 4 ($r = -0.692$, $P = 0.001$), while had no correlation at wk 12; leptin and IL had a negative correlation at wk 4 ($r = -0.738$, $P = 0.001$), while had no correlation at wk 12.

DISCUSSION

Multiple lines of evidence show that about 20-50% IUGR cannot catch up the growth after birth, and remains small till they become adults. Growth is mainly regulated by heredity, nutrition, and endocrine system. The early postnatal growth (the first year after birth) is mainly regulated by nutrition. Mother malnutrition during pregnancy not only delays the fetal growth, but also impairs many organ and tissue structures and functions of the fetus^[3]. Zhang *et al.*^[2], showed that the weight, length and many morphologic structures of intestine in newborn IUGR rats are significantly lower than those of normal newborn rats. Only few reports about the development of stomach and intestine and disaccharidase activity of IUGR are available at present.

Due to the effect of early nutrition on growth, Lucas^[4] have raised the “nutritional programming” hypothesis: nutritional conditions during the critical or sensitive stage of growth have long-term or life-long effects on organic structure or function. The mechanism is that early nutrition stimulates clone selection and differentiation of blast cells and causes irreversible changes in cell number of organism. Based on the hypothesis, we carried out the early nutritional intervention during the first 4 wk after birth -a sensitive and critical stage of growth. We investigated its effects on the development of intestine and jejunum mucosa disaccharidase activity and their correlations with serum leptin.

Our research showed that the impaired development of intestine recovered quickly in SH group after high protein diet was given after birth. Ziegler *et al.*^[5], found that the development of intestine mainly depends on the proliferation of cells before weaning. Enough nutrition can not only promote intestinal neuron's activity and increase blood supply of viscera but also stimulate the secretion of growth factor. Intestinal epithelium can absorb more nutrition for catch up growth. Although SC group was fed with normal diet after birth, it failed to catch up the normal control group at wk 4. SL group even failed to catch up normal growth at wk 12 and remained small till they became adults, suggesting that early postnatal protein diet has great effects on the development of intestine. Intestine and body catch up growth of IUGR rats depends on sufficient nutrition after birth, especially enough protein.

Intestine is the main organ to absorb sugar and protein. Disaccharidase, gastrin, and intestinal hormones play an important role in this process. Lactase and maltase are often produced at the late stage of gestation, while saccharase activity increases quickly only after intake of solid food. Stomach and intestine develops very fast in neonatal stage. As the stomach and intestine of neonates become mature, their lactase activity decreases, while maltase and saccharase activities increase^[6]. Therefore, it is beneficial to the

understanding of the development of stomach and intestine by detecting disaccharidase activities. Our research suggested that the premature of lactase and maltase activity in newborn IUGR rats was an adaptive compensation to intrauterine malnutrition. Saccharase activity in newborn IUGR rats was not affected, suggesting that saccharase is not regulated by intrauterine nutrition. Our research also demonstrated that maltase and saccharase activities in SL groups were markedly lower than those in C and SC groups at wk 4, which is consistent with the study by Nichol *et al.*^[7]. The relatively higher lactase activity in SL group may be an accommodation response to lack of nutritional supply. The nutrition of neonatal rats is mainly from milk and lactose is the main component of carbohydrate in milk. The high lactase activity is an advantage for neonatal rats to absorb more lactose to compensate for the shortage of protein. But the reason why maltase activity in SH group was markedly lower than that in C and SC groups at wk 4 is still unknown. Gomez *et al.*^[8], gave high protein diet to the rats suffering from abdominal wound and found that its lactase activity is markedly higher than in other rats given normal level protein diet. Further research is needed to test whether the decrease of maltase activity in SH group is related to the increase of lactase activity. There was no significant difference in disaccharidase activity between groups at wk 12, suggesting that disaccharidase activity might change with different kinds of food after birth, such as milk, solid food, and different protein diet.

It was reported that IUGR rats are insensitive to leptin during catch up growth^[9]. Jaquet *et al.*^[10], found that IUGR children are relatively resistant to leptin in order to catch up growth and leptin is closely related to catch up growth and fat tissue development. We know that blood and umbilical leptin level of newborn baby is positively related to birth weight. Leptin reflects not only the body fat level but also nutritional status. Leptin is a medium between neuroendocrine system and fat tissue. It builds a negative loop between fat tissue and neuropeptide Y (NPY). When weight decreases to some extent, the inhibitory effect of leptin on the secretion of NPY from hypothalamus is also weakened^[11]. NPY is a strong stimulator of appetite, high level of NPY is advantageous for IUGR children to take in more nutrition and energy to accumulate body fat.

Correlation analysis showed that leptin was negatively related to BW, IW, and length at wk 4. The BW in SL group was the lowest but leptin level was the highest in all groups at wk 4. We found that IUGR rats were relatively resistant to leptin during catch up growth, but this phenomenon disappeared at wk 12, suggesting that leptin resistance is only related to catch up growth in IUGR children.

In conclusion, high protein diet is a reasonable early nutritional mode for IUGR rats. High leptin level in IUGR rats is related to catch up growth and nutritional status.

Abstract

AIM: To elucidate the mechanism of liver protection by inhibition of Kupffer cells (KCs) function.

METHODS: All the animals were randomly divided into three groups. Blockade group (gadolinium chloride solution (GdCl_3) injection plus ischemia/reperfusion (I/R) injury): GdCl_3 solution was injected once every 24 h for 2 d via the tail vein before I/R injury. Non-blockade group (saline solution injection plus I/R injury): saline instead of GdCl_3 as a control was injected as in the blockade group. Sham group: saline was injected without I/R injury. Liver samples were collected 4 h after blood inflow restoration. The blockade of the function of KCs was verified by immunostaining with an anti-CD68 mAb. Toll-like receptor 2 (TLR2) was immunostained with a goat antimouse polyclonal anti-TLR2 antibody. Membrane proteins were extracted from the liver samples and TLR2 protein was analyzed by Western blot. Portal vein serum and plasma were taken respectively at the same time point for further detection of the levels of tumor necrosis factor- α (TNF- α) and alanine aminotransferase (ALT), an indicator of liver function.

RESULTS: Compared to non-blockade group, CD68⁺ cells significantly reduced in blockade group (OPTDI, optical density integral): 32.97 ± 10.55 vs 185.65 ± 21.88 , $P < 0.01$) and the liver function impairment was relieved partially (level of ALT: 435.89 ± 178.37 U/L vs 890.21 ± 272.91 U/L,

$P < 0.01$). The expression of TLR2 protein in blockade group significantly decreased compared to that in non-blockade group (method of immunohistochemistry, OPDTI: 75.74 ± 17.44 vs 170.58 ± 25.14 , $P < 0.01$; method of Western blot, A value: 125.89 ± 15.49 vs 433.91 ± 35.53 , $P < 0.01$). The latter correlated with the variation of CD68 staining ($r = 0.745$, $P < 0.05$). Also the level of portal vein TNF- α decreased in blockade group compared to that in non-blockade group (84.45 ± 14.73 ng/L vs 112.32 ± 17.56 ng/L, $P < 0.05$), but was still higher than that in sham group (84.45 ± 14.73 ng/L vs 6.07 ± 5.33 ng/L, $P < 0.01$).

CONCLUSION: Inhibition of the function of KCs may protect liver against I/R injury via downregulation of the expression of TLR2.

INTRODUCTION

Hepatic ischemia/reperfusion (I/R) injury is one of the major complications of liver resection surgery, transplantation, and hypovolemic shock^[1,2]. Although the detailed biochemical mechanisms are unclear, activation of Kupffer cells (KCs) may play an important role. During the very early phase of I/R injury, the secretion of proinflammatory cytokines by activated KCs, such as TNF- α , interleukin-1, participates in liver I/R injury, which precedes the activation of adhesion factors, chemotactic agents, and the sequestration of neutrophils in liver. Neutrophil accumulation in the liver causes direct hepatocellular damage through exhaustion of hepatic microcirculation by blocking the capillary perfusion and releasing proteases. So that we can see that KCs are among the first and key cells that mediate hepatic I/R injury^[3]. Inhibition of the function of KCs elicits the protection against liver I/R injury. The mechanism of KCs in such an insult remains unclear. Endotoxin or lipopolysaccharide is a strong stimulator inducing KCs to secrete proinflammatory

mediators and ultimately leading to endotoxin-induced liver injury^[4,5]. In order to clarify the mechanism of I/R injury without the effect of endotoxin and the corresponding cytokines evoked by endotoxin^[5,6], we reproduced a lobar rather than total hepatic I/R injury in a mouse model to produce a severe hepatic ischemic insult without mesenteric venous congestion. So that the development of intestinal congestion and leakage of bacteria or bacterial products into the circulation can be avoided^[6,7].

TLR family members, a kind of newly found transmembrane peptides, recognize pathogen-associated molecular patterns derived from both Gram-negative and Gram-positive bacteria such as endotoxin and are capable of sensitizing danger signals in *in vivo* environment^[1,7,8]. TLRs participate in the initiation of the downstream inflammatory cascades^[8,9]. In previous studies, we have proved that TLR2 and TLR4 are involved in the hepatic I/R pathologic process and the activation of them is not related to endotoxin^[10,11]. Whether TLR2 expression is affected by the function of KCs is still unknown. GdCl₃ is a kind of experimental drug, which is capable of blocking KC function specifically, while it has no effect on other macrophages, such as those residing in lung or intestinal canals^[12,13]. CD68 is a pan-macrophage endosomal glycoprotein, which belongs to a family of acidic, highly glycosylated lysosomal glycoproteins and is found in cytoplasmic granules. It is considered as a specific indicator of KC activation^[14]. That is why we used CD68 immunohistological staining to assess the inhibition of KC function.

This experiment aimed to observe the variation of TLR2 expression after the inhibition of the function of KCs and to further clarify the protective mechanism against hepatic I/R injury induced by inhibition of the function of KCs.

MATERIALS AND METHODS

Animal model and grouping

Male BALB/c mice weighing 20-25 g were supplied by Experimental Animal Center in Tongji Medical College. Their age ranged 6-8 wk. The animals were fasted for 12 h with free access to water and randomly divided into GdCl₃ injection plus I/R injury group (blockade group), saline solution injection plus I/R injury group (non-blockade group), and sham operation group (sham group). The animals in blockade group received injections of GdCl₃ solution (0.1 mmol/kg body weight, Sigma, USA) via tail vein once every 24 h for two times. The operation was performed 24 h after the last injection. The animals in non-blockade group were injected saline solution as control. Mice were anesthetized with pentobarbital (60 mg/kg). Laparotomy was performed through a midline incision and an atraumatic clip was placed across the hepatic hilar to interrupt blood supply to the left and median lobes of the liver. After 60 min of partial hepatic ischemia, the clip was removed to initiate hepatic reperfusion. Sham group mice underwent the same protocol as the control group without vascular occlusion. After the tissue was removed, animals were euthanized by injection of an overdose of pentobarbital. All studies were approved by the Institutional Animal Care and Use Committee of Tongji Medical College.

Detection of KC function variation after injection of GdCl₃ by CD68 stain

Liver samples from ischemic lobes were taken after 4 h of blood supply restoration and immediately fixed with 40 g/L formaldehyde, dehydrated, and embedded in paraffin for immuno-histopathologic examination. Four micrometers of thick sections were stained with anti-CD68 Ab (Boster Bio. Co., Wuhan, China). The results were analyzed with a HPIAS pathological image analyzer and expressed as optical density integral (OPTDI).

Detection of TLR2 protein in ischemic hepatic lobes

Membrane proteins of ischemic liver tissues (100 mg) were extracted (1× PBS, 10 mL/L NP40, 5 g/L sodium desoxycholate, 1 g/L sodium dodecyl sulfate, 10 g/L phenylmethylsulfonyl fluoride, 30 mL/L aprotinin, 1 mol/L sodium orthovanadate). After quantification and aliquot, the samples were degenerated by boiling, separated on 85 g/L SDS-PAGE and transferred to nitrocellulose membranes. Filters were blocked 50 g/L nonfat milk in blocking buffer (TBS-T, 50 mmol/L Tris-Cl, pH 7.5, 150 mmol/L NaCl, 0.2 g/L Tween 20), and incubated with anti-TLR2 antibody (Santa Cruz, CA, USA) for 2 h and with peroxidase-conjugated secondary antibody for 1 h at 37 °C. Specific bands were revealed with DAB solution and analyzed by Gel-Pro-Analyzer 4 as the value of *A*.

Other 4-μm-thick sections were stained with a goat antimouse TLR2 polyclonal antibody (Santa Cruz, CA, USA). The results were expressed as OPTDI and analyzed with a HPIAS pathological image analyzer.

The relationship between the expressions of CD68 and TLR2 was analyzed with Spearman, bivariate assay.

Examination of ALT and TNF-α in portal vein after injection of GdCl₃

Blood samples from portal vein were taken for assay of plasma alanine aminotransferase (ALT) and TNF-α level. The ALT activity was determined by an automatic biochemistry analyzer (HITACHI 2000, Japan) in Laboratory of Union Hospital. TNF-α level was assayed by an ELISA kit (JINGMEI Bio. Co., China).

Statistical analysis

All numeric data were expressed as mean±SD. Differences between blockade and non-blockade groups were analyzed by *t*-test with SPSS 10.0 software. The correlation between CD68 staining and TLR2 expression was analyzed with Spearman assay. *P*<0.05 was considered statistically significant.

RESULTS

Variation of KC function after injection of GdCl₃

When KCs were blocked with GdCl₃, the CD68⁺ reaction was weaker in blockade group than in non-blockade group (Figure 1A). CD68 content was shown as absolute value OPTDI (Area×OPTDM), which was 32.97±10.55 *vs* 185.65±21.88. The difference between them was significant (*P*<0.01), suggesting that the function of KCs was inhibited in blockade group.

Detection of TLR2 in ischemic hepatic lobes by immunological stain

The positive immunoreaction of TLR2 in slices was weaker

in blockade group than in non-blockade group (Figure 1B), which was shown as OPD_{TI} (75.74 ± 17.44 vs 170.58 ± 25.14). The difference between them was significant ($P < 0.01$).

Figure 1 Effect of GdCl₃ injection on CD68 (A) and TLR2 (B) expression in blockade and non-blockade groups. ^b $P < 0.01$ vs non-blockade group.

Variation of TLR2 protein expression in ischemic hepatic lobes

After 4 h restoration of blood supply, the expression of TLR2 protein, which was detected by Western blot increased in the non-blockade group compared to sham group (A : 433.91 ± 35.53 vs 52.86 ± 13.58 , $P < 0.01$). The injection of GdCl₃ significantly down regulated the expression of TLR2 in ischemic lobes compared to the non-blockade group (125.89 ± 15.49 vs 433.91 ± 35.53 , $P < 0.01$, Figure 2). Correlation analysis indicated that the downregulation of TLR2 expression between blockade and non-blockade groups was correlated with that of CD68 ($r = 0.745$, $P < 0.05$).

Figure 2 Detection of TLR2 expression by Western blot. ^b $P < 0.01$ vs non-blockade group, ^d $P < 0.01$ vs sham group.

Effect of GdCl₃ injection on portal vein plasma ALT and serum TNF- α

After 4 h restoration of blood supply, the level of ALT in portal vein, an indicator of liver function, was higher in non-blockade group than in sham group (890.21 ± 272.91 U/L vs 40.66 ± 15.42 U/L, $P < 0.01$). The value in blockade

group decreased to 435.89 ± 178.37 U/L. The difference between blockade and non-blockade groups was significant ($P < 0.01$, Figure 3A).

The serum TNF- α level in portal vein was higher in non-blockade group than in sham group (112.32 ± 17.56 ng/L vs 6.07 ± 5.33 ng/L, $P < 0.01$) after 4 h blood supply restoration. When the function of KCs was blocked by injection of GdCl₃, the level of portal vein TNF- α was decreased remarkably (84.45 ± 14.73 ng/L vs 112.32 ± 17.56 ng/L, $P < 0.01$), which might be an indirect indicator of KC inhibition (Figure 3B).

Figure 3 Portal vein ALT (A) and TNF- α (B) levels. ^b $P < 0.01$ vs non-blockade group, ^d $P < 0.01$ vs sham group.

DISCUSSION

KCs play an important part in mediating ischemia and reperfusion injury^[15]. When activated during ischemia and subsequent reperfusion, they generate excessive inflammatory cytokines and oxygen-derived free radicals, which play a particularly important role in the pathogenesis of hepatic ischemia and reperfusion injury with an increased release of TNF- α and histological impairment. GdCl₃, a specific inhibitor of KCs, is often used as a tool for studying the role of KCs^[16]. GdCl₃ is capable of protecting liver from injury mediated by the activation of KCs through depletion of lipid peroxidation. In the present study, injection of GdCl₃ selectively inhibited the activation of KCs, but did not induce hepatotoxicity. On the contrary, the impairment of liver function was relieved.

TLR2 can be activated during the process of hepatic I/R injury^[10]. When TLR2 is activated, its cytoplasmic portion would conduct signals to two distinct signaling pathways, JNK and NF- κ B, resulting in the proinflammatory cascade and excessive production of TNF- α ^[17]. TLRs recognize two kinds of signals. One is related to pathogen-associated molecular pattern molecules, which claims the existence of pathogens^[9]; the other is linked with some danger signals inside or outside the body, which does not need the existence of pathogens^[18]. Hypothesis infers that TLRs may be the

candidate of a key “gate” through which the down stream inflammatory cascade is initiated^[17]. TLR2 and TLR4 are activated in liver I/R injury^[10,11], but the factors regulating the expression of TLRs have not been revealed.

Previous study has proved that NF- κ B activation may be important in “switching off” the cytokine cascade during I/R injury. TNF- α plays a central role in mediating such an insult^[7]. Nevertheless, what happens preceding the NF- κ B activation and TNF- α release? Where is the switch point that starts a crucial inflammatory cascade involving the activation of NF- κ B during the I/R pathological process? Activation of TLR2 results in the activation of NF- κ B^[17], and NF- κ B activation in the liver could be downregulated by KC blockade. In this paper, we confirmed that blocking the function of KCs downregulated the expression of TLR2 in ischemic lobes in mice partial hepatic I/R model, and the levels of TNF- α and ALT in portal vein decreased at the same time, suggesting that inhibition of KC function may protect liver from I/R injury by suppressing the release of TNF- α through downregulation of TLR2 expression. On the other hand, KCs might play an important role in mediating liver injuries and inflammatory disorders in the liver by changing the TLR2 signal transduction pathway. But compared to the sham group, the levels of portal vein TNF- α and ALT were still higher in blockade group, indicating that besides activation of KCs there are other factors regulating the expression of TLR2. Whether KCs themselves or cytokines secreted by KCs regulate the expression of TLR2 in ischemic lobes remains unclear.

KCs are major contributors to cytokine production in hepatic I/R injury^[15]. Although many factors, including reactive oxygen species, Ca⁺⁺ overload, adhesive molecules, nitrogen monoxide, *etc*, contribute to the pathogenesis of hepatic I/R injury, all these factors exert their role after the activation of KCs and the resulting inflammatory cascade^[3]. Further study on inflammatory reaction controlled by TLRs and KCs may resolve the enigma of hepatic I/R injury.

Abstract

AIM: To examine the effect of prostaglandin E₂ (PGE₂) on the expression of vascular endothelial growth factor (VEGF) mRNA in the human hepatocellular carcinoma (HCC) HepG2 cells and the possible involvement of *c-fos* protein in this process.

METHODS: Human HCC HepG2 cells were divided into three groups treated respectively with PGE₂, a combination of PGE₂ and *c-fos* antisense oligodeoxynucleotide (ASO), and PGE₂ plus *c-fos* sense oligodeoxynucleotide (SO). The expression of VEGF mRNA in HepG2 cells after different treatments was detected by reverse transcriptase-polymerase chain reaction (RT-PCR). The relative expression level of VEGF mRNA in HepG2 cells in each group was measured.

RESULTS: Administration of PGE₂ resulted in an increased expression of *c-fos* and VEGF mRNA in HepG2 cells. The relative expression level of *c-fos* mRNA reached the peak at 3 h (68.4±4.7%) after PGE₂ treatment, which was significantly higher than that at 0 h (20.6±1.7%, *P*<0.01). Whereas, the highest expression level of VEGF mRNA was observed at 6 h (100.5±6.1%) after PGE₂ treatment, which was significantly higher than that at 0 h (33.2±2.4%, *P*<0.01). *C-fos* ASO significantly reduced PGE₂-induced VEGF mRNA expression in HepG2 cells.

CONCLUSION: PGE₂ increases the expression and secretion of VEGF in HCC cells by activating the transcription factor *c-fos*, promotes the angiogenesis of HCC and plays an important role in the pathogenesis of liver cancer.

INTRODUCTION

PGE₂ is produced in various kinds of cancer cells and seems to be particularly important for carcinogenesis^[1-3]. PGE₂ activates multiple G-protein-linked receptor subtypes (EP1-EP4) in an autocrine or paracrine fashion, which may lead to tumor growth promotion via growth factors and oncogenes^[4-6]. However, the mechanism of PGE₂ in promoting tumor growth still remains unclear. VEGF is a regulator of pathological angiogenesis and plays an important role in tumor growth. Studies have revealed that VEGF can be produced by liver cancer cells in a paracrine manner, thus promoting the angiogenesis of liver cancer^[7,8]. Studies also indicate that many tumor growth factors stimulate the production of VEGF in tumor cells^[3,9]. This study was undertaken to estimate if PGE₂ could affect the expression of VEGF in HCC HepG2 cells and the possible involvement of the oncogene *c-fos* in this process.

MATERIALS AND METHODS

Cell culture and PGE₂ administration

HepG2 cells were cultured in RPMI-1640 medium (Gibco) containing 10 mL/L fetal bovine serum, 100 kU/L penicillin and 0.1 g/L streptomycin at 37 °C in 50 mL/L CO₂/950 mL/L air for 4-6 d and then put into fresh 35 mm dishes. Twenty-four hours later, PGE₂ (Sigma) was added into each dish in a final concentration of 1 μmol/L. The dose of PGE₂ in the present study was chosen based on the previous reports and our preliminary experiments. The cells were then cultured for 0, 1, 3, 6, 12, and 24 h, respectively (*n* = 4/each time point) and collected for RNA extraction.

C-fos ASO administration

C-fos ASO (5'-GAACATCATCGTGGC-3') was synthesized according to reported human *c-fos* mRNA sequence (GenBank Accession No. M16287). *C-fos* SO (5'-GCCA-CGATGATGTTC-3') was also synthesized as a control. Both ASO and SO were modified phosphorothioate

oligodeoxynucleotide.

HepG2 cells were cultured as mentioned above and divided into: (1) control group in which 10 μ L physical saline was added, (2) PGE₂-treated groups in which 1 μ mol/L of PGE₂ was added, (3) SO-treated group in which 10 μ L (50 μ g) *c-fos* SO was added followed by addition of 1 μ mol/L of PGE₂ after 30 min, (4) ASO-treated group in which 10 μ L (50 mg) *c-fos* ASO was added followed by addition of 1 μ mol/L of PGE₂ after 30 min. The cells were cultured for 6 h and then collected for RNA extraction.

Primer design and synthesis

Specific primers for human *c-fos* and VEGF were synthesized according to their reported mRNA sequences. The primer pair of *c-fos* were: sense: 5'-TGC TGA AGG AGA AGG AAA AA -3'; antisense: 5'-TGC ATA GAA GGA CCC AGA TA -3' (GenBank Accession No. M16287). The primer pair of VEGF were: sense: 5'-ACC CAT GGC AGA AGG AGG AG -3' antisense 5'-ACG CGA GTC TGT GTT TTT GC-3' (GenBank Accession No. M32977). The primers (sense: 5'-GGC ATC CAC GAA ACT ACC TT-3' antisense 5'-CGT CAT ACT CCT GCT TGC TG -3') for human β -actin (GenBank Accession No. M10277) were also synthesized as internal control in the PCR reaction. The length of PCR product for *c-fos*, VEGF and β -actin was 344 bp, 433 bp and 274 bp, respectively.

RNA extraction

Total cellular RNA was extracted from HepG₂ cells using TRIzol reagent (Invitrogen) according to the manufacturer's instructions. The purity and integrity of the RNA samples were assessed by $A_{260/280}$ spectrophotometric measurement.

RT-PCR

After measurement of the concentration, cDNA was reversely transcribed in a 50 μ L mixture containing 2 μ g total RNA, 10 μ L 5 \times RT buffer, 5 μ L 10 mmol/L dNTPs, 0.5 μ L RNase inhibitor (4×10^5 U/L, Invitrogen) 0.5 μ L oligo (dT)₁₂₋₁₈ (500 g/L, Invitrogen) 1 μ L SuperScript II reverse transcriptase (2×10^4 U/L, Invitrogen), 0.5 μ L 0.1 mol/L DTT at 42 $^{\circ}$ C for 60 min followed by enzyme denaturation at 70 $^{\circ}$ C for 10 min. Thirty cycles of PCR were carried out in 25 μ L reaction mixture containing 0.1 μ g synthesized cDNA, 2.5 μ L 10 \times PCR buffer, 2.5 μ L dNTPs (2 mmol/L), 2.5 μ L MgCl₂ (2.5 mmol/L), 1 μ L of each primer (20 μ mol/L), 2.5 u of Taq DNA polymerase (Takara) using a PTC-100 programmed thermal controller (MJ Research), each consisting of denaturation at 94 $^{\circ}$ C for 1 min, annealing at 56 $^{\circ}$ C for 30 s, extension at 72 $^{\circ}$ C for 1 min. Then, 10 μ L of each PCR product was separated by electrophoresis on a 30 g/L agarose gel and visualized by ethidium bromide staining.

Statistical analysis

For each template, PCR amplification was performed 2-3 times. The electrophoresis results were observed through a gel imaging system (UVP) and the density of each positive band was analyzed by Labworks software. The relative expression level of *c-fos* and VEGF mRNA was expressed as a ratio of densitometric measurements (*c-fos*/ β -actin or

VEGF/ β -actin). The data were expressed as mean \pm SE, and analyzed by analysis of variance and Dunnett's test using SPSS10.1 software.

RESULTS

Effect of PGE₂ on expression of *c-fos* and VEGF mRNA in HepG2 cells

Addition of PGE₂ to the HepG2 cells resulted in a time-dependent increase in the expression of *c-fos* and VEGF mRNA (Figure 1A). Compared to the expression level at 0 h ($20.6\pm 1.7\%$), the expression of *c-fos* mRNA induced by PGE₂ treatment reached the highest level at 1 h ($62.3\pm 4.3\%$, $P<0.01$) and 3 h ($68.4\pm 4.7\%$, $P<0.01$), and slightly higher level at 6 h ($55.3\pm 3.8\%$, $P<0.05$; Figure 1B). The expression level of VEGF mRNA significantly increased at 3 h after PGE₂ administration ($87.6\pm 6.4\%$, $P<0.01$) when compared to the expression level at 0 h ($33.2\pm 2.4\%$). Its expression level reached a maximum at 6 h ($100.5\pm 6.1\%$, $P<0.01$). At 24 h, the expression level returned to its level at 0 h ($35.2\pm 2.8\%$, $P>0.05$; Figure 1B). The expression level of β -actin mRNA remained unchanged at each time-point, indicating the equal amount of the template used in PCR.

Figure 1 RT-PCR results (A) and histograms (B) showing effect of PGE₂ on expression of *c-fos* and VEGF mRNA in HepG2 cells. ^a $P<0.05$, ^c $P<0.05$ vs 0 h.

Effect of *c-fos* ASO on PGE₂-induced upregulation of VEGF mRNA in HepG2 cells

Since the maximal expression level of VEGF mRNA was at 6 h after PGE₂ treatment, this time-point was selected to observe the effect of *c-fos* ASO. The results showed that the expression level of VEGF mRNA significantly decreased in *c-fos* ASO-treated group ($39.6\pm 3.2\%$) when compared to that in PGE₂-treated group ($98.6\pm 6.4\%$, $P<0.01$, Figure 2A

and B). In contrast, no such change in *c-fos* SO-treated group was observed ($95.2 \pm 6.3\%$, $P > 0.05$).

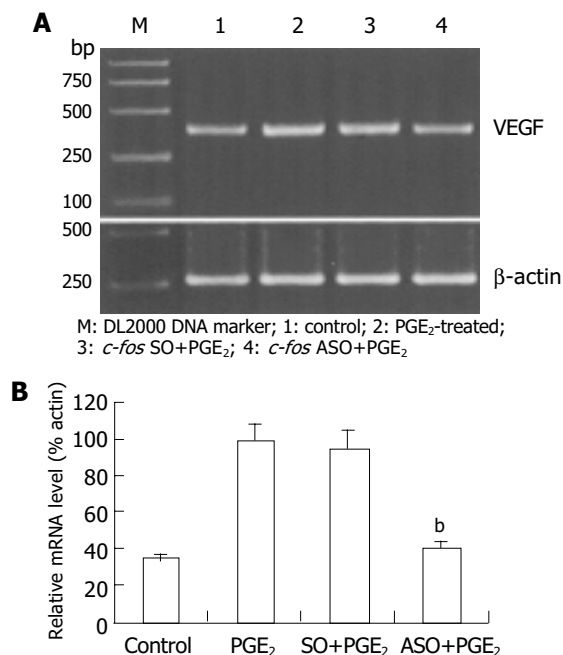

Figure 2 RT-PCR results (A) and histograms (B) showing effect of *c-fos* ASO on PGE₂-induced VEGF mRNA expression in HepG2 cells. ^b $P < 0.01$ vs PGE₂ group.

DISCUSSION

At present, the exact pathological function and mechanism of PGE₂ in tumors are not fully known. Previous studies indicate that PGE₂ can be produced by tumor cells and plays an important role in tumor immune inhibition^[10-12]. Some studies revealed that the PGE₂ level in patients with cancer is higher than that in normal people, and that tumor tissues also contain higher concentration of PGE₂ than normal tissues^[13]. Animal experiments indicate that PGE₂ produced by tumor cells, can promote the growth and development of tumors through its immune inhibitory function^[10]. Further studies have proved that PGE₂ promotes the growth of liver cancer through its receptor EP3^[14]. In the present study, we observed that PGE₂ could stimulate the expression of VEGF mRNA in HepG2 cells in a time-dependent manner, suggesting that PGE₂ may promote the angiogenesis of HCC by increasing the secretion of VEGF from liver cancer cells. This might be one of the mechanisms of PGE₂ in facilitating the growth of liver cancer.

It is well known that the oncogene *c-fos* can function as a third intracellular messenger. Its product Fos protein can form a homo-dimer itself or hetero-dimer with c-Jun protein and then binds to the AP-1 site in the target gene, thus promoting the transcription of target gene. It has been reported that the promoter region for the VEGF gene contains several AP-1 binding motifs^[15] and the expression of VEGF gene is controlled by transcription factors AP-1 and AP-2^[16-18]. In the present study, we observed that PGE₂ increased the expression of *c-fos* mRNA, the maximal level was at 1 and 3 h after PGE₂ administration, earlier than the

PGE₂-induced highest expression of VEGF mRNA. Furthermore, *c-fos* ASO significantly reversed PGE₂-induced VEGF mRNA expression. These results indicate that Fos protein is involved in the PGE₂-induced VEGF expression in HepG2 cells.

The intracellular signaling pathway coupled to PGE₂ is complicated. As a third intracellular messenger, *c-fos* is just located in the downstream of the signaling pathway. Many other molecules should also be involved in the modulation of VEGF expression by PGE₂. In addition, several PGE₂ receptors are present in HCC^[6,19]. Which receptors mediate the role of PGE₂ in tumor growth needs to be investigated.

In conclusion, PGE₂ stimulates VEGF induction in HepG2 cells by activating the transcription factor Fos protein.

ACKNOWLEDGMENT

Abstract

AIM: To evaluate the risk factors for primary liver carcinoma (PLC) in Chinese population.

METHODS: Chinese Biomedical Literature Database, China Hospital Knowledge Database and MEDLINE were searched. All the related literatures were screened, and the risk factors for PLC in Chinese population were studied. Heterogeneity was evaluated by odds ratio (OR) q test. Combined OR and its 95% confidence interval (95%CI) were calculated, the association between the investigated risk factors and PLC was determined. Validity and bias of the findings were evaluated by sensitivity analysis and funnel plot analysis respectively.

RESULTS: Fifty-five of one hundred and ninety identified studies were accepted according to the inclusive criteria. Ten factors related to PLC were demonstrated by sensitive analysis and funnel plot analysis. They were cirrhosis (OR = 11.97, P = 0.000), HBV infection (OR = 11.34, P = 0.000), HCV infection (OR = 4.28, P = 0.000), family history of liver cancer (OR = 3.49, P = 0.000), unstable emotion (OR = 2.20, P = 0.000), depressed characters (OR = 3.07, P = 0.000), aflatoxin (OR = 1.80, P = 0.000), alcoholic (OR = 1.88, P = 0.000), intake of musty food (OR = 1.87, P = 0.000) and drinking contaminated water from pond (OR = 1.77, P = 0.003).

CONCLUSION: The main risk factors for PLC in China are liver diseases, family history of liver carcinoma, poor psychic status, aflatoxin, and some unhealthy behaviors.

INTRODUCTION

Primary liver carcinoma (PLC) affects more than 500 000 people globally with 110 000 deaths annually. More than one-half of them were Chinese^[1]. The incidence rate is 14.58-46 per 100 000 people. In Qidong, Jiangsu Province and Fusui, Guangxi Zhuang Autonomous Region, the morbidity is higher than that in any other areas of China.

It is known that persistent hepatitis B virus (HBV) and HCV infection and aflatoxins are the main causes of PLC^[1]. However, most of the investigations were case-control studies. The real risk factors for PLC may be far more than the known causes. The results from different investigated areas are variable. Cohort study on risk factors for PLC in Chinese people is still not available. A meta-analysis confined to case-control studies published from January 1966 to December 2003 was carried out.

MATERIALS AND METHODS

Search strategy

The databases including Chinese Biomedical Literature Database (1979-December 2003), China Hospital Knowledge Database (1994-December 2003) and MEDLINE (1966-December 2003) were searched. The following keywords were used: liver cancer, liver carcinoma, primary liver cancer, primary liver carcinoma, malignant liver tumors, primary liver tumors, hepatocellular carcinoma, hepatocellular cancer, risk factor, cause, etiology, case-control study. In the search of MEDLINE, the keywords of Chinese population, Chinese and China were added. Further studies were identified through scanning reference lists of relevant articles, reviews, and textbooks. Articles published in both English and Chinese were accepted. To eliminate irrelevant studies, the title and abstract of the articles were screened at first, and then the whole texts of selected paper were examined for further screening based the inclusive criteria.

Inclusion and exclusion criteria

Inclusion criteria in the meta-analysis included case-control studies investigating the risk factors for PLC in Chinese population, the data from the articles including the background of population and time investigated, the articles that reported original data or statistical results of odd ratio (OR) and its 95% confidence interval (95%CI), the studies based on similar diagnostic criteria of PLC.

Exclusion criteria in the meta-analysis were poor methodological quality^[2], the republished studies, and no sufficient data and/or results in the article.

Data selection and study appraisal

Data used in this study included year of publication, number of case and control, characteristics of patients and control

(gender, age, native place, and living place), suspected risk factor and its definition of exposure, diagnostic criterion of PLC, and outcomes (OR value and its 95%CI of each factor should be provided, if the article did not report the results in the form of OR, we calculated OR and its 95%CI based on the given data).

Two researchers extracted the data from each study independently and any disagreements were discussed for consensus. Quality of the study was assessed by the guideline of Lichtenstein^[2].

Statistical analysis

OR q test for heterogeneity was used to examine gross statistical heterogeneity among included studies. If K studies were included, $OR_i (i = 1, 2, \dots, K)$ was OR of the investigated factors in each study, OR_{ui} and OR_{li} were the upper and lower limit of its 95%CI respectively. V_i was variance calculated by the formula of $V_i = [\ln(OR_i/OR_{li})/1.96]^2$ or $V_i = [\ln(OR_{ui}/OR_i)/1.96]^2$. Weight (W_i) was calculated by $W_i = 1/V_i$. Supposed $y_i = \ln(OR_i)$ and $y_w = (\sum W_i y_i) / (\sum W_i)$. The heterogeneity among included studies was tested by $q = \sum [W_i (y_i - y_w)^2]$. If the q value was low ($P > 0.05$), the results of the included studies were considered as significant homogeneity, otherwise significant heterogeneity existed among studies^[3,4].

The association between investigated factors and PLC was presented as OR and its 95%CI. If the studies had no significant heterogeneity demonstrated by OR q test, fixed-effect model was used to calculate the combined OR and its 95%CI. Otherwise, random-effect model was used. Combined OR value greater than one indicated a risk factor for PLC. The significance of the combined OR was tested by $\chi^2 = (\sum W_i y_i)^2 / (\sum W_i)$ with $g = 1$ ^[3,4], and the significant level was $P = 0.05$.

Sensitivity analysis was performed through fixed-effect model and random-effect model. Coherence of the results from two models indicated a valid outcome^[4].

Funnel plot analysis was used to assess the potential bias, and its symmetry was tested through linear regression model. Intercept 95%CI of linear regression function spanning 0 and its significant level greater than 0.1 indicated symmetric funnel plot^[4].

RESULTS

Description of studies

Fifty-five of 190 identified studies were included in meta-analysis after the quality assessment of each study. They were published in Chinese in 1984-2002. The investigated people were from 24 cities located in 13 different provinces of China.

The investigated factors included liver diseases, family history, psychic status, past history of exposure to poison and style of living. The factors for liver diseases were from 26 studies of HBV infection, 15 of HCV infection, 9 of liver cirrhosis, and 20 of hepatitis history. There were 25 studies on family history of liver carcinoma. Psychological factors for PLC included 10 for negative living events, 6 for unstable emotions, and 6 for depressed characters. The past history of exposure to poison was from five studies of

pesticide and four of aflatoxin. The living style included nine factors: drinking (22 studies), smoking (15 studies), intake of musty food (3 studies), intake of pickle (5 studies), intake of bean product (4 studies), tea (4 studies), drinking water from pond (8 studies), drinking water from river (2 studies), and drinking water from well (5 studies).

Heterogeneity of studies

OR q test was carried out in included studies (Table 1). No significant heterogeneity existed among the studies on HCV infection, unstable emotion, past history of exposure to aflatoxin, and intake of musty food ($P > 0.05$). The remaining factors in the studies all had significant heterogeneity ($P < 0.05$).

Association of outcomes

Association between the factors and PLC was shown by combined OR and its 95%CI. If heterogeneity was significant, OR was combined with random-effect model, otherwise, fixed-effect model was used (Table 2). The OR and its 95%CI of five factors including past history of exposure to pesticide, intake of bean products, tea, drinking water from river and well had no statistical significance ($P > 0.05$). According to the value of OR, the strength of association in descending turn was liver cirrhosis, HBV infection, history of hepatitis, HCV infection, family history of liver carcinoma, depressed character, negative living events, unstable emotion, alcoholic, intake of musty food, aflatoxin, drinking water from pond, intake of pickle, and smoking, with their OR value greater than one, 95%CI beyond one. There was a statistical significance ($P < 0.05$).

Sensitive analysis

The combined OR and its 95%CI of each factor were calculated by both fixed-effect model and random-effect model, and coherence of the results was assessed. The factors of exposure to pesticide and drinking water from well showed conflicting results from two models (combined OR and its 95%CI of fixed-effect model were 1.69 (1.24 and 2.29) and 0.74 (0.58 and 0.96) respectively). Other factors showed similar results from two models.

Funnel plot

Since only two studies were involved in the factor of drinking water from river, funnel plot analysis was insignificant. According to the linear regression models of funnel plots, four factors including history of hepatitis, negative living events, smoking, and intake of pickle existed as asymmetric funnel plots with their intercept 95%CI beyond 0 and $P < 0.1$. Other factors showed symmetry funnel plots with their intercept 95%CI spanning 0 and $P > 0.1$ in their linear regression models.

DISCUSSION

A considerable number of chemical agents have been proved to be directly carcinogenic for liver malignant tumor in animal experiments, and also most likely in human beings^[5]. But still no evidence is presented as yet. It was reported that the risk factors for PLC include hepatitis viruses, liver

diseases, mycotoxins or phytotoxins, nutrition, social drugs, metabolic diseases, chemical agents, inorganic substances, medication, and ionizing radiation. However, in 10–15% of patients, there is no risk factor for the development of PLC^[5]. This study investigated the association between possible risk factors and PLC in Chinese population by meta-analysis of case-control studies published in the past 37 years, and demonstrated the risk factors for PLC in Chinese population.

This study analyzed 19 suspected risk factors for PLC.

The combined outcomes showed that liver diseases were the most important factors for PLC with much a greater OR value than any other factor. Both liver cirrhosis and HBV infection were strongly associated with PLC, with their OR being 11.97 and 11.34 respectively (*P*<0.05). The association between HCV infection and PLC was moderate, with its OR being 4.28 (*P*<0.05). Though history of hepatitis was significantly associated with PLC, its funnel plot was asymmetric. Therefore this outcome might have bias, possibly due to the published bias, and heterogeneity from

the different definitions of history of liver diseases in the included studies. Family history of PLC was another risk factor for PLC, with its OR being 3.61 ($P < 0.05$), suggesting that people with family history of PLC have a higher risk. Poor psychological status can strengthen the risk for PLC. In this meta-analysis, the factors for unstable emotion and depressed character were significantly associated with PLC, with their OR being 2.20 and 3.07, respectively ($P < 0.05$). The funnel plot of negative living events was asymmetric though its combined OR was significant. The reason may be the published bias, and the conclusion on negative living events could not be made. In regard to exposure to poison, two factors including exposure to aflatoxin or pesticide were investigated. It was demonstrated that aflatoxin played an important role in PLC^[5]. In this meta-analysis, the outcome showed that aflatoxin was also a risk factor for PLC in Chinese population, with its OR being 1.80 ($P < 0.005$), but it seems to be trivial when compared to the factors for liver diseases, family history of PLC and poor psychological status. The results indicated that there was no significant association between exposure to pesticide and PLC, with its OR being 1.55 ($P > 0.05$). Furthermore, this result was unreliable because it was conflicting in sensitivity analysis. Hence, it is not clear whether exposure to pesticide is a risk factor for PLC. The living habits of drinking, intake of musty food and drinking water from pond were all significantly associated with PLC (OR was 1.88, 1.87, and 1.77 respectively, $P < 0.05$), suggesting that they may enhance the risk for PLC. Though the factors of both smoking and intake of pickle had a significant combined OR (1.24 and 1.69 respectively, $P < 0.05$), it was unable to draw conclusions because of the bias demonstrated by their asymmetric funnel plots ($P < 0.1$). Drinking water from river was not significantly associated with PLC (OR = 1.41, $P > 0.05$) and its bias was difficult to analyze by funnel plot due to its limited number of the included studies. Thus it is unknown whether it is a risk factor. The ORs of intake of bean products, tea and drinking water from well were all less than 1 (OR being 0.74, 0.69, and 0.79 respectively, $P > 0.05$). These results could not demonstrate that they are protective factors for PLC. Furthermore, the result of drinking water from well was unreliable because the results were conflicting in sensitivity analysis.

Meta-analysis is a tool, but bias in meta-analysis can cause invalid results. In this study, case-control studies were included in meta-analysis. Considering the design of the included studies, validity of their results was inferior to that of prospective studies. Thus, the significance of conclusion from this meta-analysis is limited due to the design of the included studies. Since lack of qualified cohort studies on the risk factor for PLC in Chinese population, the result of this meta-analysis is valuable for further research. Test of heterogeneity is a formal statistical analysis for examining if the observed variation in study results is compatible with

the variation expected by chance^[4]. When heterogeneity is statistically significant ($P < 0.05$), the observed different results should be explained individually. Nineteen factors in the included studies were involved in this investigation, fifteen of which had significant heterogeneity. The various risk factors for PLC were possibly interactive. When an investigated factor is involved in the included studies, the difference between other risk factors and their interaction is not easy to control among studies, thus leading to the heterogeneity. Furthermore, different studies are usually undertaken in different ways, but it is hard to attribute heterogeneity to any single factor^[4]. Since the differences in the included studies are of practical significance, random-effect model is used for the factor with significant heterogeneity to make a more conservative estimation of the combined result. In the current study, some original articles were unable to be used because of their deficient data. It is difficult to estimate the effect of these missing data on the combined results. Sensitivity analysis can test the reliability of the outcomes by assessing coherence of the combined results from fixed-effect model and random-effect model. In this study, most factors passed sensitivity analysis successfully (17/19), thus proving the reliability of the results in this meta-analysis. Publication bias is associated with funnel plot asymmetry. However, the reasons for asymmetric funnel plot may include publication bias and others such as selection biases, poor methodology of smaller studies, true heterogeneity and chance^[4]. Since the funnel plots of history of hepatitis, negative living events, smoking, and intake of pickle were found asymmetric, conclusions about these factors should not be drawn due to the bias.

In conclusion, the main risk factors for PLC in Chinese population are related to liver diseases, family history of liver carcinoma, poor psychological status, aflatoxin, and bad living style. Liver diseases are most important in all these factors. Control of HBV infection, HCV infection, and liver cirrhosis is the essential measure for the prevention of PLC. In addition, balanced psychological status, avoidance of musty food or food polluted by aflatoxin-contaminated food, and no alcoholic can reduce the risk for PLC.

Abstract

AIM: To investigate the mechanisms of sulfasalazine (SASP) in the treatment of ulcerative colitis (UC).

METHODS: Changes of pathological signs and histological grading of 106 patients with active UC were observed before and after the treatment with SASP, 1 g, thrice daily for 6 wk.

RESULTS: The effect of SASP on the vasculitis in lamina propria was 48.2% and 17.4% in the mild active UC ($P<0.001$) and 68% and 26.7% in the moderate active UC ($P<0.001$) before and after treatment. Fibroid necrosis of vessel wall was found in one case of mild UC and two cases of moderate UC before treatment and was not found after treatment. No thrombosis was found in mild UC before and after treatment, while thrombosis was found in one case of moderate UC before treatment. The effect on mucosal glandular abnormality was 30.4% and 13.0% in mild UC ($P<0.05$), and 42% and 40% in moderate UC ($P>0.05$) before and after treatment. The rate of eosinophil infiltration was 98.2% and 80.4% in mild UC ($P<0.01$), and 100% and 91.1% in moderate UC ($P<0.05$) before and after treatment. The effect on crypt abscess was 21.4% and 4.4% in mild UC ($P<0.05$), and 48% and 13.3% in moderate UC ($P<0.001$) before and after treatment. The effect on mucosal pathohistological grading was 2.00 ± 0.84 and 0.91 ± 0.46 in mild UC ($P<0.001$), and 2.49 ± 0.84 and 1.31 ± 0.75 in moderate UC ($P<0.001$) before and after treatment.

CONCLUSION: SASP can improve small vessel lesions and crypt abscesses and reduce neutrophilic and eosinophilic leukocyte infiltration in inflammatory mucosa of UC.

INTRODUCTION

Ulcerative colitis (UC) is an inflammatory bowel disease mainly characterized by inflammatory changes in mucosa and submucosa of the rectum and colon. The continuous inflammatory lesions commonly involve rectum and extend to the proximal colon and even to pancolitis. The main clinical manifestations are chronic relapsing diarrhea, mucopurulent hematochezia and abdominal pain.

Though sulfasalazine (SASP) has been used to treat active UC for more than 60 years, its mechanisms have not been completely clarified^[1]. The purpose of the present study was to investigate the mechanisms of SASP in treatment of active UC.

MATERIALS AND METHODS

Patients^[2]

Following patients were enrolled in the study: patients aged 14-69 years with chronic or relapsing diarrhea, mucopurulent hematochezia, abdominal pain and systemic symptoms, and extraintestinal presentations of their joints, skin, eyes, mouth, liver, and gall bladder, as well as those with inflammatory lesions of rectum and colon. Patients with bacillary or amoebic dysentery, fungous or tuberculous colitis, ischemic bowel disease, radiation colitis, Crohn's disease and large bowel cancer and those who did not complete the course of treatment due to drug allergy or quitted the study were excluded.

Objects of study

A total of 106 patients (50 males and 56 females) with active UC were enrolled in the study^[2]. The ratio of male to female was 0.98:1. Their age was 20-66 years (41.6 ± 11.4 years). Fifty-six cases (22 males and 34 females) had mild UC, and their age was 22-66 years (41.5 ± 10.6 years). Fifty cases (28 males and 22 females) had moderate UC, and their age was 20-65 years (42.8 ± 12.1 years). There were no significant

differences in their age, ratio of male to female and clinical types between the two groups ($P>0.05$). Forty-six of fifty-six cases of mild UC and 45 of 50 cases of moderate UC were followed up.

Treatment

The patients received 1 g SASP thrice daily for 6 wk. Endoscopy was carried out before and after treatment. Biopsy specimens were taken at the same sites before and after treatment.

Grouping

Patients were divided into two groups according to the criteria of mild and moderate UC^[2].

Endoscopy and mucosal biopsy

The colon and rectum were examined with electronic colonoscope and 3-5 biopsy specimens were taken from the most obvious inflammatory lesions on the left side of colon or rectum. The specimens were fixed in 40 g/L formaldehyde and embedded in paraffin wax, then cut into continuous sections and stained with hematoxylin and eosin. Pathologic morphometry was analyzed by one pathologist with double blind method. The final morphologic results were obtained from the average of three observations under a high power microscope.

Observed pathological items^[3-6]

The following pathological items were observed: small vessel lesions in lamina propria such as vasculitis, fibroid necrosis of vessel wall, thrombosis and focal hemorrhage; mucosal gland lesions including glandular abnormality, epithelial cell regeneration, atypical hyperplasia, goblet cell depletion (GCD) and Paneth cell metaplasia (PCM); inflammatory cell infiltration in mucosal epithelium such as lymphocyte hyperplasia, lymphoid follicular formation, eosinophils (Eos) and plasmacytes; cellular stromal lesions including granulation tissue formation, fiber tissue hyperplasia and pseudo-polyp; crypt abscess.

Pathohistological grading criteria^[7,8]

Grade 0: no neutrophilic leukocyte infiltration in lamina

propria; grade I: a small number of neutrophilic leukocytes (<10 /HPF) in lamina propria with minimal infiltration of crypts; grade II: prominent neutrophilic leukocytes ($10-50$ /HPF) in lamina propria with infiltration of more than 50% of crypts; grade III: a large number of neutrophilic leukocytes (>50 /HPF) in lamina propria with crypt abscesses; grade IV: significant acute inflammation with ulcerations in lamina propria.

Statistical analysis

Results were expressed as mean \pm SD. The data of two groups were analyzed using independent and paired t test. The counted data were expressed as rate or ratio, and analyzed by χ^2 test. All data were analyzed with SPSS10.0 software.

RESULTS

Effects of SASP on small vessel lesions in lamina propria

No significant changes were found in all specimens before and after SASP treatment ($P>0.05$). The effect of SASP on vasculitis in lamina propria was 48.2% and 17.4% in mild active UC ($P<0.001$), and 68% and 26.7% in moderate active UC ($P<0.001$) before and after treatment. Fibroid necrosis of vessel wall was found in one case of mild UC and two cases of moderate UC before treatment but was not found after treatment. Thrombosis was not found in mild UC before and after treatment, but was found in one case of moderate UC before treatment and not found after treatment (Table 1).

Effect of SASP on mucosal gland lesions

The effect of SASP on mucosal glandular abnormality was 30.4% and 13.0% in mild UC ($P<0.05$), and 42% and 40% in moderate UC ($P>0.05$) before and after treatment. No significant effect of SASP on epithelial cell regeneration, atypical hyperplasia, GCD, and PCM was observed before and after treatment ($P>0.05$, Table 2).

Effects of SASP on inflammatory cell infiltration

The rate of Eos infiltration was 98.2% and 80.4% in mild UC ($P<0.01$), and 100% and 91.1% in moderate UC ($P<0.05$)

Table 1 Effect of SASP on small vessel lesions in lamina propria (n%)

	<i>n</i>	Focal hemorrhage	Vessel inflammation	Fibroid necrosis	Thrombosis
Before treatment (mild)	56	41 (73.2)	27 (48.2)	1 (1.8)	0
After treatment (mild)	46	25 (54.3)	8 (17.4)	0	0
Before treatment (moderate)	50	32 (64.0)	34 (68.0)	2 (4.0)	1 (2.0)
After treatment (moderate)	45	22 (48.9)	12 (26.7)	0	0

Table 2 Effect of SASP on mucosal gland lesions (n%)

	<i>n</i>	Glandular abnormality	Epithelial cell regeneration	Atypical hyperplasia	GCD	PCM
Before treatment (mild)	56	17 (30.4)	19 (34.0)	8 (14.3)	3 (5.4)	0 (0)
After treatment (mild)	46	6 (13.0)	13 (28.3)	2 (4.4)	2 (4.4)	1 (2.2)
Before treatment (moderate)	50	21 (42.0)	15 (30.0)	15 (30.0)	12 (24)	2 (4.0)
After treatment (moderate)	45	18 (40.0)	7 (15.6)	8 (17.8)	6 (13.3)	0 (0)

Table 3 Effects of SASP on inflammatory cell infiltration (n%)

	n	Lymphocyte hyperplasia	Lymphoid follicle	Eos infiltration	Plasmacyte infiltration
Before treatment (mild)	56	42 (75.0)	44 (78.6)	55 (98.2)	50 (89.3)
After treatment (mild)	46	30 (65.2)	32 (69.6)	37 (80.4)	37 (80.4)
Before treatment (moderate)	50	37 (74.0)	35 (70.0)	50 (100)	46 (92)
After treatment (moderate)	45	32 (71.1)	26 (57.8)	41 (91.1)	39 (86.7)

before and after treatment. No significant effects of SASP on lymphocyte hyperplasia, lymphoid follicular formation and plasmacyte infiltration were observed before and after treatment ($P>0.05$, Table 3).

Effect of SASP on cellular stromal lesions

No significant effect of SASP on granulation tissue formation, fiber tissue hyperplasia and pseudo-polyp was found before and after treatment ($P>0.05$).

Effect of SASP on crypt abscess

The effect of SASP on crypt abscess was 21.4% and 4.4% in mild UC ($P<0.05$), and 48% and 13.3% in moderate UC ($P<0.001$) before and after treatment.

Effect of SASP on mucosal pathohistological grading

The effect of SASP on mucosal pathohistological grading was 2.00 ± 0.84 and 0.91 ± 0.46 in mild UC ($P<0.001$), and 2.49 ± 0.84 and 1.31 ± 0.75 in moderate UC ($P<0.001$) before and after treatment (Table 4).

Table 4 Effect of SASP on mucosal pathohistological grade (mean \pm SD)

	n	Mild	n	Moderate
Before treatment	46	2.00 ± 0.84	45	2.49 ± 0.84
After treatment	46	0.91 ± 0.46	45	1.31 ± 0.75

DISCUSSION

The common drugs used in treatment of patients with active UC are still SASP and glucocorticoids. Sangfelt *et al.*^[9], used prednisolone enema to treat active UC and showed that the release quantity of neutrophil myeloperoxidase (MPO), eosinophil cationic protein (ECP) and eosinophil peroxidase (EPO) in enema liquid is correlated with their clinical, endoscopic and histological activities before treatment. When the patients respond to the treatment, their MPO markedly decreases, but ECP and EPO do not decrease. The results suggest that glucocorticoids can reduce mucosal neutrophil infiltration, but cannot improve Eos infiltration. The increase of MPO is correlated with neutrophil-activated peptide-interleukin 8 and tumor necrosis factor- α ^[10].

The mechanism of SASP against active UC is that it depresses the production of leukotrienes (LTs), prostaglandin and free radicals^[1,11]. SASP plays a role in the treatment of active UC by interfering with synthesis of inflammatory media^[12]. SASP can depress immune responses of immune cells and prevent relapse of UC. But the mechanisms have not been completely clarified^[1]. Wright *et al.*^[13], used

20 mg/100 mL sucralfate once or twice daily to treat distal active UC for 4 wk and showed that it can improve the clinical, endoscopic and histological scores.

The present study using oral SASP to treat active UC for 6 wk showed that it could improve small vessel inflammation and crypt abscess in lamina propria of inflammatory mucosa, decrease neutrophil and Eos infiltration in mucosal epithelium, and decline the histological grading after treatment. There was no fibroid necrosis of vessel wall and thrombosis in all specimens after treatment. Significant effect of SASP on mucosal glandular abnormality, lymphocyte hyperplasia and lymphoid follicular formation, plasmacytes infiltration and cellular stromal lesions was not observed.

The insufficient mucosal blood supply and submucosal vessel lesions are also the pathogenic factors for active UC. SASP could improve mucosal small vessel lesions, crypt abscess, mucopurulent hematochezia and mucosal inflammation in patients with active UC, thus improving and promoting the healing of inflammatory mucosa.

One cause of inflammatory lesions include all kinds of hydrolase and cationic protein released from neutrophil granules of damaged local tissues, which play an important role in the course of inflammation of type III hypersensitivity^[14]. The activated neutrophils produce active oxygen and several active molecules that promote occurrence and development of inflammation^[15]. SASP could decrease neutrophil infiltration and histological grading, thus decreasing the production of inflammatory factors and improving inflammation.

In this study, SASP obviously decreased mucosal Eos infiltration. Mucosal Eos infiltration is associated with chronic intestine inflammation^[16]. Eos collected from the inflammatory mucosa is attracted by immune complex and Eos chemokine releases from mast cells. Eos could synthesize prostaglandins E and E₂, which restrain the synthesis of histamine, neutralize hypersusceptibility and inflammatory reactants. Eos accompanying degranulation phenomena result from allergic reaction by main degranulation way^[17]. The number of Eos not only reflects the degree of inflammation^[18], but also is an important index of prognosis^[19]. There are more acidophil granules in Eos's cytoplasm, containing four toxic cationic proteins: alkaline protein, ECP, neurotoxin and peroxidase, all of which have toxic effect on normal cells^[14]. Raab *et al.*^[20], also confirmed that there are more Eos infiltrating lamina propria of active UC, and ECP obviously increases. The activation or degranulation of Eos is correlated with mucosal inflammatory responses. The changes in intestinal mucosa resulted from Eos infiltration in the inflammatory mucosa that are activated and cause mucosal lesions during degranulation and release

of ECP^[21].

In conclusion, SASP can effectively treat patients with active UC and improve small vessel lesions, crypt abscesses, and decrease neutrophil and Eos infiltration.

Abstract

AIM: To evaluate whether intratumoral injection of liposome-endostatin complexes could enhance the antitumor efficacy of radiation therapy in human liver carcinoma (BEL7402) model.

METHODS: Recombinant plasmid pcDNA3.End was transfected into human liver carcinoma cell line (BEL7402) with lipofectamine to produce conditioned medium. Then BEL7402 cells and human umbilical vein endothelial cells (HUVECs) were treated with the conditioned medium. Cell cycle and apoptosis were analyzed by flow cytometer and endothelial cell proliferation rates were determined by MTT assay. The antitumor efficacy of endostatin gene combined with ionizing radiation in mouse xenograft liver tumor was observed.

RESULTS: Endostatin significantly suppressed the S phase fraction and increased the apoptotic index in HUVECs. In contrast, endostatin treatment had no effect on BEL7402 cell apoptosis ($2.1 \pm 0.3\%$ vs $8.9 \pm 1.3\%$, $t = 8.83$, $P = 0.009 < 0.01$) or cell cycle distribution ($17.2 \pm 2.3\%$ vs $9.8 \pm 1.2\%$, $t = 4.94$, $P = 0.016 < 0.05$). The MTT assay showed that endostatin significantly inhibited the proliferation of HUVECs by 46.4%. The combination of local endostatin gene therapy with radiation therapy significantly inhibited the growth of human liver carcinoma BEL7402 xenografts, the inhibition rate of tumor size was 69.8% on d 28 compared to the untreated group. The tumor volume in the pcDNA3.End combined with radiation therapy group ($249 \pm 83 \text{ mm}^3$) was significantly different from that in the untreated group ($823 \pm 148 \text{ mm}^3$, $t = 5.86$, $P = 0.009 < 0.01$) or in the pcDNA3 group ($717 \pm 94 \text{ mm}^3$, $t = 6.46$, $P = 0.003 < 0.01$). Endostatin or the radiation alone also inhibited the growth of liver tumor *in vivo*, but their inhibition effects were weaker than those of endostatin combined with radiation, the inhibition rates on d 28 were 44.7% and 40.1%, respectively.

CONCLUSION: Endostatin not only significantly suppresses tumor growth but also enhances the antitumor efficacy of radiation therapy in human carcinoma xenograft.

INTRODUCTION

Tumors are dependent on angiogenesis for sustained growth^[1]. Endostatin, an endogenous antiangiogenic agent, is a M_r 20 000 COOH-terminal fragment of collagen XVIII. It is a potent inhibitor of angiogenesis *in vitro*, and has significant antitumor effects in a variety of preclinical tumor models^[2,3]. Endostatin specifically inhibits endothelial cell proliferation without direct effects on tumor cell or non-neoplastic cell growth^[4-7], whose overexpression can lead to primary tumor regression and growth inhibition^[8].

Most therapeutic investigations of endostatin utilized the purified protein, but the protein purification process is difficult and may denature endostatin. For maintaining therapeutically effective serum levels the protein must be repeatedly used because it has a short half-life *in vivo*. One possible approach to overcome this problem may be the utilization of gene therapy strategy. Studies using viral vectors to deliver endostatin gene have demonstrated its efficacy in treatment of mouse tumor models^[9-11].

Although antiangiogenic therapies have shown significant antitumor effects in preclinical investigations, angiogenesis inhibitors cannot achieve tumor cures on their own. Antiangiogenic strategies in combination with conventional anticancer approaches may achieve better results. The involvement of antiangiogenic agents during the course of radiotherapy have been shown to produce significant therapeutic effects^[12-15].

In this study, we investigated whether intratumoral injection of liposome-endostatin complexes could enhance the treatment efficacy of ionizing radiation in a human liver carcinoma (BEL7402) model.

MATERIALS AND METHODS

Plasmid and cell lines

The plasmid pcDNA3.End containing a synthetic rat insulin leader sequence and the full-length mouse endostatin cDNA was kindly provided by Dr. Wang Jianli (Shandong Medical University, Jinan, China). The synthetic rat insulin leader was cloned in front of the endostatin gene. Human liver carcinoma cell line BEL7402 and human umbilical vein endothelial cell line (HUVEC) were kept in our laboratory. HUVECs and BEL7402 cells were maintained in DMEM (Gibco) containing 10% FBS.

In vitro transfection and production of conditioned endostatin medium

BEL7402 cells were grown in 6-well plates at the density of 2×10^5 cells/well to 50-80% confluence, then transfected with 10 μ L of lipofectamine (Invitrogen) mixed with 4 μ g of plasmid (pcDNA3.End or pcDNA3) as described by the Invitrogen protocol. After 24 h transfection, the cells were extensively rinsed with PBS and incubated in serum-free DMEM for another 24 h. The conditioned media were collected, centrifuged and cell debris was cleared off. Endostatin in the culture media was measured with a murine endostatin enzyme immunoassay kit (Chemicon Inc.). The conditioned media were concentrated 20-fold with Amicon membranes (Amicon Inc.), and endostatin protein levels were determined by immunoassay before being stored at -80°C for further use.

Cell cycle assay

BEL7402 cells and HUVECs were plated in 6-well plates at the density of 2×10^5 cells/well and allowed to attach overnight. The cells were treated with conditioned medium containing certain concentration of endostatin and 10% FBS after removal of the medium. Forty-eight hours later, the cells were trypsinized, counted and fixed in 50% ethanol overnight, then treated with PBS (containing 1 g/L RNase) for 30 min. Samples were washed with PBS twice and resuspended in PBS at a concentration of 1×10^6 cells/mL. The cells were stained with PI in darkness for 30 min and cell cycle distribution was analyzed with a flow cytometer (Becton-Dickinson FACS Calibur).

Apoptosis assay

BEL7402 cells and HUVECs were cultured in 6-well plates at the density of 2×10^5 cells/well and incubated for 24 h. The medium was replaced with 2 mL of conditioned medium containing certain concentration of endostatin and 10% FBS. After being incubated for 48 h, the cells were trypsinized, counted, washed twice with cold PBS and then resuspended in $1 \times$ binding buffer at a concentration of 1×10^6 cells/mL. Five microliters of annexin V-FITC and five microliters of PI were added. The cells were gently vortexed and incubated for 15 min at RT in the dark, and then 400 μ L of $1 \times$ binding buffer was added. Apoptosis was analyzed with a flow cytometer.

Endothelial cell proliferation assay

HUVECs were incubated in 96-well dishes at the density of 10^4 cells/well and allowed to attach overnight. The

medium was then replaced with 20 μ L of conditioned medium and incubated for 30 min. Eighty microliters of DMEM containing with 10% FBS and 1 μ g/L bFGF (Sigma) were then added. After the cells were incubated for 48 h, 20 μ L MTT solution (5 g/L) was added. Then, 4 h later, 100 μ L 100 g/L SDS was added. After being vortexed gently for 10 min, the number of cells was quantified by colorimetric MTT assay.

In vivo treatment of tumor cells by liposome-DNA complex injection combined with radiation therapy

Female nude mice aged 4-6 wk were obtained from Animal Center of Shandong Medical University and fed with a standard rodent diet. To establish xenografts, animals were subcutaneously injected into the right flank with 1×10^6 BEL7402 cells suspended in 200 μ L 0.9% saline. Seven days after the injection of tumor cells, the mice were randomly divided into five treatment groups: untreated, empty vector (Lip-pcDNA3), Lip-pcDNA3.End, pcDNA3.End combined with radiation, and radiation. Six mice were enrolled in each group. To deliver the gene therapy, each mouse in groups 2, 3, and 4 received three intratumoral injections of liposome-DNA complex which consisted of 40 μ L lipofectamine and 20 μ g of DNA (1 g/L) and 40 μ L 0.9% saline on d 7, 14, and 21 after the injection of tumor cells. Irradiations were performed using a 6 MV Varian 2100 C linear accelerator, operating a single dose of 10 Gy 7 d after injection of tumor cells. Before irradiation, the mice were confined in plastic containers. The animals' tumor-bearing sites extended through openings in the containers allowing the tumors to be irradiated locally. Tumors were measured every 3-4 d. Tumor response to treatment was determined by growth delay assay. The tumor volume was calculated by the formula: tumor volume = $ab^2 \times 0.52$, where a is the length, and b is the width.

RESULTS

In vitro endostatin quantification

Unconcentrated media (100 μ L) collected from BEL7402 cells transfected with pcDNA3.End and pcDNA3 were measured with a murine endostatin enzyme immunoassay kit. The experiment showed that BEL7402 cells transfected with pcDNA3.End efficiently secreted endostatin protein into the culture media. Endostatin levels were 486.2 ± 56.5 mg/L in conditioned media from BEL7402 cells transfected with pcDNA3.End, and 6.8 ± 2.6 mg/L in conditioned media from BEL7402 cells transfected with pcDNA3. There were significant differences in endostatin levels between the two groups ($t = 14.68$, $P = 0.005 < 0.01$, Figure 1).

Endostatin-affected HUVEC cell cycle and apoptosis

After being treated with conditioned medium, compared to conditioned medium from BEL7402 cells transfected with pcDNA3, conditioned medium from BEL7402 cells transfected with pcDNA3.End significantly suppressed the S phase fraction ($17.2 \pm 2.3\%$ vs $9.8 \pm 1.2\%$, $t = 4.94$, $P = 0.016 < 0.05$) and increased the apoptotic index ($2.1 \pm 0.3\%$ vs $8.9 \pm 1.3\%$, $t = 8.83$, $P = 0.009 < 0.01$) in HUVECs. In contrast, after being treated with the two-conditioned media respectively,

there were no differences in BEL7402 cell apoptosis or cell cycle distribution, suggesting that endostatin treatment had no effect on BEL7402 tumor cell apoptosis or cell cycle distribution.

Figure 1 Mean concentration of endostatin protein in supernatant. 1: Secretion of endostatin by BEL-7402 cells transfected with pcDNA3; 2: secretion of endostatin by BEL-7402 cells transfected with pcDNA3.End.

Endostatin-inhibited endothelial cell proliferation

After 24 h incubation with conditioned media, endostatin-inhibited HUVECs proliferation by $46.4 \pm 9.7\%$, while the conditioned media derived from cultures of BEL7402 cells transfected with pcDNA3 control vector did not affect endothelial cell proliferation, the inhibition rate was $8.7 \pm 0.5\%$ ($t = 6.72$, $P = 0.02 < 0.05$, Figure 2).

Figure 2 HUVEC proliferation rates inhibited by endostatin. 1: Proliferation rate inhibited by conditioned media derived from cultures of BEL7402 cells transfected with pcDNA3; 2: proliferation rate inhibited by conditioned media derived from cultures of BEL7402 cells transfected with pcDNA3.End; 3: control group.

Endostatin gene therapy combined with radiation-inhibited tumor growth in nude mice

As shown in Figure 3, tumors treated with Lip-pcDNA3. End combined with radiation group grew very slowly in nude mice, the inhibition rate of tumor size was 69.8% on d 28 compared to untreated group. The tumor volume of the pcDNA3.End combined with radiation group ($249 \pm 83 \text{ mm}^3$) was significantly different from that of the untreated group ($823 \pm 148 \text{ mm}^3$, $t = 5.86$, $P = 0.009 < 0.01$) or the pcDNA3 group ($717 \pm 94 \text{ mm}^3$, $t = 6.46$, $P = 0.003 < 0.01$). Tumors of the pcDNA3.End group and radiation group also grew slower than those of the untreated group or the pcDNA3 group, but the inhibitory effects on tumor growth were slightly weaker than those of the pcDNA3.

End combined with radiation group, the inhibitory rates on d 28 were 44.7% and 40.1%, respectively. The tumor volume of the pcDNA3.End group ($492 \pm 97 \text{ mm}^3$) or the radiation group ($455 \pm 124 \text{ mm}^3$) was significantly different from that of the untreated group (the pcDNA3.End group, $t = 3.14$, $P = 0.039 < 0.05$ and the radiation group, $t = 3.30$, $P = 0.03 < 0.05$) or the pcDNA3 group (the pcDNA3.End group, $t = 2.89$, $P = 0.045 < 0.05$ and the radiation group, $t = 2.92$, $P = 0.047 < 0.05$).

Figure 3 Tumor growth after intratumoral injections of liposome-plasmid complexes or irradiation or both.

DISCUSSION

Radiotherapy is one of the most important treatment modalities for solid tumors. Today, 45-50% of all cancer patients can be cured, and nearly 70% of those who are cured have received radiation either alone or in combination with other modalities, but a large number of patients have no response to radiotherapy treated with curative intent ultimately fail, not only because of metastasis of the disease, but also because of relapse at the local treatment site. One reason responsible for radiotherapy failure may be the tumor vasculature. Numerous studies have shown that tumor cells stop growing when the diameter of tumor exceeds 1-2 mm if new blood vessels supplying the tumor fail to generate^[16]. Hence, the combined radiotherapy with antiangiogenic agents has aroused great concerns^[17,18].

Angiogenesis is a complex process with multiple, sequential, and interdependent steps. Tumor cells promote new vessel formation by releasing endothelial cell growth factors that support endothelial cell proliferation, migration, and survival. Tumor angiogenesis is the consequence of enhanced expression of proangiogenic factors relative to antiangiogenic factors in the tumor microenvironment.

The combination of radiation treatment with endostatin may improve radiotherapy outcome by enhancing antitumor efficacy, reducing the total radiation dose, improving local tumor control rate, alleviating radiation damage. These considerations, along with the extensive clinical use of radiotherapy, make thorough investigation of strategies combining conventional treatment modality with endostatin. It was reported that combined endostatin gene therapy with radiotherapy can improve tumor response^[19-22].

We chose liposome to transfect BEL7402 cells with endostatin gene due to its high transfection efficiency. In

our pre-experiment, we chose lipofectamine to transfect BEL7402 cells with pcDNA3.GFP, the transfection rate was 73.5%. ELISA analysis of conditioned media from BEL7402 cells transfected with pcDNA3.End showed that the level of endostatin protein was 486.2 ± 56.5 mg/L, suggesting that BEL7402 cells transfected with pcDNA3.End plasmids secrete endostatin proteins into the culture media. The conditioned medium significantly suppressed the S phase fraction and increased the apoptotic index in HUVECs. However, it had no effect on BEL7402 cell apoptosis or cell cycle distribution. *In vivo*, endostatin significantly enhanced the treatment efficacy of ionizing radiation. The antitumor inhibition rate of combined endostatin gene therapy with radiation in BEL7402 human liver tumor model was 69.8%, which was significantly different from the untreated group ($t = 5.86$, $P = 0.009 < 0.01$) or the empty vector group ($t = 6.46$, $P = 0.003 < 0.01$) on d 28. Tumors of the radiation group and the pcDNA3.End group grew slower than those of the untreated group or the pcDNA3 group. These results indicate that intratumoral injection of liposome-endostatin complex significantly enhances the antitumor efficacy of radiation therapy.

In summary, gene therapy can deliver antiangiogenic polypeptide endostatin. Cationic liposomes transfected to endostatin gene can not only suppress endothelial cell proliferation, but also enhance the treatment efficacy of ionizing radiation.

Abstract

A 44-year-old man was referred to our hospital with intermittent abdominal pain. Because distention of fluid- and gas-filled loops of small intestine was proved by X-ray, the patient was diagnosed as having small bowel obstruction. A laparotomy revealed a segmental stenosis in the jejunum, which showed diffuse thickening of the intestinal wall. Some mesenteric lymph nodes were swollen. Pathological examination was defined. We diagnosed diffuse large B-cell lymphoma based on the pathological findings of diffuse transmural infiltration of large lymphoid cells and flow-cytometric analyses. Rituximab was administered as adjuvant therapy at weekly doses of 375 mg/m². Four cycles were performed every 6 mo and he remained CR. Rituximab may be effective as adjuvant therapy.

INTRODUCTION

Primary gastrointestinal lymphoma (PGL) accounts for 4-

20% of all non-Hodgkin's lymphomas (NHL)^[1,2]. The location most frequently involved has been the ileocecal region, followed by small bowel, accounting for 20-40% of PGL^[1]. Small bowel lymphoma tends to be annular in the distal ileum, not proximal^[2]. Jejunum obstruction in a patient with NHL has been exceptionally described.

Regarding treatment, it has been established that the primary surgical treatment had the most favorable influence on failure-free survival in localized diseases and hence the resection may be appropriate as the primary treatment^[3]. On the other hand, the effectiveness of adjuvant therapy for localized NHL remains to be unclear, because some cases could be cured only by surgical resection.

In this study, we have described the primary jejunal NHL with small bowel obstruction, which remained in complete remission by surgical resection followed by rituximab administration.

CASE REPORT

A 44-year-old man was admitted to our hospital in May 2002 because of intermittent abdominal pain. Small bowel series and computed tomography (CT) of the abdomen showed stenosis at jejunum and dilatation of small bowel (Figures 1 and 2), indicating small bowel obstruction. However, the cause of obstruction remained unclear in spite of several workups. Laparotomy disclosed a 3 cm long jejunal segment stenosis at 110 cm from the ligament of Treitz and some mesenteric lymph nodes were swollen.

Figure 1 Small bowel series and CT showed both the distention of fluid- and gas-filled loops of small intestine and segmental stenosis indicated by arrow.

Figure 2 Resected jejunum show. **A:** Resected jejunum showed diffuse thickening of the intestinal wall (oral side); **B:** multiple hyperplastic follicles (anal side).

The resected specimens showed diffuse thickening of the intestinal wall, histopathological analysis of which showed that large lymphoid cells aggregated diffusely. Mesenteric lymph nodes were also involved. Flow-cytometric studies showed that the tumor cells expressed HLA-DR (84.8%), s-IgA (46.6%), γ (69.8%), CD10 (44.7%), CD19 (68.1%), and CD20 (62.4%) with a high-intensity signal. Results for CD5 were negative (26.2%) with a low-intensity signal. Postoperative workup did not demonstrate the evidence of systemic involvement. Thus, the patient was diagnosed having primary jejunal diffuse large B-cell lymphoma at stage II₁. Rituximab was administered as adjuvant therapy at weekly doses of 375 mg/m². Four courses were performed every 6 mo and the patient is in complete remission with a follow-up time of 24 mo with no significant adverse effects.

DISCUSSION

We experienced a rare case of primary jejunal NHL as radiological workup including CT and angiography provided no evidence for final diagnosis, we performed laparotomy and segmental intestinal resection. The recognition of the possibility of jejunal obstruction due to NHL may facilitate

early diagnosis. Yamamoto *et al.*, have recently developed double-balloon endoscopy. This method enables us to survey all intestines with ease^[4]. In future, this method may become the routine mode of study for small bowel obstruction.

Regarding treatment, we performed segmental resection of jejunum and rituximab therapy as adjuvant treatment. The efficacy and toxicity of adjuvant therapy for localized NHL remained unclear because excess chemotherapy may provoke secondary malignancies. On the other hand, a new anti-CD20 mAb, rituximab, is effective in the treatment of B-cell lymphoma with slight adverse effects^[5,6]. Thus we treated the patient under study with rituximab as adjuvant therapy. He tolerated this adjuvant therapy well, with slight nausea. Rituximab may be effective as adjuvant therapy for PGL. The efficacy and toxicity should be examined in large series.

Abstract

Ascites is a common and debilitating complication of cirrhosis. However, patients with chronic liver disease are not spared from other causes of ascites and physicians should be careful not to miss an underlying malignancy. Ovarian cancer is an insidious disease, which is difficult to diagnose and it ranks first in mortality among all gynecological cancers. Here, we present two cases of patients with chronic liver disease that developed ascites not simply because of cirrhosis but as a manifestation of ovarian cancer. We would like to emphasize that the causes of ascites, other than the liver itself, should not be overlooked in patients with chronic liver disease.

INTRODUCTION

Ascites is the most common complication of viral, alcoholic or metabolic liver cirrhosis. Approximately half of the cirrhotic patients are expected to develop ascites within 10 years after the diagnosis^[1]. Development of ascites is an important prognostic sign in the usual course of chronic liver disease since it shortens the 5-year survival rate of a cirrhotic patient^[2-4].

Ascites may develop in 75% of all patients with liver disease. The remaining 25% is due to malignancy (10%), cardiac failure (3%), pancreatitis (1%), tuberculosis (2%) and

other uncommon causes^[5]. However, it is important to comprehend that cirrhotic patients are not spared from these non-cirrhotic causes. Herein we present two patients with chronic liver disease who were diagnosed to have ovarian cancer after a thorough investigation of their ascites.

CASE REPORT

Case 1

A 45-year-old woman with chronic liver disease was seen at the outpatient clinic, because of her recent complaints. She complained of abdominal swelling, in the previous 2 mo. She had abdominal pain radiating to her back, which was aggravated after meals. Famotidine was of no use in relieving the pain. She also complained of weight loss as much as 5 kg in 20 d. The patient had been followed up for chronic hepatitis B infection for 8 years. The diagnosis was confirmed with a liver biopsy, which showed cirrhosis at developmental stage. She underwent esophageal variceal band ligation and transjugular intrahepatic portosystemic shunt (TIPSS) for the management of chronic ascites before 5 years. TIPSS was performed once again before 3 years. She received medical treatment while awaiting liver transplantation. She had no evident family history.

Physical examination revealed that she had massive ascites and was admitted to our hospital for further investigation. Ultrasonographic examination of the abdomen had no remarkable finding except ascites and parenchymal changes in the liver. Hepatic and portal venous systems were normal since the portosystemic shunt functioned well. Diagnostic paracentesis was performed and biochemical analysis was as follows: LDH: 318 U/L (concomitant serum LDH was 337 U/L), albumin: 2.4 g/dL (serum albumin: 2.9 g/dL). Cytological investigation of the ascites showed malignant cells. Abdominal computed tomography (CT) revealed peritoneal carcinomatosis and solid mass lesions of both the ovaries. CT of the thorax showed metastatic nodules on the pleural surface. Serum CA 125 level was 9 853 U/mL.

The patient underwent total abdominal hysterectomy, bilateral salpingo-oophorectomy, omentectomy, and pelvic-paraaortic lymph node dissection. Tumor debulking surgery and histopathological examination of the specimens reported that she had ovarian serous papillary adenocarcinoma (stage III). Paclitaxel-carboplatin therapy was started. Unfortunately, during the first course of chemotherapy she developed acute pneumonia and empyema, which rapidly progressed to septic shock leading to her death.

Case 2

A 40-year-old woman was admitted to hospital because of ascites. She was also suffering from loss of weight and appetite

in the last 10 d. She was known to have had chronic hepatitis B and D. She received interferon treatment for 6 mo, followed by another course of pegylated interferon 2 years later. She had no significant complication of chronic liver disease.

Biochemical analysis of ascites showed an LDH level of 564 U/L and serum-ascites albumin gradient was 0.7. Computed tomography of the abdomen showed massive ascites, omental cake sign and mass lesions of 4-5 cm in both adnexal regions. Serum CA 125 level was 3 028 U/mL. She underwent total abdominal hysterectomy, bilateral oophorectomy, lymph node dissection and tumor debulking surgery. Pathological diagnosis of the tumor was poorly differentiated adenocarcinoma, which was positive for CA 125 and CK7, thus confirming an ovarian origin. Serum CA 125 value of the patient decreased to 25.9 U/mL after the operation.

DISCUSSION

Ovarian carcinoma is difficult to diagnose and it is usually discovered only in its advanced stages. It therefore has the highest mortality among all gynecological malignancies. Cachexia with pelvic mass, ascites and elevated CA125 levels generally lead to its correct diagnosis, but usually there are no pathognomonic radiological or laboratory findings. Therefore, a laparotomy is usually necessary for its final diagnosis.

In the majority of ovarian cancer cases, the etiology is unknown. A small percentage of cases may be attributed to hereditary disorders. Close follow-up with annual transvaginal ultrasound examination and measurement of CA125 levels is advocated for patients with high at genetic risk. Prophylactic oophorectomy after completion of fertility may be a reasonable option for BRCA mutation carriers and might be effective in preventing both ovarian or breast cancers. However, such an approach has not been evaluated^[6]. Multiple pregnancies or the use of oral contraceptives might have a protective effect as they can reduce ovulation and related hormonal effect^[7].

The 5-year survival rate for advanced disease is about 30%. In a study reviewing the general practice records of patients with epithelial ovarian cancer, the most frequent symptoms are abdominal pain, change in bowel habits, abdominal swelling, vaginal bleeding, weight loss, and backache^[8]. The same study revealed that the most significant independent variable for survival is the stage of the disease at surgery^[8].

Ascites is an important clinical finding in ovarian cancer. Any patient who presents with ascites should undergo a thorough investigation of ascites influencing cytological analysis and measurement of amylase level. Though an elevated CA125 level should raise a suspicion of ovarian cancer, its interpretation in patients with any serosal involvement may not be easy, since any type of pleural, peritoneal or pericardial irritation can lead to elevated serum level of this high molecular weight glycoprotein^[9].

CA125 level greater than 35 U/mL has been reported in 35-75% of cirrhotic patients, most commonly in those with ascites. Studies have shown that cirrhotic patients with ascites have different mean serum CA125 levels of 291 and 572 U/mL, respectively^[10-12]. All these data show that CA125 is not a strong diagnostic tool for ovarian cancer in patients with preexisting cirrhotic ascites.

Though it is not possible to define a strict dividing line between "expected" and "alarming" ascites during the course of chronic liver disease, some clues may help physicians to find other underlying causes. We believe that the two cases in our study contribute to this. The first patient had a rapid development of ascites despite a functional TIPSS. The other patient did not have overt signs of cirrhotic changes of the liver, the reason why ascites occurred is not clear. In both cases, the presence of an exudative rather than transudative peritoneal fluid is another underlying cause other than cirrhosis^[13]. As mentioned above, an elevated CA125 level is not a specific diagnostic marker for ovarian cancer as it may be elevated in a cirrhotic patient, due to peritoneal irritation. Thus, extremely high CA125 levels merit further investigation.

We conclude that the development of ascites in patients with chronic liver disease should never be considered as "normal" and a search for other causes should be considered. Prompt diagnosis and surgical intervention may be life-saving in such cases.

Abstract

Two cases of acute pancreatitis with leptospirosis are reported in this article. Case 1: A 68-year-old woman, presented initially with abdominal pain, nausea, vomiting, and jaundice. She was in poor general condition, and had acute abdominal signs and symptoms on physical examination. Emergency laparotomy was performed, acute pancreatitis and leptospirosis were diagnosed on the basis of surgical findings and serological tests. The patient died on postoperative d 6. Case 2: A 62-year-old man, presented with fever, jaundice, nausea, vomiting, and malaise. Acute pancreatitis associated with leptospirosis was diagnosed, according to abdominal CT scanning and serological tests. The patient recovered fully with antibiotic treatment and nutritional support within 19 d.

INTRODUCTION

Leptospirosis is a spirochetal bacterial infection and causes clinical illness in animals and humans. This zoonosis is common in some other parts of the world but rather rare in Turkey^[1,2]. This disease is predominantly seen in farmers, trappers, veterinarians, and rice-field workers. Leptospirosis mainly affects liver and kidney. Rarely, other organs such as lung, heart, gallbladder, brain, and ophthalmic tissues are involved, mainly due to vasculitis^[3,4]. Hyperamylasemia can be present in leptospirosis infection due to renal impairment^[5-7]. Therefore, the diagnosis of acute pancreatitis is controversial in this disease.

Pancreatitis is a rare complication of leptospirosis and only a few cases have been reported in literature^[1,5,8,9]. We report two cases here.

CASE REPORT

Case 1

A 68-year-old woman was referred to Ondokuz Mayis University hospital for abdominal pain, nausea, vomiting, and jaundice with 1-d history. She had no history of contact with jaundiced persons, blood transfusions and drug abuse. She was operated on 3 years ago for hip fracture and occasionally she took some analgesics. On physical examination, she was in poor general condition with dehydration and her scleras were icteric. Her pulse rate was 120/min, blood pressure 14.6/10.6 kPa and she was tachypneic. Urine output was normal. There was a marked tenderness in her whole abdomen with guarding and rebound tenderness. No other abnormalities were noted. Laboratory investigations on admission revealed Hb: 13 g/dL, Htc: 39.7, WBC: 9 000/mm³, platelet count: 120 000/mm³ (*n*: 150×10³-300×10³), BUN: 60 mg/dL (*n*: 5-24), creatinine (Cr): 2.7 mg/dL (*n*: 0.4-1.4), lactate dehydrogenase (LDH): 2 321 U/L (*n*: 95-500), total/direct bilirubin: 6.5/4.7 mg/dL, Ca: 7.8 mg/dL (8-10), amylase: 630 U/L (28-100), lipase: 642 U/L (*n*: 0-190), aspartate transaminase (AST): 2 500 U/L (*n*: 8-46), alanine transaminase (ALT): 1 900 U/L (*n*: 7-46), serum C-reactive protein (CRP): 192 mg/L (*n*: 0-5), PaO₂: 7.71 kPa, base excess (BE): -5 mmol/L, with negative viral hepatitis markers. The Ranson score was 8. Abdominal ultrasonographic examination revealed acute calculus cholecystitis and abdominal fluid collection. Biliary dilatation was not observed in ultrasonographic examination.

The patient was operated on with the diagnosis of surgical acute abdomen. On exploration, 500 mL sero-hemorrhagic fluid was found in the abdominal cavity, and gallbladder and pancreas were found to be markedly edematous. Areas of fatty necrosis were seen on peripancreatic tissues. Cholecystectomy and common bile duct exploration were done. Pre-operative cholangiogram was normal. Histopathologic diagnosis of the gallbladder was acute cholecystitis. Leptospire were seen in blood, intra-abdominal fluid and bile on dark-field microscopy. *Leptospira microagglutination* test was positive (at 1:100 *Leptospira samaranga Patoc I*). Penicillin G, 3 million units four times per day was given to the patient intravenously. Total parenteral nutrition was also started for artificial nutrition. The patient recovered after operation and oral intake was started on postoperative d 5. Although liver function tests and laboratory values returned to normal within 5 d, others included Hb: 11 g/dL, platelet count: 170 000/mm³, BUN: 43 mg/dL, Cr: 0.8 mg/dL, total/direct bilirubin: 1.9/1.56 mg/dL, AST: 47 U/L, ALT:

168 U/L. Six days after the operation the patient died due to a suddenly developed cardiopulmonary arrest.

Case 2

A 62-year-old man was admitted to Ondokuz Mayıs University hospital with fever, marked jaundice, nausea, and vomiting. The patient had also 2 wk' history of malaise, fever, and dizziness before hospital admission. On examination, the patient was icteric and there was conjunctival hyperemia. His temperature was 39 °C and blood pressure was 19.9/11.9 kPa. Urine output was 30 mL/h. The remainder of the physical examination was normal. Laboratory investigations on admission showed Hb: 8.6 g/dL, Htc: 27.8, WBC: 23 000/mm³, platelet count: 53 000/mm³, glucose 140 mg/dL, total/direct bilirubin: 48/44 mg/dL, AST: 70 U/L, ALT: 85 U/L, alkaline phosphatase: 516 U/L (*n*: 95-280), γ -glutamic transpeptidase: 104 U/L (*n*: 7-49), BUN: 120 mg/dL, Cr: 17 mg/dL, LDH: 1 638 U/L, total protein 4.8 g/dL (*n*: 6-8.5), albumin: 2.2 g/dL (*n*: 3.5-5), amylase 980 U/L, pancreatic amylase: 830 U/L (*n*: 13-53), lipase: 797 U/L, Ca: 7.5 mg/dL, CRP: 68, negative viral hepatitis markers. The Ranson score was 6. Leptospira microagglutination test was positive (at 1/800, *L. icterohemorrhagica*). Leptospire were seen in blood on dark-field microscopy. Abdominal CT examination revealed bilateral pleural effusion, intra-abdominal minimal fluid collection, pancreatic edema and peripancreatic tissues heterogeneity (Figure 1A).

A diagnosis of leptospirosis with acute pancreatitis was made. The patient had renal failure in acute non-oliguric form. Hemodialysis was performed at the beginning of the treatment. Intravenous fluid resuscitation and ampicillin-sulbactam treatment were given. Nasojejunal feeding tube was inserted endoscopically for adequate caloric intake. Four days after the treatment, body temperature decreased to 37.5 °C, amylase levels decreased to normal value 150 U/L and platelet count increased to 150 000/mm³. Bilirubin levels, liver function tests, and creatinine level slowly returned to normal within 2 wk (laboratory tests at the discharge time revealed WBC: 9 000/mm³, Hb: 90 g/L, total/direct bilirubin: 2/1.8 mg/dL, BUN: 30 mg/dL, Cr: 1.2 mg/dL, AST: 24 U/L, ALT: 45 U/L, LDH: 380 U/L). Oral intake was started on d 19 of admission and the patient was discharged. Abdominal CT findings at the discharge time revealed minimal edema in the pancreas (Figure 1B). The patient was examined 2 mo later and he was in a completely healthy condition.

Figure 1 Abdominal CT scan of case 2. **A:** Pancreatic edema, heterogeneity and minimal intra-abdominal fluid collection; **B:** minimal edema in the pancreas after treatment. P: pancreas.

DISCUSSION

Leptospirosis is a spirochetal zoonosis that causes clinical illness in humans as well as in animals. The source of infection in humans is usually either direct or indirect contact with the urine of infected animals. These bacteria infect humans by entering through abraded skin, mucous membrane, conjunctivae. Direct transmission between humans is rare^[3,4]. Leptospirosis is a common disease in rice-field workers due to prevalence of wild rats^[4,8]. Both of our patients were from rural area of the middle Black Sea region of Turkey and have worked in rice fields. Rice field with stagnant water and humid condition is an ideal environment for leptospira.

Leptospirosis is characterized by the development of vasculitis, endothelial damage, and inflammatory infiltration. This disease mostly affects tissues of the liver and kidney. Other tissues such as the pancreas can be affected due to vasculitis^[4].

This disease occurs as two clinically recognizable syndromes: the anicteric leptospirosis (80-90% of all cases) and the remainder icteric leptospirosis^[3,4]. Icteric leptospirosis is known as Weil's disease, which is characterized by hemorrhage, renal failure, and jaundice. Icteric leptospirosis is a much more severe disease than anicteric form. The clinical course is often rapidly progressing. Our cases seemed to be icteric leptospirosis. Serological tests confirmed on blood samples as *L. icterohemorrhagica* and *L. samaranga Patoc*. First of these is responsible for icteric form of the disease. *L. samaranga Patoc* sero-type is not the cause of Weil's disease but cross-reaction is possible between the serotypes of leptospirosis.

Thrombocytopenia is a common finding in leptospirosis, occurring in 40-85% of this disease. But the exact reason for thrombocytopenia is unknown. Vasculitis, increased peripheral destruction and decreased thrombocyte production have been considered as potential causes of thrombocytopenia^[4,10]. Thrombocytopenia was also present in the two cases reported here which were remedied by our treatment.

Oliguric and non-oliguric acute renal failure may be observed in icteric leptospirosis^[7], as also seen in our cases. It was reported that oliguria was a significant predictor of death in leptospirosis^[4]. Urine output was normal in case 1 but case 2 was oliguric. Renal insult was treated with intravenous fluid replacement and other supportive treatment including antibiotic and hemodialysis in case 2.

Jaundice occurring in leptospirosis is not commonly associated with hepatocellular necrosis and impaired liver function. There are moderate rises in transaminase levels, and minor elevation of alkaline phosphatase level usually occurs^[3,4]. Hepatic dysfunction occurs but resolves, and it is rarely the cause of death. The serum bilirubin level is usually <20 mg/dL but can be as high as 60-80 mg/dL. The bilirubin level of case 2 was close to this value (48 mg/dL). In case 1, transaminase levels were very high (more than 2 000 U/dL). The elevation of transaminases that is more than threefold of the normal value is not usual. Some sporadic cases with very high transaminase level were reported in the medical literature^[11]. Furthermore, hepatocyte degeneration and liver cell necrosis have been reported in biliary pancreatitis^[12,13]. So, elevated transaminases levels as high as that in case I may be seen in leptospirotic hepatitis. Pancreatic and bile tree involvement can be additional factors

for liver cell necrosis. Acute cholecystitis was pathologically confirmed and leptospire were seen in bile in case 1. Therefore, we believe that hepatobiliary and pancreatic involvement could be possible in this case.

For the diagnosis of acute pancreatitis, a simultaneous determination of both amylase and lipase is recommended for the evaluation of patient with abdominal pain. The serum amylase test is available in nearly all laboratories and at all hours. Elevation of lipase level with serum amylase is important for the diagnosis of acute pancreatitis. Elevation of pancreatic isoamylase level also supports the diagnosis^[14]. Hyperamylasemia also can be seen in leptospirosis due to renal function alterations or other unknown reasons^[5,6]. The serum amylase and lipase levels were elevated more than threefold of normal level in both cases. Pancreatic isoamylase level was also elevated at diagnostic level in case 2.

CT scan is a gold standard in diagnosis of acute pancreatitis, as shown by many authors who use it. This diagnostic test has 100% specificity and over 90% sensitivity for this disease^[15-17]. We also routinely use CT for both diagnosis and follow-up of the treatment as in case 2. Because abdominal CT scan was not available in the emergency condition in our hospital, we could not use it in case 1. However, the pathologic findings of acute pancreatitis were clearly observed at laparotomy in this case. So, there is no diagnostic dilemma for both of two presented cases.

The treatment of acute pancreatitis in leptospirosis includes antibiotic treatment against leptospira and supportive treatments for acute pancreatitis (including intravenous fluid resuscitation and nutrition). We preferred the nutritional support (parenterally or enterally but mostly enterally) in severe acute pancreatitis. This regime was successful in case 2. Case 1 also completely recovered after d 5 and she could feed orally. We believe that the reason of mortality was pulmonary embolism in case 1.

In conclusion, pancreatitis may be seen in leptospirosis infection. Leptospirosis should also be considered in the differential diagnosis of hyperamylasemia, pancreatitis, and obstructive jaundice in endemic areas. Early diagnosis and appropriate treatment is essential for life saving.

Abstract

AIM: To study the role of P38 kinase in esophageal cancer cell apoptosis induced by genotoxin, cisplatin and the unfolded protein response (UPR) inducer, dithiothreitol (DTT).

METHODS: Esophageal carcinoma cell line Eca109 was cultured in RPMI 1640 medium to 70% confluency and treated with either cisplatin, DTT, or cisplatin plus DTT in the presence or absence of P38 inhibitor, SB203580. The untreated cells served as the control. The esophageal carcinoma cell apoptosis was detected by agarose gel DNA ladder analysis and quantified by flow cytometry. The P38 phosphorylation was detected by immunohistochemistry using antibodies specific to phosphorylated P38 protein.

RESULTS: (1) Both cisplatin and DTT induced apoptosis in the esophageal cancer cell line Eca109 as shown by DNA ladder formation; (2) As detected by antibodies specific for the phosphorylated P38 protein (p-P38), both cisplatin and DTT treatments activated the stress-activated enzyme, MAP kinase P38. The number of positive cells was about 50% for the treatment groups, comparing to that of 10% for untreated group. DTT treatment, but not cisplatin treatment, induces nuclear localization of p-P38; (3) As measured by flow cytometry, inhibition of P38 activity by SB203580 blocks DTT- and cisplatin-induced apoptosis. The rates for DTT, cisplatin, and DTT plus cisplatin-induced apoptosis were 16.8%, 17.1%, and 21.4%, respectively. Addition of the SB compound during the incubation reduced the apoptotic rate to about 7.6% for all the treatment groups, suggesting that P38 activation is essential for cisplatin- and DTT-induced apoptosis in Eca109 cells.

CONCLUSION: (1) Both DTT and cisplatin were able to induce apoptosis in esophageal cancer cell line Eca109; (2) P38 MAP kinase is essential for DTT- and cisplatin-

induced apoptosis in Eca109 cells; (3) P38 activation may be the common signaling component relaying the multiple upstream signaling events to the downstream cell death program.

INTRODUCTION

Apoptosis is a programmed cell death stringently controlled by cell signaling pathways and the expression of pro- and anti-apoptotic genes. Inactivation of pro-apoptotic genes or signaling pathways or activation of anti-apoptotic genes or signaling pathways would compromise the ability of the cell to undergo apoptosis, thus contributing to the genesis and development of cancer. Therefore, a thorough understanding of the signaling events leading to the apoptotic program in tumor cells may assist in the development of novel strategies for cancer therapy.

Mitogen-activated protein kinases (MAPK) are members of a family of serine/threonine protein kinases activated by dual phosphorylation at threonine 188 and tyrosine 190 positions. They mainly consist of ERK, JNK/SAPK, and P38. Despite structural similarities, MAPKs play diverse roles in regulating cell function. The activation of ERK promotes cell proliferation and survival, while activation of the stress-activated protein kinases JNK/P38 can mediate different cell responses ranging from stress-induced cell apoptosis to various inflammatory responses^[1-3]. In different cells, the activation of P38 kinase is reportedly either pro-apoptotic or anti-apoptotic^[6-10], and is likely to be determined by the type of stress stimuli and/or the state of cell proliferation and differentiation. Cisplatin is a genotoxin that causes nuclear damage and nuclear stress. It was found that JNK/P38 MAP kinase is activated during cisplatin-induced apoptosis in human lung and ovarian cancer cells^[11,12], which might play an important role in signaling cancer cell apoptosis during cisplatin therapy. The unfolded protein response (UPR) or ER stress response is an ER-based cell stress response^[13-15], which can be triggered by many agents

such as DTT, tunicamycin, and thapsigargin^[16-20]. These agents induce the UPR by interfering with protein folding in the endoplasmic reticulum (ER), thus resulting in the build up of unfolded proteins in the ER. Activation of the UPR triggers cellular compensatory responses such as slowing down of protein translation and speeding up the production of molecular chaperone and, when the rescue efforts fail, it induces cell apoptosis. Whether the activation of P38 is required for the UPR-mediated cell apoptosis remains to be elucidated.

Esophageal carcinoma is one of the most common and debilitating malignancies in China. It was reported that cisplatin could induce apoptosis in esophageal cancer cells^[21]. However, the role of P38 MAP kinase in cisplatin-induced esophageal cancer cell apoptosis is unclear. In this study, it was tested whether P38 kinase is activated in cisplatin-treated esophageal cancer cells and, if it is, whether the P38 activation is an essential step for cisplatin-induced apoptosis. And it was further investigated whether P38 kinase activation is required for the UPR inducer DTT-induced apoptosis in esophageal cancer cells. This study may provide new insights into the role of P38 kinase in esophageal cancer cell apoptosis triggered by diverse cell stressors.

MATERIALS AND METHODS

Materials

The anti-phosphorylated P38 antibodies were kindly provided by Dr. Tao Zhu, National University of Singapore. SB203580, DTT, RPMI 1640, and FBS were from Sigma. The other reagents were purchased from Beijing Zhongshan Biotechnology Co., Ltd.

Cell culture

Eca109 cells were provided by our department and grown in RPMI 1640 medium supplemented with 10% heat-inactivated fetal calf serum, 100 U/mL penicillin and 100 U/mL streptomycin. All cell cultures were done at 37 °C with 5 mL/L CO₂ in a humidified incubator.

Induction of apoptosis by cisplatin and DTT

Eca109 cells were cultured to 70% confluency in RPMI 1640 medium. The cultures were continued in the RPMI 1640 medium for additional 24 h with or without 10 µg/mL cisplatin, 2 mmol/L DTT, or 10 µg/mL cisplatin plus 2 mmol/L DTT. For testing the effects of P38 inhibitor SB203580 on cell apoptosis, cells were pretreated with 10 µg/mL SB203580 for 2 h before switching to cisplatin, DTT or cisplatin+DTT containing media. Each experimental condition was set up in flask. The untreated cells were the control. At the end of the treatment, the cells were collected from the cell culture flasks and further analyzed either for cell apoptosis by DNA ladder formation, P38 activation by immunostaining or cell apoptosis by flow cytometry.

DNA isolation and gel electrophoresis

DNAs for fragmentation analysis were prepared as previously described^[22]. DNA was analyzed for each condition by 1.5% agarose gel electrophoresis in TBE buffer. The gel was stained with ethidium bromide (0.5% µg/mL) and visualized under UV light.

Immunohistochemistry

Cells were harvested from the flasks, washed with cold PBS and fixed onto glass slides by using 40 g/L paraformaldehyde solution. p-P38 kinase was detected using anti-phosphorylated P38 antibody (1:200 dilution), according to the protocol of Beijing Zhongshan Biotechnology Co., Ltd. Negative control was provided by the untreated Eca109 cells, without the incubation with anti-phosphorylated P38 antibody. DAB staining system was used to demonstrate the amount of p-P38, which is the activated form of P38. The slides were counter-stained by Methyl Green dye to visualize the cell structure. The 100 cells from each condition were scored based on the immunostaining signal intensity as follows: -: 0, -/+ : 0.5, +: 1, ++: 2.

Flow cytometry analysis

The cells were harvested and washed twice with PBS (pH 7.2) and suspended in 80% ethanol at 20 °C for 24 h, then thawed quickly at room temperature and centrifuged to collect the cells. The cells were washed with PBS twice again and resuspended in the extraction buffer (0.2 mol/L Na₂HPO₄ 0.1 mol/L citric acid) for 5 min, and finally re-suspended in PBS containing RNase A (100 µg/mL) and 50 µg/mL propidium iodide for 30 min. The cell cycle distribution and quantitation of apoptotic cells were determined by the fluorescence of individual cells measured by flow cytometry (Beckman-Coulter Epics Altra).

Statistical analysis

Biostatistical analyses were done using SPSS10.0 software package. The data from immunohistochemistry and flow cytometry were analyzed by χ^2 and Kruskal-Wallis tests.

RESULTS

Detection of cisplatin- and DTT-induced apoptosis by DNA ladder formation in esophageal cancer cell line Eca109

Cisplatin is known to induce cell death via apoptosis in many cell types, by damaging DNA and disturbing nuclear function. DTT, on the other hand, is a well-known ER stress inducer and induces cell apoptosis via UPR. A biochemical hallmark of apoptosis is the characteristic degradation of the genomic DNA by cleavage at the internucleosomal sites, generating a 'ladder' of DNA fragments, which can be detected by agarose gel electrophoresis^[23-25]. To determine whether cisplatin and DTT induce Eca109 cell apoptosis, Eca109 cells were treated with cisplatin, DTT and cisplatin plus DTT. The total DNA was resolved on agarose gel. DNA ladders were observed for all three treatment groups, while only large molecular weight DNA with no obvious ladder formation was seen for the untreated cells (Figure 1). This result demonstrates that both cisplatin and DTT were able to induce apoptosis in esophageal cancer Eca109 cells. In addition, spontaneous apoptosis of Eca109 cells is minimal under these experimental conditions.

The DNA samples were analyzed by 1.5% agarose gel in TBE buffer and visualized by UV-ethidium bromide method. Lane 1: cisplatin plus DTT; lane 2: DTT; lane 3: cisplatin; lane 4: untreated cells; lane 5: DNA molecular weight marker. The DNA bands of 400, 600, 800, and 1 000 bp were clearly seen on lanes 1-3.

Figure 1 Cisplatin and DTT treatments induce DNA ladder formation in Eca109 cells.

Cisplatin and DTT treatments activate P38 kinase in Eca109 cells

Activation of P38 kinase is achieved via the phosphorylation of P38 protein by the upstream kinases, which can be detected by antibodies specifically for the phosphorylated P38 protein (p-P38). To detect the P38 activation upon cell stresses, the Eca109 cells were cultured and treated with cisplatin, DTT, and cisplatin plus DTT for 24 h. The cells were stained with anti-p-P38 antibodies. The untreated Eca109 cells without incubation with anti-p-P38 antibodies were used as negative control. The cells were grouped into four groups, based on their signal intensity for the immunostaining. The percentage of cells positively stained with anti-p-P38 antibodies are summarized in Table 1.

Both cisplatin and DTT treatments markedly increased the number of the cells positive for p-P38 kinase. About 50% of the treated cells were positive for p-P38, when compared to that of 10% for the untreated cells. Few positive cells were observed in negative control (Figure 6). Moreover, comparing with the untreated group, the level of the phosphorylated P38 was dramatically increased upon treatment with cisplatin and DTT ($P < 0.01$). Treatment with DTT in combination with cisplatin showed only a modest increase in the number of the positive cells and the level of p-P38 signal. The difference did not reach statistical significance ($P < 0.05$).

Interestingly, the subcellular localization of p-P38 kinase was markedly different between DTT- and cisplatin-treated cells (Figures 2-5) though both treatments achieved the same level of P38 activation. The p-P38 was largely localized in the nucleus for DTT-treated cells, while the distribution of p-P38 for cisplatin-treated cells was mostly cytoplasmic, accentuated in the peri-plasma membrane region. Addition of DTT to the cisplatin treatment resulted in partial nuclear

Figure 2 Activation of P38 kinase in DTT-treated Eca109 cells.

Figure 3 Activation of P38 kinase in cisplatin-treated Eca109 cells.

Figure 4 Activation of P38 kinase in DTT- and cisplatin-treated Eca109 cells.

localization of the p-P38 kinase. The significance of the different localization of p-P38 by different death inducers is unclear.

Inhibiting P38 kinase blocks DTT- and cisplatin-induced Eca109 cell apoptosis

To test whether the activation of P38 kinase is required for DTT- and cisplatin-induced Eca109 cell apoptosis, the P38 kinase inhibitor SB203580 was employed to inhibit P38 kinase activity in DTT- and cisplatin-treated cells. The rate of apoptosis was determined by flow cytometry analysis. The data are shown in Figure 6 and summarized in Table 2. The rates of Eca109 cell apoptosis were 16.8%, 17.1%, and 21.4% for DTT, cisplatin, and DTT plus cisplatin, respectively. Consistent with the data of P38 kinase activation, DTT and cisplatin induced apoptosis to a similar

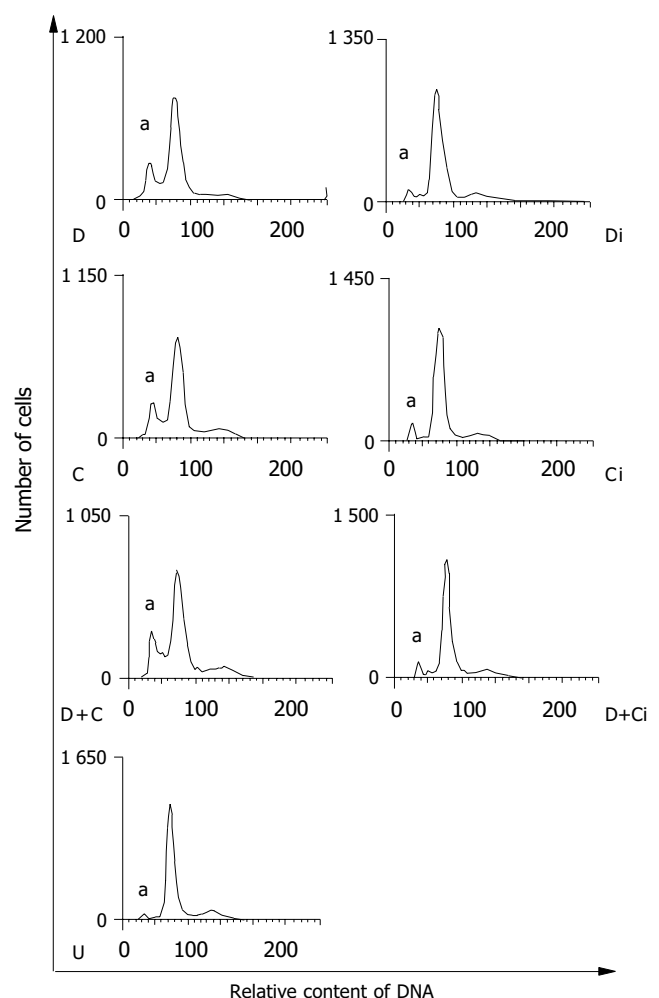

**Figure 5** Activation of P38 kinase in untreated Eca109 cells.**Figure 6** Negative control.

extent. The rate of apoptosis for DTT plus cisplatin-treated cells was moderately higher. Remarkably, SB203580 compound effectively inhibited Eca109 cell apoptosis in all three treatment groups ($P<0.01$). These results strongly suggest that P38 activation is essential for both cisplatin- and DTT-induced apoptosis in Eca109 cells. The fact that both DTT- and cisplatin-induced cell apoptosis requires P38 activity implies that P38 kinase might be the common component shared by both stress response pathways (Figure 7).

DISCUSSION

As a commonly used chemotherapeutic agent, cisplatin exerts its cytotoxic effect by intrastrand and interstrand crosslinking of DNA at specific base sequences^[26]. Recent studies have shown that the mechanism of cisplatin-induced cell death is through apoptosis^[21]. It was found that P38 MAP kinase is activated during cisplatin-induced apoptosis in human lung and ovarian cancer cells, which might play an important role in signaling cancer cell apoptosis during cisplatin therapy. However, no reports showed the role of P38 MAP kinase in cisplatin-induced esophageal cancer cell apoptosis. Our studies show that cisplatin treatment strongly activates P38 kinase in esophageal cancer cells. Moreover, inhibition of P38 activity by the specific inhibitor SB203580 almost completely blocked cisplatin-induced apoptosis. Our results and the data reported by others^[11,12] support the notion that P38 activation is a critical step in cisplatin-induced apoptosis.

The exact position of P38 activation in the chain of signaling pathways leading to the execution of cell death program is still undetermined. Previous data suggest that P38 kinase is involved in histone H₃ phosphorylation^[27], nuclear condensation, and cell blebbing^[28] during cisplatin-induced apoptosis. It is conceivable that the activation of

**Figure 7** The effects of SB203580 on DTT- and cisplatin-induced Eca109 cell apoptosis – flow cytometry analysis. SB sharply decreased the apoptotic peak of the group treated with DTT or cisplatin or DTT plus cisplatin. D: DTT, Di: DTT-SB203580, C: cisplatin, Ci: cisplatin-SB203580, D+C: DTT+cisplatin, D+Ci: DTT+cisplatin-SB203580, U: untreated, a: apoptotic peak.

P38 kinase is an early intermediate event branching out from the cell stress response pathways but before the execution of cell death program.

DTT is known to induce the unfolded protein response, probably by perturbing the ER oxidoreductive potential, important for disulfide bond formation and protein folding. Several branches of the UPR can lead to cell death program^[29]. Few studies focus on the effects of DTT on apoptosis and none of the reports had showed the relationship between UPR and P38 MAP kinase signaling pathway. Our data indicate that DTT treatment effectively triggered Eca109 cell apoptosis with potency comparable to that of cisplatin. Remarkably, P38 kinase was strongly activated by DTT treatment. This provides the first link between the UPR and P38 kinase activation. Furthermore, inhibition of P38 kinase activity blocks DTT-induced apoptosis, indicating that P38 activation is an indispensable intermediate step for the UPR-mediated cell apoptosis. It was reported previously that Japanese encephalitis virus (JEV) infection triggers the UPR and apoptosis in fibroblast and neuronal cells^[30]. Japanese encephalitis virus-induced apoptosis can be partially blocked by P38 kinase inhibitor SB203580.

An intriguing finding was that the subcellular localization of the activated P38 was markedly different in DTT- and cisplatin-treated cells. In DTT-treated cells, p-P38 was mainly seen in the nucleus, while in cisplatin-treated cells, p-P38 is mostly localized in the cytoplasm. The basis for this observation remains speculative. One possibility is that the nuclear perturbation exerted by cisplatin treatment hinders the p-P38 nuclear entry or retention. Surprisingly, the different localization of p-P38 does not significantly affect the apoptotic rate of the treated cells. This might suggest that p-P38 localization is not essential for p-P38 to relay its signal to the downstream apoptotic pathways. Alternatively, the nuclear fraction and cytoplasmic fraction of the p-P38 might trigger different downstream signaling pathways, which are able to transduce the signal to cell death program with similar efficacies. More studies are needed to address this issue.

The data obtained here raises the possibility that P38 kinase is the common central component relaying multiple cell stress pathways to the cell death program. If this notion proved to be true, then it might be possible to develop anticancer agents, which could specifically activate P38 kinase along with minimal nonspecific toxicities. This might also help to formulate newer drug combinations with synergistic activation of P38 kinase, to achieve better therapeutic efficacy and lesser side effects. Furthermore, DTT might be another apoptosis inducer. More studies should be carried out using different cell lines.

Abstract

AIM: To investigate the effect and significance of selenium in early experimental gastric carcinogenesis.

METHODS: Weaning male Wistar rats were divided randomly into normal control group, experiment control group, low selenium (2 mg/L) group and high selenium (4 mg/L) group. Wistar rat gastric carcinogenesis was induced by *N*-methyl-*N*-nitro-*N*-nitroso guanidine (MNNG) (20 mg/kg) gavage daily for 10 d. Na₂SeO₃ was given by piped drinking 1 wk prior to MNNG gavage. The rats were killed at the 43rd wk. The surface characteristics of gastric mucosa were observed with naked eyes. Histopathologic changes of rat gastric mucosa were observed by HE staining and AB-PAS methods. The changes of cellular ultrastructure were observed under transmission electron microscope. Statistical analysis was carried out by SPSS.

RESULTS: The incidence rate of gastric mucosa erosion, hemorrhage and intestinal metaplasia was 0, 45.5%, 66.7%, and 92.9%, respectively (92.9% vs 45.5%, $P < 0.05$) in the normal control group, experiment control group, low selenium group, and high selenium group. Leiomyoma formed in the process of inducement of rat gastric carcinoma. Dietary Na₂SeO₃ (2 and 4 mg/L) slightly increased the incidence rate of leiomyoma (0, 23%, 46.6%, and 46.6%). gastric mucosa did not change in the course of rat gastric carcinogenesis. Dietary Na₂SeO₃ by pipe drinking could expand the intracellular secretory canaliculus of parietal cells and increase the number of endocrine cells and lysosomes.

CONCLUSION: Dietary Na₂SeO₃ by pipe drinking aggravates gastric erosion, hemorrhage and promotes intestinal metaplasia of gastric mucosa. The mechanism may be related with the function of parietal cells.

INTRODUCTION

Gastric cancer results from chronic superficial gastritis, atrophic gastritis, intestinal metaplasia, and heterotypic hyperplasia. Previous studies showed that selenium (Se) supplementation or selenium deficiency causes changes in the cellular ultrastructure^[1-4]. Selenium is an essential trace element in mammals. The results of laboratory investigations and cohort studies suggest that selenium exhibits a bivalent effect in cancer, either increasing or decreasing the risk of cancer^[5,6]. We conducted this study to investigate the effect and significance of selenium in experimental gastric carcinogenesis.

MATERIALS AND METHODS

Materials

A total of 62 weaned male Wistar rats, weighing 31-56 g, were purchased from Department of Experimental Animals, Health Science Center of Peking University. The rats were housed in wire-bottomed metal cages at controlled temperature (21-22 °C) with a humidity of 30-50%, and in light-dark cycle. The rats were divided into the normal control group (group 1) which was given dimethyl sulfoxide (DMSO)-0.9% NaCl vehicle gavage with drinking normal tap water, experiment control group (group 2) which was given *N*-methyl-*N*-nitro-*N*-nitroso guanidine (MNNG), 20 mg/kg (presented by Professor Deng-DJ) gavage with drinking normal tap water, low selenium (2 mg/L) group (group 3) which was given MNNG (20 mg/kg) gavage with drinking water containing 2 mg selenium/L as sodium selenite before 1 wk administration of MNNG, or at the beginning of the experiment, and high selenium (4 mg/L) group (group 4) which was given MNNG (20 mg/kg) gavage with drinking water containing 4 mg selenium/L as sodium selenite before 1 wk administration of MNNG (Table 1).

Methods

The rats in groups 2-4 were given MNNG (20 mg/kg) gavage daily for 10 d, 1 wk after the experiment. MNNG was dissolved in DMSO at the concentration of 100 g/L

Table 1 Groups of Wistar rats

Group	Number	Dose of MNNG (mg/kg)	Dose of selenium in water (mg/L)	Time of selenium given
Normal control	10	0	0	/
Experimental control	22	20	0	/
Low selenium	15	20	2	1 wk before MNNG gavage
High selenium	15	20	4	1 wk before MNNG gavage

and kept in a cool, dark place. The stock solution was diluted to 1 g/L with 0.9% physiological saline before use. The rats in normal group were given DMSO-0.9% NaCl vehicle gavage. Selenium containing water was prepared. The low and high selenium groups were given selenium containing water at the beginning of experiment, 1 wk before administration of MNNG. The experiment rats had free access to diet and water. The animals were examined and weighed twice a week.

The animals were killed at the 43rd wk. The rats were starved for 12 h and anesthetized with 2.5% pentobarbitone intraperitoneal injection before they were killed. The stomach and other organs of the rats were carefully examined. Tissues from the stomach were fixed in 10% neutral Phosphate-buffered formalin solution and embedded in paraffin. Serial sections (5-6 μ m thick) were obtained from the stomach and stained with hematoxylin and eosin (HE), or Alcian blue-Periodic acid-Schiff (AB-PAS). Metaplasia of gastric mucosa was found as blue or purple blue granules in gastric mucosa cells after AB-PAS staining. For electron microscopy, the tissues from stomach were fixed for 2 h at 4 $^{\circ}$ C in 2.5 glutaraldehyde solution in 0.1 mol/L phosphate buffer, postfixed in 1.0% osmium tetroxide in the same buffer at 4 $^{\circ}$ C for 1 h, and then embedded in Epoxy resin. Ultrathin sections were stained with uranium acetate and lead acetate according to double stained method. The results were examined under a JEM-JEOL 100 \times electron microscope.

Statistical analysis

The clinicopathological results were statistically analyzed by SPSS software and χ^2 test.

RESULTS

Clinicopathological results

The results are shown in Table 2. The stomachs in the normal control group were smooth on the surface of serosa. Their inner surfaces clearly presented longitudinal branching folds and gastric pits. All the surface cells of rat gastric mucosa in group 1 had violet red granules (Figure 2A). Erosion and hemorrhage of gastric mucosa were found in 10 of 22 rats (45.5%) in the experimental control group (Figure 1A). There were many blue or purple blue granules in the erosive gastric mucosa of group 2 (Figure 2B). Similar erosive, hemorrhagic and intestinal metaplasia of gastric mucosa was found in 10 of 15 rats (66.7%) of low selenium group, 13 of 14 rats (92.9%) of high selenium group. The incidence rate of intestinal metaplasia was significantly higher in low and high selenium groups than in experiment control group ($P < 0.05$). The incidence of intestinal metaplasia was not significantly different between the high and low selenium groups. There were no significant changes by HE staining,

but the glandular cavity of fundic gland was slightly larger in high selenium group than in the other groups. In experimental control group, a single neoplasm was found on the surface of serosa breaching the serosa (Figure 1B). The diameter was about 0.2-1 cm. A similar neoplasm was also found in low and high selenium groups. The incidence of neoplasm was slightly higher in these two groups than in experimental control group. The neoplasm was diagnosed as leiomyoma by HE staining.

Figure 1 Erosive mucosa of rat stomach (A) and leiomyoma under serosa (B).

Figure 2 Normal mucosa (A) and erosive mucosa (B) of rat stomach, AB-PAS, $\times 200$.

Table 2 Results of pathologic diagnosis

	Number of rats	Incidence rate of leiomyoma (%)	Incidence rate of intestinal metaplasia (%)
Normal control	10	0	0
Experimental control	22	23	45.5
Low selenium	15	46.6	66.7 ^a
High selenium	14	42.8	92.9 ^a

^a $P < 0.05$ vs experiment control group.

Ultrastructural changes of gastric mucosa

In normal control group, the most distinctive feature in the ultrastructure of gastric mucosa was the presence of a deep invagination of the apical membrane forming a secretory canaliculus. The membrane lining the canaliculus had numerous microvilli projecting into its lumen. About 40% of the cytoplasmic volume was occupied by large mitochondria (Figure 3). Fewer endocrine cells were found in the normal gastric mucosa. Pinosomes distributed in the capillary endothelium of normal control group were large in diameter. Compared to normal control group, the secretory canaliculi in parietal cells were scarce, microvilli projecting into canaliculus lumen were sparse, the pinosomes were more in number and smaller in diameter than in experimental control group. Compared to the normal and experimental control groups, the following characteristics were observed in selenium supplement group: (1) the secretory canaliculus expanded and the microvilli projecting into canaliculus were scarce (Figure 4); (2) endocrine cells scattered in gastric mucosa contained granules with a different diameter and high electron density, there were a few secondary lysosomes in cytoplasm of some endocrine cells (Figure 5); (3) more eosinophils were found in the erosive gastric mucosa (Figure 6); (4) the chief cells had abundant rough endoplasmic reticulum, mitochondria were more in number and larger in volume; (5) the pinosomes in capillary endothelium were slightly less. These characteristics were significant in high selenium group.

DISCUSSION

Selenium, a constituent of antioxidant enzyme, has been proposed as a chemopreventive agent for many kinds of cancer^[7-10]. Selenium supplement to diet or drinking water can prevent tumorigenesis and decrease the incidence rate of cancer^[11-14]. The effect of selenium on carcinoma is still controversial^[5,6]. It was reported that selenium promotes carcinogenesis and tumor development^[15]. Gastric cancer is the second most frequent cause of cancer death in the world and the leading cause of cancer death in China. Studies have been focused on randomized nutritional intervention trial to prevent gastric cancer^[16-20] and epidemiology in serum selenium concentrations and esophageal and gastric cancer^[21]. Wu *et al.*^[22], reported that gastric cancer tissues have significantly higher concentrations of Fe, K, Mg, Na, Rb, Se, and Zn than normal gastric mucosal tissues. At present, the information on the effect of selenium in early experimental gastric carcinogenesis is scarcely available. This experiment was conducted to investigate the effect and significance of selenium on experimental gastric carcinogenesis by morphologic methods. The findings in this study showed that 2.0 and 4.0 g/L selenium in drinking water for 43 wk aggravated gastric mucosa erosion and hemorrhage and promoted intestinal metaplasia of gastric mucosa. Because gastric cancer results from chronic superficial gastritis, atrophic gastritis, intestinal metaplasia, heterotypic hyperplasia, supplement of selenium as sodium selenite does not decrease the risk of gastric cancer induced by MNNG. Furthermore, leiomyoma formed in the process of gastric carcinogenesis

induced by MNNG. Dietary Na_2SeO_3 (2 and 4 mg/L) increased the incidence of leiomyoma. Since the general dose of selenium is 0.5-6 g/mL (or /g)^[23] supplemented to diet and drinking water, the selenium dose in this study did not reach the toxic limits. Consequently the effects of sodium selenite maybe related to the kind of selenium, type of cancer, and different carcinogens.

Selenite induces oxidation and cross-linking of protein thiol groups, mitochondrial permeability transition, decrease in mitochondrial membrane potential, and release of cytochrome *C* in mitochondria isolated from rat liver, thus possibly inducing tumor cell apoptosis^[1]. Zhong and Oberley^[2] reported that oxidative stress is induced by sodium selenite at high concentrations, but outcomes are different. After acute exposure to selenite, cells display mitochondrial injury and cell death. After chronic exposure to selenite, cells show growth inhibition due to cell cycle arrest, increase the number of mitochondria and the levels of mitochondrial enzymes. Lysosomes in the liver and kidneys of selenium-deficient rats are enlarged and contain electron-dense areas^[3]. Demirel-Yilmaz *et al.*^[4], reported that low or high doses of sodium selenite and vitamin E in diet can alter the microvascular permeability of different organs. Our findings in this study indicate that selenium supplement can lead to the expansion of secretory canalculus, increase in the number of endocrine cells in gastric mucosa, alterations in the mitochondria and changes in the number and shape of pinosomes. Furthermore, our results also indicate that selenium supplement as sodium selenite can alter the ultrastructure of gastric mucosa. Though we did not find gastric cancer and gastric precancerosis, the results indicate that selenium supplement cannot prevent gastric carcinogenesis in early period of MNNG-induced gastric cancer. These mechanisms should be studied by future experiments.

Abstract

AIM: To explore the growth inhibition and apoptosis-inducing effect of apigenin on human gastric carcinoma SGC-7901 cells.

METHODS: The effects of apigenin on the growth, clone formation and proliferation of human gastric carcinoma SGC-7901 cells were observed by MTT, clone-forming assay, and morphological observation. Fluorescent staining and flow cytometry analysis were used to detect apoptosis of cells.

RESULTS: Apigenin obviously inhibited the growth, clone formation and proliferation of SGC-7901 cells in a dose-dependent manner. Inhibition of growth was observed on d 1 at the concentration of 80 $\mu\text{mol/L}$, while after 4 d, the inhibition rate (IR) was 90%. The growth IRs at the concentration of 20, 40, and 80 $\mu\text{mol/L}$ were 38%, 71%, and 99% respectively on the 7th d. After the cells were treated with apigenin for 48 h, the number of clone-forming in control, 20, 40, and 80 $\mu\text{mol/L}$ groups was 217 ± 16.9 , 170 ± 11.1 ($P < 0.05$), 98 ± 11.1 ($P < 0.05$), and 25 ± 3.5 ($P < 0.05$) respectively. Typical morphological changes of apoptosis was found by fluorescent staining. The cell nuclei had lost its smooth boundaries, chromatin was condensed, and cell nuclei were broken. Flow cytometry detected typical apoptosis peak. After the cells were treated with apigenin for 48 h, the apoptosis rates were 5.76%, 19.17%, and 29.30% respectively in 20, 40, and 80 $\mu\text{mol/L}$ groups.

CONCLUSION: Apigenin shows obvious inhibition on the growth and clone formation of SGC-7901 cells by inducing apoptosis.

INTRODUCTION

Apigenin (4', 5, 7-trihydroxyflavone), a phytopolyphenol, is widely distributed in vegetables and fruits such as celery, onion, apple, orange, etc. Recent studies have shown that apigenin exhibits anti-proliferation effects on several forms of cancer cells such as prostate cancer cells^[1], breast cancer cells^[2], leukemia cells^[3], colon cancer cells^[4-6], and enhances gap junctional intracellular communication changes in human liver cells^[7] and induces morphological changes in some cells^[8,9]. In addition, apigenin can suppress tumor-promoting effects of ultraviolet radiation on mouse skin^[10]. Compared with other flavonoid substances, apigenin is characterized by low toxicity and non-mutagenesis^[11]. Besides, it has other bioactivities such as anti-inflammatory^[12] and anti-oxide^[13] effects. Apigenin is a promising cancer inhibitor that may provide a new approach for the treatment of human cancers. In this article, we report the anti-proliferation effect and apoptosis-inducing effect of apigenin on human gastric carcinoma SGC-7901 cells.

MATERIALS AND METHODS

Chemicals

Apigenin (95% purity), 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyl tetrazolium bromide (MTT) and 4',6-diamidino-2'-phenylindole-dihydrochloride (DAPI) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). RPMI 1640 medium, ethylene diaminetetraacetic acid (EDTA), N'-2-hydroxyethyl piperazine-N'-ethane sulfonic acid were obtained from Gibco Chemical Co. (Rockville, MD, USA).

Cell culture and apigenin treatment

Human gastric cancer SGC-7901 cells, obtained from Cancer Research Institute of Beijing (China), were grown as a monolayer in RPMI 1640 medium containing 1% penicillin/streptomycin, and 0.2% gentamicin sulfate supplemented with 100 mL/L fetal bovine serum (FBS) at 37 °C in a 50 mL/L CO₂ humidified atmosphere. Apigenin was dissolved in dimethyl sulfoxide (DMSO) and mixed with a fresh medium to achieve the desired concentration. The final DMSO concentration in all media was 0.2%. This concentration of DMSO did not alter cell growth and cell cycle measurement when compared with the vehicle-free medium.

Cell growth assay

The effect of apigenin on the viability of cells was determined by MTT assay. Near-confluent stock cultures of cells were harvested with 0.2% EDTA and plated at a density of 2.5×10^3 /well in 96-well microtiter plates. After an overnight incubation to allow cell attachment, the medium was replaced by fresh medium containing different concentrations (0, 20, 40, and 80 $\mu\text{mol/L}$) of apigenin. Control wells received DMSO (0.2%). Each concentration of apigenin was repeated in four wells. After incubation for 24 h, one plate was assayed with a microplate reader at the wavelength of 570 nm. Before the assay, MTT (5 mg/mL in PBS) was added to each well and incubated for 4 h, then MTT solution was removed from the wells by aspiration. After careful removal of the medium, 0.1 mL of DMSO was added to each well, and the plate was shaken for 15 min. The data of 7 d were fed into the computer and the growth curve was drawn. The growth inhibition rate (IR) was calculated according to the following formula.

$$\text{Clone efficiency} = \frac{\text{absorbance of vehicle control} - \text{absorbance of apigenin treatment group}}{\text{absorbance of vehicle control group}} \times 100\%$$

Clone formation assay

The cells were plated at a density of 500/well on 24-well microtiter plates. After an overnight incubation to allow cell attachment, the medium was replaced by fresh medium containing DMSO (0.2%) at different concentrations (20, 40, and 80 $\mu\text{mol/L}$) of apigenin, with each concentration repeated in five wells. After being incubated for 24 or 48 h, the medium was replaced by fresh medium containing 10% FBS. The cells were incubated for another 7 d, then washed thrice with PBS and fixed in methanol for 15 min. The cells were stained with Giemsa stain. Then the number of clone-forming cells (>50 cells) was calculated under the microscope. The data were expressed as mean \pm SD. Clone-formation rate was calculated as follows:

$$\text{Clone efficiency} = \frac{\text{average clone number of five wells}}{\text{number of plating cells}} \times 100\%$$

Cell morphological change

The cells were harvested with 0.2% EDTA and plated in 25-mL culture bottles at the density of 1×10^5 . After an overnight incubation to allow cell attachment, the medium was replaced by fresh medium containing DMSO (0.2%) at different concentrations (20, 40, and 80 $\mu\text{mol/L}$) of apigenin. Morphological change of the cells was observed microscopically and photographed at 24 and 48 h after the addition of apigenin.

Besides, the cells were exposed to various concentrations of apigenin (20, 40, and 80 $\mu\text{mol/L}$) for 48 h, then harvested with EDTA and washed twice with PBS. The cells were stained with 2 mg/L DAPI ethanol solution and incubated at 37 °C for 15 min. Morphological changes of the stained cells were observed under fluorescent microscope (300-500 nm) and photographed.

Flow cytometry analysis

The cells (70% confluent) were treated with apigenin (40 and 80 $\mu\text{mol/L}$) for 48 h, then harvested with EDTA, washed twice with PBS, and centrifuged. The pellet was resuspended in 70% cold ethanol for 24 h at 4 °C. The cells were centrifuged at 110 r/min for 5 min, washed twice with PBS, suspended with 200 μL RNase A (20 $\mu\text{g/mL}$ final concentration) and incubated at 37 °C for 30 min. The cells were chilled over ice for 10 min and stained with 800 μL propidium iodide (50 $\mu\text{g/mL}$ final concentration) for 1 h and analyzed by flow cytometry.

Statistical analysis

All data were expressed as mean \pm SD and analyzed with SAS statistic software. $P < 0.05$ was considered statistically significant.

RESULTS

Growth curve and growth inhibition rate of SGC-7901 cells treated with apigenin

Apigenin inhibits the cell proliferation. Previous studies have proved that apigenin can inhibit the growth of several kinds of cancer cells. In our study, we examined whether apigenin exerted a similar anti-proliferative effect on human gastric cancer SGC-7901 cells. As shown in Figure 1, the cells in control group entered the logarithmic growth phase on the 1st d after they were plated and reached their peak on the 6th d. While in the treatment groups, the growth of

Figure 1 Inhibition effect of apigenin on growth curve (A) and growth IR (B) in

human gastric cancer SGC-7901 cells.

cells was inhibited in a dose- and time-dependent manner. Inhibition of growth was evident on d 1 at the concentration of 80 $\mu\text{mol/L}$, after 4 d the IR was 90%. The growth IR of 20, 40, and 80 $\mu\text{mol/L}$ of apigenin was 38%, 71%, and 99% respectively on the 7th d.

Effect of apigenin on clone formation of SGC-7901 cells

As shown in Figure 2, after exposure to apigenin for 24 or 48 h, the clone formation of SGC-7901 cells was suppressed in a dose- and time-dependent manner. The cloning efficiency in 80 $\mu\text{mol/L}$ was 9.8% and 5% after treatment with apigenin for 24 and 48 h, while in the control group it was 40.4% and 43.4% (Table 1).

Table 1 Effect of apigenin on clone formation in SGC-7901 cells ($n = 5$, mean \pm SD)

Groups ($\mu\text{mol/L}$)	Number of clone-forming cells		Cloning efficiency (%)	
	24 h	48 h	24 h	48 h
Control	202 \pm 12.1	217 \pm 16.9	40.4	43.4
20	192 \pm 10.5	170 \pm 11.1 ^a	38.4	34.0
40	147 \pm 11.3 ^a	98 \pm 11.1 ^a	29.4	19.6
80	49 \pm 6.7 ^a	25 \pm 3.5 ^a	9.8	5.0

^a $P < 0.05$ vs control group.

Morphological changes of SGC-7901 cells

Figure 3 shows the morphological changes of SGC-7901 cells treated for 48 h with 80 $\mu\text{mol/L}$ apigenin or vehicle.

In the vehicle control group, DMSO (0.2%) did not induce any marked morphological change in the cells. In the DMSO group, the cells were transparent and in the great density, the boundaries of the cells were dim, the nucleolus was very clear. While in the treatment group, there was a significant decrease in quantity and transparency of the cells, the cells crimped and the boundaries became clear, the nucleolus could not be observed clearly.

After being stained with DAPI, the cells were visualized under blue fluorescence. In the control group, the nuclei were almost round in shape with clear and smooth boundaries, the staining was equal. After treatment with apigenin for 48 h, the nuclei of cells were broken and the staining was unequal. The chromatins of cells were condensed, and the nuclei lost their smooth boundaries.

Result of flow cytometry analysis

During apoptosis, the DNA is broken into small fragments and released from cells. In this experiment, apoptosis was induced by apigenin. Flow cytometry analysis results are shown in Figure 4. Apigenin (20, 40, and 80 mmol/L) treatment for 48 h induced a significant apoptosis and accumulation of cells in S phase. The apoptosis rates were 5.76%, 19.17%, and 29.30%, respectively.

DISCUSSION

The pathogenesis of cancer is a multi-phase process. Inherited and environmental factors play an important role in the occurrence of cancer. Gastric cancer is one of the most

Figure 2 Morphological changes in SGC-7901 cells after treated with vehicle (A) and apigenin (B) for 48 h ($\times 200$).

Figure 3 Morphological changes of SGC-7901 cells after being treated with DMSO (A) and apigenin (B) for 48 h ($\times 400$).

Figure 4 FACS analysis of cells treated with DMSO (A), 20 $\mu\text{mol/L}$ apigenin (B), 40 $\mu\text{mol/L}$ apigenin (C), and 80 $\mu\text{mol/L}$ apigenin (D).

common malignant tumors in China. Some bioactive substances such as polyphenolic and isoflavone exist mainly in plant-based food (fruits and vegetables). Apigenin, one of the most common flavonoids, is widely distributed in many fruits and vegetables. Studies^[14] have proved that apigenin has strong anti-cancer effects.

In our experiment, we used MTT and clone-forming assay to detect the growth inhibition effect of apigenin on human gastric SGC-7901 cells. The results showed that apigenin dramatically suppressed the growth and clone formation of the cells in a dose- and time-dependent manner. After treatment of cells with 80 $\mu\text{mol/L}$ apigenin for 4 d, the growth IR was above 90% and other concentrations of apigenin also suppressed cell growth to different degrees. Clone formation reflects the proliferative ability of tumor stem cells, which is the important target of anticancer treatment. Inhibition of stem cells is more effective than that of common carcinoma cells during the treatment of cancer. With fluorescence microscope, we observed typical morphological changes such as the disintegrality of nuclear membrane, condensation of chromatin and broken nuclei. FACS analysis detected special apoptosis peak, which further supports the results in fluorescence morphological observation.

In conclusion, apigenin can suppress the growth of human gastric cancer SGC-7901 cells, which is associated with its apoptosis-inducing effect.

ACKNOWLEDGMENTS

We thank Yan Zhao, Lan Zhao and Xiao-Hua Zhang for their help and encouragement throughout the whole experiment.

Abstract

AIM: To evaluate the outcome of transarterial chemoembolization (TACE) in patients with unresectable hepatocellular carcinoma (HCC) <5 cm in diameter eligible for radiofrequency ablation (RFA).

METHODS: The treatment-related mortality, morbidity, long-term survival, and prognostic factors of HCC patients who had TACE and fulfilled the present inclusion criteria for RFA were evaluated.

RESULTS: Of the 748 patients treated with TACE between January 1990 and December 2002, 114 patients were also eligible for RFA. The treatment-related mortality and morbidity were 1% and 19%, respectively. Survival at 1, 3, and 5 years was 80%, 43%, and 23%, respectively. Older age and a high albumin level were associated with a better survival, whereas a high α -fetoprotein level (AFP) and the size of the largest tumor >3 cm in diameter were adverse prognostic factors in multivariate analysis.

CONCLUSION: The morbidity, mortality, and survival data after TACE for small HCCs eligible for RFA are comparable to those reported after RFA in the literature. Our data suggest the need for a randomized comparison of the two treatment modalities for small HCCs.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common human cancers with poor prognosis if left untreated, and only a small proportion is eligible for intentional curative surgical resection^[1,2]. Transarterial chemoembolization (TACE) has been used as a palliative treatment for patients with inoperable disease and those with recurrence after resection. TACE is also used as a (neo-)adjuvant treatment before or after surgical resection, and before liver transplantation^[3-6]. Hence, TACE is one of the most frequently performed treatment modalities for HCC. However, this treatment is still controversial and unsupported by evidence of early randomized controlled trials^[7-9]. Renewed interest in this form of treatment that has emerged as evidence from recent randomized trials is in favor of this treatment^[10,11]. A systematic review has convincingly shown a significant survival benefit for treatment with chemoembolization compared to no treatment^[12]. Moreover, in some patients, TACE has even shown a similar survival compared to certain patients who underwent hepatic resection^[13].

Local ablative, either open or percutaneous, techniques are considered alternatives for hepatic resection, if HCC is located either bilobar or multifocal rendering the disease unresectable, or if the patient has poor liver function reserve. Radiofrequency ablation (RFA) for HCC is a relatively new and popular local ablative technique. However, the lack of sufficient long-term follow-up data to support the treatment is well recognized. Strict criteria for RFA have not yet been clearly defined, but in general RFA is considered suitable if there are less than four lesions and the largest lesion is 5 cm or less in diameter^[4,14,15]. RFA may not be suitable for tumors with portal vein, hepatic vein or vena cava involvement and in patients with severe cirrhosis^[16,17]. Given these criteria and the reported promising results of RFA, some patients who might have been given TACE treatment prior to the advent of RFA may now be treated with RFA as the preferred alternative. However, TACE is a better documented treatment that is still used in many centers for HCC even if the tumor is eligible for RFA. Currently there are no studies in the literature directly comparing the results of the two treatment modalities. Such comparative studies may not be available in the near future because in most centers, RFA has been employed for a short duration with no long-term follow-up data, and not many centers have abundant experience in both treatment modalities. The results of TACE treatment for unresectable HCCs <5 cm in diameter eligible for RFA are also unknown because previous studies on TACE for

HCC usually included a heterogeneous group of patients, including those with large tumors and vascular invasion.

This study that applied the currently accepted RFA inclusion criteria to our vast experience with TACE in patients with HCC reports the outcome of these patients and the factors associated with poor prognosis of TACE treatment in this particular group.

MATERIALS AND METHODS

A prospective database, which contained the data of all patients with surgical and non-surgical treatments for HCC at the Department of Surgery, Queen Mary Hospital, Hong Kong, was used. All patients with newly diagnosed HCC who had TACE as their initial treatment between January 1990 and December 2002 and had HCC with their largest nodule being <5 cm in diameter were identified and retrospectively analyzed. Other criteria included the number of tumor nodules less than four, absence of severe cirrhosis reflected by a Child's C grading, and absence of portal vein (intrahepatic or main trunk), hepatic vein or inferior vena cava involvement.

Patients who had a diagnosis of HCC, confirmed either by biopsy or needle cytology, by two diagnostic imaging modalities (contrast computed tomography (CT) scan, magnetic resonance imaging or arteriography) showed typical HCC nodules with arterial hypervascularization or one diagnostic a persistently raised serum α -fetoprotein level (AFP) >400 ng/mL according to the Barcelona-2000 EASL conference criteria^[18]. We selected patients for TACE treatment if they had inoperable bilobar disease or unilobar disease in combination with sufficient hepatic function reflected by a bilirubin level <50 μ mol/L and no metastatic disease.

Our technique of TACE has been described elsewhere^[19,20]. Superselective cannulation of the artery supplying the tumor was performed whenever possible. An emulsion of cisplatin (1 mg/mL) and lipiodol (Lipiodol Ultrafluide®; Laboratoire Guerbet, Aulnay-Sous-Bois, France) at a volume ratio of 1:1 was injected up to a maximum of 60 mL. Embolization was performed with 1-mm² particles of gelatin-sponge (Spongostan®, Johnson and Johnson Ltd, Skipton, UK) mixed with 40 mg of gentamycin. Repetition of TACE treatment was tailored to response of tumor and tolerance of liver rather than a fixed regimen. TACE was repeated every 8-12 wk if there was tumor response ($\geq 50\%$ decrease in tumor size according to World Health Organization criteria) or if the tumor was static in size (<50% decrease or <25% increase in tumor size). Treatment of TACE was terminated if there was no evidence of tumor on reassessment CT (i.e. complete response), disease progression ($\geq 25\%$ increase in tumor size or appearance of new lesions), evidence of liver failure (rise of bilirubin >50 μ mol/L, uncontrollable ascites or hepatic encephalopathy), severe life-threatening complications such as liver abscess, or extrahepatic metastasis.

Patient demographics, laboratory data, and tumor characteristics were used for analysis. The Child-Pugh classification (A or B) was used to categorize the patients according to their status of liver cirrhosis and the new TNM classification according to the American Joint Committee

on Cancer (AJCC)^[21] was used for staging.

Continuous, normally distributed data were expressed as mean \pm SD, and other continuous data were expressed as medians with their interquartile range. Survival was analyzed by Kaplan-Meier survival curves. Prognostic variables for recurrence and survival were studied with univariate and multivariate Cox proportional hazards regression. Variables were categorized according to their quartile distribution wherever possible. This regression yields a hazard ratio, which may be interpreted as a relative risk within the average follow-up period. We used sex, age, laboratory data (bilirubin, albumin, AFP, platelet count) and tumor characteristics (bilobar disease, size of largest tumor, number of tumors, TNM stage) in a univariate Cox proportional hazard analysis. Next, variables for which univariate test had a *P* value less than 0.25 and biologically important variables (sex and age) were included in a multivariate analysis with survival as the outcome^[22]. For model building, we applied backward stepwise elimination of variables. All reported *P* values were two-tailed. *P*<0.05 was considered statistically significant.

RESULTS

In the period between January 1990 and December 2002, a total of 2 850 patients were seen at our outpatient clinic for HCC and included in our database. Of these, 748 patients with newly diagnosed HCC underwent TACE as their initial treatment, and 200 patients had the largest tumor nodule <5 cm in diameter. This group included 15 patients who were considered unresectable during laparotomy and subsequently given TACE as the primary treatment. Patients who had more than three nodules (*n* = 60) subsequently undergoing hepatic resection (*n* = 14), and those who had portal vein (intrahepatic or main portal vein, *n* = 2) were excluded from this study. There were no patients with hepatic vein or inferior vena cava involvement. Of the remaining 124 patients, another 5 patients were excluded because of Child's C cirrhosis and an additional 5 patients did not fulfill the criteria of HCC diagnosis used in this study. Hence, this study involved 114 patients and all analyses were performed in this group of patients.

The diagnosis of 17 patients was confirmed by either histology (*n* = 2) or cytology (*n* = 15). In 93 patients, confirmation of HCC was done by CT and hepatic arteriogram, in 2 patients by magnetic resonance imaging and hepatic arteriogram, and in the remaining 2 patients by an ultrasound of the liver and a consistently increased AFP combined with a hepatic arteriogram.

Patient characteristics are shown in Table 1. One patient died as a direct result of TACE treatment, the treatment-related mortality was 1%. This patient had four previous TACE sessions and developed both a liver abscess and deterioration of liver function after his 5th TACE treatment. He subsequently developed sepsis and pneumonia and died of respiratory failure. The overall treatment morbidity was 18%, the patient who died had two complications. Other complications as a result of TACE were hematoma at the puncture site in the groin (*n* = 1, 1%) and liver failure, defined as elevated bilirubin >50 μ mol/L, development of uncontrolled ascites or hepatic encephalopathy (*n* = 20, 17%).

Table 1 Characteristics of 114 patients eligible for RFA but received TACE treatment

Characteristics	Median	Interquartile range
Age (yr)	63	55-71
Gender: male/female (<i>n</i>)	87/27	76/24

Table 2 Causes of death in 74 patients after TACE treatment

Causes	<i>n</i>	%
Malignant cachexia	45	61
Bleeding	3	4
Hepatic failure	9	12
Respiratory failure	1	1
Multiorgan failure	2	3
Sepsis	4	5
Other	10	14
Total (<i>n</i>)	74	

TACE: transarterial chemoembolization.

Seventy-four patients died during our observation period and the reasons for their death are given in Table 2. One patient was lost to follow-up (1%). The 1-, 3-, and 5-year survival rates were 80%, 43%, and 23% respectively (Figure 1). The median survival was 31 months (95%CI: 24-38 mo).

Univariate and multivariate analyses are shown in Tables 3 and 4, respectively. Higher age and a high albumin level (above 41 g/L) were associated with a better survival whereas AFP (above 81.50 ng/mL) and the size of the largest tumor >3 cm in diameter were the risk factors for death in the multivariate analysis.

DISCUSSION

We evaluated the morbidity, mortality and long-term survival, and identified several independent risk factors for

**Figure 1** Kaplan-Meier curve for survival of patients undergoing TACE as treatment.

death in patients who underwent TACE treatment with patient and tumor characteristics that fulfilled all our present criteria for RFA treatment. Although there are numerous reports on the results of TACE for inoperable HCC, many included patients with large or advanced HCC with vascular invasion for which the outcome is expectedly worse^[3,5,6,19]. Such reports may give the impression that results after TACE are worse than those after RFA, because most studies of RFA on HCCs focused on small HCCs and hence reported more favorable results. To our knowledge, the survival and prognostic factors in this specific group of patients with HCC who were eligible for RFA but underwent TACE treatment have not been reported before. As many patients

CI: confidence interval. ¹Hazard ratio of albumin and AFP is given relative to the lowest quartile. ²Hazard ratio is given relative to the size of the largest tumor smaller than 3 cm in diameter.

who were considered to have unresectable HCC <5 cm in diameter received TACE treatment before the RFA era, this knowledge may be of specific interest to those who are rethinking the concept of TACE and RFA and wish to refine their indications for both TACE and RFA treatments. With the availability of RFA, patients with small HCCs <5 cm in diameter previously treated by TACE are now treated by RFA instead as the preferred treatment in some centers, although there is no direct evidence to show that RFA is superior to TACE in terms of treatment safety and long-

term survival benefit. The exact place of local ablative techniques and TACE in the overall management of HCC still needs to be determined. Offering a strict order of treatment options to the patient, i.e. first hepatic resection, then local ablative techniques and then TACE, may not be fully justified. Indeed, percutaneous ethanol injection appears to acquire similar results as resection for small HCC in terms of treatment efficacy, recurrence, and survival rates^[23]. In addition, Bronowicki *et al.*^[24], found similar survival after surgery and TACE, while the patients who underwent surgery

were younger and had a better staging, and, just recently, TACE has been shown to be as effective as hepatic resection in certain patients^[13]. Moreover, evidence from randomized controlled trials comparing even two local ablative techniques is hardly available, not to mention trials comparing two different treatment modalities such as TACE and RFA. Therefore, one must be careful not to jump to conclusions^[25]. In patients who do not want surgery, which is still necessary in a large proportion of cases for RFA because of tumor location at the superior portion of the liver or close to the adjacent viscera^[26], TACE is still one of the best options. Furthermore, some centers may not have the availability and/or equal expertise of all treatment options and may stick to the use of TACE as the preferred treatment for all unresectable HCC.

Given the potentially curative intent of RFA, many clinicians consider RFA as the treatment of choice for unresectable small HCC, although long-term survival results of RFA are scarce^[27]. In addition, complications and treatment mortality after RFA are generally expected to be fewer than those after TACE, and RFA may result in less deterioration of liver function. The treatment mortality in this study (1%), however, appears comparable to that of RFA^[28]. A recent literature review suggests that the treatment morbidity of RFA in the early reports is probably underestimated^[28]. The treatment morbidity of TACE for small HCC in this study was 18%, which is comparable to the complication rates of 13–20% after RFA for HCC reported in some of the more recent studies^[28,29]. The complication rate is 14% in our preliminary experience with RFA in 86 patients with HCC between May 2001 and December 2002^[30]. The 1-year survival rate of the HCC patients treated by TACE in the current study was 80%, which is comparable to the 1-year survival observed after RFA for HCC in our preliminary experience^[30]. The 3-year survival rate of 43% is also comparable with that of 33–50% in recent reports of more long-term survival results of RFA for HCC^[31,32]. In this study, the 5-year survival after TACE for HCCs <5 cm in diameter that were eligible for RFA was 23%. Data on 5-year survival rate after RFA for HCC are scarce. In a recent study, Buscarini *et al.*^[33], reported a 5-year survival rate of 33% after RFA for HCCs ≤3.5 cm in diameter, which appears comparable to that after TACE for tumors of a similar size in our study.

In this study, we did not directly compare our TACE results to similar patients who underwent RFA treatment in our institution. We have started RFA only 4 years before, like many others, and long-term follow-up is unavailable yet. Furthermore, most patients in this study were treated with TACE in the era long before the availability of RFA. Naturally, a future comparison between similar patients undergoing TACE and RFA within the same time-frame will be made. Ultimately, however, a randomized controlled trial may be needed. This study may serve as a reference to compare present and future RFA series, as in many centers that perform RFA, TACE is either losing ground or experience with TACE is not so large in the first place. Our results of TACE in patients with HCC <5 cm in diameter suggest that the safety of TACE and survival results may be comparable to those of RFA, which is an important message

for clinicians treating HCCs. This highlights the need for randomized studies to compare the two treatment modalities rather than simply considering RFA as the preferred treatment based on perceived benefits.

RFA is still an evolving technique and it is therefore understandable that there is a large diversity in indications for RFA. Our inclusion criteria for RFA are consistent with the reported criteria^[14–17,27]. A largest tumor size ≤5 cm in diameter, the number of tumors less than four and tumors not invading or abutting major hepatic veins or portal vein branches have all been reported as the inclusion criteria for RFA. In our database of HCC patients treated with TACE, 114 of 748 patients who underwent TACE treatment (15%) fulfilled the criteria for RFA treatment. We found that a high albumin concentration was associated with better survival. We believe that this reflects the better liver function of these patients compared to those with low albumin concentrations. Indeed, it is reasonable to speculate that patients with poor liver function may do better with local ablative techniques, such as RFA, because these techniques result in less liver damage than TACE. Child's B grade liver function did not appear to be an independent predictor in the multivariate analysis because it possibly interacted with albumin concentration. A higher age results in a risk reduction of 2% per year. Others have found that age is an adverse prognostic factor^[34,35]. We cannot explain this interesting observation but we propose that it might be related to selection or, partially a more malignant behavior of HCC in younger patients. In any case, age may not be a clinically important factor that influences the clinician's decision to treat the patient with RFA or TACE. Both a high AFP, which reflects tumor volume and perhaps also tumor aggressiveness, and tumor size are associated with poorer survival. These risk factors have been identified previously in other prognostic studies of TACE^[35–38]. Patients with tumors measuring between 3 and 5 cm performed worse compared to those with smaller tumors when put on TACE treatment. Perhaps this particular group may do better when treated by local ablative techniques such as RFA. Advances in RFA technology have allowed ablation of larger HCC. RFA may effectively treat tumors up to 5 cm in diameter by using a clustered probe or by inflow occlusion with the Pringle maneuver^[4,30].

This is the first study that investigated the outcomes of TACE for a group of patients with HCC <5 cm in diameter who would now be treated with RFA instead in many centers. TACE for small HCC has been reported before but focused mainly on the technical aspects, and those studies did not specifically look at patients who were also eligible for RFA treatment. Moreover, these are all Japanese studies with mainly hepatitis C patients^[39–41]. Our results compare favorably with the results of Nakao *et al.*^[39], (34% 3-year survival), and are similar to the results of Yamada *et al.*^[40], (47% 3-year survival). Takayasu *et al.*^[41], have reported a 77% 3-year survival in their patients with HCC <5 cm in diameter. However, the mean tumor size was only 1.9 cm in their study.

In conclusion, this study provides the morbidity, mortality and long-term survival results of a group of patients who were otherwise eligible for RFA treatment but received

TACE. Our data, based on a retrospective analysis, suggest that the immediate and at least the short-term and intermediate-term survival results of TACE for small HCC may be comparable to those of RFA reported in the literature. The data may serve as a useful reference for comparison to RFA treatment when long-term survival of the latter treatment becomes available. This study highlights the need for a prospective comparative study of the two treatment modalities rather than simply replacing TACE with RFA for small inoperable HCCs as the treatment of choice, as what many centers are doing with the availability of this new technology. The identification of the prognostic factors may help in better selection of patients for TACE or RFA treatment.

Abstract

AIM: To investigate the regulation of phosphatase and tensin homolog deleted on chromosome ten (*PTEN*) gene expression in human hepatocellular carcinoma (HCC) cell lines.

METHODS: The mRNA and protein levels of *PTEN* were detected by Northern blot and Western blot in HCC cell lines, respectively. Plasmids containing different fragments of *PTEN* promoter with Luciferase reporter were constructed and transiently transfected into HCC cell lines to study the promoter activity. DNA analysis and RT-PCR were performed to detect the mutation of *PTEN* promoter and *PTEN* cDNA.

RESULTS: Either protein or mRNA levels of *PTEN* in L02 cells (as a control) were significantly higher than that in HCC cell lines. The profile of *PTEN* promoter activity in 8 cell lines was closely correlated with levels of *PTEN* mRNA and *PTEN* protein. Furthermore, the sequence analysis of 8 cell lines showed no mutation in the region of *PTEN* promoter and *PTEN* cDNA.

CONCLUSION: *PTEN* expression is down-regulated in HCC cell lines probably due to loss of activity of *PTEN* promoter.

INTRODUCTION

The tumor suppressor gene phosphatase and tensin homolog deleted on chromosome ten (*PTEN*), mutated in a wide range of human cancers^[1,2], encodes a protein containing 403 amino acids with phospholipid and protein phosphatase activity^[3-6]. Consequently, *PTEN* inhibits the generation of phosphatidylinositol 3,4,5-trisphosphate (PIP3)^[7] and then blocks the activation of proto-oncogene PKB/Akt^[8,9]. The loss of *PTEN* in human tumors leads to an increase in PI(3,4,5)P3 and the uncontrolled stimulation of growth and survival signals^[10]. *PTEN* also dephosphorylated focal adhesion kinase because of its tyrosine phosphatase activity^[11,12], which might lead to the inactivation of Ras/mitogen-activated protein kinase (MAPK) pathway^[12-15]. It is well known that both pathways mentioned above are intimately involved in control of cell growth and survival, so *PTEN* appears to impinge on cell proliferation, adhesion, cell migration, and cell invasion^[14,15]. Moreover, germline mutations in *PTEN* cause Cowden disease, which is characterized by the formation of multiple hamartomas and increased susceptibility to skin, thyroid, and breast tumors^[16]. Together, these findings suggest that loss of *PTEN* activity sensitizes cells to malignant transformation and *PTEN* is an important protein to regulate various physiological pathways. Despite extensive characterization of *PTEN* mutations in human cancers and relatively good understanding of the molecular roles of *PTEN* in the control of cellular processes, little is known about modes of *PTEN* regulation. Recently, scientists have paid more attention to the regulation of *PTEN* expression. It was reported that the transcription of *PTEN* could be regulated by p53 and Sp1^[17,18]. In addition, 5'-untranslated region (5'-UTR) of *PTEN* gene was responsible for constitutive *PTEN* expression in mice^[18]. Salvesen *et al.*^[19], found that *PTEN* promoter methylation was relatively frequent in endometrial carcinoma. Till now, the regulation of *PTEN* expression is still unclear especially in HCC cells. It is well known that the regulation of gene expression is a multi-step process in eukaryotes, and the transcriptional regulation plays a important role in it. So, we attempted to study the transcriptional regulation of *PTEN* expression in HCC cell lines.

MATERIALS AND METHODS

Cell culture

Human hepatocellular carcinoma (HCC) cell lines (SMMC-7721, BEL-7402, BEL-7404, and BEL-7405) and human liver immortal cell line L02, purchased from Institute

of Biochemistry and Cell Biology, Chinese Academy of Sciences (Shanghai, China), were routinely maintained in RPMI 1640 (Gibco BRL, USA) supplemented with 100 mL/L fetal bovine serum (HyClone, USA) at 37 °C in a humidified atmosphere containing 50 mL/L CO₂ in air. HepG2 (human hepatoblastoma) was obtained from American Type Culture Collection (ATCC). HCC cell lines MHCC-97H and MHCC-97L kindly provided by Liver Cancer Institute of Zhongshan Hospital, Fudan University (Shanghai, China), were maintained in Dulbecco's modified Eagle's medium (Gibco BRL, USA) supplemented with 100 mL/L fetal bovine serum (HyClone, USA) at 37 °C in a humidified atmosphere containing 50 mL/L CO₂ in air.

Western blot analysis

After being grown into confluence, cells were washed twice with ice-cold phosphate-buffered saline (PBS) and lysed in cold lysis buffer (50 mmol/L HEPES, pH 7.5, 150 mmol/L NaCl, 1.5 mmol/L MgCl₂, 1 mmol/L EDTA, 0.2 mmol/L EGTA, 10 mL/L NP-40, 100 g/L glycerol, 1 mmol/L dithiothreitol, 1 mmol/L phenylmethylsulfonyl fluoride, 20 mmol/L sodium fluoride, 5 mmol/L sodium orthovanadate, 10 g/L aprotinin, 10 g/L leupeptin, 2 g/L pepstatin, and 1 mmol/L benzamide). Lysates were incubated for 20 min on ice and centrifugated at 12 000 *g* for 20 min. The supernatants were collected and protein concentration was determined by Lowry protein assay. Cell lysates were electrophoresed by SDS-PAGE and then transferred onto polyvinylidene fluoride (PVDF) membrane. The membranes were blocked with 50 g/L nonfat dry milk in PBST (PBS, 0.5 mL/L Tween-20) for 4 h at room temperature and incubated overnight at 4 °C with a mAb against human *PTEN* (Santa Cruz, CA, USA), followed by incubation with HRP-conjugated secondary antibody at room temperature for 3 h. Antibody binding was detected by enhanced chemiluminescence (ECL).

Northern blot analysis

Total RNA was isolated using the TRIzol reagent (Invitrogen, CA, USA) according to the manufacturer's directions. The 20 µg RNA was electrophoresed on a 12 g/L agarose/formaldehyde gel and blotted onto a nylon membrane (Schleicher & Schuell, Germany) by capillary transfer. Hybridization was performed in 0.2 mol/L Na₂HPO₄/NaH₂PO₄ (pH 7.2), 1 mmol/L EDTA, 10 g/L BSA, 70 g/L SDS and 150 mL/L formamide at 50 °C, and the filters were washed extensively with 40 mmol/L Na₂HPO₄/NaH₂PO₄ (pH 7.2), 1 mmol/L EDTA, 10 g/L SDS at 65 °C. A 1.2 kb DNA fragment representing the entire coding region of *PTEN* was used as a probe and was labeled by Prime-a-Gene labeling system (Promega, Madison, WI, USA). Air-dried blots were autoradiographed onto Kodak film (Eastman Kodak, Rochester, NY, USA) and the RNA signal was detected using an ImageMaster VDS system (Pharmacia Biotech, San Francisco, CA, USA) and normalized against the signal for β-actin using ImageMaster TotalLab 1D software.

Isolation of 5'-flanking and promoter region of *PTEN* gene

Based on the published sequence of *PTEN* (accession

number AF067844), a 2.7 kb DNA fragment of *PTEN* containing 5'-flanking region, 5'-untranslated region (5'-UTR) and full-length of *PTEN* promoter region were obtained by PCR using primers 5'-GATAGATCTGGGTG-GGGTGC GGGGTAGGAGTGC-3' and 5'-GAGAAG-CTTGCTGCGGCGGCTGCTGGATGGTTG-3'. The fragment was subcloned into the luciferase reporter plasmid pGL3-basic (Promega, Madison, WI, USA) which was digested twice with *Bgl*II and *Hind*III restriction enzymes. Positive clones, pGL3-2768, from 8 cell lines were identified by restriction enzymes digest and DNA sequencing, and aligned with the GenBank databases.

Reporter gene plasmids constructions

Several specific primers containing *Bgl*II and *Hind*III restriction enzyme sites (listed below) were designed to amplify serial deletion fragment of *PTEN* using the clone pGL3-2768 (-2 927/-160) as a template.

5'-CGGAGATCTGTGTTTGATGTGGGTGCTTTT-3' (-2 403),

5'-CAGAGATCTGGTCTGAGTCGCCTGTCAACATTT-3' (-458),
5'-GAGAAGCTTGCTGCGGCGGCTGCTGGATGGTTG-3' (-160).

Fragments of 2 234 (-2 403/-160), 1 635 (-1 794/-160), 1 230 (-1 389/-160), 1 526 (-2 403/-778), 1 016 (-1 794/-778), 612 (-1 389/-778), 341 (-1 118/-778), 139 (-916/-778), 81 (-858/-778) and 299 (-458/-160) were cloned into the vector pGL3-basic at the *Bgl*II and *Hind*III sites to individually generate pGL3-2234, pGL3-1635, pGL3-1230, pGL3-1526, pGL3-1016, pGL3-612, pGL3-341, pGL3-139, pGL3-81, pGL3-299, respectively. These constructs were sequenced and aligned with the GenBank databases.

Transient transfections and luciferase activity assays

Cells were seeded into 6-well plates at a density of 150 000 cells per well 1 day before transfection. The transfection was performed with the Lipofectamine™ 2000 transfection reagent (Invitrogen, CA, USA) according to the manufacturer's guidelines. Typically, 3 µg of pGL3 vector and 1 µg of pGFP-β-Gal (a gift from Houyan Song, Department of Molecular Genetics, Shanghai Medical College, Fudan University, Shanghai, China) were used per well. After 48 h, cells were lysed with lysis buffer (Promega, Madison, WI, USA). The mixtures were centrifugated at 12 000 *g* for 15 s at 4 °C, and the supernatant was preserved at -70 °C. Activities of firefly luciferases were measured in a luminometer Lumat LB 9507 using the luciferase assay system (Promega, Madison, WI, USA). β-Gal activity was measured by β-galactosidase enzyme assay system (Promega, Madison, WI, USA). Promoter activity was quantified by calculating the ratio of firefly luciferase activity/β-gal activity of the same sample. Transfection efficiency was determined through the positive cells with green fluorescence from the green fluorescence protein (GFP) under fluorescent microscope. All the luciferase assays were carried out at least in triplicate, and the experiments were repeated thrice.

RT-PCR and DNA sequencing of *PTEN* cDNA and *PTEN* promoter

Total RNA was isolated from cell lines using the TRIzol RNA isolation kit (Invitrogen, CA, USA) according to the manufacturer's protocols. After synthesis of first strand cDNA using oligo-d(T)₁₂₋₁₈ primer and moloney murine leukemia virus (M-MuLV) reverse transcriptase (Promega, Madison, WI, USA), *PTEN* cDNA was amplified using PCR with pyrococcus furiosus (Pfu) DNA-polymerase (Promega, Madison, WI, USA). The primer sequences were as follows: upper primer, 5'-ACAGGC-TCCCAGACATGACA-3' and lower primer, 5'-TCAG-ACTTTTGTAATTTGTGTATG-3'. PCR amplification was carried out for 30 cycles under denaturing-annealing-extension conditions of 94 °C for 30 s, 60 °C for 1 min and 72 °C for 1 min, respectively. The PCR product was cloned into the T vector and was identified by DNA sequencing of at least three independent clones and aligned with the GenBank databases.

Statistical analysis

F test was used for statistical analysis.

RESULTS

PTEN protein and mRNA expression in 8 cell lines

Most mammalian cells containing the wild-type *PTEN* gene expressed detectable levels of *PTEN* mRNA and protein under normal growth conditions^[17]. L02, a human liver immortal cell line, was used as a control in the present study. There was one 55 ku *PTEN* protein detected with various levels in 8 cell lines by Western blot analysis (Figure 1). The protein level of *PTEN* in L02 cells was the highest among the 8 cell lines, whereas the *PTEN* protein in HepG2 cells was almost undetectable. Simultaneously, Northern blot analysis showed a major 2.5-kb transcript and a lower abundance 5.0-kb transcript of *PTEN* mRNA in all 8 cell lines, which was consistent with previous reports^[20] (Figure 2). The total mRNA of *PTEN* was calculated in both 5.0-kb and 2.5-kb transcripts. The mRNA level of *PTEN* was much higher in L02 cells than the other 7 HCC

cell lines, especially in HepG2 cells (Figure 2). The mRNA level of *PTEN* in L02 cells was over five-folds than in HepG2 cells. However, the profile of *PTEN* protein level in each of 8 cell lines closely parallelized with its *PTEN* mRNA.

Absence of *PTEN* promoter and *PTEN* cDNA mutation in 8 cell lines

Deletions or mutations of *PTEN* encoding gene are associated with a variety of human cancers^[12]. Furthermore, decreased expression of *PTEN* was associated with advanced glioma, melanoma, and prostate cancer, implicating losses of *PTEN* by mutation involved in tumor progression^[21-23]. To investigate whether the deletion or mutation exists in *PTEN* gene, leading to the lost expression of *PTEN* in HCC cell lines, we analyzed the sequence of *PTEN* cDNA and *PTEN* promoter (-2 927/-160 bp) in 8 cell lines. We found no mutation in *PTEN* cDNA and *PTEN* promoter region of 8 cell lines (data not shown), indicating that the different levels of *PTEN* mRNA and protein in 8 cell lines were not caused by the mutation of *PTEN* cDNA and promoter region. It might be related to *PTEN* transcriptional or post-transcriptional regulation.

Core region of *PTEN* promoter identified in SMMC-7721 and L02 cell lines

It is well known that promoter plays the most important role in gene transcription. In an attempt to analyze the function of *PTEN* promoter, we isolated a DNA fragment containing 5'-flanking region and the 5'-untranslated region (5'-UTR) from *PTEN* gene, and performed a series of promoter deletion. Eleven fragments of *PTEN* gene promoter were constructed into pGL3-basic with luciferase reporter (Figure 3 A) and were transiently transfected into L02 and SMMC-7721 cell lines. It was found that the profiles of luciferase activities of various plasmids were the same in the two cell lines (Figures 3B and C). The 612-bp fragment (-1 389/-778) was sufficient to induce maximum luciferase activity in L02 and SMMC-7721 cell lines. The plasmid pGL3-2768 (-2 927/-160), which

Figure 1 Western blot analysis for *PTEN* protein expression in 8 cell lines under normal growth conditions.

Figure 2 Northern blot analysis of *PTEN* mRNA expression in 8 cell lines under normal growth conditions.

Figure 3 *PTEN* promoter deletion analysis in SMMC-7721 and L02 cell lines. **A:** Schematic representation of serial deletion constructs of human *PTEN* genomic

locus; **B:** promoter activity of serial deletion constructs of *PTEN* in L02 cell lines; **C:** promoter activity of serial deletion constructs of *PTEN* in SMMC-7721 cell lines.

contained full-length promoter, appeared to have lower activity than that of pG13-612 (-1 389/-778), indicating that the suppressor elements or special DNA structure may exist in double ends, especially in 3' end fragment (-777/-160). The 341 bp fragment (-1 118/-778) possessed over 60% of the promoter activity of the 612 bp fragment. The 81-bp fragment (-858/-778), however, appeared to be insufficient for inducing transcriptional activation of *PTEN*. The 299-bp downstream fragment (-458/-160) possessed no significant promoter activity in L02 and SMMC-7721 cells. No further increase in activity was observed when longer fragments than 612 bp were transfected, which was consistent with previous report^[24]. Taken together, these data showed that the 612-bp fragment (-1 389/-778) had optimal promoter activity and the core region of *PTEN* promoter was located within the -1 118 to -778 region.

Different activities of *PTEN* promoter in 8 cell lines

When transfecting the plasmid pG13-612 that possessed maximum *PTEN* promoter activity into the 8 cell lines, we found the activity of pG13-612 in SMMC-7721 and L02 cells were much higher than that in others (Figure 4), while the activity of pG13-612 in HepG2 cells was the lowest, only 17% of that in L02 cells. The activities of pG13-612 in BEL-7402, BEL-7404, BEL-7405, MHCC-97H and MHCC-97L were 55%, 65%, 62%, 45%, and 39% of that in L02 cells, respectively. The profile of *PTEN* promoter activity in 8 cell lines was mostly parallelized to

the profiles of *PTEN* protein and *PTEN* mRNA. These results demonstrated that the changes of *PTEN* protein and *PTEN* mRNA in 8 cell lines might result from the function of *PTEN* promoter.

DISCUSSION

Since the isolation of *PTEN/MMAC1/TEP1* (acronyms for phosphatase and tensin homolog^[2], mutated in multiple advanced cancers^[1], and TGF- β (transforming growth factor- β)-regulated and epithelial cell-enriched phosphatase^[25] as a candidate tumor suppressor gene, hundreds of reports have been published focusing on its structure and function, as well as on mutations that cause human diseases^[26]. Mutations of the *PTEN* gene arise during cancer progression in a remarkable variety of cancers, including brain, prostate, breast, endometrial cancers and melanoma^[26]. The frequency of *PTEN* mutations observed in endometrial tumors^[26], malignant glial tumors^[25], malignant melanoma cell lines^[26] and metastatic prostate carcinomas^[27] was about 45%, 24%, 40%, and 10%, respectively. In addition, germline mutations in the *PTEN* gene have been associated with Cowden syndrome and a significantly increased risk of certain tumors, including cancer of the breast and thyroid^[21,28]. These data further support that *PTEN* is a tumor suppressor gene.

The structure of *PTEN* contains a phosphatase domain that has a structure resembling tyrosine phosphatase and a C2 domain appears to bind *PTEN* to the plasma membrane, which might orientate the catalytic domain appropriately for interactions with phosphatidylinositol 3,4,5-trisphosphate (PIP3) and other potential substrates^[29]. A PDZ binding motif in the tail might also play a role in altering the balance of *PTEN* effects on potential downstream signaling targets such as Akt^[16]. *PTEN* is also known to be critically important both during embryonic development and in mature organisms as a tumor suppressor^[30-32]. Studies of *PTEN* functions have provided a novel insight into the regulation of apoptosis, migration and tumor progression. *PTEN* appears to serve as a hub or switchpoint linking complex signaling pathways^[33,34].

HCC presents a major health threat in South-East Asia, especially in China. It ranks the third among all malignancies both in incidence and mortality in China and accounts for approximately 42.5% of the total incidence worldwide^[35].

Figure 4 Activity of *PTEN* promoter in 8 cell lines.

As a tumor suppressor gene, *PTEN* expression is downregulated in tumors and tumor cell lines by genetic and epigenetic mechanisms^[26]. Therefore, it is very important to study the regulation of *PTEN* expression in human HCC cell lines. In this study, the results of Western blot analysis demonstrated that the protein level of *PTEN* in L02 cells was the highest among 8 cell lines, whereas there was almost undetectable *PTEN* protein expression in HepG2 cells. Northern blot analysis showed that the profile of *PTEN* mRNA in 8 cell lines almost parallelized to the profile of *PTEN* protein, indicating that the variation of *PTEN* protein was mostly dependent on the change of *PTEN* mRNA. Moreover, deletions or mutations of *PTEN* gene are associated with a variety of human cancers^[12]. Does such deletion or mutation of *PTEN* gene exist in HCC cell lines, causing the cut down of *PTEN* expression in HCC cell lines? The sequence analysis of *PTEN* cDNA and *PTEN* promoter region showed no mutations in these HCC cell lines. Hence the downregulation of *PTEN* expression in HCC cell lines probably existed in transcriptional or post-transcriptional levels.

The deletion analysis of *PTEN* promoter showed that the fragment of 612 bp (-1 389/-778) could produce maximum promoter activity in 8 cell lines and the core region of *PTEN* promoter was within the 341 bp (-1 118/-778) fragment. The full-length fragment possessing low activity indicated that the double ends of the 612 bp fragment contained suppressive elements or special structures. We used the Genomatix Suite/MatInspector software^[36] to analyze the potential binding sites in *PTEN* core promoter region and its downstream DNA sequence (-1 118/-160 bp), and found a variety of binding sites for p53, NF-kappaB, Ap2, MAZ, Sp1, E4F and Egr-1. Particularly, there were five MAZ binding sites in core promoter region (-1 118/-778) area and 11 Egr-1 in its downstream area (-779/-160). Our results suggested that these two transcription factors might play an important role in control of *PTEN* expression. After the transfection of pGL3-612 (-1 389/-778), which could produce maximum promoter activity into 8 cell lines, we found the profile of *PTEN* promoter activity was almost parallelized with the profiles of *PTEN* mRNA and *PTEN* protein in 8 cell lines. Furthermore, a recent study reported that the *PTEN* had no internal ribosome entry site (IRES) that could mediate cap-independent initiation of translation^[18]. Taken together, we conclude that the downregulation of *PTEN* expression in 7 HCC cell lines may not be responsible for the mutation of *PTEN*, but mainly contribute to the loss of *PTEN* promoter activity.

ACKNOWLEDGMENT

We gratefully acknowledge the kind support of Dr. Sui-Quan Wang in our research for the using of luminometer Lumat LB 9507.

Abstract

AIM: Type IV collagenase including MMP-2 and -9 plays an important role in cancer cell invasion and metastasis and is an attractive target for mAb-directed therapy. The immunoreactivity of mAb 3G11, a mAb directed against type IV collagenase in human colorectal carcinomas, was studied by immuno-histochemical (IHC) staining. mAb 3G11 was conjugated to an antitumor antibiotic lidamycin (LDM). The antitumor activity of 3G11-LDM conjugate against colon carcinoma was investigated in mice.

METHODS: ELISA, gelatin zymography, and Western blot assay were used for the biological characterization of mAb 3G11. The immunoreactivity of mAb 3G11 with human colorectal carcinomas was detected by IHC staining. The cytotoxicity of LDM and 3G11-LDM conjugate to human colon carcinoma HT-29 cells was examined by clonogenic assay and MTT assay. The therapeutic effect of conjugate 3G11-LDM was evaluated with colon carcinoma 26 in mice.

RESULTS: As shown in ELISA, mAb 3G11 reacted specifically with type IV collagenase, while 3G11-LDM conjugate also recognized specifically its respective antigen. In IHC assay, mAb 3G11 showed positive immunoreactivity in most cases of colorectal carcinoma, and negative immunoreactivity in the adjacent non-malignant tissues. By gelatin zymography, the inhibition effect of mAb 3G11 on the secretion activity of type IV collagenase was proved. In terms of IC_{50} values in MTT assay, the cytotoxicity of LDM to human colon carcinoma HT-29 cells was 10 000-fold more potent than that of mitomycin C (MMC) and adriamycin (ADM). 3G11-LDM conjugate also displayed extremely potent cytotoxicity to human colon carcinoma HT-29 cells with an IC_{50} value of 5.6×10^{-19} mol/L. 3G11-LDM conjugate at the doses of 0.05 and 0.1 mg/kg inhibited the growth of colon carcinoma 26 in mice by 70.3 and 81.2%, respectively.

INTRODUCTION

There were 622 000 deaths of colorectal cancer globally in 2002 according to the World Health Report 2004 of WHO. Colorectal cancer can be considered as a complex disease, with a combination of predisposing genetic variants and environmental factors that contribute to the illness as a whole. Since colorectal carcinoma is a leading cause of cancer death in the world, many therapeutic strategies are being investigated, among which the recent major achievements are Avastin and Erbitux, as antibody therapeutics approved for treatment of refractory and advanced colorectal carcinoma by the FDA of USA in 2004. This indicates that antibody-based drugs are promising for colorectal cancer therapy.

Lidamycin (LDM), also called C-1027, is a member of enediyne antitumor antibiotics family and binds to the minor groove of DNA, causing double-strand breaks and apoptosis. LDM consists of an apoprotein (LDP) of 10.5 ku and an enediyne chromophore (LDC) of 843 Da. These two parts of the molecule, connected each other through non-covalent binding, can be dissociated and reconstituted^[1,2]. Because of its extremely potent cytotoxicity against cancer cells and its remarkable activity of anti-angiogenesis and anti-metastasis, LDM can serve as an "effector" agent or "warhead" molecule to construct immunoconjugates^[3-5]. In addition, as a potential chemotherapeutic agent for cancer treatment, LDM has recently entered phase I clinical trials.

Type IV collagenase (also called gelatinases including MMP-2 and -9), as the main member of MMPs family, is of particular interest in the study of antibody-based drugs because the enzyme plays an important role in cancer invasion and metastasis. Using type IV collagenase as a molecular target, mAb 3G11 directed against MMP-2 and -9 was herein produced, analyzed, and evaluated for targeting

cancer therapy. Previous studies have demonstrated that 3G11-LDM immunoconjugate remarkably suppresses the growth of hepatoma 22 (H22) and increases the survival time of tumor bearing mice. Moreover, the antitumor efficacy of the conjugate was higher than that of free LDM or mAb 3G11 alone^[6]. In order to reduce the molecular size of agent, e.g. from the mAb to Fab' and even to the Fv, a series of antibody-based drugs have been studied in our laboratory^[7,8]. Utilizing anti-tumor and anti-metastasis mAb 3G11 as a therapeutic agent or as a carrier in cancer treatment may enhance the selectivity of chemotherapy.

In this study, we observed the immunoreactivity of mAb 3G11 with 32 cases of human colorectal carcinoma specimens by IHC staining. For further characterization of the mAb, Western blot assay, ELISA, and gelatin zymography were performed. mAb 3G11 was used as a targeting carrier for colon cancer as it demonstrated a highly specific immunoreactivity to human colorectal carcinoma. 3G11-LDM immunoconjugate was prepared and its antitumor efficacy against colon carcinoma was examined.

MATERIALS AND METHODS

Materials

Highly purified LDM was prepared in our institute. MTT was obtained from Sigma Chemical Co., (St. Louis, MO, USA). Mitomycin C (MMC) was purchased from Kyowa Hakko Kogyo Co., Ltd.

Preparation of monoclonal antibody and conjugate

mAb 3G11, a murine IgG1-type mAb, was prepared using type IV collagenase (SIGMA Inc.) to immunize BALB/c mice. According to our previous methods, mAb 3G11 was purified by sequential affinity and size-exclusion chromatography on protein G and Superose-12 columns and then used for conjugation with LDM immediately. The 3G11-LDM conjugate was formed by heterobifunctional crosslinking reagent *m*-maleimidobenzoyl-*N*-hydroxy-succinimide ester (MBS) through linkage of the amino group of LDM apoprotein with the 3G11 molecule at molecular ratio of 1:1 in our laboratory.

Cells and cell culture

The following cancer cell lines were used: human colon carcinoma HT-29 cells, human fibrosarcoma HT-1080 cells, human breast carcinoma MCF7 cells, mouse colon carcinoma 26 cells, mouse hepatoma 22 cells. All the cell lines were cultured in RPMI 1640 medium (Gibco BRL Inc.) supplemented with 10% heat-inactivated fetal bovine serum (FBS, Gibco BRL Inc.), 0.03% L-glutamine, 100 µg/mL streptomycin and 100 IU/mL penicillin at 37 °C in a humidified atmosphere containing 50 mL/L CO₂. For use in experiments, cells grown in exponential phase were disaggregated to single cells by treatment with trypsin/EDTA for 2 min.

Specimens of human colorectal carcinomas

Tumor tissue specimens collected by standard surgical oncology procedures were obtained from the Pathology 20% glycerin, 2% SDS, 0.1% bromophenol blue. Samples

Department of Friendship Hospital in Beijing. A total of 32 cases of colorectal carcinoma were examined. The specimens were fixed in 40 mL/L formaldehyde in PBS (pH 7.0) and embedded in paraffin.

Immunohistochemical staining

Paraffin-embedded tissue sections of 4 µm thickness were placed on APES-coated slides. Immunohistochemical (IHC) staining of the sections was performed after dewaxing and rehydrating. Then the sections were incubated in 0.3% H₂O₂ for 15 min, blocked by normal mouse serum for 30 min, and incubated with primary mouse mAb (3G11) overnight at 4 °C. IHC staining was performed by the labeled streptavidin-biotin immunoperoxidase technique with SABC kit (Bostern Inc.). After each step, the sections were washed thrice with PBS. Finally, 3,3'-diaminobenzidine-hydrogen peroxide (DAB, Bostern Inc.) was used as a chromogen for visualized reaction. For negative control, PBS and irrelevant mAb F9 were used instead of the primary antibody.

The IHC intensity of various colorectal carcinoma cases was assessed by image analysis and semiquantitative scoring, respectively. The sections were observed under a microscope. Manual evaluation of staining results was performed according to the general methods by semiquantitative scoring^[9]. For quantitative evaluation of mAb 3G11 staining, each tumor section was examined by the image progressing and analysis system (Leica Inc.) in 20 representative high-power fields (×400).

Western blot assay

Total cell extraction from human colon carcinoma HT-29 cells, human fibrosarcoma HT-1080 cells and human breast carcinoma tissue lysate (Prosci Inc.) was performed by Western blot assay. The samples in the cold lysate buffer (50 mmol/L Tris-HCl, 150 mmol/L NaCl, 1% Nonidet P40, 0.5% sodium deoxycholate, 2 mg/L aprotinin, 2 mg/L leupeptin, 2 mmol/L AEBSF, pH 8.0) were electrophoresed on 10% gradient SDS-polyacrylamide gels in the presence of β-mercaptoethanol. The proteins were transblotted onto a PVDF membrane, blocked with 5% BSA/TBS for 2 h and incubated with primary antibody (mAb 3G11) overnight at 4 °C and then with peroxidase-conjugated goat anti-mouse IgG (Zhongshan Inc.) at room temperature for 1 h. The membrane was washed and the antibody reaction was visualized using Western blot luminol reagent: sc-2048. The membrane was scanned and the data were fed into the computer by image analysis system (AIO Inc.).

Gelatin zymography

Gelatinolytic activity of HT-29 cells was analyzed according to the method described previously^[10]. The cells at the concentration of 1×10⁶/mL were incubated for about 18-24 h with mAb 3G11 in serum-free 1640 medium and PBS. After low-speed centrifugation at 3 000 r/min to remove cellular debris, the condition medium (CM) was collected. All sample volumes were adjusted with PBS to 1 g/L of total protein to obtain a uniform protein content of 20 µg per sample. Then 20 µL of CM was mixed with 10 µL of 3× sample buffer containing 10 mmol/L Tris-HCl (pH 6.8),

(30 μ L) were then separated by electrophoresis on 10% polyacrylamide gel containing 0.1% SDS and 1% gelatin as a substrate. Thereafter, gels were washed in the reaction buffer (50 mmol/L Tris-HCl, pH 7.6, 0.15 mol/L NaCl, 10 mmol/L CaCl₂, 0.02% NaN₃) containing 2.5% Triton-X 100 for 1 h to remove SDS. During this process, progelatinases A and B were autocatalytically activated *in situ*. Gels were then incubated for 24 h at 37 °C in the reaction buffer and stained with 0.1% Coomassie-brilliant blue R-250. The location of gelatinolytic activity was detectable as a clear band in the background of uniform staining. The blank bands were scanned and saved by the image system (AIO Inc.).

Enzyme-linked immunosorbent assay

Above-mentioned single-cell suspension volume was placed into the poly-L-lysine-coated 96-well ELISA plates (Costar Inc.) containing 1×10^5 cells/100 μ L per well at 4 °C overnight. After being blocked with a solution of BSA (1 mg/100 mL in PBS) and washed thrice with 0.05% Tween-20 in PBS (PBST), plates were incubated with primary antibody (mAb 3G11 or 3G11-LDM conjugate) and goat-anti-mouse IgG-conjugated horseradish peroxidase for 1 h at 37 °C, respectively. Following six washes with PBST, *o*-phenylenediamine-hydrogen peroxide (OPD-H₂O₂) substrate was used as a chromogen for visualization. Finally, the reaction was stopped by the addition of 100 μ L of 0.1 mol/L H₂SO₄, and the absorbance readings (490 nm) were taken using a microplate reader (Bio-Rad Inc.).

MTT assay

Cells were detached by trypsinization and seeded at 3 000 cells/well in a 96-well plate (Costar, Cambridge, MA, USA) overnight. Then different concentrations of LDM, adriamycin (ADM), and MMC were added and incubated for an additional 48 h. The effect on cell growth was examined by MTT assay. Briefly, 20 μ L of MTT solution (5 mg/mL) was added to each well and incubated at 37 °C for 4 h. The supernatant was aspirated, and the MTT formazan formed by metabolically viable cells was dissolved in 150 μ L of DMSO, and then monitored by a microplate reader (Bio-Rad) at a wavelength of 560 nm.

Clonogenic assay

Cancer cells at the concentration of 50 cells/well were seeded in 96-well plates and cultured for 24 h, then treated with LDM or 3G1-LDM at 37 °C for 1 h. Subsequently they were incubated for 5-7 d. Colonies formed were scored microscopically and the survival fractions (% control) were calculated using the following formula: survival fraction = (colony number of control well-colony number of treated well)/colony number of control well.

In vivo therapy studies

Female BALB/c mice (20 \pm 2 g, 7 wk of age, obtained from the Institute for Experimental Animals, CAMS) were inoculated subcutaneously with murine colon carcinoma 26 cells (1.5×10^6 cells/mouse). Mice were divided randomly into untreated control group and six treatment groups, and carefully monitored for general well-being, body weight, and

tumor size. Diameter of the tumor was measured twice a week with a caliper. Tumor volume was calculated with the following formula: $v = 1/2ab^2$, where *a* and *b* are the long diameter and its perpendicular short diameter of the tumor, respectively. The data were presented as mean \pm SD. Student's *t*-test was used to determine statistically significant differences.

RESULTS

Immunohistochemical staining of tumors with mAb 3G11

MAb 3G11 showed positive immunoreactivity in 81.3% (26/32) of cases of colorectal carcinoma, 43.8% (7/16) of cases of mammary carcinoma, 63.6% (7/11) of cases of gastric carcinoma, and 66.7% (4/6) of cases of esophageal carcinoma, respectively. Cytoplasmic staining tended to be strongest in the cells at the periphery or invasive margin of the tumors and in the cells at the margin of tumor nests, whereas adjacent non-neoplastic tissues showed negative staining (Figure 1).

Figure 1 Immunohistochemical staining of mAb 3G11 in human colon carcinoma section. **A:** Colon carcinoma (100 \times , the bar represents 400 μ m in length.); **B:** the same case of A (400 \times , the bar represents 100 μ m in length.); **C:** (100 \times) and **D:** (400 \times): another case of typical colon adenocarcinoma.

Moreover, we found a significant correlation between the evaluation method of 3G11 immunostaining by computer image analysis and by semi-quantitative scoring (Figure 2). The consistent results assessed by both manual methods and quantitative image analysis system proved that 3G11 showed highly specific immunoreactivity with human colon carcinomas and that quantitative estimation might also serve as an useful approach for IHC analysis.

Western blot analysis

MAb 3G11 was characterized by Western blot analysis and two specific electrophoretic bands of 72 and 92 ku in the cell or tissue lysates are shown, supporting the IHC results (Figure 3). The appearance of two bands indicated that other matrix metalloproteinase present in the samples did

not cross-react with mAb 3G11. The intensity of two bands of 72 and 92 ku was different in various cell lines and tissue lysates. The results indicated that the expression level of gelatinase was different in various tumors.

Gelatin zymography assay

Both active and latent species could be visualized by using this technique. It showed that the clearance of the gelatin substrate by gelatinases with 72 and 92 ku was detected as a negative staining band, respectively. As shown, both the secreted activity of 72 and 92 ku gelatinases in human colon carcinoma HT-29 cells was inhibited by mAb 3G11 in a dose-dependent manner (Figure 4).

Immunoreactivity of mAb 3G11 and immunoconjugate 3G11-LDM

The binding of mAb 3G11 to antigen-related cancer cells including HT-29, H22, and C26 cells, which expressed type IV collagenases including MMP-2 and -9, is shown in a concentration-dependent manner ranging from 0.01 to 0.3 $\mu\text{mol/L}$ of 3G11 (Figure 5A). The immunoconjugate 3G11-LDM still retained the immunoreactivity at a range

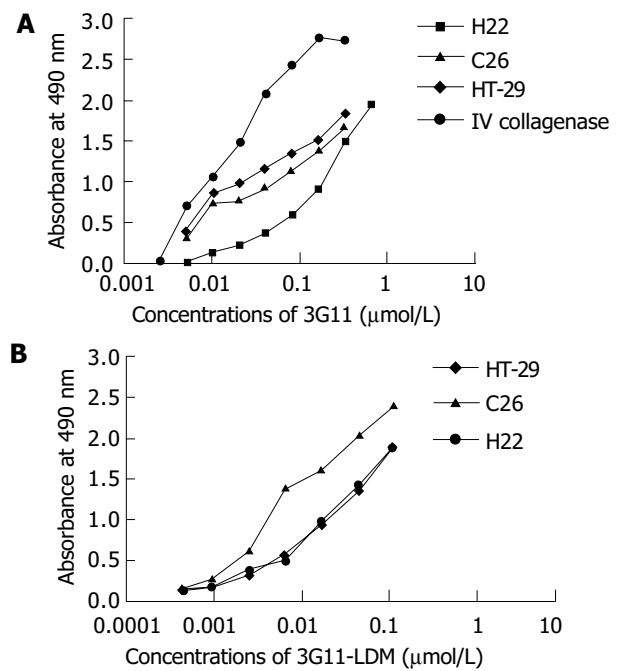

Figure 5 Immunoreactivity of 3G11(A) and 3G11-LDM (B) with type IV collagenase and various cancer cells in ELISA.

of concentrations between 0.01 and 0.1 $\mu\text{mol/L}$ (Figure 5B).

Cytotoxicity of LDM to human colon carcinoma cells

As determined by MMT assay, the IC_{50} values for LDM, ADM, and MMC to human colon carcinoma HT-29 cells were 0.042 ± 0.007 , 528.3 ± 97.7 , and 992.0 ± 93.0 nmol/L, respectively (Figure 6A).

In terms of IC_{50} values, the effect of LDM on HT-29 cells

Table 1 Growth inhibition of colon carcinoma 26 by immunoconjugate 3G11-LDM in mice

Groups	Doses (mg/kg)	Mice number (begin/end)	BWC (g)	Tumor volume (cm ³) mean±SD	Inhibition rate (%)
Control		10/10	+0.5	1.0±0.20	
3G11	0.75	10/10	+0.6	0.8±0.20	25.7 ^b
LDM	0.05	10/10	-0.2	0.4±0.16	56.4 ^b

^aP<0.05 vs LDM; ^bP<0.01 vs control; BWC = body weight change.

was 10 000-fold more potent than that of ADM and MMC.

Cytotoxicity of 3G11-LDM to human colon carcinoma cells

By clonogenic assay, the conjugate 3G11-LDM displayed extremely potent cytotoxicity to human colon carcinoma HT-29 cells (Figure 6A). The IC₅₀ value of 3G11-LDM for HT-29 cells was 5.6×10^{-10} nmol/L and that of the free LDM was 3.48×10^{-9} nmol/L.

In vivo therapy with immunoconjugate 3G11-LDM

According to the results on d 10 (Table 1), the tumor growth of colon carcinoma 26 in mice treated with 3G11-LDM was significantly inhibited by 54.5%, 70.3%, and 81.2% at the dose of 0.025, 0.05, and 0.1 mg/kg, respectively. It proved that 3G11-LDM showed higher anti-tumor efficacy against colon carcinoma in mice, as compared to the results of either free LDM or mAb 3G11.

DISCUSSION

Though numerous patients with alimentary tract carcinoma could be successfully induced into first remission by chemotherapy or radiotherapy, most of these patients ultimately have a relapse within 3-5 years. In addition, chemotherapy is accompanied with substantial side effects because of the non-specificity of the cytotoxic drugs. Therefore, it is clear that novel or additional therapy approaches are required. A promising therapy is antibody-targeted chemotherapy, which allows the specific delivery of cytotoxic drugs to the tumor tissues and is likely to have minimal toxic side effects^[11,12]. Owing to its high potency cytotoxicity and molecular constitution, LDM may be successfully applied as a promising “warhead” in the production of antibody-based targeting therapeutics. The FDA-approved Zevalin and Bexxar are radioimmunotherapeutics derived from murine mAb. Their clinical application indicates that murine mAb may be used for cancer therapy under certain circumstances.

MMPs are now known to contribute tumor progression in addition to invasion, including tumor promotion, angiogenesis, and the establishment and growth of metastatic lesions in distant organ sites^[13]. There is evidence that the expression of MMP-2 and -9, two of the most important MMPs, are linked to enhanced tumor angiogenesis, tumor invasion, and metastasis^[14-16]. By IHC staining in our studies, mAb 3G11 showed significant immunoreactivity with gelatinases in various human tumor tissues, especially in human colon carcinoma specimens, and no cross-reaction

with adjacent non-neoplastic tissues was found. The IHC staining of mAb 3G11 was found to localize in most colon carcinoma cells and a few of surrounding fibroblasts. Our IHC results are in accordance with some previous reports^[17]. MMP-2 and MMP-9 expression is more frequently found at the lateral and deep margins of the tumors as observed by immunohistological staining. Among the examined human cancer specimens, mAb 3G11 had the strongest staining intensity and the highest positive rate in colon carcinomas, suggesting that mAb 3G11 has highly specific immunoreactivity with human colon carcinoma and this is the key reason for the use of mAb 3G11 as a carrier for antibody-based therapy.

Inhibitors of MMPs (MMPIs) can be used to halt the spread of cancer. MMPIs do not directly kill cancer cells, but instead targets processes such as cancer cell invasion and metastasis. However, many initial clinical trials using MMPIs proved to be disappointing^[18]. 3G11-LDM is a conjugate composed of a mAb directed against type IV collagenase, including MMP-2 and -9, and LDM displays extremely potent cytotoxicity. This antibody can inhibit the enzyme activity and selectively bind to the target enzyme in tumor tissues. 3G11-LDM conjugate has potent antitumor efficacy both *in vivo* and *in vitro*.

In conclusion, 3G11-LDM is a promising agent for targeted cancer chemotherapy, especially for colorectal carcinoma.

INTRODUCTION

The safety of current treatments for chronic hepatitis C is still under debate. Studies published to date demonstrate that pegylated interferons (both alpha [α]-2a and α -2b) in combination with ribavirin could eradicate the hepatitis C virus (HCV) in 47-56% of infected subjects^[1,2]. However, a consistent number of patients experience significant adverse events, such as severe gastrointestinal symptoms, psychiatric disorders, dermatological symptoms, autoimmune disorders and significant laboratory abnormalities (neutropenia, anemia, thrombocytopenia)^[3]. The severity of these adverse events has led to treatment discontinuation in both controlled trials and in clinical practice. In the first clinical trial^[1] of pegylated interferon (PEG-IFN) α -2b with ribavirin, side effects prompted withdrawal of therapy in 13-14% of patients. In the first clinical trial of PEG-IFN α -2a with ribavirin^[2], 22% of patients treated with the combination and 32% treated with PEG-IFN α -2a alone, discontinued therapy. The discontinuation rates reported with standard formulations of IFN- α were high. The pivotal IFN- α -2b and ribavirin trial performed by McHutchinson *et al.*^[4], demonstrated a discontinuation rate of 21% in patients treated for 48 wk.

Not surprisingly, the side effects may have pronounced negative impact in the general population than in clinical trial subjects; Gaeta and colleagues found that 24.5% of patients treated with IFN- α plus ribavirin in the regular clinical-practice setting failed to complete treatment due to adverse events^[5]. Therefore, safe and effective alternatives to IFN- α could be of value to patients who cannot tolerate PEG-IFN.

Previous pilot studies have shown that IFN β -1a is effective in HCV eradication^[6] and its use is safe and well tolerated^[7,8]. A trial was performed in patients resistant to a previous treatment with IFN- α treated with recombinant human interferon (IFN) β -1a at different schedules

Abstract

AIM: To compare the efficacy and safety of recombinant human IFN β -1a alone or in combination with ribavirin in treatment-naïve subjects with chronic hepatitis C.

METHODS: Open, randomized trial was performed in 6 Italian tertiary centers: 102 of the 108 patients screened were randomized to receive 6 MIU of recombinant human IFN β -1a subcutaneously daily for 24 wk, alone (Group 1, $n = 51$) or in combination with ribavirin 1 000 to 1 200 mg/d (Group 2, $n = 51$).

RESULTS: The end-of-treatment virologic response rate was 29.4% in Group 1 and 41.2% in Group 2 (non-significant). Twenty-four weeks after stopping therapy, sustained virologic response rate was 21.6% in Group 1 and 27.4% in Group 2 (non-significant). All subjects in Group 1 completed treatment, while two subjects in Group 2 stopped therapy due to treatment-related adverse events.

CONCLUSION: Recombinant human IFN β -1a, alone or in combination with ribavirin, has an excellent safety profile and, may represent an alternative for chronic hepatitis C patients who are unable to tolerate pegylated α -interferon.

(up to 24 MIU every d for 48 wk) but it failed to induce a significant response rate. A post hoc analysis was performed to stratify the patients according to the race and it showed a sustained virological responses of 21.7% in the Chinese subjects enrolled in the trial^[9].

In this open clinical trial, we investigated the safety and efficacy of subcutaneous r-hIFN β -1a alone or in combination with ribavirin in the treatment of chronic hepatitis C patients naïve to therapy.

MATERIALS AND METHODS

Study design

Using a 4-block, centralized randomization list, patients were randomly assigned to receive r-hIFN β -1a 6 MIU/d (22 μ g/d) subcutaneously for 24 wk, either alone (Group 1, $n = 51$) or in combination with ribavirin (Group 2, $n = 51$).

Ribavirin was given at a dose of 1 000 mg/d (five capsules) to patients weighing less than 70 kg and 1 200 mg/d (six capsules) to those weighing 70 kg or over.

Randomized patients who withdrew from the study without taking the first treatment dose were substituted. Patients who withdrew from the study after receiving the first treatment dose were not substituted and were considered as dropouts.

Patient selection

Patients from six tertiary centers in Italy were recruited. Subjects were eligible for inclusion in the trial if they met the following criteria: age between 18 and 70 years; positive serum anti-HCV and HCV-RNA tests; no previous therapy with IFN; alanine-aminotransferase (ALT) level more than 1.5 times the upper normal limit, on two different assessments in the past 12 mo and at the screening visit; and a liver biopsy performed within 36 mo prior to enrollment consistent with a diagnosis of chronic hepatitis C without cirrhosis.

Patients were excluded if they had leukopenia (less than $3.0 \times 10^9/L$), neutropenia (less than $1.5 \times 10^9/L$), anemia (hemoglobin less than 12 g/dL in women and 13 g/dL in men), thrombocytopenia (less than $100 \times 10^9/L$), serum albumin less than 30 g/L, total bilirubin more than three times the upper normal limit, other significant hepatic diseases (including HBV infection), psychiatric disorders requiring treatment, or serious chronic diseases (including tumors and HIV infection). Patients were also excluded if they had received antiviral or immunosuppressive drugs during 6 mo preceding inclusion in the study. Females were included if they were pregnant or breast-feeding, and were not considering childbearing for the entire treatment period.

The therapeutic protocol was approved by the local ethical committee and the study was carried out according to the 1975 Declaration of Helsinki and Good Clinical Practice guidelines. All patients provided written informed consent before treatment was initiated.

Assessment of efficacy

Quantitative viremia was assessed at baseline to allow patient classification on the basis of viral load. A cut-off limit of

800 000 IU/mL (corresponding to 2 million copies/mL) was used to classify patients as having either low or high viral counts. From the fourth week of treatment to the end of follow-up, the virologic assessment was performed using qualitative viremia. Evaluations were performed using a polymerase chain reaction (PCR) assay (Cobas Amplicor HCV test, version 2.0; Roche Diagnostics, Basel, Switzerland; lower limit of detection 100 copies, corresponding to 40 IU/mL).

The trial endpoints were: (1) the rate of sustained virological responses (SVR); (2) the percentage of patients with normal aminotransferase levels at 24 wk of treatment (wk 24) and 24 wk post-treatment (wk 48); and (3) the safety and tolerability of r-hIFN β -1a alone or in combination with ribavirin.

Data were evaluated using an intention-to-treat analysis and included all subjects who received at least one treatment dose. Patients were considered as sustained virologic responders, if the qualitative serum HCV-RNA test performed 24 wk post-treatment (wk 48) was negative. Patients treated with r-hIFN β -1a alone were withdrawn from the trial if HCV viremia persisted after 12 and 18 wk of treatment.

Safety assessment

Patients were examined at baseline, after 4, 8, 12, 18, and 24 wk of treatment and at wk 12 and 24 post treatment. Routine laboratory tests, and autoantibody and IFN- β binding antibody (BAB) assessments were performed at each visit.

The following autoantibody evaluations were conducted at the coordinating center: ANA (anti-nuclear), AMA (anti-mitochondrial), ASMA (anti-smooth muscle), LKM (anti-liver/kidney microsome type 1), APC (anti-parietal cells), ABBA (anti-brush border), MT (anti-thyroid microsomal), TGA (anti-thyroglobulin), MB (anti-basement membrane of tubule/glomerular), R1 (anti-R1 type reticulin) and R2 (anti-R2 type reticulin). Autoantibodies were tested by indirect immunofluorescence on murine liver, kidney and stomach and human thyroid. IgA, IgG, and IgM were detected with fluorescein isothiocyanate^[10]. BABs were determined using a radioimmunobinding assay (RIBA)^[11].

In cases of grade III adverse events (according to the WHO classification), the dose of r-hIFN β -1a was reduced to 3 MIU/d. If anemia occurred, the dose of ribavirin was reduced according to the investigator's judgment.

Statistical analysis

Statistical analyses and data processing were performed using SAS software (version 8 for Windows). Both descriptive analyses and inferential tests were used to analyze the data. The significance level of all tests was set at 5%. The baseline characteristics of the two groups were compared using t -test and χ^2 test. χ^2 test was used to evaluate the significant difference between two treatment groups for end-of-treatment response rate (ETR), SVR rate, and ALT/AST normalization. Logistic regression model was used to evaluate the SVR rate adjusting the ORs for factors predictive of treatment response, like viral levels, genotype, class of age, etc.

The proportion of patients in each treatment group experiencing at least one adverse event that was likely related

to the study drug(s) was compared using the χ^2 test.

RESULTS

Patient characteristics

One-hundred-and-eight patients were enrolled from May 29, 2000 to June 1, 2001. One-hundred-and-two met the inclusion criteria and were randomized to one of the two study groups: 51 patients received r-hIFN β -1a alone and 51 received r-hIFN β -1a in combination with ribavirin. Of the six subjects not admitted into the trial (i.e., not included in the intention-to-treat analysis), two did not meet the inclusion criteria and four refused to sign the informed consent form.

The baseline characteristics were similar in the two groups (Table 1). Twenty-one patients (41.1%) in Group 1 and 24 (47%) in Group 2 had high viral levels. Thirty-one patients (60.8%) treated with r-hIFN β -1a alone and 33 (64.7%) treated with combination therapy were infected with HCV genotype 1.

Table 1 Summary of demographic and clinical characteristics at baseline

	Group 1	Group 2
Patients (n)	51	51
Sex (M/F)	29/22	36/17
Mean age (yr) \pm SD	45 \pm 11.7	43.9 \pm 9.0
Hemoglobin (g/dL)	14.8 \pm 1.3	15 \pm 1.3
Platelets ($\times 10^9$ /L)	195.9 \pm 45	203.9 \pm 54
Leukocytes ($\times 10^9$ /L)	6.7 \pm 1.4	6.8 \pm 1.9
ALT (mean \pm SD)	142.7 \pm 86.2	123.2 \pm 78.7
HCV-RNA quantitation (Meq/mL)		
Low viremia	27	23
High viremia	21	24
Undetermined	3	4
Genotype		
1	31	33
2	6	8
3	12	8
4	2	1
Undetermined	0	1

Virologic response

After 12 wk of treatment, 41.2% (21/51) of patients in Group 1 and 47.1% (24/51) in Group 2 showed clearance of serum HCV-RNA (Table 2). By the end of the treatment period (wk 24), the response rate had diminished to 29.4% (15/51) and 41.2% (21/51) in Groups 1 and 2, respectively. After the 24-wk post-therapy follow-up (wk 48), 11 patients (21.6%) in Group 1 and 14 (27.4%) in Group 2 maintained a SVR. There was no statistically significant difference between the two groups in the percentage of

patients negative for viremia at the end of the treatment period ($P = 0.2138$) or at the completion of follow-up (wk 48) ($P = 0.4898$).

Multivariate analysis showed that genotype (OR = 0.39; 95%CI, 0.21-0.72; $P = 0.0025$) and baseline viremia level (OR = 2.1; 95%CI, 1.17-3.96; $P = 0.0141$) were factors predictive of response. Among patients with genotype 1, the rate of response was 12.9% (4/31) in Group 1 and 12.1% (4/33) in Group 2, respectively *vs* 35% (7/20) in Group 1 and 52.9% (9/17) in Group 2 patients with genotype non-1 (NS, Table 3). The genotype was not determined in one patient in Group 2 who responded to therapy.

Among subjects with high viral loads, the response rate was 4.8% (1/21) and 16.6% (4/24) in Groups 1 and 2, respectively, compared to 33.3% (9/27) and 34.8% (8/23) in patients with low viremia in Groups 1 and 2, ($P = 0.2972$, Table 4). The viral load was not determined in three patients in Group 1 and four patients in Group 2.

Table 3 Rate (number responding/total treated) of patients with negative viremia after the 24-wk post-therapy follow-up according to genotype

	1	Non-1	Not determined
r-hIFN β -1a	12.9% (4/31)	35.0% (7/20)	–
r-hIFN β -1a + ribavirin	12.1% (4/33)	52.9% (9/17)	(1/1)

Between group difference not significant.

Table 4 Rate (number responding/total treated) of patients with negative viremia after the 24-wk post-therapy follow-up according to viral load (cut-off 800 000 IU)

	Low	High	Not determined
r-hIFN β -1a	33.3% (9/27)	4.8% (1/21)	(1/3)
r-hIFN β -1a + ribavirin	34.8% (8/23)	16.6% (4/24)	(2/4)

Between group difference, $P = 0.2972$.

Biochemical response

At the end of the treatment period, 27.5% of patients (14/51) in Group 1 and 39.2% (20/51) in Group 2 exhibited normal aminotransferases associated with a virologic response. At the end of the follow-up period (wk 48), 21.6% (11/51) and 25.5% (13/51) of patients in Groups 1 and 2, respectively, maintained normal aminotransferase levels; the χ^2 test showed no significant difference between

Table 2 Rate (number responding/total treated) of patients with negative viremia during the course of the trial

	Screening	T4	T8	T12	T18	T24	T48
r-hIFN β -1a (n = 51)	0 (0%)	18 (35.3%)	16 (31.4%)	21 (41.2%)	16 (31.4%)	15 (29.4%)	11 (21.56%)
r-hIFN β -1a + ribavirin (n = 51)	0 (0%)	13 (25.5%)	22 (43.1%)	24 (47.1%)	21 (41.2%)	21 (41.2%)	14 (27.45%)

treatment groups ($P = 0.2076$ at wk 24; $P = 0.6406$ at wk 48). Three patients showed abnormal levels of aminotransferase despite the clearance of HCV-RNA in serum, possibly due to concomitant steatohepatitis.

Among the patients who remained viremic, 22.2% (8/36) of those in monotherapy and 36.6% (11/30) of those in combination treatment exhibited normal aminotransferase levels at the end of therapy ($P = 0.1969$); Of these patients, 17.5% (7/40) in Group 1 and 37.8% (14/37) in Group 2 maintained normal levels at wk 48 ($P = 0.0453$).

Safety evaluation

Ninety-nine of the one hundred and two patients enrolled completed treatment according to protocol. Drug discontinuation due to adverse events occurred in three (all in the combination therapy group) of the 102 patients. One patient stopped treatment due to the incidental discovery of ovarian cancer (not related to the study drugs). In the remaining two cases, treatment was discontinued due to depression and acute psychosis; both events were considered to be related to therapy.

At each time-point of the study, between 86.4% and 100% of patients received the expected doses of IFN- β and ribavirin according to protocol. No patient failed to complete the study due to poor compliance.

In patients treated with combination therapy, the mean hemoglobin level dropped from 14.9 to 12.6 g/dL, while in Group 1 from 14.8 to 14.3 g/dL. Treatment interruptions or dose reductions were not required in any subject. In patients treated with monotherapy, there was a mean drop in platelet count from $195.9 \pm 45 \times 10^9/L$ to $175.0 \pm 41.5 \times 10^9/L$; in Group 2, there was a mean increase from $204.1 \pm 54.0 \times 10^9/L$ to $206.1 \pm 66.4 \times 10^9/L$. The leukocyte count dropped from $6.7 \pm 1.4 \times 10^9/L$ to $5.8 \pm 1.3 \times 10^9/L$ and from $6.7 \pm 1.9 \times 10^9/L$ to $5.2 \pm 1.8 \times 10^9/L$ in Groups 1 and 2, respectively.

Thirty-seven percent of subjects (19/51) treated with IFN- β and 49% (25/51) of those in Group 2 reported at least one mild adverse event during the study (Table 5). The difference between the two groups was not significant.

Only mild titer increases of pre-existing autoantibodies were observed. Compared to baseline, ANA increased in two patients and decreased in one; ASMA decreased in two cases and MT as well as MB increased in one patient. None of the patients developed autoimmune disease.

BABs developed in 11 patients (12%) and usually appeared within 8 to 12 wk of treatment; titers ranged between 5.0 and 20 AU in three of these patients and were less than 5.0 AU in eight patients. There was no difference between Group 1 and Group 2 with regards to BAB development and no correlation was found between BABs development and response to treatment.

DISCUSSION

In contrast to the variety of IFN- α , of which there are 25 subtypes with molecular weights ranging from 17.5 to 23 ku^[12], only one type of IFN- β has been identified in human beings. Though its amino-acid sequence differs from IFN- α by as much as 70%, IFN- β shares many antiviral properties of interferon alpha, thereby providing an alternative treatment for chronic hepatitis C.

Three forms of IFN- β are available: (1) the fibroblast-derived natural IFN- β ^[13]; (2) the r-hIFN β -1a produced by mammalian cells (identical to the IFN- β naturally occurring in humans); and (3) r-hIFN β -1b produced by *E. coli*. The r-hIFN β -1a formulation was chosen for this study as it offers several advantages over the other two: it can be produced in unlimited quantities by bioengineering techniques, its batch-to-batch consistency and purity allows for dosage by mass instead of international units, and it is identical to the IFN- β naturally occurring in human beings but more potent and less immunogenic^[14].

Previous experience with IFN- α indicates that the efficacy of these agents is related to the frequency of administration. Therefore, the rationale behind the newest pegylated formulation is that a more steady and sustained release of IFN- α is more effective than the thrice-a-week administration.

The pharmacokinetic data obtained with natural IFN- β have demonstrated the significant bioequivalence of the intramuscular, intravenous, and subcutaneous routes of administration^[15]. Therefore, we have chosen to administer the cytokine via the more convenient subcutaneous route. Since the safety of r-hIFN β -1a in combination with ribavirin has not been previously determined, a 6- rather than 12-mo course of therapy was selected for this initial study.

PEG-IFN with ribavirin is currently the gold standard for the treatment of chronic hepatitis C. Though less efficacious than PEG-IFN, that consents to achieve 47-56% of SVR^[1,2], our findings suggest that r-hIFN β -1a alone or in combination with ribavirin, is as effective as conventional non-PEG-IFN α . The overall 21.6% and 27.5% SVR rates achieved in our patients treated with r-hIFN β -1a alone or in combination with ribavirin, respectively, are comparable to the 6-13% and 31-38% response rates reported with the use of IFN α -2b alone or in combination with ribavirin, respectively, for 24-48 wk^[4].

In both treatment groups, viral response rates were higher at 12 wk of therapy than at the end of the treatment period (wk 24). A possible reason for this decrease, which was more pronounced in Group 1, could be the low dosage of IFN- β used in this trial. Analogous to the results of previous IFN- α studies that assessed the efficacy of IFN monotherapy *vs* the association of the same IFN with ribavirin, combination therapy in this trial yielded better

Table 5 Adverse events possibly or probably related to study treatment, occurring with a frequency higher than 5%

results for both virologic and biochemical endpoints compared to IFN- β monotherapy.

The major factors influencing the response rate in clinical trials of IFN- α were the genotype of the infecting HCV and the level of baseline viremia: genotype 1 and high viremia were associated with a reduced response, while genotypes 2 or 3 and low viremia had a higher response. This was also the case with r-hIFN β -1a; the end-of-treatment virologic and biochemical response rates were significantly higher in our patients of genotype 2-3 and low viremia, compared to those with genotype 1 and high viremia.

The use of ribavirin, as well as prolongation of IFN treatment up to 48 wk (instead of 24 wk), not only enhances the therapeutic response, but also decreases the relapse rate after the end of treatment. This effect is negligible in patients with easy-to-treat HCV genotype 2 or 3, for whom 24 wk of IFN is sufficient to achieve a maximal SVR. On the other hand, subjects infected with HCV genotype 1 achieve a higher SVR rate after 48 wk of therapy when compared to 24 wk (despite similar end-of-treatment virological response rates after 24 and 48 wk of treatment). Unfortunately, this effect could not be evaluated in the present study, which was designed to provide a 24 wk course of treatment. In fact, several post-therapy relapses occurred in HCV-genotype 1 patients treated with combination therapy for 6 mo, resulting in an off-therapy response rate distinctly lower than that achieved upon completion of treatment.

The overall safety profile of r-hIFN β -1a, both alone and in combination with ribavirin, was remarkably favorable. Compared to previous IFN- α data, the drop-out rate in our study was low (0/51 [0%] in Group 1 and 3/51 [5.9%] in Group 2) and was due primarily to two patients who withdrew from the study as a result of treatment-related psychiatric problems.

In contrast to the 2% of patients treated with IFN- α who had developed autoimmune disorders^[16], none of our patients treated with r-hIFN β -1a developed clinical features of autoimmune diseases. Furthermore, systematic autoantibody monitoring failed to demonstrate the emergence of autoimmune reactivities during therapy or significant titer increases of pre-existing autoantibodies. Likewise, IFN- β BAB titers rose in only 12% of our patients; these increases were in the low titer ranges and were not clinically significant.

Decreases in WBC and platelet counts observed in the present study (two patients on combination therapy and three subjects on IFN monotherapy respectively) were not clinically relevant to induce discontinuation of therapy. On the contrary, IFN- α led to higher reductions in WBC and platelet counts that are often responsible for premature termination of therapy. The fall in hemoglobin level noted in our patients treated with combination therapy was expected as it is a well-recognized, side-effect of ribavirin^[17].

In conclusion, the satisfactory therapeutic effects and excellent tolerability profile of r-hIFN β -1a could represent a treatment option for patients with chronic hepatitis C who cannot tolerate PEG-IFNs. IFN β -1a may also be used as initial therapy in subjects at high risk of significant side effects with IFN- α treatment. Future studies should

evaluate the efficacy and safety of r-hIFN β -1a in subpopulations of patients with chronic hepatitis C and cirrhosis or cryoglobulinemia.

Abstract

AIM To examine the fetal and neonatal esophagogastric junction region (EGJ) histologically for the presence of an equivalent to adult cardiac mucosa (CM); to study the expression patterns of all cytokeratins (CK) relevant to the EGJ during gestation; to compare the CK profile of the gestational and the adult EGJ; and to determine the degree of development in the adult EGJ histology and CK profile during gestation.

METHODS: Forty-eight fetal autopsy specimens of the EGJ were step-sectioned and stained with hematoxylin and eosin (H&E) to select sections showing the mucosal lining. Immunohistochemistry for CK5, 7, 8, 13, 18, 19, and 20 was performed. Antibody staining was then graded for location, intensity, and degree.

RESULTS: The distal esophagus was lined by simple columnar epithelium from 12-wk gestational age (GA). The proximal part of this segment consisted of mucus-producing epithelium, devoid of parietal cells. CK5 and 13 were present exclusively in multilayered epithelia and CK8, 18, and 19 predominantly in simple columnar epithelium. There were no differences in the frequencies of the co-ordinate CK7+/20+ and the CK7-/20- immunophenotypes between different locations. The prevalence of the CK7+/20- immunophenotype decreased, and that of the CK7-/20+ immunophenotype increased significantly from the distal esophagus to the distal stomach.

CONCLUSION: Fetal columnar-lined lower esophagus (fetal CLE) may be the equivalent and precursor of the short segments of columnar epithelium found in the distal esophagus of some normal adult subjects. Esophageal simple columnar epithelium without parietal cells (ESN) may be the precursor of adult CM. The similarities between the fetal and adult EGJ and stomach CK expression patterns support the conclusion that adult CM has an identifiable precursor in the fetus. This would then indicate that at

least a part of the adult CM has a congenital origin.

INTRODUCTION

Since the mid-1970s, there has been a continuing increase in the incidence of gastric cardiac adenocarcinoma in the USA and other Western countries^[1]. This increase is probably genuine, because it cannot be explained by improved diagnostic methods or classification changes^[2]. The pathogenesis of gastric cardiac adenocarcinoma remains unclear. These tumors may arise from foci of intestinal metaplasia, secondary to inflammation of the gastric cardia (carditis)^[3]. It is controversial, however, whether factors like gastroesophageal reflux disease, *Helicobacter pylori* infection or others contribute to the development of inflammation and intestinal metaplasia in the cardia region^[4,5]. Research on this topic is hampered by the limited knowledge of the normal histology of the esophagogastric junction region (EGJ). There is no consensus on the normal histology, location, and length of cardiac mucosa (CM). Histological investigation of hematoxylin and eosin (H&E)-stained sections of the EGJ in adults and children has led some investigators to suggest that CM is actually a metaplasia^[6-9]. Others, however, support the concept that CM is present from birth as a normal structure^[10-14].

Immunohistochemical investigation of the cytokeratin (CK) profile in the EGJ can be used for the study of the origin of adult CM. The keratins are the largest group of intermediate filament proteins expressed by epithelial cells. There are at least 30 different keratins, which are divided into two types. CK filaments are obligate heteropolymers composed of type I and type II proteins. Keratins are typically expressed as pairs in a tissue- and differentiation-specific manner. In 1999, Ormsby *et al.*, described a CK7 and 20 immunoreactivity pattern typical for intestinal metaplasia in long-segment Barrett's esophagus (LSBE)^[15].

This pattern consists of superficial CK20 staining and strong CK7 staining of both superficial and deep glands. It has been claimed by the same group that Barrett's CK7/20 pattern also identifies a subset of patients with suspected short-segment Barrett's esophagus (SSBE) who have a patient profile similar to that seen in LSBE^[16]. Glickman *et al.*, reported that intestinal metaplasia of the EGJ shows a similar pattern of CK7/20 reactivity as LSBE and SSBE. They also found that non-intestinalized CM was diffusely positive for CK7 and showed surface positivity only for CK20, irrespective of its location in LSBE, SSBE or in the most proximal portion of the stomach. This CK7/20 staining pattern was clearly different from that seen in the normal antrum. According to these authors, the results suggest that CM, whether present in the esophagus or at the EGJ, may already represent a form of metaplastic epithelium^[17]. DeMeester *et al.*, found the Barrett's CK7/20 pattern in 85% of CM biopsies^[18]. On the basis of these and other findings, they conclude that there is a strong evidence but no conclusive proof that all CM is acquired.

We have earlier done a histological study on mucosal development in the EGJ of embryos and fetuses^[19]. In this study, CM was defined as a structure composed of columnar foveolar and surface epithelium overlying glandular structures containing no parietal cells. We found that CM develops during pregnancy and we concluded that it is present at birth as a normal structure. The description of the Barrett's CK7/20 pattern in adult CM and the fact that this finding has been used to claim a metaplastic origin for CM have urged us to examine our material for the presence of Barrett's CK7/20 pattern. In addition, we studied the expression patterns of all other CKs relevant to the EGJ during gestation.

MATERIALS AND METHODS

Study group

The study material was derived from 48 embryonic, fetal and neonatal autopsies performed between August 1999 and March 2004 in Leuven University Hospital Gasthuisberg. All autopsies were performed between 6 and 24 h after death. The presence of congenital malformations involving the gastrointestinal tract was considered as an exclusion criterion.

Autopsy protocol

At autopsy, a careful *in situ* examination of the EGJ was carried out. A hiatus hernia was absent in all cases. About 1 cm of the distal esophagus and the whole stomach were excised together as a single piece, with a ring of diaphragmatic muscle. Two specimens were snap-frozen in isopentane, cooled by liquid nitrogen and stored at -80 °C. The other specimens were opened along the greater curvature or transversely and fixed overnight in 10% neutral-buffered formalin. The fixed specimens were routinely processed and embedded in paraffin.

Histology

Five-micrometer-thick step sections of all cases were stained with H&E and evaluated microscopically to select sections

showing the EGJ mucosae. The number of sections selected varied between 10 and 40.

The epithelial lining of the EGJ was classified into five types according to Salenius^[20] and Chandrasoma^[21]. Foregut embryonic epithelium was defined as pseudostratified columnar epithelium consisting of undifferentiated cells; esophageal ciliated epithelium as multilayered epithelium covered by ciliated cells; esophageal squamous epithelium as non-keratinizing multilayered squamous epithelium; esophageal simple columnar epithelium without parietal cells (ESN) as simple columnar epithelium which is either flat or shows crypts, but is devoid of parietal cells; and esophageal simple columnar epithelium with parietal cells (ESP) as simple columnar epithelium with crypts and parietal cells.

The following parameters were measured at four evenly spaced points along the esophageal perimeter: length of abdominal esophagus (defined as the distance between the upper rim of the attachment of the diaphragm to the esophagus and the level of the angle of His); length of esophagus lined by simple columnar epithelium (defined as the distance from the squamocolumnar junction to the level of the angle of His); and length of ESN. These distances were measured along the mucosal surface using a calibrated graticule in the eyepiece of a Leitz DMRB microscope (objectives: Fluotar, eyepieces: L PLAN 10×/25).

Cytokeratin immunohistochemistry

Serial sections were immunostained with mAbs for CK5, 7, 8, 13, 18, 19, and 20. Murine mAbs against human CK7, 18, 19, and 20 were purchased from DakoCytomation (Glostrup, Denmark); mAbs against CK5, 8, and 13 were purchased from Novocastra Laboratories (Newcastle upon Tyne, UK, Table 1). After standard avidin-biotin-peroxidase complex immunostaining, all slides were counterstained with hematoxylin. Positive controls consisted of sections from prostate (CK5, 18, and 19), bile duct (CK7 and 8), tonsil (CK13), and ileum (CK20). Negative controls consisted of slides without application of primary antibody.

Antibody staining was graded for location, intensity (absent, weak, moderate, or strong) and degree (focal = <50% of epithelium, diffuse = ≥50% of epithelium) and compared with controls. The coordinate CK7/CK20 pattern was defined as CK7 positivity at least in surface and pit cells, and CK20 positivity at least in surface cells. The slides were scored independently by two of the authors (GDH and KG), and differences in interpretation were resolved by consensus at a multihead microscope.

Statistical analysis

The Pearson correlation coefficient *r* was calculated to investigate the degree of linear relationship between two continuous variables. A Fisher's *r* to *z* transformation was carried out on the correlation allowing the calculation of a *P*-value for the null hypothesis that the correlation was equal to zero. The ANOVA test was used to study the effect of a nominal independent variable on a continuous dependent variable. To detect relationships between two nominal variables, the χ^2 test or the Fisher's exact test was used, wherever appropriate. *P* values <0.05 were considered significant.

Figure 1 Foregut embryonic epithelium as seen in the esophagus and stomach at 7-wk GA. Note the presence of depressions in the epithelial surface (arrowheads): these may be primitive pits. The immunostaining is for CK19 and shows diffuse moderate to strong positivity (original magnification, OM $\times 400$).

Figure 2 Overview of the fetal EGJ at 20-wk GA. The upper border of the abdominal esophagus is indicated by a red arrowhead. The angle of His (the anatomic boundary between the tubular esophagus and the sacculus stomach) is easily recognizable (arrow). The distal end of the esophagus is located at the level of the angle of His. Esophageal simple columnar epithelium is present in the distal esophagus (indicated by black arrowheads at its proximal and distal margins, H&E, OM $\times 125$).

RESULTS

Study group characteristics

Of the 48 autopsy specimens included in this study, 9 were rejected because of epithelial dehiscence, delocalization and fragmentation due to autolysis. The remaining 39 autopsy specimens belonged to 1 embryo of 7 wk gestational age (GA), 35 fetuses (GA: range 12-30 wk, mean \pm SD: 20 ± 4 wk) and 3 neonates (of 38, 40, and 43 wk GA) (Table 1).

Histology

At 7 wk GA, both esophagus and stomach were lined by foregut embryonic epithelium, which contained depressions surrounded by radially placed cells along the lesser curvature of the stomach (Figure 1).

The distal end of the esophagus was located at the level of the angle of His. This anatomic boundary between the tubular esophagus and the sacculus stomach was easily identifiable in the microscopy slides of all cases from 12-wk GA (Figure 2). At this time point, the tubular esophagus was lined by ciliated epithelium (Figure 3A), except in its most distal part. With advancing pregnancy, the ciliated epithelium was progressively replaced by squamous epithelium. Ciliated cells were absent from 40 wk GA (Figure 3B).

The distal esophagus was lined by simple columnar epithelium from 12-wk GA. This segment was between 0.480 and 7.505 mm in length (mean \pm SD: 2.185 ± 1.619 mm). Its length increased significantly during gestation ($r = 0.344$, $P = 0.0494$), as did the length of the abdominal esophagus ($r = 0.540$, $P = 0.0025$). The length of esophageal simple

columnar epithelium expressed as a percentage of length of the abdominal esophagus ranged between 21.569 and 100.000% (mean \pm SD: $50.884 \pm 18.259\%$). This percentage remained nearly constant during gestation ($r = -0.140$, $P = 0.4815$).

Throughout gestation, esophageal simple columnar epithelium could be divided into two parts (Figure 3C). The distal part contained parietal cells with roughly triangular shape and highly acidophilic cytoplasm (ESP). This segment was continuous with the stomach fundus. The proximal part of the esophageal simple columnar epithelium, however, was always devoid of parietal cells (ESN). Crypts were present over the entire length of the ESN from 16 wk GA. The length of the ESN ranged between 0.160 and 1.308 mm (mean \pm SD: 0.612 ± 0.304 mm). There was no significant difference between the lengths of ESN at four evenly spaced points along the esophageal perimeter (ANOVA test, $P = 0.4704$). The length of ESN expressed as a percentage of total length of esophageal simple columnar epithelium ranged between 8.120% and 91.447% (mean \pm SD: $38.499 \pm 24.089\%$). This percentage decreased significantly during gestation ($r = -0.572$, $P = 0.0004$).

Cytokeratin immunohistochemistry

The CK immunostaining patterns for all locations are summarized in Table 2.

CK5 and CK13 were first detected in a fetus of 14 wk GA. They were seen exclusively in multilayered epithelia.

Table 1 Summary of antibodies used in this study

Antigen	Clone	Antigen retrieval technique ¹	Application of primary Ab ²
CK5	XM26	M	1:50; 1 h; room temperature
CK7	OV-TL 12/30	T	1:50; 1 h; room temperature
CK8	TS1	M	1:50; 1 h; room temperature
CK13	KS-1A3	M	1:50; 1 h; room temperature
CK18	DC 10	M	1:10; 1 h; room temperature
CK19	RCK108	M	1:20; 1 h; room temperature
CK20	Ks20.8	T	1:50; 1 h; room temperature

¹M = heat-induced antigen retrieval by boiling deparaffinized and rehydrated sections in 10 mmol/L citrate buffer (pH 6) in a microwave oven during 20 min; T = antigen retrieval by trypsin digestion. ²Dilution; application time; application temperature.

Figure 3 Tubular esophagus. **A:** Esophageal ciliated epithelium at 20-wk GA. The immunostaining is for CK5 and is more intense in the basal and intermediate cell layers than in the superficial cell layer (OM $\times 400$); **B:** Esophageal squamous epithelium in a 3-wk-old neonate. The immunostaining is for CK13 and is absent in the basal cell layer and diffuse moderate to strong in the intermediate and superficial cell layers (OM $\times 200$); **C:** Esophageal simple columnar epithelium at 20-wk GA. To the left: parietal cells with roughly triangular shape and highly acidophilic cytoplasm (ESP, arrowhead). To the right: no discernible parietal

cells are present (ESN, H&E, OM $\times 400$); **D:** Esophageal simple columnar epithelium at 20-wk GA. The immunostaining is for CK7 and shows moderate positivity at the mucosal surface and deep in the glands (arrowhead and arrow, respectively, OM $\times 200$); **E:** Esophageal simple columnar epithelium at 20-wk GA (same case as in Figure 3D). The immunostaining is for CK20 and shows patchy positivity of the mucosa (surface and pit epithelium: arrowhead and arrow, respectively, OM $\times 200$).

CK5 staining was stronger and more diffuse in the basal and intermediate cell layers than in the superficial cell layer (Figure 3A). CK13 staining was diffused in the intermediate and superficial cell layers (Figure 3B). Its staining intensity increased significantly throughout gestation ($r = 0.476$ and 0.523 respectively, $P < 0.0001$).

CK8, CK18, and CK19 were all present in foregut embryonic epithelium (Figure 1). CK8 and CK18 staining were less intense in multilayered epithelia than in simple columnar epithelium. In ciliated epithelium, the basal cell layer was more often negative for these CKs than the other cell layers. In simple columnar epithelium, parietal cells stained weaker for CK8 and CK19 than mucus-secreting cells.

CK7 was first detected at 12-wk GA. Throughout gestation, it was more commonly present in the esophagus than in the stomach (Figure 3D). In multilayered epithelia, basal cells were always negative. Parietal cells contained no

CK7, whereas the deepest crypt cells in the ESN were focally and weakly positive. This was the only statistically significant difference between the CK immunophenotypes of ESN and ESP (χ^2 : $P < 0.0001$).

CK20 was seen in the stomach from 14 wk GA and in the esophagus from 17 wk GA (Figure 3E). It was expressed in the surface or pit cells of simple columnar epithelia. Expression of CK20 was always focal.

Coordinate CK7/20 expression for all locations is summarized in Table 3. We observed no statistically significant differences in the frequencies of the CK7+/20+ and the CK7-/20- immunophenotypes between different locations. The prevalence of the CK7+/20- immunophenotype decreased significantly from proximal to distal (33% in esophageal simple columnar epithelium *vs* 0% in the stomach, Fisher's exact test $P = 0.0039$). The positive predictive value of the CK7+/20- immunophenotype for location in the esophagus (*vs* location in the stomach) was 100%. The usefulness of

¹CK7+ is positivity at least in surface and pit cells; CK20+ is positivity at least in surface cells.

this feature was limited however, by its low sensitivity (33%). The prevalence of the CK7-/20+ immunophenotype increased significantly from proximal to distal (0% in ESN vs 40% in the stomach antrum, Fisher's exact test $P = 0.0285$).

DISCUSSION

In this study, we examined the histology and CK expression patterns of the esophageal and gastric mucosae in fetuses and neonates, using autopsy material. We believe that the results of such a study may be relevant to the description of the normal adult situation. This is important in view of the current controversy on the origin and significance of CM. Our results can be summarized as follows: (1) the distal esophagus was lined by simple columnar epithelium from 12-wk GA; (2) the proximal part of this segment consisted of mucus-producing epithelium devoid of parietal

cells; and (3) the reported adult CK expression pattern was established during gestation.

We found that the distal esophagus was lined by simple columnar epithelium from 12-wk GA. We propose the term "fetal columnar-lined lower esophagus" (fetal CLE) for this condition. Fetal CLE has been mentioned only infrequently until now. Salenius states that "The gastroesophageal limit is by no means sudden, but the epithelial change occurs quite abruptly. Glands typical of the esophagus are found over a distance of a few millimeters in the cardiac area at the junction of the esophagus and stomach."^[20] Thus, it may be difficult to decide whether simple columnar epithelium is actually located in the distal esophagus or in the proximal stomach of fetuses. Ellison *et al.*, mentioned the presence of "the squamocolumnar junction in the tubular esophagus proximal to the gastric dilatation" in 1 case out of 49 fetal and pediatric autopsies. They considered this

finding suggestive of a hiatus hernia^[22]. We excluded the presence of hiatal hernia by a careful *in situ* examination of the EGJ at autopsy. In our material, fetal CLE had a length ranging between 0.480 and 7.505 mm, with a mean of 2.185 mm. We admit that these segments of simple columnar epithelium are very short. This might influence the decision whether to locate the simple columnar epithelium in the fetal esophagus or stomach. However, we are quite sure that this simple columnar epithelium was in the distal esophagus in our cases. We have two arguments: (1) the angle of His, the level of which marks the distal margin of the tubular esophagus, was always easily identifiable; and (2) the length of esophageal simple columnar epithelium expressed as a percentage of length of the abdominal esophagus ranged between 22% and 100%, with a mean of 51%. The last finding indicates that the fetal squamo-columnar junction was located definitely in the abdominal esophagus, often mid-way between the angle of His and the diaphragm.

The significance of fetal CLE is unclear. It is known since 1953 that the most distal part of the adult tubular esophagus can be lined by columnar epithelium^[23]. Since the 1970 landmark experimental report by Bremner *et al.*, it has been widely accepted that adult columnar-lined esophagus is an acquired condition in which the squamous esophageal epithelium destroyed by gastroesophageal reflux is replaced by columnar cells^[24]. However, even normal subjects may have short segments of columnar epithelium within 2 cm of the proximal margin of the gastric folds^[25,26]. In our material, the length of fetal CLE showed no tendency to decrease during gestation. Moreover, its length expressed as a percentage of abdominal esophagus length remained nearly constant. The fetal squamo-columnar junction thus had an almost constant position. Therefore, the possibility exists that fetal CLE may be the equivalent (and the precursor) of the short segments of columnar epithelium found in the distal esophagus of some normal adult subjects. On the other hand, we cannot formally exclude that fetal CLE may differentiate into squamous epithelium in the esophagus and gastric mucosa in the stomach once the gastroesophageal sphincter is fully developed^[21].

From 12-wk GA, the fetal CLE could be divided into two parts. Parietal cells were present in the distal part, which was continuous with the fundus part of the fetal stomach. We call this part of the fetal CLE as ESP. ESP may be the equivalent of oxyntocardiac mucosa, which was first described by Chandrasoma *et al.*^[7]. Oxyntocardiac mucosa differs from pure oxyntic mucosa by the absence of chief cells in the former.

The proximal part of the fetal CLE was lined circumferentially by a mucus-producing epithelium devoid of parietal cells. We call this part of the fetal CLE as ESN. From 16-wk GA, ESN contained crypts over its entire length at least as deep as those in the ESP. Therefore, we assume that mucus-secreting glandular structures devoid of parietal cells are present proximally in the fetal CLE. This description equates the histological definition of adult CM^[4,7,8]. Consequently, we consider ESN as the equivalent (and forerunner) of adult CM. An alternative name for ESN would thus be "fetal CM". Besides the histologic aspect of the epithelium,

several other arguments are in favor of this conclusion. Like adult CM, ESN is located between multilayered esophageal epithelium and simple columnar epithelium with parietal cells. Also like adult CM, it is very short (range in our material: 0.160–1.308 mm, mean 0.612 mm)^[7,8]. Even its position in the distal esophagus cannot be objected, if one accepts that fetal CLE may be the precursor of the short segments of columnar epithelium found in the distal esophagus in some normal adults. Our view on ESN is shared by other investigators^[14].

Since classical morphological techniques cannot definitely solve the riddle of the origin of adult CM, we also investigated the CK expression patterns of the developing EGJ and stomach. We chose to do this for two reasons: (1) there is a large body of literature on CK expression in the adult EGJ mucosae, particularly on the so-called Barrett's CK7/20 pattern^[15–18]; and (2) Barrett's CK7/20 pattern has also been found in adult CM and this similarity to intestinal metaplastic epithelium in Barrett's esophagus has been used as an argument for its metaplastic origin^[17,18].

CK expression in the adult EGJ mucosae has been investigated by Glickman *et al.*^[27]. CK13 positivity was restricted to esophageal squamous epithelium. The basal layer of this epithelium stained for CK19 in 90% of cases. CK7 and CK8/18 were present focally and weakly in 61% and 18% of cases, respectively. CK7, 8/18, 19, and 20 were present in all biopsies of esophageal columnar and gastric cardiac epithelium. CK20 was only seen in columnar epithelia, where it was present in all cases. The CK expression pattern of adult ciliated respiratory epithelium has been studied by Hicks *et al.*^[28]. Basal cells typically stained for CK5, and columnar cells were positive for CK7, 8, and 18. CK19 was positive in both cell types. CK13 expression was not detected.

We observed similar CK expression patterns in the fetal EGJ mucosae. The only notable difference from the adult situation was the initially weak expression of CK13 in multilayered epithelia. However, CK13 immunostaining increased significantly throughout gestation. This finding may be related to the maturation of ciliated into squamous esophageal epithelium.

The co-ordinated CK7/20 immunophenotypes of the non-intestinalized mucosae of the adult EGJ and stomach have been described and illustrated in several publications^[29–31]. From these data, it seems that in general CK7 positivity is more common and more extensive in CM than in gastric body or antrum mucosa. Conversely, CK20 positivity is more intense and more widespread in the stomach. These observations are concordant with our findings showing that the prevalence of the CK7+/20- immunophenotype decreases significantly from fetal CM to fetal antrum, while the prevalence of the CK7-/20+ immunophenotype increases significantly in the same direction.

The fetal CK7+/20+ immunophenotype in the esophagus is illustrated in Figures 3D and E, showing patchy superficial CK20 positivity and superficial and deep CK7 positivity. This pattern is similar to the expression reported in non-intestinalized CM by DeMeester *et al.*^[18]. The patchy superficial CK20 positivity is slightly different from the adult Barrett's CK7/20 pattern. Ormsby *et al.*, studied CK7/20 expression in LSBE. They described the Barrett's CK7/20

pattern as band-like (i.e., diffuse) CK20 staining of surface epithelium and superficial glands, with moderate to strong CK7 staining of both superficial and deep glands in the specialized mucosa^[15,16].

The fetal equivalent to adult CM thus shows already co-ordinated CK7/20 expression (in our material in 25% of cases). Together with the other similarities between the fetal and adult EGJ and stomach CK expression patterns, this supports the conclusion that a cardia-type mucosa is established during gestation. This would then indicate that at least a part of the adult CM has a congenital origin.

Abstract

AIM: The origin of putative liver cells from distinct bone marrow stem cells, e.g. hematopoietic stem cells or multipotent adult progenitor cells was found in recent *in vitro* studies. Cell culture experiments revealed a key role of growth factors for the induction of liver-specific genes in stem cell cultures. We investigated the potential of rat mesenchymal stem cells (MSC) from bone marrow to differentiate into hepatocytic cells *in vitro*. Furthermore, we assessed the influence of cocultured liver cells on induction of liver-specific gene expression.

METHODS: Mesenchymal stem cells were marked with green fluorescent protein (GFP) by retroviral gene transduction. Clonal marked MSC were either cultured under liver stimulating conditions using fibronectin-coated culture dishes and medium supplemented with SCF, HGF, EGF, and FGF-4 alone, or in presence of freshly isolated rat liver cells. Cells in cocultures were harvested and GFP+ or GFP- cells were separated using fluorescence activated cell sorting. RT-PCR analysis for the stem cell marker Thy1 and the hepatocytic markers CK-18, albumin, CK-19, and AFP was performed in the different cell populations.

RESULTS: Under the specified culture conditions, rat MSC cocultured with liver cells expressed albumin-, CK-18, CK-19, and AFP-RNA over 3 weeks, whereas MSC cultured alone did not show liver specific gene expression.

CONCLUSION: The results indicate that (1) rat MSC from bone marrow can differentiate towards hepatocytic lineage *in vitro*, and (2) that the microenvironment plays a decisive role for the induction of hepatic differentiation of rMSC.

INTRODUCTION

The existence of putative liver stem cells in the bone marrow was first demonstrated by Petersen *et al.*, who showed that bone marrow cells transplanted into lethally irradiated mice engrafted in the recipient's liver differentiated into liver stem cells (oval cells) or mature liver cells (hepatocytes)^[1]. These *in vivo* results were confirmed by mouse experiments^[2] and in patients who received a bone marrow transplantation or peripheral blood stem cell transplantation for hematological disorders^[3-5]. Furthermore, Lagasse *et al.*, found liver-specific gene expression and function in FACS-sorted mouse hematopoietic stem cells (HSC, KTLS cells: c-kit^{high}, thy1^{+/+}, lin^{neg}, sca-1⁺) after transplantation into FAH-deficient mice^[6]. Recent studies in the same animal model indicated that cells observed in the recipients' liver after stem cell transplantation bearing donor markers and liver specific markers were rather a product of cell fusion than of a real "transdifferentiation"^[7,8]. However, variable data concerning cellular fusion *vs* transdifferentiation as the mechanism of liver-like differentiated cells derived from bone marrow were found in other animal models: Engraftment of human albumin producing cells in livers of NOD/SCID recipient mice was observed after xenogeneic transplantation of human hematopoietic or umbilical cord blood stem cells. However, fusion events were not ruled out^[9]. In contrast to these results, two studies using similar settings found liver specific differentiation of the transplanted cells occurring without any evidence of cell fusion events after transplantation of human sorted CD34+ or unsorted mononuclear cord blood cells into NOD/SCID mice^[10,11]. These results were supported by a recent report of Jang *et al.*^[12], showing conversion of HSC into viable hepatocytes *in vitro* and *in vivo*, notably without any cell fusion.

Several *in vitro* studies suggested the differentiation potential of various types of bone marrow cells/stem cells towards hepatocytic cells under appropriate culture

conditions. Oh *et al.*, found an expression of the liver specific genes alpha-fetoprotein (AFP) and albumin in cultures of unsorted rat bone marrow cells after 21 d. The liver specific gene expression was induced by hepatocyte growth factor (HGF) and was mediated by the expression of its receptor c-met^[13]. The expression of liver specific genes (albumin, cytokeratins (CK)) in cultured human CD34-positive hematopoietic stem cells or mononuclear cord blood cells was also demonstrated to be induced by HGF in culture^[14,15].

From cultures of mature hepatocytes it is known that important stimuli for an adequate maintenance of cellular function *in vitro* are (1) the addition of growth hormones and cytokines to the culture medium^[16,17], (2) coating culture dishes with extracellular matrix (ECM) molecules^[18,19], and (3) coculturing with other cell types^[20,21]. In stem cell cultures, Miyazaki *et al.*, showed an induction of the liver specific genes, albumin, tryptophan-2, 3-dioxygenase and tyrosine amino-transferase of rat bone marrow cells indicating a maturation towards hepatocytes when cultured in a hepatocyte growth medium supplemented with HGF and epidermal growth factor (EGF)^[22]. Avital *et al.*, demonstrated that β_2 -microglobulin-negative Thy1-positive stem cells residing in rat bone marrow expressed the liver marker albumin. In cocultures of these cells with hepatocytes (separated by a PTFE-membrane), cells were shown to adopt metabolic activity after 7 d in culture^[23]. An important influence of hepatocytes on the differentiation of stem cell enriched bone marrow was also highlighted by Okumoto *et al.*, Here, immuno-selected bone marrow stem cells cultured in the presence of HGF and fetal bovine serum (FBS) expressed the markers, hepatic nuclear factor 1 (HNF1- α) and CK-8 only after 7 d. In cocultures with hepatocytes separated by a semipermeable membrane, the stem cells additionally expressed the liver specific markers-AFP and albumin^[24]. This suggested that cocultured hepatocytes have a stimulatory effect for the differentiation of stem cells toward liver cells, which was mediated by soluble factors. For the culture of adult hepatocytes, it has been shown that cell-to-cell or cell-to-matrix contacts also play an important role for the control of liver specific differentiation^[25]. Thus, an optimal *in vitro* environment for the induction of liver specific differentiation in stem cells should be achieved by cocultures with liver cells.

Besides the HSCs, bone marrow contains nonhematopoietic, i.e. mesenchymal stem cells (MSC) reported to differentiate into cell lineages of all three germ layers^[26-29]. One distinct adherent growing cell population derived from bone marrow was described by Schwartz *et al.*^[30]. The authors isolated CD45- and GlycophorinA-depleted multipotent adult progenitor cells (MAPC) from rat, mouse, or human plastic-adherent bone marrow cells that expressed liver specific markers after 14 d in culture with FGF and HGF, e.g. albumin and CK-18. However, the relation between MSC and MAPC remains unclear. MAPCs were separated differently from bone marrow in comparison to MSCs and appear after long periods of time *in vitro* using low serum concentrations. For cloned MSCs, differentiation in hepatic cells has not been shown yet. Additionally, little evidence for cell fusion in MSC cultures has been published so far. Recently, coculture of MSCs with heatshocked airway

epithelial cells revealed the differentiation into epithelial cells^[31]. Cell fusion in this setting was a rather frequent than a rare event with a frequency of $\approx 10^{-2}$ and has to be expected in other experimental settings as well.

In this study, we investigated the potential of rat mesenchymal stem cells derived from adult bone marrow to differentiate into hepatic lineage cells *in vitro*. Furthermore, we assessed the impact of coculture with adult liver cells permitting cell-cell contacts for the initiation of liver specific gene expression.

MATERIALS AND METHODS

An outline of the experimental design is shown in Figure 1.

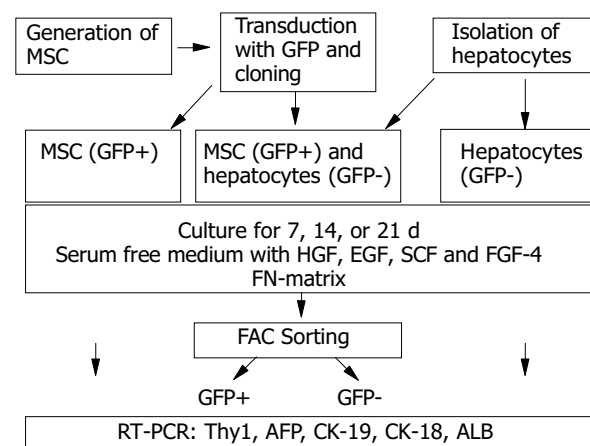

Figure 1 Experimental design. rMSC were harvested from rat bone marrow and were transduced with GFP and cloned. Cloned GFP+ rMSC were expanded and either seeded with hepatocytes in cocultures or alone. Controls included hepatocytes cultured alone. Cells were cultured for 7, 14, or 21 d. Cocultured cells were sorted by FACS into GFP+ (rMSC-derived) or GFP- (hepatocyte-derived) cells. Gene expression analysis for stem cell marker or liver specific genes was performed by RT-PCR.

Isolation, transduction, and cloning of rat mesenchymal stem cells

Bone marrow was harvested from Lewis.1WR2 rats by flushing femurs and tibiae with icecold IMDM (Gibco BRL, Karlsruhe, Germany) and 10% fetal calf serum (FCS, Gibco). Cells were centrifugated at 400 r/min for 10 min at 4 °C. The pellet was suspended in DMEM/Hams-F12 medium (1:1; Biochrom, Berlin, Germany) supplemented with 20% preselected fetal bovine serum (FBS, Biochrom), 2 mol/L L-glutamine (Gibco), 100 U/mL penicillin, and 100 mg/mL streptomycin (both Gibco). Cells of one femur and one tibia were seeded in tissue culture flasks ($A = 75 \text{ cm}^2$, Greiner, Frickenhausen, Germany). Non-adherent cells were removed after 3 d by washing the cultures with PBS (Gibco). Plastic adherent cells were grown to near confluency, and were passaged twice. Retroviral gene transduction with ectopic-packaged GFP was performed as described elsewhere^[32]. In brief, cells were removed from cultures with Trypsin/EDTA (Gibco), and 1×10^3 MSC/well were seeded in six-well culture plates. 2×10^6 virus particles containing the ectopic vector SF α 11-

GFP^[33] and 4 µg/mL protamine sulfate (Gibco) were added, and the culture plates were centrifuged for 1 h with 1 000 r/min at room temperature. Transduction efficiency was 25.5%, as determined by FACS analysis (BD FACScan with CellQuest software, BD Heidelberg, Germany). After transfection, 0.3 cells were seeded per well in 96 well plates for cloning. The clones were checked for GFP expression with a fluorescence microscope. GFP-positive clones were expanded and the clone with the highest proliferation capacity was chosen for further work (IG3 clone). Clonal GFP-marked rMSC were stored frozen at -196 °C until culture for cell differentiation.

Hepatocyte isolation

Hepatocytes were isolated from Sprague-Dawley rats by two step collagenase perfusion described by Seglen^[34] and performed in our laboratory^[35]. Briefly, donor animals received 250 U heparin (Liquemin, Hoffmann La-Roche, Mannheim, Germany) prior to cell isolation. After cannulation of the portal vein, the liver was perfused with a calcium-free buffer solution [1 000 mL distilled water, 8.3 g NaCl, 0.5 g KCl, 2.38 g HEPES (Sigma, Seelzen, Germany); pH 7.4; flow 30 mL/min] at 37.0 °C for 7 min. Then, the liver was perfused with a collagenase solution [1 000 mL distilled water, 8.3 g NaCl, 0.5 g KCl, 2.38 g HEPES, 0.7 g CaCl₂·2H₂O, 7.5 mg trypsin-inhibitor (ICN, Eschwege, Germany) and 500 mg collagenase (Collagenase H, Boehringer Mannheim, Mannheim, Germany); pH 7.35; flow 30 mL/min] at 37 °C for 8-11 min. The perfused liver was resected, and the cells were released by gentle shaking and collected in 20 mL Williams medium E without L-glutamine (Gibco). The cell suspension was filtered using a 200 µm nylon mesh and washed twice with Williams medium E (centrifugation at 50 r/min; 4 °C for 3 min). Cells were purified by Percoll[®] (density 1.13 g/mL; Sigma) gradient centrifugation (400 r/min; 4 °C for 12 min) and washed twice in Williams medium E.

Coculture of rMSC with rat hepatocytes

GFP-transduced and cloned rMSC from passage (*P*) nine or later ($\geq P 9$) were cocultured with freshly isolated rat hepatocytes. As controls, rMSC and rat hepatocytes cultured alone were included. Cultures were analyzed at d 0, 7, 14, and 21. Cells were seeded into culture wells coated with

4 µg/well fibronectin (FN, Sigma) in 24-well plates (Greiner). The culture medium used for the differentiation in cocultures consisted of Stem Span serum-free essential medium (SFEM, Stem Cell Technologies, St. Katherinen, Germany) supplemented with 100 mg/mL penicillin/streptomycin (Gibco), 2.5 nmol/L dexamethasone (Sigma), 100 ng/mL human recombinant stem cell factor (SCF), 20 ng/mL hepatocyte growth factor (HGF, both Immunotools, Friesoythe, Germany), 50 ng/mL epidermal growth factor (EGF), and 10 ng/mL fibroblast growth factor-4 (FGF-4, both R&D, Wiesbaden, Germany).

9×10^4 rMSC were seeded per well for MSC-controls, or 6×10^4 hepatocytes per well for hepatocyte controls. For cocultures of rMSC with rat hepatocytes 9×10^4 rMSC per well were preseeded in 24 well-plates for 2-3 h. Then, 6×10^4 hepatocytes per well were added to the cultures. Medium was changed twice a week.

Separation of GFP-positive and -negative cells in cocultures by fluorescence activated cell sorting (FACS)

After the culture period, cells from cocultures were trypsinized, counted with trypan blue, and resuspended in 3 mL PBS. To get single cell suspension, cells were filtered through a 35 µm filter (BD, Heidelberg, Germany). Cells were sorted using the FACS Aria[™] Cell Sorter (BD) into GFP-positive (GFP+) or GFP-negative (GFP-) cells, focusing on the highest possible purity of GFP+ cells.

RNA extraction from cells, reverse transcription and polymerase chain reaction (RT-PCR)

RNA was extracted using the Invisorb Spin Cell-RNA[™] Mini-kit (Invitek, Berlin, Germany) according to the manufacturer's instructions. RNA was stored at -80 °C. Reverse transcription (RT) of extracted RNA was performed using the bulk first-strand c-DNA synthesis kit (Amersham, Freiburg, Germany). The cDNA was stored at -20 °C. For the semiquantitative PCR reaction, 5 µL cDNA-template was mixed with 2.5 µL 10× PCR-buffer, 0.5 µL 10 mmol/L dNTPs, 0.5 µL of each primer (50 ng/µL), and 0.5 µL polymerase (Ampli-Taq, Gibco) in a total volume of 25 µL for each probe. PCR was carried out in a programmable Biometra Uno-Thermobloc (Biometra, Göttingen, Germany) using the primers and conditions is shown in Table 1. Negative controls were performed for each set of

Figure 2 Light-microscopic pictures of cultured cells. Cultured rMSC (A), hepatocyte controls (B), or cocultures of rMSC with hepatocytes (C + enlargement D) after 3 wk. Cultured rMSC grew adherent and adopted a polygonal cell morphology after weeks in culture (A). Hepatocytes formed clumps of rounded cells, and few viable cells were observed after 3 wk in culture (B). In mixed cultures,

mainly MSC attached to the substratum, whereas hepatocytes grew over the MSC-layer forming clusters (C). Binucleated cells were found within the attached layer of the cultured MSC beginning with 1 wk in culture. Shown is one example at wk 2 out of three experiments. Original magnification $\times 200$.

primers. Samples were analyzed on 1% agarose gels. The size of the PCR-fragments was estimated using a 100-base-pair ladder (Gibco BRL).

RESULTS

Culture morphology

rMSC cultured alone attached to the culture substratum within 3 h and grew to confluency within 3 d as long, spindle-shaped cells. Within 3 wk, they adopted a polygonal cell morphology (Figure 2A). Freshly isolated hepatocytes were round in shape and showed a high nuclear to cytoplasm ratio. A minimal proportion of cells attached within the 1st day to the culture substratum. In the first week of culture, the cells tend to form clumps of rounded cells. After 3 wk, only few viable cells were found in the cultures of

hepatocytes alone (Figure 2B). In mixed cultures, mainly mesenchymal cells attached to the culture substratum, whereas hepatocytes attached to the mesenchymal cell layer forming clusters (Figure 2C). Hepatocytes were smaller in size compared to mesenchymal stem cells. From the second week onwards big polygonal shaped diploid (Figure 2D) cells were observed in the attached cell layer. As revealed by morphological studies, attached and adjacent cells were still viable after 21 d in the cocultures.

Gene-expression of GFP+ rMSC

GFP-transduced rat MSC ($\geq P9$) showed no expression of the liver specific genes, CK-18, CK-19, albumin, or AFP, as detected by RT-PCR (Figure 3, lanes M). In contrast, fetal liver cells as positive control cells revealed a constant expression of all markers analyzed (Figure 3, lanes C).

Figure 3 RT-PCR analysis of cloned GFP+ rMSC. rMSC (M) and liver control cells (C) were investigated before differentiation. GAPDH showed a strong signal in both liver controls and rMSC, whereas no liver specific genes (AFP,

CK-19, CK-18, and albumin ALB) were expressed in GFP+rMSC (results from one out of three experiments).

Figure 4 FACS-pictograms. One example out of three experiments from sorting of GFP+ and GFP- cells of cocultures at wk 2 is shown. **A:** Viable cells were gated as P1; **B:** P1 cells were gated in GFP- or GFP+ (P2); **C:** For highest purification of GFP+ cells, P2 was analyzed and only GFP+

cells were sorted in the sample tube for PCR-analysis (dark gray peak). 80.8% of cells from P2 were GFP+ (sorted into the GFP+ test tube) and 19.2% were GFP-.

FAC sorting of cocultured cells

The sorting strategy aimed at maximal purity of GFP+ cells to exclude contamination with hepatocyte-derived RNA used in the RT-PCR. A representative example for FACS-sorting 2 wk after coculture from 1 out of 3 experiments is shown in Figure 4. First, the viable cells were gated according to forward and side scatter properties (Figure 4A). Two populations were seen, which varied in size and granulation. GFP-expression of this gated cells were detected in two populations, differing in granulation (Figure 4B) and were gated as P2. From these P2-cells, the contaminating GFP-cells were sorted out (Figure 4C). All non-P1, non-P2 and non-GFP cells were collected as GFP-cells.

Comparing the number of seeded cells set as 100%, recovered cell numbers were decreased at all three time points in two experiments (Figure 5). In one experiment, cocultured cells proliferated between wk 1 and 2 leading to a non-significant increase at d 14 in the mean of all experiments. An identical picture was observed for sorted GFP+ and GFP- cells: in 2 wk a slight increase in the number of GFP-cells and the maintenance of GFP+ counts could be observed. It is important to note that the GFP-cell population contained not only hepatocytes but also all dead/dying cells as well as conflicting events.

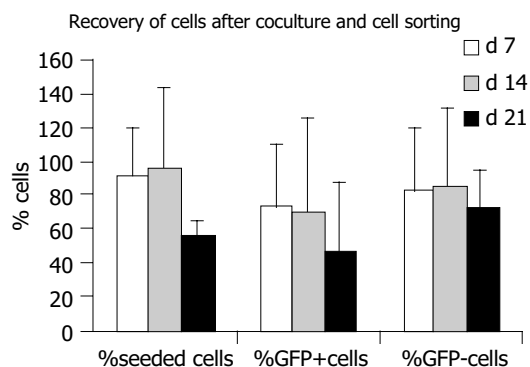

Figure 5 Recovery of cultured cells in cocultures. Recovery of seeded cells decreased from 91.6 ± 28.8 % in the 1st wk towards 56.7 ± 8.6 % in the 3rd wk (data from 3 experiments). Recovery of GFP+ cells decreased from 72.2 ± 38.5 % to 46.3 ± 41.6 %, and recovery of GFP-cells from 81.9 ± 38.2 % to 71.5 ± 24.3 % from the 1st to the 3rd wk in culture, respectively.

Gene-expression of Thy1 in GFP+ rMSC cocultured with hepatocytes

GFP+ and GFP-cells from cocultures showed a stable Thy1 gene-expression (Figure 6A) over the whole observation period (lanes GFP-or GFP+ cocultures). Also, in cultures of rMSC, a stable Thy1 expression was observed (lane rMSC), whereas hepatocytes showed no Thy1 expression (Figure 6A, lane rHep).

Liver specific gene-expression (AFP, CK-19, CK-18, albumin)

GAPDH expression in cultured rMSC, hepatocytes, GFP+ and GFP-FACS-sorted cells was similar at all time points (not shown). Although we used the same amounts of cDNA for all analyses, we found slightly different signals. Therefore, only semiquantitative assessments were possible. Cultures of rMSC alone showed no expression for AFP, CK-19, CK-18, or albumin (Figure 6B-E, lane rMSC). Cultured hepatocytes were found to express AFP and CK-19 weakly, and CK-18 and albumin stable over the whole culture period (Figure 6 B-E, lane rHep). In mixed cultures, the GFP-cells (lane GFP-cocultures) showed a strong expression of AFP (Figure 6B), albumin (Figure 6E) and CK-19 (Figure 6C), and a weak expression of CK-18 (Figure 6D). The GFP+ cells (lane GFP+ cocultures) showed a stable expression of AFP (Figure 6B), CK-18 (Figure 6D), and albumin (Figure 6E), and weak expression of CK-19 (Figure 6C), respectively. Negative controls without template were negative at all times and probes (not shown).

DISCUSSION

In this study, cloned GFP+ rMSC from passage ≥ 9 were used to analyze hepatic differentiation potential of MSC. For liver specific differentiation, cells were cultured on a fibronectin matrix in serum-free medium containing the hepatocytic growth factors- HGF, EGF, FGF-4, and the stem cell growth factor- SCF. The impact of liver cells on hepatic differentiation was assessed in cocultures of GFP+ rMSC with freshly isolated rat hepatocytes (GFP-negative) and was compared to pure cultures of rMSC or hepatocytes, respectively. For gene-expression analysis, cells from cocultures were separated in GFP+ or GFP-cells by FACS-sorting before RT-PCR analysis (Figure 1).

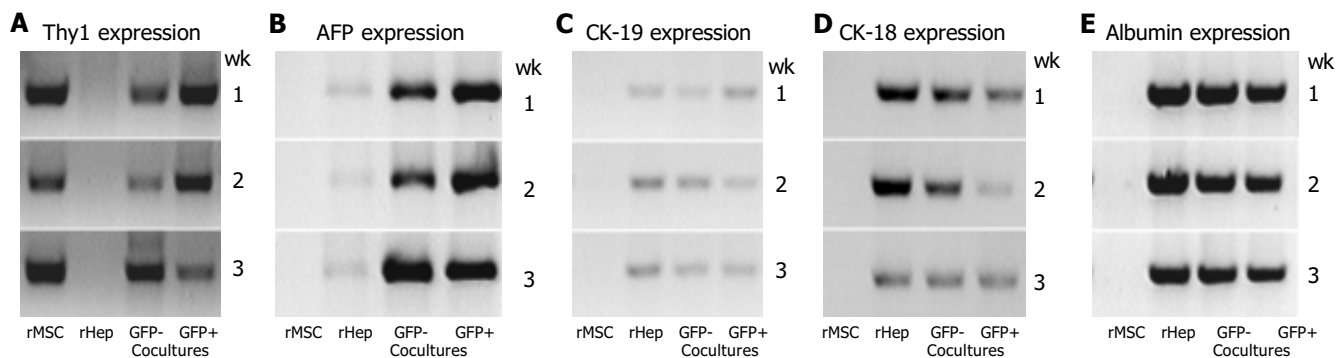

Figure 6 Gene expression profile. Cultured rMSC, hepatocytes (rHep), and GFP+ or GFP- cells of the cocultures after 1-3 wk were investigated for their expression of the stem cell marker Thy1 (A) and of the liver specific markers AFP (B), CK-19 (C), CK-18 (D), or albumin (E). Results from one out of three experiments are shown. rMSC (lane rMSC), GFP- (lane GFP- cocultures) or GFP+ (lane GFP+ cocultures) cells showed a stable Thy1 gene expression over the whole observation period, whereas hepatocytes (lane rHep) showed no signal for Thy1 gene expression in the RT-PCR analysis (A). In cultures of hepatocytes, GFP- or GFP+ cells show, the expression of the studied liver

markers was observed, whereas in cultured rMSC none of the studied liver specific genes was observed at all time points (B-E). Cultured hepatocytes expressed AFP and CK-19 weakly (B and C), and CK-18 (D) and albumin (E) stable. GFP- cells from cocultures showed a stable expression of AFP (B), CK-19 (C) or albumin (E), and a weak signal for CK-18 expression (D). The GFP+ cells showed a stable expression of the liver specific genes AFP (B), CK-18 (D), and albumin (E), and a weak expression of CK-19 (C) over the whole observation period.

AFP in the liver is a marker of immature (e.g. fetal) liver cells or oval cells in adult liver^[36]. CK19 has been shown to be expressed on hepatic oval cells as well as on adult biliary epithelial cells. Albumin is a typical marker of mature hepatocytes, whereas CK18 is expressed by several liver cells types, including biliary epithelial cells and hepatic oval cells^[37]. Our data indicated, that rMSC possess a differentiation potential towards hepatocytic cells *in vitro*; expression of the liver specific genes CK-18, albumin, CK-19, and AFP was demonstrated in GFP+ cells of the cocultures for the observation period of 3 wk. Thy1 is a marker for CD34-positive stem cells, activated endothelial cells and fetal liver cells^[38,39]. In the adult liver, Thy1 is expressed on oval cells but not on mature hepatocytes^[37,40]. It has also been found on mesenchymal stem cells generated from rat bone marrow^[41,42]. Expression of Thy1 in cultured MSC suggests that the rMSC should have the potential to differentiate toward hepatic cells by exhibition of a liver stem cell-like gene expression profile, as it is found in adult liver stem cells (oval cells). Oval cells are tissue residing liver stem cells, which possess a bipotential ability to generate biliary and hepatocytic cells, which can clonally repopulate the regenerating liver under certain conditions (reviewed in Ref.^[37]). Also, for other multipotential stem cell types from bone marrow, a hepatocytic differentiation potential was shown: sorted hematopoietic stem cells^[14,23], side population cells in the liver derived from bone marrow^[43], or multipotential adult progenitor cells^[30] were found to express liver specific genes, when cultured in the presence of certain growth factors. Previous studies in our laboratory have shown the tri-lineage differentiation potential of the cloned rMSC used, e.g. into adipogenic, chondrogenic, or osteogenic cells^[41]. In the present study, an additional differentiation potential towards hepatic progenitor cells was shown for the first time for clonally derived MSC. Thus, MSC seem to possess a multilineage differentiation potential, including a potential to differentiate into hepatocyte-like cells at least *in vitro*.

In our study, we found that hepatocyte-specific gene

expression was induced by the coculture of isolated hepatocytes. Cultured rMSC alone did not express any of the liver specific genes studied in the presence of a FN-coating and hepatic growth factors, suggesting that the added growth factors are not sufficient to induce hepatic differentiation. In contrast, a hepatocyte-like gene expression profile was observed in rMSC-derived cells in cocultures with hepatocytes. Additionally, we found binucleated GFP+ cells beginning with wk 1 (in the adult rat liver $\approx 10\%$ are binucleated cells). Very recently, a first report described the differentiation of rMSC into hepatocytic cells induced by growth factors. However, the authors used non-clonal cells of early passages. According to our experience, MSC isolated from bone marrow of rodents in early passages still contain hematopoietic cells. Thus, in these experiments a differentiation of contaminating cells into hepatic lineages cannot be conclusively excluded. In our experiments, a differentiation of MSC into hepatic cells without coculture was not successful. This could be due to either an impaired differentiation capability of the chosen clonal MSC or the high purity of MSC without contamination of HSC.

It has been shown that MSC express HGF as well as the respective receptor, c-met^[44]. Thus, MSC should be accessible for differentiation induction via this pathway. Furthermore, cocultured liver cells (GFP-) also showed a stable liver specific gene expression and viability over the whole observation period, whereas the hepatocyte controls rapidly lost cell viability and differentiation within the first week of culture. This is consistent with findings of other groups that investigated the differentiation of stem cells into hepatic lineages using coculture models. A positive influence for the induction of hepatocyte-specific genes in stem cells was found to be dependent on the presence of hepatocytes, even in cultures with separation of the cells by a semi-permeable membrane^[23,24]. A coculture of hepatocytes with stromal bone marrow cells allowing cell-cell contacts was first established by Mizuguchi *et al.*^[45]. They found that in cocultures the proliferation of hepatocytes and small hepatocytes was significantly enhanced by marrow stromal

cells compared to controls. Furthermore, a prolonged hepatocyte-specific gene expression was demonstrated by analysis of the markers, albumin^[45] and tryptophan-dioxygenase, and activated hepatocyte-specific transcription factors were revealed by Northern blot analysis. By immunolabeling, the presence of Jagged1 protein was found in the cocultured marrow stromal cells^[24] and it was suggested to mediate differentiation events via the Notch signal pathway. However, no analysis of differentiation of the cocultured MSC was performed. Okumoto *et al.*, highlighted the role of the Jagged1 and Notch expression as one pathway of bone marrow cell differentiation towards hepatocytic cells^[24]. Thus, a liver-specific differentiation of stroma cells might be possible but remained unknown from these studies. The cells used in our study were similarly generated from bone marrow, at least they were characterized by plastic adherence and clonal expansion. It is important to note, that the coculture of MSC and hepatocytes seemed also to improve the viability of the cultured hepatocytes.

Our *in vitro* data indicate that mesenchymal stem cells from rat bone marrow possess a differentiation capacity towards hepatocytic cells *in vitro*. Furthermore, we showed a strong influence of cocultures with isolated liver cells permitting cell-to-cell contacts for the induction of liver specific gene expression of cultured stem cells. Bone marrow-derived liver stem cells, and herein the MSC are promising candidates for new cell-based approaches for the treatment of liver diseases^[46]: (1) these cells can easily be harvested from adult bone marrow and expanded tremendously *in vitro*; (2) transduction of MSC may result in the expansion of "cured" daughter cells; (3) the use of adult stem cells is favorable over other stem cells, such as embryonic stem cells or fetal stem cells, regarding ethical issues; (4) MSC have been proven to suppress T-cell activation in unrelated donor-recipient situations and seem to be an alternative in some areas of tissue regeneration^[47]. The differentiation of such cells toward liver cells by cocultures may permit the generation of artificial liver tissue for tissue engineering of the liver or liver cell transplantation^[48]. In our experiments, we have not investigated the influence of fusion on differentiation of MSC into hepatic cells. Still, the debate about fusion or true "transdifferentiation" continues. For liver cells, fusion seems to be a common process. However, for our experimental setting the mechanism remains to be explored in future. But even in the case of fusion, the generated cells would be equipped with two new informations: expansion and hepatic differentiation. Thus, the potential of MSC to differentiate towards potential liver cells should be of high interest for new cell-based therapies. Therefore, coculture of rMSC with hepatocytes is a model worth studying for further characterization of the mechanisms underlying a differentiation of stem cell into the hepatocytic lineage.

Abstract

AIM: To produce an antibody against rat eosinophil cationic protein (ECP) and to examine the effects of the antibody in rats with dextran sulfate sodium (DSS)-induced colitis.

METHODS: An antibody was raised against rat ECP. Rats were treated with 3% DSS in drinking water for 7 d and received the antibody or normal serum. The colons were examined histologically and correlated with clinical symptoms. Immunohistochemistry and Western blot analysis were estimated as a grade of inflammation.

RESULTS: The ECP antibody stained the activated eosinophils around the injured crypts in the colonic mucosa. Antibody treatment reduced the severity of colonic ulceration and acute clinical symptoms (diarrhea and/or blood-stained stool). Body weight gain was significantly greater and the colon length was significantly longer in anti-ECP-treated rats than in normal serum-treated rats. Expression of ECP in activated eosinophils was associated with the presence of erosions and inflammation. The number of Ki-67-positive cells in the regenerated surface epithelium increased in anti-ECP-treated rats compared with normal serum-treated rats. Western blot analysis revealed reduced expression of macrophage migration inhibitory factor (MIF)

in anti-ECP-treated rats.

CONCLUSION: Our results indicate that treatment with ECP antibody, improved DSS-induced colitis in rats, possibly by increasing the regenerative activity of the colonic epithelium and downregulation of the immune response, and suggest that anti-ECP may promote intestinal wound healing in patients with ulcerative colitis (UC).

INTRODUCTION

Eosinophil accumulation in the gastrointestinal tract is a common feature of numerous gastrointestinal disorders, including classic IgE-mediated food allergy, eosinophilic gastroenteritis, allergic colitis, eosinophilic esophagitis, inflammatory bowel disease (IBD)^[1-3] and gastroesophageal reflux disease. In IBD, eosinophils usually represent only a small percentage of the infiltrating leukocytes^[3,4] but their levels has been proposed as a negative prognostic indicator^[4,5]. Several studies have found an association between allergic colitis and later development of IBD, but this association is controversial^[6].

Eosinophils and one of their granule proteins, eosinophil cationic protein (ECP)^[7] and eosinophil protein X (EPX), are generally recognized as being involved in the host defense against invading parasites. They are markedly cationic proteins with cytotoxic capacities that can potentially cause tissue destruction and could act as modulators of immune response^[8]. The eosinophil may also be involved in the pathogenesis of IBD because we have already reported activation of eosinophils in patients with active ulcerative colitis (UC), using the techniques of indirect immunoenzymatic method and electron microscopic examination of eosinophils, measurement of serum ECP^[9,10], as well as increased percentages of hypodense eosinophils in the peripheral blood. Moreover, bowel biopsies from patients with IBD have demonstrated infiltration of eosinophils in the lamina

propria and marked extracellular deposits of ECP^[11,12]. There is also an excess release of the eosinophil proteins ECP and EPX in the luminal fluid and fecal material of patients with UC or Crohn's disease^[13]. However, the pathophysiological role played by activated eosinophils in the inflammatory process in UC has not yet been elucidated.

The aim of this study was to produce an antibody against rat ECP and to examine the antibody in dextran sulfate sodium (DSS)-induced colitis model. Rats treated with DSS develop severe colorectal damage mimicking IBD in humans^[14,15]. We herein present evidence for the effectiveness of ECP antibody against DSS-induced colitis in rats, possibly by increasing the regenerative activity of the colonic epithelium and downregulation of the immune response.

MATERIALS AND METHODS

Antibody raised against rat ECP

TRAQWFIAQHISLNPPR^[16] was synthesized based on human ECP amino acid sequence^[17], which has homology to rat ECP^[18]. Anti-ECP sera were generated by immunizing New Zealand white rabbits. In brief, rabbits were inoculated intradermally with 100 µg of ECP diluted in complete Freund's adjuvant at weeks 2, 4, 6, 8, 10, 12, and 14. The serum was prepared according to the protocol provided by the manufacturer.

Induction of experimental colitis

Male Wistar rats/IZM (8 wk old) were obtained from Charles River Japan, Inc. Rats were kept in a specific pathogen-free environment at the Animal Center in accordance with the rules and regulations of the Institutional Animal Care and Use Committee of Nagasaki University. Food as well as drinking water with or without DSS (MW 5 000; Wako Pure Chemical Industries, Osaka, Japan) were provided *ad libitum*. The rats were treated with 3% DSS in drinking water for 7 d^[19], and then received either antibodies or normal serum intraperitoneally. The rats were weighed daily and visually inspected for gross rectal bleeding and diarrhea. The colons were examined histologically and correlated with clinical symptoms. Hematoxylin and eosin (HE)-stained sections were prepared from the distal colon. The severity of ulceration was quantified by the Ulcer Index (ulcer length/circumference length, %) in the distal colon. Furthermore, the severity of colitis was evaluated by assessment of colon length and histological examination. Similarly, we evaluated the effect of anti-ECP antibodies with regard to clinical signs and pathologic features.

Administration of antibodies specific for ECP

The polyclonal ECP antibody (0.25 mL/rat at d 0 and 1, 0.5 mL/rat at d 2, 3, 4, 5, 6, and 7 after DSS treatment) or non-immune rabbit serum was injected intraperitoneally.

Immunohistochemical studies

Anti-ECP antibody as eosinophils, anti-ED1 antibody (Serotec, Oxford, UK) as activated macrophages, anti-Ki-67 antibody (MIB-5, Dako Cytomation Denmark A/S, Denmark) as proliferative cells were used. The sections were deparaffinized and rehydrated. Then, they were microwaved

for 10 min in 0.01 mol/L citrate buffer, pH 6.0, to unmask the antigenicity, and trypsin digested for 15 min, for Ki-67 and for ED1 as pre-treatment, respectively. The slides were placed in methanol with 0.3% H₂O₂ for 10 min to block endogenous peroxidase activity. They were then incubated with ECP, Ki-67, and ED1 for 60 min and further processed for immunohistochemistry using the Histofine Simple Stain kit (Nichirei, Tokyo, Japan). Peroxidase activity was developed in diaminobenzidine as a chromogen. In the procedures described above, tissue sections that were not incubated with ECP, ED1, or Ki-67 served as negative controls.

Western blot analysis

Western blots were prepared for expression of ED1 and macrophage migration inhibitory factor (MIF). For this purpose, the colonic tissue was collected from the lesion area, and then suspended in 5 volumes of ice-cold 50 mmol/L Tris-HCl (pH 7.2) containing 150 mmol/L NaCl, 1% NP-40, 1% sodium deoxycholate, and 0.05% SDS, broken into pieces on ice, and subjected to three freeze-thaw cycles. After centrifugation at 15 000 *g* for 10 min at 4 °C, 2-mercaptoethanol and bromophenol blue were added to the supernatant at final concentrations of 2% and 0.001%, respectively. The tissue extracts (30 µg protein) were subjected to 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis, and the separated proteins transferred onto Hybond ECL nitrocellulose membrane. After blocking nonspecific binding sites with 5% skim milk, the membrane was incubated with 1 000× diluted antibody, against ED1 and MIF (N-20, Santa Cruz Biotechnology, Inc.) at room temperature for 1 h. The bound antibodies were detected using an enhanced chemiluminescence detection kit (ECL Plus, Amersham Life Science, Buckinghamshire, UK) and the amount of each protein was quantified by densitometric analysis^[20].

Statistical analysis

All data were expressed as mean±SE. Differences between groups were examined for statistical significance using the Student's *t*-test or Cochran and Cox test. A *P* value less than 0.05 denoted the presence of a statistically significant difference.

RESULTS

Clinicopathological findings

The body weight gain was significantly greater in anti-ECP-treated rats at d 4 and 7 after DSS treatment compared with normal serum-treated rats (Figure 1). ECP antibody clearly reduced acute clinical symptoms (diarrhea and/or blood-stained stool, Table 1). Moreover, ECP antibody improved various mucosal parameters; it reduced colonic ulceration severity (Ulcer Index) from 61.1±25.5% (DSS) to 43.1±29.4% (DSS+anti-ECP). The colon length was 13.4±0.4 cm in anti-ECP-treated rats and 12.3±0.6 cm in normal serum-treated rats at 7 d after DSS treatment (Table 2). DSS-induced shortening of the colon length was significantly abrogated in anti-ECP-treated rats (*P*<0.05).

ECP expression in normal colonic mucosa and in colitis

HE- and immunohistochemically-stained sections showed

Figure 1 Changes in body weight in normal serum- (open columns), anti-ECP- (closed columns) treated rats during DSS treatment. The body weight gain after DSS treatment was significantly greater in anti-ECP-treated rats compared with normal serum-treated rats. Rats treated with the antibodies or normal serum intraperitoneally were also treated with 3% DSS in drinking water for 7 d ($n = 7$, $^aP < 0.05$ vs DSS+normal serum).

Table 1 Clinical findings

Time (d)	Gross bleeding		Diarrhea	
	NS	Anti-ECP	NS	Anti-ECP
1	0	0	0	0
2	0	14.3	14.3	14.3
3	14.3	0	14.3	14.3
4	0	0	0	0
5	14.3	0	28.6	14.3
6	42.9	14.3	28.6	0
7	42.9	28.6	0	0

Data are percentage of animals ($n = 7$).

Table 2 Effects of anti-ECP antibody on ulcer index and colon length (mean \pm SE, $n = 7$)

Group	Ulcer index (%) ¹	Colon length (cm)
DSS+normal serum	61.1 \pm 25.5	12.3 \pm 0.6
DSS+anti-ECP	43.1 \pm 29.4 ^a	13.4 \pm 0.4 ^b

¹Ulcer length/circumference length $\times 100$. ^a $P < 0.05$ vs DSS+normal serum. ^b $P < 0.01$ vs DSS+normal serum.

eosinophils and ECP-positive eosinophils in close proximity to damaged crypts in the lamina propria and partially in the extracellular interstitium of the colon of rats with DSS-induced colitis (Figures 2A and B). The ECP antibody stained activated eosinophils. In the normal colon, eosinophil infiltration was hardly observed and ECP-positive activated eosinophils were never seen in the colonic tissue (data not shown).

Histological findings

ECP antibody treatment clearly suppressed DSS-induced colitis as confirmed in HE-stained sections (Figures 2C and D). Moreover, immunohistochemical studies for Ki-67 and ED1 revealed that the ECP antibody treatment increased the regenerative activity of the colonic epithelium and downregulation of immune response (Figure 3). Expression of ECP in activated eosinophils was associated with the presence of erosions and inflammation. The number of Ki-67-positive cells in the regenerative surface epithelium/circumference significantly increased in anti-ECP-treated

Figure 2 Colonic mucosa at 3 d post-DSS treatment showing eosinophils in the lamina propria. HE staining (A) and immunostaining for ECP (B) as described under Materials and methods. ECP-positive cells (brown) appear in close proximity to damaged crypts in the lamina propria and partially in the extracellular interstitium of DSS-induced colitis. Original magnification, $\times 400$. Colonic mucosa at 7-d treatment of DSS. (C) Colonic ulceration in normal serum-treated rats. (D) Reduced severity of colonic mucosal ulceration in anti-ECP-treated rats. HE stain. Original magnification, $\times 100$.

Table 3 Effects of anti-ECP antibody on the Ki-67-positive cells in the regenerative surface of colonic epithelium at d 7 after DSS treatment (mean \pm SE, $n = 7$)

Group	Ki-67-positive cells ¹
DSS+normal serum	14.0 \pm 6.5
DSS+anti-ECP	21.3 \pm 10.4 ^a

¹Number of Ki-67-positive cells/circumference. ^a $P < 0.05$ vs DSS+normal serum.

rats (21.3 \pm 10.4) compared with normal serum-treated rats (14.0 \pm 6.5) at d 7 after DSS treatment ($P < 0.05$, Table 3 and Figure 3).

The number of ED1-positive macrophages in the lamina propria of anti-ECP-treated rats at d 7 after DSS treatment was less than that in normal serum-treated rats. Moreover, the size of ED1-positive macrophages in the lamina propria of anti-ECP-treated rats at d 7 after DSS treatment was smaller than that of normal serum-treated rats.

Western blot analysis

ECP antibody treatment significantly downregulated

Figure 3 Colonic mucosa in normal serum-treated rats (A, C, and E) and anti-ECP1-treated rats (B, D, and F) at 7-d treatment of DSS. HE staining (A and B), immunostaining for Ki-67 (C and D) and ED1 (E and F) as described under Materials and methods. Treatment with ECP antibody increased the number of

Ki-67-positive cells in the regenerated surface epithelium and reduced the size of activated macrophages present in the lamina propria. Original magnification, $\times 400$.

Figure 4 Detection of ED1 (A) and MIF (B) by Western blot analysis in colonic tissues after 7 d of DSS treatment in normal serum-treated rats (lanes 1-4) and anti-ECP-treated rats (lanes 5-7). The colonic tissue was collected from the lesion area and examined by Western blot analysis as described under Materials and methods. The relative expression levels of ED1 and MIF in the damaged colonic tissue were significantly lower in anti-ECP-treated rats than in normal serum-treated rats. The relative protein expression was quantified by densitometric analysis ($n = 7$, $^aP < 0.05$ vs DSS+normal serum).

macrophage activation during 7-d treatment of DSS (Figure 4). The expressions of both ED1 and MIF in the damaged

colonic tissue at d 7 after DSS treatment decreased significantly in anti-ECP-treated rats. The relative ED1 expression was significantly lower in anti-ECP-treated rats (1.25 ± 0.79) than in normal serum-treated rats (3.62 ± 1.83 , $P < 0.05$, $n = 7$). Furthermore, the relative expression of MIF was significantly lower in anti-ECP-treated rats (0.74 ± 0.08) than in normal serum-treated rats (0.94 ± 0.08 , $P < 0.05$, $n = 7$).

DISCUSSION

A variety of clinical and experimental models has revealed that eosinophils promote pro-inflammatory changes mediated by their ability to release various cytotoxic substances and a variety of lipid mediators and cytokines. In type-2 helper T (Th2) cells-associated gastrointestinal inflammatory conditions, increased levels of eosinophils occur in the lamina propria in an eotaxin 1-dependent manner^[21]. After mucosal allergen challenge, eosinophils under the regulation of IL-5 accumulate in the esophagus, an organ normally devoid of eosinophils. However, the main role of IL-5 in DSS-induced colonic inflammation is to attract a population of eosinophils that do not appear to

contribute significantly to the initiation or development of tissue damage in this model of colitis^[22].

In 1974, the existence of an eosinophil-granule protein, ECP, with a highly cytotoxic action, was reported by Olsson and Venge^[7]. ECP is antibacterial^[23], helminthotoxic^[24], elicits the Gordon phenomenon when injected intrathecally into rabbits, and is cytotoxic to tracheal epithelium^[25,26]. Although the mechanism of its cytotoxicity is not completely understood, it is suggested to be due to the pore-forming activity of ECP, which destabilizes lipid membranes^[27], but is unrelated to RNase activity^[28]. We demonstrated here that a polyclonal antibody to eosinophil granule protein ECP exhibits beneficial effects on various mucosal parameters of DSS-induced colitis in rats. ECP expressed in activated eosinophils of the colonic mucosa in DSS-induced colitis were associated with the presence of injured crypts and inflammation. The body weight gain was significantly greater in anti-ECP-treated rats, compared with control rats. The ECP antibody reduced acute clinical symptoms (diarrhea and/or blood-stained stool), severity of colonic ulceration and shortening of the colon length. Immunohistochemical studies for Ki-67 and ED1 revealed that ECP antibody treatment increased the regenerative activity of the colonic epithelium and downregulation of the immune response.

Mucosal repair involves both the rapid migration of cryptal enterocytes into the injured area of the mucosa, and replacement of the mucosa by cell replication^[29]. Various peptide growth factors regulate epithelial cell function within the mucosal epithelium of the gastrointestinal tract. Recently, Sinha *et al.*, reported preliminary data suggesting that epidermal growth factor enemas are effective in the treatment of active left-sided UC^[30]. Furthermore, Dignass *et al.*^[31], demonstrated that hepatocyte growth factor (HGF) modulates intestinal epithelial cell proliferation and migration, thus enhancing epithelial cell restitution, the initial step of gastrointestinal wound healing, in an *in vitro* model. Moreover, it was demonstrated that administration of recombinant human HGF lessened colitis-associated weight loss in rats as well as improved the clinical signs of colitis *in vivo*^[32]. In our rat model, mucosal erosion was observed on d 5 and accelerated on d 7, whereas the colon length was reduced on d 7. Importantly, the ECP antibody enhanced epithelial regeneration, leading to a reduction in size of colonic mucosal erosions, although it was administered concomitantly with DSS. In this regard, enhanced mucosal repair allows for a more rapid recovery of epithelial barrier function leading to reduced exposure to various luminal agents that contribute to persistent colitis. Accordingly, treatment with ECP antibody should reduce the inflammatory response to these luminal stimuli.

MIF was originally identified as a lymphokine derived from activated T cells that inhibits the random migration of macrophages *in vitro* and is involved in delayed-type hypersensitivity^[33]. Moreover, it is postulated that tumor necrosis factor (TNF)- α and interferon (IFN)- γ upregulate MIF production in macrophages and, conversely, MIF induces TNF- α production, forming a proinflammatory loop within the cytokine network^[34]. Gut monocyte macrophages are responsible for production of MIF, which in turn stimulates Th-1-type cytokines and features characteristic

of colitis. Swollen macrophages induced by DSS have been seen in the mucosa with gland dropout and inflammatory cell infiltration even under intact colonic epithelium^[35]. It seems that macrophage dysfunction, alterations of luminal bacteria, and DSS toxic effects on the colonic epithelium acted together to result in inflammatory ulcerative changes of the colonic mucosa. Therefore, in our study, the ECP antibody reduced macrophage activation such as the size of ED1-positive macrophages and the expressions of ED1 and MIF proteins in damaged colonic mucosa induced by DSS, resulting in downregulation of the immune response.

ECP is one of the major components of eosinophilic granules with a molecular mass ranging from 16 to 21.4 ku. It exhibits various biological effects both *in vitro* and *in vivo*^[8,36]. It is classified as a member of the ribonuclease (RNase) A supergene family based on the homology of both nucleotide and amino acid sequences. The homology of amino acid sequence between rat ECP^[18] and human ECP^[37] is 54%. When the amino acid sequence of rat ECP was compared with that of human ECP, eight structural cysteines and three amino acids, H15, K38, and H128, that are required for RNase activity^[37] were found to be highly conserved. The length of the signal peptide of rat ECP is equivalent to that of human ECP. Maeda *et al.*^[38], demonstrated that ECP is growth-inhibitory and this ability of ECP to bind to heparin or other carboxy hydrates on the cell surface is dependent on tryptophan residues, W10 and W35. Interestingly, W10 is located at the P2 subsite of the catalytic domain of RNase and controls the weak RNase activity of the protein^[39]. ECP alters the coagulation cascades^[40], augments fibrinolysis^[41], and regulates the classical pathway of complement^[42]. Our results showed that the ECP antibody clearly reduced acute clinical symptoms of blood-stained stool. Our evaluation of the ECP molecule including W10 and H15 in human ECP enabled us to test the beneficial effects of anti-ECP treatment on inflammatory disease, in which uncontrolled cell growth could contribute to a delay in wound healing. Further studies are needed to investigate this issue.

In summary, we demonstrated that treatment with an antibody to ECP improved DSS-induced colitis in rats possibly by increasing the regenerative activity of the colonic epithelium and downregulation of the immune response. This supports the concept that humanized anti-ECP treatment could also be an effective therapy for IBDs.

Abstract

AIM: Eph receptors and ephrin ligands play a pivotal role in development and tissue maintenance. Since previous data have indicated an involvement of ephrin-B2 in epithelial healing, we investigated the gene expression and downstream signaling pathways induced by ephrin-B mediated cell-cell signaling in intestinal epithelial cells.

METHODS: Upon stimulation of ephrin-B pathways in IEC-6 cells with recombinant rat EphB1-Fc, gene expression was analyzed by Affymetrix® rat genome 230 high density arrays at different time points. Differentially expressed genes were confirmed by real-time RT-PCR. In addition, MAP kinase pathways and focal adhesion kinase (FAK) activation downstream of ephrin-B were investigated by immunoblotting and fluorescence microscopy.

RESULTS: Stimulation of the ephrin-B reverse signaling pathway in IEC-6 cells induces predominant expression of genes known to be involved into wound healing/cell migration, antiapoptotic pathways, host defense and inflammation. Cox-2, c-Fos, Egr-1, Egr-2, and MCP-1 were found among the most significantly regulated genes. Furthermore, we show that the expression of repair-related genes is also accompanied by activation of the ERK1/2 MAP kinase pathway and FAK, two key regulators of epithelial restitution.

CONCLUSION: Stimulation of the ephrin-B reverse signaling pathway induces a phenotype characterized by upregulation of repair-related genes, which may partially be mediated by ERK1/2 pathways.

INTRODUCTION

Eph receptor tyrosine kinases (RTKs) and their receptor-like ligands, the ephrins, represent the largest family of RTKs and are specialized on directing coordinated cell migration in development and possibly in tissue repair^[1,2]. Based on their sequence homology, structure, and binding affinity, the Eph RTKs and ephrins are divided into two subclasses A and B. Usually, EphA receptors interact with ephrin-A ligands and EphB receptors with ephrin-B ligands. Both the receptors and the ligands are membrane-bound. A-ephrins are tethered to the outer leaflet of the plasma membrane by virtue of a glycosyl-phosphatidylinositol anchor, whereas B-ephrins are transmembrane proteins^[3,4]. As a unique feature, upon receptor-ligand interaction, both receptor mediated “forward” and a “reverse” cellular signaling response are induced. Therefore, Eph/ephrin signaling represents a bidirectional cell-cell signaling system with ephrin ligands taking over receptor-like functions^[5].

The rapid restitution of the intestinal surface after disruption of the epithelial barrier relies on the highly adaptive ability of epithelial wound-edge cells to rapidly form pseudopodial protrusions, reorganize the cytoskeleton, and migrate into a wound defect in a coordinated manner^[6-8]. This fast epithelial healing is particularly important considering the necessity to protect the host against a considerable microbial threat and exposure to a multitude of immunogenic and toxic factors present in the gut^[6].

Recent data suggest a pivotal role of Eph/ephrin signaling in tissue repair and maintenance of the gut. EphA2/ephrinA1 signaling has already been suggested to be involved in the homeostasis of the intestinal barrier in adults^[9]. Moreover, differential expression of ephrin ligands and Eph-RTKs along the crypt-villus axis determines the correct positioning and allocation of the proliferating vs differentiating compartment during development of the intestinal crypts^[10]. Interestingly, knockout of EphB2/B3 in mice leads to intermingling of both compartments and also displacement of Paneth cells to the top of the villi. More recently, the expression of a variety of Eph receptors and ephrin ligands has been demonstrated in the adult human gut by our group, with most prominent expression of EphA2, EphB2, ephrin-A1 and ephrin-B1/2^[11]. Considering the important role of

Eph receptors and ephrins development and their life-long highly organized expression in gut epithelium, a role in epithelial maintenance and repair seems possible. As a further step to understand their role in intestinal physiology, we investigated gene expression profiles in response to the stimulation of the ephrin-B dependent signaling pathways. Since many links between ephrin-B2 and MAP kinase (ERK) as well as focal adhesion kinase (FAK) mediated pathways have already been demonstrated^[12,13], these pathways were also analyzed in more detail.

MATERIALS AND METHODS

Cell culture and total RNA isolation

Non-transformed rat intestinal IEC-6 cells^[14] were cultured in Dulbecco's MEM (Biochrom AG, Berlin, Germany) supplemented with 5% fetal calf serum (FCS PAN Biotech, Aldenbach, Germany). After reaching 80% confluence, cells (passage 6) were starved overnight with 0.1% FCS and stimulated with 0.5 µg/mL (-3.3 nmol/L) rat recombinant EphB1-Fc (R&D Systems, Minneapolis, USA). Doses were determined according to the efficient stimulation of intestinal epithelial wound healing in scratch wound assays. Cells were harvested at 0 (control), 30, and 120 min in RLT buffer (Qiagen, Hilden, Germany). After homogenization, RNA isolation for further array analysis was performed using the RNeasy Mini Kit (Qiagen). RNA quality was assessed with an Agilent 2100 bioanalyzer (Agilent Technologies, Palo Alto, USA) and quantity was measured spectrophotometrically.

High density arrays

For investigation of downstream transcriptional responses of EphB1-Fc stimulated pathways in IEC-6 cells, gene expression was analyzed by the Affymetrix® rat genome expression set 230A (version 2.0). Sample preparation for microarray hybridization was carried out as described in the Affymetrix GeneChip® Expression Analysis Technical Manual. Briefly, 15 µg of total RNA were used to generate double-stranded cDNA (Invitrogen). Synthesis of Biotin-labeled cRNA was performed using the BioArray™ HighYield™ RNA Transcript Labeling Kit (ENZO Diagnostics). The length of the cRNA and fragmentation was confirmed using the Agilent 2100 bioanalyzer (Agilent Technologies, Palo Alto, USA). Affymetrix® Microarray Suite (MAS) 5.1 was used for Single Array and Comparison Analysis. A global scaling strategy was applied, setting the average signal intensity of all arrays to a target value of 100. For RNA quality control and stringent data evaluation, the quality standards were applied as defined at a regional German Affymetrix® Core Facility and Service Provider, the "CFB" (Competence Centre for Fluorescent Bioanalytics, www.kfb-regensburg.de).

Ingenuity® pathway analysis

Analysis of 331 regulated genes with changed *P*-values lower than 0.003 and higher than 0.997 (fold change >1.5) by the Ingenuity® Pathway Analysis Software tool was used to get a better defined concept of the complex downstream events.

Real-time RT-PCR

To confirm the differential expression of a selection of

more than twofold regulated genes, real-time TaqMan® RT-PCR (PE Applied Biosystems, Darmstadt, Germany) was performed on an ABI Prism 7900 HT Sequence Detection System as published elsewhere^[11]. Briefly, cDNA was synthesized using the Reverse Transcription Kit from Promega (Madison, USA) according to the manufacturer's protocol. Rat primers and probes for Cox-2, Egr-1/2, c-Fos, and monocyte chemotactic protein 1 (MCP-1) were obtained as Assays on Demand® (Applied Biosystems). The standard curve method was used for the quantification of the relative amounts of gene expression products. This method provides unit less normalized expression values that can be used for direct comparison of the relative amounts of target mRNA in different samples^[11]. All reactions were performed as triplicates. Probes and primers for TaqMan® analysis for ephrin-B1 and -B2 were designed on the basis of gene-specific non-homologous DNA sequence of the corresponding members^[11]. The sequences were as follows: ephrin-B1 (MGB probe TGTACTGGCTTGGGCC, forward CCTCC CCAGGCTTTGTGA, reverse TCCTGGCTGACCACA TCGT), ephrin-B2 (MGB probe TGCTCAGCGCTTAAA, forward GATGTGAAATTCAT-TTGTGGCAAT, reverse CCAGAAGTAGCTGTCA-ATTTGTTT).

Immunocytochemistry

IEC-6 cells were plated on fibronectin coated Lab-Tek chamber glass slides (Nalge Nunc Int., Naperville, USA) (100 000 cells/slide) and grown in Dulbecco's MEM plus 5% FCS overnight. After washing with PBS, cells were fixed with 4% paraformaldehyde and after repeated wash steps with PBS blocked with 3% H₂O₂/CH₃OH. Cells were again washed with PBS and incubated with Super Block (Zytomed, Berlin, Germany). For immunocytochemical staining, the following antibodies were used (30 min, 37 °C): goat EphB2 (1:100), rabbit ephrin-B1 (1:100), and rabbit ephrin-B2 (1:75) (Santa Cruz, CA, USA). Cells were incubated with Anti-Broad Spectrum Biotinylated antibody for 15 min (37 °C), and ZytoChemPlus HRP solution was added for 10 min at room temperature (Zytomed). After washing with PBS, the slides were stained with AEC chromogen for 10 min at room temperature (Dako, Hamburg, Germany). The reaction was stopped with H₂O and counterstained with hemalaun. For negative control, the protocol was performed as mentioned above, but primary antibodies were omitted.

Immunoblotting

IEC-6 cells were grown in Dulbecco's MEM (Biochrom AG, Berlin, Germany) supplemented with 5% FCS to 80% confluence. Cells were starved overnight with 0.1% FCS, then stimulated with 0.25 µg/mL (-1.65 nmol/L) rat recombinant EphB1-Fc (R&D Systems, Minneapolis, USA) and harvested at 0, 5, 10, 20, 30, and 45 min. Protein was isolated from the cells and the protein lysates were analyzed by SDS-PAGE and blotted according to standard protocols.

Activated (phosphorylated) FAK and pan-FAK were detected by the anti-(phosphotyrosine)-pY397 FAK antibody from Sigma (St. Louis, USA) and anti-FAK from Biosource (Camarillo, CA, USA). For detection of MAP-kinase phosphorylation, the following antibodies were used: anti-ERK1/2 (pT185, pY187) 1:1 000, anti-JNK1/2 (pT183,

pY185) 1:2 500, anti-p38 (pT180, pY182) 1:1 000 (Biosource, Camarillo, CA, USA). Rabbit polyclonal anti-protein disulfide isomerase (PDI) antibody (dilution 1:4 000) served as a control for equal protein load (StressGen, Victoria, Canada). As secondary antibody, the anti-Rabbit-HRP (Cell signaling, Beverly, MA, USA) was used.

Immunofluorescence microscopy

IEC-6 cells were plated on fibronectin coated glass cover slips and grown for 16 h in Dulbecco's MEM plus 5% FCS. The monolayer was starved with Dulbecco's MEM plus 0.1% FCS overnight, wounded by a cell scraper and stimulated with 0.5 $\mu\text{g/mL}$ EphB1-Fc (-3.3 nmol/L). IgG-Fc (R&D Systems, Minneapolis, USA) served as a control. Cells were fixed with 4% paraformaldehyde for 5 min at room temperature and permeabilized with 0.1% Triton-X 100 for 5 min at 37 °C. After washing with PBS, cells were blocked with 1% bovine serum albumin for 15 min at 37 °C. For detection of activated FAK, an anti-(phosphotyrosine)-pY397 antibody (Sigma, St. Louis, USA) was used as primary

and an anti-rabbit FITC-labeled antibody as secondary (Vector, Burlingame, USA). Cell nuclei were stained with DAPI (Chemicon, Temecula, USA). Images from the wound margin were taken on a Leitz microscope equipped with a fluorescence lamp and adequate filters. Cells were photographed at 400 \times magnification.

RESULTS

IEC-6 cells express ephrin-B1/2 ligands

In the human small intestine and colon, coexpression of EphB2 and ephrin-B1/2 ligands has previously been demonstrated by our group^[11]. To evaluate the suitability of IEC-6 cells as a model for investigation of EphB/ephrin-B dependent cell-cell signaling, the expression of both EphB2 receptor and ephrin-B1/2 ligands in IEC-6 cells was investigated. Real-time TaqMan[®] RT-PCR revealed mRNA expression of ephrin-B1 and, more abundantly, ephrin-B2 in IEC-6 cells (Figure 1A). In addition, the expression of the EphB2 receptor and two corresponding high-affinity ligands in IEC-6 cells could be confirmed on the protein

Figure 1 Rat IEC-6 intestinal epithelial cells express ephrin-B ligands on the mRNA and protein level. **A:** Real-time RT-PCR shows expression of ephrin-B1 and -B2 mRNA. As the curve of ephrin-B2 demonstrates lower C_t -values, the amount of ephrin-B2 mRNA starting material was higher than the amount of ephrin-B1 mRNA. The values were normalized by detection of the 18S rRNA

(data not shown); **B:** IEC-6 cells coexpress ephrin-B1/2 and the corresponding EphB2 receptor on the protein level. IEC-6 cells may therefore be able to interchange cell-cell signals via EphB2/ephrin-B1/2 contacts. The coexpression of the EphB2 receptors and ephrin-B1/2 ligands is in accordance with previous data on human adult intestinal tissue in these cells^[11].

level by immunocytochemistry (Figure 1B). Hence, comparable to the human *in vivo* expression^[11], IEC-6 cells coexpress the EphB2 receptor and two ephrin-B ligands *in vitro*. Therefore, cell-cell signaling between these cells seems possible.

High-density cDNA array analysis

Since previous investigations showed that ephrin-B mediated 'reverse' signals generated upon binding of EphB receptors can specifically enhance intestinal wound healing *in vitro*, we were interested in the "downstream" target genes of the corresponding signaling cascades. Therefore, the transcriptional response to ephrin-B reverse signaling induced by recombinant EphB1-Fc was analyzed on the Affymetrix[®] platform. The cells were stimulated with 0.5 $\mu\text{g/mL}$ (-3.3 nmol/L) rat recombinant EphB1-Fc for 30 and 120 min. To identify the genes with highest possible probability to be truly regulated in these experiments, only genes were collected with significant detection-*P* values (exclusion of any false positives due to mismatch hybridization) and significant change-*P* values according to Affymetrix[®] algorithms. In addition, a minimum twofold change was set as cut-off. Table 1 shows the list of significantly regulated candidate genes after applying these stringent rules. Most of the genes are "early responders", i.e., detectable after 30 min. However, a few of those genes were differentially regulated still after 120 min. Based on the current knowledge on gene function annotated to individual probe sets of the Affymetrix[®] rat chip, the regulated genes fell into seven major categories: Genes with direct links to (I) wound healing, (II) cell migration, (III) wound edge activation, (IV) pleiotrope transcription factors which also can directly participate in cell migration and wound healing, (V) genes that are functionally involved in apoptotic pathways, (VI) genes linked to host defense and inflammation, and (VII) genes that have host defense functions such as osmoregulation and detoxification (Table 1).

Real-time RT-PCR confirms differential regulation of c-Fos, Cox-2, MCP-1, Egr-1 and Egr-2

As real-time TaqMan[®] RT-PCR has been proven to be a sensitive and reliable method for quantitative gene expression analysis^[11], differential mRNA expression of selected candidate genes (c-Fos), cyclooxygenase 2 (Cox-2), early growth response gene 1 and 2 (Egr-1 and -2) and MCP-1 was confirmed using this method. The real-time RT-PCR results confirmed the array data very well (Figure 2). The c-Fos mRNA displayed a 7.1-fold upregulation after 30 min. Likewise, the strong induction of Egr-1, Egr-2, and Cox-2 after 30 min could be confirmed. In addition, RT-PCR revealed a 2.2-fold downregulation of Egr-1 mRNA after 120 min, which was not observed in the array data.

Ingenuity[®] pathway analysis reveals a complex network of interacting genes, which are possibly related to intestinal repair, upon EphB1-Fc stimulation

A total of 331 genes that were more than 1.5-fold regulated after 30 min of EphB1-Fc treatment and with MAS (Affymetrix[®] Microarray Suite) change, *P*-values lower than 0.003 or higher than 0.997 respectively were used for the

Figure 2 Real-time RT-PCR analysis confirmed the differential expression of COX-2, Egr-1, Egr-2, MCP-1, and c-Fos in accordance to Affymetrix[®] array data. The results are indicated as positive (= upregulation) or negative (= downregulation) fold changes of mRNA amount compared to the control (*t* = 0 min, values normalized to 18S rRNA).

pathway analysis. The Affymetrix[®] ProbeSet IDs were imported together with the fold changes into the Ingenuity[®] Pathway Analysis Software (Ingenuity[®] Systems). One hundred and thirteen genes were eligible for generating networks. All 21 networks found were ranked by score. The score is a numerical value, used to rank networks according to how relevant they are to the genes within the dataset. The network with the highest score contained 28 genes. A functional network of differentially regulated genes could be established including the confirmed candidates c-Fos, Egr-1 and Egr-2 together with further genes related to growth and apoptosis (Figure 3). Interestingly, the pathway tools revealed that the strongly upregulated genes Egr-2 and c-Fos are linked by mutual activation, expression and transcription of each other. Both Egr-1 and c-Fos interact with jun, which obviously has a central position in the demonstrated network. Furthermore, Egr-1 enhances the expression of the growth factor receptor EGFR and is further linked to the cell cycle via CDKN1A. The details of the conceptual ephrin-B dependent network are shown in Figure 3.

Stimulating the ephrin-B reverse signaling pathways in IEC-6 induces temporary activation of ERK 1/2 map kinase stress pathways and FAK

Previous work has shown that signaling responses to changes in the microenvironment regarding the presentation of Eph-RTKs or ephrins on neighboring cells involve major MAP kinase pathways such as JNK and Erk^[13,15,16]. To identify the MAP kinase pathways involved in EphB/ephrin-B signaling in IEC cells, we screened for MAP kinase phosphorylation status in time-course experiments using stimulation with EphB1-Fc (0.25 $\mu\text{g/mL}$). As shown in Figure 4, there is a temporary induction of ERK1/2 phosphorylation that peaks after 20-30 min before returning to base levels.

Another important biological read-out of ephrin-B activation is the recruitment of FAK^[2]. FAK is a crucial player in integrin-mediated attachment and migration as well as reorganization of focal adhesion complexes, which also protect from anoikis^[17,18]. As shown in Figure 4, blotting with the anti-pY397-FAK indicates a time course of FAK phosphorylation upon EphB1-Fc stimulation in IEC-6 cells, which is almost identical to ERK 1/2 activation.

The latter observations could be further substantiated by immunofluorescence microscopy of wounded IEC-6 cell monolayers. Compared to IgG-Fc controls, EphB1-Fc stimulated IEC-6 cells revealed prominent induction of active pY397-FAK in neighboring cells at the wound margin (Figure 5).

DISCUSSION

Recent data generated by our group had suggested that EphB/ephrin-B cell-cell signaling can enhance epithelial wound closure of IEC-6 intestinal cells. In particular, the ephrin-B reverse signals seem to activate wound closure. *In*

vivo, such functions could be essential for the protection of the host against microbial antigens and toxic factors abundantly present in the gut. In this context, it is also very interesting that we had observed significant imbalance of the ephrin-B ligand expression in intestinal epithelial cells isolated from patients with Crohn's disease compared to healthy controls. Therefore, to elucidate further details of an assumed protective action of EphB-ephrin-B signal exchange in intestinal cells, we analyzed 'downstream' effects of the ephrin-B pathway. The most important finding of this study is that Affymetrix® gene chip data revealed a significant upregulation of a set of genes known to be fundamentally involved into wound healing, e.g. c-Fos, Egr-1,

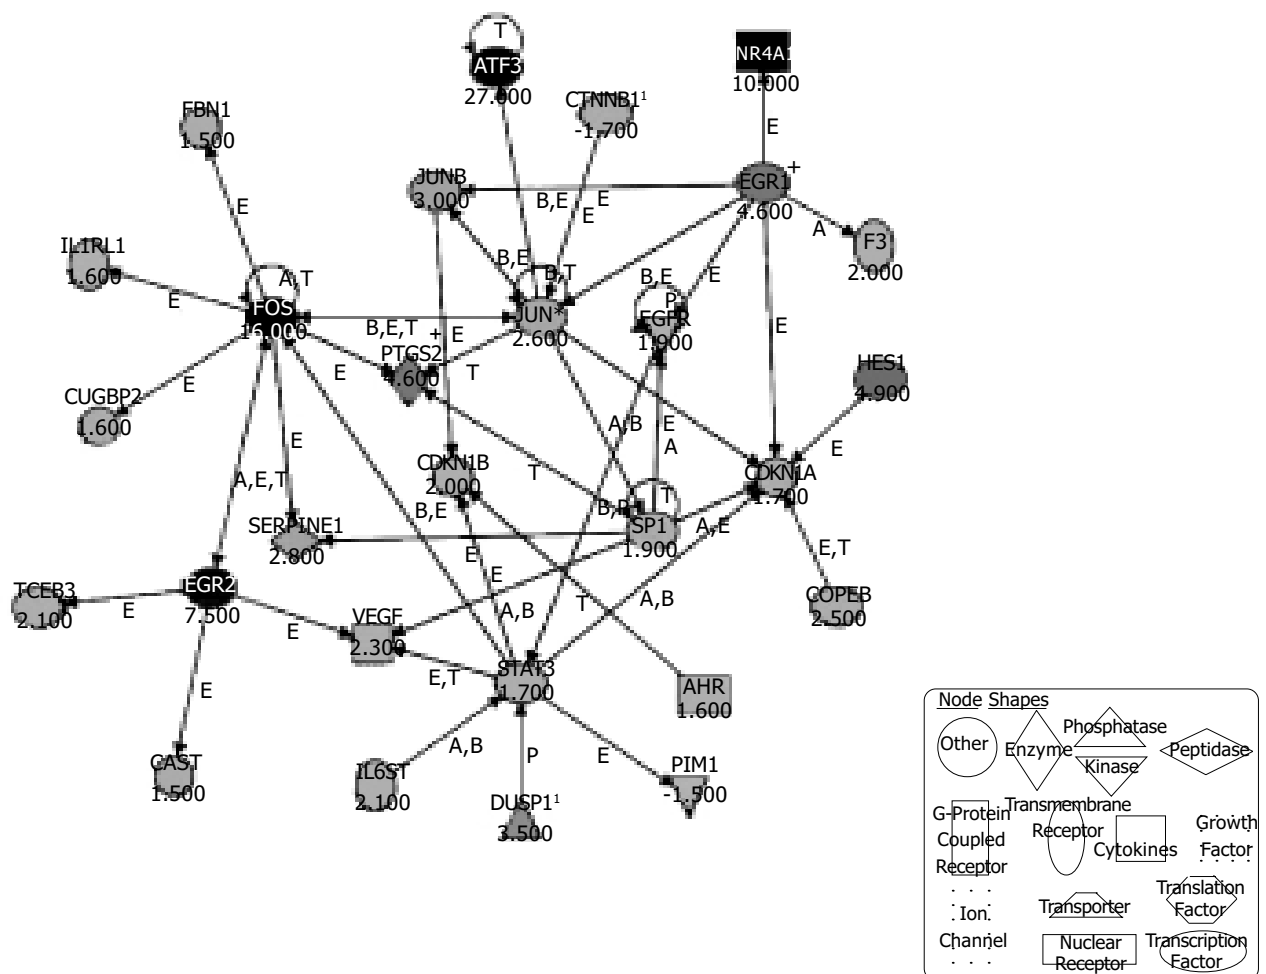

Figure 3 Ingenuity® Pathways Analysis reveals a possible network of genes activated in IEC-6 cells upon induction of the ephrin-B pathway. Three hundred and thirty-one regulated genes with changed *-P* values lower than 0.003 and higher than 0.997 were selected and entered the Ingenuity® pathway analysis. The displayed network features only genes with functional interactions. Many of those genes are associated with cellular growth, proliferation and control of cell death. Arrows pointing from one gene to another indicate that one causes activation of the other one (includes any direct interaction: e.g. binding, phosphorylation, dephosphorylation, etc.). For ligands/receptors arrows pointing from a ligand to a receptor signify that the ligand binds the receptor and subsequently leads to activation of the receptor. The respective fold-changes are given below the gene symbols. Further abbreviations are: A, Activation/deactivation; B, Binding; E, Expression; M, Biochemical Modification; P, Phosphorylation/dephosphorylation; T, Transcription; *Duplicate-user input gene that had duplicate identifiers in the dataset file mapping to a single gene in the Ingenuity® Pathways Knowledge Base. + Indicates there are other networks from the analysis that contain this gene. Gene names are: AHR:

Aryl hydrocarbon receptor; ATF3: Activating transcription factor 3; CAST: Calpastatin; CDKN1A: Cyclin-dependent kinase inhibitor 1A; CDKN1B: Cyclin-dependent kinase inhibitor 1B; COPEB: Core promoter element binding protein; CTNNB1: Catenin (cadherin-associated protein), beta 1; CUGBP2: UG triplet repeat, RNA-binding protein 2; DUSP1: Dual specificity phosphatase 1; EGFR: Epidermal growth factor receptor; EGR1: Early growth response 1; EGR2: Early growth response 2; F3: Coagulation factor 3; FBN1: Fibrillin-1; FOS: v-fos FBJ murine osteosarcoma viral oncogene homolog; HES1: Hair cell enhancer of split 1 (Drosophila); IL1RL1: Interleukin 1 receptor-like 1; IL6ST: Interleukin 6 signal transducer; JUN: v-jun sarcoma virus 17 oncogene homolog (avian); JUNB: Jun-B oncogene; NR4A1: Nuclear receptor subfamily 4, group A, member 1; PIM1: Proviral integration site 1; PTGS2: Prostaglandin-endoperoxide synthase 2; SERPINE1: Serine (or cysteine) proteinase inhibitor, member 1; SP1: Sp1 transcription factor; STAT3: Signal transducer and activator of transcription 3; TCEB3: Transcription elongation factor B (SIII), polypeptide 3; VEGF: Vascular endothelial growth factor.

¹IEC-6 cells were treated with 0.5 mg/mL (- 3.3 nmol/L) rat recombinant EphB1-Fc and RNA was harvested after 30 and 120 min. FC: fold changes; NC: no changes.

Egr-2, and COX-2 (30 min after stimulation with recombinant EphB1-Fc). Egr-1 (4.6-fold) and c-Fos (16-fold) were among the most strongly early-induced genes. Egr-1 is known as a

key activator of injury-induced gene expression^[19]. Egr-1 might also be responsible for the observed induction of NR4A1 (immediate early gene transcription factor NGFI-

Figure 4 Stimulating the ephrin-B reverse signaling pathway in IEC-6 with recombinant EphB1-Fc induces temporary activation of Erk1/2 map kinase stress pathways and FAK phosphorylation, demonstrated by immunoblotting. PDI served as a loading control.

Figure 5 Immunofluorescence microscopy demonstrates that compared to the control (A), stimulation of IEC-6 cells with recombinant EphB1-Fc leads to induction of active pY397-FAK in neighboring cells most prominently at the wound edge (B).

B; 10-fold) and EGFR (epidermal growth factor receptor; 1.9-fold), as well as for the induction of jun B (3.0, fold) and c-jun (2.6, fold) according to the Ingenuity[®] pathway analysis. In turn, the resulting AP-1 activity is known to be responsible for the observed prolonged induction of COX-2 (prostaglandin-endoperoxide synthase 2; 4.6-fold), but also MCP-1 (small inducible cytokine A2, 2.0-fold). COX-2 induction is considered as a further important line of defense for the gastrointestinal mucosa, necessary for maintenance of mucosal integrity and ulcer healing^[20,21]. On the other hand, MCP-1 is a proinflammatory cytokine with a well defined role in inflammatory bowel disease^[22-24]. Taken together, the Ingenuity[®] pathway analysis suggests that stimulation of the ephrin-B signaling can induce a complex network of wound healing associated genes in intestinal

epithelial cells with major interconnections to growth regulation and antiapoptosis, but also inflammation.

The exact anatomy of the signaling pathways activated in order to reseal epithelial defects in the gut remains poorly understood. IEC-6 cells, derived from fetal rat duodenal crypt cells, are one of the best-studied *in vitro* models for epithelial restitution^[19]. Previous work on IEC-6 wounding has implicated the extracellular signal-regulated kinase (ERK), mitogen-activated protein kinase as a central mediator of wound-signal transduction and regulator of epithelial restitution. Monolayer injury results in rapid activation of ERK1/2 (p42 and p44) in IEC-6 cells^[25]. Interestingly, our immunoblotting results are consistent with the view that ephrin-B signaling contributes to this pivotal wound-healing cascade. Moreover, in accordance with our data it has already been shown by another group that wounding of IEC-6 cells leads to ERK-dependent induction of Egr-1 and c-Fos. Both, direct blocking of ERK activation and interference with Egr-1 function resulted in diminished cell migration after injury^[19]. This suggests that stimulation of ephrin-B is a part of the injury response program in intestinal epithelial cells involving ERK1/2, Egr-1, and c-Fos. Interestingly, activation of forward signaling by ligand-mediated stimulation of EphA2 and EphB2 receptors is also linked to the ERK/MAPK signaling cascade^[26,27].

Recently, the receptor-like functions of B-ephrins and their intimate links to cell migration mechanisms could be defined in more detail on the molecular level^[2,13]. Upon binding and dimerization of the cognate receptors of neighboring cells, the cytoplasmic c-terminus of ephrin-B undergoes phosphorylation due to the recruitment of Src-family kinases^[15]. Subsequently, the phosphorylated cytoplasmic domain of ephrin-B provides a binding domain for SH2/SH3-adaptor proteins such as Grb4 (Nck2). In turn, Grb4 has three further SH3-domains that function as a scaffold for binding and activation of a variety of SH3-binding effectors. Some of them directly influence the dynamic control of the cytoskeleton, e.g., FAK, Paxillin, Abi-1, Axin, CAP, dynamin, hnRNPK, and Pak1^[2,28]. Among those effectors, FAK is particularly interesting in this context, because active FAK is essential to control cell spreading, movements and also integrin-dependent survival of IEC^[17,29]. Therefore, we analyzed FAK phosphorylation both by immunoblotting and by fluorescence microscopy. We show that in starved IEC-6 cells ephrin-B activation with nmol/L doses of EphB1-Fc leads to rapid induction of pY397-FAK, which seems to be most prominently detectable in wound-edge cells. The phosphorylation of FAK on Tyr397 is known to correlate with increased catalytic activity and appears to be important for the tyrosine phosphorylation of focal adhesion complex-associated proteins such as paxillin and Cas^[17]. Theoretically, the directed turnover of such complexes finally determines the speed of cell movements and the capacity of an epithelium to reseal defects.

We conclude that ephrin-B signaling induces complex pathways, which are essential for rapid epithelial wound closure in the intestine. Functional links to major determinants of epithelial defense and coordinated cell movement place EphB/ephrin-B into the list of targets for future molecular therapies trying to intervene with such pathways, for instance

in the context of inflammatory bowel disease. However, firstly the specifics of the side-effects such as the production of proinflammatory cytokines like MCP-1 and the complexity of seemingly counteracting downstream targets have to be investigated in more detail.

Abstract

AIM: To explore the mechanisms underlying the apoptosis of human pancreatic cancer BXPc-3 cells induced by indole-3-acetic acid (IAA) in combination with horseradish peroxidase (HRP).

METHODS: BXPc-3 cells derived from human pancreatic cancer were exposed to 40 or 80 $\mu\text{mol/L}$ IAA and 1.2 $\mu\text{g/mL}$ HRP at different times. Then, MTT assay was used to detect the cell proliferation. Flow cytometry was performed to analyze cell cycle. Terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling assay was used to detect apoptosis. 2,7-Dichlorofluorescein diacetate uptake was measured by confocal microscopy to determine free radicals. Level of malondialdehyde (MDA) and activity of superoxide dismutase (SOD) were measured by biochemical methods.

RESULTS: IAA/HRP initiated growth inhibition of BXPc-3 cells in a dose- and time-dependent manner. Flow cytometry revealed that the cells treated for 48 h were arrested at G_1/G_0 . After exposure to 80 $\mu\text{mol/L}$ IAA plus 1.2 $\mu\text{g/mL}$ HRP for 72 h, the apoptosis rate increased to 72.5%, which was nine times that of control. Content of MDA and activity of SOD increased respectively after treatment compared to control. Meanwhile, IAA/HRP stimulated the formation of free radicals.

CONCLUSION: The combination of IAA and HRP can inhibit the growth of human pancreatic cancer BXPc-3 cells *in vitro* by inducing apoptosis.

INTRODUCTION

Indole-3-acetic acid (IAA) is an important plant growth hormone found in higher plants, and plays a role in the regulation of plant cell division, elongation and differentiation^[1]. It is present in human urine^[2], blood plasma^[3], and central nervous system^[4]. IAA is well tolerated in humans^[5] and not oxidized by mammalian peroxidases. Recent researches suggest that the combination of IAA and horseradish peroxidase (HRP) is cytotoxic to mammalian cells, and can be used as a novel anticancer drug^[6-10], while neither IAA nor HRP alone shows any cytotoxic effect^[6]. HRP is a heme-containing peroxidase and can oxidize a wide variety of substrates including IAA in the presence of hydrogen peroxide. It has been reported that IAA activated by HRP produces free radicals, such as indolyl, skatolyl, and peroxy radicals, which can cause lipid peroxides^[11-13]. There are differences in endurance to the combination of IAA and HRP among the different types of cells^[14]. In the present study, we investigated the effects of IAA/HRP on BXPc-3 cells, a cell line derived from human pancreatic cancer, and found that IAA/HRP treatment could induce than increase of free radicals within the cells and cause apoptosis of BXPc-3 cells.

MATERIALS AND METHODS

Drug and reagents

IAA, HRP, and 3-(4,5-dimethylthiazol)-2,5-diphenyl tetrazolium bromide (MTT) were purchased from Sigma Chemical Co. 2,7-Dichlorofluorescein diacetate (DCFH-DA) was from Molecular Probes Co., and *in situ* cell apoptosis detection kit was from Sino-American Biotechnic Co. Commercial kits used for determining lipid peroxide and superoxide dismutase (SOD) activity were obtained from the Jiancheng Institute of Biotechnology (Nanjing, China).

Cell culture

Cells (1.0×10^5 cells/mL) were cultured in RPMI supplemented with 100 mL/L fetal bovine serum containing 2.0 mmol/L glutamine and 20 μg penicillin-streptomycin/mL in 50 mL/L CO_2 at 37 °C.

Experimental design

The experiments were divided into three groups: control group, 40 $\mu\text{mol/L}$ IAA+1.2 $\mu\text{g/mL}$ HRP (40 $\mu\text{mol/L}$ IAA/HRP) and 80 $\mu\text{mol/L}$ IAA+1.2 $\mu\text{g/mL}$ HRP (80 $\mu\text{mol/L}$ IAA/HRP) treatment groups. All tests were carried out in triplicate.

MTT assay for cell viability

Cells (2×10^4 cells/well) were seeded onto 96-well plates and incubated with test substances for an indicated time at 37 °C in 50 mL/L CO_2 . Then, 20 μL /well of MTT solution (5 mg/mL) was added and incubated for another 4 h. Supernatants were removed and formazan crystals were dissolved in 200 μL of dimethylsulfoxide. Finally, optical density was determined at 540 nm by a POLARstar⁺ OPTIMA (BMG Labtechnologies).

Detection of apoptosis

Apoptotic cells were identified using an *in situ* cell apoptosis detection kit. The cells were treated with IAA/HRP for a given time, and processed following the manufacturer's instruction. At least 1 000 cells were counted in each test, and the percentage of terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL)-positive cells was calculated.

Measurement of MDA content and SOD activity in cells

The number of cells was adjusted to 1×10^6 cells/mL, and broken by ultrasonic with PBS. Homogenates were centrifuged (1 000 r/min, 10 min, 4 °C) and the supernatant was used immediately for the assays of malondialdehyde (MDA) and SOD according to the instructions of the kits. MDA content was determined by the thiobarbituric acid method^[15] and expressed in nanomole per milligram protein. The assay for total SOD was based on its ability to inhibit the oxidation of oxyamine by the xanthine-xanthine oxidase system. The red product (nitrite) had an absorbance at 550 nm. One unit of SOD activity was defined as the quantity reducing the absorbance at 550 nm by 50%. The activity of SOD was expressed in nanounit per milligram protein.

Quantitative image analysis of intracellular ROS in live cells by confocal microscopy

Cells (2×10^4 cells/well) were seeded onto 24-well plates with cover slide and incubated with test substances for an indicated time at 37 °C in 50 mL/L CO_2 . The cells adhered to the glass flake were incubated with 50 $\mu\text{mol/L}$ of DCFH-DA for 5 min in dark in a CO_2 incubator. DCFH-DA is a nonpolar and nonfluorescent compound, which diffuses into the cells and is hydrolyzed into a polar 2',7'-dichlorofluorescein (DCFH)^[16]. The intracellular DCFH was rapidly oxidized to produce highly fluorescent 2',7'-dichlorofluorescein (DCF) at the presence of ROS or hydrogen peroxide within the cells. After incubation, the remaining dye was removed and the cells were washed twice with RPMI-HEPES before imaging collection. All confocal imaging analyses were performed under a Leica confocal laser scanning microscope using the 488-nm excitation laser line and simultaneous dual display mode (522 nm emission

and phase-contrast) of the BioRad LaserSharp imaging program. Five random images were collected to determine the average fluorescence intensity.

Cell cycle analysis by flow cytometry

DNA content per duplicate was analyzed using a FACStar flow cytometer (Becton Dickinson, Mountainview, CA). The adherent cells were harvested by brief trypsinization, and washed with PBS, fixed in 70% ethanol, stained with 20 $\mu\text{g/mL}$ propidium iodide containing 20 $\mu\text{g/mL}$ RNase (DNase free) for 30 min, and analyzed by flow cytometry. The populations of G_0/G_1 , S, and G_2/M cells were quantitated.

Statistical analysis

The data were expressed as mean \pm SD and analyzed by software of SPSS10.0. $P < 0.05$ was considered statistically significant.

RESULTS

Inhibition of cell growth and arrest of cell cycle

The growth of human pancreatic cancer BXPc-3 cells was measured using MTT assay at varying time points after treatment. As shown in Figure 1, the combination of IAA and HRP could inhibit the growth of BXPc-3 cells. The inhibition of cell growth after treatment with 80 $\mu\text{mol/L}$ IAA/HRP was higher than that after treatment with 40 $\mu\text{mol/L}$ IAA/HRP, suggesting that the inhibition was in an IAA dose-dependent manner. Because the inhibition of cell growth was the highest 2 d after the treatment, we checked the cell cycle using a flow cytometer at the time of 2-d treatment. The cell cycle distribution of BXPc-3 cells in control group was 62.28% at G_1/G_0 , 0.43% at G_2/M and 37.28% at S. In the IAA/HRP treatment group, the cell cycle distribution of BXPc-3 cells significantly increased at G_1/G_0 phase, and decreased greatly at S phase, implying that IAA/HRP could induce the arrest of cells at G_1/G_0 phase.

Figure 1 Effect of IAA and HRP treatment on growth of BXPc-3 cells.

Effect of IAA/HRP treatment on apoptosis of BXPc-3 cells

After TUNEL staining, the apoptotic cells markedly increased after IAA/HRP treatment. When the cells were treated with IAA/HRP for 72 h, the apoptosis rate increased to 72.5%, which was nine times that of the control ($P < 0.05$, Figure 2).

Figure 2 Apoptosis rate of BXPc-3 cells 3 d after IAA and HRP treatment.

Production of free radicals in BXPc-3 cells induced by IAA/HRP

The formation of ROS in BXPc-3 cells treated with IAA/HRP could be detected by confocal microscopy as the product was able to show fluorescence. As shown in Figure 3, DCF fluorescence in cells exposed to IAA/HRP for 3, 6, 24, and 48 h was much brighter compared to that in control group, suggesting that free radicals were formed in a IAA dose- and time-dependent manner (Table 1, Figure 4).

Level of MDA and activity of SOD in BXPc-3 cells treated with IAA/HRP

To investigate the damage of free radicals induced by IAA/HRP in BXPc-3 cells, MDA content and SOD activity were measured. The content of MDA and activity of SOD

in BXPc-3 cells increased after IAA/HRP treatment (Table 2). There were significant differences between treatment group and control group (*P*<0.01).

DISCUSSION

Although IAA/HRP-induced cell death and its potential application in cancer therapy has been recognized^[8,17,18], the sensitivity of different cell types to IAA/HRP might not be the same^[14]. We chose human pancreatic cancer BXPc-3 cells to evaluate IAA/HRP, which could be used in treatment of human pancreatic cancer. In this study, the MTT assay showed that the viability of BXPc-3 cells decreased with increase of IAA in the presence of HRP (Figure 1). In addition, TUNEL analysis showed that IAA/HRP induced apoptosis of BXPc-3 cells (Figure 2). In agreement with our results, it was also reported that the photoproducts of IAA induce apoptosis of human HL-60 and murine tumor cells^[19].

There are two important arrest points in cell cycle at G₁/G₀ and G₂/M^[20-23]. Flow cytometric analysis of propidium iodide-stained cells showed that cells accumulated at the G₁/G₀ phase compared to control (Table 1). These cell cycle changes suggest that pancreatic cancer cells have oxidative stress response to IAA/HRP treatment with DNA damage leading to apoptosis.

Figure 3 Confocal images of intracellular ROS generation after 3, 6, 24, and 48 h exposure of BXPc-3 cells to IAA/HRP. A: Control; B: 40 μmol/L IAA/HRP; C: 80 μmol/L IAA/HRP.

Figure 4 Production of free radicals in BXPc-3 cells exposed to IAA and HRP.

DCFH is widely used to measure the oxidative stress in cells^[24-26]. When the diacetate form of DCFH is added to cells, it diffuses across the cell membrane and is hydrolyzed by intracellular esterases to liberate DCFH, which upon reaction with oxidizing species forms its two-electron oxidation product, the highly fluorescent compound DCF. The fluorescence intensity can be easily measured by confocal microscopy and is the basis of the popular cellular assay for oxidative stress. In this study, DCF was used to investigate the production of free radicals in BXP-3 cells treated with IAA/HRP. The fluorescence intensity increased in the treatment group in comparison to control group (Figure 3), suggesting that the formation of free radicals increases in an IAA dose- and time-dependent manner (Figure 4).

It is known that tumor cells exhibit metabolic characteristics in terms of oxygen consumption and oxidative metabolism. The fact that tumor tissues are more susceptible to oxidative stress than the surrounding normal cells is supported by the increase of lipid peroxidation and DNA damage^[27] and the decrease of antioxidant enzyme activities^[28]. Folkes *et al.*^[6], found that lipid peroxidation in liposomes is stimulated by the IAA/HRP treatment, but it cannot be measured in mammalian cells. To investigate the damage of free radicals in cells, MDA content, and SOD activity were measured in this study. The results showed that the content of MDA and the activity of SOD in BXP-3 cells increased when treated with IAA/HRP (Table 2). In agreement with our results, it was also reported that incubation of neutrophils for 24 h in the presence of IAA increases the activities of SOD, catalase (CAT) and glutathione peroxidase^[29]. Recently, it was reported that ROS activates the ERK signaling cascade^[30-32]. Kim *et al.*^[33], proved that IAA/HRP can activate p38 mitogen-activated protein (MAP) kinase and c-Jun N-terminal kinase (JNK) in G361 human melanoma cells, which are almost completely blocked by antioxidants.

In summary, the combination of IAA and HRP can inhibit the growth of human pancreatic cancer BXP-3 cells *in vitro* by inducing apoptosis, which is associated with the increase of free radicals.

Abstract

AIM: To study the changes of endogenous interleukin 18 (IL-18) levels and evaluate the role of IL-18 on lung injury following gut ischemia/reperfusion.

METHODS: A superior mesenteric artery occlusion model was selected for this research. The mice were randomly divided into four groups: Sham operation (sham), ischemia (0.5 h) followed by different times of reperfusion (I/R), and I/R pretreated with exogenous IL-18 (I/R+IL-18) or IL-18 neutralizing antibody (I/R+IL-18Ab) 15 min before ischemia. Serum IL-18 levels were detected by Western blot and ELISA, and the levels of IL-18 in lung tissue were evaluated by immunohistochemical staining. For the study of pulmonary inflammation, the lung myeloperoxidase (MPO) contents and morphological changes were evaluated.

RESULTS: Gut ischemia/reperfusion induced rapid increase of serum IL-18 levels, peaked at 1 h after reperfusion and then declined. The levels of IL-18 in lung tissue were gradually enhanced as the progress of reperfusion. Compared with I/R group, exogenous administration of IL-18 (I/R+IL-18) further remarkably enhanced the pulmonary MPO activity and inflammatory cell infiltration, and in I/R+IL-18Ab group, the content of MPO were significantly reduced and lung inflammation was also decreased.

CONCLUSION: Gut ischemia/reperfusion induces the increase of IL-18 expression, which may make IL-18 act as an important proinflammatory cytokine and contribute to gut ischemia/reperfusion-induced lung inflammation.

INTRODUCTION

Multiple organ dysfunction syndrome (MODS) is the leading cause of death in critically ill patients. Although systemic inflammation characteristic of MODS can result in damage to any organ, onset of the syndrome is usually heralded by the development of respiratory insufficiency^[1,2]. Gut ischemia and reperfusion (I/R) is a prime mechanism that results in the pathogenesis of MODS partly dependent on neutrophils^[2]. Neutrophils can be activated in response to reperfusion of ischemia tissue or exposure to endotoxin and pro-inflammatory cytokines^[1]. Activated neutrophils adhere to endothelium through adhesion molecules, resulting in localized release of proteases, reactive oxygen species (ROS) and various cytokines and inflammatory mediators that contribute to tissue injury and failure^[1,2].

Interleukin 18 (IL-18), known initially as an IFN- γ -inducing factor, is a pleiotropic proinflammatory cytokine and it has direct proinflammatory properties. In this respect, IL-18 induces production of proinflammatory cytokines such as TNF- α , IL-1 β and chemokines such as IL-8, MIP-1 α and MCP-1^[3,4], and upregulates expression of adhesion molecules such as ICAM-1, VCAM-1 on endothelial cells^[3,5]. Furthermore, IL-18 is found to activate neutrophils and promote neutrophil migration, adhesion and accumulation *in vivo*^[6]. These data suggest that IL-18 may be involved in the inflammatory injuries associated with I/R^[1,2,7,8]. Therefore, recent evidence showing that some local tissue ischemic injuries are associated with increased IL-18 levels^[9,10], and elevated IL-18 levels have been detected in response to hepatic I/R injury^[11]. A direct correlation has been observed between IL-18 levels and liver neutrophils sequestration and liver injury, which suggests that IL-18 is required for facilitating neutrophil-dependent hepatic I/R injury^[11]. Similarly, increased levels of IL-18 have been detected in isolated atrial trabeculae during I/R injury^[12]. Inhibition of IL-18 or caspase-1 activity attenuated tissue and circulating levels of IL-18 and improved myocardial contractility, suggesting that endogenous IL-18 play a significant role in I/R-induced human myocardial injury^[12]. Furthermore, Melnikov *et al.*, reported that caspase-1 and IL-18 play an important role in the ischemic acute renal failure^[13]; however,

there is also evidence suggesting that activated caspase-1 and its inflammatory products are not crucial to the induction of inflammation after renal I/R^[14]. It is intriguing to consider the role of IL-18 in the I/R-induced local organ injury, and no evidence exists on the role of IL-18 in the MODS following I/R. Therefore, the major aim of present study was to determine the change of expression and role of IL-18 in the acute pulmonary injury after gut ischemia/reperfusion.

MATERIALS AND METHODS

Reagents and mice

C57BL/6J mice (SPF) were obtained from animal center, SIBS, Shanghai. For the experiments, 8-10-wk-old mice weighing 22-26 g were used. rmIL-18 was expressed and purified in our lab (purity >95% by SDS-PAGE) and the activity was confirmed by its ability to induce IFN- γ production by mouse spleen cells. For immunohistochemical analysis, polyclonal rabbit anti-mouse IL-18 antibody was purchased from Boster (Wuhan, China). For immunoprecipitation and Western blot analysis, polyclonal rabbit anti-murine IL-18 antibody was provided by PeproTech (Rocky Hill, NJ, USA).

Ischemia/reperfusion model

Mice were anesthetized by intraperitoneal injection of urethane (250 mg/mL, 1.25 mg/g wt of mouse, Sigma). The abdomen was rinsed with 75% ethanol, a midline laparotomy was performed and the superior mesenteric artery was occluded with an arterial clamp. Intestinal ischemia was confirmed by pulselessness of the mesenteric artery and paleness of the jejunum and ileum. Sham-operated mice underwent the same procedure, but without vascular occlusion. After 30 min, the clamp was removed, sterile saline was injected into the peritoneal cavity for resuscitation, and the mice were sutured.

Experimental protocols

The mice were randomly divided into four groups ($n = 5$ in each): sham, I/R, I/R+IL-18, and I/R+anti-IL-18. For exogenous IL-18 studies, animals were pretreated with either IL-18 (5 μ g/mouse) or sterile saline via the lateral tail vein 15 min before ischemia. For IL-18 neutralization studies, mice received monoclonal anti-IL-18 antibody (25 μ g/mouse, MBL, Nagoya, Japan) or sterile saline 15 min before ischemia. Animals underwent 30 min of superior mesenteric artery occlusion (or sham operation) followed by indicated periods of reperfusion were killed, lung tissues, and blood samples were taken for analysis. Excised lungs were frozen in liquid nitrogen and stored at -70 °C before determination of myeloperoxidase (MPO) activity. For histological or immunohistochemical studies, lungs were immersed in 10% neutral buffered formalin before sectioning. All blood samples were kept at room temperature for 2 h to clot, and serum was removed and stored at -70 °C until the time of assay.

Serum IL-18 measurements

Animals underwent cardiac puncture to obtain blood at the indicated times in the reperfusion period. Systemic levels of IL-18 were evaluated by immunoprecipitation followed by Western blot. Serum was diluted to 1 mL with PBS, and

serum IL-18 was immunoprecipitated with rabbit anti-murine IL-18 antibody. Then, the immunoprecipitates were resolved by SDS-PAGE (12-15% acrylamide) under reducing conditions. Gels were transferred to NC membranes and incubated with primary antibodies (1:1 000) at 4 °C overnight. Then mouse anti-rabbit IgG peroxidase was added and developed by ECL. Serum levels of IL-18 were further measured by ELISA according to the manufacturer's instructions (Boster, Wuhan, China). The detection limit for IL-18 was <5 pg/mL.

MPO assay

MPO activity is an indicator of neutrophil accumulation. The content of MPO in the tissues was measured as previously described with slight modification^[7]. The lungs were homogenized for 30 s in 4 mL 50 mmol/L potassium phosphate buffer (pH 6.0) and then centrifuged for 30 min at 16 000 g at 4 °C. The pellet was resuspended in 1.5 mL 50 mmol/L potassium phosphate buffer (pH 6.0) containing 5 g/L cetrimonium bromide. The samples were sonicated for 90 s and then incubated in a 60 °C water bath for 2 h, and centrifuged for 30 min at 35 000 g at 4 °C. The supernatant 50 μ L was added to 950 μ L of 50 mmol/L potassium phosphate buffer (pH 6.0) containing 0.167 mg/mL *o*-dianisidine (Sigma) and 5 μ L/L hydrogen peroxide. Absorbance of 460 nm was measured at 1 and 3 min. MPO content per gram of wet tissue was calculated as: MPO content (A/g wet tissue) = $(A_{460}(3 \text{ min}) - A_{460}(1 \text{ min})) / \text{tissue weight (g)}$.

Histopathology and immunohistochemistry

Lungs were immersed in 10% neutral buffered formalin before sectioning. Sections (4 μ m) were obtained from paraffin-embedded tissue samples, stained with hematoxylin-eosin (HE), and examined for histological evaluation of tissue damage under a microscope and photographed. For immunohistochemical analyses, paraffin-embedded lung sections of 4 μ m were incubated overnight at 4 °C with polyclonal rabbit anti-mouse IL-18 antibody (dilution 1:100). Biotinylated IgG was added as second antibody. Horseradish peroxidase-labeled streptomycin-avidin complex was used to detect second antibody. Slides were stained with diaminobenzidine, counterstained with hematoxylin, and finally examined under light microscope. The brown or dark brown stain was considered as positive.

Statistical analysis

All data are presented as mean \pm SD. Significant differences between groups were determined using Student's *t*-test. $P < 0.05$ is considered as statistically significant.

RESULTS

Ischemia/reperfusion-induced upregulation of IL-18 levels

IL-18 has been shown to be upregulated after ischemia in the kidney, heart, and liver. Therefore, we investigated whether the levels of IL-18 changed in response to gut ischemia/reperfusion. The serum, obtained from sham and from gut I/R model at different times of reperfusion, was first evaluated by Western blot, and the change of IL-18

levels is shown in Figure 1A. Two bands were detected in all serum samples, which are consistent with the “pro” and “mature” form of IL-18. At time 0, the content of IL-18 from I/R group, for both pro and mature, was elevated as compared with that from sham-operated mice, and the levels of mature IL-18 (mIL-18) was further considerably elevated 1 h after reperfusion, and then decreased at 3 h (Figure 1A).

Mouse serum IL-18 was further detected by ELISA after gut ischemia/reperfusion or sham operation. As shown in Figure 1B, IL-18 levels from normal mouse were <200 pg/mL. Consistent with the previous results, there was a marked increase in serum IL-18 from I/R group, peak at 1 h (at 660 pg/mL), followed by a decline. In the sham group, there was little measurable change in IL-18 levels during all reperfusion time.

Furthermore, lung tissues obtained from normal mouse and I/R mice with 1 or 3 h reperfusion was examined by immunohistochemistry. Besides the constitutive expression of IL-18 in air way epithelium, normal lung tissue lacked immunoreactive IL-18 (Figure 1C, a and b); during 1-3 h of reperfusion, gradually increased levels of IL-18 were observed with prominent IL-18 staining (Figure 1C, c and d). These data indicated that IL-18 is induced at the early phase of ischemia/reperfusion and may participate in the pulmonary inflammation.

Effects of rmIL-18 on lung inflammation after gut I/R

Ischemia-induced expression of IL-18 increased remarkably at the early phase of reperfusion, suggesting that IL-18 may be an early inflammatory mediator and involved in the injurious processes in lung after gut I/R, which prompted

us to suppose whether administration of exogenous IL-18 could exert early effects on neutrophil activation and accelerate lung injury. As shown in Figure 2, in the IL-18-nontreated group, gut ischemia/reperfusion induced gradually increased MPO activity in the lungs at 0.5, 1, or 3 h after reperfusion (0.65 ± 0.08 , 0.86 ± 0.19 , or 1.99 ± 0.17 respectively), and IL-18 injection further dramatically enhanced the MPO activity in the lung tissues at each indicated times after reperfusion: the MPO value in IL-18-treated mice was further increased to 1.54 ± 0.38 (a 237% increase), and 2.63 ± 0.20 (a 306% increase) at 0.5 or 1 h after ischemia respectively, as compared with IL-18-nontreated group ($P < 0.05$); and IL-18 administration induced much more neutrophils infiltration in lung within 1 h of reperfusion than that of 3 h of reperfusion in IL-18-nontreated group (Figure 2A). Furthermore, after 3 h of reperfusion, the MPO activity was further increased to higher level (3.68 ± 0.45 , a 184% increase) compared with that from IL-18-nontreated mice ($P < 0.05$). These data suggested that IL-18 injection enhanced pulmonary MPO activity and augmented the neutrophil accumulation in lung.

Lung inflammation in this model was evident from histological analysis (Figure 2B). As previously reported, massive neutrophil infiltration was observed in the lung tissues from gut I/R model within 3 h of reperfusion (Figure 2B, b). Although the infiltration in IL-18-nontreated mice at 1 h after ischemia was not obvious (Figure 2B, a), IL-18 injection significantly enhanced the pulmonary infiltration after 1 h of reperfusion (Figure 2B, c). Furthermore, treatment of IL-18 induced more serious inflammatory cell infiltration compared with that of IL-18-nontreated mice as the reperfusion

Figure 1 Gut ischemia/reperfusion results in increased levels of IL-18 in serum and lung. (A and B) The circulating levels of IL-18 after gut ischemia/reperfusion. Mice were subjected to gut ischemia/reperfusion or sham. Serum IL-18 at the indicated times after reperfusion was collected, part of which was immunoprecipitated with polyclonal rabbit anti-murine IL-18 antibody and analyzed by immunoblotting

(A), and another part was assayed with ELISA (B) ($n = 5$). (C) Gut ischemia/reperfusion results in elevated levels of IL-18 in lung tissue. Immunohistochemistry of lung sections obtained from normal (a, ×100, and b, ×200), 1 h (c) or 3 h (d) I/R model. The positive staining for IL-18 shows as dark brown. Magnification (c and d) ×200.

Figure 2 The effect of exogenous IL-18 on the ischemia/reperfusion-induced lung injury. **A:** IL-18 injection further remarkably enhanced the neutrophil sequestration in lung. After indicated times of reperfusion, the MPO activity was determined in lung tissue ($n = 5$), ^a $P < 0.05$ vs I/R. **B:** Comparison of pulmonary

histopathology. Lungs from IL-18-nontreated (a, for 1 h of reperfusion and b, for 3 h) or IL-18-treated (c, for 1 h and d, for 3 h of reperfusion) mice subjected to gut I/R and stained with HE. Magnification $\times 100$.

time extended to 3 h (Figure 2B, b and d), which in accordance with the higher MPO activity in IL-18-treated group. Both indices of lung inflammation, including histological changes and MPO activity, suggest that IL-18 injection may accelerate and augment the lung inflammatory injury in response to gut I/R, and IL-18 may be involved in the lung pathogenesis in this I/R model as an early inflammatory mediator.

Effects of anti-IL-18 on lung inflammatory induced by gut ischemia/reperfusion

To further determine the role of induced IL-18 in the lung pathogenesis, we investigated whether *in vivo* neutralization of IL-18 could modify neutrophil-mediated acute inflammatory response induced by gut I/R. Anti-IL-18Ab (25 μ g/mouse) was administered 15 min before ischemia insult, and after 3 h of reperfusion, the MPO levels were determined and

the lung inflammation was evaluated histopathologically. As shown in Figure 3, anti-IL-18 recipient mice exhibited significantly reduced tissue MPO activity (more than 50% decrease in the lung MPO levels) as compared with the positive control ($P < 0.05$, Figure 3A). Consistent with this, the inflammatory infiltration was significantly reduced in anti-IL-18-treated mice (Figure 3B). These data suggested the IL-18Ab attenuated lung inflammation induced by gut I/R and supported the concept that endogenous IL-18 functioned as an important proinflammatory factor, which may be involved in the neutrophil sequestration and lung injury in this gut I/R model.

DISCUSSION

To date, IL-18 has been known for its role in infectious

Figure 3 The effect of anti-IL-18 antibody on the ischemia-induced lung injury. **A:** Anti-IL-18 antibody injection remarkably inhibited the lung MPO activity. After 3 h of reperfusion, the MPO activity was determined in lung tissues ($n = 5$),

^a $P < 0.05$ vs others. **B:** Comparison of pulmonary histopathology. Lungs from ischemic mice (a, for 3 h of reperfusion), and ischemic mice treated with IL-18Ab (b, for 3 h of reperfusion) and stained with HE. Magnification $\times 100$.

inflammatory injury. However, few investigations have been accomplished regarding the role of IL-18 during non-infectious acute inflammatory reactions such as those that occur in ischemia/reperfusion. Previous reports have shown that IL-18 have important regulatory role during organ injury induced by local ischemia/reperfusion^[11-13]. In the current study, we used a model of acute lung inflammation induced by gut ischemia/reperfusion, which results in damage of capillary endothelial cells and neutrophil influx, and oxidants, proteases released from inflammatory cells damage lung cells and tissue matrix^[1-3]. The role of IL-18 in this model of lung injury has not been explored. The current study provides evidence that endogenous IL-18 may act as a proinflammatory cytokine and contribute to gut ischemia/reperfusion-induced lung inflammation.

Our results, consistent with the previous reports, have shown that local ischemia may induce the elevation of IL-18 level^[11-13]. It promptly reached peak at 1 h and then declined to baseline. However, the levels of IL-18 in lung tissue were not the same. Constitutively, expression of IL-18 in airway epithelium has been observed by using immunohistochemistry, and as the reperfusion time extended to 3 h, the level of IL-18 in air way epithelium was greatly enhanced and immunoreactive IL-18 dispersed all over the lung tissue, which suggests that pulmonary expression of IL-18 may be enhanced during reperfusion as the inflammatory agents secreted from intestine reached the lung tissue and further, the IL-18 receptor mediated mechanism may also account for the pulmonary accumulation of IL-18, which in accordance with the rapid decline of serum IL-18 level during reperfusion.

IL-18 has been known to be produced as a proform and stored in cytoplasm. After the cleavage of caspase-1, it turns to a functional, mature protein. By Western blot analysis, the IL-18 mature protein was quickly increased after 1 h of reperfusion (Figure 1A), which suggests that gut ischemia may result in the activation of caspase-1 and enhance the maturation and secretion of IL-18. Furthermore, previous reports have shown that ischemia also induces IL-1 β expression. Therefore, it is possible that intestinal caspase-1 may play a key role in expression of both the mature IL-18 and IL-1 β , and ischemic gut may serve as a major source for circulating IL-18 in this model.

Experimental studies have suggested that IL-18 protects against bacterial and viral agents^[3], which is thought to be attributable in part to the infiltration of inflammatory cells after treatment with IL-18. There is also evidence suggesting that IL-18 may activate neutrophils and promote neutrophil migration and accumulation *in vivo*^[6]. In the current studies, we showed that the *in vivo* exogenous administration of IL-18 before gut ischemia greatly enhanced neutrophil recruitment as well as lung inflammation (Figure 2). Conversely, IL-18 blockade reduced the evidence of lung inflammation by neutralizing Ab (Figure 3). These results suggest that IL-18 may, like IL-1 β , be an important early pro-inflammatory cytokine involved in the pathogenesis of acute lung inflammation induced by gut ischemia/reperfusion. Furthermore, these data also suggest that the preoperative levels of serum IL-18 may represent a valuable parameter to aid the postoperative prognostic determinant in clinical

patients with ischemia-induced MODS.

But how IL-18 is activated, and how it enhances the pulmonary inflammation during ischemia/reperfusion is still unknown. There is evidence indicating that NO suppresses IL-18 processing by inhibiting caspase-1 activity^[15,16]. It is likely that ischemia-induced decrease of NO levels may result in the activation of caspase-1 and the further secretion of mature IL-18. Furthermore, it is clear that IL-18, a pleiotropic proinflammatory cytokine, has an endogenous role in enhancing production of several early response cytokines during lung inflammation, such as TNF- α , IFN- γ , and IL-1 β . Previous reports have shown that IL-18 may activate neutrophil and promote neutrophil migration and accumulation *in vivo* via a TNF- α -dependent pathway^[6,17]. However, the mechanism of pulmonary neutrophils sequestration is possibly independent of TNF- α in this lung injury model^[18], which suggests that the function of IL-18 may not be totally dependent on the role of TNF- α . These works are now in progress in our group.

The present data expand our knowledge of the immunoregulatory properties of IL-18. Our findings are clinically applicable to ischemia/reperfusion injury during surgical operation such as small intestinal transplantation, and modulation of IL-18 expression may enhance endogenous protective effects, leading to a reduction in organ injury.

Abstract

AIM: To observe the relationship between ethanol-induced oxidative damage in human primary cultured hepatocytes and cytochrome P450 2E1 (CYP2E1) activity, in order to address if inhibition of CYP2E1 could attenuate ethanol-induced cellular damage.

METHODS: The dose-dependent (25–100 mmol/L) and time-dependent (0–24 h) exposures of primary human cultured hepatocytes to ethanol were carried out. CYP2E1 activity and protein expression were detected by spectrophotometer and Western blot analysis respectively. Hepatotoxicity was investigated by determination of lactate dehydrogenase (LDH) and aspartate transaminase (AST) level in hepatocyte culture supernatants, as well as the intracellular formation of malondialdehyde (MDA).

RESULTS: A dose- and time-dependent response between ethanol exposure and CYP2E1 activity in human hepatocytes was demonstrated. Moreover, there was a time-dependent increase of CYP2E1 protein after 100 mmol/L ethanol exposure. Meanwhile, ethanol exposure of hepatocytes caused a time-dependent increase of cellular MDA level, LDH, and AST activities in supernatants. Furthermore, the inhibitor of CYP2E1, diallyl sulfide (DAS) could partly attenuate the increases of MDA, LDH, and AST in human hepatocytes.

CONCLUSION: A positive relationship between ethanol-induced oxidative damage in human primary cultured hepatocytes and CYP2E1 activity was exhibited, and the inhibition of CYP2E1 could partly attenuate ethanol-induced oxidative damage.

INTRODUCTION

The enzymes that are believed to be primarily responsible for the oxidation of ethanol are alcohol dehydrogenase, catalase, and cytochrome P450 2E1 (CYP2E1), all of which appear to be relatively widely distributed in mammalian cell types^[1,2]. Ethanol has long been known to have cytotoxic effects on a wide variety of animal cell types, even at relatively low doses^[3,4]. In several cell types and organs such as liver^[5], it is now believed that the toxicity of ethanol stems principally from free radicals produced during oxidation^[6] that can then damage cellular components such as DNA, proteins, and membrane lipids.

CYP2E1 is of special interest because of its ability to metabolize and activate numerous hepatotoxic substrates in the liver such as ethanol, carbon tetrachloride, acetaminophen, and *N*-nitroso dimethylamine, to more toxic products. CYP2E1 exhibits enhanced reduced form of nicotinamide adenine dinucleotide phosphate oxidase activity and is very reactive in catalysis of lipid peroxidation and production of reactive oxygen intermediates (ROI) such as H₂O₂ in higher amounts relative to other P450 isoforms^[7]. Induction of cytochrome CYP2E1 by ethanol appears to be one of the central pathways by which ethanol generates a state of oxidative stress. In addition, oxidation of ethanol by CYP2E1 produces acetaldehyde, a highly reactive compound that may contribute to the toxic effect of ethanol^[8]. Hence, there is considerable interest in the role of reactive oxygen species (ROS) during ethanol metabolism by which ethanol is hepatotoxic.

CYP2E1 is shown to be more effective in catalyzing lipid peroxidation compared to several other forms of cytochrome P450 enzymes. Increases in formation of ROS by microsomes isolated from ethanol-treated rats were prevented by anti-CYP2E1 IgG, thus linking them to induction of CYP2E1^[9]. In the intragastric ethanol feeding, significant alcoholic injury occurred^[10]. In addition, large increases in lipid peroxidation have been observed, and the ethanol-induced liver pathology has been shown to correlate with CYP2E1 levels and elevated lipid peroxidation, and to be blocked by inhibitors of CYP2E1. Moreover, CYP2E1

inhibitors also reduced ethanol-induced ROS formation, suggesting that CYP2E1 contributes to ROS formation. Inhibitors of CYP2E1 were also shown to prevent ethanol cytotoxicity in transduced HepG2 cells^[11].

However, question arises whether the responses to expression of different forms of cytochromes P450 are similar in rats and humans. The concentrations of ethanol required to increase CYP2E1 in cultured human hepatocytes are dramatically lower than those required to induce these forms of P450 in cultured rat hepatocytes. The activity of alcohol dehydrogenase, a major enzyme involved in ethanol metabolism, is lower in human liver than in rat liver. Thus, in the human hepatocyte cultures, more ethanol may be available intracellularly to induce the P450s due to lower metabolism. Alternatively, the mechanism of induction of these forms of P450s may be different in human than in rat hepatocytes^[12]. In this study, we investigated the effects of ethanol administration on human primary culture hepatocytes in order to determine if there is a correlation between CYP2E1 activity and ethanol-induced oxidative damage in human hepatocytes, and further address if diallyl sulfide (DAS), an inhibitor of CYP2E1^[13], could partly attenuate ethanol-induced oxidative damage.

MATERIALS AND METHODS

Materials

Williams' medium E (with Glutamax-1), HEPES, and penicillin/streptomycin were obtained from Life Technologies (Karlsruhe, Germany), insulin and hydrocortisone were supplied from Sigma (Deisenhofen, Germany), while calf serum was purchased from PAA Ltd (Linz, Austria), anti-mouse CYP2E1 antibody was purchased from Amersham (Germany). Western blot development kits were purchased from Amersham (ECL, Buckinghamshire, UK). All other reagents were obtained from Sigma unless indicated otherwise.

Isolation and culture of human hepatocytes

Human liver tissue weighing 5–10 g was obtained from liver resections of cholecystectomy of patients who had no known liver pathology, nor had they received medication during 4 wk prior to surgery. None of the patients was a habitual consumer of alcohol or other drugs. The collection of tissue was done according to institutional guideline, and the patient's written consent. Immediately after resection, a wedge section of the normal tissue was transferred under sterile conditions to the laboratory in culture media. Human hepatocytes were isolated by a two-step collagenase perfusion technique followed by a Percoll centrifugation step as previously described^[14]. Hepatocyte purity assessed under light microscope was over 95% and viability consistently exceeded 93% by trypan blue exclusion. The freshly harvested human hepatocytes were then seeded onto rat-tail collagen-coated Petri dishes or 12-well culture trays. The medium consisted of Williams' E medium supplemented with 1 μ mol/L insulin, 15 mmol/L HEPES, 1.4 μ mol hydrocortisone, 10% calf serum, penicillin (100 U/mL), and streptomycin (100 μ g/mL). Cells were incubated in a humidified incubator in 950 mL/L air and 50 mL/L CO₂ at 37 °C until cell attachment. On the following day, cells

were exposed to various concentrations of ethanol (25–100 mmol/L) for 9 h. Time-dependent studies were undertaken in human hepatocytes using 100 mmol/L ethanol between 0.5 and 24 h. At the corresponding time intervals, cells and supernatants were collected in agreement with the applied technique.

CYP 2E1 enzyme activity

Human hepatocytes were seeded onto 12-well dishes at a concentration of 0.5×10^6 cells. The cells were cultured overnight, fresh medium alone or medium containing various concentrations of ethanol or DAS (25–100 μ mol/L) was added, and the cells were incubated for various lengths of time. Cells were harvested with a cell scraper and washed with PBS twice. The activity of CYP2E1 was determined by the rate of hydroxylation of *p*-nitrophenol^[15], at 546 nm. Plates were washed with saline to remove traces of phenol red and incubated with 0.5 mmol/L *p*-nitrophenol up to 60 min. The extinction coefficient for *p*-nitrophenol is 10.28 mmol/(L·cm). Results were expressed as formed *p*-nitrophenol pmols/min/mg protein.

Cellular damage

LDH and AST measurement Both enzymes, LDH and AST, were measured using a commercially available test kit. Results were expressed as units per liter.

Lipid peroxidation measurement MDA, formed from the breakdown of polyunsaturated fatty acids, was used as a convenient index for determining the extent of lipid peroxidation reactions. It was assayed in human hepatocytes using the thiobarbituric acid reaction as described by Wrighton *et al.*^[12]. The absorbance of the resulting organic layer was measured spectrophotometrically at 532 nm and calculated in relative to an external standard (1,1,3, 3-tetraethoxypropane) of MDA. Results were expressed as nmol/mg of protein.

Western blot analysis Cells were washed twice with PBS and homogenized in a buffer containing protease inhibitors. Protein concentrations were determined by the method of Lowry, using bovine serum albumin as the standard. Proteins were separated on a 10% SDS polyacrylamide gel, and then transferred onto polyvinylidene difluoride membranes^[16,17]. Nonspecific binding sites were blocked by overnight incubation of membranes in nonfat milk (5/100 g) solution solved in PBS/Tween-20 at 4 °C. After washing with PBS/Tween-20, the membranes were incubated with a CYP2E1 antibody, followed by an incubation with a horseradish-peroxidase-conjugated antibody at room temperature for 1 h. Then, membranes were washed again with PBS/Tween-20 for 1 h, and the immune complexes were developed using a chemiluminescence detection system. Equal loading of total protein was verified using a commercially available antibody against β -actin^[18].

Statistical analysis

Values were expressed as mean \pm SD of three values per experiment and experiments were repeated at least twice. Differences were analyzed by using the ANOVA test. Statistical significance was established at a *P* value <0.05.

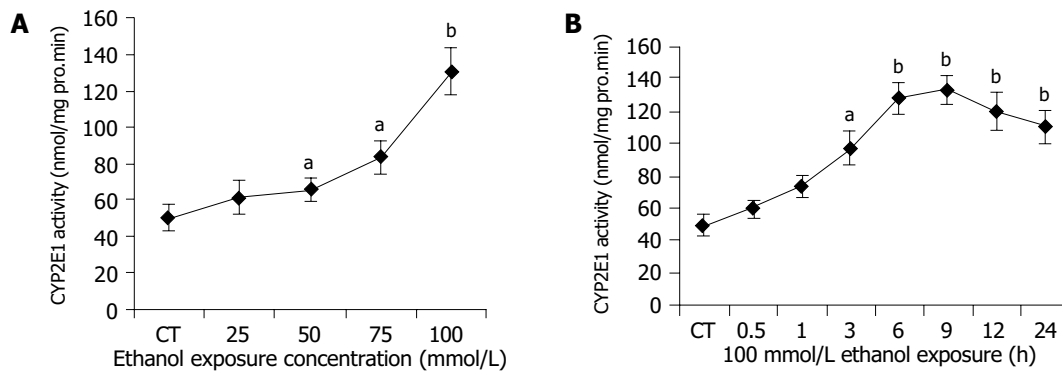

Figure 1 Dose- and time-dependent CYP2E1 activity by ethanol administration. **A:** Ethanol dose-dependent induction of CYP450 2E1. Hepatocytes were incubated with various concentrations of ethanol (0-100 mmol/L) for 9 h. CYP2E1 enzyme activity was measured as described in Materials and methods. CT: control; ^a $P < 0.05$, ^b $P < 0.01$ vs untreated control cultures. Each point represents the mean \pm SE of triplicates of five independent experiments;

B: Ethanol time-dependent induction of CYP2E1 enzyme activity in human hepatocytes. Hepatocytes were incubated with medium in the presence or absence of 100 mmol/L ethanol for various lengths of time (0-24 h). CYP2E1 enzyme activity was measured. CT: control; ^a $P < 0.05$, ^b $P < 0.01$ vs untreated control cultures. Each point represents the mean \pm SE of triplicates of five independent experiments.

RESULTS

Dose- and time-dependent CYP2E1 activity by ethanol administration

As depicted in Figure 1A, we observed a dose-dependent increase in CYP2E1 activity, which reached its maximum at 100 mmol/L ethanol after 9 h exposure as compared to untreated control cultures (CT: 50.09 ± 6.68 pmol/mg protein per min vs 100 mmol/L ethanol: 130.7 ± 12.61 pmol/mg protein per min; $P < 0.01$). We found that the exposure to 100 mmol/L ethanol led to a continuous increase in CYP2E1 activity in human hepatocytes (Figure 1B). CYP2E1 activity increased rapidly and reached its maximum between 6 and 12 h after ethanol exposure. Then, by 24 h we saw a decline of CYP2E1 activity. CYP2E1 activity between 3 and 24 h was significantly higher compared to untreated control cultures.

Time-dependent CYP2E1 protein expression after ethanol exposure

Figure 2 shows a time-dependent expression of CYP2E1 protein in human hepatocytes. We demonstrated that the exposure to 100 mmol/L ethanol of human hepatocytes induced continuous increase of CYP2E1 protein expression during the investigation period.

Cytotoxicity of ethanol in human hepatocytes

The formation of various radicals was closely linked to

Figure 2 Western blot analysis of time-dependent induction of CYP2E1 protein expression in human hepatocytes. Human hepatocytes were incubated with medium alone or medium containing 100 mmol/L ethanol for 0-24 h. Each was loaded with 100 μ g of the sample. Experiments were carried out as described under Materials and methods (CT: control).

oxidative injury. A typical characteristic of radical formation was lipid peroxidation, where malondialdehyde (MDA) was a by-product that could be easily measured in cells and tissue. Figure 3 shows that MDA levels increased with time, reaching first time significant level already after 3 h ($P < 0.05$ vs controls) of ethanol exposure. The maximum MDA formation in human hepatocytes after ethanol exposure was seen at 9 h and thereafter a slow decline of the lipid peroxidation could be seen. Moreover, there appeared to be a positive relation between CYP2E1 activity and MDA level ($r = 0.9724$, $P < 0.01$).

Further, the degree of cellular injury caused by ethanol can be estimated by the leakage of enzymes from the hepatocytes. In order to evaluate the hepatocellular damage caused by ethanol, supernatants taken from hepatocyte cultures were screened for the presence of LDH and AST. In our experiments, ethanol caused a clear time-dependent release of LDH and AST. (LDH: CT = 15.6 ± 1.66 U/L, 100 mmol/L ethanol (24 h): 84.5 ± 7.86 U/L, $P < 0.01$ vs CT; Figure 4. AST: CT = 94.22 ± 9.52 U/L, 100 mmol/L

Figure 3 Ethanol-dependent formation of MDA in human hepatocytes. Hepatocytes were incubated with 100 mmol/L ethanol for various lengths of time (0-24 h). MDA formation was measured as described in Materials and methods. CT: control; ^a $P < 0.05$, ^b $P < 0.01$ vs untreated control cultures. Each point represents the mean \pm SE of triplicates of five independent experiments.

Figure 4 Time course experiments for LDH release after ethanol (100 mmol/L) exposure between 0.5 and 24 h. CT: control; ^a $P < 0.05$, ^b $P < 0.01$ vs untreated control cultures. Each point represents the mean \pm SE of triplicates of five independent experiments.

Figure 5 Time course experiments for AST release after ethanol 100 mmol/L exposure between 0.5 and 24 h. CT: control; ^a $P < 0.05$, ^b $P < 0.01$ vs untreated control cultures. Each point represents the mean \pm SD of triplicates of five independent experiments.

ethanol (24 h): 181.91 ± 11.55 U/L, $P < 0.01$ vs CT Figure 5). The above results indicated that ethanol was toxic to human hepatocytes, and there was positive relationship between CYP2E1 activity induced by ethanol and ethanol-induced cellular damage.

Protection from ethanol-induced oxidative damage by CYP2E1 inhibitors

In the following set of experiments we addressed the question whether the inhibition of CYP2E1 could protect human hepatocytes from ethanol-induced cellular damage. First, we found that the co-induction of ethanol with 25 or 50 μ mol/L DAS, produced no cellular protection against the ethanol-induced cytotoxicity. In contrast, when cells were co-induced with 100 μ mol/L DAS and ethanol for 9 h, we saw a profound reduction of MDA formation caused by ethanol (Table 1). However, MDA formation was still higher than that of untreated control cultures. This reversing effect of DAS was also seen with regard to the release of LDH and AST (Table 1). There was no effect on MDA, LDH, and AST, when 25–100 μ mol/L DAS was incubated with ethanol, respectively (Table 1). Thus, the inhibition of CYP2E1 could partly attenuate ethanol-induced cytotoxicity in human primary hepatocytes.

Table 1 Ethanol exposure of hepatocytes causes cellular damage in human hepatocytes

Group	MDA (nmol/mg protein)	LDH (U/L)	AST (U/L)
CT	36.37 \pm 3.64	15.6 \pm 1.66	94.22 \pm 9.52
100 mmol/L ethanol	69.05 \pm 4.41	84.5 \pm 7.86	181.91 \pm 11.55
100 mmol/L ethanol plus 25 μ mol/L DAS	65.31 \pm 9.32	80.4 \pm 8.86	174.51 \pm 17.12
100 mmol/L ethanol plus 50 μ mol/L DAS	59.54 \pm 7.02	75.5 \pm 7.06	160.42 \pm 17.86
100 mmol/L ethanol plus 100 μ mol/L DAS	56.13 \pm 6.32 ^a	70.8 \pm 6.24 ^a	156.42 \pm 15.55 ^a
25 μ mol/L DAS	37.43 \pm 3.45	16.7 \pm 1.85	93.056 \pm 9.64
50 μ mol/L DAS	36.43 \pm 4.15	15.8 \pm 1.33	92.16 \pm 9.04
100 μ mol/L DAS	38.43 \pm 4.05	17.6 \pm 1.95	96.32 \pm 10.08

^a $P < 0.05$ vs 100 mmol/L ethanol ($n = 5$).

DISCUSSION

Ethanol consumption and its effects on CYP2E1 in animals have long been studied in the past. However, reports about the influence of CYP2E1 inhibition on human primary hepatocytes and its possible positive effects on ethanol-induced toxicity are very limited. The concentrations of ethanol required to increase CYP2E1 in cultured human hepatocytes are dramatically lower than those required to induce the same forms of P450 in cultured rat hepatocytes. The activity of alcohol dehydrogenase, a major enzyme involved in ethanol metabolism, is lower in human liver than in rat liver. Thus, in the human hepatocyte cultures, more ethanol may be available intracellularly to induce the P450s due to lower metabolism. Alternatively, the mechanism of induction of these forms of P450s may be different or more sensitive in human than in rat hepatocytes^[12]. It was reported that 25–100 mmol/L ethanol could lead to sustained cellular damage such as teratogenesis in guinea pigs, ethanol-induced unconsciousness or even death in humans^[19]. In the present study, 25–100 mmol/L ethanol was used to investigate the relationship between ethanol exposure and CYP2E1 gene expression. Meanwhile, cellular LDH, AST, and MDA levels were chosen to assess hepatocyte damage caused by ethanol exposure.

CYP2E1 is induced by a broad variety of chemicals, such as ethanol. The production of ROS via CYP2E1 induction may contribute to the development of alcoholic liver disease or at least increase cytotoxic effects of alcohol^[20]. Ethanol is an essential CYP2E1 inducer in human hepatocytes, which was also confirmed in a recent study by Ponsoda *et al.*^[21], showing that human hepatocytes incubated with 100 mmol/L ethanol showed a two- to threefold increase in CYP2E1 enzyme activity compared with untreated control cultures. By use of recombinant retroviral expression, in addition to ethanol (20–100 mmol/L) exposure, the culture medium of the HepG2 cell line exhibited both a large increase of CYP2E1 content and enzyme activity^[22]. Our data confirmed these results, clearly showing a dose-dependent and time-dependent relationship between CYP2E1 enzyme activity in human hepatocytes and ethanol exposure. Western blot analysis further proved ethanol-induced CYP2E1 expression in a time-dependent manner.

Lipid peroxidation (and associated membrane damage) is a key feature in alcoholic liver injury. It resulted in increased excretion of MDA in the urine of rats following short- and long-term administration of relatively low doses of ethanol^[23]. Lipid peroxidation results directly from the increased oxygen radical production induced by CYP2E1. In the present work, we have demonstrated that time-dependent increased MDA levels were directly linked to the presence of ethanol and there was a clear relationship between MDA levels and CYP2E1 changes in hepatocytes after ethanol administration.

The increase in LDH activity is seen in many pathologic conditions. Release of the intracytoplasmic enzyme LDH into cell culture medium is frequently used as a measure of cellular injury. AST is present only in hepatocytes, located in mitochondria and cytoplasm. Like LDH, its increase is an early sign of cellular injury. In the present study, ethanol clearly caused a time-dependent release of LDH and AST, and there was a positive relationship between the induction of CYP2E1 activity and the release of LDH and AST. Ethanol exposure could cause marked cellular damage in human primary cultured hepatocytes.

It was demonstrated that ethanol cytotoxicity was directly related to CYP2E1 enzyme activity. Cytotoxicity of ethanol in rat hepatocytes was prevented either by alcohol/aldehyde dehydrogenase inhibitors or by CYP2E1 inhibitors. Cederbaum observed that ethanol-induced ROI formation was also reduced in the presence of CYP2E1 inhibitors in HepG2 cells, suggesting that CYP2E1 directly contributes to ROI formation^[24]. Leclercq *et al.*^[25], using the knockout mice observed that other CYPs, notably CYP4A10 and CYP4A14, were upregulated in the CYP2E1 knockout but not the wild-type mice; these CYPs were, like CYP2E1, active generators of reactive oxygen and catalysts of lipid peroxidation, and in the absence of CYP2E1 served as alternative initiators of oxidative stress. Furthermore, French and collaborators found that the ethanol-induced oxidative inactivation of the proteasome and increase in oxidized proteins were completely prevented in these CYP2E1 knockout mice^[26]. Our experiments showed that DAS, the inhibitor of CYP2E1, could partly protect human hepatocytes from ethanol-induced cellular injury, or reduce cellular MDA, LDH and AST levels. However, in contrast to these observations, studies by Thurman and colleagues have suggested that CYP2E1 may not play a role in alcoholic liver injury based upon studies in CYP2E1 knockout mice^[1,27,28]. In some cells, ethanol-induced damage may not be the consequence of oxidative reactions, but may result directly from the direct interaction of ethanol with cell membranes or from its non-oxidative incorporation into fatty acid ethyl esters^[29,30]. Clearly, further studies are necessary to resolve the above discrepancies.

In summary, this study revealed that an innocuous concentration of DAS significantly decreased the ethanol-induced oxidative damage in human primary cultured hepatocytes. This protection appeared to be, at least in part, due to the attenuation of oxidative stress. These findings warrant future *in vivo* studies of DAS for the prevention and/or treatment of alcoholic liver disease. The inhibition of CYP2E1 in cells or organs could lead to new strategies

for better prevention and treatment of ethanol-induced oxidative damage in human liver.

ACKNOWLEDGMENT

We thank Professor Andreas K Nussler, Department of General-, Visceral-, and Transplantation Surgery, Humboldt University, Charité, Campus Virchow, Berlin, Germany, for his countless help in the performance of this study.

Abstract

AIM: To investigate the pathological characteristics and carcinogenesis mechanism of benign lymphadenosis of oral mucosa (BLOM).

METHODS: The expressions of Ki-67, CD34 and apoptosis were evaluated by immunohistochemical SP staining in 64 paraffin-embedded tissue samples. Of them, 9 were from BLOM with dysplasia, 15 from BLOM without dysplasia, 15 from oral squamous cell carcinoma (OSCC), 15 from oral precancerosis, and 10 from normal tissues. Cell proliferation, apoptosis and angiogenesis of tissue samples were also analyzed.

RESULTS: The expression of Ki-67 in BLOM with dysplasia, oral precancerosis and OSCC was significantly higher than in BLOM without dysplasia and normal mucosa. The microvascular density (MVD) in BLOM with and without dysplasia, oral precancerosis, and OSCC was significantly higher than in normal mucosa. Apoptosis in BLOM and oral precancerosis was significantly higher than in OSCC and normal mucosa.

CONCLUSION: Benign lymphadenosis of oral mucosa has potentialities of cancerization.

INTRODUCTION

Benign lymphadenosis of oral mucosa (BLOM), which could be commonly found clinically, usually occurs in the mucosae of lips, cheeks, tongue or gingiva. Sometimes, BLOM may develop in all of the oral mucosa and accompany

other oral diseases. As far as we know, few reports have ever mentioned BLOM, and there has been no international definition about it. Most researchers considered it as a kind of reactive proliferation. Since 1970s, our department have been studying BLOM from the aspects of morphology and immunopathology. Ultrastructural changes of this disease is similar to that of leukoplakia^[1,2]. Clinically, BLOM has a malignant trend^[3,4]. At present, it is regarded as a kind of precancerous lesion^[5]. To investigate the pathological characteristics and carcinogenesis mechanism of BLOM, we studied cell proliferation, cell apoptosis and angiogenesis of different types of oral mucosa diseases, including BLOM with dysplasia and without dysplasia, OSCC, oral precancerosis and normal tissues by immunohistochemistry method.

MATERIALS AND METHODS

Materials

A total of 64 paraffin-embedded tissue samples were from Pathological Research Laboratory, School of Stomatology, Peking University. Of them, 9 were from BLOM with dysplasia, 15 from BLOM without dysplasia, 15 from oral OSCC (8 in stage III, 7 in stage I or II), 15 from oral precancerosis, and 10 from normal tissues around the neoplasms. Streptavidin-biotin-immunoperoxidase system kit was purchased from Fuzhou Maixin Immunotech Corporation, China; mouse monoclonal antihuman Ki-67 antibody was provided by Beijing Immunotech Zhonghshan Corporation, China; and cell death detection kit was from Boehringer Mannheim, Germany.

Immunohistochemistry protocol for Ki-67 and CD34

Five micrometer thick sections were dewaxed with xylene, and rehydrated in graded ethanol. Endogenous peroxidase activity was blocked by immersion of slides in methanol with 0.03% hydrogen peroxide for 10 min. In order to retrieve antigenicity, these sections were then heated in a pressure cooker in 10 mmol/L citrate buffer (pH 6, 90 s after water boiled). After washing in distilled water, these sections were rinsed in phosphate-buffered saline (PBS) and incubated for 60 min at room temperature with CD34 or Ki-67 mAb. Reaction was visualized with a streptavidin-biotin-immunoperoxidase system using diaminobenzidine (DAB) as chromogen. All sections were then counterstained with hematoxylin.

Positive staining for CD34 or Ki-67 was regarded as positive control. For negative control, the primary antibodies were replaced with PBS. Staining was measured as the percentage of positively stained nuclei (Ki-67, labeling index, LI) or cytoplasm (CD34, microvascular density, MVD). Ki-67 reaction was scored at ×400 magnification, a total of 1 000 epithelial cells (normal tissue and BLOM) or tumor cells

(OSCC) were evaluated. Reactive nuclei were considered positive, regardless of staining intensity. The percentage of Ki-67 positive was then calculated and positivity of lymphocytes was not evaluated. Criteria for counting included individual or cluster of cells with or without lumen positivity for CD34 immunoreactivity. Areas of inflammation, necrosis, and fibrosis were excluded. For determination of mean MVD, sections were first observed under low power ($\times 200$) for areas with dense vascularity. These were then counted in three different fields under high power ($\times 400$). The average counts were recorded as MVD for each case.

TUNEL protocol for apoptosis evaluation

Detection of apoptosis in tissue was determined by TUNEL assay, employing in situ. The procedure is based on the detection of chromatin DNA strand breaks, the most characteristic biochemical feature of apoptosis caused by activation of endogenous nuclease activity.

Sections were dewaxed, rehydrated, and washed in distilled water for 10 min. The nuclei in tissue sections were stripped from proteins with 4% pepsin diluted in sterile buffer (10 mm Tris-HCl, pH 7.4) for 60 min at 37 °C, followed by quenching of endogenous peroxidase. The sections were rinsed in 50 μ L of a label mixture containing the labeled nucleotide and enzyme, and incubated in a humidified chamber for 60 min at 37 °C. After washing with PBS, the sections were incubated for 30 min at 37 °C with alkaline phosphatase reagent. The substrate reaction was developed using diethyl chlorophosphite (DECP) and counterstained with nuclei fast red.

Positive staining for CD34 or Ki-67 was regarded as positive control. For negative control, the primary antibodies were replaced with PBS. A cell was considered apoptotic only when unequivocal nuclear labeling was observed in the areas with no inflammation. Cells exhibiting necrotic nuclear karyorrhexis as well as those in necrotic foci were excluded. TUNEL reactivity was always estimated in relation to characteristic histological criteria of apoptosis, including overall shrinkage, homogeneously dark basophilic nuclei, presence of nuclear fragments, sharply delineated cell borders and homogenous eosinophilic cytoplasm. To evaluate the different rates of TUNEL reactivity in each sample, 1 000 cells were counted randomly under high power ($\times 400$) and the percentage of positively stained nuclei (AI) was calculated.

Statistical analysis

The expression of Ki-67, MVD and extent of TUNEL reactive nuclei in different tissue samples was analyzed by *t*-test and χ^2 -test using SPSS10.0 for Windows. $P < 0.05$ was considered significant.

RESULTS

The histological characteristics of BLOM is that lymphoid follicles or dense lymphocytes foci could be seen in the basal cell layer. The expression of Ki-67, which was stained brown in nuclei, could be found in normal tissues, BLOM, BLOM with dysplasia, precancerosis and OSCC. Positive cells distributed dispersedly in epithelium of normal tissues and BLOM without dysplasia (Figure 1A). Meanwhile, many cells appeared positive in lymphoid follicles. The expression of Ki-67 obviously increased in BLOM with dysplasia and in some samples Ki-67 positively stained nuclei were seen in all layers of epithelium (Figure 1B). The expression of Ki-67 also increased in precancerous tissues and OSCC, in the center of which positive cells distributed diffusely (Figure 1C). The positive rates of Ki-67 expression in different groups are shown in Table 1.

Table 1 The positive rates of Ki-67 expression in different groups (mean \pm SD)

Group	Ki-67 positive rate (%)
Normal	14.19 \pm 6.18
BLOM	22.29 \pm 11.39
BLOM with dysplasia	45.42 \pm 9.89 ^a
Precancerosis	47.15 \pm 6.84 ^{a, c}
OSCC	65.89 \pm 9.09 ^{a, c, e}

^a $P < 0.05$ vs normal, ^c $P < 0.05$ vs BLOM, ^e $P < 0.05$ vs BLOM with dysplasia.

The expression of CD34 was positive in all samples, and distributed punctately, located in the cytoplasm of vascular endotheliocytes (Figure 2A). Only a few microvessels in the connective tissues of normal mucosa could be seen. But in BLOM, BLOM with dysplasia and precancerosis, their number increased obviously (Figure 2B). A great amount of microvessels also could be found in OSCC. MVD values in different groups are shown in Table 2.

Figure 1 Ki-67 expression in A: BLOM without dysplasia (IHC $\times 400$), B: BLOM with dysplasia (IHC $\times 200$), and C: oral cancer (IHC $\times 200$).

Figure 2 CD34 expression in **A**: BLOM without dysplasia (IHC $\times 100$) and

B: BLOM with dysplasia (IHC $\times 100$).

Table 2 MVD in different groups (mean \pm SD)

Group	MVD value
Normal	14.31 \pm 2.71
BLOM	44.81 \pm 10.20
BLOM with dysplasia	43.89 \pm 8.78 ^a
Precancerosis	45.28 \pm 11.09 ^{a,c}
OSCC	62.73 \pm 8.13 ^{a,c,e}

^a $P < 0.05$ vs normal, ^c $P < 0.05$ vs BLOM, ^e $P < 0.05$ vs BLOM with dysplasia.

Cell apoptosis was found in 2/10 normal tissues, 10/15 BLOM, 8/9 BLOM with dysplasia, 13/15 precancerosis and 8/15 OSCC. Apoptosis was seldom seen in the stromal layer of normal mucosa, but it increased obviously in BLOM, BLOM with dysplasia and precancerosis (Figure 3). At the same time, apoptosis could be found in connective tissues of BLOM, BLOM with dysplasia and precancerosis. The positive rate of apoptosis in OSCC was significantly lower than that in other groups except the normal mucosa.

DISCUSSION

Ki-67 is an acknowledged marker that indicates the proliferation capacity of cells, and many studies demonstrated that it was overexpressed in oral premalignancy and oral cancer^[6-9]. Tabor *et al.*^[10], studied 43 samples from patients who had undergone resection of their squamous cell carcinoma in oral cavity/oropharynx. With the consensus score, 12 samples were classified as normal, and 31 as dysplastic (21 mild, 6 moderate, and 4 severe). They found that there was a high coincidence between loss of heterozygosity (LOH) and the expression of Ki-67. The Ki-67 index in LOH-positive cases was significantly higher than that in LOH-negative cases. It was suggested that the expression of Ki-67 was correlated with other factors (beta-catenin, p53R2, *etc*)^[11-14]. Other scholars found there was a significant correlation between Ki-67 LI, stroma/tumor proportion and the degree of keratinization^[15,16]. In the present study, over-expression was found in the epithelium of BLOM with dysplasia, precancerosis and OSCC. But the expression in epithelium of BLOM without dysplasia was similar to that in the normal mucosa and there was an abundant expression in lymphoid follicles. This suggested that the epithelial cells of BLOM without dysplasia had not undergone genetic

Figure 3 Apoptosis in BLOM with dysplasia (TUNEL $\times 200$).

transformation, and the cells of germinal center had a strong proliferation capacity. In the connective tissues of BLOM and BLOM with dysplasia, a great amount of positive cells could be found in the center of lymphoid follicles. However, no obvious difference was revealed. This indicated that the center had a strong capacity of proliferation, but not a malignant trend, because the proliferation of lymphocytes was a kind of benign and reactive proliferation. Why we considered BLOM benign was also due to this reason. The number of Ki-67 positive cells and the staining in BLOM without dysplasia had no obvious difference from those in normal mucosa, indicating that epithelial cells did not appear abnormal. In the epithelium of BLOM with dysplasia and precancerosis, the number of positive cells obviously increased and the distribution of positive cells extended from the lower basal layer to the upper basal layer and prickle cell layer. In some samples, positive cells were distributed in all the layers of epithelium. This indicated that the proliferation capacity of basal cells was strengthened. Angiogenesis is a process involved in the development of new blood vessels, by the division and migration of existing vasculature^[17-20]. It is an important mechanism to sustain tumorigenic potential in neoplasm and in dysplastic lesions, indicating abundant capillaries leading to intense vascularization in cancer. Therefore, evaluation of angiogenesis may be of prognostic significance in the assessment of tumor progression. Iwasa *et al.*^[21], suggested that negative DNA instability lesions had a higher MVD in proliferating cell nuclear antigen (PCNA)-positive cells than positive DNA instability lesions.

Other scholars proved that in non-small cell lung cancer and oral cancer, the mean AIs of the lower-MVD and the higher-MVD patients were significantly different^[22-24]. Our study has confirmed that insufficient angiogenesis could accelerate apoptotic cell death. The angiogenesis in BLOM with and without dysplasia, and in precancerosis was significantly higher than in normal tissue, and new blood vessels were more abundant. Sauter *et al.*, suggested that the angiogenesis in precancerosis was between oral normal tissue and OSCC^[17].

Apoptosis is a programmed cell death under genetic control. A fine balance between the cell proliferation and cell death is very important to normal development and maintenance of tissue size and shape. In another word, the imbalance between the positive and negative regulation of cell growth could cause a series of diseases including neoplasm. In neoplasm, the disorder of homeostasis may result in the development of tumor^[25-27]. Some studies showed that epidermal growth factor receptor blockade, cyclin dependent kinase inhibitor and 5-FU could induce cell apoptosis^[28-30]. Other scholars also found that the overexpression of p27(Kip1) and retinoic acid receptor could induce growth arrest and apoptosis in an oral cancer cell line^[31,32]. Results of the present study indicated that the apoptosis was significantly higher in BLOM, BLOM without dysplasia, and precancerosis than in normal tissue. However, it was lower in tumor tissue (OSCC). This suggested that the body tried to control the balance of cell number by increasing cell apoptosis with the increase in cell proliferation. However if the body fails, tumor develops. Similar result could be found in the study of Guan *et al.*^[33,34].

Previous studies also showed that BLOM should be regarded as a kind of precancerous lesion. In the present study, the cell proliferation, angiogenesis and apoptosis of BLOM were similar to that of precancerosis, and in BLOM without dysplasia the angiogenesis was significantly higher than that in normal oral tissue. But the expression of Ki-67 was similar to that in normal tissue. Therefore, the changes of cell proliferation, cell apoptosis, and angiogenesis in connective tissue were earlier than in epithelium; BLOM had the potential of carcinogenesis. Many factors may induce the proliferation of cancer cells, enhance their survival by escape of apoptosis, and provide abundant nutrients during early-stage carcinogenesis of oral precancerous lesions. Comparison of gene expression profiles between head and neck squamous cell carcinoma and normal tissues showed that altered expression levels of genes were involved in the control of cell growth and differentiation, angiogenesis, apoptosis, cell cycle, and signaling, most of which had not been previously described in head and neck squamous cell carcinoma^[35]. Which factor contributes to cell proliferation, and inhibits cell apoptosis during the carcinogenesis of BLOM is still a subject to be investigated in future.

Abstract

AIM: To investigate the visceral response to acute retrograde gastric electrical stimulation (RGES) in healthy humans and to derive optimal parameters for treatment of patients with obesity.

METHODS: RGES with a series of effective parameters were performed via a bipolar mucosal electrode implanted along the great curvature 5 cm above pylorus of stomach in 12 healthy human subjects. Symptoms associated with dyspepsia and other discomfort were observed and graded during RGES at different settings, including long pulse and pulse train. Gastric myoelectrical activity at baseline and during different settings of stimulation was recorded by a multi-channel electrogastrography.

RESULTS: The gastric slow wave was entrained in all the subjects at the pacing parameter of 9 cpm in frequency, 500 ms in pulse width, and 5 mA in amplitude. The frequently appeared symptoms during stimulation were satiety, bloating, discomfort, pain, sting, and nausea. The total symptom score for each subject significantly increased as the amplitude or pulse width was adjusted to a higher scale in both long pulse and pulse train. There was a wide diversity of visceral responses to RGES among individuals.

CONCLUSION: Acute RGES can result in a series of symptoms associated with dyspepsia, which is beneficial to the treatment of obesity. Optimal parameter should be determined according to the individual sensitivity to electrical stimulation.

INTRODUCTION

Motility is one of the most critical physiological functions of the stomach. Coordinated gastric contractions are necessary for the emptying of ingested food, and impairment in gastric motility may result in delayed gastric emptying. Gastric motility (contractile activity) is regulated by the myoelectrical activity of the stomach, called slow waves^[1]. The gastric slow wave originates in the proximal stomach, propagates distally toward the pylorus, and dominates the maximum frequency, propagation velocity and propagation direction of gastric contractions. Abnormalities in gastric slow waves including uncoupling and gastric dysrhythmia lead to gastric motor disorders and are frequently observed in patients with functional disorders of the stomach, such as gastroparesis, functional dyspepsia, anorexia, etc. Gastric myoelectrical abnormalities are believed to be the fundamental factors for gastric hypomotility^[2-5]. Gastric prokinetics are used to treat patients with gastric hypomotility and cisapride has been proved to be effective on both gastric hypomotility and myoelectrical abnormality^[6]. But there are still a lot of patients who are refractory or could not tolerate these drugs.

Gastric electrical stimulation is used to affect gastric motility with the rationale as a forward gastric pacing to trigger the gastric myoelectrical propagation from proximal towards pylorus of stomach. It has been accepted as a therapy for chronic gastroparesis associated with drug refractory nausea and vomiting secondary to diabetic or idiopathic etiology^[7,8]. Researchers adopt its mechanism with converse effects and have developed implantable gastric stimulation (IGS) to treat obesity that is attributed to rapid gastric emptying or hypermotility^[9-11].

IGS for weight loss is an exciting new concept for the treatment of obesity^[12]. It is unique in that it relies on neither gastric restriction nor intestinal malabsorption but instead induces early satiety. IGS is also a relatively invasive procedure that does not alter the gastrointestinal anatomy. The system comprises an electrical pulse generator similar to a cardiac pacemaker and a serosal lead implanted in the muscular layer of the distal gastric wall. Both animal^[13] and human studies^[14-18] revealed that it results in decreased food intake and a substantial weight loss.

Up to now, whether there is responsive diversity among individuals to gastric electrical stimulation is unknown. An optimal parameter, which should be of high efficiency, low energy expenditure and acceptability, has not been determined. This study aimed to investigate the visceral response to RGES with mucosal electrode, and to derive optimal parameter for therapy of obesity.

MATERIALS AND METHODS

Subjects

Twelve healthy volunteers were recruited in this study, including six males and six females, with their age being 29.4 ± 8.6 years, body weight being 62.63 ± 8.29 kg (48-80 kg) and body mass index being 23.18 ± 2.62 kg/m². None of the subjects had gastrointestinal diseases or symptoms or a history of gastrointestinal surgery. All women were studied during their follicular phase of the menses to minimize possible hormonal influences^[19]. No medications were used by any of the participants except for oral contraceptives 2 wk prior to the study. Organic diseases of stomach, such as erosive gastritis, gastric ulcer, esophagitis, etc., were ruled out by endoscopy. Subjects with swallowing disorders such as dysphagia, achalasia, and hypersensitivity to nasal intubation were excluded. Females in pregnancy, or nursing period were also excluded. Written consent form was signed by each subject before the study, and the protocol was approved by the Ethical Committee of the University Hospital.

Implantation of mucosal electrodes

The subjects were fasted for 8 h or more before implantation of the electrodes. A temporary transvenous cardiac pacing lead system (Model 6416, Medtronic, Netherlands) composed of an active fixation, a lead with bipolar electrodes and a soft-tipped, lubricated guide catheter was used (Figure 1). This lead was intubated into the stomach through a nasal cavity before endoscopy. At a good exposure of the antrum under endoscopy, the distal electrode was screwed into the mucosa along the greater curvature 5 cm above the pylorus and fixed with a titanium clamp. The proximal electrode was affixed to the surface of the gastric mucosa with one or two titanium clamps (Figure 2). After the placement, the guide catheter was pulled out of the stomach. An X-ray picture was taken once daily to ensure that the electrodes were located at the original positions in the stomach.

A multi-channel electrogastrograph (POLYGRAM NETTM, Medtronic Functional Diagnostics A/S, Denmark) was used to record gastric myoelectrical activity. Two channel gastric myoelectrical recordings were obtained by connecting each of the mucosal electrodes to a common reference electrode placed on the leg of the subject. These myoelectrical recordings were used to further confirm the attachment of electrodes to the gastric mucosa. A recording of rhythmic 3 cpm gastric slow waves would be indicative

of a good attachment of the electrodes. The entrainment of gastric myoelectrical activity by RGEs was also observed to assess its electrophysiological effectiveness.

Experimental protocol

After a baseline recording of gastric slow waves for 30 min, symptomatic responses to gastric electrical stimulation with various parameters were assessed in the fasting state. Visceral sensation (symptomatic response) to gastric electrical stimulation was assessed by three parameters: initial sensation, maximum tolerance, and the symptom score. The initial sensation was defined as the stimulation with which the subject first reported one or more of any symptoms. The maximum tolerance was defined as the stimulation with which the subject reported the maximally tolerable symptoms.

Symptoms, including satiety, bloating, discomfort (the character and location of a symptom could not be described clearly and precisely), upper abdominal pain, sting, belching, nausea, vomiting, were recorded and graded during RGEs at different settings. Each symptom was graded from 0 to 3 (0: no symptom; 1: mild symptoms, requiring intention to feel the symptoms; 2: moderate symptoms, being aware of the symptoms, but not interfering with daily activities; 3: severe symptoms, interfering with daily activities). The total symptom score in each subject was derived and its correlation with the stimulation energy was determined.

Retrograde gastric electrical stimulation

RGEs was performed via the bipolar electrodes attached to the mucosa/submucosa of the distal antrum using a universal pulse generator (Acupulser, model A310, World Precision Instrument, Inc., Sarasota, FL, USA). Two models of electric stimulation, long pulse and pulse train, were applied to the pacing electrodes in the constant current mode. The long pulse was composed of periodic rectangular pulses with a frequency of 9 cpm, pulse width of 500 ms, and adjustable pulse amplitude (current) consisting three settings of 5, 10, and 15 mA. The pulsed train was on for a period of 2 s and off for 3 s. The pulse frequency was 20 Hz, an adjustable pulse width consisting three settings of 5, 10, and 20 ms. The amplitude was adjusted from 10 to 15 mA. If maximal intolerable symptom did not appear, the amplitude was adjusted to 20 mA. Each session of

stimulation lasted for about 20 min and there was a 10 min or more resting period between consecutive stimulation sessions. For all tests, the subject was blinded about the stimulation and stimulation parameters.

Stimulation energy was calculated for each stimulation session. The stimulation energy was defined as $\propto I^2R$, where t is stimulation time, I is stimulation current and R is the impedance between two stimulation electrodes. In this study, R was ignored since it was constant for various stimulation sessions, I was the pulse amplitude and t was the total on-time of pulses within a minute. For long pulses, t = pulse frequency (pulses/min) \times pulse width. For pulse trains, t = number of trains/min \times number of pulses/train \times pulse width. The unit of stimulation energy used in this study was s (mA)² or simply smA².

Statistical analysis

Results of specific symptom scores and total symptom score in each subject to different parameters were expressed as mean \pm SE. Statistical analysis was performed by one-way ANOVA. Pearson's linear correlation and regression method was used to assess the correlation between responsive severity and stimulation energy. $P < 0.05$ was considered statistically significant.

RESULTS

All the 12 subjects completed the study with good compliance. Regular gastric slow waves were recorded from stimulation electrodes attached to the gastric mucosa at baseline. Typical tracings are presented in Figure 3. The dominant frequency of the gastric slow waves was 2.71 ± 0.16 cpm. The gastric slow waves in all the subjects were completely entrained by the signal of RGEs at the frequency 9 cpm, pulse width 500 ms and amplitude 5 mA (112.5 smA², Figure 4).

**Figure 3** Intrinsic myoelectrical activities from mucosa/submucosa electrodes in stomach.

Frequently appeared symptoms during stimulation were satiety, bloating, discomfort, upper abdominal pain, sting, and nausea. The sum of these six symptoms was used as an overall total symptom score. The severity of specific symptoms to different parameters is shown in Table 1.

The output energy of electrical stimulation for inducing initial sensation showed a wide distribution among individuals. The initial sensation appeared in three subjects at 112.5 smA² (long pulse: 9 cpm, 500 ms, 5 mA), six subjects at 240 smA² (pulse train: 2 s-on, 3 s-off, 20 Hz, 5 ms, 10 mA), one subject at 450 smA² (long pulse: 9 cpm, 500 ms, 10 mA), and two subjects at 480 smA² (pulse train: 2 s-on, 3 s-off, 20 Hz, 10 ms, 10 mA). The maximal energy for inducing initial sensation was more than four times that of the minimum. The initial sensation occurred as different symptoms. Bloating appeared in three subjects, satiety in two, discomfort and pain in five, sting and nausea in one, respectively.

The output energy for inducing maximal tolerable sensation also showed a wide diversity among individuals. The maximal tolerable sensation was recorded at 480 smA² in two subjects, at 2 160 smA² (pulse train: 2 s-on, 3 s-off, 20 Hz, 20 ms, 15 mA) in nine subjects and at 3 840 smA² (pulse train: 2 s-on, 3 s-off, 20 Hz, 20 ms, 20 mA) in one subject. The maximal energy for maximal tolerable sensation was eight times that of the minimum. The major symptoms resulted from the maximally tolerable stimulation included upper abdominal pain in nine subjects, nausea in two subjects, and both pain and nausea in one subject. Some mild to moderate symptoms were simultaneously noted with the maximally tolerable stimulation, including satiety, bloating, discomfort, belching, and nausea.

The most common symptomatic response to stronger RGEs was upper abdominal pain. It appeared synchronously with stimulus signals, such as 9 cpm at long pulse, and became

**Figure 4** Entrainment of gastric myoelectrical activity by RGEs.

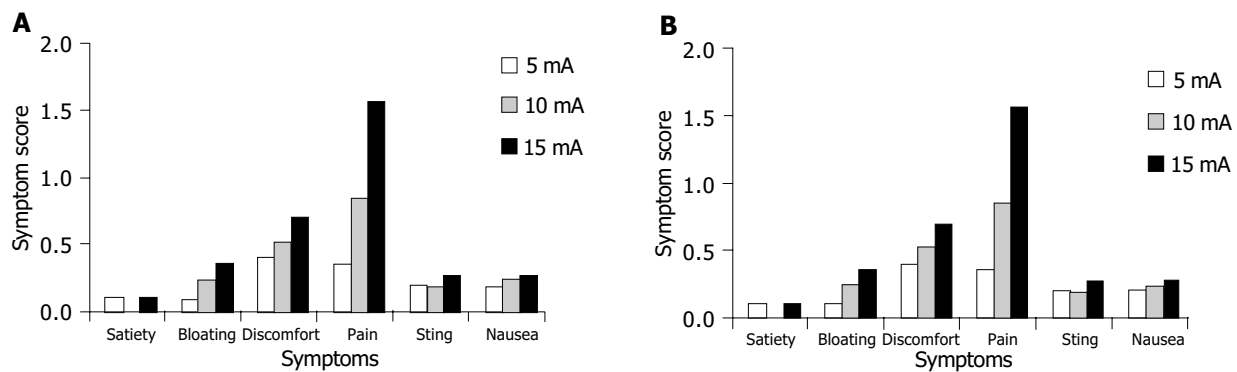

Figure 5 Symptom scores at different parameters of long pulse (A) and pulse

train (B).

persistent in three subjects when the maximal stimulation was applied. It disappeared immediately as the stimulation terminated in seven subjects and gradually ceased within 4 min in five subjects. Other symptoms, such as bloating, discomfort, nausea, etc., also disappeared as soon as the stimulation ended.

During stimulation with long pulse, the severity of the symptoms including bloating, discomfort, and pain significantly increased when the pulse amplitude was adjusted to a higher scale ($P < 0.01$, Figure 5A). The severity of symptoms including satiety, bloating, pain, and nausea also significantly increased when the pulse width or amplitude was set to higher scales during pulse train ($P < 0.05$, Figure 5B). The mean total symptom score for the seven settings of gastric electrical stimulation was linearly correlated with stimulation energy ($r = 0.96$, $P < 0.001$, Figure 6). That is, the total symptom score for each subject significantly increased as the output energy was adjusted to a higher scale in both long pulse and pulse train.

Figure 6 Correlation of total symptom score with output energy of stimulation.

DISCUSSION

Obesity, defined by an excess of body fat, is a highly prevalent disorder in the Western world. In the USA, it has been estimated that one of three adults is obese^[20]. Obesity predisposes to or aggravates many clinical conditions, such as hypertension, hyperlipidemia, diabetes, gout, atherosclerotic heart disease, etc.^[21]. Obesity is of a multifactorial pathogenesis. The basic mechanism is believed that obesity results from food intake greater than energy

needs. The quantity of food intake is directly determined by sensory and motor function of stomach, i.e., gastric accommodation (capacity) and emptying. Previous studies using an intragastric balloon to assess proximal stomach capacity showed that it is larger in both moderate and severe obese individuals^[22,23]. In the studies of gastric capacity in obese people, distal gastric volume is also found larger in obese individuals in the fasting state from imaging with single photon emission computed tomography^[24], suggesting that the increased gastric volume causes changes in the sensation of satiety with a consequent increase of food intake in these subjects.

In addition to stomach capacity, the retaining time of food in stomach also influences mechano- and chemosensitive satiety signals and it is a reasonable hypothesis that an enhanced rate of gastric emptying predisposes to overeating. Although the contribution of changes in gastrointestinal motility to the pathogenesis of obesity is unclear, several noteworthy changes in gastrointestinal motility have been observed in obesity^[25]. For example, some studies suggest more rapid gastric emptying in obesity^[9-11], although normal^[26-29] or even slower^[30-32] emptying has also been reported in other studies. But in a better designed study of 77 subjects including 46 obese and 31 age-, sex-, and racematched nonobese individuals, obese subjects are found to have a more rapid emptying rate than nonobese subjects^[9].

Based on the pathogenesis of obesity, great efforts from different fields have been tried to conquer obesity. Medicines and neuroendocrine agents or analogs are found to be able to inhibit appetite or to delay gastric emptying^[33,34]. Surgical approaches can weaken the gastric capacity, as implantation of balloon in the stomach^[35-37]. By doing this, symptoms associated with dyspepsia, such as satiety, bloating, anorexia, discomfort or pain of upper abdomen, are duplicated in fasting state or postprandial. The occurrence of these symptoms results in reduction of food intake, eventually loss of body weight, which is the goal for the treatment of obesity.

As the stomach contractility is controlled by gastric myoelectrical activity, electrophysiological approaches can alter stomach motility. A recent preliminary study indicates the potential of gastric electrical stimulation for weight loss^[13]. The first human study using a gastric stimulator for the treatment of morbid obesity was performed in 1995, which results in decreased food intake and a substantial

weight loss^[14]. IGS for human obesity has been investigated in different institutes in the world since then^[15-18].

Recently, we have proposed retrograde gastric electrical stimulation (RGES). In this method, electrical stimulation is performed at a tachygastrial frequency and via a pair of mucosal electrodes placed in the distal antrum, mimicking an ectopic pacemaker generating tachygastria. Experiments in dogs have revealed a successful inhibition of antral contractions in the fed state and a delayed gastric emptying of liquid^[38,39]. This study was designed to observe the acute symptomatic responses induced by RGES via bipolar mucosal electrodes. During seven settings of RGES, the frequently appeared symptoms were satiety, bloating, discomfort, pain, sting, and nausea, which are all associated with dyspepsia. These symptoms were typically seen during initial sensation by less energy. Even during maximum stimulation, the frequently appeared symptom was pain of upper abdomen, which is the key symptom of dyspepsia. Furthermore, some mild to moderate symptoms simultaneously occurred such as bloating, discomfort, nausea, satiety, and belching. These symptoms are all associated with dyspepsia. When these symptoms are present with activation of gastric stimulation, the subjects will change their eating behavior and ingest less food, eventually leading to their weight loss. All these are expected for the treatment of obese patients.

In this study, we found that the severity of some symptoms, such as bloating, discomfort and pain, significantly increased when the output energy of stimulation was adjusted to a higher scale. The total symptom score for each subject also simultaneously increased with the increase of energy, suggesting that there is a linear correlation between symptom score and stimulation energy, which is consistent with that of dosage-efficacy seen in pharmacology. In this sense, RGES meets the essential qualification for a potential therapy of obesity.

IGS can induce weight loss in patients with morbid obesity, but its mechanism remains largely unknown. Recent animal studies suggested that this increased satiety is attributed to gastric distention induced by gastric stimulation^[38]. Gastric distention contributes to the feeling of fullness or satiety. The mechanism is unclear, but distending the stomach stimulates gastric stretch receptors, thus triggering vagal discharges that activate hypothalamic neurons^[40] and induce the feeling of satiety^[41]. The stimulation-induced gastric relaxation or distention is mediated by the intrinsic nitrergic pathway, as the inhibitor of nitric oxide synthase blocks the effect whereas vagotomy does not^[42].

Satiety as a signal of reduction of food intake is also regulated by endocrine system especially the peptides in gastrointestinal tract^[43]. Peptides like cholecystokinin (CCK), glucagon-like peptide (GLP)-1, leptin and ghrelin have been shown to evoke satiety, thereby reducing food intake^[43,44]. Cigaina and Hirschberg^[16] have investigated the mechanism behind the changed eating behavior in patients treated with IGS. Gastric electrical stimulation can lead to significant weight loss and decrease in plasma levels of CCK, somatostatin, GLP-1, and leptin. Weight loss correlates significantly with decreased leptin levels. In this study, RGES induced a series of symptoms associated with dyspepsia, suggesting that the stimulation results in gastric distention

via neuroendocrine pathways. As gastric electrical stimulation is a novel and promising therapy for morbid obesity, more studies are necessary to elucidate the correlations between satiety, weight loss, and digestive neuro-hormone changes.

The results of our study reveal a wide diversity of visceral sensitivity to RGES among individuals and we should determine the optimal parameters according to the individual responsive severity. However, we should not select the pulse amplitude that is more than 15 mA, at which it would induce intolerable symptoms to most human subjects. The subjects who get initial sensation with low stimulation energy may be expected to get desirable therapeutic effect from RGES, but those insensitive to RGES may not. As for those insensitive subjects, we should include them in this therapy with deliberation. They may take other effective option such as bariatric surgery.

Abstract

AIM: To investigate the effect of release behavior of sustained-release dosage forms of sinomenine hydrochloride (SM·HCl) on its pharmacokinetics in beagle dogs.

METHODS: The *in vitro* release behavior of two SM·HCl dosage forms, including commercial 12-h sustained-release tablets and 24-h sustained-release pellets prepared in our laboratory, was examined. The two dosage forms were orally administrated to beagle dogs, and then the *in vivo* SM·HCl pharmacokinetics was investigated and compared.

RESULTS: The optimal SM·HCl sustained-release formulation was achieved by mixing slow- and rapid-release pellets (9:1, w/w). The SM·HCl release profiles of the sustained-release pellets were scarcely influenced by the pH of the dissolution medium. Release from the 12-h sustained-release tablets was markedly quicker than that from the 24-h sustained-release pellets, the cumulative release up to 12-h was 99.9% vs 68.7%. From a pharmacokinetic standpoint, the 24-h SM·HCl sustained-release pellets had longer t_{max} and lower C_{max} compared to the 12-h sustained-release tablets, the t_{max} being 2.67 ± 0.52 h vs 9.83 ± 0.98 h and the C_{max} being $1\ 334.45 \pm 368.76$ ng/mL vs 893.12 ± 292.55 ng/mL, respectively. However, the AUC_{0-t_n} of two SM·HCl dosage forms was comparable and both preparations were statistically bioequivalent. Furthermore, the two preparations had good correlations between SM·HCl percentage absorption *in vivo* and the cumulative percentage release *in vitro*.

CONCLUSION: The *in vitro* release properties of the dosage forms strongly affect their pharmacokinetic behavior *in vivo*. Therefore, managing the *in vitro* release behavior of dosage forms is a promising strategy for obtaining the optimal *in vivo* pharmacokinetic characteristics and safe therapeutic drug concentration-time curves.

INTRODUCTION

Sinomenine [(9 α , 13 α , 14 α)-7,8-didehydro-4-hydroxy-3,7-dimethoxy-17-methyl-morphinan-6-one] is an active alkaloid, which can be extracted from the stems of *Sinomenium acutum* Rehd. et Wils. Generally, sinomenine hydrochloride (SM·HCl) is the main chemical form for pharmaceutical purposes. Recent studies have shown that SM·HCl possesses potent anti-inflammatory, analgesic, and immunoinhibitory pharmacological effects, which provide the basis for the treatment of rheumatoid arthritis. Many clinical therapeutical trials have confirmed the effectiveness of SM·HCl in treating rheumatoid arthritis and the efficacy is as high as 90%^[1].

The conventional SM·HCl dosage forms (injection and rapid-release tablets) require frequent administration (3-4 times/d) and even the sustained-release tablets available on the market require administration twice per day, thus leading to poor patient compliance. Additionally, the high fluctuation in the SM·HCl plasma levels during multi-dose therapy with the marketed SM·HCl dosage forms contributes to side effects, such as gastrointestinal tract toxicity and allergic reactions^[2]. Accordingly, it is necessary to develop 24-h SM·HCl sustained-release dosage forms (for once-daily administration) in order to reduce side effects and increase patient compliance.

Currently, many controlled/sustained-release dosage forms are being converted from single unit drug delivery systems (DDS) such as tablets to multiple unit DDS such as pellets for the following reasons. Firstly, pellets seem to be less influenced by physiologic factors such as gastric emptying and intestinal transit than tablets, resulting in less marked inter-individual differences. Secondly, pellets are widely and evenly distributed over the surface of the gastrointestinal tract, increasing drug-gastrointestinal contact, thus improving oral bioavailability. Thirdly, release failures of individual units hardly affect the total release behavior due to the presence of multiple units, unlike the case with

tablets^[3]. Finally, optimal release characteristics can be achieved using a mixing strategy involving pellets with different release properties^[3].

For these reasons, we decided to design SM·HCl sustained-release pellets, and to manage the *in vitro* drug release in a manner that would allow 24-h sustained release. Furthermore, the *in vivo* pharmacokinetic properties of the 24-h sustained-release pellets were compared with those of the marketed 12-h sustained-release tablets in beagle dogs.

MATERIALS AND METHODS

Materials

SM·HCl was obtained from Hunan Zhengqing Pharm. Co. (Changsha, China). Microcrystalline cellulose (MCC, Avicel PH101) was provided by Changshu Pharm. Adjunct Co. (Changshu, China). Eudragit® NE 30D was provided by Röhm Pharma GmbH (Darmstadt, Germany). Reference formulation: SM·HCl sustained-release tablets (Zhengqing Pharm. Co., each tablet containing 60 mg of SM·HCl); Test formulation: SM·HCl 24-h sustained-release pellets in capsules (each containing 120 mg).

Preparation of SM-HCl sustained-release pellets

Preparation of blank core pellets Blank core pellets (0.8-1.1 mm in diameter) were prepared using MCC as a matrix and water as the adhesive by a rotary layering process (BZJ-360IIM rotary processor, 15th Institute of Academy for Chinese Carrier-Rocket Technology, Beijing). Four hundred grams of MCC was placed in the rotary processor chamber. The inlet airflow was 10-20 L/min, the atomizing pressure was 0.1-0.3 MPa and the rotation speed was 200 r/min. Then, the adhesive was sprayed at a flow rate of 15-25 r/min. Finally, the products were dried at 60 °C and then sieved to obtain blank core pellets of the required size.

Preparation of SM·HCl pellets Four hundred grams of blank core pellets were placed in the rotary processor chamber at a rotation speed of 200 r/min. SM·HCl in the drug supply container was added to chamber at 10-20 r/min. One percent of hydroxypropylmethyl cellulose (5 cps) in water was used as an adhesive, and sprayed over the pellets at a rate of 10-15 r/min. Finally, the products were dried at room temperature^[4,5].

Preparation of SM-HCl 24-h sustained-release pellets

The pellets were coated in a fluidized-bed coating apparatus (Shenyang Pharmaceutical University, China). For the coating process, the nozzle port size was 1 mm, the inlet air temperature was 18-23 °C, the atomizing pressure was 1.0 kg/cm², and the coating solution was sprayed onto the pellets at a flow rate of 0.8-1.2 mL/min. The coating solution was an aqueous dispersion of Eudragit® NE 30D. Talc- an antiadherent agent and sodium dodecyl sulfate- an anti-static agent, were added to the coating solution. Finally, the coated pellets were cured by heating at 40 °C for 24 h^[6,7].

Dissolution test Dissolution studies were carried out using the basket method at a rotation speed of 100 r/min at 37 °C in 900 mL dissolution medium according to ChP 2000. The dissolution tests were performed in 0.1 HCl, pH 6.8 or 7.4 PBS and distilled water, respectively. Samples were

collected at predetermined time points, and the SM·HCl content was analyzed using a UV-spectrophotometer (UV-9100, Ruili Co., China) at 365 nm. Then cumulative percentage of SM·HCl release was calculated.

Pharmacokinetic evaluation of SM-HCl sustained-release dosage forms

Experimental protocol All animal studies were performed according to the Guidelines for the Care and Use of Laboratory Animals approved by the Ethics Committee of Animal Experimentation of Shenyang Pharmaceutical University. Six male beagle dogs (weighing 20±2.5 kg) were randomly assigned to one of two crossover experiments with a 7-d washout period. Dogs were fasted for 12 h before administration with free access to water. Each dog was given orally either reference (two sustained-release tablets) or test formulation (one capsule of sustained-release pellets). Blood samples were collected at predetermined times for each protocol: (1) 0, 0.5, 1, 2, 3, 4, 5, 6, 8, 10, 12, 14, and 24 h for the reference; (2) 0, 1, 2, 4, 6, 8, 9, 10, 11, 12, 14, 24, and 36 h for the test. Plasma was immediately obtained by centrifuging blood samples at 3 000 r/min for 10 min. The plasma samples were stored in a freezer at -20 °C until analysis.

Chromatographic conditions Quantitative determination was performed on a high-performance liquid chromatograph (HPLC) equipped with a PU-980 pump (Jasco, Japan) and UV-975 detector (Jasco). An ODS C-18 (4.6 mm×200 mm, 5 μm) was used and the mobile phase consisted of methanol: acetonitrile:0.3% PBS (pH 4.8, 240:80:1 180, v/v)^[7]. The eluates were monitored at 265 nm. The flow rate was 0.9 mL/min and the column temperature was maintained at 30 °C.

Sample preparation Each plasma sample (0.5 mL) was mixed with 100 μL of 1.5 μg/mL caffeine and 200 μL amine-ammonium chloride aqueous solution (pH 11) in a glass centrifuge tube, followed by the addition of 3 mL of a solution of hexane:dichloride methane:isopropyl alcohol (100:50:5, v/v). The mixture was then shaken on a vortex mixer for 3 min and centrifuged at 3 000 r/min for 10 min. The organic layer was transferred to a clean tube and evaporated to dryness under nitrogen at 50 °C. The residue was dissolved in 100 μL of 0.5% phosphoric acid and 20 μL was subjected to HPLC.

Data analysis The term t_{\max} denotes the time to reach peak concentration, and C_{\max} is the peak concentration, and they were obtained directly from the measured values. The elimination rate constant (K_e) was calculated from the slope of the logarithm of the plasma concentration *vs* time using the final four points. The parameter $t_{0.5}$ was derived from $0.693/K_e$. The area under the plasma concentration-time curve (AUC_{0-t_n}) until the last sampling time (t_n) was calculated by the trapezoidal method. The relative bioavailability ($F\%$) was calculated as $AUC_{\text{Test formulation}}/AUC_{\text{Reference formulation}}$. The percentage absorption *in vivo* was calculated by Wagner-Nelson method.

RESULTS

Preparation of 24 h SM-HCl sustained-release pellets

The SM·HCl-loaded pellets were coated using the coating

formulation consisting of 117 g/L Eudragit® NE 30D, sodium dodecyl sulfate (1% of Eudragit® NE 30D, w/w) as an antistatic agent and talc (45% of Eudragit® NE 30D, w/w) as an antiadherent agent in aqueous dispersion. The effect of the coating level on the *in vitro* release behavior of SM·HCl sustained-release pellets is shown in Figure 1A. Clearly, higher the coating level, slower the release of SM·HCl from the coated pellets. Judged from the initial release rate and cumulative percentage release up to 20 h, the ideal release behavior was achieved at a coating level of 6.5%. However, drug release was still rather slow in the initial phase, with 2.84% being released up to 2 h. Therefore, SM·HCl rapid-release pellets were prepared with a coating level of 0.1%, and their release profiles are shown in Figure 1B, and almost complete release was obtained within 2 h. When employing a 9:1 (w/w) mixture ratio of slow- and rapid-release pellets, the SM·HCl cumulative release was 10% at 2 h, 48% at 8 h, and more than 85% up to 20 h (Figure 1B). This formulation was regarded as the optimal sustained-release formulation for the following studies.

The effect of the pH of the dissolution medium on the release profiles of SM·HCl sustained-release pellets is shown in Figure 2. The pH had no significant effect on the SM·HCl release properties of the coated pellets. The release profiles of the reference 12-h and test 24-h sustained-release tablets and pellets were compared (Figure 3). The reference formulation released drug completely up to 12 h, while the

test formulation only released 68% up to 12 h with near complete release until 24 h.

In vivo pharmacokinetics of 24 h SM·HCl sustained-release pellets

Either SM·HCl reference formulation (two 60 mg 12-h sustained-release tablets) or SM·HCl test formulation (one capsule containing 120 mg 24-h sustained-release pellets) was orally administered in the two crossover experiments in beagle dogs. The concentration-time curves of SM·HCl in plasma for the two dosage forms are illustrated in Figure 4. The pharmacokinetic parameters were calculated (Table 1). The t_{\max} was 2.67 ± 0.21 and 9.83 ± 0.40 h for SM·HCl reference and test formulations, respectively, indicating that the test pellets underwent a slower release and prolonged absorption than the reference tablets. Also, the C_{\max} of SM·HCl 24-h sustained-release pellets was 893.1 ± 119.4 ng/mL, which was significantly lower than that of 12-h sustained-release tablets ($1\,334.5 \pm 150.5$ ng/mL, $P < 0.05$). Furthermore, the AUC_{0-36} of the SM·HCl test formulation (13.50 ± 1.47 mg·h/L) was similar to the AUC_{0-24} of the SM·HCl reference formulation (13.06 ± 9.45 mg·h/L), with the F (%) being 103.4. Hence, the two formulations were statistically bioequivalent ($P < 0.05$).

The percentage absorption *in vivo* of the two formulations was assessed by the Wagner-Nelson method. The percentage absorption ($F(t)$) exhibited a good linear relationship with

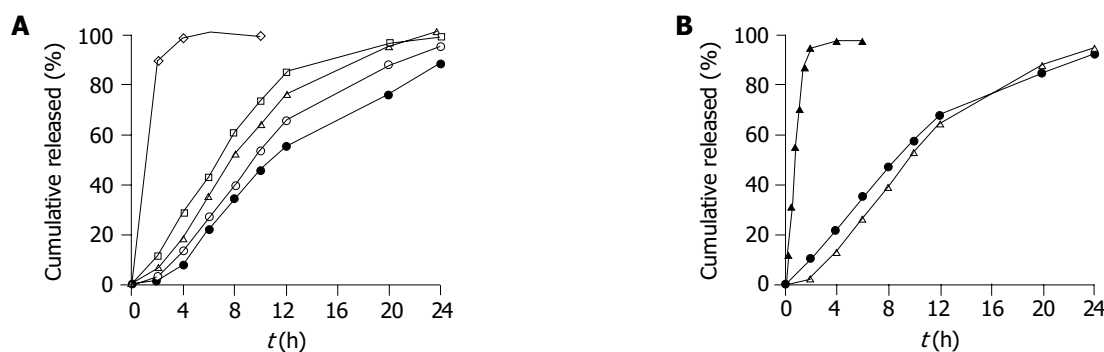

Figure 1 Effect of different coating levels on SM·HCl release behavior from the coated pellets in distilled water ($n = 6$). A: Pellets coated at five levels of 0% (\diamond), 3% (\square), 5% (\triangle), 6.5% (\circ), 8% (\bullet, w/w, total solid applied); B: rapid-

release pellets (\blacktriangle) and slow-release pellets at a 6.5% coating level (\triangle) and a mixture of slow- and rapid-release pellets (9:1, w/w, \bullet).

Figure 2 Effect of pH of the dissolution medium on SM·HCl release from coated pellets of the optimal formulation ($n = 6$). Distilled water (\circ), 0.1 mol/L HCl (\bullet), pH 6.8 (\triangle) and pH 7.4 (\square) PBS.

Figure 3 Comparative SM·HCl release profiles of 24-h test sustained-release pellets (\bullet) and 12-h reference sustained-release tablets (\circ, $n = 6$).

Figure 4 SM-HCl plasma concentration-time profiles after oral administration of 24-h test sustained-release pellets (●) and 12-h reference sustained-release tablets (○) in beagle dogs at a single dose of 120 mg/animal. Each value represents mean±SE ($n = 6$).

Table 1 Pharmacokinetic parameters after oral administration of either SM-HCl 24-h test sustained-release pellets or 12-h reference sustained-release tablets in beagle dogs at a single dose of 120 mg/animal ($n = 6$, mean±SD)

Parameter	Test formulation	Reference formulation
C_{max} (ng/mL)	893.1±119.4	1 334.5±150.5
t_{max} (h)	9.83±0.40	2.67±0.21
K_e (1/h)	0.044±0.01	0.084±0.01
$t_{0.5}$ (h)	20.7±8.7	8.6±1.9
AUC ₀₋₂₄ (mg·h/L)	13.50±1.47	13.06±9.45
F (%)	103.41	-

the cumulative percentage release ($f(t)$, r being 0.98 and 0.97 for the test and reference formulations, respectively, Figure 5), demonstrating a good correlation between the *in vitro* release and *in vivo* absorption processes.

DISCUSSION

It has been well established that SM-HCl is in an effective treatment for rheumatoid arthritis comparable with another traditional Chinese medicine, total glycosides of *tripterygium Wilfordii* Hook f. However, SM-HCl has markedly reduced side effects and improved safety, compared to the latter in terms of gastrointestinal tract effects and urogenital toxicity^[8]. In spite of this, the conventional SM-HCl dosage forms give rise to higher peak to trough plasma concentration fluctuation, resulting in moderate side effects. For this reason, we attempted to develop a 24-h SM-HCl sustained-release preparation (once daily), and to prolong the absorption phase and reduce the degree of concentration fluctuation *in vivo* by managing the drug release characteristics of dosage forms *in vitro*.

The multiple unit drug DDS and SM-HCl pellets were prepared by a rotary layering process and the sustained-release behavior was obtained by standard industrial coating technology. The coating formulation consisted of an aqueous dispersion of Eudragit® NE 30D^[9], with the addition of talc as the antiadherent agent and sodium dodecyl sulfate as the antistatic agent. The coating layer of Eudragit® NE 30D was moderately permeable to water molecules, which are capable of penetrating into the pellet core. Thus, a

Figure 5 Relationship between cumulative SM-HCl percentage release *in vitro* $f(t)$ and percentage absorption *in vivo* $F(t)$ of the two dosage forms. S , I and R are the abbreviations for the slope, intercept and correlation coefficient for the correlation equation, respectively. Twenty-four-hour test sustained-release pellets (●) and 12-h reference sustained-release tablets (○).

saturable drug solution was formed within the Eudragit® NE 30D coating layer and provided the primary drive for drug release. Two mechanisms were assumed to account for drug release from the coated pellets. Provided the coating layer was a homogenous uninterrupted membrane, the additives were evenly distributed, and there were many interstices of the correct molecular size in the membrane. Drug molecules initially dissolved in the membrane, then diffused down the concentration gradient through these micro-gaps, and finally released into the outer medium. In addition, if a water-soluble channeling agent was added, a number of aqueous micro-channels formed across the membrane when coming into contact with water, and acted as release paths for soluble drug molecules, such as SM-HCl^[10].

In this study, when a small amount of channeling agent (1% PEG 4000 of Eudragit® NE 30D, w/w) was added to the coating formulation, SM-HCl-coated pellets at the coating level of 6.5% released drug completely up to 12 h (unpublished data). Thus, the channeling agent was absent in the coating formulation, and the former mechanism is responsible for water-soluble SM-HCl release from the coated pellets. Its release behavior corresponds to Fick's diffusion equation: $dC/dt = -DAk\Delta C/b$, where dC/dt is the diffusion rate, D the diffusion coefficient, A the surface area of membrane, k the partition coefficient, ΔC the concentration difference across membrane, and b the thickness of membrane. Since D , k and A were given for SM-HCl and coating membrane, and ΔC was constant in the initial release phase and decreased exponentially in the later phase, dC/dt was inversely related to b , as evidenced in Figure 1A. When the 6.5% coating level was used, ideal release behavior was achieved. Unfortunately, it exhibited a rather slower release in the initial phase up to 2 h. With regard to mixing pellets with different release rates to obtain the desired release behavior, rapid-release pellets with complete release within 2 h were prepared and combined with the above slow-release pellets (1:9, w/w). The final product exhibited optimal release behavior with 10.5% being released up to 2 h (Figure 1B), indicating that mixing pellets with different release rates is a powerful strategy for the management of *in vitro* drug release properties^[11].

The release profile of the final SM-HCl sustained-release

pellets was unaffected by the pH of dissolution medium (Figure 2). This was to be expected because the matrix (Eudragit® NE 30D) of the membrane was insensitive to pH and the drug release was unaffected by the pH. The 24-h SM·HCl sustained-release pellets maintained a zero-rate release up to 14 h, and exhibited prolonged release up to 24 h, in contrast to the 12-h SM·HCl sustained-release tablets (Figure 3). In order to investigate the effect of *in vitro* release behavior on *in vivo* absorption of the coated pellets, an *in vivo* comparative pharmacokinetic evaluation was undertaken using 24-h SM·HCl sustained-release pellets *vs* marketed 12-h sustained-release tablets in beagle dogs.

After oral administration at a single dose of 120 mg to beagle dogs, the t_{\max} of the 12-h sustained-release tablets was 2.67 ± 0.52 h, 7 h faster than 9.83 ± 0.98 h for the 24-h sustained-release pellets (Table 1 and Figure 4). In addition, the C_{\max} of the 12-h sustained-release tablets (1334.45 ± 368.76 ng/mL) was significantly higher than that of the 24-h sustained-release pellets (893.12 ± 292.55 ng/mL). Combining the C_{\max} and t_{\max} , the 24-h test pellets exhibited more significant sustained release and prolonged absorption characteristics than the 12-h reference tablets, including a reduced peak concentration and a prolonged time to reach the peak concentration. More importantly, the $t_{0.5}$ of the 24-h test pellets (20.7 ± 8.7 h) was higher than that of the 12-h reference tablets (8.6 ± 1.9 h). This result is obviously inconsistent with the theory that the intrinsic biologic half-time depends on a given drug while being independent of the type of dosage forms. The prolonged $t_{0.5}$ of the 24-h test pellets suggested a reduced apparent K_e compared to the 12-h reference tablets (Table 1), which was accounted for by prolonged absorption to partially counteract the intrinsic elimination capability during the terminal phase. In effect, the absorption of the 24-h test pellets was markedly slower than that of the 12-h reference tablets (Figure 4), due to more prolonged drug release compared to the reference tablets. The aforementioned results clearly indicate that the release characteristics of dosage forms, play a significant role in mediating their pharmacokinetic behavior. As a consequence, an optimal pharmacokinetic performance could be achieved by producing the desired release profiles of dosage forms. The AUC_{0-t_n} of the two SM·HCl dosage forms was comparable and both were statistically bioequivalent preparations ($P < 0.05$). Moreover, the SM·HCl percentage absorption *in vivo* correlated well with the cumulative percentage release *in vitro* as far as two preparations were concerned (Figure 5), validating the *in vitro* dissolution conditions and verifying the utility of the sustained-release dosage forms (Figure 4). In addition, the slopes of two correlation equations for the two dosage forms were similar. In contrast, the intercept of the 24-h test formulation (-11.6%) was greater than that of the 12-h reference tablets (-24.6%), suggesting that the percentage absorption of the 12 h reference tablets is 13% lower than that of the 24-h test formulation when the percentage release

is the same. Ren *et al.*^[12], reported that the permeability of SM·HCl in jejunum and ileum is poorer than that in the colon, which might be responsible for the above relatively reduced absorption of the 12-h reference tablets due to the main site of residence being the jejunum and ileum.

In summary, 24-h SM·HCl sustained-release pellets can be successively prepared by a conventional rotary layering process and standard industrial coating technology. Optimal *in vitro* release properties can be achieved by a mixing strategy involving pellets with different release rates. Moreover, the SM·HCl release characteristics of the dosage forms have a marked effect on their pharmacokinetics *in vivo*. Accordingly, managing the *in vitro* release behavior of dosage forms is a promising strategy for obtaining optimal *in vivo* pharmacokinetic characteristics and safe therapeutic drug concentration–time curves.

Abstract

AIM: To review the experience in surgery for 508 patients with portal hypertension and to explore the selection of reasonable operation under different conditions.

METHODS: The data of 508 patients with portal hypertension treated surgically in 1991-2001 in our centers were analyzed. Of the 508 patients, 256 were treated with portaazygous devascularization (PAD), 167 with portasystemic shunt (PSS), 62 with selective shunt (SS), 11 with combined portasystemic shunt and portaazygous devascularization (PSS+PAD), 9 with liver transplantation (LT), 3 with union operation for hepatic carcinoma and portal hypertension (HCC+PH).

RESULTS: In the 167 patients treated with PSS, free portal pressure (FPP) was significantly higher in the patients with a longer diameter of the anastomotic stoma than in those with a shorter diameter before the operation ($P<0.01$). After the operation, FPP in the former patients markedly decreased compared to the latter ones ($P<0.01$). The incidence rate of hemorrhage in patients treated with PAD, PSS, SS, PSS+PAD, and HCC+PH was 21.09% (54/256), 13.77 (23/167), 11.29 (7/62), 36.36% (4/11), and 100% (3/3), respectively. The incidence rate of hepatic encephalopathy was 3.91% (10/256), 9.58% (16/167), 4.84% (3/62), 9.09% (1/11), and 100% (3/3), respectively while the operative mortality was 5.49% (15/256), 4.22% (7/167), 4.84% (3/62), 9.09% (1/11), and 66.67% (2/3) respectively. The operative mortality of liver transplantation was 22.22% (2/9).

CONCLUSION: Five kinds of operation in surgical treatment of portal hypertension have their advantages and disadvantages. Therefore, the selection of operation should be based on the actual needs of the patients.

Key words: Portal hypertension; Surgical operation; Shunt

INTRODUCTION

In order to discuss operation indications, the data of 508 patients with portal hypertension treated surgically with portaazygous disconnection (PD), portasystemic shunt (PSS), selective shunt (SS), combined portasystemic shunt and portaazygous devascularization (PSS+PAD), liver transplantation (LT), and union operation for hepatic carcinoma and portal hypertension (HCC+PH) in 1991-2002 in our centers were analyzed.

MATERIALS AND METHODS

General data

Of the 508 patients, 425 were males and 83 females, aged 3-71 years (average 40.8 years). Three hundred and fifty-eight patients (70.47%) had a history of bleeding from the upper digestive tract, 150 patients (37.24%) had esophageal varices in different degrees with no history of bleeding from the upper digestive tract. Child-Pugh classification of liver function showed grade I in 260 patients, grade II in 164, grade III in 84. Etiology was posthepatic cirrhosis in 468 patients, biliary cirrhosis with biliary tract stenosis in 22, extrahepatic portal obstruction in 6, alcoholic cirrhosis in 8, schistosomiasis cirrhosis in 3, and idiopathic portal hypertension in 1.

Types of operation

Portaazygous disconnection (PAD) was performed in 256 patients (50.39%); portasystemic shunt (PSS) in 167 patients (32.87%, Table 1); selective shunt (SS) including distal splenorenal shunt (DSRS), distal splenocaval shunt (DSCS), coronary vein-left renal vein shunt and coronary vein-caval shunt in 62 patients (12.20%, Table 2).

Statistical analysis

The data were expressed as mean \pm SD, and analyzed with SPSS 10.0 for Windows. $P<0.05$ was considered statistically significant.

RESULTS

Free portal pressure (FPP)

The changes of free portal pressure (FPP) in 215 cases

Table 1 Patients treated with PSS

Types of operation	Cases
Portacaval shunt (PCS)	14
Portacaval shunt with prosthetic H-graft (PCS-H)	25
Mesocaval shunt (MCS)	66
Inferior mesocaval shunt (IMCS)	26
Splenorenal shunt (SRS)	12
Juxtal splenocaval shunt (SCS)	16
Branch of mesenterico-caval shunt (BMCS)	5
Inferior meso-left renal vein shunt	2
Colonic media vein-caval shunt	1
Total	167

Table 2 Patients treated with selective shunt (SS)

Types of operation	Cases
Distal splenocaval shunt (DSCS)	42
Distal splenorenal shunt (DSRS)	16
Coronary vein-caval shunt	4
Total	62

were observed before and after operation. The results are summarized in Table 3.

The results showed that FPP in the four groups of operation showed a marked post-operative decrease, especially in the PSS group with a diameter of anastomotic stoma in 8-12 mm compared to pre-operation ($P<0.01$). The pre-operation FPP in the PSS (diameter 8-12 mm) group was notably higher than that in other groups ($P<0.01$). The decreased absolute value of post-operation FPP in the PSS (diameter 8-12 mm) group (1.23 ± 0.5 kPa) was also much higher than that in the PAD group (0.5 ± 0.47 kPa) and SS group (0.51 ± 0.46 kPa, $P<0.01$). No significant difference was found in the post-operation FPP of the above-mentioned four groups ($P>0.05$).

The FPP in 9 of 11 patients who underwent combined PSS+PAD decreased 0.79 kPa (81 cm H₂O) averagely after operation with no change of FPP in the other 2 patients. The degrees of esophageal varices in 7 of the 11 patients were alleviated with no change in the other 4 patients after operation as confirmed by barium meal.

Table 3 Changes of free portal pressure (FPP) in three types of operation (mean \pm SD)

Types of operation	Cases	Pre-operation (kPa)	Post-operation (kPa)
Portaazygous disconnection (PAD)	81	3.78 ± 0.50	3.26 ± 0.57
PSS (diameter of anastomotic stoma in 8-12 mm)	52	4.29 ± 0.80	3.11 ± 0.63
PSS (diameter of anastomotic stoma in 6-8 mm)	42	3.91 ± 0.48	3.12 ± 0.46
Selective shunt (SS)	62	3.85 ± 0.59	3.26 ± 0.45

Rehemorrhage

Ninety-one of the five hundred and eight cases (16.8%) had rehemorrhage. The incidence rate of hemorrhage in patients treated with PAD, PSS, SS, and PSS+PAD was

21.09% (54/256), 13.77 (23/167), 11.29 (7/62), and 36.36% (4/11), respectively. Twenty-four (44.44%) of the fifty-four rebleeding patients treated with PAD had rebleeding within a year after operation, the incidence rate of rehemorrhage was 9.38% (24/256). Fourteen cases had rebleeding 5 years after PAD. Hepatectomy combined with splenic artery ligation, coronary vein and cardia and fundus varix ligation, or portacaval shunt with H-grafts (8 mm in diameter) was performed in three patients with hepatocellular carcinoma complicated by portal hypertension. The incidence rate of rebleeding was 100% (3/3).

Hepatic encephalopathy

The total incidence rate of hepatic encephalopathy was 6.50% (33/508). The incidence rate of hepatic encephalopathy in patients treated with PAD, PSS, SS, PSS+PAD, and HCC+PH was 3.91% (10/256), 9.58% (16/167), 4.84% (3/62), 9.09% (1/11), and 100% (3/3), respectively.

Operative mortality and its causes

The total operative mortality was 5.91% (30/508).

PAD The operative mortality was 5.86% (15/256). The cause of death was rebleeding. The high mortality was associated with severe disease. After being discharged from hospital, 21 cases died of rebleeding (10 cases), primary hepatocellular carcinoma (5 cases), liver function failure (5 cases) and malignant lymphoma (1 case).

PSS The operative mortality was 4.19% (7/167). Three patients died of severe hepatorenal syndrome, two died of rebleeding after operation, two underwent emergency MCS (12 mm in diameter of the anastomotic stoma), and died of hepatic encephalopathy 5 d after operation due to the improper operation method and large diameter of the anastomotic stoma. After being discharged from hospital, 16 cases died of primary hepatocellular carcinoma (5 cases), liver function failure (7 cases) and of rebleeding (4 cases).

SS The operative mortality was 4.84% (3/62). Three patients died of cerebral hemorrhage 5 d after operation, hepatorenal syndrome, and, rehemorrhage and infection in the subphrenic area and left lung. After discharge, two patients died of primary peritonitis, one of severe hepatitis, one of rebleeding.

PSS+PAD The operative mortality was 9.09% (1/11), this patient died of persistent deterioration of hepatic function and renal failure.

HCC+PH The operative mortality was 66.67% (2/3). One patient died of postoperative hemorrhage, the other died of hepatic failure. The last one succumbed to hepatic function failure 10 mo later after operation.

Liver transplantation We performed liver transplantation in 9 (1.77%) cases. The operative mortality was 2/9 (22.22%). The major reason of death was liver failure and infection after operation.

Portacaval shunt for patients with portal hypertension combining ascites

Nineteen patients with ascites before operation underwent portacaval shunt. They all had hematemesis, dark stools, moderate and severe esophageal varices, ascites, and no hypertension and kidney disease. The liver function of all

the patients was Child's grade B, and their HBsAg was positive. Eleven patients underwent portacaval shunt with H-graft, and eight patients, portacaval side-to-side anastomosis. No ascites were found by B-type ultrasound reexamination in the abdominal cavity before discharge. Hepatic tissue biopsy showed liver cirrhosis. But mild and moderate hepatic coma occurred in three patients with diameter of anastomotic stoma of 8-10 mm after operation.

Emergency operation for massive hemorrhage of gastrointestinal tract due to portal hypertension

Twenty (3.94%) of the above-mentioned patients underwent emergency operation. Ten of the patients (50%) had massive hemorrhage in gastrointestinal tract for the first time, the other 10 patients had a past medical history of massive hemorrhage in the gastrointestinal tract. They received endoscopic sclerotherapy (four cases) and loop ligation of varices (two cases), TIPSS (one case), balloon tamponade compression by a four-lumen tube (three cases). The causes of portal hypertension were cavernous transformation of portal vein, idiopathic portal hypertension, and posthepatic cirrhosis. Liver function was Child's grade A (2 cases), Child's grade B (7 cases), Child's grade C (11 cases). Of the 20 cases, 12 cases received emergency PSS, 8 emergency PAD (gastroesophageal devascularization, 4 cases had ligation of splenic artery without splenectomy). The ratio of preoperative liver function as Child's grade C was 58.33% (7/12) in the PSS group and 50% (4/8) in the PAD group. Postoperative mean loss of FPP was 9.6 cm H₂O in the PSS group and 1.8 cm H₂O in the PAD group. Surgical hemostasis had an effect on all the patients. Of the eight patients who underwent PAD, none had hepatic encephalopathy, five recovered smoothly, three (37.5%) had rehemorrhage within 2 wk after operation. We could not determine whether rupture of varices or hemorrhagic gastritis was the cause of postoperative bleeding. Of 12 patients who received PSS, 3 (25%) had hepatic encephalopathy, 2 (16.67%) rehemorrhagia, 4 died of liver failure. The total operative mortality was 25%. The operative mortality was 33.33% in the PSS group and 12.5% in the PAD group.

DISCUSSION

Portal hypertension refers strictly to an increase in the portal venous pressure (>5 mm Hg or 7 cm H₂O). Based on data in China, the normal portal venous pressure ranges from 13 to 24 cm H₂O, its mean value is 18 cm H₂O. Portal hypertension can be diagnosed when free portal venous pressure exceeds 25 cm H₂O, but the term is used to the clinical syndrome associated with an increased portal venous pressure characterized by splenomegaly and the development of abnormal portalsystemic venous anastomosis. Increased resistance to blood flow in the portal venous system is the most important cause, though increased portal blood flow may contribute to it in a few cases. The causes of increased portal venous resistance may lie in the presinusoidal vessels outside the liver or in the intrahepatic vessels at pre-sinusoidal, sinusoidal or post-sinusoidal levels. No consistent therapeutic method has been successful due to its complex etiology, pathophysiology and hemodynamics. Which kind of surgical

treatment should be used depends on portal hemodynamics, etiology, age, liver pathology, liver function, bleeding history of upper digestive tract, size of spleen and hypersplenism.

PAD

PAD has no significant effect on portal perfusion. Nutritional factors such as insulin and glucagons are favorable for maintaining normal liver function^[1,2]. Portal hypertension is important in maintaining hepatopetal blood flow during liver cirrhosis^[3-6]. The present study showed that FPP of the pre-PAD-operation decreased by 0.59 kPa averagely compared to that of post-PAD-operation ($P<0.01$). In a small number of patients treated with PAD, the mean FPP decreased much more than 0.59 kPa, suggesting that PAD is an effective hemostatic method for patients with massive hemorrhage of the upper digestive tract^[7]. A few of the patients with plentiful collateral circulation in gastric fundus and pericardial and recurrent upper gastrointestinal bleeding, had no change of FPP or a slightly elevated FPP after PAD and might have had rehemorrhage shortly after PAD operation.

One typical male patient had a massive hemorrhage of upper digestive tract combined with primary peritonitis, jaundice and ascites, and underwent emergency PAD. His hemorrhage ceased, and liver function and general state improved. Four years later, the patient had a massive rehemorrhage of upper digestive tract without jaundice and ascites, and received emergency MCS with a diameter of the anastomotic stoma in 10 mm. From then on, we followed him up continuously and found no rebleeding and hepatic encephalopathy. Animal experimental study showed that during cirrhotic portal hypertension, the defensive capacity of mucosa is progressively weakened, resulting in pathologic changes of the gastric mucosa^[8]. After disconnection of portaazygous junction, desquamation of the epithelial cells of the gastric mucosa, edema and thickening of the submucosal layer, and narrowing of its capillaries occur^[9]. The epithelium of the gastric mucosa is obviously ischemic and hypoxic, the defensive capability of the gastric mucosa is further deteriorated, indicating that it is one of the causes of high hemorrhage rate after disconnection^[10,11]. A few patients may have rebleeding shortly after PAD^[12,13].

Another typical case, a female, had recurrent bleeding four times (hematemesis and hemaecia) accompanied with hydrothorax and ascites within 3 mo, underwent emergency PAD, then she could take food as her hydrothorax and ascites gradually receded. Seventeen days after operation, hematemesis occurred, she had a massive rehemorrhage of upper digestive tract the next day, balloon tamponade compression had no effect on hemostasis. Two days later, emergency MCS was performed, 1 000 mL ascites was found during operation, then rebleeding ceased. The rebleeding of this case was due to the pathologic changes of the gastric mucosa that resulted from PAD^[14].

Based on the above data about PAD, the operation indications for PAD include: massive bleeding of upper digestive tract which cannot be controlled by non-surgical methods; the FPP<3.92-4.41 kPa (40-45 cm H₂O) after splenectomy; esophageal varicosis, splenomegaly, anteroposterior diameter of the spleen>7 cm and apparent hypersplenism; recurrent

bleeding of the upper digestive tract, debility or poor condition, and poor liver function; rebleeding after DSCS or DSRS, thrombosis of anastomotic stoma of splenic vein; regional portal hypertension.

PSS

PAD combined with small stoma PSS is widely used in the therapy of portal hypertension^[15,16]. The diameter of the anastomosis stoma of PSS mentioned in this paper was from 6 to 8 mm. Small-diameter portacaval shunt for patients is in favor of hepatic reserve^[17,18]. After PSS, the FPP level was (3.15 ± 0.39) kPa and the incidence rate of rehemorrhage of upper digestive tract reduced by alleviating pathological changes of gastric mucosa and prevented the formation of lateral branch circulation. In order to preserve hepatopetal perfusion to support and improve liver function, the FPP should be maintained at the level no more than $(3.92-4.41)$ kPa. The FPP level was as high as 9.58% (16/167) in patients treated with PSS, which might be associated with improper selection of patients and large anastomotic stoma. In recent years, we have performed some kinds of PSS with small caliber and low blood flow discharge such as inferior mesocaval shunt (IMCS)^[19], inferior meso-left renal vein shunt^[20,21] and branch of mesenterico-caval shunt (BMCS), which are technically easy to operate and popularize. Experimental animal study suggested that the portacaval shunt significantly improves the microcirculation of gastric mucosa^[22] and can promote gastric mucosa to synthesize and secrete glycoprotein and prostaglandins, thus increasing the defensive capability of the gastric mucosa^[23,24]. It was reported that the levels of plasma renin activity (PRA), angiotensin converting enzyme (ACE), angiotensin II and portal venous pressure (PVP) decrease significantly in cirrhotic patients with portal hypertension after portacaval shunts, which may be the major causes of ascites disappearance in cirrhotic patients after portacaval shunt^[25]. Surgical PSS might be considered for acute or chronic portal bleeding if medical treatment fails^[26]. Some kinds of diseases must be operated with PSS, such as extrahepatic portal vein obstruction and portal hypertension resulting from biliary cirrhosis of liver due to bile duct stenosis.

The operation indications for PSS include recurrent multiple bleeding of the upper digestive tract and liver function in Child's grades A and B status, no ascites, extrahepatic portal vein obstruction, portal hypertension resulting from biliary cirrhosis of liver due to hepatic duct stenosis, rebleeding after PAD, and rebleeding after PAD combined with PSS.

Selective shunt (SS)

The theoretical bases for designing selective shunt (SS) are as follows^[27,28]. PSS (unselective shunts) is effective in hemostasis of the upper digestive tract, but it decreases portal perfusion leading to deterioration of liver function^[29,30]. PAD aggravates pathologic changes of gastric mucosa and has a high rate of rebleeding. The functional reserve of the liver depends on portal perfusion^[17,31]. These thoughts have led to the development of selective portasystemic shunts. Warren first reported DSRS in 1967^[32], and Inokuchi

designed and reported coronary vein-caval shunt in 1968^[33] and 1969^[34]. Holmin *et al.*^[35], operated DSCS in rats in 1977, Bhalarao *et al.*^[36], firstly reported DSCS in patients in 1978. Since 1984, Cai *et al.*^[37], have begun to operate DSCS in patients in China. Preliminary data indicate that DSRS in a subgroup of patients with good liver function and a correct portaazygous disconnection, more effectively prevents variceal rebleeding than endoscopic sclerotherapy^[38]. It was reported that DSCS selectively improves microcirculation and functions of the gastric mucosa^[39]. DSCS and PAD are better than MCS and PCS (portacaval shunt) in protecting the hepatic reserve function in rats with cirrhotic portal hypertension^[40-44]. Experimental study also revealed that the blood viscosity after DSCS is lower than that after PAD^[45]. DSRS and DSCS have all the advantages of both PAD and PSS, but they are technically difficult. The incidence rates of rebleeding and hepatic encephalopathy in our patients treated with SS were lower compared to the patients treated with other kinds of operation, which might be partly associated with the different conditions of patients. Our results are in accord with other reports^[46-48].

Gradual development of encephalopathy also exists after selective shunts, and is related with loss of hepatic perfusion of portal blood^[49]. Based on other reports, portal blood flows to the liver in the early postoperative period in about 88% of patients but in about 42% after 3 years; no patient with a continuing flow of portal blood to the liver suffers from encephalopathy. Final loss of portal blood flow may be due to continuing superior mesenteric venous hypertension causing the development of collateral vessels which convert the selective shunt to an unselective shunt. The selective shunts have not yet been shown to improve long-term survival, which may in any case be limited by progressive liver disease, but their advantages in the shorter term may allow more patients a better survival.

The role of selective shunts in the treatment of gastrointestinal bleeding due to portal hypertension is still controversial. It has already established that it is not suitable to patients with ascites because it may become uncontrollable after the operation and cannot improve portal flow to the liver. It should never be done when there is centrifugal portal blood flow, as in the Budd-Chiari syndrome.

The operation indications for SS include liver function stabilized in Child's grade A or B, portal blood flow velocity higher than 8-10 cm/s, degree I or II of portal vein displaying during arterial portography^[50], more than 1.96 kPa (20 cm H₂O) of the difference between splanchnic obstructive portal pressure (SOPP) and free portal pressure (FPP), no active hepatitis, esophageal varicosis with history of hemorrhage or severe esophageal varicosis without history of hemorrhage, splenomegaly and anteroposterior diameter of the spleen >7 cm and no apparent hypersplenism, no chronic pancreatitis and splenic phlebitis or periphlebitis, no ascites, no retro-peritoneal edema, no Budd-Chiari syndrome.

Combined PSS+PAD

Compared to PAD, PSS+PAD had a higher operative mortality, but their postoperative hemorrhage incidence rates had no difference. The number of our cases that underwent

PSS+PAD was too small to induce a definite objective evaluation.

PSS+PAD was performed in the early 1980s. Huang Yaoquan^[51] reported the experience of 33 cases operated with PSS+PAD. Then some similar reports showed that this type of operation cannot only decrease free portal pressure to achieve the goal of persistent hemostasis, but also not reduce excessive hepatopetal blood flow^[16,52]. After PAD, spontaneous shunt will be gradually emerged. PSS+PAD, ahead of schedule replaces spontaneous shunt, which slowly occurs after PAD with artificial shunt in operation. Combined devascularization and splenorenal shunt (PAD+PSS) significantly decreases portal venous flow and portal pressure, as well as maintaining hepatopetal flow, thus entailing fewer complications compared to either PAD or PSS, some scholars even advocated that PSS+PAD could be a primary selection in the operations for portal hypertension^[53,54].

Compared to PSS or PAD, PSS+PAD prolongs operation time, aggravates surgical trauma, and damages liver function, which are the reasons why PSS+PAD cannot be generally performed. Based on the incomplete statistics of 24 famous Chinese hospitals in 1998, only 204 (only accounted for 1.7%) cases received PSS+PAD in more than 12 000 cases of operations for portal hypertension^[55].

Prognosis of the patients is mainly dependent on the condition of the whole body and hepatic function. We should select the operations which have minimal adverse effect on the whole condition and liver function in the patients. PSS has few advantages because of a negative effect on hepatic blood perfusion in contrast to PAD. In China, Yang Zhen and Qiu Fazu^[6,56] reported that patients that underwent standard PAD have a postoperative rebleeding incidence rate lower than 10%. Thus, it should be emphasized that surgeons should be careful when choosing PSS+PAD as a treating method for the patients with portal hypertension.

The operation indications for PAD combined with small stoma PSS (usually mesocaval shunt or portacaval shunt) include recurrent or massive bleeding of varices of esophagus and gastric fundus and stable liver function in Child's grades A and B, overt varices of esophagus and gastric fundus and Child's grade A status of hepatic function with FPPs more than 3.92-4.41 kPa (40-45 cm H₂O) after splenectomy in operation and no ascites or small amounts of ascites, and a relatively younger age (generally less than 60 years).

Surgical treatment of primary hepatic carcinoma concurrent with portal hypertension

Surgical treatment of primary hepatic carcinoma complicated by portal hypertension is based on appraisal of hepatosis and prediction of life expectancy of the patients with portal hypertension^[57,58]. The 5-year survival rate of the patients with liver cirrhosis and hemorrhage of upper digestive tract is 25-35%. Pinto *et al.*^[59] reported that 287 patients with hemorrhage of the upper digestive tract have a total 5-year survival rate of 26.2%, and that hepatic function condition of the patients exerts great effects upon their survival. Yang *et al.*^[60] reported that poor liver

function increases postoperative rebleeding and mortality. Zhang *et al.*^[61] showed that onestage hepatocellular carcinoma excision and splenectomy and portal azygous disconnection can be simultaneously performed for patients with good hepatic function. Our datas showed that hepatectomy and portacaval shunt greatly exacerbate the hepatic function, if these two operations are performed simultaneously.

During the treatment of patients with hepatocellular carcinoma and portal hypertension, the following must be considered. Hepatic function of the patients is a fundamental factor in determining the prognosis and long-term survival. In recent years, many domestic hospitals have performed whole liver transplantation in order to treat the liver-function decompensation (Child's grade C or more serious) patients with hepatocellular carcinoma (mainly small HCC) and upper gastrointestinal hemorrhage due to portal hypertension, and have achieved good therapeutic effects. Prophylactic PAD and PSS should not be done for the patients with varices of esophagus and gastric fundus but without upper gastrointestinal hemorrhage. One-stage hepatectomy and PAD (splenectomy and pericardia disconnection) should be a better choice for patients with HCC and portal hypertension^[62]. Interventional therapy (hepatic artery embolism) plus PAD and hepatectomy plus either sclerotherapy or loop ligature can reduce operational risk^[63,64].

Liver transplantation

Liver transplantation can treat portal hypertension, and rehemorrhage, and encephalopathy do not occur in treated patients. Liver transplantation was carried out abroad much earlier. The domestic practice of liver transplantation in recent years indicates that liver transplantation is feasible not only in patients with chronic progressive hepatic failure, refractory ascites and jaundice, but also in patients with recurrent hemorrhage, especially with poor hepatic function, if they are not old and their other vital organs function well. For example, one patient with multiple upper gastrointestinal bleeding received repeated sclerotherapy and TIPS, but no effective results were achieved. He then underwent a whole liver transplantation because of carcinomatous changes in his liver, and his free portal pressure decreased to normal level and conditions were very satisfactory.

In China, most patients who underwent liver transplantation were those with advanced-stage hepatocellular carcinoma and malignant diseases of biliary tract, the few were those with benign irreversible liver diseases including liver failure and recurrent upper gastrointestinal hemorrhage.

The indication for liver transplantation is end-stage liver disease. Not all patients with variceal bleeding have end-stage liver disease, and not every patient with variceal bleeding needs a new liver. Although the availability and increasingly successful outcome of liver transplantation have significantly altered the management of patients with cirrhosis, the question "does this patient really need a transplant now, or is the patient likely to need a transplant in the future?" should always be asked.

We believe that the therapy of hepatic cirrhosis and portal hypertension complicated by upper digestive

hemorrhage will change greatly.

Portacaval shunt for patients with portal hypertension and ascites

Many researches have confirmed that blood renin activity of the patients with liver cirrhosis and portal hypertension, especially those with ascites^[25,65,66], increases obviously. Vice versa, increased renin activity can raise portal vein pressure (PVP) via initiating renin-angiotensin-aldosterone system and plays an important role in ascites due to cirrhosis.

The reasons why their ascites disappear after portacaval shunt are as follows. Portal vein pressure (PVP) decreases significantly. After portacaval shunt, returned blood volume and effective blood volume increase, and then renal blood flow relatively raises, making the juxtaglomerular cells secrete less renin. The blood level of glucagons reduced by portacaval shunt also inhibits the secretion of renin^[30,67], that may weaken the role of renin-angiotensin-aldosterone system and reduce ascites.

It is well known that hepatic coma usually occurs in patients after portacaval shunt operation. We should use a small diameter (6-8 mm) of anastomosis stoma of portacaval shunt as best as we can.

Emergency operation for upper gastroesophageal massive hemorrhage due to portal hypertension

The results in our study demonstrate that emergency operation rank non-negligible position in the treatment of portal hypertension.

Once the varices rupture, the chance of rehemorrhage is very high shortly after the first hemorrhage, and the mortality rate due to rehemorrhage is nearly twice that of the first hemorrhage. Thus, the indications of emergency surgery include massive hemorrhage which cannot be controlled within 12 h, recurrent massive upper gastrointestinal hemorrhage, and no obvious surgical contraindications.

Which surgical procedure should be adopted depends upon the condition of patients, liver function and findings in surgery. Generally, shunt operation can be performed in patients with relatively better condition and liver function, a great quantity of collateral vessels surrounding the spleen and higher portal pressure (>3.43 kPa or 35 cm H₂O). On the contrary, patients with poor body condition and liver function, a few collateral vessels, obvious atrophy of liver volume and portal vein pressure less than 3.43 kPa (35 cm H₂O), are fit for splenectomy and disconnection. Our data showed that only a slight difference in operative mortality between the two groups of patients was found, and that no operative mortality and encephalopathy occurred in the PAD group, suggesting that PAD can be performed when possible.

With regard to emergency operation, we should decide whether the spleen is resected according to the condition of patients. It was reported that splenic artery ligation in these patients achieves the same therapeutic effects as splenectomy^[68]. Therefore, when the patients undergo disconnecting combined with shunting (except for splenorenal shunt), their spleen may not be excised, and splenic artery may be ligated.

It was considered previously that the patients with poor liver function should not be operated because of high operative

mortality. In the shunting group in this article, three of seven patients with Child's grade C died of surgical treatment. In the disconnecting group in this article, none of the three patients with Child's grade C died of PAD operation, suggesting that surgical therapy should be taken and PAD is the proper selection for patients with poor liver function^[69].

In regard to the surgical therapy of patients with portal hypertension, a suitable surgical procedure can achieve satisfactory therapeutic results. Different patients at different stages in their disease may require different therapies. An emphasis of this management is the full evaluation of the underlying liver disease. Our data showed that PAD as a major operation accounted for 50.39% of all the operations in this article. If the diameters of anastomotic stoma of PSS are restricted, favorable therapeutic effects can be achieved. When PSS needs to be conducted, the diameter of the anastomotic stoma should be 6-8 mm and the most usual operative approach is side-to-side meso-caval shunt. Selective shunt is a relatively ideal surgical procedure, but technically it is difficult. Although disconnection plus shunt seems to be a better procedure of choice because it can lower the portal pressure and maintain the portal flow, it will give the patient a big strike and should be carefully selected according to the liver function of patients. Liver transplantation can treat portal hypertension and achieve better long-term results, but it should not be the first choice in treating portal hypertension in China. Doctors should evaluate liver function comprehensively of patients with hepatocellular carcinoma and portal hypertension and carefully select combined operation in order to prolong their survival time. The cirrhotic patients with ascites can be treated with PSS with a small diameter (6-8 mm) of the stoma anastomosis. If acute continuous gastroesophageal variceal bleeding in cirrhotic patients cannot be controlled by medical treatment, and if no operational contraindication exists, emergency surgical treatment should be given immediately.

Abstract

AIM: To study the portal hemodynamics and their relationship with the size of esophageal varices seen at endoscopy and to evaluate whether these Doppler ultrasound parameters might predict variceal bleeding in patients with liver cirrhosis and portal hypertension.

METHODS: One hundred and twenty cirrhotic patients with esophageal varices but without any previous bleeding were enrolled in the prospective study. During a 2-year observation period, 52 patients who had at least one episode of acute esophageal variceal hemorrhage constituted the bleeding group, and the remaining 68 patients without any previous hemorrhage constituted the non-bleeding group. All patients underwent endoscopy before or after color Doppler-ultrasonic examination, and images were interpreted independently by two endoscopists. The control group consisted of 30 healthy subjects, matched to the patient group in age and gender. Measurements of diameter, flow direction and flow velocity in the left gastric vein (LGV) and the portal vein (PV) were done in all patients and controls using color Doppler unit. After baseline measurements, 30 min after oral administration of 75 g glucose in 225 mL, changes of the diameter, flow velocity and direction in the PV and LGV were examined in 60 patients with esophageal varices and 15 healthy controls.

RESULTS: The PV and LGV were detected successfully in 115 (96%) and 105 (88%) of 120 cirrhotic patients, respectively, and in 27 (90%) and 21 (70%) of 30 healthy controls, respectively. Among the 120 cirrhotic patients, 37 had F1, 59 had F2, and 24 had F3 grade varices. Compared with the healthy controls, cirrhotic group had a significantly lower velocity in the PV, a significantly greater diameter of the PV and LGV, and a higher velocity in the LGV. In the cirrhotic group, no difference in portal flow velocity and

diameter were observed between patients with or without esophageal variceal bleeding (EVB). However, the diameter and blood flow velocity of the LGV were significantly higher for EVB (+) group compared with EVB (-) group ($P < 0.01$). Diameter of the LGV increased with enlarged size of varices. There were differences between F1 and F2, F1 and F3 varices, but no differences between F2 and F3 varices ($P = 0.125$). However, variceal bleeding was more frequent in patients with a diameter of LGV > 6 mm. The flow velocity in the LGV of healthy controls was 8.70 ± 1.91 cm/s ($n = 21$). In patients with liver cirrhosis, it was 10.3 ± 2.1 cm/s ($n = 12$) when the flow was hepatopetal and 13.5 ± 2.3 cm/s ($n = 87$) when it was hepatofugal. As the size of varices enlarged, hepatofugal flow velocity increased ($P < 0.01$) and was significantly different between patients with F1 and F2 varices and between patients with F2 and F3 varices. Variceal bleeding was more frequent in patients with a hepatofugal flow velocity > 15 cm/s (32 of 52 patients, 61.5%). Within the bleeding group, the mean LGV blood flow velocity was 16.6 ± 2.62 cm/s. No correlation was observed between the portal blood flow velocity and EVB. In all healthy controls, the flow direction in the LGV was hepatopetal, toward the PV. In patients with F1 varices, flow direction was hepatopetal in 10 patients, to-and-fro state in 3 patients, and hepatofugal in the remaining 18. The flow was hepatofugal in 91% patients with F2 and all F3 varices. Changes in diameter of the PV and LGV were not significant before and after ingestion of glucose (PV: 1.41 ± 1.5 cm before and 1.46 ± 1.6 cm after; LGV: 0.57 ± 1.7 cm before and 0.60 ± 1.5 cm after). Flow direction in the LGV was hepatopetal and to-and-fro in 16 patients and hepatofugal in 44 patients before ingestion of glucose. Flow direction changed to hepatofugal in 9 of 16 patients with hepatopetal and to-and-fro blood flow after ingestion of glucose. In 44 patients with hepatofugal blood flow in the LGV, a significant increase in hepatofugal flow velocity was observed in 38 of 44 patients (86%) with esophageal varices. There was a relationship between the percentage changes in flow velocity and the size of varices. Patients who responded excessively to food ingestion might have a high risk for bleeding. The changes of blood flow velocity in the LGV were greater than those in the PV (LGV: $28.3 \pm 26.1\%$, PV: $7.2 \pm 13.2\%$, $P < 0.01$), whereas no significant changes in the LGV occurred before and after ingestion of glucose in the control subjects.

CONCLUSION: Hemodynamics of the PV is unrelated to the degree of endoscopic abnormalities in patients with liver cirrhosis. The most important combinations are endoscopic findings followed by the LGV hemodynamics. Duplex-Doppler ultrasonography has no value in the identification of patients with cirrhosis at risk of variceal

bleeding. Hemodynamics of the LGV appears to be superior to those of the PV in predicting bleeding.

INTRODUCTION

Esophageal variceal bleeding (EVB) is a potentially deadly complication in patients with liver cirrhosis and portal hypertension^[1-4]. In patients with cirrhosis, the incidence of esophageal varices ranges from 35% to 80% and approximately a third of patients with esophageal varices experience variceal bleeding, and up to 70% of the survivors have one or more additional episodes of bleeding^[5]. The ultrasonographic examination is a simple, inexpensive, accurate, and noninvasive technique. It has been widely used to investigate the relationship between EVB and hemodynamics associated with portal hypertension and liver cirrhosis^[6-9]. However, no consistent results have been reported yet. In this study, we investigated the hemodynamic features of the portal vein (PV) and left gastric vein (LGV) before and after oral glucose (75 mg), and evaluated whether these Doppler ultrasound parameters might predict variceal bleeding in patients with liver cirrhosis.

MATERIALS AND METHODS

Materials

One hundred and twenty cirrhotic patients with esophageal varices without any previous bleeding (mean age 57.6 ± 6.8 years; 42 females and 78 males) were enrolled in the prospective study. During a 2-year observation period, 52 patients who had at least one episode of acute esophageal variceal hemorrhage constituted the bleeding group, and the remaining 68 patients without any previous hemorrhage constituted the non-bleeding group. The diagnosis of cirrhosis was based on clinical and imaging findings or pathologic findings.

The control group consisted of 30 healthy subjects, matched to the patient group in age (mean age 53.8 ± 6.7 years) and gender (10 females and 20 males). None of the controls had a history or clinical evidence of liver disease. All subjects provided written informed consent prior to participation.

Methods

All patients underwent endoscopy before or after color Doppler-ultrasonic examination, and images were interpreted independently by two endoscopists. Esophageal varices were graded according to the criteria of the Japanese Research Society for Portal Hypertension and endoscopic finding of PV hypertension^[10] in straight and small-calibered varices (F1), moderately enlarged beady varices (F2), or markedly enlarged nodular or tumor-shaped varices (F3).

Ultrasonographic examinations were performed using HDI5000 and HPsona4500 color Doppler units with a 3.75-MHz convex probe. All the patients and controls were kept fasting overnight prior to the procedure. They were examined in the supine position during quiet respiration. Measurements of diameter, flow direction and flow velocity in the LGV and PV were done in all patients and controls. The PV blood flow was measured at the crossing point with the hepatic artery or just distally to it. The LGV usually originates from the portal-splenic vein junction or its vicinity and runs to the esophagogastric junction. It was identified longitudinally by ultrasonography in a left oblique scan in the epigastrium. Blood flow measurement was made in the straight portion of the LGV, usually within 5 cm from its origin^[11,12]. The diameters of the LGV and PV were calculated from the inner surface within the vessel as seen in a longitudinal view. The sample volume was selected from 2 to 5 mm widths to include the width of the vessel. Flow direction was assessed according to the upward or downward position of the Doppler waveform over the baseline. The beam-vessel angle was less than 60° in every patient. Flow velocity was calculated as an average value of three consecutive measurements. The operator was blind to any information on the endoscopic findings of varices and the portal pressure.

After baseline measurements, 30 min after oral administration of 75 g glucose in 225 mL, changes of the diameter, flow velocity and direction in the PV and LGV were examined in 60 patients with esophageal varices and 15 healthy controls.

Statistical analysis

Student's *t*-test was used for single comparison, one-way analysis of variance for multiple comparisons. A *P*-value less than 0.05 was considered statistically significant. Statistical analyses were performed with the SPSS 10.0 software program.

RESULTS

The PV and LGV were detected successfully in 115 (96%) and 105 (88%) of 120 cirrhotic patients, respectively, and in 27 (90%) and 21 (70%) of 30 healthy volunteers, respectively. Among the 120 cirrhotic patients, 37 had F1, 59 had F2, and 24 had F3 grade varices.

Table 1 summarizes the duplex sonography findings. Compared with the healthy controls, cirrhotic group had a significantly lower velocity in the PV, a significantly greater diameter of the PV and LGV, a higher velocity in the LGV. In the cirrhotic group, no difference in portal flow velocity and diameter was observed between patients with or without EVB. However, the diameter and blood flow velocity of the LGV were significantly higher in EVB (+) group compared with EVB (-) group ($P < 0.01$).

Diameter of the LGV increased with enlarged size of varices. In patients with F1, F2, and F3 varices, the diameter was 0.48 ± 0.16 , 0.62 ± 0.23 , and 0.72 ± 0.24 cm, respectively. There were differences between F1 and F2, F1 and F3 varices, but no differences between F2 and F3 varices ($P = 0.125$). However, variceal bleeding was more frequent in patients with a diameter of the LGV > 6 mm, suggesting that the diameter of LGV had a relationship with the size of esophageal varices, but had no value in the identification of patients with cirrhosis at risk for EVB (Table 2).

Figure 1 Relationship between hemodynamics of the LGV and the size of esophageal varices. **A:** Hepatopetal blood flow in the LGV; **B:** hepatofugal blood

flow in the LGV; **C:** hepatofugal blood flow in the LGV.

Table 1 Hemodynamics in cirrhotic and healthy groups (mean±SD)

Group	Diameter (cm)		Velocity (cm/s)	
	PV	LGV	PV	LGV
Controls	1.12±0.11	0.40±0.18	15.3±1.41	8.70±1.91
EVB (-)	1.48±0.15 ^b	0.52±0.21 ^{a,b}	13.7±1.54 ^b	14.8±1.11 ^{a,b}
EVB (+)	1.56±0.28 ^b	0.71±0.34 ^b	12.8±1.18 ^b	16.6±2.62 ^b

EVB, esophageal variceal bleeding; PV, portal vein; LGV, left gastric vein. ^a $P<0.05$ compared with EVB (+); ^b $P<0.01$ compared with the healthy controls.

Table 2 Hemodynamics in relation to the development of esophageal varices in cirrhotic group (mean±SD)

Varices	Diameter (cm)		Velocity (cm/s)	
	PV	LGV	PV	LGV
F1	1.47±0.19	0.48±0.16	14.2±2.15	7.80±2.15
F2	1.51±0.18	0.62±0.23	13.1±1.81	11.5±2.03
F3	1.55±0.21	0.72±0.24	12.0±1.72	16.0±3.19

The flow velocity in LGV, in healthy controls, was 8.70 ± 1.91 cm/s ($n = 21$). In patients with liver cirrhosis, it was 10.3 ± 2.1 cm/s ($n = 12$) when the flow was hepatopetal and 13.5 ± 2.3 cm/s ($n = 87$) when the flow was hepatofugal (Figure 1). As the size of varices enlarged, hepatofugal flow velocity increased ($P<0.01$) and was significantly different between patients with F1 and F2 varices, and between patients with F2 and F3 varices. Variceal bleeding was more frequent in patients with a hepatofugal flow velocity >15 cm/s (32 of 52 patients, 61.5%). Within the bleeding group, the mean LGV blood flow velocity was 16.6 ± 2.62 cm/s. No correlation was observed between the portal blood flow velocity and EVB. Hepatofugal flow velocity of the LGV in relation to the development of esophageal varices is shown in Figure 2.

In all healthy controls, the flow direction in the LGV was hepatopetal, toward the PV (Figure 3). In patients with

Figure 2 Hepatofugal flow velocity in LGV in relation to the size of esophageal varices.

Table 3 Flow direction in the LGV in relation to the development of esophageal varices in cirrhotic group, n (%)

Varices	n	Flow direction		
		Hepatopetal	Hepatofugal	To-and-fro
F1	31	10 (32)	18 (58)	3 (10)
F2	53	2 (4)	48 (91)	3 (5)
F3	21	0	21 (100)	0
Sum	105	12 (11)	87 (83)	6 (6)

F1 varices, flow direction was hepatopetal in 10 patients, to-and-fro state in 3 patients, and hepatofugal in the remaining 18. The flow direction was hepatofugal in 91% patients with F2 and all F3 varices (Table 3).

Changes in diameter of the PV and LGV were not significant before and after ingestion of glucose (PV: 1.41 ± 1.5 cm before and 1.46 ± 1.6 cm after; LGV: 0.57 ± 1.7 cm before and 0.60 ± 1.5 cm after). Flow direction in the LGV was hepatopetal and to-and-fro in 16 patients and hepatofugal in 44 patients before ingestion of glucose. Flow direction changed to hepatofugal in 9 of 16 patients with hepatopetal and to-and-fro blood flow after ingestion of glucose (Figure 4). In 44 patients with hepatofugal blood flow in the LGV, a

Figure 3 Hepatopetal blood flow in the LGV of normal subjects.

significant increase in hepatofugal flow velocity was observed in 38 of 44 patients (86%) with esophageal varices (Figure 5). The changes of blood flow velocity were greater in the LGV than in the PV (LGV: $28.3 \pm 26.1\%$, PV: $7.2 \pm 13.2\%$, $P < 0.01$). The degree of changes in percentages in the LGV and PV of patients with hepatofugal flow after ingestion of glucose is shown in Figure 6. There was a relationship between the percentage changes in flow velocity and the size of varices. Patients who responded excessively to food ingestion might have a high risk for bleeding, whereas no significant changes occurred in the

LGV before and after ingestion of glucose in the control subjects.

DISCUSSION

EVB is a potentially deadly complication in patients with liver cirrhosis and portal hypertension. Once esophageal varices occur, the risk for EVB ranges from 10% to 60%, and the mortality rate related to EVB ranges from 20% to 60%^[1-4]. Since esophageal varices-induced hemorrhage in patients with cirrhosis can be fatal, these patients must be routinely classified according to their risk status and appropriate prophylactic measures should be taken to prevent hemorrhage. The size of esophageal varices is one of the strongest risk factors for variceal rupture^[1-5]. Differences in connecting venous structures and their underlying hemodynamics may be predisposing factors in the progression of esophageal varices. The ultrasonographic examination is a simple, inexpensive, accurate, and noninvasive technique to evaluate the hemodynamics under physiological conditions and has been widely used experimentally and clinically, but there is a continuing debate concerning the hemodynamics of the PV system in relation to the development of esophageal varices^[6-9].

The notable findings of this study are related to the hemodynamics of the PV. Compared with the healthy controls, cirrhotic group had a significantly lower velocity in the PV and a significantly greater diameter of the PV.

Figure 4 Change in flow direction in the LGV. **A:** Hepatopetal blood flow in the LGV before ingestion of glucose; **B:** changes of flow direction from hepatopetal

to hepatofugal after ingestion of glucose.

Figure 5 Doppler sonograms in the LGV with hepatofugal blood flow before (A) and

after (B) ingestion of glucose in a patient with a significant response to glucose.

Figure 6 Changes in blood flow in the PV and LGV of patients with hepatofugal blood flow before and after ingestion of glucose.

These findings indicate that the portal venous system in cirrhotic patients with portal hypertension is the site of passive congestion and increased blood flow. During the period of 2 years, 52 (43%) patients had at least one episode of acute esophageal variceal hemorrhage. The portal hemodynamic features had no differences between the EVB (+) and EVB (-) subgroups. It is generally thought that elevated vascular resistance and increased portal blood inflow are the two principal mechanisms involved in the development of portal hypertension secondary to cirrhosis^[13]. The former is an initiating factor, while the latter plays an important role in maintaining a chronic portal hypertensive state. Therefore, portal flow velocity is unrelated to the degree of endoscopic abnormalities in patients with liver cirrhosis and has no value in the identification of patients with cirrhosis at risk for EVB. Therefore, passive congestion of portal blood has no direct relationship with EVB.

In cirrhotic patients, because of portal outflow obstruction (i.e., elevated intrahepatic portal vascular resistance), increased blood flow in the splenic vein cannot enter the liver via the PV, and a considerable percentage of splenic vein flow is forced to bypass the liver. One of the most important shunting routes is the LGV, which may normally arise from the PV and splenic vein. When increased flow in the splenic vein is prominent, the diversion of a large quantity of portal flow via the LGV would result in more severe esophageal varices and might trigger the occurrence of EVB^[14,15].

This study showed a close relationship between the velocity of hepatofugal flow in the LGV and esophageal variceal size. EVB was more frequent in patients with a hepatofugal flow velocity >15 cm/s (32 of 52 patients, 61.5%). Preservation of hepatopetal flow in the LGV in patients with portal hypertension may be associated with a low risk for variceal hemorrhage. Because the LGV is the major source of blood supply to esophageal varices, velocity of hepatofugal flow may be the more important determinant in the development of varices. These results are similar to those of previous studies^[16-18]. Therefore, detection of a high-flow velocity in the LGV may be suggestive of hemodynamically active esophageal varices that carry a high risk for bleeding.

The diameter of the LGV increased as the size of varices enlarged, there were differences between patients with F1 and F2, F1 and F3 varices, but no differences between patients with F2 and F3 varices, suggesting that diameter

of the LGV has a relationship with the size of esophageal varices, but has no value in the identification of patients with cirrhosis at risk for EVB. The diameter of the LGV may measure up to 6 mm on sonograms of normal subjects. However, variceal bleeding is more frequent in patients with a diameter of the LGV >6 mm.

It is generally thought that flow direction in the LGV changes from hepatopetal to hepatofugal during variceal development^[17,18]. However, in our study the flow direction in the LGV was still hepatopetal and LGV did not seem to contribute to the formation of esophageal varices in 32% patients with F1 varices. Blood flow in the stomach wall from the left gastric artery also participates in variceal blood flow^[19-21]. These blood flows in the gastric wall alone possibly contribute to the formation of esophageal varices in its early stage, where LGV flow does not significantly constitute to the variceal flow. In advanced portal hypertension, esophageal varices become large as the LGV flow changes to hepatofugal and drains into the varices. Whereas a to-and-fro flow state is generally considered to be present in the LGV during the period when the flow becomes reversed^[19], which was observed in six patients in the present study. Other studies reported that there is a relationship between esophageal varices and venous collaterals outside the esophageal wall in patients with portal hypertension. Collaterals are divided into periesophageal collateral veins and paraesophageal collateral veins. Periesophageal collateral veins play a more important role in the formation of esophageal varices than paraesophageal collateral veins in the early stage of esophageal varices^[21-24].

Food intake usually increases portal blood flow. In this study, we gave a dose of glucose and an increase of hepatofugal blood flow velocity was observed in the LGV and PV. Also the changes of blood flow velocity were greater in the LGV than in the PV. Out of 44 patients with hepatofugal blood flow in the LGV, a significant increase in hepatofugal flow velocity was observed in 38 patients (86%) with esophageal varices. There was a relationship between the percentage changes in flow velocity and the size of varices. Patients who responded excessively to food ingestion might have a high risk for bleeding. High flow resistance in a portal hypertensive liver may exaggerate the increase in intestinal inflow into the LGV, henceforth into the esophageal varices under such conditions^[17], because blood flow in the LGV tends to increase readily when the portal blood flow increases or portal flow resistance is elevated. In patients with portal hypertension, an increase in variceal blood flow may contribute to bleeding from esophageal varices. The analysis of these factors influencing blood flow in esophageal varices seems to be important to understand the pathophysiology of variceal bleeding and helps us to estimate the risk for variceal hemorrhage^[25-28].

In conclusion, PV is unrelated to the degree of endoscopic abnormalities in patients with liver cirrhosis and its measurement by Duplex-Doppler ultrasonography has no value in the identification of patients with cirrhosis at risk for variceal bleeding. Hemodynamics of the LGV appears to be superior to those of the PV in predicting bleeding, allowing physicians to optimize therapy^[29]. Therefore, the likelihood index, adopted to determine the best parameters related to variceal

bleeding showed that the most important combinations are endoscopic findings followed by the LGV hemodynamics.

Abstract

AIM: In the inflammatory state, intercellular adhesion molecule-1 (ICAM-1) and vascular cellular adhesion molecule-1 (VCAM-1) play a key role in promoting migration of immunological cells from the circulation to target site. Aim of our study was to investigate soluble forms of these molecules in patients with virus-related chronic liver diseases, to assess their behavior in different pathologies and correlation with severity of liver damage.

METHODS: Circulating ICAM-1 and VCAM-1 were assayed by EIA commercial kits (R&D System Co., Abington, UK) in 23 patients with chronic active hepatitis (CH), 50 subjects affected by liver cirrhosis (LC) and 15 healthy controls comparable for sex and age. In patients, serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were also detected by autoanalyzer.

RESULTS: LC patients had significantly higher ICAM-1 values than CH patients (38.56 ± 7.4 ng/mL vs 20.89 ± 6.42 ng/mL; $P < 0.001$) and these ones had significantly higher values than controls (12.92 ± 1.08 ng/mL; $P < 0.001$). In CH group, ICAM-1 levels were significantly related to inflammatory activity ($P = 0.041$) and ALT values ($r = 0.77$; $P < 0.05$). VCAM-1 values were significantly increased only in LC patients ($P < 0.001$) and related to severity of liver impairment.

CONCLUSION: These findings suggest that the determination of serum ICAM-1 can be considered as an additional useful marker of hepatocellular necrosis and inflammatory activity in chronic hepatitis, while serum VCAM-1 is an indicator of liver fibrogenesis and severity of disease in cirrhosis.

INTRODUCTION

During inflammation, cytokines enhance the presentation on cell endothelial surface of adhesion molecules, which interact with corresponding leukocyte receptors and promote their adhesion and migration from the circulation to target site^[1].

Intercellular adhesion molecule-1 (ICAM-1) and vascular cellular adhesion molecule-1 (VCAM-1), are single-chain membrane-bound glycoproteins, belonging to the immunoglobulin supergene family. They are expressed on endothelial and other cells and play a crucial role in the trans-migration of inflammatory cells^[2,3].

Cellular expression is associated to the release of soluble forms (sICAM-1 and sVCAM-1) which are detectable in the peripheral blood^[4,5].

Although the biological function of these soluble forms are not clearly established yet, their increased serum concentration reflects cellular overexpression in inflammatory state^[6].

In patients with inflammatory diseases of the liver, increased sICAM-1 and sVCAM-1 values have been reported but their clinical usefulness is still controversial^[7-11].

Aim of the study was to investigate circulating ICAM-1 and VCAM-1 in patients affected by virus-related liver diseases, namely chronic active hepatitis (CH) and liver cirrhosis (LC), compared to healthy control subjects, to verify whether there are differences between these two molecules and to evaluate a possible correlation with severity of liver damage as clinically and histologically assessed.

MATERIALS AND METHODS

We examined three groups of subjects: 23 neodiagnosed and untreated patients with CH, 50 patients with LC and 15 control subjects.

All groups were comparable for sex and age.

Diagnosis, in patients, was based on clinical (medical history, physical examination), instrumental (ultrasonography,

endoscopy) and laboratory (liver function tests) data. In all patients with chronic hepatitis and in 24 cirrhotic subjects, diagnosis was confirmed by liver biopsy (in the remaining cirrhotic subjects the procedure was not necessary, as diagnosis was clinically evident).

Patients with evidence of other chronic or acute infective processes (altered white blood cells count, temperature, urinary tract infection, spontaneous bacterial peritonitis, airway infections) were excluded as well as those with suspected hepatocellular carcinoma (on the basis of ultrasonography, alpha-fetoprotein and carcinoembryonic antigen levels performed during the screening).

In 6 out of 23 CH patients, the etiological agent was HBV while in the remaining 17 hepatitis C virus (HCV). Of the 50 LC subjects, 19 were infected by HBV, and 31 by HCV.

All sections from liver biopsies were examined by a histopathologist who was unaware of the clinical details. With regard to histological findings, all patients with chronic hepatitis had none or mild fibrosis (staging score 0-1); according to grading score, they were classified into two groups: (a) 12 subjects with minimal or mild inflammatory activity (score 1-8); (b) 11 subjects with moderate or severe inflammatory activity (score 9-18).

As liver biopsy was not performed in all cirrhotics, we could not grade severity of histological picture in this group. For this reason we chose the Child-Pugh's classification^[12] to state the seriousness of liver impairment.

Twenty-three cirrhotic patients were in class B and 27 belonged to class C.

Informed consent was obtained for the whole study series and the study confirmed to Helsinki Declaration.

A blood sample was withdrawn, fasting in the morning, from all subjects. Sample was centrifugated and plasma was stored at -20 °C until determination.

Circulating ICAM-1 and VCAM-1 were assayed by EIA commercial kit (R&D System Co., Abington, UK), according to procedures described by the manufacturer and concentrations expressed as nanogram per milliliter. The sensitivity of sVCAM-1 assay was less than 2.0 ng/mL. Intra- and inter-assay variability averaged 4.3% and 8.5%, respectively. For sICAM-1 assay, the sensitivity was <0.35 ng/mL. Intra- and inter-assay variability averaged 4.0% and 7.0%, respectively.

Figure 1 Mean sICAM-1 values in controls, patients affected by chronic hepatitis (CH) and cirrhotic subjects (LC).

In patients, alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were also detected by autoanalyzer.

Analysis of variance and Kruskal-Wallis test were used to compare mean ± SD between various groups. Relationship between continuous variables was investigated by correlation test. Statistical significance was set at $P < 0.05$.

RESULTS

Mean ± SD. ICAM-1 was 12.92 ± 1.08 ng/mL in controls, 20.89 ± 6.42 ng/mL in CH patients and 38.56 ± 7.4 ng/mL in LC patients.

Mean ± SD. VCAM-1 was 15.96 ± 4.02 ng/mL in controls, 17.96 ± 8.43 ng/mL in CH patients and 42.29 ± 5.76 ng/mL in LC patients, respectively.

Mean ± SD. AST was 73.9 ± 9 U/L in CH patients and 62.7 ± 8.5 U/L in LC subjects.

ALT values averaged 84 ± 12 U/L in CH subjects and 58 ± 7.2 U/L in cirrhotic patients.

Statistical analysis showed that LC patients had significantly higher ICAM-1 values than CH patients ($P < 0.001$) and these ones had significantly higher values ($P < 0.001$) than controls (Figure 1). Among CH patients, a significant difference in serum was found between ICAM-1 with score 1-8 and those with score 9-18 (18.1 ± 4.9 ng/mL *vs* 23.5 ± 6.9 ng/mL, respectively; $P = 0.041$).

VCAM-1 values were significantly higher in LC patients than in CH subjects ($P < 0.001$) and controls ($P = 0.000$). There was no significant difference ($P > 0.05$) in VCAM-1 values between controls and CH patients and among these ones with regard to grading score (17.41 ± 8.3 ng/mL *vs* 18.13 ± 8.2 ng/mL; $P > 0.05$).

With regard to Child-Pugh classification, in cirrhotic patients there was no difference in ICAM-1 levels ($P > 0.05$) between class B (37.7 ± 6.1 ng/mL) and class C (40.2 ± 4.3 ng/mL) subjects; circulating VCAM-1 was significantly higher ($P = 0.005$) in class C (43.6 ± 4.1 ng/mL) than in class B (40.5 ± 3.1 ng/mL) patients.

Correlation test showed a significant relationship ($r = 0.77$; $P < 0.001$) between ICAM-1 and ALT values in CH patients (Figure 2). No significant correlation was found between ICAM-1 and AST values in CH patients, as well as between VCAM-1 concentration and ALT and AST values both in CH and in LC patients.

Figure 2 Relationship between ALT and sICAM-1 values in patients with chronic hepatitis.

Main characteristics and findings of our investigated patients are summarized in Table 1.

Table 1 Main characteristics and results of our investigated subjects

	Controls, <i>n</i> = 15	CH patients, <i>n</i> = 23	LC patients, <i>n</i> = 50

DISCUSSION

Increased serum ICAM-1 and VCAM-1 have been previously described in patients with liver diseases, but such increase does not seem to be able to distinguish among various etiologies and its clinical significance is still controversial.

Some authors reported that circulating levels of these molecules are related to degree of inflammatory activity and to histological score, suggesting a putative role in monitoring the follow-up^[13,14]. Others have declared that their measurement adds little to the information provided by traditional biochemistry^[15].

Recently, it has been reported that treatment with alpha-interferon, in chronic hepatitis, is capable to decrease circulating ICAM-1 in responder but not in non-responder patients, while VCAM-1 does not differentiate between these two groups^[11,16,17].

Our results show that, in patients affected by chronic hepatitis, serum ICAM-1 is increased and mean values in subjects with moderate or severe inflammation (score 9–18) are significantly higher ($P<0.05$) than in those with minimal or mild inflammation (score 1–8).

Conversely, in this group, serum VCAM-1 was similar to controls and no difference was observed with regard to inflammatory activity.

Moreover, we found a significant positive correlation between ICAM-1 and ALT values.

Then, our findings appear in agreement with literature data and suggest that ICAM-1, but not VCAM-1, can be considered, in subjects with chronic hepatitis, a useful marker to assess severity of inflammation and hepatocellular necrosis.

Nevertheless, the relationship between ICAM-1 and ALT values does not implicate a direct involvement of this adhesion molecule in physiopathology of hepatocellular damage but it could only reflect the activation of undergoing immunological mechanisms.

Elevated serum VCAM-1 in chronic hepatitis have been reported by some authors^[16,18], but we found enhanced levels only in cirrhosis, when fibrosis progresses to an irreversible state.

This discordance is likely due to the selection of patients.

Notably, our CH patients had none or mild fibrosis (staging score 0–1). Therefore, we cannot exclude that subjects with chronic hepatitis and more severe fibrosis have increased sVCAM-1.

On the other hand, in cirrhotic patients, both circulating ICAM-1 and VCAM-1 were higher than in CH patients and controls. However, in this group, neither ICAM-1 nor VCAM-1 values correlated to AST and ALT levels.

In advanced phases of evolving liver diseases, the formation of fibrous tissue, stimulated by chronic inflammation, can be predominant on cellular necrosis, leading to structural alterations of hepatic architecture and development of cirrhosis.

In fact, our cirrhotic patients had lower transaminases values than subjects affected by chronic hepatitis.

In these conditions, increased ICAM-1 likely reflects the persistence of inflammation rather than severity of cellular necrosis. This could explain the lack of correlation between serum ICAM-1 and transaminases values in cirrhotic patients.

Interestingly, in our experience, no overlapping resulted in VCAM-1 values between LC and CH patients because the lowest value in LC group was greater than highest value in CH group (Figure 3). Furthermore, mean serum ICAM-1 was similar in classes B and C cirrhotic subjects while in the last ones mean VCAM-1 value was higher than in class B patients (43.6 ± 4.1 ng/mL *vs* 40.5 ± 3.1 ng/mL; $P = 0.005$).

Figure 3 Scatter plot of sVCAM-1 values in controls, chronic hepatitis and liver cirrhosis.

Therefore, cirrhotic subjects with disease in a more advanced phase, belonging to Child-Pugh class C, had a greater VCAM-1 increase.

These findings, altogether considered, suggest the association of VCAM-1 levels to amount of liver fibrosis rather than to severity of inflammation and cellular necrosis.

However, the pathogenic link between VCAM-1 and liver fibrosis remains unclear.

In the liver, the formation of fibrous tissue depends upon the balance between matrix synthesis and its removal. Extra-cellular matrix production and degradation is a complex process involving cells, cytokines and proteinases. The interaction between membrane receptors of stellate cells (also called Ito cells) and proteins, included in the

extra-cellular matrix, is modulated by adhesion molecules. Such interaction determines its effects through cytoplasmic signaling pathways which can influence collagen synthesis and metalloprotease activity, resulting in a raised production and/or a reduced removal of hepatic connective tissue.

Thus, a role in this process can be supposed even though, to date, the expression of VCAM-1 on stellate cell surface has not been demonstrated.

Alternatively, enhanced VCAM-1 values could be the consequence of persistent activation of vascular endothelial cells which are able to produce connective tissue growth factor, a highly profibrogenic molecule involved in several fibrotic disorders, including those of the liver^[19].

Activated endothelial cells may also contribute, by expressing *de novo* integrins in the space of Disse, to the formation of a pathological basement membrane in the capillarized sinusoids of cirrhotic liver^[20].

Even though further investigations are required, from a clinical overview, the serial determination of serum VCAM-1 could be useful to weigh intensity of fibrogenesis and to identify the switch from prevalence of necro-inflammation to prevalence of sclerofibrotic processes, marked by an accentuated increase of values.

In conclusion, our results confirm that, in patients with chronic virus hepatitis, serum ICAM-1 is increased and related to severity of necro-inflammation as assessed by biochemistry and histological score. In cirrhotic patients, ICAM-1 is also augmented but it is not related to transaminase values. Circulating VCAM-1 is increased in cirrhosis and appears related to seriousness of liver impairment.

These findings suggest that serum ICAM-1 is an additional useful marker of cytonecrotic activity in chronic hepatitis. Serum VCAM-1 could be instead considered as a noninvasive indicator of liver fibrosis and severity of disease in cirrhosis.

Abstract

AIM: To compare the causes and clinical outcome of patients with acute upper gastrointestinal bleeding (AUGB) and a history of gastric surgery to those with AUGB but without a history of gastric surgery in the past.

METHODS: The causes and clinical outcome were compared between 105 patients with AUGB and a history of gastric surgery, and 608 patients with AUGB but without a history of gastric surgery.

RESULTS: Patients who underwent gastric surgery in the past were older (mean age: 68.1 ± 11.7 years vs 62.8 ± 17.8 years, $P = 0.001$), and the most common cause of bleeding was marginal ulcer in 63 patients (60%). No identifiable source of bleeding could be found in 22 patients (20.9%) compared to 42/608 (6.9%) in patients without a history of gastric surgery ($P = 0.003$). Endoscopic hemostasis was permanently successful in 26 out of 35 patients (74.3%) with peptic ulcers and active bleeding or non-bleeding visible vessel. Nine patients (8.6%) were operated due to continuing or recurrent bleeding, compared to 23/608 (3.8%) in the group of patients without gastric surgery in the past ($P = 0.028$). Especially in peptic ulcer bleeding patients, emergency surgery was more common in the group of patients with gastric surgery in the past [9/73 (12.3%) vs 19/360 (5.3%), $P = 0.025$]. Moreover surgically treated patients in the past required more blood transfusion (3.3 ± 4.0 vs 1.5 ± 1.7 , $P = 0.0001$) and longer hospitalization time (8.6 ± 4.0 vs 6.9 ± 4.9 d, $P = 0.001$) than patients without a history of gastric surgery. Mortality was not different between the two groups [4/105 (3.8%) vs 19/608 (3.1%)].

CONCLUSION: Upper gastrointestinal bleeding seems to be more severe in surgically treated patients than in non-operated patients.

INTRODUCTION

Surgical management of peptic ulcer diseases has steadily decreased over the past 20 years. Several therapeutic improvements, such as the widespread use of acid suppressive drugs and the eradication of *Helicobacter pylori*, are responsible for this decrease^[1-3]. Upper gastrointestinal bleeding, however, remains a common emergency situation presenting a high rate of morbidity and mortality^[4-6]. This, despite the introduction and wide application of endoscopic hemostasis, has significantly reduced the need for emergency surgical hemostasis and improved the mortality and morbidity in these patients^[7-11]. High or subtotal gastrectomy and antrectomy supplemented with vagotomy have been successfully applied in the past to the treatment of bleeding peptic ulcer. Anastomotic ulcer is a post-gastrectomy complication and bleeding of such an ulcer is a particularly frightening complication. Several factors mainly related to surgical inadequacies or uncommonly to the presence of ectopic hormone-producing tumors, are associated with the formation of an anastomotic ulcer after gastric surgery^[12,13]. Few reports are available on the role of endoscopic hemostasis in active ulcer bleeding.

The purpose of this study was to compare the outcome between patients with a history of gastric surgery and active bleeding anastomotic ulcers and those with active upper gastrointestinal bleeding but without gastric surgery in the past.

MATERIALS AND METHODS

During the last 5 years, 105 patients with a history of gastric surgery and active upper gastrointestinal bleeding (AUGB) were admitted to our hospital. The outcome of this group of patients was compared to 608 patients with AUGB but without a history of gastric surgery. No patient was excluded because of age or concurrent diseases. Patients presented with hematemesis and/or melena, as well other clinical or laboratory evidence of acute blood loss, and those with iron deficiency anemia and history of gastric surgery who reported melena and/or hematemesis were included in this

study. All patients underwent emergency endoscopy either during the first 24 h after admission or immediately after resuscitation in case of massive bleeding. Three senior gastroenterologists performed all endoscopic examinations. Pre-medication included local pharyngeal anesthesia with xylocaine spray. Stigmata of active or recent bleeding were classified according to the Forrest classification^[14]: Forrest Ia: active spurting bleeding; Ib: active oozing bleeding; IIa: non-bleeding visible vessel (NBVV); IIb: adherent clot; and IIc: spots. A NBVV was defined as a raised, red spot resistant to washing. Endoscopic injection hemostasis with adrenaline diluted at 1:10 000 in 0.9% saline (A/S) and/or end or clips were performed on all patients with active spurting or oozing bleeding or NBVV.

Endoscopic A/S hemostatic injections were performed via the working channel of an endoscope using a disposable injector. The injections were administered into the ulcer base in a circumferential fashion as close as possible to the visible vessel. As a routine, a total of 15 mL was injected, approaching to 30 mL was injected when control of bleeding was not easily achieved. Marginal ulcer was defined as the recurrent ulceration at or around the gastro-jejunal stoma or within the afferent or efferent loop.

After endoscopic hemostasis, patients were carefully observed and managed by the same medical team of gastroenterologists and surgeons. Blood pressure and pulse rate were checked before endoscopy, during and after injection therapy. After hemostasis, all patients with peptic ulcer bleeding routinely received intravenously the standard doses of proton pump inhibitors (omeprazole 40 mg/d). Blood transfusion was given, if Hb was less than 100 g/L and if there were signs of ongoing bleeding. After early stabilization of the patients, recurrence of bleeding was considered when vomiting of fresh blood and signs of massive melena were found in conjunction with either shock or decrease in hemoglobin concentration by at least 20 g/L over a 24-h period. In case of re-bleeding, endoscopy was repeated and in most cases, a second endoscopic hemostasis either by A/S injection, or by placement of endoclips was carried out. Although the criteria for emergency surgical hemostasis were individualized, in most cases patients received emergency surgery when bleeding was not controlled after endoscopic hemostasis and transfusion of more than 5 U of blood over a 24-h period or 12 U over 48 h, and when intra-hospital re-bleeding occurred while on sufficient medical treatment with hemodynamic evidence of shock (systolic pressure <100 mmHg, pulse rate >100/min).

After discharge, all patients were routinely followed up. A second endoscopy with biopsies was performed after 4-6 wk and if the ulcer was completely healed, a third endoscopy was performed after 1 year.

The patient's age, sex, type of gastric operation, previous consumption of non-steroidal anti-inflammatory drugs (NSAIDs), clinical presentation, initial hemodynamic status, hemoglobin at admission, endoscopic findings, number of blood transfusions, days of hospital stay and clinical outcome were also analyzed.

Differences between groups were tested for significance. Continuous variables were expressed as mean±SD and compared using Student's *t* test. Categorical variables were

expressed as percentages and compared using χ^2 test. A *P* value less than 0.05 was considered statistically significant. Statistical analysis was performed using SPSS version 10.0 for Windows.

RESULTS

A total of 105 patients (96 men and 9 women, mean age 68.1±11.7 years) with a history of gastric surgery were admitted to our hospital due to AUGB. The investigated parameters in this patient group were compared to those in the well-matching group of patients with AUGB but without gastric surgery in the past and the cause of bleeding was due to a benign peptic ulcer. Table 1 provides an overview of the clinical characteristics and emergency endoscopic findings in both patient groups. A marginal ulcer with endoscopic stigmata of hemorrhage was identified in 63 patients (60%) in the first group. Endoscopy failed to show any source of bleeding in 22 patients (21%) and none of these patients received a new surgical intervention for severe bleeding. Spurting bleeding was identified in 10 (13.7%), oozing bleeding in 7 (9.6%) and NBVV in 18 (24.6%) patients (Table 2). Endoscopic hemostasis was permanently successful in 26 out of 35 (74.3%) patients. Twelve patients underwent a second endoscopic hemostasis with injection of A/S and/or endoclips because of re-bleeding while four patients with re-bleeding did not undergo second endoscopic injection therapy or any other hemostatic treatment. Emergency surgical hemostasis for persistent or recurrent bleeding was required in 9 out of 105 patients (8.6%) and in 9 out of 73 patients (12.3%) with peptic ulcer bleeding (Table 3). Four patients died (3.8%), two of them died after surgery with a post-surgical mortality of 22.9%. Causes of death were respiratory failure (*n* = 2, one of them preoperatively), cerebral ischemia (*n* = 1, the patient died post-operatively) and hemorrhagic shock (*n* = 1, the patient died pre-operatively).

Table 1 Characteristics of patients recruited in the study

When the results of patients with a history of gastric surgery were compared with those patients who had no

gastric surgery, there was a statistically significant difference in age, consumption of NSAIDs, number of blood transfusions, length of hospital stay, percentage of patients with spurting bleeding and need for surgical intervention (Tables 1-3). In the control group, endoscopy failed to show any source of bleeding in 42 (6.9%) patients ($P = 0.0003$). Similarly in the control group, the re-bleeding/continued bleeding rate and the mortality rate did not differ statistically from the patients who had gastric surgery in the past. Nineteen patients in the control group (3.1%) died after surgery.

DISCUSSION

Gastric surgery has been successfully used in the treatment of peptic ulcer disease; however, the potential complications after gastric surgery are numerous^[15,16]. Ulcer recurrence rate after surgery for peptic ulcer diseases varies according to the nature of the procedure, pathophysiology of the underlying disease, and operator's skill. One of the major complications is bleeding from marginal ulcers^[17,18]. Recurrent ulcers after Billroth II gastrectomy may result in retained antral mucosa in the closed duodenal stump, which can be a source of hypergastrinemia. In patients after vagotomy and pyloroplasty, a recurrent ulcer may be due to an incomplete vagotomy^[19-25].

In this study, recurrent ulcers were found in 70% of patients with AUGB after gastric surgery. Marginal ulcer was detected in 63% of patients, while recurrent duodenal

ulcer was found in 8.6%. All patients with recurrent duodenal ulcers underwent pyloroplasty and elective vagotomy. Two patients in the group had Dieulafoy's ulcer. The majority were male and elderly patients. It is well known that patients after partial gastrectomy are at high risk of developing adenocarcinoma^[26,27]. In our study, three patients (2.9%) after Billroth II gastrectomy were proved to have adenocarcinoma in the anastomotic area. In patients who had gastric surgery in the past, diagnostic failure at emergency endoscopy for AUGB occurred in 22 patients (21%), and 18 of them underwent a new endoscopy check after 24 h, though it failed to detect any lesions. These patients were admitted because of iron deficiency anemia and reported melena and/or hematemesis. None needed emergency surgical intervention. An explanation for this high incidence of missed lesions at the emergency endoscopy stage is that the presumed lesions are superficial and they heal quickly. Anemia is a sequel of gastrectomy. AUGB was not found in 42 (6.9%) of the control group of patients. According to Cheng *et al.*^[27], peptic ulcers including marginal ulcer and Dieulafoy's lesions are the major missed diagnosis during AUGB. Limited endoscopic vision due to excessive blood and clots is a well-known problem which results in inadequate examination during AUGB.

When the two groups of patients were compared, the upper gastrointestinal bleeding seemed to be more severe in patients with a history of gastric surgery. The need for new surgical intervention was greater in this group. This may be due to the differences in blood supply in the anastomotic area. The marginal ulcer receives blood from the jejunal branches of the superior mesenteric artery or gastric branches of the celiac artery^[28]. In this study, the presence of a spurting artery was noted more in patients who had gastric surgery in the past. Similarly, the successful rate of endoscopic intervention was higher in the control group. In a previous study, we also found that an anastomotic ulcer is a factor associated with failure of endoscopic injection hemostasis in bleeding peptic ulcers^[29]. A new surgical intervention was required in 8.6% of patients after gastric surgery, compared to 3.8% of patients in the control group who underwent surgical hemostasis. Seven of the nine operated ulcers in the gastric surgery group were marginal ulcers and located mostly at the saddle area of the jejunal loop. The angulation phenomenon characterizing the saddle area makes it a weak point during food impulsion. Furthermore, it also receives the least supply of blood^[28]. Whether blood supply or other aggressive factors attribute to the development of resistant bleeding marginal ulcers needs to be confirmed. The mortality rate (overall and post-surgery) was the same in the two groups.

In conclusion, upper gastrointestinal bleeding in surgically treated patients seems to be more severe than that in non-operated patients. New surgical intervention is a significant challenge, not only because of the technical difficulties of a further operation, but also because of the requirement of a more radical procedure. More studies are required to confirm our findings.

Abstract

AIM: To study the association between host immunity and hepatitis B virus (HBV) recurrence after liver transplantation.

METHODS: Peripheral blood mononuclear cells (PBMC) were isolated from 40 patients with hepatitis B and underwent orthotopic liver transplantation (OLT) before and 2, 4, 8 wk after surgery. After being cultured *in vitro* for 72 h, the levels of INF- γ and TNF- α in culture supernatants were detected with ELISA. At the same time, the quantities of HBV DNA in serum and PBMCs were measured by real time PCR.

RESULTS: The levels of INF- γ and TNF- α in PBMC culture supernatants decreased before and 2, 4 wk after surgery in turns (INF- γ 155.52 \pm 72.32 ng/L vs 14.76 \pm 9.88 ng/L vs 13.22 \pm 10.35 ng/L, $F = 6.946$, $P = 0.027 < 0.05$; TNF- α 80.839 \pm 46.75 ng/L vs 18.59 \pm 17.29 ng/L vs 9.758 \pm 7.96 ng/L, $F = 22.61$, $P = 0.0001 < 0.05$). The levels of INF- γ and TNF- α were higher in groups with phytohemagglutinin (PHA) than in those without PHA before surgery. However, the difference disappeared following OLT. Furthermore, INF- γ and TNF- α could not be detected in most patients at wk 4 and none at wk 8 after OLT. The HBV detection rate and virus load in PBMC before and 2, 4 wk after surgery were fluctuated (HBV detected rate: 51.4%, 13.3%, 50% respectively; HBV DNA: 3.55 \pm 0.674 log(10) copies/mL vs 3.00 \pm 0.329 log(10) copies/mL vs 4.608 \pm 1.344 log(10) copies/mL, $F = 7.582$, $P = 0.002 < 0.05$). HBV DNA in serum was 4.48 \pm 1.463 log(10) copies/mL before surgery and $< 10^3$

copies/mL after OLT except for one with 5.72 $\times 10^6$ copies/mL 4 wk after OLT who was diagnosed as HBV recurrence. The levels of INF- γ and TNF- α were lower in patients with a high HBV load than in those with a low HBV load (HBV DNA detected/undetected in PBMCs: INF- γ 138.08 \pm 72.44 ng/L vs 164.24 \pm 72.07 ng/L, $t = 1.065$, $P = 0.297 > 0.05$, TNF- α 80.75 \pm 47.30 ng/L vs 74.10 \pm 49.70 ng/L, $t = 0.407$, $P = 0.686 > 0.05$; HBV DNA positive/negative: INF- γ 136.77 \pm 70.04 ng/L vs 175.27 \pm 71.50 ng/L, $t = 1.702$, $P = 0.097 > 0.05$; TNF- α 75.37 \pm 43.02 ng/L vs 81.53 \pm 52.46 ng/L, $t = 0.402$, $P = 0.690 > 0.05$).

CONCLUSION: The yielding of INF- γ and TNF- α from PBMCs is inhibited significantly by immunosuppressive agents following OLT with HBV load increased, indicating that the impaired immunity of host is associated with HBV recurrence after OLT.

INTRODUCTION

Liver transplantation is the most effective therapy for end-stage liver diseases. The recurrence of primary diseases becomes the main problem, which impedes the long-term survival rate of patients undergoing liver transplantation despite the improvements of surgery and the perioperative management. Chronic hepatitis B virus (HBV) infection is one of the most common diseases leading to a high morbidity and mortality in Asians. In China, there are more than 30 million people suffering from HBV infection. Despite anti-HBs immunoglobulin therapy, HBV infection recurs in a high proportion of patients with HBsAg positive and serum HBV DNA-negative, chronic liver disease after liver transplantation. Therefore, the recurrence of hepatitis B is the critical issue of liver transplantation in China^[1]. It was reported that host immunity is closely related with the prognosis of chronic and acute hepatitis B. Few HBV-specific T cells have been found in peripheral blood mononuclear

cells (PBMCs) of patients with chronic hepatitis B. Lymphocytes are infected with HBV^[2]. However, little is known about the immune condition of HBV-infected patients after orthotopic liver transplantation (OLT). After OLT, the HBV load decreases immediately and dramatically, but HBV hiding in extrahepatic tissues especially in PBMCs can infect the graft again^[3,4]. Since the function of PBMCs is an important indication of the host immunity status^[5], we investigated the function of PBMCs in producing INF- γ and TNF- α , and the association between host immunity and HBV recurrence after liver transplantation.

MATERIALS AND METHODS

Patients

A total of 40 patients with hepatic cirrhosis and hepatocellular carcinoma (HCC) who underwent liver transplantation at Sun-Yat Sen University, Guangzhou, from November 2003 to April 2004 were enrolled. Blood samples were obtained one day before and 2, 4 and 8 wk after surgery.

Immunosuppression consisted of tacrolimus-based/cyclosporin-based dual therapy with prednisolone. The doses were adjusted to maintain desired blood levels (5-15 μ g/L tacrolimus, 100-250 μ g/L cyclosporin) for the 1st year. Prednisolone was commenced at a daily dose of 60 mg, reduced by 8 mg every 4 d after the 2nd wk, and withdrawn completely at a median of 3 mo. mAbs were used for patients whose ascites >3 000 mL or serum Cr >132.6 μ mol/L or were used for those infected with bacteria within 2 wk before surgery. The protocol for prevention of HBV recurrence after liver transplantation was as follows: intra-operative administration of 400 IU hepatitis B immunoglobulin intramuscular injection during the an-hepatic phase, followed by 400 IU intramuscular injection for the first 14 postoperative days, then 400 IU every other day for 2 wk, followed by 400 IU once a week. Immunoprophylaxis was continued indefinitely with monthly administration of 400 IU of HBIg by intramuscular injection. All patients received HBIg and lamivudine (100 mg/d) immuno-noprophylaxis. HBV recurrence following liver transplantation was defined as the reappearance of HBsAg-HBV DNA in serum and/or positive staining for HBsAg on liver biopsy.

Isolation and culture of PBMCs

PBMCs isolated from heparinized venous blood by gradient centrifugation using Ficoll-Hypaque (Shenggong, Ltd, Shanghai, China) were suspended in RPMI-1640 supplemented with 10% heat-inactivated fetal calf serum (RPMI-1640/10% FCS) and penicillin-streptomycin (Sigma). A total of 2×10^6 PBMC were added to each well (48-well plates, Invitrogen, Carlsbad, CA, USA) for stimulation with or without 2 pg/L of phytohemagglutinin (PHA-P, Atlanta, GA, USA) at 37 °C for 72 h. All supernatants were collected and stored at -20 °C until use.

Measurement of cytokine concentration by ELISA

Immunoreactive IFN- γ and TNF- α levels in PBMCs were quantified with human IFN- γ and TNF- α ELISA kits (U-CyTech, Dutch). Optical density was measured at 450 nm with a Bio-Rad 550 microplate reader (Bio-Rad Laboratories

Inc., Hercules, CA, USA). The cytokine concentration was estimated from the standard curve generated by a curve-fitting program. The minimum detectable IFN- γ and TNF- α concentration was 5.0 ng/L.

Quantification of HBV DNA using real-time PCR

HBV DNA was extracted from 200 μ L of patient's sera according to the manufacturer's instructions. For total HBV quantification, PCR amplification was performed with a HBV DNA diagnostic kit (DaAn Gene Diagnostic Center, China) using ABI 7000HT sequence detection system. The PCR program consisted of an initial denaturation at 95 °C for 10 min, followed by 40 amplification cycles at 95 °C for 15 s and at 61.5 °C for 1 min.

Statistical analysis

All the data were analyzed with SPSS statistics software version 10.0. Repeated measures analysis of variance was used to measure IFN- γ and TNF- α levels at different time points. Independent sample *t* test was used to assess the differences between groups of various HBV load. $P < 0.05$ was considered statistically significant.

RESULTS

Demographic data of patients before surgery

The mean age of patients was 49.65 ± 9.06 years, the male and female ratio was 36:4, the positive and negative HBeAg ratio was 10:30, HBV DNA >1 000/<1 000 copies/mL was 21/19, Child-Pugh grade of hepatic function (A/B/C) was 12/11/27.

Kinetics of IFN- γ and TNF- α level in culture supernatants of PBMCs

The levels of IFN- γ and TNF- α in PBMC culture supernatants decreased before and 2, 4 wk after operation in turn (INF- γ : 155.52 ± 72.32 ng/L *vs* 14.76 ± 9.88 ng/L *vs* 13.22 ± 10.35 ng/L, $P < 0.05$; TNF- α : 80.839 ± 46.75 ng/L *vs* 18.59 ± 17.29 ng/L *vs* 9.758 ± 7.96 ng/L, $P < 0.05$; Tables 1 and 2). The levels of IFN- γ and TNF- α were higher in groups with PHA than in those without PHA. However, the difference disappeared following OLT. Furthermore, INF- γ and TNF- α could not be determined in most patients at wk 4 and none at wk 8 after OLT.

HBV DNA in serum before and after surgery

The level of HBV DNA was more than 10^3 copies/mL (2.75×10^3 - 6.95×10^7 copies/mL) in 52.5% (21/40) of patients before surgery. Almost all patients had an undetectable HBV DNA level ($< 10^3$ copies/mL), except for one patient who had a detectable HBV DNA level at wk 4 after surgery (5.72×10^6 copies/mL). Recurrence of hepatitis B was confirmed by an immunohistochemistry of liver biopsy in this patient.

HBV DNA in PBMCs

The HBV detectable rate and HBV DNA load in PBMCs before and 2, 4 wk after surgery fluctuated (HBV detectable rate: 51.4%, 13.3%, 50% respectively; HBV DNA: 3.55 ± 0.674 *vs* 3.00 ± 0.329 *vs* 4.608 ± 1.344 , $F = 7.582$, $P = 0.002$).

Effect of HBV DNA on IFN- γ and TNF- α level and PBMC culture supernatants

According to the HBV DNA level in serum and PBMCs before surgery, patients were divided into four groups. HBV DNA was >1 000 and <1 000 copies/mL in two groups respectively. HBV DNA was detected and undetected in the other two groups. Comparing the IFN- γ and TNF- α levels in various groups, we found that the HBV DNA level was higher, the cytokine level was lower (Table 3).

DISCUSSION

Several studies showed that the following factors influence the HBV recurrence after OLT^[6-11]: the HBV infection before surgery, the administration of immunosuppressive agents, the HBV level in extrahepatic tissues and the genotype of HBV. It is generally accepted that patients with active replication of HBV before the surgery and on high dose immunosuppressive agents are easier to be reinfected. In addition, the infection of PBMC might lead to the selection of HBV variants which contribute to immunologic escaping^[4]. Previous studies showed that the pattern of cytokines produced by circulating PBMCs from patients underwent OLT would determine the immunologic state of transplanted allograft^[12]. However, the function of PBMCs of HBV-infected patients who underwent OLT is still unclear.

Cytokines play an important role in antiviral immunity. After infecting the host cells, HBV is eliminated by the host immune system through two pathways^[13,14]. One is the cytolytic pathway characterized by activated HBV-specific T cells, mediating the effect of cellular cytotoxicity and lysis of HBV-infected cells. The other is mediated by

cytokines, especially by IFN- γ and TNF- α , which depress the replication and expression of HBV, degrade HBV^[15-17]. Recently, evidence supports that the non-cytolytic immune-mediated pathway is the principal way to eliminate viruses. Since the function of PBMCs reflects the host immunity to HBV^[18], it is useful to evaluate the graft immunity state and the change of host anti-viral immunity through monitoring the function of PBMCs in producing IFN- γ and TNF- α post OLT.

In our study, the levels of IFN- γ and TNF- α in PBMCs culture supernatants decreased dramatically post operation, consistent with literature reports, 50% cytokine reduction under clinical dose of CsA and FK506^[19]. Other reports showed that the TNF- α plasma level increased in the 1st wk post OLT^[20]. However, we did not detect the cytokine plasma concentrations. Since liver transplantation may lead to changes in the metabolic activity of neutrophils, it is necessary to perform further detailed study about IFN- γ and TNF- α plasma levels.

We also found that there were no differences between the groups with and without PHA, suggesting that PBMCs do not respond to the stimulation of PHA. On the contrary, in Chen's study^[12], the increased IFN- α mRNA expression after stimulated by PHA was reported. TNF- α expression induced by PHA in PBMC was higher in patients with an acute rejection episode. There are several underlined reasons that contributed to the difference between the two studies: first, the patients enrolled in Chen's study had previous rejection episodes, while in our study none had rejection. Second, in China, most patients who underwent OLT had serious complications and the human mAb of Tac was given to inhibit and then impair the function of T cells completely. Third, FK506 is preferred in our immunosuppressive

protocol. Sakuma *et al.*^[21], found that compared with CsA and DEX, FK506 may be most effective in specifically preventing T cell activation mediated inflammatory cytokine production in a clinic setting. We are not clear which immunosuppressive agents were favored in Chen's study.

The present study showed no differences between the groups with and without PHA. It may be because the multi-immunosuppressive agents downregulated the receptors on T cells and fewer signals were transmitted into the cells. However, the function of T cells was partially suppressed in this period and produced cytokines. In clinic, acute rejection occurs within 1 mo and more frequently within 2 wk after surgery^[22], indicating that the cell-mediated immunity is partially depressed during this period. At the same time, HBV DNA in PBMCs decreases, suggesting that it was a relatively safe period to avoid HBV reinfection. Four weeks following surgery, cytokines in culture supernatants cannot be detected in most patients. This may be explained by the following reasons. Firstly, immunosuppressive agents block the activation and proliferation of T cell and the production of cytokines are suppressed. Secondly, these patients are at high risk before surgery and human monoclonal antibody of Tac is given during and 2, 5 d after surgery. Thirdly, lymphocytes die following activation. Therefore, the suppression of T cells is reinforced. In our study, one case of hepatitis B recurrence was found 4 wk after surgery. We suggested that the following reasons contributed. The anti-virus capability was the lowest at this time, the HBV replication was accelerated and the host immunity of anti-virus was impaired. Eight weeks following OLT, no cytokines could be detected in PBMC culture supernatants, indicating that the function of lymphocytes is depressed completely. At the same time, the detectable rate of HBV DNA in PBMCs increased, and the virus load in PBMCs was near to that before surgery.

The HBV DNA level in serum affects the cytokine level in PBMCs. Higher HBV DNA would inhibit the production of IFN- γ induced by IL-12 in chronic hepatitis B patients^[23]. The reduction of virus load and antigen would repair the response function of cytotoxic T lymphocytes^[24,25]. We also found that the IFN- γ and TNF- α level would likely decrease when HBV DNA level increased.

In conclusion, the yielding of IFN- γ and TNF- α from PBMCs is inhibited significantly by immunosuppressive agents following OLT with HBV load increased, indicating that the impaired immunity of host is associated with HBV recurrence after OLT.

Abstract

AIM: To investigate the effects of garlicin on apoptosis and expression of bcl-2 and bax in lymphocytes in rat model of ulcerative colitis (UC).

METHODS: Healthy adult Sprague-Dawley rats of both sexes, weighing 180 ± 30 g, were employed in the present study. The rat model of UC was induced by 2,4,6-trinitrobenzene sulfonic acid (TNBS) enema. The experimental animals were randomly divided into garlicin treatment group (including high and low concentration), model control group, and normal control group. Rats in garlicin treatment group and model control group received intracolonic garlicin daily at doses of 10.0 and 30.0 mg/kg and equal amount of saline respectively 24 h after colitis model was induced by alcohol and TNBS co-enema. Rats in normal control group received neither alcohol nor only TNBS but only saline enema in this study. On the 28th d of the experiment, rats were executed, the expression of bcl-2 and bax protein was determined immunohistochemically and the apoptotic cells were detected by the terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate fluorescence nick end labeling (TUNEL) method. At the same time, the rat colon mucosal damage index (CMDI) was calculated.

RESULTS: In garlicin treatment group, the positive expression of bcl-2 in lymphocytes decreased and the number of apoptotic cells was more than that in model control group, CMDI was lower than that in model control group. The positive expression of bax in lymphocytes had no significant difference.

CONCLUSION: Garlicin can protect colonic mucosa against damage in rat model of UC induced by TNBS enema.

INTRODUCTION

Ulcerative colitis (UC), one of the chronic nonspecific inflammation diseases of the intestine, is related to infection, heredity, and immunologic inadequacy. In recent years, studies have shown that apoptosis plays an important role in the pathogenesis of UC^[1-3]. Apoptosis of enterocytes and lymphocytes are the main reasons for UC and inflammation^[4,5]. Apoptosis of lymphocytes is closely related with UC^[6-8]. Garlicin is a kind of chemical compound extracted from garlic corn. It has many biological activities against inflammation, fungi, anti-oxidant, and tumor, *etc.*^[9-11]. Therefore, we performed this study to observe the effects of garlicin on expression of bcl-2 and bax protein in rats with UC and its possible mechanism against the damage to colonic mucosa.

MATERIALS AND METHODS

Materials

Healthy adult Sprague-Dawley rats of both sexes, weighing 180 ± 30 g, employed in this study were purchased from the Experimental Animal Center, Hubei Academy of Medical Sciences, housed in a temperature conditioned room ($22-24^{\circ}\text{C}$) with a 12-h light-dark cycle, allowed free access to standard rat chow and water *ad libitum*, and acclimatized to the surroundings for 1 wk before the experiment. The study protocol was in accordance with the guideline for animal research and approved by the Ethical and Research Committee of the hospital.

Reagents

Garlicin was purchased from Hubei Wusan Drug Manufactory. 2,4,6-Trinitrobenzene sulfonic acid (TNBS) was bought from Sigma Corp. Immunohistochemical assay kits for bcl-2 and bax were provided by Wuhan Boster Reagent Corp. Apoptosis assay kits and S-P assay kits were provided by Roche Reagent Corp.

Experimental protocol

Rat model of UC was induced by TNBS enema as previously described in the literature^[12]. According to different treatment regimens, the experimental animals were randomly divided into garlicin treatment group (including high and low concentration), model control group, and normal control group. Rats in garlicin treatment group and model control group received intracolonic garlicin daily at doses of 10.0 and

30.0 mg/kg and equal amount of saline (8:00 am) 24 h after colitis model was induced by 50% alcohol and TNBS (150 mg/kg) co-enema. Rats in normal control group received neither alcohol nor TNBS but saline enema. On the 28th d of the experiment, rats were executed, the expression of bcl-2 and bax in lymphocytes was determined immunohistochemically and apoptotic cells were detected by the TUNEL method. At the same time, the colon mucosal damage index (CMDI) was evaluated.

Colon mucosal damage index

CMDI was evaluated by the methods as previously reported^[13]. The evaluation standard of CMDI includes adhesion, congestion, ulcer inflammation, and pathological change depth. Adhesion and congestion according to the difference of pathological change degree were scored as 0, 1 and 2 respectively. The inflammation and ulcer of colonic mucosa scored 1; the pathological change of submucous membrane, muscular layer, serous coat layer scored 1, 2, and 3 separately. Each point was added to get the total points.

Immunohistochemistry detection

The expression of bcl-2 and bax protein in colon tissue was determined immunohistochemically as previously described^[14,15], formalin-fixed, paraffin-embedded tissue blocks were cut into 5- μ m-thick sections mounted on glass slides, and then kept in an oven at 4 °C overnight. Immunostaining was performed as previously described with a slight modification^[16]. Sections were deparaffinized in xylene and rehydrated. Endogenous peroxidase activity was blocked with 1% hydrogen peroxide for 20 min. To improve the quality of staining, microwave oven-based antigen retrieval was performed. Slides were probed with either anti-bcl-2 (1:100, mouse mAb) or anti-bax (1:100, mouse mAb). Sections were washed thrice with PBS for 10 min each and incubated with biotin-labeled anti-mouse IgG for 1 h at room temperature. After washing thrice with PBS for 10 min each, sections were stained with a streptavidin-peroxidase detection system. Incubation with PBS instead of the primary antibody served as a negative control. In specimens containing positive cells, the positive cells were counted in 10 randomly selected fields under 200- or 400-fold magnification for each sample, and the average was expressed as the density of positive cells.

Determination of apoptosis

The TUNEL assay, originally described by Gavrieli *et al.*^[17], was used with minor modifications. Briefly, 5- μ m-thick tissue sections were mounted onto glass slides, deparaffinized,

hydrated, and treated with proteinase-K (Roche Corp.; 20 μ g/mL in 10 mmol/L Tris-HCl buffer, pH 7.4) for 15-30 min at 37 °C. Slides were rinsed twice with PBS. Then, 50 μ L of TUNEL reaction mixture (450 μ L nucleotide mixture containing fluoresceinated dUTP in reaction buffer plus 50 μ L enzyme TdT from calf thymus, Roche Corp.) was added to the samples. To ensure homogeneous spread of the TUNEL reaction mixture on tissue sections and to avoid evaporative loss, slides were covered with coverslips during incubation and incubated in a humidified chamber for 60 min at 37 °C. After rinsing, slides were incubated with anti-fluorescein antibody, Fab fragment from sheep, conjugated with horse-radish peroxidase for 30 min at 37 °C. Slides were rinsed twice with PBS. Then, 50-100 μ L of DAB substrate was added and incubated for 10 min at room temperature. Samples were counterstained prior to analysis by light microscopy. Positive signals were defined as presence of a distinct brown nuclear staining of the neoplastic cells or were morphologically defined as apoptotic bodies. The apoptotic index (AI) was determined by counting at least 1 000 neoplastic nuclei in 10 randomly chosen fields at 400-fold magnification. Apoptotic cells were identified by TUNEL assay in conjunction with characteristic morphological changes such as cell shrinkage, membrane blebbing, and chromatin condensation, to distinguish apoptotic cells and bodies from necrotic cells.

Statistical analysis

All statistical analyses were performed with SPSS10.0 statistical package for Microsoft Windows. Measurement data were expressed as mean \pm SD, *t* test and one-way analysis of variance were used to compare continuous variables among groups. *P*<0.05 was considered statistically significant.

RESULTS

Protective effects of garlicin on rat colonic lesion

Pronounced pathological changes of colonic mucosa were similar to those in human IBD which were observed in rats colitis model induced by both alcohol and TNBS co-enema. CMDI significantly increased in experimental animals compared to normal controls (*P*<0.01). Treatment groups with different doses of garlicin could effectively reduce the severity of gut injury and CMDI significantly decreased in a dose-dependent manner in rats treated with garlicin compared to that in model control group (*P*<0.05-0.01, Table 1).

Effects of garlicin on expression of bcl-2 and bax protein

In the present study, the expression of bcl-2 and bax was

Table 1 Effect of garlicin on CMDI in rats with experimental colitis (mean \pm SD, *n* = 10)

Group	CMDI							
	0	1	2	3	4	5	6	7
Normal control	2	5	3					
Model control				1 ^d	2 ^d	3 ^d	3 ^d	1 ^d
Garlicin (10.0 mg/kg)		2 ^a	2 ^a	3 ^a	2 ^a	1 ^a		
Garlicin (30.0 mg/kg)			5 ^b	3 ^b	2 ^b			

^a*P*<0.05, ^b*P*<0.01 vs model control; ^d*P*<0.01 vs normal control.

also investigated by immunohistochemistry. Immunostaining specific for bcl-2 and bax was shown as brown. Positive expression of bcl-2 in lymphocytes significantly increased in rat model of UC induced by alcohol and TNBS enema compared to the normal control group ($P<0.01$), which were significantly inhibited by different doses of garlicin ($P<0.01$ - 0.05 vs model control, Table 2 and Figure 1). Positive expression of bax in lymphocytes was common in normal group, which had no alteration in model control group and garlicin treatment group.

Apoptosis

TUNEL staining was restricted to the nuclei of apoptotic cells. TUNEL-positive staining cells were detected in normal control group, model control group, and garlicin treatment group. The AI significantly decreased ($P<0.01$) in model control group compared to normal control group, and increased in garlicin treatment group compared to model control group ($P<0.01$ - 0.05 , Table 2 and Figure 2).

Table 2 Effect of garlicin on expression of bcl-2 and bax and AI in rats with experimental UC (mean \pm SD, $n = 10$)

Group	Bcl-2	Bax	AI
Normal control	9.8 \pm 1.4	30.1 \pm 3.2	20.8 \pm 0.7
Model control	41.0 \pm 2.5 ^d	9.9 \pm 0.8 ^d	2.3 \pm 1.6 ^d
Garlicin (10.0 mg/kg)	22.4 \pm 0.8 ^a	11.2 \pm 4.3	9.8 \pm 1.3 ^a
Garlicin (30.0 mg/kg)	10.2 \pm 2.5 ^b	13.1 \pm 2.5	15.3 \pm 0.6 ^b

^a $P<0.05$, ^b $P<0.01$ vs model control; ^c $P<0.01$ vs normal control.

DISCUSSION

The term “apoptosis” describes the change of morphology different from cell necrosis. Hallmarks of apoptosis include chromatin condensation, nuclear segmentation, cytoplasmic shrinkage, blebbing, and formation of apoptotic bodies^[18]. Bcl-2 is a suppressor gene of apoptosis, which was found from follicular B cell lymphoma with t(14,18) chromosome malposition^[19]. Orientating as 18q21, bax, and bcl-2 are homologous proteins, and bax is an induction gene of apoptosis. Bcl-2 and bax can exist in the form of homodimer and form heterodimer too. When the expression of bax increases, the homodimer of bax–bax can induce apoptosis. When the expression of bcl-2 increases, bax can combine with bcl-2 to form more stable heterodimers which can inhibit apoptosis. The ratio of bcl-2/bax can regulate apoptosis^[20].

The important pathological change in UC are inflammatory damage of intestine, during which a large number of inflammatory cells infiltrate the intestinal wall and activate continuously^[21]. Apoptosis of the lymphocytes has a close relation with UC, and apoptosis of lymphocytes in colonic mucosa is the main reason for the development of UC^[6,22-24]. This experiment has proved that apoptosis of lymphocytes is delayed in UC, which is consistent with previous reports^[2,3,20]. The positive expression of Bcl-2 in lymphocytes increased while that of bax was relatively rare, which is in agreement with previous reports^[20]. Garlicin is a kind of chemical compound extracted from garlic corn. It has many biological activities against inflammation, fungi, anti-oxidant, etc.^[9-11].

Figure 1 Immunohistochemical staining of bcl-2 in tissue sections of model control group (A) and garlicin treatment group (B).

Figure 2 TUNEL staining in tissue sections of model control group (A) and garlicin treatment group (B).

It can protect colonic mucosa against damage. In this study, the apoptosis of lymphocytes increased in garlicin treatment group and the positive expression of bcl-2 in lymphocytes decreased, suggesting that garlicin has protective effects on UC by promoting apoptosis of lymphocytes and reducing expression of bcl-2 protein.

We observed the effects of garlicin on the expression of bcl-2 and bax in lymphocytes in rat model of UC induced by TNBS. The results showed that the CMDI of garlicin treatment group was obviously lower than that of the model control group, indicating that the garlicin can prevent and cure UC. At the same time, the apoptosis of lymphocytes increased in garlicin treatment group, showing that the protective effects of garlicin in rats with UC are related with the induction of apoptosis of lymphocytes. The results of this experiment may open up a new way for the treatment of UC.

Abstract

AIM: To investigate the immunogenicity of a novel DNA vaccine, pSW3891/HBc, based on HBV core gene in Balb/c mice.

METHODS: A novel DNA vaccine, pSW3891/HBc, encoding HBV core gene was constructed using a vector plasmid pSW3891. Balb/c mice were immunized with either pSW3891/HBc or empty vector DNA via gene gun. IgG anti-HBc responses in mouse sera were demonstrated by ELISA. Specific cytotoxicity of cytotoxic T lymphocytes (CTLs) of mice was quantitatively measured by lactate dehydrogenase release assay.

RESULTS: HBcAg was expressed effectively in 293T cell line transiently transfected with pSW3891/HBc. Strong IgG anti-HBc responses were elicited in mice immunized with pSW3891/HBc. The end-point titers of anti-HBc reached the highest 1:97 200, 4 wk after the third immunization. The specific CTL killing with the highest specific lysis reached 73.25% at effector:target ratio of 20:1 in mice that received pSW3891/HBc DNA vaccine.

CONCLUSION: pSW3891/HBc vaccination elicits specific anti-HBc response and induces HBc-specific CTL response in immunized Balb/c mice.

INTRODUCTION

Chronic infection with HBV affects more than 250 million people worldwide, and is considered to be a high risk factor for developing cirrhosis and hepatocellular carcinoma. Although some antiviral drugs for HBV can effectively inhibit viral replication, they rarely eliminate the intra-nuclear viral covalently close circular DNA, which is responsible for the persistence of infection. Recent data indicate that immunotherapeutic strategies stimulating both cellular and humoral immune responses to HBV antigens are essential to cure chronic HBV infection. Since genetic immunization, i.e. *in vivo* transfection of somatic cells with antigen-encoding DNA, effectively induces major histocompatibility complex (MHC) class I-restricted cell-mediated immunity in CD8⁺ cytotoxic T lymphocytes (CTLs) and elicits humoral immune reactions which are dependent on MHC class II-restricted activation of T helper (Th) cells. In this regard, DNA-based vaccination appears to be a particularly pertinent approach for chronic hepatitis B therapy. It has been demonstrated that plasmid DNA encoding HBV surface antigen (HBsAg) and core antigen (HBcAg) elicits vigorous humoral and cellular response in many species^[1-5]. However, the vectors used for animal testing cannot be applied in human studies. On the basis of our previous work, we designed a novel plasmid vector pSW3891. In this study, we investigated the immunogenicity of plasmid pSW3891/HBc encoding HBcAg with this new vector pSW3891 in Balb/c mice.

MATERIALS AND METHODS

Plasmid construction and *in vitro* expression of HBc

To construct plasmid pSW3891/HBc, plasmid pJW4303/HBc^[6] was digested with *Bam*HI and *Pst*I. The HBc gene fragment was isolated by gel electrophoresis and purified with QIAquick gel extraction kit (Qiagen, Valencia, CA, USA). The purified HBc gene was cloned into the *Bam*HI and *Pst*I sites of the pSW3891 vector, resulting in pSW3891/HBc. The pSW3891/HBc DNA vaccine plasmids transformed in *E coli* (HB101 strain) were propagated in LB medium containing kanamycin (0.06 g/L). The pSW3891/HBc plasmid DNA was isolated and verified by restriction enzyme analysis. Large prep of pSW3891/HBc was prepared using the Maxi-plasmid purification kit (Qiagen).

The expression of HBc antigen from DNA vaccine plasmid was confirmed in 293T cells transiently transfected with pSW3891/HBc. The 293T cells were grown in Dulbecco's modified Eagle's medium (Invitrogen, Gaithersburg, MD, USA) supplemented with 10% heat-

inactivated fetal bovine serum, 0.1 g/L of streptomycin, and 100 IU/mL penicillin. Each of the 60-mm tissue culture dishes (2.5×10^6 cells) was transfected with 10 μ g of pSW3891/HBc DNA vaccine plasmid or the empty pSW3891 vector by calcium phosphate precipitation. The levels of HBcAg in the supernatant and the lysate of the 293T cell culture harvested after 48-72 h were detected by Western blot analysis.

Animals and DNA immunization

Seven-week-old female Balb/c mice were purchased from Millbrook Farm (Amherst, MA, USA) and housed in the animal facility at the Department of Animal Medicine of the University of Massachusetts Medical School in accordance with Institutional Animal Care and Use Committee (IACUC) approved protocol. Ten mice were randomly assigned into two groups. Both groups of mice received DNA immunizations by a Bio-Rad Helios gene gun (Bio-Rad, Hercules, CA, USA). The experimental group was vaccinated thrice at 4-wk intervals with pSW3891/HBc, while the control group received only the empty vector pSW3891. The DNA vaccine plasmids were coated onto the 1.0-micron gold beads at a ratio of 2 μ g of DNA per mg of gold. Each gene gun shot delivered 1 μ g of DNA, and a total of six non-overlapping shots were delivered to each mouse on shaved abdominal skin at each immunization. Blood samples before immunization and 4 wk after the last immunization were collected from orbital sinus. The sera were isolated and stored at -70°C until use.

Western blot analysis

The HBc antigens in supernatant from transiently transfected 293T cells were subjected to SDS-PAGE and blotted onto polyvinylidene difluoride membrane (PVDF; Bio-Rad). Blocking was done with 0.1% I-Block (Tropix, Bedford, MA, USA). The membranes were incubated with immunized mouse sera at 1:500 dilution for 45 min and subsequently reacted with AP-conjugated goat anti-rabbit IgG at 1:5 000 dilution for 10 min. Membranes were washed with blocking buffer after each step. Western-light substrate was then applied to the membranes for 5 min. Once the membranes were dried, X-ray films were exposed to the membrane and developed by a Kodak processor.

Measurement of CTL response

HBcAg-specific CTL responses were detected by the CytoTox 96[®] non-radioactive cytotoxicity assay (Promega, Madison, WI, USA) according to the manufacturer's instructions. Briefly, single cell suspensions were prepared from spleens of mice, 4 wk after the last immunization. For specific re-stimulation, 3×10^6 /mL splenocytes were cultured *in vitro* with recombinant human IL-2 (25 U/mL) and 0.01 g/L of the HBc-specific polypeptide SYVNTNMGL (Life Technologies, Gaithersburg, MD, USA). After 7 d of re-stimulation, the splenocytes were used as effector cells in the CTL assays. The effector cells and target cells (P815) at the effector:target ratio of 20:1, 10:1, 5:1, or 2.5:1, respectively were co-cultured with 0.01 g/L specific polypeptide. After 4-h incubation at 37°C with 50 mL/L CO_2 , the absorbance of culture supernatant from each well

was quantitatively measured using a standard 96-well plate reader according to the instructions. The percent cytotoxicity for each effector:target cell ratio was calculated using the following formula: %cytotoxicity = (experimental-effector spontaneous-target spontaneous)/(target maximum-target spontaneous) $\times 100$. The results represented the mean of the triplicate data set.

Enzyme-linked immunosorbent assay

Mouse sera were tested for HBc-specific IgG antibody responses by ELISA. Microtiter plates (Corning, NY, USA) were first coated overnight with 0.005 g/L of purified HBcAg (Aldevron, Fargo, ND, USA) in 0.05 mol/L sodium carbonate buffer at pH 9.2. After coating buffer was removed, 200 μ L/well blocking buffer (5% Marvel skim milk in 0.1% PBS-Triton X100) was added for 1 h at room temperature. Blocking buffer was then removed and primary antibody (100 μ L/well) was added at different dilutions in blocking buffer and plates were incubated at room temperature. Plates were washed thrice in 0.1% PBS-Triton X100 and diluted anti-mouse biotinylated antibodies (Caltag, Burlingame, CA, USA) were added, followed by 1-h incubation. Plates were washed thrice in 0.1% PBS-Triton X100, then streptavidin-horseradish peroxidase (Caltag) was added, and plates were incubated for 1 h. The horseradish peroxidase activity was detected with ortho-phenylenediamine substrate solution. The reaction was stopped by the addition of 50 μ L/well of 3 mol/L H_2SO_4 after 35 min in the dark. The optical density (A) was read at 450 nm in an ELISA reader (BioRad). The end titration titer was determined when the A reading at the last sera dilution was twofold above the A reading of the negative control wells with the normal mouse sera.

RESULTS

Construction of recombinant plasmid pSW3891/HBc

The cloning of the HBc gene into vector pSW3891 was confirmed by restriction enzyme analysis (Figure 1). A small molecular weight band (662 bases) corresponding to the HBc gene insert was observed when the plasmid was restricted with *Bam*HI and *Pst*I. Single band representing the full length plasmid was observed in *Xba*I-digested lane because there was one *Xba*I site in the HBc gene but not in vector pSW3891.

Figure 1 Digestion of pSW3891/HBc. Marker: λ /Hind III; C6, C7: clone no.

Expression of pSW3891/HBc in 293T cells

A protein with expected molecular weight of M_r 21 000 was efficiently expressed in the lysate of 293T cells transiently transfected with pSW3891/HBc as shown by Western blotting (Figure 2). No specific bands were detected in the supernatant of 293T cells transfected with pSW3891/HBc, nor in the supernatant and lysate of 293T cells transfected with pSW3891 (Figure 2).

Figure 2 *In vitro* HBc expression in pSW3891/HBc transiently transfected 293T cells. V: pSW3891; L: lysate; C6: pSW3891/HBc/C6; S: supernatant.

Anti-HBc IgG response in Balb/c mice immunized with pSW3891/HBc

Strong anti-HBc IgG responses were elicited in mice immunized with pSW3891/HBc, the end-point titers of anti-HBc reached the highest 1:97 200, 4 wk after the third immunization. The antibody titers were significantly higher in the group immunized with pSW3891/HBc than in the group immunized with empty vector pSW3891 (Figure 3).

Figure 3 End-point titres of anti-HBc in sera of Balb/c mice immunized with pSW3891/HBc.

HBc-specific CTLs in mice

Four weeks following the last immunization, splenocytes from mice immunized with pSW3891/HBc or vector pSW3891 were isolated and stimulated *in vitro* with the HBc-specific peptide. Specific cell-mediated cytotoxic activities with different effector/target ratios are shown in Figure 4.

Compared to the control group, the specific CTL killing with the highest specific lysis reached 73.25% at effector:target ratio of 20:1 in the experimental group of mice that received pSW3891/HBc DNA vaccine.

Figure 4 Specific cytotoxicity of splenocytes in Balb/c mice immunized with pSW3891/HBc.

DISCUSSION

It is well known that immune responses play a significant role in both virus clearance and pathogenesis of hepatitis B. The vigorous polyclonal and multi-specific immune responses to HBV have been associated with recovery from acute infection. It has been shown that specific cellular immunity against HBcAg is a key factor for the control of HBV infection^[7]. CTLs and Th cells with specificity for HBcAg are detectable in the circulation during acute infection^[8-10]. In contrast, defective CTL- and Th-cell responses have been observed in chronic HBV carriers^[11].

There is evidence that DNA plasmid encoding HBcAg is a promising vaccine candidate against HBV infection. Our previous data have also shown that plasmid pJW4303/HBc encoding HBc elicits high titer antibodies and CTL responses in mice and monkeys^[6]. However, the plasmids used in these experiments are not suitable for humans because of their vector components. For example, the ampicillin resistant gene for selection may cause antibiotic resistance in clinic, and the sequence derived from SV40 virus promoter region might potentially cause or promote lymphomas and other cancers. We deleted SV40 virus sequence and substituted ampicillin resistant gene in the vector pSW4303 with kanamycin resistant gene to generate a new vector pSW3891. Then the HBc gene was inserted into this new vector to develop a novel DNA vaccine pSW3891/HBc suitable for humans.

Restriction enzyme analysis of pSW3891/HBc confirmed that the HBc gene was inserted correctly into vector pSW3891. The HBc gene could release from pSW3891/HBc with *Bam*HI and *Pst*I, which was not observed in the control vector pSW3891. The expression of pSW3891/HBc *in vitro* was confirmed in transiently transfected 293T cells. Western blotting analysis showed that HBcAg was detectable in the cell lysate but not in supernatant of the transfected 293T cells in accordance with the early reports^[6]. This is consistent with the observation that HBcAg only exists in hepatic cells where capsids of HBV particles have been found in patients with hepatitis B.

To investigate the ability of pSW3891/HBc to elicit humoral responses in vaccinated Balb/c mice, two groups of mice were immunized with different plasmids. The experimental group of mice that received pSW3891/HBc induced a potent anti-HBc response with the titers reaching

1:97 200. In contrast, anti-HBc antibody was undetectable in the control group of mice that received only vector DNA alone. These results suggest that pSW3891/HBc can elicit strong specific anti-HBc humoral responses in Balb/c mice after DNA vaccination.

Lee *et al.*^[12], have shown that specific CTL responses can be induced by a DNA vaccine encoding HBcAg in C57BL/6 mice. Our results are in agreement with this finding. We measured the CTL component of immune response by the specific killing of syngeneic target cells pulsed with a recognized CTL epitope peptide. Our result showed the specific CTL killing with the highest specific lysis reached 73.25% at effector:target ratio of 20:1, suggesting that pSW3891/HBc vaccination induces HBc-specific CTL responses in immunized Balb/c mice.

Clinical studies of DNA vaccine against HBV infection are still in the early stage and focused on investigating the effects of prophylactic immunization in healthy volunteers. Roy *et al.*^[13], demonstrated that all healthy volunteers immunized with 1, 2, or 4 µg of DNA encoding HBsAg using the gene gun deliver system develop protective antibody titers. Volunteers who are positive for HLA-A2 have detectable antigen-specific CD8⁺ T cells identified by flow cytometry analysis following staining with HLA-A2/HBsAg 335-343 tetramers. Tacket *et al.*^[14], conducted the phase I safety and immune response study of an HBV DNA-based vaccine in healthy volunteers who received two immunizations with plasmid DNA encoding HBsAg on d 0 and 56 by gene gun, and found that although volunteers fail to develop protective antibody responses, it is attributed to the extremely low dose of DNA (0.25 µg) used.

In conclusion, pSW3891/HBc vaccination can elicit specific anti-HBc response and induce HBc-specific CTL response in immunized mice.

Abstract

AIM: To study the expressions of p27^{kip1} protein and p27mRNA, the hypermethylation of p27^{kip1} and the relation between them in various stages of hepatocarcinogenesis.

METHODS: p27 protein and p27mRNA were detected by immunohistochemical staining and *in situ* hybridization respectively in 68 cases of normal liver, liver cirrhosis, pericancerous cirrhosis and hepatocellular carcinoma (HCC). The hypermethylation of p27^{kip1} was detected by methylation-specific PCR (MSP) in 44 cases of normal liver, liver cirrhosis, and HCC.

RESULTS: The positive rate of p27 protein was 66.7% (4/6) in normal liver, 60.0% (6/10) in liver cirrhosis, 50.0% (12/24) in pericancerous cirrhosis and 21.4% (6/28) in HCC. There were no statistical differences in normal liver, liver cirrhosis and pericancerous cirrhosis, but the positive rate of p27 protein significantly decreased in HCC compared to that in the other groups ($P = 0.006$, $\chi^2 = 7.664$). The positive rate of p27^{kip1} mRNA was 83.3% (5/6) in normal liver, 70.0% (7/10) in liver cirrhosis, 75.0% (18/24) in pericancerous cirrhosis and 25.0% (7/28) in HCC. There were no statistical differences in normal liver, liver cirrhosis and pericancerous cirrhosis, but the positive rate of p27^{kip1} mRNA also significantly decreased in HCC compared to that in the other groups ($P = 0.000$, $\chi^2 = 16.600$). In addition, there was a significant correlation between the expression of p27 protein and p27mRNA in the integrated group of normal liver and liver cirrhosis. However, no significant correlation was found between pericancerous cirrhosis and HCC. Using MSP, we found that 1 HCC in 44 cases (including 6 cases of normal liver, 10 cases of liver cirrhosis and 28 cases of HCC) was methylated, whose p27 protein and p27mRNA were negative.

CONCLUSION: The reduction or loss of p27 protein and

INTRODUCTION

Disruption of cell cycle regulation plays a significant role in carcinogenesis. p27^{kip1}, located at chromosome 12p13, is a regulator of the mammalian cell cycle and a tumor suppressor^[1]. It was reported that the expression of p27^{kip1} protein in hepatocellular carcinoma (HCC) is lost or reduced, when compared to that in liver cirrhosis and normal liver^[2,3], as well as the transcription of p27mRNA^[4]. The mechanism of loss and reduction of p27^{kip1} expression during hepatocarcinogenesis still remains unclear. Specific alterations of the p27^{kip1} gene, including mutations and homozygous deletions, are exceedingly rare in HCC, suggesting that p27^{kip1} might be inactivated by transcription rather than genomic aberrations.

In normal tissues, methylation of the promoter region CpG islands is associated with transcriptional silencing of imprinted alleles and genes on the inactive X chromosome^[5,6]. Indeed, aberrant DNA methylation of the promoter region CpG islands can serve as an alternative to mutations in the coding region for the inactivation of tumor suppressor genes, including the APC gene, p16INK4A, and p15INK4B^[7-9]. p27^{kip1} promoter methylation has not been studied in HCC. We focused on analyzing the DNA methylation patterns in CpG islands of the p27^{kip1} gene.

MATERIALS AND METHODS

Specimens

Specimens obtained from surgical resection, autopsy of livers from 1970 to 2003 were fixed in 40 g/L formaldehyde, embedded in paraffin, and stained with routine HE. The specimens were divided into four groups: normal liver tissue specimens used as controls ($n = 6$), liver cirrhosis tissue specimens ($n = 10$), pericancerous tissue specimens ($n = 24$) and HCC tissue specimens ($n = 28$). All specimens were examined by two pathologists.

Immunohistochemical staining

Immunohistochemistry S-P method was used to detect p27^{kip1} protein expression. Mouse monoclonal antibody to human p27^{kip1} was purchased from Fuzhou Maixin Biotechnical Company. The main steps were as follows. The tissues were treated with 3% H₂O₂ to block endogenous peroxidase at room temperature for 10 min, heated to boiling for 5 min in 10 mmol/L sodium citrate (pH 6.0) buffer in a pressure cooker, incubated in endogenous peroxidase blocking solution at room temperature for 10 min, and then incubated in normal nonimmune serum at room temperature for 10 min. The mouse anti p27^{kip1} antibody was added to tissue sections and incubated overnight at 4 °C. Biotin-conjugated secondary antibody was added to the sections and incubated at room temperature for 10 min. S-P complex was added at room temperature for 10 min and then DAB was used for the color reaction. The tissue sections were washed with PBS (0.01 mol/L, pH 7.4) between each step. Positive and negative controls were simultaneously used to ensure specificity and reliability of the staining process. A positive section provided by the company was taken as positive control. In the negative control, PBS was used to replace the primary antibody.

The immunohistochemical staining (IHC) was independently assessed by two experienced pathologists in a double-blind fashion. Positive p27 staining was mainly localized in the cell nuclei and only rarely in the cytoplasm. All fields of each section were observed. If there was no positive cell, the grade was 0; under 30% of positive cells the grade was 1; 31-70% positive cells the grade was 2; >70% positive cells the grade was 3. The criterion of the staining intensity was determined by the staining characteristics of most cells in each section. If there was no staining, the scale was 0; weak yellow staining was grade 1; brown yellow staining was grade 2; brown staining was grade 3. The final staining results were determined by the total of the staining and intensity grade. If the total grade was 0, the result was regarded as negative (-); grades between 1 and 3 as weakly positive (+); grades between 4 and 6 as strongly positive (++)^[10].

In situ hybridization

In situ hybridization (ISH) was used for the detection of p27^{kip1} mRNA. The p27^{kip1} probe with digoxin-labeled and ISH kit was purchased from Wuhan Boster Biological Technology Ltd. The main steps were as follows. All slides were baked overnight at 58-60 °C. The tissues were deparaffinized by xylene and graded alcohols, treated with 3% H₂O₂ at room temperature for 10 min. Proteinase K freshly diluted with 3% citrate acid was added at 37 °C for 10-15 min. The tissues were pre-hybridized for 3 h at 37 °C in pre-hybridization liquid. Digoxin-labeled probe with coverslip was added, the tissues were hybridized at 37 °C for about 16 h. The slides were washed four times with SSC at 37 °C. Block liquid was added for 3 min at 37 °C. Mouse biotin-antidigoxin antibody was applied for 60 min at 37 °C, followed by detection with nitroblue tetrazolium and 5-bromo-4-chloro-3-indolyl phosphate (NBT/BCIP) for 20 min. Positive control provided by the company was used. Hybridization liquid replaced by PBS served as negative control.

ISH staining was evaluated according to the following scales: no positive cell for negative, 1+ for staining in <25% of cells, 2+ for staining in 25-70% of cells, and 3+ for staining in >70% of cells^[11].

Methylation-specific PCR

Tissues were deparaffinized by xylene and graded alcohols. Genomic DNA was then extracted with a standard phenol/chloroform procedure. DNA methylation patterns in the CpG islands of the p27^{kip1} gene were determined by methylation-specific PCR (MSP)^[12]. MSP distinguishes unmethylated from methylated alleles based on sequence changes produced after bisulfite treatment of DNA, which converts unmethylated (but not methylated) cytosine to uracil, and subsequent PCR using primers were designed for either methylated or unmethylated DNA. Sodium bisulfite modification was performed using the CpGenome™ DNA modification kit (Intergen, Oxford, UK) according to the manufacturer's protocol with minor modifications. Briefly, DNA was denatured by NaOH (final concentration, 0.2 mol/L) for 15 min at 37 °C. Sodium bisulfite solution at pH 5.0, freshly prepared, was added (550 µL), and incubated at 50 °C for 20 h. The modified DNA was treated with NaOH (final concentration, 0.3 mol/L) for 5 min at room temperature. After precipitation by ethanol, the DNA was resuspended in TE buffer (10 mmol/L Tris pH 8.0, 0.1 mmol/L EDTA)^[13]. The primer sequences for the p27^{kip1} methylated reaction were 5'-AAGAGGCGAG-TTAGCGT-3' (sense) and 5'-AAAACGCCGCCGAACGA-3' (antisense); 5'-ATGGAAGAGGTGAGTTAGT-3' (sense) and 5'-AAAACCCCAATTAAAAACA-3' (antisense) for the p27^{kip1} unmethylated reaction^[14]. PCR was carried out in a 10 µL volume containing PCR buffer (10 mmol/L Tris-HCl pH 8.3, 50 mmol/L KCl, 1.5 mmol/L MgCl₂), dNTPs (250 µmol/L each), primers (2.5 pmol each), 0.4 unit of TaKaRa taq™ (DR100A, TaKaRa Biotech, Dalian, China) and approximately 10-100 ng bisulfite-modified DNA. Amplification was carried out in a DNA Amplifier thermocycler (Eppendorf) with initial denaturing at 95 °C for 3 min followed by 34 cycles of denaturing at 94 °C for 1 min, annealing for 1 min at 53 °C (for p27^{kip1} methylated reaction) or at 58 °C (for p27^{kip1} unmethylated reaction), extension for 1 min at 72 °C, and then a final extension for 10 min at 72 °C. DNA extracted from HCC treated with methylase (SssI, New England BioLabs, Beverly, MA, USA) was used as the methylated control and DNA extracted from relatively normal liver was the unmethylated control. Amplified products were electrophoresed on 2% agarose gels and visualized with ethidium bromide staining. In the total, we tested 44 cases including 6 cases of normal liver, 10 cases of liver cirrhosis and 28 cases of HCC.

Statistical analysis

The Fisher's exact test, χ^2 test and Spearman's correlation were used.

RESULTS

p27 protein expression

The positive rate of p27 protein was 66.7% (4/6) in normal

Figure 1 Expressions of p27. **A:** p27 protein was expressed in nuclei of liver cirrhosis (SP $\times 400$); **B:** p27 protein was expressed in pericancerous cirrhosis, but not in HCC (SP $\times 200$); **C:** p27mRNA was positive in liver cirrhosis (ISH

$\times 200$); **D:** p27mRNA was positive in pericancerous cirrhosis, but negative in HCC (ISH $\times 100$).

liver, 60.0% (6/10) in liver cirrhosis, 50.0% (12/24) in pericancerous cirrhosis and 21.4% (6/28) in HCC. There were no statistical differences in normal liver, liver cirrhosis and pericancerous cirrhosis, but the positive rate of p27 protein significantly decreased in HCC compared to that in the other groups ($P = 0.006$, $\chi^2 = 7.664$). In addition, the positive signals of p27 protein were mainly located in nuclei in normal liver and liver cirrhosis (Figure 1A), while they were located in cytoplasm in pericancerous cirrhosis and HCC (Figure 1B).

p27^{kip1} mRNA expression

The positive result showed blue coloration in the cytoplasm (Figures 1C and D). The positive rate of p27^{kip1} mRNA was 83.3% (5/6) in normal liver, 70.0% (7/10) in liver cirrhosis, 75.0% (18/24) in pericancerous cirrhosis and 25.0% (7/28) in HCC. There were no statistical differences in normal liver, liver cirrhosis and pericancerous cirrhosis, but the positive rate of p27^{kip1} mRNA also significantly decreased in HCC compared to that in the other groups ($P = 0.000$, $\chi^2 = 16.600$). There was a significant correlation between the expression of p27 protein and p27mRNA in the integrated group of normal liver and liver cirrhosis ($P = 0.082 < 0.1$, $\chi^2 = 0.447$, $r = 0.447$, Table 1). However, no significant correlations were between pericancerous cirrhosis ($P = 0.368$, $\chi^2 = 0.192$, $r = 0.192$) and HCC ($P = 0.611$, $\chi^2 = 0.101$, $r = 0.101$, Tables 2 and 3).

p27^{kip1} hypermethylation

p27^{kip1} promoter hypermethylation was only detected in 1 of 28 HCC cases, which was negative when detected by

Table 3 Correlation between expression of p27mRNA and p27 protein in HCC

ISH and IHC. $p27^{kip1}$ methylation was not detected in any of 10 cases of liver cirrhosis and 6 cases of normal livers. Methylated and unmethylated control DNA showed the expected fragment sizes of 195 and 212 bp (Figure 2).

Figure 2 MCP of CpG islands of $p27^{kip1}$ promoter. Lane 1: marker; lanes 2, 4, 6, 8 and 10: PCR products of each case to unmethylated specific primers. Lanes 3, 5, 7, 9 and 11: PCR products of each case to methylated specific primers. In HCC19 case, only methylated DNA (M) was present. HCC88 case and L.C21 case (liver cirrhosis case) showed unmethylated status (U). Positive control (P.C) for methylated DNA was treated with SssI methylase first, normal control (N.C) for unmethylated DNA.

DISCUSSION

$p27$ is involved in cancer because of its essential role in controlling cell cycle progression^[1]. Decreased expression of $p27$ protein is inversely correlated with stage of disease at the time of surgery in HCC, reduced $p27$ is significantly related to advanced locoregional extent of the primary tumor and tumor size^[15]. The expression of $p27$ is a favorable prognostic indicator in patients with HCC^[16] and other tumors^[17,18]. Our results revealed that $p27$ protein was expressed in normal liver, liver cirrhosis, pericancerous cirrhosis and HCC, but the positive expression rate of $p27$ protein significantly decreased in HCC compared to that in the other groups. The loss or decrease of $p27$ protein may lead to reduction or disappearance of its cell cycle negative regulation, thus cells pass the G_1 phase into S phase, resulting in division and autonomous program^[19].

Our results also revealed that the positive rate of $p27$ mRNA was high in the normal liver, liver cirrhosis and pericancerous cirrhosis, and there were no differences in them. But the level of $p27$ mRNA was low in HCC compared to that in the other groups, suggesting that reduced $p27$ expression may be at least partly responsible for human hepatocarcinogenesis^[4]. There was a significant correlation between the expression of $p27$ protein and $p27$ mRNA in the integrated group of normal liver and liver cirrhosis. However, no significant correlations were found between pericancerous cirrhosis and HCC. This phenomenon has not been reported. Whether the expression of $p27$ protein is regulated by $p27$ mRNA before carcinogenesis or by other mechanisms remains to be verified.

After having analyzed 44 cases (including 6 cases of normal liver, 10 cases of liver cirrhosis and 28 cases of HCC) by MSP, we found that one HCC case was hypermethylated, whose $p27$ protein and $p27$ mRNA were negative, suggesting that $p27$ methylation might lead to its

loss of transcription, contributing to cell proliferation. The same result has been reported in a few other tumors^[20-22], but not in HCC^[23]. Because there are few reports on the $p27$ methylation in HCC, only one HCC case was hypermethylated in our study, we could not analyze the relationship between the $p27$ mRNA expression and $p27$ gene methylation.

In conclusion, reduction or loss of $p27$ protein and $p27$ mRNA is potentially involved in hepatocarcinogenesis, and hypermethylation of $p27$ may lead to the loss of $p27$ mRNA transcription^[20-22].

Abstract

AIM: To discuss the helical computed tomography (CT) characteristics of gastric cancer and evaluate the diagnostic value of contrast-enhanced helical hydro-CT (HHCT) in staging gastric cancer.

METHODS: A total of 50 patients with gastric cancer were included in this study. The CT findings in them were retrospectively analyzed and correlated with pathologic findings at surgery. All patients were preoperatively imaged by plain and contrast-enhanced helical CT after orally ingesting 1 000-1 500 mL water. Peristalsis was minimized by intravenous administration of spasmolytics.

RESULTS: The foci of gastric cancer became more prominent in all the 50 patients and showed strong enhancement in contrast-enhanced HHCT. The tumor was located at the gastric cardia in 14 cases, at the gastric fundus in 3 cases, at the gastric body in 8 cases, at the gastric antrum in 4 cases, at the gastric fundus and the body in 8 cases, at the gastric body and antrum in 11 cases, and at three segments of the stomach in 2 cases. The CT features of gastric cancer were focal or diffuse mural thickening, soft tissue mass, cancerous ulcer, stenosis of stomach, infiltration to adjacent tissues, lymph node and distant metastases. Strong contrast enhancement of the gastric wall was closely related to gastric cancer. The accuracy rate of contrast-enhanced HHCT in staging gastric cancer was 86% (43/50). The detection rate of lymph node metastases by CT was 60% (12/20).

CONCLUSION: Contrast-enhanced HHCT is a reliable method to diagnose and stage gastric cancer.

INTRODUCTION

Gastric cancer is one of the most common malignancies in China. Its accurate staging contributes to its pre-operative management^[1-4]. In the evaluation of gastric diseases, gastroscopy is used for the detection of gastric abnormality. Computed tomography (CT) is a valuable tool in addition to gastroscopy in the evaluation of gastric diseases^[5-7]. With the clinical application of helical CT and the improvement of CT equipments, helical CT has been used for the detection of gastric abnormality and in staging of gastric cancer^[8-11]. Since January 1999, 50 patients with gastric cancer have been scanned. CT results are correlated with surgical and pathologic findings. This work aimed to analyze the characteristic findings of gastric cancer, stage the tumor and evaluate the clinical value of CT imaging of the stomach.

MATERIALS AND METHODS

Patients

A total of 50 cases of gastric cancer were examined by helical hydro-CT (HHCT) and their clinical data were collected from January 1999 to April 2004. There were 36 male and 14 female patients with an age range of 39-81 years (mean 58.3 years).

CT examination

All patients included in the study were fasting for at least 5 h before CT imaging with a commercially available scanner (Hispeed CT/i unit GE Medical Systems, Milwaukee, WI, USA). Thirty minutes before scanning, the patients ingested 500-1 000 mL of water, and were then examined in the supine position during full inspiration. Immediately before helical scanning, the patients received 20-40 mg of anisodamine (raceanisodamine hydrochloride, Hangzhou, China) intramuscularly to minimize peristalsis. An additional 500 mL of water was then offered to improve distension of the proximal part of the stomach. First, a plain scan of the upper abdomen was obtained using 10-mm sections. If the tumor was located at the antral or pyloric antrum, patients were then examined in the prone position, followed by injection of 80-100 mL of contrast material (Omnipaque, Schering, Germany) at a rate of 2.5-3.0 mL/s (Madrid power injector, SA) into the antecubital vein. Helical scanning of

the stomach was performed at 30, 60-70, 150-180 s after contrast material was injected. It started above the diaphragm to cover the gastric cardia by obtaining contrast images with 5- or 7-mm collimation, a pitch of 1.5:1.0 or 1.1:1.0 (120 kV, 210 mA), and a matrix size of 512×512, then 3-mm axial scans were reconstructed for image evaluation.

Image interpretation

Without prior knowledge of endoscopic, surgical, or histological findings, one reviewer interpreted all CT studies. First, the gastric wall was evaluated for the presence of tumor. Carcinoma of the stomach was suspected if thickening and marked contrast enhancement of the gastric wall were visible on CT. The depth of infiltration and perigastric invasion of gastric tumors were evaluated according to the TNM system^[11].

CT staging of gastric tumor was performed as follows: T1, invasion of the lamina propria or submucosa, when thickening was limited to the inner layer; T2, invasion of the muscularis propria, when all three layers of the gastric wall were grossly thickened and replaced by a homogeneous or inhomogeneous soft tissue mass with no serosal irregularity; T3, tumor invasion of the serosa, when high-density irregularities of the outer layer or micronodularity or strands in the fat planes contiguous to the lesion were evident; T4, invasion of adjacent organs and structures, when cleavage fat planes between neoplastic gastric wall and contiguous organs were replaced by mass or when the invasion was clearly demonstrated.

Soft tissue nodules were classified as lymph nodes, which were divided into loco regional peri-gastric lymph nodes (N1/N2 = 3 cm away from the gastric tumor) and distant nodes which were classified as metastatic disease (M1) according to the TNM system if it has tumor infiltration. All visible lymph nodes were judged to be infiltrated by carcinoma independent of size or contrast enhancement. In abdominal M staging, any hepatic or splenic lesion other than a cyst was regarded as potentially malignant. Nodular thickening of the peritoneum or ascites without signs of liver cirrhosis was assumed to be peritoneal carcinomatosis.

CT-histopathologic correlation

All resected specimens were carefully examined both macroscopically and microscopically. A lesion-by-lesion analysis was performed, and gastric carcinoma was staged according to the American Joint Committee on Cancer (AJCC) classification^[11]. The histological studies were correlated with the CT data, and comparative evaluation of location, size, depth of tumor infiltration, and extent of the primary tumor was performed. The presence of lymph node metastasis was histologically determined, and the histological N stage of the tumor was correlated with CT findings. In all patients who underwent surgery, the abdomen was carefully explored to exclude metastatic disease.

Statistical analysis

According to the AJCC classification, TNM staging criteria were applied to all cases. The accuracy of CT imaging to predict the T, N, and M stage of gastric cancer was determined. The overall detection rate of gastric cancer was determined.

The maximum diameter of each cancer was calculated and compared with the maximum diameter of the tumor determined by pathology. The largest tumor diameter was used for correlation with the pathologic size of the tumor.

RESULTS

All CT studies were successfully completed. A lesion-by-lesion analysis revealed that 43 of 50 (86%) gastric cancer were correctly staged by HHCT. Gastrectomy was performed in 46 patients, 4 patients with T1 tumor underwent partial gastrectomy. In all cases, histology revealed malignant ulcer corresponding to early gastric cancer.

Location and histological classification of the tumor

The maximum diameter of the resected gastric tumors ranged 0.7-15 cm (mean 5.3 cm). Fourteen cancers were located at the gastric cardia, three of them showed infiltration of the distal esophagus, three of them invaded the gastric body, and two of them infiltrated both the distal esophagus and the gastric body. The remaining cancers were located at the gastric fundus ($n = 3$), the gastric body ($n = 8$), the gastric antrum ($n = 4$), the gastric fundus and the body ($n = 8$), and the gastric body and antrum ($n = 11$). In two cases, the gastric cancer involved three segments of the stomach (*limitis plastica*).

The histological classifications were papillary adenocarcinoma (5 cases), mucous carcinoma (2 cases), low-grade adenocarcinoma (35 cases), undifferentiated carcinoma (2 cases), squamous carcinoma (3 cases), and adenosquamous carcinoma (3 cases).

Contrast-enhanced HHCT findings of gastric cancer

In 13 of 50 cases (26%), single layer normal gastric wall was demonstrated. In the remaining 37 cases (74%), two- or three-layer structure was shown at arterial phase of contrast-enhanced HHCT scans. Abnormal local gastric wall thickening and area of strong contrast medium enhancement were found in one of four early gastric cancers confirmed by pathology. Two layers of gastric wall were found in 3 patients with early gastric cancer and in 5 of 46 patients with advanced gastric cancer. In the three advanced gastric cancers, low attenuation was found with no enhancement below the strong enhancement inner layer, their pathological diagnosis was mucous carcinoma. Single or triple layer gastric wall with homogeneous or heterogeneous strong enhancement was shown in the remaining advanced gastric cancer, their mean increase of CT values was 26.47 ± 6.67 HU. Gastric wall thickening was found in 37 cases (Figures 1A and B), intramural soft mass in 23 cases (Figure 1C), lymph node metastasis in 12 cases, tumor spread to perigastric area and infiltration to adjacent organs in 9 cases, and distant metastasis in 7 cases. In our study, the detection rate of lymph node metastasis by CT was 60% (12/20).

Gastric cancer staging by CT and pathology

The TNM staging of gastric cancer by contrast-enhanced HHCT was compared to the pathological results in 50 cases (Table 1). In 43 of 50 cases, HHCT staging of gastric cancer was in accordance with pathological staging. The accurate

Figure 1 Enhancement patterns of gastric cancer on contrast-enhanced HHCT. **A:** Focal wall thickening in gastric antrum with marked enhancement of mucosal layer and narrowing of gastric lumina; **B:** focal wall thickening with marked

enhancement of mucosal layer in greater curvature of the gastric body; **C:** homogeneous enhancement of soft tissue mass in anterior wall of the gastric body.

rate of T staging by HHCT was 86.0% (43/50). Findings at HHCT were concordant with histological findings in 2 of 4 T1 tumors (50%), in 17 of 20 T2 tumors (85%), in 15 of 17 T3 tumors (83.3%), and in 7 of 9 T4 tumors (77.8%). Overstaging occurred in 2 T1 tumors and in 3 T2 tumors on CT images. In addition, 2 T4 tumors were understaged.

DISCUSSION

Normal architecture of gastric wall and enhancement pattern of gastric cancer on contrast-enhanced HHCT

Normal gastric wall is histologically classified as four slices: mucosa, submucosa, muscular layer, and serosa. The structure of gastric wall is shown as a single slice in conventional CT. The excellent spatial resolution of helical CT makes it possible to identify the triple-layer structure of the gastric wall after contrast material is intravenously injected. The inner layer with high attenuation corresponds to the mucosa and its muscular layer, the middle layer with low attenuation corresponds to the submucosal layer, and the outer layer with slightly high attenuation corresponds to the muscular layer and serosa^[12-15]. The results of our study are concordant with the previous reports^[16,17]. After gastric lumen was sufficiently filled, the mean thickness of normal gastric wall was 2-3 mm on CT image, while it was 4-5 mm at cardia and antrum^[18]. Otherwise it was regarded as abnormal. The thickness of gastric lumen may be equal to 1.0 cm or above, if not being sufficiently filled. Therefore, it is a prerequisite to fill gastric lumen before CT examination.

Significance of contrast-enhanced HHCT in staging gastric cancer

CT is most frequently used in staging gastric cancer. Helical CT in combination with the water-filling method has led to

marked improvements in the detection and characterization of gastric cancer^[19]. The main CT findings of gastric cancer are local or diffuse thickenings of gastric wall with variable enhancement and intraluminal soft tissue mass. In this study, gastric wall thickening was found in 37 cases, intraluminal soft tissue mass in 13 cases, local and distant lymph metastasis in 12 cases. Tumor can also infiltrate into perigastric tissue, encroach on adjacent organs and metastasize to distant places. Contrast-enhanced HHCT can reflect blood supply to gastric cancer.

Reports on staging gastric cancer by conventional CT prior to surgery are available^[20]. Recently more and more studies have been focused on staging gastric cancer by helical CT^[21]. Our study demonstrated that TNM staging by CT was closely related with pathology. The accuracy of HHCT (86.0%) in our study was higher than that of conventional CT (72%)^[13]. TNM staging by HCT depends upon the improvement of CT equipments and stomach filling with water. Contrast-enhanced HHCT can further improve the accuracy of gastric cancer staging before operation.

Our results showed 60.0% of all lymph nodes were detected by HHCT. The sensitivity of detecting lymph node metastasis was not high. The detection of regional lymph nodes can be improved by hypotension of the stomach, because the delineation of regional lymph nodes and gastric wall can be improved^[22]. Enlarged lymph nodes may be missed if they are located close to the gastric cancer. For the assessment of lymph node metastasis, the size of lymph nodes is the most frequently used criterion. But there is no agreement concerning the upper limits of normal lymph node size. The diameter of normal lymph nodes in the upper abdomen may vary from 6 to 11 mm depending on their location^[23-25]. Lymph nodes in the gastro-hepatic ligament region have to be considered as abnormal if they exceed 8 mm in diameter. A diameter of lymph nodes in 8-15 mm is used in studies as the upper limit for normal lymph nodes^[26-28]. However, when these criteria are used, false-negative and false-positive results may occur because micrometastases do not result in enlargement or inflammatory changes in lymph nodes^[4,13,29,30]. Contrast enhancement of lymph nodes can be useful in differentiating lymph nodes with and without metastasis^[11]. Further study is needed to improve methods for the detection of lymph node metastasis such as dynamic CT^[4,31].

In conclusion, the primary pathologic condition of gastric cancer and its metastasis to adjacent or distant structures can be demonstrated by contrast-enhanced HHCT. HHCT can provide more information for surgeons to make an appropriate therapy for gastric cancer patients.

Abstract

AIM: To investigate the effects of polo-like kinase-1 (PLK1) antisense phosphorothioate oligodeoxynucleotide (ASODN) on apoptosis and cell cycle of human colon cancer cell line SW480.

METHODS: After SW480 colon cancer cells were transfected with PLK1 ASODN, Northern and Western blot analyses were used to examine PLK1 gene expression in cancer cells. We studied apoptosis using terminal uridine deoxynucleotidyl nick end labeling. Apoptosis and cell cycle of SW480 cells were examined by fluorescence-activated cell sorter scan.

RESULTS: The levels of PLK1 mRNA and protein were greatly inhibited by PLK1 ASODN in SW480 cancer cells transfected with PLK1 ASODN. Apoptosis index (AI) induced PLK1 ASODN in a time- and dose-dependent manner. Results from FLM showed that sub-2N DNA content of transfected cancer cells was significantly increased and arrested at G₂/M compared with control groups.

CONCLUSION: PLK1 ASODN can induce apoptosis of human colon cancer cell line SW480.

INTRODUCTION

The polo kinase family includes mammalian polo-like kinase (PLK) 1, Snk, Fnk, *Xenopus laevis* Plx1, *Drosophila* polo,

fission yeast PLO1, and budding yeast Cdc5^[1]. Genetic and biochemical experiments in various organisms indicate that PLK are important regulators of many cell-cycle-related events, including activation of Cdc2, chromosome segregation, centrosome maturation, bipolar spindle formation, regulation of anaphase-promoting complex, and execution of cytokinesis^[1,2]. The importance of PLK1 as a measure for the aggressiveness of a tumor seems to result from its different functions during mitotic progression in particular, its role in the G₂/M transition (phosphorylation of cyclin B1, a component of the mitosis-promoting factor)^[3-5]. PLK1 also phosphorylates substrates that are involved in several additional steps of mitotic progression, including components of the anaphase-promoting complex and the cytokinesis machinery^[6,7]. The activity of PLK1 is elevated in tissues and cells with a high mitotic index, including cancer cells^[8,9]. An increasing body of evidence suggests that the level of PLK1 expression has prognostic value for predicting outcomes in patients with different cancers, including non-small cell lung cancer, squamous cell carcinoma of the head and neck, esophageal carcinoma, oropharyngeal carcinoma, ovarian cancer, breast cancer, endometrial carcinoma, colorectal cancer, and glioma^[10-18]. Takahashi *et al.*^[18], found that some crypt cells in normal colon mucosa show weakly positive staining for PLK1, and PLK1 overexpresses in most of colorectal cancers. Moreover, PLK1 expression is associated with pT (primary tumor invasion) ($P < 0.0006$), pN (regional lymph nodes, $P < 0.008$) and the Dukes' classification ($P < 0.0005$). The results suggest that overexpression of PLK1 might be of pathogenic, prognostic and proliferative importance, so that this kinase might have potential as an invasion and metastasis marker for colorectal cancer. But whether PLK1 plays a role in colon cancer cell is not clear.

In this article, we used ASODN to inhibit the expression of PLK1 in human cancer cell lines SW480 and determined the role of PLK1 in tumorigenesis.

MATERIALS AND METHODS

Cell culture

New fetal calf serum, RPMI-1640, phosphate-buffered saline (PBS), oligofectamine, penicillin and streptomycin, and trypsin were obtained from Invitrogen (Karlsruhe, Germany). Colon cancer line SW480 was obtained from the Institute of Cell Biology, Shanghai, China. Cells were maintained in RPMI 1640 supplemented with 10% newborn bovine serum at 37 °C in 50 mL/L CO₂ atmosphere. The sequence of antisense phosphorothioate oligodeoxynucleotide (ASODN) target PLK1 was 5'-GCAGACCTCGATCC-GAGCAG-3', 20-mer^[20].

***In vitro* transfection with ASODN**

Cancer cells were transfected with ASODN using the oligofectamine protocol (Invitrogen). In brief, 1 d prior to transfection, cancer cells were seeded without antibiotics onto 24-well plates, 1×10^5 cells/well, corresponding to a density of 40–50% at the time of transfection. Cancer cells were transfected with ASODN at different doses (25, 50, 100 nmol/L). There were two control groups: control cells were incubated with RPMI 1640 alone without ASODN or oligofectamine. Cells were harvested 12, 24, 48, and 72 h after the transfection. All transfections were performed in triplicate at each time point.

Northern blot

At 12, 24, 26, 48, 72 h after transfection, total RNAs was isolated using TRIzol according to the manufacturer's protocol (Invitrogen). 18 and 28 S were used as an inner standard. Probes for Northern blots were generated by radiolabeling using 250 μ Ci of [α - 32 P] dCTP (6 000 Ci/mmol) according to the Prime-a-gene labeling System's protocol for each reaction. Northern blotting and hybridizations were carried out routinely.

Western blot

Protein level was determined with Western blot. At 12, 24, 26, 48, and 72 h after transfection, total protein of cancer cells of controls and each transfected group was extracted and protein concentration was determined. Western blot assay was performed with routine methods.

Terminal deoxynucleotidyltransferase-mediated dUTP nick-end labeling (TUNEL) assay

Terminal uridine deoxynucleotidyl nick end labeling (TUNEL) assay was performed by using the *in situ* cell detection kit (FITC) following the manufacturer's instructions (Roche Molecular Biochemicals). In brief, cells grown on glass coverslips were fixed by a freshly prepared paraformaldehyde solution (4% in PBS, pH 7.4) for 1 h at room temperature. Coverslips were then washed with PBS and incubated in permeabilization solution (0.1% Triton X-100, 0.1% sodium citrate) for 2 min in ice. Then, 50 μ L of TUNEL reaction mixture was added on coverslips and incubated in a humidified chamber for 1 h at 37 °C in the dark. Finally, cells were mounted and examined by microscopy as described above. TUNEL-positive (apoptotic) cells were stained bright green. Apoptosis index (AI) was calculated by apoptosis cells/total cell $\times 100\%$.

FACScan analysis

Cell cycle distribution and apoptosis were analyzed using a fluorescence-activated cell sorter (FACS) scan apparatus (BD Biosciences, Heidelberg, Germany). For the determination of cell cycle distribution, cells were harvested, washed with PBS and probed with CycleTEST™ PLUS DNA reagent kit (BD Biosciences) according to the manufacturer's protocol. For each transfection (control and different doses of ASODN), 30 000 cells were analyzed in triplicate. The percentage of cells in different cell cycle phases was calculated using ModFit LT for Mac (BD Biosciences). For the detection of apoptotic phenotypes, harvested cells were fixed

with ice-cold 70% ethanol and treated for 20 min at 37 °C with RNase A at 5 μ g/mL and propidium iodide (PI) at 50 μ g/mL. Subsequent analyses of cell cycle distribution and apoptosis were performed using CELLQuest software (BD Biosciences).

Statistical analysis

SPSS 10.0 was performed to assay the data. Data were analyzed using SPSS. $P < 0.05$ was considered statistically significant.

RESULTS

Inhibition of PLK1 mRNA and protein expression by ASODN

We first tested the ability of ASODN to reduce the endogenous level of PLK1 mRNA and protein in the SW480 cancer cell line. PLK1 mRNA and protein levels in untransfected control cells were not significantly influenced. Transfection with PLK1 ASODN at a concentration of 50 nmol/L led to a statistically significant loss of PLK1 mRNA at 12 h after the beginning of transfection (Figure 1). We found that SW480 cancer cells transfected with ASODN showed a statistically significant reduction in PLK1 protein levels 24 h after ASODN transfection as compared with untransfected control cells. The results showed that ASODN could exert inhibitory effects on mRNA and protein expression of PLK1 gene in SW480 cancer cells at 50 nmol/L.

Figure 1 Inhibition of PLK1 mRNA and protein expression by ASODN demonstrated in Northern blot (A) and Western blot (B) analyses. Lane 1: control group; lane 2–5: groups treated by ASODN (50 nmol/L) after 12, 24, 48 and 72 h.

AI induced by ASODN

As shown in Figure 2, apoptosis was observed in cancer cells transfected with PLK1 ASODN. AI increased in a time- and dose-dependent manner. These data suggested that ASODN could induce apoptosis of colon cancer cell line SW480.

FACScan results

To study the apoptosis induced by ASODN, we investigated whether PLK1 levels were associated with apoptosis in all cancer cell lines by determining the sub-2N DNA content with FACScan analysis. Untransfected cells contained 1.9% cells with sub-2N DNA, transfection with ASODN was associated with 16.5% sub-2N DNA content in SW-480

Figure 2 AI induced by ASODN in control group (A) and PLK1 group (B).

cells. Next, we analyzed the effect of PLK1 depletion on cell-cycle progression using FACSscan. As shown in Figure 3, no substantial change in cell cycle distribution was detected in control (untransfected or oligofectamine-treated alone) cells. Transfection of PLK1 ASODN induced significant G_2/M arrest 48 h after transfection with 50 nmol/L ASODN: SW-480 cells showed a fivefold increase in the percentage of cells in G_2/M compared to untransfected cancer cells. These data suggested that ASODN could induce apoptosis and G_2/M arrest in human colon cancer cell line SW480.

DISCUSSION

The polo family of protein kinases is an important group of cell cycle regulators^[1]. PLK1 is one of mammalian members of this gene family. In lower organisms, members of the polo family have been shown to control centrosomal function, chromosomal segregation, and cytokinesis^[8]. A close correlation between mammalian PLK1 expression and carcinogenesis was recently documented. Mammalian PLK1 was found to be overexpressed in various human tumors^[10-17]. It has been proposed that PLK1 could be used as a novel diagnostic marker for several types of cancers^[9,19]. Furthermore, constitutive expression of PLK1 in NIH 3T3 cells causes oncogenic focus formation and induces tumor growth in nude mice^[20]. Therefore, inhibition of PLK1 function is important for cancer therapy.

Immunohistochemical analyses showed that PLK1 is expressed in 78 primary colorectal cancers as well as 15 normal colorectal specimens^[18]. In normal colon mucosa, some crypt cells showed weakly positive staining for PLK1 in 13 out of 15 cases, the remaining cases being negative. Elevated expression of PLK1 was observed in 57 (73.1%)

of colorectal cancers, which was significantly associated with pT ($P<0.0006$), pN ($P<0.008$) and the Dukes' classification ($P<0.0005$). The results suggest overexpression of PLK1 might be of pathogenic, prognostic and proliferative importance, and might have potential as a marker for colorectal cancer. In this study, PLK1 is upregulated in colon cancer cell line SW480, suggesting that PLK1 was overexpressed in colon cancer and may play an important role in colon cancer development and progression.

Antisense oligonucleotides can downregulate some oncogenes associated with malignant tumor, and synthetic oligonucleotides have been currently evaluated in clinical trials for the treatment of cancer, inflammation, and viral diseases^[21]. Li *et al.*^[19] tested some ASODN, ASODN 9 that is most effective in blocking PLK1 expression in liver carcinoma cell line HepG2. But no studies of PLK1 ASODN are available on colon cancer. In the present study, SW480 cancer cells were transfected with ASODN 9. mRNA and protein expression of PLK1 gene could be induced significantly by Western and Northern blot. Our results suggest that transfection of ASODN is efficient in suppressing PLK1 expression in SW480 colon cancer cells.

After PLK1 expression was downregulated, we detected apoptosis of cancer cells by TUNEL assay. We observed that transfection with PLK1 ASODN significantly induced AI in a time- and dose-dependent manner. To further confirm the induction of apoptosis in SW480 cells was through the activation of an apoptotic program, we detected apoptosis program by sub-2N DNA content by flow cytometry. It was found that sub-2N DNA content of cancer cells transfected with ASODN increased significantly compared with untransfected cells. Results from flow cytometry analysis further confirmed that ASODN could induce significant apoptosis in SW480 cells. All these data indicate that downregulation of PLK1 expression with ASODN may induce apoptosis in colon cancer cell line SW480.

Meanwhile, cell viability was significantly decreased in cells after ASODN treatment as compared with untreated controls, suggesting that apoptosis may be related to inhibition of SW480 colon cancer cell line.

In addition, we examined the cell cycle distribution changes in ASODN-transfected SW480 cells by flow cytometry. Forty-eight hours after transfection with ASODN, SW480 cancer cells showed a stronger G_2/M arrest compared with control cells.

In conclusion, targeting PLK1 expression using ASODN

Figure 3 Effect of ASODN on cell cycle distribution of cancer cells. A: Control; B: Treatment cells; C: Cells in G_2/M .

may hold promise as one of the effective therapies for colon cancer. It is hoped that application of this strategy in clinic may improve the efficacy of treatment of patients with colon cancer.

Abstract

AIM: To investigate the clinical characteristics of fulminant hepatitis in pregnancy.

METHODS: We compared and analyzed the etiology, clinical characteristics, and laboratory examinations of 25 cases of fulminant hepatitis in pregnancy and 30 cases of fulminant hepatitis not in pregnancy.

RESULTS: HBV infection and chronic fulminant hepatitis were most common both in the pregnant and in the non-pregnant groups. Jaundice, digestive tract symptoms, increase of bilirubin and thrombinogen activity were the main manifestations. The incidence of hepatic encephalopathy (HE) and hepato-renal syndrome (HRS) was significantly different between the two groups. The incidence of preterm labor, dead fetus and neonatal asphyxia was high.

CONCLUSION: Fulminant hepatitis is likely to occur in late pregnancy with more severe complications, which significantly influences maternity, perinatal fetus, and newborn.

<http://www.wjgnet.com/1007-9327/11/4600.asp>

INTRODUCTION

Fulminant hepatitis (FH) refers to a kind of severe clinical type of hepatitis characterized by acute onset, fast progression, complicated manifestations and poor prognoses. The average mortality rate of FH in our country is over

60%. Hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis D virus (HDV), hepatitis E virus (HEV), transfusion transmitted virus (TTV), herpes simplex virus (HSV) and cytomegalo virus (CMV) can all lead to FH, with HBV being the commonest cause (accounting for about 85%). The basic pathologic changes are massive necrosis and degeneration of hepatocytes. The main clinical manifestations are icteric sclera and xanthochromia, hypodynamia and loss of appetite, nausea and vomiting. Bilirubin increases to more than 171 mmol/L, prothrombin time (PT) decreases to less than 40%, progressive shrinkage of liver, significant deterioration of liver function, deviation of enzyme and bilirubin, and inversion of albumin/globulin ratio. The severe complications include hepatic encephalopathy (HE) and hepato-renal syndrome (HRS). The incidence of FH in pregnancy (FHP) is 66 times that of patients not in pregnancy^[1]. The former is more dangerous with a significantly higher incidence of dead fetus, preterm labor and neonatal asphyxia because of interactions of pregnancy and liver disease. It is also among the major causes of maternal and perinatal death and is still left to be solved in the field of liver disease.

We compared 25 cases of FHP and 30 cases of FH not in pregnancy (FHNP) retrospectively to enhance our knowledge about FHP.

MATERIALS AND METHODS

A total of 55 female reproductive-age patients who met the clinical diagnostic criteria approved by Chinese Medical Association (2000, Xi'an)^[2] were admitted in our hospital from January 1993 to February 2004. In the FHP group, there were 25 cases aged from 23 to 37 years, with an average age of 26.7 ± 3.8 years. There were 30 cases in the FHNP group, aged from 18 to 39 years, with an average age of 28.1 ± 5.6 years. There were no significant differences in age distribution ($t = 1.053$, $P > 0.05$), etiology and clinical classification ($P > 0.05$) between the two groups.

In the improved FHP group, there were eight cases of primipara and three cases of multipara with an average gestational period of 29.8 ± 6.3 wk. Four cases were simple virus infection, four cases had co-infection and three cases had infection of unknown causes. In the death group, there were 10 primipara and 4 cases of multipara with an average gestational period of 30.6 ± 7.0 wk. Nine cases were simple virus infection, one case had co-infection and four cases had infection with unknown causes. There was no significant difference between the two groups in general conditions.

We compared the etiological markers, clinical groups, symptoms and signs, complications, biochemical indices, B-ultrasonography and pregnancy outcomes. The results were analyzed by “*t* test”, “ χ^2 test”, “fidelity rate test” and

Table 1 Laboratory findings of FHP group and FHNP group (mean±SD)

Items	FHP group	FHNP group	<i>t</i>	<i>P</i>
Glutamate-pyruvate transaminase (ALT, U/L)	424.05±285.12	747.04±621.23	1.996	>0.05
Glutamic-oxalacetic transaminase (AST, U/L)	436.92±304.52	534.93±525.73	1.657	>0.05
ALT/AST	0.89±0.96	1.32±1.56	1.201	>0.05
Alkaline phosphatase (ALP, U/L)	199.42±101.02	142.23±50.03	-2.716	<0.05
Total bilirubin (Tbil, μmol/L)	403.11±162.32	460.54±246.45	0.998	>0.05
Direct bilirubin (Dbil, μmol/L)	240.05±111.69	230.44±112.85	-0.316	>0.05
Bile acid (TBA, μmol/L)	105.92±72.17	205.96±37.20	3.053	<0.05
Serum albumin (ALB, g/L)	28.00±4.45	33.49±5.92	3.818	<0.05
Cholesterol (CHOL, mmol/L)	1.70±0.75	1.91±1.00	0.838	>0.05
Cholinephospholipid (CHE, U/L)	3 132.55±983.57	3 885.81±1 510.60	1.490	>0.05
Blood glucose (GLU, mmol/L)	3.03±1.50	5.25±3.82	2.728	<0.05
Blood urea nitrogen (BUN, mmol/L)	9.66±9.07	4.34±4.02	-2.888	<0.05
Creatinine (Cr, mmol/L)	230.99±205.46	60.55±37.47	-4.459	<0.05
Serum calcium (Ca, mmol/L)	2.00±0.24	2.14±0.21	2.100	<0.05
Alpha-fetoprotein (AFP, ng/mL)	186.11±135.74	456.47±1 374.12	0.805	>0.05
Blood ammonia (NH ₃ , μmol/L)	92.05±55.39	127.71±83.30	1.263	>0.05
PT (s)	43.93±43.66	44.10±26.32	0.018	>0.05
PTA (%)	25.33±12.30	20.81±9.44	-1.513	>0.05

“sum of ranks test” through SPSS software. $P<0.05$ was considered statistically significant.

RESULTS

Etiological markers

The infection rate of HBV was 68% (17/25), HDV 4% (1/25), HEV 24% (6/25) and unidentified type 28% (7/25) in the FHP group. The infection rate of HAV was 3.3% (1/30), HBV 63.3% (19/30), HEV 20% (6/30) and unidentified type 20% (6/30) in the FHNP group. There was no significant difference in etiology between the two groups ($\chi^2 = 3.249$, $P>0.05$).

Clinical groups

In the FHP group, there were 7 cases of acute FH, 3 cases of sub-acute FH, and 15 cases of chronic FH. In the FHNP group, there were 4 cases of acute FH, 5 cases of sub-acute FH, and 21 cases of chronic FH. There was no significant difference between the two groups ($\chi^2 = 1.879$, $P>0.05$).

Hepatitis history

Seven cases had hepatitis history in the FHP group and four died. While 17 cases had hepatitis history in the FHNP group and 8 died. There was a significant difference in hepatitis history between the two groups ($\chi^2 = 4.556$, $P<0.05$).

Clinical manifestations

The main clinical manifestations of FHP were icteric sclera and xanthochromia (100%), yellow urine (100%), hypodynamia and loss of appetite (96%), nausea and vomiting (64%), abnormal behavior (44%), edema of lower limbs (40%), fever, abdominal pain, oliguria (24%), abdominal distention (16%), tarry stools (12%), skin pruritus, gingival bleeding, and loss of weight.

We compared the clinical symptoms of the two groups and found no significant differences except for abdominal distention ($P>0.05$).

Laboratory findings

Between the two groups, there were significant differences in such indices as alkaline phosphatase (ALP), bile acid (TBA), serum albumin (ALB), blood urea nitrogen (BUN), creatinine (Cr), blood glucose (GLU) and serum calcium (Ca, $P<0.05$). In the FHP group, ALP, BUN, Cr were higher while TBA, ALB, GLU, and Ca were lower (Table 1).

B-ultrasonography

In the FHP group, 1 case had liver enlargement, 9 cases liver shrinkage, 15 cases spleen enlargement, 15 cases ascites, and 3 cases had no B-ultrasonography results. In the FHNP group, 2 cases had liver enlargement, 6 cases liver shrinkage, 18 cases spleen enlargement, 16 cases ascites, and 2 cases had no B-ultrasonography results. There were no significant differences in B-ultrasonography results between the two groups (χ^2 liver = 1.190, χ^2 spleen = 0.000, χ^2 ascites = 0.246, $P>0.05$).

Complications

The most common complication was HE (76%). Others were HRS (64%), peritonitis (56%), hemorrhage (56%), and pulmonary infection (16%). Compared to the FHNP group, there were significant differences in the incidence rates of HE, HRS and hemorrhage ($P<0.05$). Complications were more likely to develop in the FHP group (Table 2).

Table 2 Comparison of complications between FHP group and FHNP group

Complications	FHP (<i>n</i> = 25, %)	FHNP (<i>n</i> = 30, %)	χ^2	<i>P</i>
Peritonitis	14 (56)	13 (43.3)	0.875	>0.05
HE	19 (76)	15 (50.0)	3.905	<0.05
HRS	16 (64)	4 (13.3)	15.128	<0.01
Hemorrhage	14 (56)	1 (3.3)	13.221	<0.01
Pulmonary infection	4 (16)	4 (13.3)	0.000	>0.05
DIC	6 (24)	0 (0)	5.801	<0.05

Gestational period of FHP onset and pregnancy outcome

Onset of FHP in 25 cases was all in middle (28%, 7/25) or late pregnancy (72%, 18/25).

Two cases had spontaneous abortion, five cases dead fetus, six cases preterm labor, seven cases term labor, and four cases had no labor in our hospital. One patient died before labor. The incidence rate of preterm labor and neonatal asphyxia was 33.3% (6/18) and 27.7% (5/18), respectively.

DISCUSSION

HBV infection is the most common cause of both FHP and FHNP, because China is an area with a high incidence of HBV infection^[4,5]. It was reported in national epidemiologic survey from 1992 to 1995 that 9.57% of Chinese are hepatitis B surface antigen positive^[4]. While the carrier state of HBV infection may be the underlying cause of chronic liver diseases^[6-8]. Once triggered, massive liver necrosis or FH will occur. In our study, chronic FH was most common both in FHP group (60%, 15/25) and in FHNP (70%, 21/30). During pregnancy, the vigorous metabolism puts heavy burden on liver and makes it hard to recover^[9,10]. Infection with HBV during pregnancy is more likely to lead to FH with a fast progression.

The onset of FHP is more rapid, which can develop during the whole pregnancy, and most common during late pregnancy^[11] due to heavy burden in late pregnancy^[12]. Because of the interaction between pregnancy and hepatitis, severe immune response and damage caused by multi-factors, a large number of liver cells will undergo necrosis in a short period. Therefore, the conditions of FHP can aggravate very quickly and complications are more likely to develop^[13]. In our study, the main clinical manifestations were as follows: extreme hypodynamia, digestive tract symptoms such as loss of appetite and frequent vomiting, yellow urine, icteric sclera and xanthochromia, liver shrinkage, hepatic odour and early stage of ascites. Whereas abdominal distention was rare, which may be due to the insensitiveness caused by enlarged uterus, HE was most common. The incidence of other complications, such as hemorrhage^[14,15] and HRS^[16] was significantly higher in the FHP group^[17-20], and influenced the prognoses of FHP^[21,22], especially postpartum hemorrhage and disseminated intravascular coagulation (DIC)^[21,23-25], suggesting that postpartum hemorrhage and DIC are common death causes of FHP.

Bilirubin rose, PT prolonged, prothrombin activity (PTA) decreased, hypoproteinemia occurred, albumin/globulin reversed and cholesterol-enzyme separated. Between FHP and FHNP, there were significant differences in ALP, TBA, ALB, BUN, Cr, GLU, and Ca ($P < 0.05$). Since ALP can be produced not only by liver, but also by placebo, ALP is higher in FHP than in FHNP and returns to normal after labor. During pregnancy, progesterone can suppress smooth muscle to weaken gallbladder contractions and relax bile tract smooth muscle. Evacuation of gall bladder is longer, thus leading to cholestasis. Less TBA is discharged, causing decrease of TBA in blood. During pregnancy, the metabolism is high, serum protein and storage of glucogen reduced, while the blood volume increased. Therefore

hypoproteinemia and hypoglycemia are more notable than in FHNP. The fetus in pregnancy needs calcium for development of bones, causing increase of Ca in maternity, meanwhile, ALB and protein-bound Ca decrease. The incidence of higher BUN and Cr is caused by the development of HRS in FHP.

The main dangers of FHP are fetal malformation, preterm labor, abortion, dead fetus in uterus and stillbirth. The incidence of fetal distress and perinatal death is higher^[26]. In our study, such labor outcomes as dead fetus in uterus (20%, 5/25), preterm labor (33.3%, 6/18) and fetal distress (27.7%, 5/13) were significantly higher in FHP group. In normal pregnancy, the incidence of preterm labor is 5-15% and asphyxia is 3-10%^[11]. In FH, there are metabolic disorders all over the body and insufficient energy generation, blood and oxygen supply through placenta. Accordingly, fetal distress, fetus death in uterus and preterm labor are likely to develop, increasing the rate of perinatal distress and mortality.

In order to decrease maternal and perinatal death rate and increase obstetrical quality, we should recognize FHP comprehensively to the make right diagnosis and treat FHP in its early stage.

Abstract

AIM: To understand the correlation of serum cholinesterase (CHE) activity with gastric cancer and to assess their clinical significance.

METHODS: The velocity method was adopted to detect the activity of serum CHE in patients with gastric cancer and in patients with non-malignant tumor as controls.

RESULTS: The serum CHE activity in the treatment group was significantly lower than that in the control group with a very significant difference between the two groups (83.3 ± 113.1 , $P = 0.0003$). Age was significantly associated with the incidence of gastric cancer.

CONCLUSION: Serum CHE activity has a close relation with the incidence of gastric cancer.

INTRODUCTION

CHE is a type of glycoprotein^[1-4], existing *in vivo* in multiple forms of isozyme^[5-7]. The decrease of serum CHE activity is often observed in patients with organic phosphorus poisoning^[8] and damage of parenchymal cells^[9-12]. In clinical practice, we have discovered that there is a decrease of serum CHE activity in patients with gastric cancer. This study aimed to detect the serum CHE activity in patients with gastric cancer, and to observe the correlation of serum CHE activity with the incidence of gastric cancer.

MATERIALS AND METHODS

Subjects

The treatment group included 81 patients (61 males and 20 females aged 30-80 years with an average age of 58.8 ± 12.0 years) with gastric cancer hospitalized from January 1998 to June 2002. The disease was confirmed by gastroscopic examination and/or pathological examination. Clinical and pathologic classifications followed the General Rules for Gastric Cancer Study in Surgery and Pathology in Japan. The control group included 80 patients (44 males and 36 females) with non-malignant tumor hospitalized during the same period. Their age ranged 26-86 years with an average age of 57.7 ± 15.3 years. Patients with organic phosphorus poisoning or damage of parenchymal cells were excluded.

Methods

All the patients were fasted for more than 12 h, then venous blood was taken. After centrifugation, serum was subjected to detection on the same day. Serum CHE activity was measured by the velocity method with Hitachi 7170 full automatic biochemical instrument and Hitachi 7170 special reagent. The normal reference value was $75-217 \mu\text{kat/L}$.

Statistical analysis

All the data were fed into a computer. The SPSS10.0 software package was employed for analysis and processing. The chi-square test was conducted. With the CHE difference between the gastric cancer group and the control group, *F* test was adopted. For the purpose of reviewing the relation between sex, age and CHE, the multi-factor regression analysis was conducted with respect to the above three factors. The statistical significance level was defined as <0.05 with two-sided detection.

RESULTS

Serum CHE activity in gastric cancer
